viscosity (Fig. 1). The viscosity measurements have been carried out over the entire concentration range (Table II) and the data have been treated using Jones-Dole equation (11), $\eta/\eta_0 = 1 + AC^{1/2} + BC$ for low concentrations and for high concentrations, an extended form of this equation (12, 13), $\eta/\eta_0 = 1 + AC^{1/2} + BC + DC^2$ has been used. Here η is the viscosity of the solution, η_0 is the viscosity of the solvent, C is the concentration in moles/liter, and the constants A and B are characteristic of ion-ion and ion-solvent interactions. The data for dilute solutions can be represented by the equation $\eta/\eta_0 = 1 + 0.1326C^{1/2} - 0.632C$ and for concentrated solutions, the data can be represented by the equation $\eta/\eta_0 = 1 + 0.1326C^{1/2} - 0.2759C + 1.0887C^2$. For concentrated solutions, both conductance and viscosity were measured at 25°, 40°, and 60°C. The plots of log Λ *vs.* $1/T$ and log η *vs.* $1/T$ were linear from which energies of activation for conductance and for viscous flow were obtained (Table III). The large increase in the energy of activation for conductance and for viscous flow with increase of concentration can be explained in terms of strong ion-ion and ion-solvent interactions giving rise to complex aggregates, particularly at high concentrations. The cyclic voltammetric studies have been carried out on 2.0, 1.8, 1.5, 1.0, and 0.6M solutions of $LiAlCl_4$-$SOCl_2$ solutions. The voltammogram of the 1.5 $LiAlCl_4$-$SOCl_2$ solution shows a large reduction peak around 2.7V and two very small peaks around 1.8 and 1.4V *vs.* Li/Li^+ (Fig. 3). In the anodic direction, a very small, but broad peak appears around +2.65V *vs.* Li/Li^+. Similar cyclic voltammo-

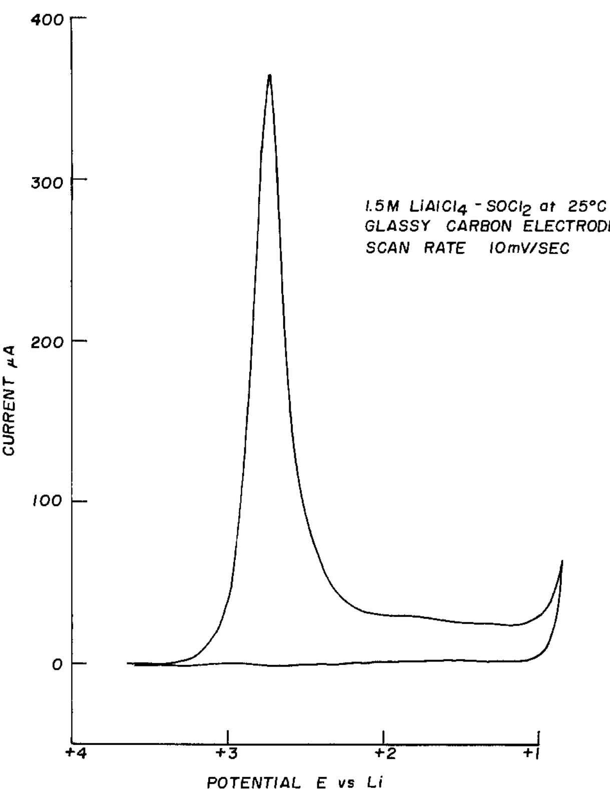

Fig. 3. Cyclic voltammetry of $LiAlCl_4$-$SOCl_2$ solution at 25°C

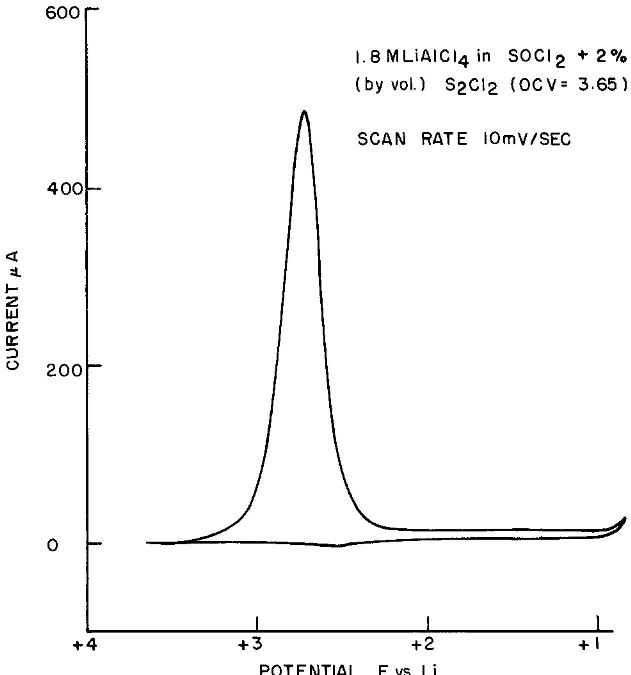

Fig. 4. Cyclic voltammetry of $LiAlCl_4$-$SOCl_2$ solution with 2% (by volume) of S_2Cl_2.

grams were observed for 2.0, 1.8, 1.0, and 0.6M $LiAlCl_4$-$SOCl_2$ solutions. The peak currents for the large reduction peak around 2.7V increased with increasing scan rate and the peak potentials shifted to more negative potentials indicating that the reduction involves an irreversible charge transfer process (14). The large reduction peak occurring around 2.7V *vs.* Li/Li^+ can be attributed to the electrochemical reduction of thionyl chloride represented by one of the following reduction reactions in lithium-thionyl chloride cell (1, 2, 6)

$$4Li^+ + 2SOCl_2 + 4e \rightarrow 4LiCl + SO_2 + S \quad [I]$$

$$8Li^+ + 3SOCl_2 + 8e \rightarrow 6LiCl + Li_2SO_3 + 2S \quad [II]$$

$$8Li^+ + 4SOCl_2 + 8e \rightarrow 6LiCl + Li_2S_2O_4 + S_2Cl_2 \quad [III]$$

It has been shown that during the reduction of thionyl chloride in lithium-thionyl chloride cell, products such as sulfur monochloride (2, 4, 6) and sulfur dichloride (15) are formed. Therefore, the cyclic voltammograms of 1.8M $LiAlCl_4$-$SOCl_2$ solution containing small amounts of sulfur monochloride (S_2Cl_2) were studied. The cells have a slight increase in open-circuit potential. The main peak of $SOCl_2$ appearing around 2.7V *vs.* Li/Li^+ shows an increase in amplitude (Fig. 4) and the remaining peaks are the same as in $LiAlCl_4$-$SOCl_2$ solutions. The cyclic voltammogram of 1.8M $LiAlCl_4$-$SOCl_2$ solution containing 2% (by volume) of sulfur dichloride (SCl_2) shows an increased open-circuit potential (3.9V) and three reduction peaks at about 3.65, 3.5, and 2.7V *vs.* Li/Li^+ (Fig. 5). Since SCl_2 is known to undergo dissociation to S_2Cl_2 and Cl_2 (16) according to

$$2SCl_2 \rightleftharpoons S_2Cl_2 + Cl_2$$

the peaks observed at 3.65 and 3.5V can be attributed to the reduction of chlorine. When a solution of 1.5M $LiAlCl_4$-$SOCl_2$ is maintained for 5 min at 4.5V *vs.* Li/Li^+ using glassy carbon and platinum electrodes and the cyclic voltammogram is run in the cathodic mode, two reduction peaks are observed at about 3.65 and 3.5V *vs.* Li/Li^+ (Fig. 6). On bubbling dry nitrogen

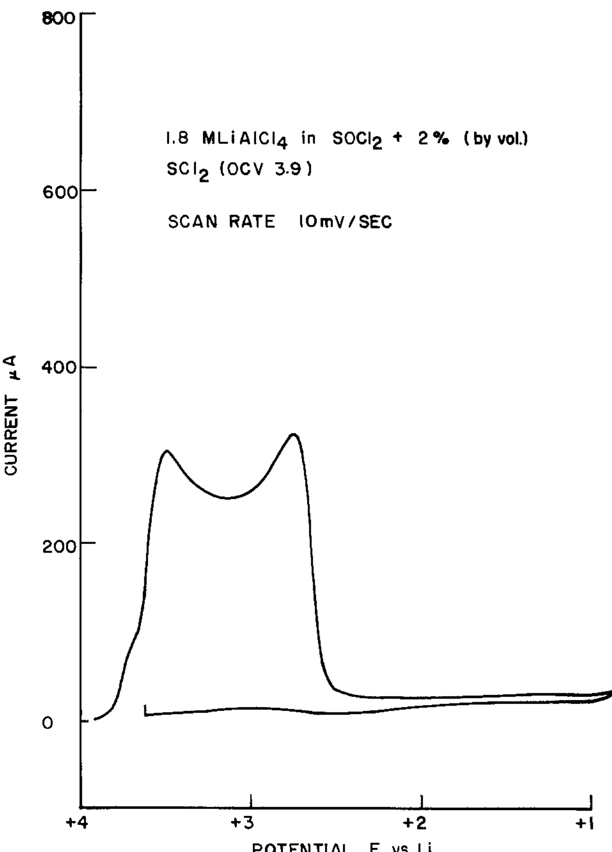

Fig. 5. Cyclic voltammetry of $LiAlCl_4$-$SOCl_2$ solution with 2% (by volume) of SCl_2.

through this solution and then running cyclic voltammetry, only one peak around 3.5V *vs.* Li/Li^+ is observed. It is possible that when chlorine is generated anodically at the glassy carbon electrode, there is free chlorine and chlorine combined with $SOCl_2$. On bubbling dry nitrogen, the free chlorine is removed and the chlorine in combination with the solvent $SOCl_2$ remains in solution and undergoes reduction at about 3.5V. This interpretation is verified by bubbling chlo-

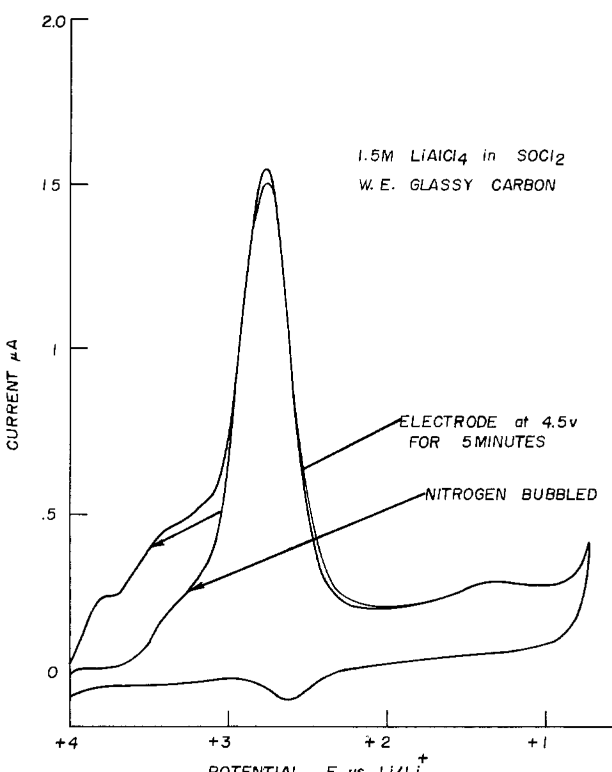

Fig. 6. Cyclic voltammetry of $LiAlCl_4$-$SOCl_2$ solution

rine gas through a solution of 1.5M $LiAlCl_4$-$SOCl_2$ and running cyclic voltammetry. There are two small peaks at 3.65 and 3.4V *vs.* Li/Li$^+$ and a large peak at 2.75V *vs.* Li/Li$^+$ (Fig. 7).

The cyclic voltammogram of 1.8M $LiAlCl_4$-$SOCl_2$ solution saturated with sulfur dioxide (OCV = 3.6V) at 25°C shows a large reduction peak around 2.7V followed by two very small peaks at about 1.8 and 1.4V *vs.* Li/Li$^+$ (Fig. 8). When the voltammogram for this solution was run at 0°C, the amplitude of the main peak appearing around 2.7V decreases, whereas the small peaks at about 1.8 and 1.4V take a fairly well-defined shape and a small and broad oxidation peak appears around 2.8V. The cyclic voltammograms of

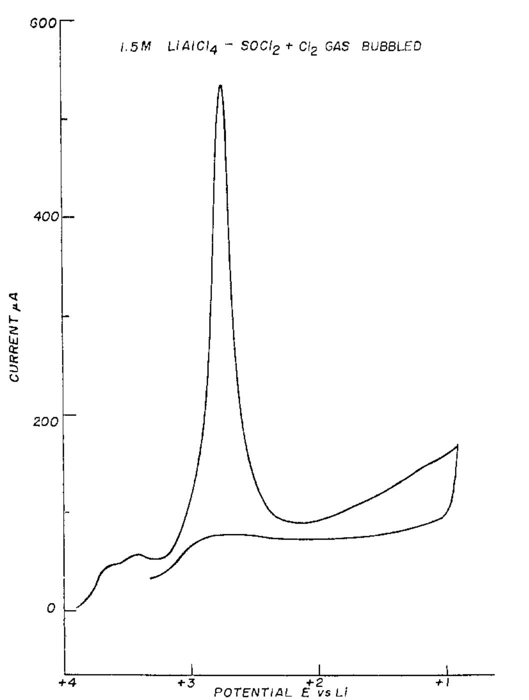

Fig. 7. Cyclic voltammetry of $LiAlCl_4$-$SOCl_2$ solution + Cl_2 gas bubbled.

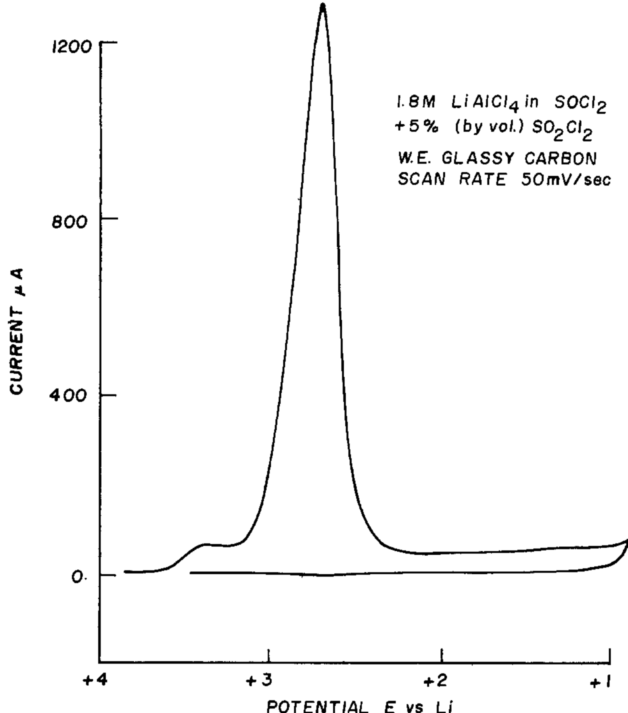

Fig. 8. Cyclic voltammetry of $LiAlCl_4$-$SOCl_2$ solution saturated with SO_2.

1.8M $LiAlCl_4$-$SOCl_2$ solutions containing 5% and 13% (by volume) of sulfuryl chloride (SO_2Cl_2) (OCV = 3.9) show a reduction peak around 3.45V followed by the major reduction peak for $SOCl_2$ at about 2.7V *vs.* Li/Li$^+$ and small reduction peaks at about 1.8 and 1.4V *vs.* Li/Li$^+$ (Fig. 9). The peak around 3.45V can be attributed to the reduction of chlorine produced by the decomposition of SO_2Cl_2 (17), according to the equation

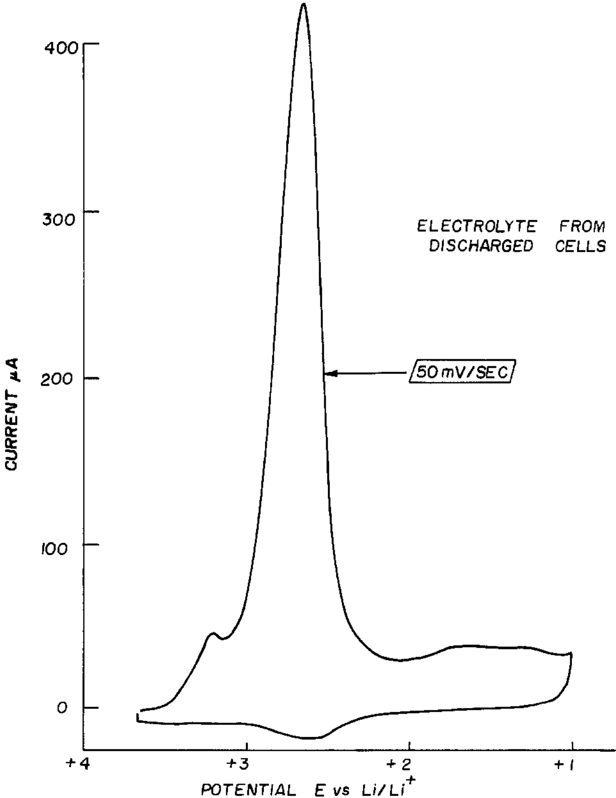

Fig. 9. Cyclic voltammetry of $LiAlCl_4$-$SOCl_2$ solution with 5% (by volume) of SO_2Cl_2.

$$SO_2Cl_2 \rightarrow SO_2 + Cl_2$$

The cyclic voltammogram of $LiAlCl_4$-$SOCl_2$ solution from a battery discharged to 0.0V shows a peak around 3.35V, a large peak around 2.7V, and two small peaks around 1.8 and 1.4V *vs.* Li/Li^+ (Fig. 10). These results seem to suggest that the electrolyte solution from a discharged cell contains chlorine and sulfur dioxide. Chlorine can possibly result due to the dissociation of SCl_2 to S_2Cl_2 and Cl_2.

Sulfur monochloride, being a good solvent for sulfur, may minimize lithium sulfur reaction which is highly exothermic (4). Chlorine evolved may interact with the oxidant giving rise to oxides of chlorine which are explosive in the presence of reducing agents (16, 18).

Conclusion

The conductance and viscosity data indicate that the electrolyte $LiAlCl_4$ is highly associated in $SOCl_2$. The associated electrolyte can affect the mass transport and the charge transfer process during $Li/SOCl_2$ cell discharge, particularly at low temperatures. The cyclic voltammetric studies show that chlorides of sulfur and chlorine are likely to be generated during the cell discharge.

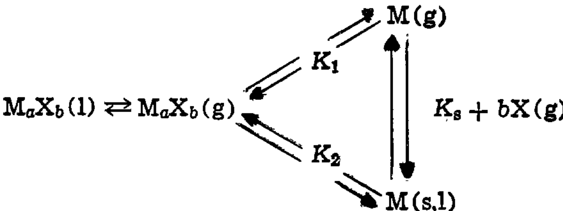
Chemical Reactivity in Halide Discharges: Effects of Condensed Phases and Common Components

D. M. Speros, R. K. Datta, and D. A. Lynch

General Electric Company, Lighting Research and Technical Services Operation, Nela Park, Cleveland, Ohio 44112

ABSTRACT

Theoretical analysis of the cyclic equilibria



defines the conditions leading to (*i*) condensation of metal M and (*ii*) suppression of dissociation of halide M_aX_b by halogen X(g). The analysis is extended to include cases in which X is a common component of several coexisting halides. The theoretical conclusions are applied to the system M_aX_b-SiO_2-W where M is reactive toward SiO_2. It is shown that chemical reactivity in this system is determined by the thermodynamic activity of M in the gas phase. This result is applied to a common type of halide discharge lamp and leads directly to the proposal of a mechanism of reaction between the halides, the vitreous silica envelope, and the tungsten electrodes. Experimental investigations employing both established and new techniques confirm each step of the reaction sequence and the reaction sequence as a whole. It is concluded that outlines are provided for: (*i*) a thermodynamic basis for electrode-atmosphere cycles, (*ii*) an overall mechanism for wall-atmosphere interactions, (*iii*) experimental methods for the study of chemical reactivity in discharges, and (*iv*) an interpretive basis for experimental results.

Introduction and Basic Concepts

In a previous publication on molecular arcs (1), the origin, consequences, and applications of a condensed phase of Sn in discharge envelopes containing tin halides were described. Likewise, the role of Sn vapor as a "common component" between SnI_x and $SnCl_y$ vapors in the discharge atmosphere was elucidated. It was shown that a condensed phase of "excess" Sn is necessary in order to obtain a chemically stable discharge system.

This paper reports investigations of the occurrence and effects of condensed phases when the condensing metal, unlike Sn, is reactive toward the walls and electrodes of the discharge, and the common component is not a metal but a halogen. Specifically, the factors determining chemical reactivity in the system M_aX_b-SiO_2-W were explored. M_aX_b is the halide of metal M which is reactive toward SiO_2. Examples of such metals include Al, lanthanides such as Dy, actinides such as Th, and the alkali metals, Zr, Sc, Ti, Si, etc. Of these, the iodides of Na, Sc, and Th were chosen for study. The reason for this choice is that combinations of these iodides find applications in discharge lamps of widespread use especially in outdoor lighting (2, 3). Thus, the experimental part of this investigation included actual lamps of various configurations as, for example, that of Fig. 3 in Ref. (1) which is of sub-centimeter dimensions.

The common component effect is completely analogous to the well-known "common ion effect" in solution chemistry: the dissociation of halide M_aX_b in the discharge atmosphere will be suppressed by the presence of another halide which has a common component, halogen X or metal M, with M_aX_b.

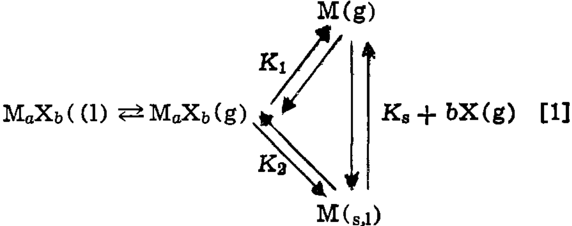
Key words: lamps (halide), high temperature chemistry, transport of silicon and silica, tungsten silicides, electrodes.

Of special importance is the fact that the dissociation will be suppressed also if excess M or X is introduced in the discharge either deliberately, as was the case with the Sn system, or because of reaction between the metal M of M_aX_b and the walls of the discharge device thereby liberating unassociated or "excess" halogen X. The latter is the case of interest here.

Condensed phases can occur because of supersaturation when the partial pressure of M, P_M, from the dissociation of M_aX_b is higher than the saturation or equilibrium pressure of M, P_M (satd.), over condensed M. Therefore, it is not sufficient to consider only the dissociation

$$M_aX_b(1) \rightleftarrows M_aX_b(g) \overset{K_1}{\rightleftarrows} aM(g) + bX(g)$$

because it is necessary to consider also the possibility of condensation. This is expressed here by the cyclic equilibria



from which it is readily shown that

$$P_M = \frac{K_1}{K_2} \leqq K_s = P\text{ (satd.)} \quad [2]$$

The unequal sign refers to conditions under which P_M is not sufficiently large to attain P(satd.), and

therefore condensation does not occur. As can be seen from these relations, examples of such conditions include: (*i*) $K_s >> K_l$ as is the case with NaI, (*ii*) limited amount of M_aX_b in the discharge envelope, and (*iii*) excess of X which suppresses dissociation of M_aX_b due to common component effect.

The last case is of particular importance because it shows the interrelation between the effects of common components and condensed phases.

Finally, according to Eq. [1], the gaseous and condensed phases of all species are in equilibrium at each locale. Therefore, the tendency for reaction of each species is thermodynamically indistinguishable from that of another species. For example, reduction of P_M because of reaction of M(g) with the wall will cause some M(s, l) to evaporate, and depletion of M(s, l) because of reaction with the wall will cause some M(g) to condense, all phases being replenished by further evaporation of $M_aX_b(l)$ and dissociation of $M_aX_b(g)$. In summary, what counts is the thermodynamic activity of M in the gas phase.

These concepts would be implicitly included in comprehensive free energy minimization computations; however, their explicit application to the systems of Th and Sc halides in the following section leads directly to the proposal in the section on Reaction Mechanism and Experimental Results of a set of reaction mechanisms between the halides, the vitreous silica envelope, and tungsten electrodes and to experimental investigations confirming each step of the reaction sequence as a whole.

Theoretical Results and Confirming Experimental Evidence

It is possible to obtain a semiquantitative description of the effects of common components and condensed phases by making the following approximations:

1. Local thermodynamic equilibrium is assumed.
2. The vapor pressure of the halides is determined by the temperature of the coldest region in the discharge envelope. At this region exists a liquid phase reservoir of the halides.
3. Almost certainly the liquid phase cannot be considered an ideal solution since, for example, molecular complexes of NaI-ScI_3 are known to exist (4); however, since disagreements in reported vapor pressure data seem difficult to reconcile (4), it may be preferable at present to employ ideal solution relations.
4. Lower iodides such as ThI_2 are neglected not only because of paucity in thermodynamic data but also because (*i*) the complete dissociation of the iodides represents the limiting case of interest here and (*ii*) the procedure of involving the lower iodides is the same except for added mathematical complexity.

Because of these approximations, it is emphasized that this analysis forms only a base line on which to "factor" the effects of other possible variables, particularly molecular complexing. Conversely, analysis of the effects of other variables must take into account the results given here.

Established procedures (1, 3) are adapted to this set of constraints, see Appendix, to obtain the partial pressures of the species as a function of temperature. These are plotted in Fig. 1 for the ScI_3-NaI system and in Fig. 2 for the ThI_4-NaI system; in both cases the mole fraction, *N*, of NaI has been taken as equal to 0.9 for the sake of correspondence to actual systems. The liquid phase reservoir temperature has been taken as equal to 1100 K.

Common component effect.—In Fig. 1, the dashed lines show the partial pressures of Na, curve B, and Sc, curve C, calculated without taking into account the common component effect of iodine. When this effect is taken into account, the partial pressure of Sc is severely suppressed as shown by the thin solid line, curve D. The partial pressure of Na (not plotted) is suppressed to a lesser extent. Likewise, the suppression

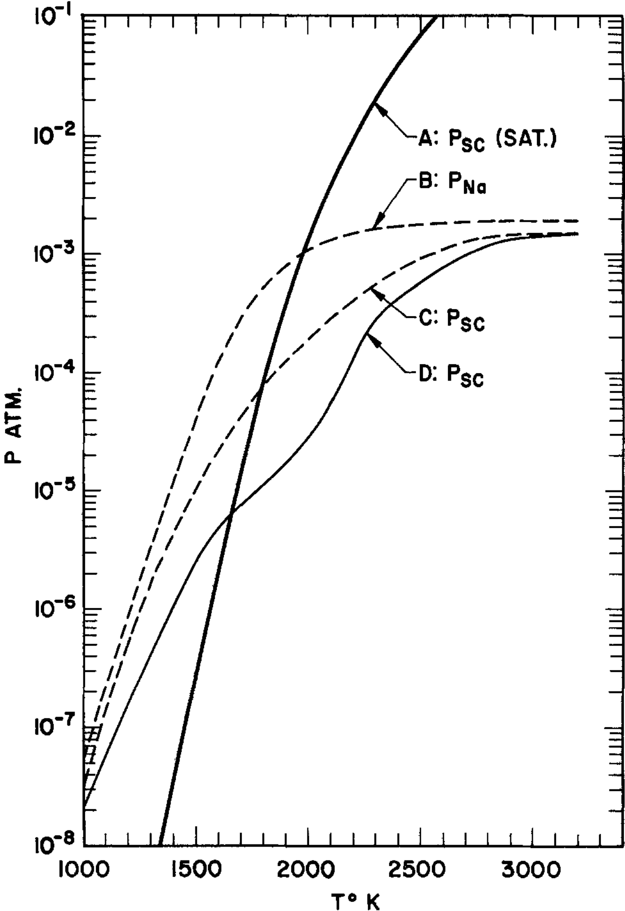


Fig. 1. Partial pressures of Na and Sc over liquid phase reservoir at 1100 K containing mole fractions $N_{NaI} = 0.9$ and $N_{ScI} = 0.1$. A: equilibrium pressure of Sc(g) over condensed Sc(c). B and C: partial pressures of Na and Sc, respectively, calculated without taking into account the common component effect. D: calculated partial pressure of Sc taking into account the common component effect.

of the partial pressures of Na and Th are shown in Fig. 2 and are discussed below.

These results show that the effect of the iodine common component is to suppress the vapor pressures of the metallic vapors; consequently, the intensity of metal atom spectral lines should decrease.

Experimental confirmation of this is seen in the spectra of Fig. 3A and 3B.[1] Figure 3A shows the spectrum of a discharge of NaI and ScI_3 of mole fractions $N_{NaI} = 0.9$ and $N_{ScI_3} = 0.1$ and containing in addition Hg and A. Figure 3B shows the spectrum of the same discharge, but to which a small amount of ThI_4 ($N_{ThI} = 0.01$) has been added. It is seen that the lines of Na and Sc are suppressed as predicted. The intensity of the Hg lines is essentially unaffected, Hg being completely vaporized in either case.

It is concluded that changes such as these in discharge spectra affecting severely lamp color and efficacy (lumens/watt) can be accounted for, at least in part, by the effect of common components.

Condensed phase effects.—In Fig. 1, it is seen that the partial pressure of Sc, P_{Sc}, curve D, from the dissociation of ScI_3 is higher than the equilibrium vapor pressure of Sc, P_{Sc}(satd.) over condensed Sc, curve A, up to approximately 1650 K. Therefore, up to this temperature Sc should tend to condense.

In Fig. 2 is seen that P_{Th}, curve E, is higher than $P_{Th(satd.)}$, curve A, for all temperatures in the range of the figure and, therefore, condensation of Th should likewise be expected.

[1] Obtained by G. Kazek.

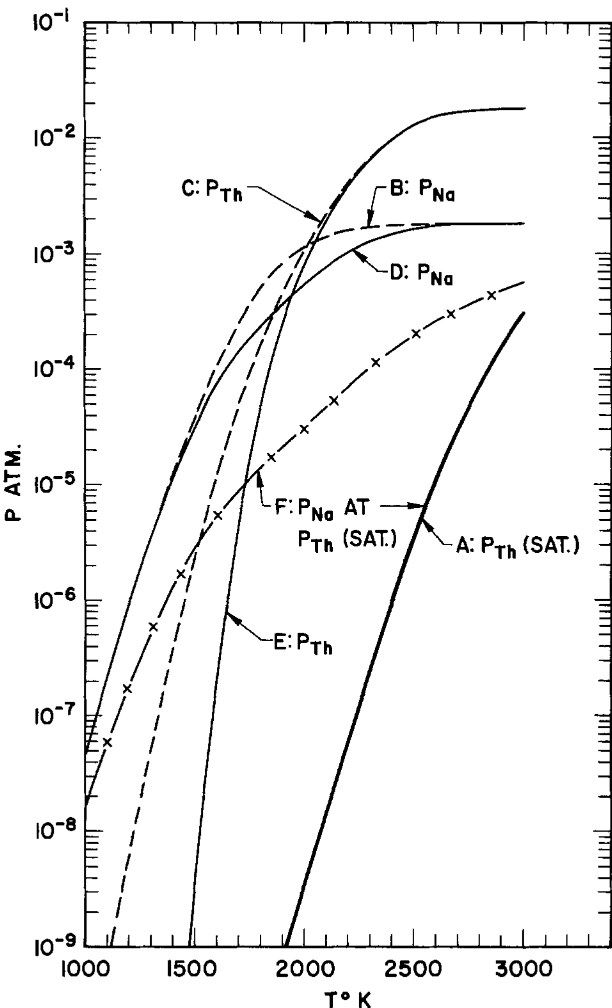

Fig. 2. Partial pressures of Na and Th over liquid phase reservoir at 1100 K containing mole fractions $N_{NaI} = 0.9$ and $N_{ThI_4} = 0.1$. A: equilibrium pressure of Th(g) over condensed Th(c). B and C: partial pressures of Na and Sc, respectively, calculated without taking into account the common component effect. D and E: calculated partial pressures of Na and Th, respectively, taking into account the common component effect. F: partial pressure of Na when there is sufficient excess iodine to prevent condensation of Th.

P_{Na}(satd.) is of the order of 10^{-1} atm already at 1000 K, *i.e.*, higher than P_{Na} and, therefore, no condensation of Na should be expected.

Elemental Sc and Th can be expected to come in contact with the SiO_2 walls and the electrodes. In particular, Th can be expected to condense even on the hottest parts of the electrodes, i.e., at temperatures often exceeding 2500 K. The earliest published evidence for this is photograph 9.9, p. 248 of Ref. (2), which shows a hemispherical deposit of Th on the W electrode of a lamp containing ThI_4. Electron emission measurements from cathodes under discharge conditions using the methods developed in this laboratory (5) confirm that electron emission is enhanced under conditions conducive to Th deposition because Th reduces the work function from the 4.5 eV of bare W to the 3.5 eV of Th.

According to Fig. 1 and 2, condensation could take place in the gaseous phase provided nucleation conditions exist. Our observations confirm the statement in Ref. (2), p. 285 that occasionally a fog of metal droplets is seen within the gaseous phase of the discharge.

Finally, Fig. 1 and 2 indicate that condensation could take place on the walls of the discharge envelope where reactions between Th and Sc species and SiO_2 can be expected. This is the subject of the remainder of the paper; however, since excess iodine will be formed as

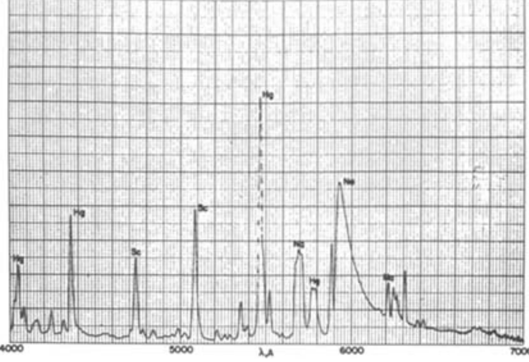

Fig. 3A. Spectrum of discharge of NaI and ScI_3 of mole fraction $N_{NaI} = 0.9$ and $N_{ScI} = 0.1$ (also involving Hg and A).

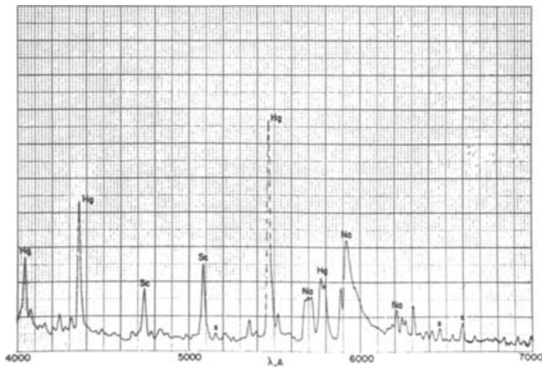

Fig. 3B. Spectrum of same discharge as in Fig. 3A but also containing a small amount of ThI_4 ($N_{ThI} = 0.01$).

a result of these reactions, an important effect of this excess iodine is treated immediately below.

Suppression of condensation by excess iodine.—The amount of excess iodine, P_I, is calculated (Appendix) which will be sufficient to suppress the dissociation of the iodides, due to common component effect, until P_{Th} and P_{Sc} are equal to their respective P(satd.). In other terms, the values of P_I are calculated which will cause in Fig. 1 curve D to coincide with curve A up to 1650 K; and in Fig. 2 curve E to coincide with curve A at all temperatures shown. These then will be the partial pressures of iodine which will just suffice to prevent condensation of Th and Sc.

The results are shown in Fig. 4: curve A gives the partial pressures of excess iodine as a function of temperature that will prevent condensation of Th. Curve B is the equivalent curve for the Sc case. This is compared to curve C which shows the iodine pressure from the normal dissociation of the ScI_3 and NaI, *i.e.*, the iodine pressure in the absence of excess iodine. It is seen that above 1650 K this is sufficient to prevent condensation of Sc as already deduced from Fig. 1.

In addition to suppressing the dissociation of Th and Sc iodides, excess iodine will also suppress the dissociation of NaI. In Fig. 2, curve F shows the partial pressure of Na when there is sufficient iodine to cause P_{Th}, curve E, to coincide with P_{Th}(satd.), curve A. It is seen that P_{Na} is severely suppressed and consequently the spectral lines of Na of discharges containing excess iodine should be severely suppressed. This is an additional reason for the suppression of Na and Sc lines in the spectrum of Fig. 3B as confirmed by the fact that an amount of red HgI_2, formed by the reaction between excess iodine and Hg, was visible on the walls of this lamp at room temperature. In new lamps where wall reactions have not progressed sufficiently for excess iodine to form to the extent that HgI_2 is visible, the suppression of Na lines is less but nevertheless occurs, demonstrating the common component effect due only to iodide dissociation.

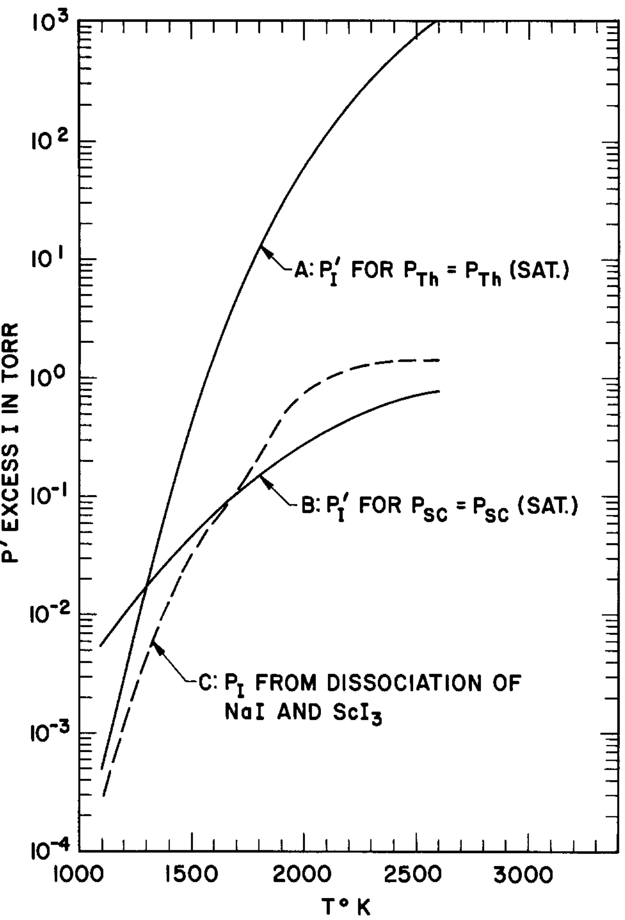

Fig. 4. Partial pressure, P_I, of excess iodine necessary to prevent condensation of Th and Sc. A: P_I to prevent condensation of Th. B: P_I to prevent condensation of Sc. C: iodine pressure from normal dissociation of ScI_3 and NaI, mole fractions $N_{ScI} = 0.1$ and $N_{NaI} = 0.9$. Liquid phase reservoir temperature in all cases is 1100 K.

Reaction Mechanism and Experimental Results

The considerations in the previous sections indicate the conditions under which reactivity should be expected between discharge components. These are applied here to the example of a vitreous silica envelope containing a halide reservoir with a ThI_4 or ScI_3 component and tungsten electrodes.

Table I gives a summary of the understanding that seems to be emerging of the overall mechanism of reaction between discharge atmosphere electrodes and walls for the case of ThI_4. ScI_3 gives completely analogous behavior.

On the left-hand side of the table are given the steps of the reaction sequence. On the right-hand side is given the kind of experimental evidence obtained in support of each step.

The effects of the reactivities in Table I are intricately interrelated and cover the range from subtle to obvious. Therefore, it proved necessary to employ not only established experimental procedures but also to devise new ones. In this paper only the bare essentials of these techniques are given pending their full description elsewhere, particularly of the "closed system" high temperature x-ray diffraction, and near-infrared spectroscopic detection of reaction products in high intensity gas discharge lamps. At the other extreme, in some cases confirming experimental results or observations already existed such as the appearance of red HgI_2 on the walls, and the distortion of electrodes of lamps containing Th and Sc iodides.

Step 1: According to Eq. [1], the gaseous and condensed phases of M_aX_b, M and I_x are at equilibrium at each locale. This is expressed by the equation of Step 1 in the table.

Step A: According to the theoretical and experimental evidence, Th condenses on the electrodes enhancing electron emission.

Step 2: This step postulates attack of the SiO_2 wall by Th to produce condensed products such as interoxides, "Th_xO_y·excess SiO_2," (and possibly oxyiodides), and volatile SiO(g). Formation of SiO(g) is postulated because, as will be explained in detail below, transport of SiO_2 is observed within the envelope.

(a) Detection of wall attack: Microscopic and scanning electron microscope (SEM) examination of SiO_2 envelopes of discharges involving Th and/or Sc iodides revealed that these were etched possibly because of evolution of SiO. Figure 5 is an SEM photograph[2] of such an attacked region.

(b) Detection of condensed products: Energy dispersive mode SEM revealed Th and Sc in these regions.

(c) Detection of volatile Si product(s) from the Th-SiO_2 interaction by means of ion scattering spectroscopy.[3]

In order to determine whether any volatile products such as SiO could result from this interaction, a mixture of Th and vitreous SiO_2 powders, the latter in great excess, was placed in the vitreous silica sample container of an Ainsworth thermobalance, Fig. 6. Above the furnace region of the thermobalance tube was placed a platinum cylinder which had been cleaned with 25% HF solution. The system was evacuated to 10^{-6} Torr and the sample was heated between 900 and 1000 K for 1 hr. A slight decrease in weight was indicated and a light brown deposit was obtained on the platinum cylinder. Examination of a small piece of the Pt cylinder by means of ion scattering spectroscopy revealed that the brown deposit contained Si in a thin (~100Å) layer.

X-ray diffraction of the reacted mixture in the container gave the peaks corresponding to ThO_2 and a pattern of broad bands. These matched the bands obtained from a commercial (Union Carbide) preparation of "SiO."

It is concluded that these experimental results are consistent with the second step of the proposed mechanism.

Step 3: This step postulates transport of SiO_2. Examination of the same discharge envelopes that show etching also revealed deposits in other regions as seen in Fig. 7. These spheroidal deposits proved to be pure SiO_2 as determined by electron microprobe, ion scattering spectroscopic, and energy dispersive SEM

* xs = excess, x,y: stoichiometric parameters.

analyses which were corroborated by high temperature mass spectroscopic studies.[4]

This evidence is consistent with Step 3 of the proposed mechanism since SiO is known (6) to disproportionate into SiO_2 and Si. The absence of elemental Si in the regions of the deposit is related to the next process, Step 4, of the mechanism indicating reaction between this Si and excess iodine to form volatile SiI_4.

Step 4: This reaction relies on the existence of excess iodine: the initiation of the chain of Steps 1-6 depends on iodine from the dissociation of the iodides in Step 1 which is left unassociated by the interaction of Th with SiO_2 in Step 2. Chain propagation then is possible by excess iodine increasing with each reaction cycle, Steps 1-6.

[4] In collaboration with S. K. Gupta.

Commonly used halide lamps contain large amounts of Hg which is completely vaporized. Calculations (3) indicate that the resulting P_{Hg} can vary from 4 atm to in excess of 10 atm depending on lamp type. A consideration of the Si-I-Hg system shows that, since K_{SiI} and K_{HgI} are within one or two orders of magnitude of each other

$$P_{SiI_4} \cong 10^{-3}\, P_{HgI_2}{}^2$$

for P_{Hg} of the order of 10 atm. Even for $P_I \cong 100$ Torr (see Fig. 4) $P_{HgI} \cong 10^{-4}$ atm and, therefore, $P_{SiI_4} \cong 10^{-11}$ atm. Consequently, the excess iodine will be manifested in the discharge as Hg-I species much more than as Si-I species.

This was demonstrated by means of near-infrared spectroscopy using a Hitachi 340 Recording Spectrophotometer modified slightly in order to obtain emission spectra of high intensity lamps situated externally to the instrument.

Figure 8 is the spectrum of a discharge lamp containing a small amount of SiI_4 and sufficient Hg to result in P_{Hg} of several atmospheres, in addition to approximately 100 Torr of A (cold pressure). Except for minor differences, this spectrum is the same as that obtained when the SiI_4 is replaced by HgI_2. These spectra show the reported Hg lines (7) and additional lines marked U in the figure. Between 800 and 1400 nm a broad band is prominent.

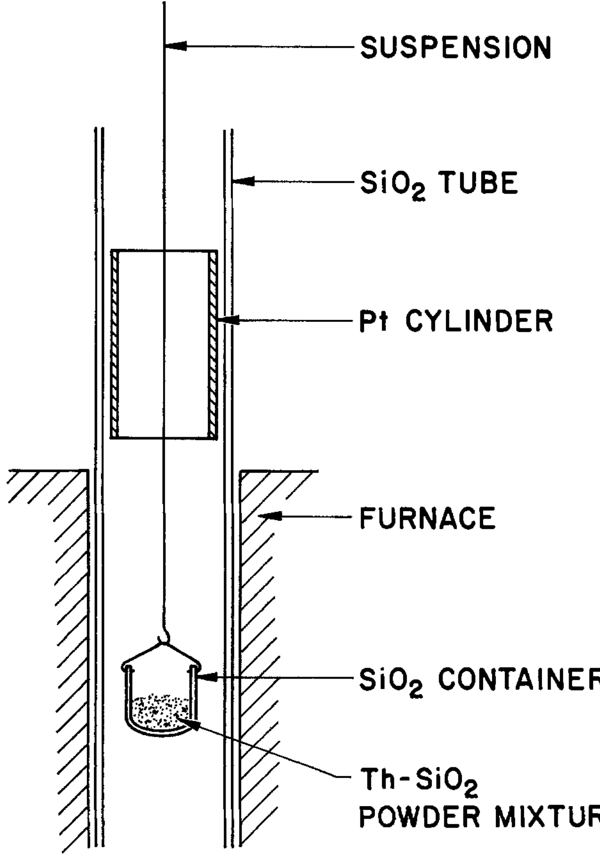

Fig. 6. Experimental arrangement for the detection of volatile Si compounds from the interaction between Th and SiO_2.

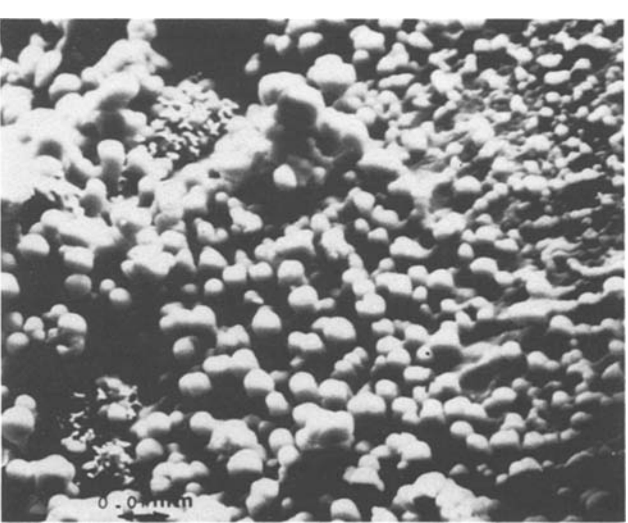

Fig. 7. Spheroidal deposits of pure SiO_2 on the discharge envelope

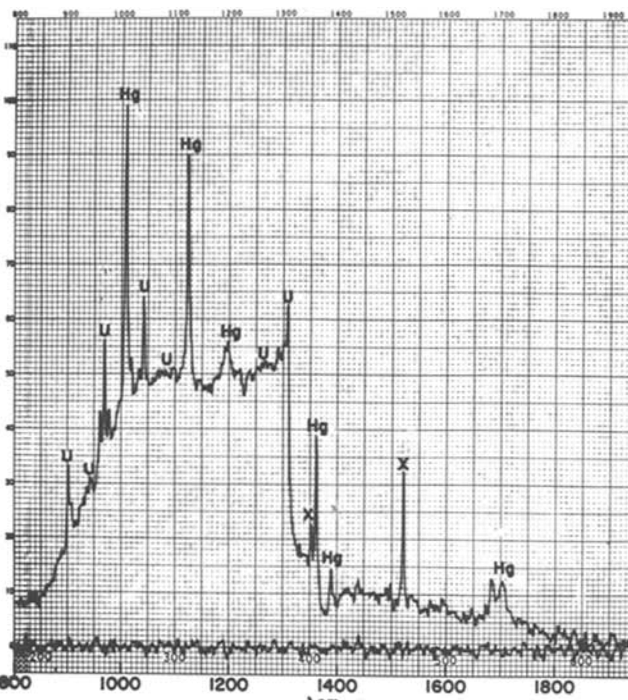

Fig. 8. Near-infrared spectrum of discharge lamp containing a small amount of SiI_4 in addition to Hg vapor at several atmospheres and 100 Torr A (cold pressure).

The U lines and the band are seen in lamps containing Th and/or Sc iodides, Fig. 9. They do not occur in lamps containing only NaI, Fig. 10.

These results are consistent with Step 4 with respect to formation of excess iodine, but proof of the coexistence of SiI_4 is based on the evidence given for Step 5.

Step 5: This step postulates attack of W electrodes by SiI_4 to form silicides whose melting point is considerably lower than that of W. In addition, silicon solution-precipitation effects can be expected along the electrode temperature gradient (8). The net effect will be distortion of the electrode structure. Figure 11 is a photograph of an electrode, originally ending in a well-defined tip, after operation for a few hours in a discharge lamp containing ScI_3. This type of distortion also occurs in lamps containing ThI_4.

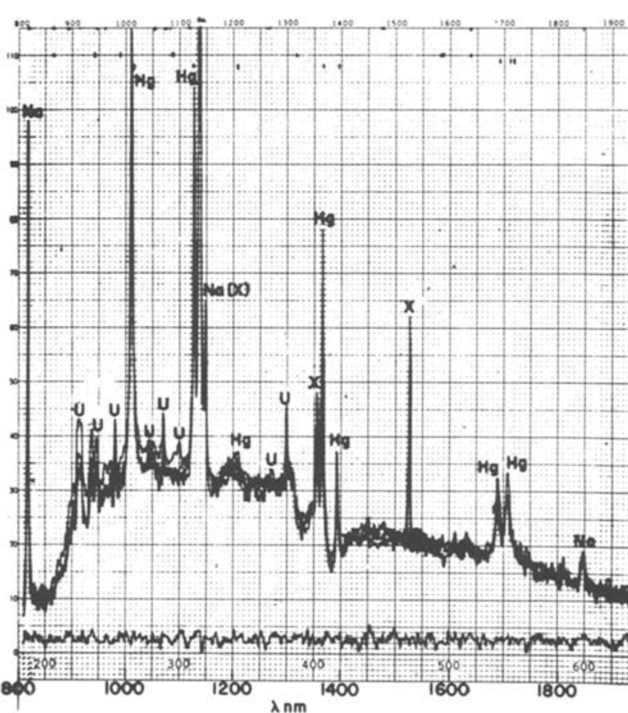

Fig. 9. Near-infrared spectrum of discharge lamps containing Th and/or Sc iodides and the same amounts of Hg and A as in Fig. 8.

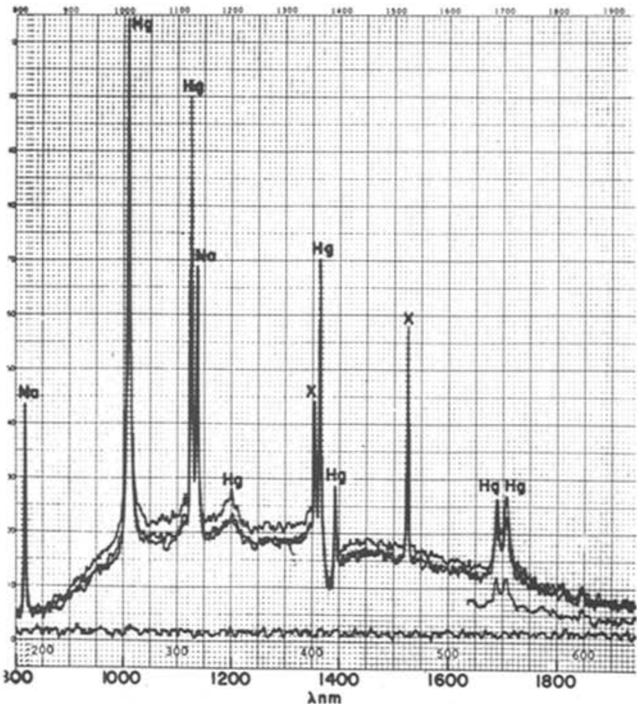

Fig. 10. Near-infrared spectrum of discharge lamps containing only NaI and the same amounts of Hg and A as in Fig. 8 and 9.

A key check of the postulated mechanism is to confirm that this distortion involves SiI_4.

(a) Direct evidence: Although the spectra of lamps containing HgI_2 and SiI_4 are essentially the same, the electrodes of the lamps containing HgI_2 remained intact but the electrodes of lamps containing SiI_4 were distorted during the short (minutes) time of spectroscopic examination. The distorted appearance is very similar to that observed in lamps containing Th and/or Sc iodides, Fig. 11.

(b) Electron microprobe identification of Si: Electrodes such as that of Fig. 11 were subjected to electron microprobe x-ray backscattering examination.

Fig. 11. Photograph of electrode originally ending in a well-defined tip after operation in discharge containing ScI_3. This distortion also occurs in discharges containing ThI_4.

Figure 12 shows that large amounts of Si are associated with the distorted area (end-on view).

(c) Scanning electron microscopy: SEM micrographs of distorted regions reveal peculiar growths, Fig. 13. These do not appear to be only the result of a simple melting process but also of a complex interaction to be discussed in the next section.

(d) Identification of WSi_2 formation by means of "closed system" high temperature x-ray diffraction: The interaction between $SiI_4(g)$ and W(s) to form Si-W condensed phases was proven by means of the experimental arrangement shown in Fig. 14.[5]

The first column of Table II gives the d values of the W peaks (9) before and after heating the system. The second column gives the d values of new peaks appearing after heating the silica envelope to approximately 100°C (~5 Torr of $SiI_4(g)$ for 30 min while holding the W filament to an estimated temperature of 1400°C. The d values of the new peaks correspond (10) to those of WSi_2.

[5] This method was developed in collaboration with J. R. Cooper of this laboratory. It is pointed out that result reproducibility is dependent on precise positioning of the sample in the x-ray beam (*i.e.*, use of a micro-manipulator), secure coupling of reaction tube to support, and the geometry of the target. The optional lower electrode can be used for reactivity studies under discharge conditions and/or measurement (5) of changes of the work function of the target (upper electrode) as a result of its interaction with the atmosphere. The attenuation of the x-ray beam by the walls of the reaction vessel did not prove to be a serious problem. Absorption measurements were in agreement with calculated values using the Victoreen procedure (11); thus, for two 1 mm wall thicknesses of vitreous silica, the attenuation proved to be ~50%.

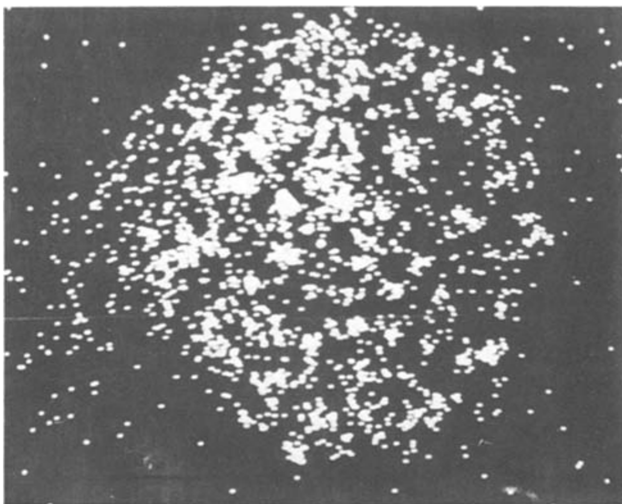

Fig. 12. Detection of Si associated with the distorted area of the electrode of Fig. 11 by means of electron microprobe x-ray backscattering.

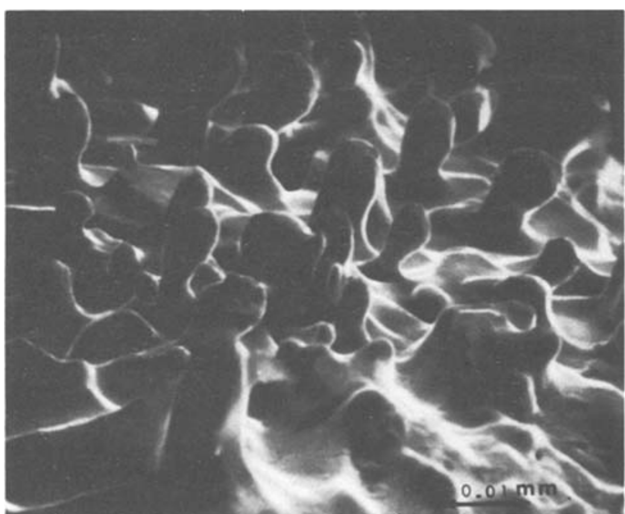

Fig. 13. Scanning electron photomicrograph of distorted region of the electrode of Fig. 11.

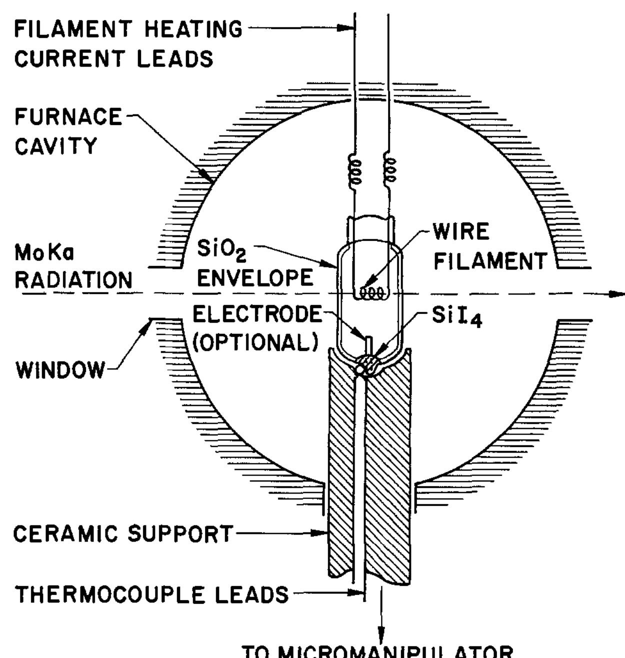

Fig. 14. Experimental arrangement of "closed system" high temperature x-ray diffraction for the study of gas-solid interactions involving condensible, corrosive, or toxic gases.

These results are consistent with Step 5 of the mechanism; it is concluded that electrode distortion involves SiI_4.

Step 6: Self-regulation of reaction mechanism: At low temperatures, the excess iodine combines with Hg to form HgI_2 which is observed as a red deposit on the discharge envelope. At higher temperatures (>100°-200°C), HgI_2 dissociates to Hg and gaseous iodine. The quantity of excess iodine increases with each reaction cycle, Steps 1-6. Eventually this provides the degree of self-regulation of the reaction mechanism described in the previous sections of this paper.

One of the effects will be the suppression of condensation of Th on the electrodes (Step A) and discharge characteristics will begin to change also because of reduction in electron emission from the electrodes. Such changes have been observed (5).

Discussion and Conclusions

Equations [1] and [2] and those in the Appendix outline a thermodynamic basis for electrode-atmosphere interactions. The exact predictions of this interaction, Fig. 1 and 2, will require more exact thermodynamic data. For example, nonideality of solution between ThI_4 and the other species in the reservoir, or formation of oxyiodides could reduce P_{Th}, *i.e.*, lower curve E in Fig. 2, by several orders of magnitude. Reduction by three orders of magnitude would result in curve E intersecting curve A, *i.e.*, the Th saturated pressure, at approximately 2500 K. Consequently, Th would not condense at the electrode tip. Reduction by four orders of magnitude would result in curve E intersecting

Table II. X-ray diffraction data

2θ and d values for W before and after heating		2θ and d values for WSi_2 after heating	
2θ	d	2θ	d
25.90	1.582	13.74	2.97
31.80	1.29	20.80	1.96
45.70	0.915	25.50	1.61
49.46	0.849	28.0	1.47
63.60	0.674	29.0	1.412
69.60	0.622	38.1	1.09

curve A at two points, one at approximately 2300 K and another at a lower temperature. Then the deposition of Th would occur only at a zone of the electrode between these two temperatures.

Finally excess iodine, Fig. 4, would prevent Th deposition altogether.

The experimental evidence supports the proposed mechanism for envelope-atmosphere interactions in Table I. However, the mechanism does not consider "sub-mechanisms" *i.e.*, ultimate reactions and species. For example, it does not attack the problem of the mechanism of formation of the spheroidal deposits of SiO_2 in Fig. 7, or of the peculiar growths in Fig. 13 from the interaction of Si species with W. The W_xSi_y phases formed may be involved in the cyclic process

$$W_xSi_y\,(s,l) \rightleftarrows W_xSi_y\,(g) \;\updownarrow\; xW(s) + ySi\,(l, g)$$

causing not only the growths of Fig. 13 by fractional distillation of Si but also wall blackening.

From both the fundamental and practical viewpoints, it is important to establish the kinetic rates of the steps of the mechanism and especially of the rate-determining step. This is difficult not only because of the intricacy of the mechanism but also because of the overlapping influence of cataphoretic and other effects.

The experimental methods described here could be useful in such kinetic studies. With the exception of the near-infrared spectra for Hg lamps given by Elenbaas (8c), we are not aware of previous studies of gas discharge lamps involving halides by means of near-infrared spectroscopy. The closed system high temperature x-ray diffraction technique illustrated in Fig. 14 is recommended for the study of gas-solid interactions involving condensable, corrosive, or toxic gases.

It is concluded that this work provides outlines for: (*i*) a thermodynamic basis for electrode-atmosphere cycles, (*ii*) an overall mechanism of wall-atmosphere interactions, (*iii*) experimental methods for the detection, monitoring, and study of chemical reactivity in discharges, and (*iv*) an interpretive basis for experimental and test results.

These results supplement those of previous investigations of the effects of oxygen containing impurities (1, 3) and photoelectron-induced electrolysis (2, 3) in halide discharges.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by General Electric Company.

APPENDIX

A complete set of equations describing the atmosphere composition in discharge lamps is given in Ref. (1). For the set of constraints given in the section on Theoretical Results and Confirming Experimental Evidence, these are simplified as follows

$$P^w_{M_aX_b} = N_{M_aX_b} \cdot P^*_{M_aX_b}$$

$$P^w_{M_aX_b} = P_{M_aX_b} + aP_M + bP_x$$

where P^w is the pressure of M_aX_b over the liquid phase reservoir, P the partial pressure of the species indicated by the subscripts anywhere in the envelope, N_{MX} the mole fraction of the halide in the liquid reservoir and P^*_{MX} the vapor pressure of the pure halide.

Introducing these equations into the expressions for the equilibrium constants of the binary system of ScI_3 and NaI results in

$$K_{NaI} = \frac{P_{Na}\,[P_{Na+3}\,P_{Sc}]}{P^w_{NaI} - 2P_{Na}}$$

$$K_{ScI_3} = \frac{P_{Sc}\,[P_{Na+3}\,P_{Sc}]^3}{P^w_{ScI_3} - 4P_{Sc}}$$

and equivalent expressions are obtained for the NaI-ThI_4 system.

These expressions are solved by iteration to obtain P_{Na}, P_{Sc}, P_{Th}, and the partial pressures of the undissociated halides as a function of temperature.

The amount of excess iodine, P_I, which will be sufficient to suppress P_{Th} until it is equal to P_{Th}(satd.), *i.e.*, to suppress the tendency of Th to condense, is calculated by setting

$$P_I = MP_{Th}$$

$$P_{Th} = P_{Th}(\text{satd.}) = K_s$$

Then

$$K_{ThI_4} = \frac{K_s\,[P_{Na} + K_s(4 + M)]^4}{P^w_{ThI_4} - 5K_s}$$

$$K_{NaI} = \frac{P_{Na}\,[P_{Na} + K_s(4 + M)]}{P^w_{NaI} - 2P_{Na}}$$

and analogous expressions are obtained for the ScI_3-NaI system. These equations are also solved by iteration as a function of temperature.

The Gibbs free energy, ΔG_T, adopted for the dissociation of ThI_4(s) to form Th(s) and $2I_2$(g) in the range 298-839 K is that reported by Fuger and Brown (12). This was combined with fusion and vaporization data for for ThI_4 (13) and Th (14) and with dissociation data for I_2 (15) to arrive at the approximate relation

$$\Delta G_T(ThI_4) = 370{,}000 - 132T$$

for ΔG_T of dissociation above 839 K.

The equivalent expression for the dissociation of ScI_3 was also taken to be a linear function of temperature and after review of the literature (13, 15-20) was estimated to be approximately

$$\Delta G_T(ScI_3) = 144{,}000 - 21T$$

ΔG_T data for the dissociation of NaI was taken from the JANAF compilation (15) and Ref. (13) and (19).

Comparison of Computer Curve-Fitting and Graphical Data Evaluations of the Galvanostatic Double Pulse Relaxation Technique for the Measurement of Kinetics of Electrode Reactions

Z. Nagy*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

The fields of applicability of the graphical and computer curve-fitting methods of data analysis for the double pulse galvanostatic relaxation technique are evaluated and compared using numerical computer simulation. The field of applicability is evaluated in terms of τ_c, the time constant of the double layer capacitance-reaction resistance system, and τ_d, the time constant of the diffusion impedance-reaction resistance system, and is graphically represented on a log κ *vs.* log τ_c diagram, where κ, the rate constant parameter, is equal to $(\pi/4\tau_d)^{1/2}$. Within the field of applicability, the technique can be used to obtain the exchange current density with an error of less than $\pm 20\%$. It is shown that a modified graphical method of data evaluation can extend the field of applicability of the technique over that of the graphical evaluation method generally used in the past. The modified technique overcomes the experimental difficulty of measuring the overpotential immediately after the prepulse and also produces a mathematically more accurate description of the overpotential-time curve. As a result, the field of applicability is extended to reactions that are about 0.5 to 2 orders of magnitude faster than measurable with the unmodified technique. The computer curve-fitting data-evaluation method further extends the field of applicability, beyond that of the modified technique, because it uses an exact overpotential-time equation in the numerical evaluation; the improvement is about one order of magnitude in the measurable rates of reactions. Furthermore, the computer curve-fitting method generally results in smaller errors for the determination of the exchange current density than the graphical methods, and, in most cases, the values of the diffusion parameter and the double layer capacitance can also be obtained from the same measurement. A comparison of the fields of applicability of the single pulse and double pulse galvanostatic techniques reveals the general superiority of the latter with the improvement being about one order of magnitude in the measurable rates of reactions.

Computer curve-fitting data-evaluation methods have been shown to be superior to graphical methods for the coulostatic (1, 2) and galvanostatic (3) relaxation techniques. The possible advantages of curve-fitting data evaluation has not been previously examined for the galvanostatic double pulse technique.

The galvanostatic double pulse technique was developed by Gerischer and Krause (4) and Matsuda, Oka, and Delahay (5) as an improved galvanostatic relaxation technique. A high-current, short-duration prepulse is applied, before the measuring pulse, to charge the double layer of the electrode. As a consequence, the technique can be used to make kinetic measurements at times short enough to avoid the disturbing diffusional effects before they become overwhelming. The theory of the original technique required that the prepulse be adjusted to produce a minimum in the overpotential-time curve exactly at the end of the prepulse. A modified theory of the technique has recently been developed (6) which takes into account the experimental fact that exact potential values cannot be measured during a short time immediately after the prepulse. The theory of the technique was extended to the case in which the minimum in the overpotential curve appears at some time after the prepulse, in a time region where exact potential measurements are possible. Two specific cases were investigated: $t_m = t_l + \Delta t$ and $t_m = qt_l$ where Δt and q are kept constant within a series of measurements. It has also been shown that, for experimental reasons, the ideal case of $t_m = t_l$ can never be achieved and that all previous applications of the technique have probably (albeit tacitly) used the case in which $t_m = t_l + \Delta t$. This case will henceforth be called the unmodified technique, whereas the case of $t_m = qt_l$ will be called the modified technique. In this communication, the

* Electrochemical Society Active Member.

graphical data evaluation for these two cases will be compared to a computer curve-fitting data evaluation.

Procedures

Theory.—The theory of the galvanostatic double pulse technique has been described before and will not be repeated here. The full overpotential-time equation has been described for the case of an ideal galvanostat, having zero risetime (5, 6), and also for the more realistic case of linearly rising current pulses (7). It is assumed that all restrictions and assumptions leading to these equations are fulfilled, including the assumption that the current density-overpotential relation can be linearized if the total overpotential (activation + concentration) is less than 5 mV. There is some controversy in the literature about this point. Kooijman *et al.* (8) showed that linearization may be valid only for much smaller overpotentials, but numerical calculations on the coulostatic (9) and galvanostatic (10) relaxation techniques indicated that they are applicable to overpotentials as large as 20-25 mV, even though a linear current density-overpotential relation is assumed.

The three quantities that are potentially determinable with this technique are (*i*) the ratio of the exchange current density to the stoichiometric number (i_o/ν), (*ii*) the diffusion parameter ($1/D_O^{1/2}C_O + 1/D_R^{1/2}C_R$), and (*iii*) the capacitance of the double layer. The first one of these is usually the main objective of the measurement, and its determination will be emphasized in this communication. It is to be noted that, since the technique is limited to the linear current density-overpotential range, the value of the exchange current density cannot be directly determined from a simple measurement. The determinable quantity is the ratio of the exchange current density to the stoichiometric number. For the sake of simplicity, the term "exchange current density" will refer to the i_o/ν ratio in the following, unless it is specifically stated to be i_o.

The full overpotential-time equations are too complicated to be used in a simple graphical data evaluation, and, for this purpose, the zero risetime equation is simplified by some series expansion which is valid only for small or for large arguments (5, 6). A graphical evaluation method is not available for the case of linearly rising pulses. Because of the inadequacies of the above-mentioned simplifications, the graphical analysis introduces an error into the determination of the exchange current density that can limit the applicability of the method, as will be shown below. It is the purpose of the computer curve-fitting data evaluation to eliminate this error by using the full overpotential-time equation, either in the form that assumes ideal pulses or in the extended form that assumes a linear rise for the pulses.

Computational techniques.—In the computer curve-fitting data evaluation, a numerical calculation was carried out to determine the values of the exchange current density, diffusion parameter, and double layer capacitance that give the best fit between the measured and calculated overpotential-time curves, using a multidimensional, nonlinear least squares technique. The curve-fitting subroutine used in this work was LMDER from the MINPACK-1 package developed by the Applied Mathematics Division of Argonne National Laboratory (11). A modified version of the driver program LMDER1 was used to access LMDER. The modifications were made to avoid large initial changes of the estimate of the solution vector by the program, in its search for the minimum in the sum of squares. These modifications were needed, in this particular case, because, in addition to the absolute minimum to be determined, there seemed to exist several local minima which would have trapped the program had the solution vector come too close to any of them. The changes in LMDER1, as compared to the published version (11), were as follows. The statement LMR11310 was replaced by

```
DATA FACTOR, ZERO/1.D-01, 0.0D0
```

and the statement LMR11450 was replaced by the following statements

```
MODE = 2
DO 99 I = 1, N
99 WA(I) = 1.D0/DABS(X(I))
```

The value of TOL was always set to 10^{-8}, as recommended in the documentation for LMDER1. The graphical evaluation was also carried out with the computer, using a linear least squares extrapolation of the overpotential to $t_1 = 0$.

During the computer calculations, the function $g(z) = \exp(z^2)\,\mathrm{erfc}(z)$ has to be evaluated repeatedly, often for complex values of z. Several algorithms were evaluated for this purpose, and their claimed precision and relative computing times are summarized in Table I. The algorithms were compared for a large number of values of the argument, and were found to agree among each other to at least their claimed precision and often to a precision that was many orders of magnitude better. They were compared also by use in the curve-fitting program. The first three algorithms in Table I gave very similar results, whereas Tacher's algorithm resulted in a somewhat larger range of applicability for the determination of the exchange current density. The Tacher algorithm was used for all final calculations. These results indicate that the curve-fitting is influenced by the accuracy of the evaluation of the function $g(z)$ and that an algorithm is needed that approaches machine precision as closely as possible. (The machine precision was sixteen significant digits in this work.) The basic algorithms calculate the function $w(z) = \exp(-z^2)\,\mathrm{erfc}(iz)$ in the first quadrant only. But $g(z) = w(iz)$, and the following symmetry relations can be utilized to obtain the function in all four quadrants: $w(-z) = 2\exp(-z^2) - w(z)$, and $w(\mathrm{conj}g(z)) = \mathrm{conj}g(w(-z))$. The algorithm is correct for all values of the argument but, because of computer limitations, it could not be used when the real part of the argument was less than $-13 \cdot 1$. It should be noted that, while there is no physical meaning attached to negative values of any of the three parameters to be determined, the curve-fitting program will occasionally assign negative values during its search for a minimum.

Error analysis.—The errors of the determination of the exchange current density can be conveniently divided into systematic and random errors. The systematic errors include those resulting from the inadequacies of the mathematical approximations used in the theory of the techniques and from the neglect of the finite risetime of the pulse generator. The random errors are caused by the uncertainties of the measurements of the current density, the electrode potential, and the time. In this discussion, the errors of the potential and time will be combined; that is, it will be assumed that all the errors of a potential-time data pair are concentrated in the error of the potential measurement. This error also includes the error of the correction or compensation for the *IR* drop between the working and reference electrodes.

Table I. Comparison of precision and relative computing times of algorithms for the calculation of the complex exponential error function

Author	Claimed precision	Relative computing time requirements	Ref. No.

Gautschi	10^{-10}	1	(12), (13)
Gautschi	10^{-10}	1	(12)
Tacher	10^{-15}	1.5	(14)

The following procedure was used to calculate the error of the exchange current density using the different data-evaluation methods. Synthetic data were generated using the full overpotential-time equation. These data were then treated as experimental data and the exchange current density was calculated with the appropriate method. The known and calculated exchange current densities were then compared to arrive at the relative error of the method. Both the data generation and evaluation were carried out with a computer.

The following general conditions were used in the calculations. It was assumed that the ringing occurring after the prepulse will subside in such a short time that the minimum in the overpotential-time curve will be observable in the time range of 50-100 nsec after the prepulse. The minimum prepulse length was set to 100 nsec. The shallowness of the minimum in the overpotential-time curve was also considered. The shallowest minimum was required to have a potential change twice that of the uncertainty of the potential measurement in a time duration not longer than ten times the prepulse length. The prepulse length and the position of the minimum were then systematically varied, during the data generation, to find a data set with an observable minimum. To minimize the effect of diffusion, the minimum was set close to the end of the prepulse; usually Δt was equal to the shortest t_l of the series and q was equal to 1.5. For the graphical data evaluation, a series of four data sets were used with t_l varying in proportion to 1, 2, 3, 4. For the curve-fitting, the data set with the shortest t_l was used with $q = 1.5$. The error of the exchange current density determination was calculated for a large number of conditions, systematically varying τ_c and τ_d (see below).

To determine the effect of the accuracy of the overpotential measurements on the error of the determination of the exchange current density, the synthetic data values were rounded off either to the nearest tenth of a millivolt or to the nearest hundredth of a millivolt, creating data sets with ± 50 and ± 5 μV random errors. A 50 μV accuracy can be achieved by the best analog oscilloscopes and the 5 μV accuracy is available with some digital oscilloscopes (transient recorders). The effect of the error of the current density was determined by offsetting the values of the current densities used in the data generation and those used in the data evaluation.

The effect of the risetime of the galvanostat was also investigated. For this purpose the synthetic data were generated with a full equation which takes into consideration the risetime (7). This equation assumes a linear rise of the current (constant slew rate) to the desired value.

The applicability diagram.—Although it has been customary (15, 16) to express the limitation of a technique as the largest measurable first-order heterogeneous rate constant, an inspection of the theory of the technique will immediately reveal that the determination of the exchange current density is influenced not only by the magnitude of k_o but also by many other parameters. Kooijman and Sluyters (17) have suggested the use of certain dimensionless parameters for the error analysis of the galvanostatic and coulostatic techniques. While this is a useful approach, it seems more appropriate, from the standpoint of obtaining a clear physical picture, to express the errors as a function of certain characteristic times of the electrode system and the length of the measuring pulse. This approach was found useful for previous error analyses of transient techniques employing galvanostatic double pulse (6), potential and voltage step (18), and galvanostatic single pulse (3).

A simple electrochemical reaction can be described by an electrical analog of series-coupled reaction resistance and diffusion impedance, both being shunted by the double layer capacitance. Neglecting one component at a time, one can obtain three simple time constants. Only two of these are, of course, independent and it is convenient to select

$$\tau_c = \frac{\nu RTc}{n\mathbf{F}i_o} \qquad [1]$$

and

$$\tau_d = \frac{\pi\nu^2 n^2 \mathbf{F}^2}{4i_o^2\left(\dfrac{1}{D_O^{1/2}C_O} + \dfrac{1}{D_R^{1/2}C_R}\right)^2} \qquad [2]$$

Here, τ_c is the well-known rc time constant of the double layer-reaction resistance system (neglecting the diffusion impedance) and is defined by

$$\eta = \frac{\nu RTi}{n\mathbf{F}i_o}\left[1 - \exp\left(-\frac{t}{\tau_c}\right)\right] \qquad [3]$$

And, τ_d is the time constant of the reaction resistance-diffusion impedance system (neglecting the double layer capacitance) and is defined by (19)

$$\eta = \frac{\nu RTi}{n\mathbf{F}i_o}\left[1 + \left(\frac{t}{\tau_d}\right)^{1/2}\right] \qquad [4]$$

As indicated by Eq. [4], at $t = \tau_d$, the activation and diffusion parts of the total overpotential are equal. To define the limitations of a technique and to allow meaningful comparison with other relaxation techniques, the errors of the measurement should be evaluated as a function of these time constants and the length of the measuring pulse.

The experimenter has full control over the pulse length although the values of τ_c and τ_d can also be varied somewhat through the control of concentrations and temperature. It is therefore practical to describe the limits of a technique as a function of τ_c and τ_d while using reasonable values for the length of the measuring pulse. It was found convenient to use the parameter κ, called the rate constant parameter, in place of τ_d. They are simply related

$$\kappa = (\pi/4\tau_d)^{1/2} = \frac{i_o}{\nu n\mathbf{F}}\left(\frac{1}{D_O^{1/2}C_O} + \frac{1}{D_R^{1/2}C_R}\right) \qquad [5]$$

The advantage of the rate constant parameter is that it can be directly related, under simplified conditions, to the first-order standard heterogeneous rate constant. If one assumes that $D_O = D_R = D$, $C_O = C_R$, and $\nu = 1$, then $\kappa = 2k_o/\sqrt{D}$; and for $D = 10^{-5}$ cm^2 sec^{-1}, $\kappa = 632k_o$.

Using the results of an error analysis, a diagram of κ *vs.* τ_c can be constructed on a log-log scale, and a field of applicability of the technique is defined in such a way that if an electrode reaction system falls within the limits of this field, its exchange current density is determinable with less than a given error. The error limit was set to $\pm 20\%$ in this work. For example, a diagram of log κ *vs.* log τ_c is shown in Fig. 1. A description of some general features of this type of representation is needed. The main scales (log κ and log τ_c) are exact and valid for any combinations of the parameters they contain; under general conditions, only these scales can be used to define the position of an electrode system on the diagram. There are also three approximate, auxiliary scales shown (i_o, k_o, and C). These are convenient because they define a system with familiar parameters, but they are exact only under restricted conditions. The i_o scale assumes that $c = 20$ μF cm^{-2}, $T = 298$ K, and $n = \nu = 1$. The concentration scale further assumes the $D_O = D_R = 10^{-5}$ cm^2 sec^{-1} and $C_O = C_R = C$. All these restrictions apply to the k_o scale.

Results

Graphical data evaluation.—Error analyses of the method, considering the systematic errors only, have already been published (6, 7). To construct the applicability diagrams, a systematic investigation of the random errors was also conducted.

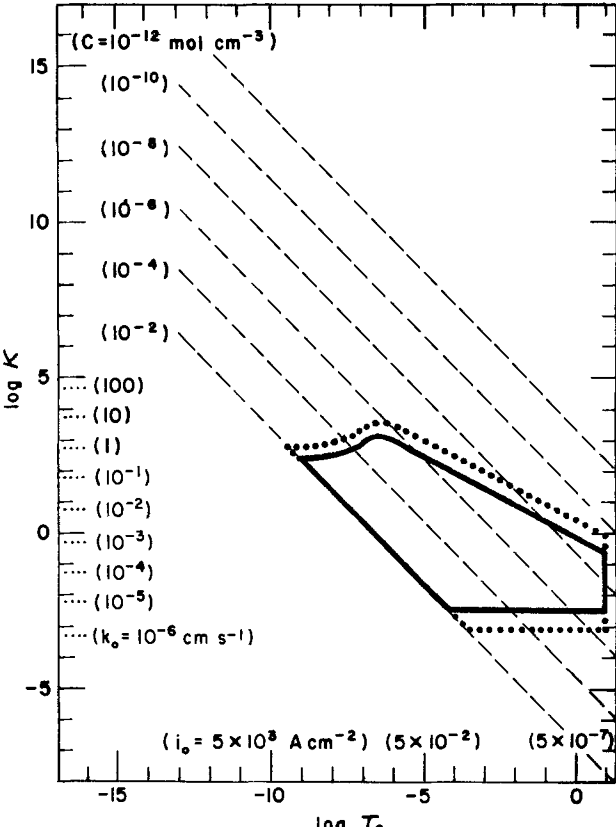

Fig. 1. Applicability diagram of the unmodified galvanostatic double pulse technique with graphical data evaluation ($t_m = t_l + \Delta t$). The solid line marks the field of applicability for measuring the exchange current density with a maximum error of ±20%, with an accuracy of overpotential measurement of ±50 μV. The dotted line extends the field for the ±5 μV accuracy case.

The applicability diagram constructed for the unmodified method ($t_m = t_l + \Delta t$) is shown in Fig. 1. The solid line demarcates the area within which the exchange currency density can be measured with an error of less than ±20% if the overpotential is measured with an accuracy of ±50 μV. The dotted line extends the field to the case of ±5 μV accuracy. The effects limiting the applicability of the method are different on each section of the diagram. They will be discussed proceeding clockwise from the upper left-hand corner. At first, the applicability is limited by the mathematical approximations that are needed to produce the simplified equations used in the graphical data evaluation. Proceeding clockwise, the measurable κ increases as the system approaches the validity range of the small-argument approximation. This is because the error caused by the inadequacy of the mathematical approximations is larger for the large-argument expansion than for the small-argument expansion of the unmodified method (6). The following decline of the measurable κ arises from a combination of two experimental limitations. As the value of τ_c increases, one needs larger t_m values to produce an observable minimum in the overpotential-time curve. Consequently, the kinetic content of the overpotential (ratio of the activation overpotential to the total overpotential) decreases and this causes an increase in the error of the determination of the exchange current density. All the above limitations can be counteracted by more precise measurements of the overpotential, as indicated in Fig. 1. The maximum allowed τ_c was set to 10 sec; at larger values, the measuring current density becomes small (less than nA cm^{-2}) and difficult to measure because of the small signal to noise ratio. If this limitation is removed, the range of applicability can be enlarged by linearly extending the upper and lower limits. The lower limit is also set by experimental effects. Below this limit, the pulse lengths required to produce an observable minimum are so long that natural convection of the solution will interfere with the diffusional mass transport. The onset of the convection was taken to be about 1 min (20). Finally, the highest usable concentration was set at 10^{-2} mole cm^{-3}, which, considering solubility limitations and the requirement of a large excess of supporting electrolyte, is probably as high as one will ever use. The approximate nature of the concentration scale should, however, be kept in mind.

Figure 2 shows the applicability diagram of the modified technique ($t_m = qt_l$). The main improvement, compared to the unmodified method, occurs at small τ_c values at the upper left-hand corner of the applicability field. As has been shown before (6), the large- and small-argument approximations give equally good results for the modified method and, therefore, the limitation at small τ_c values is due to the kinetic content of the overpotential, rather than the breakdown of the large-argument approximation. Proceeding clockwise, the maximum measurable κ goes through a minimum, being limited by the mathematical approximations of the simplified equations, since in this intermediate range neither the large- nor the small-argument expansions are good approximations. The rest of the limitations are the same as those for the unmodified technique (Fig. 1). It is to be noted, however, that the measurable κ levels are somewhat larger for the modified method at all values of τ_c. The reason for this is the generally smaller errors of the small-argument approximation for the modified method (6).

Another experimental restriction which may, in principle, limit the field of applicability is the largest practically achievable current density. This has been shown (3) to be outside the fields of applicability defined by Fig. 1 and 2.

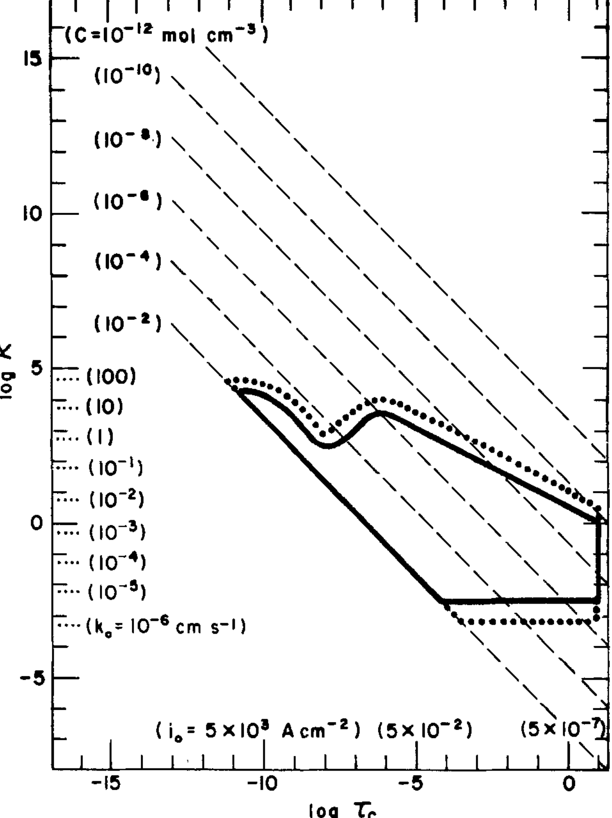

Fig. 2. Applicability diagram of the modified galvanostatic double pulse technique with graphical data evaluation ($t_m = qt_l$). The solid line marks the field of applicability for measuring the exchange current density with a maximum error of ±20%, with an accuracy of overpotential measurement of ±50 μV. The dotted line extends the field for the ±5 μV accuracy case.

The effect of the error of the measuring current density is not large. An error of the measuring current density will introduce a very nearly equal error in the exchange current density which will be approximately additive to the other errors. Figures 1 and 2 were calculated for a ±1% error of measuring current density. An increase of the error to ±5% will decrease the field of applicability only slightly.

The risetime of the galvanostat was found to have only a small effect, as has been shown previously (7). Figures 1 and 2 were calculated for a risetime of 15 nsec, but increasing the risetime to 50 nsec (and even to 0.5 μsec, for prepulses of 1 μsec or longer) will leave the fields of applicability practically unchanged.

Computer curve-fitting data evaluation.—The curve-fitting method is expected to be superior to the graphical data evaluation method because it uses the full overpotential-time equation and therefore the error introduced by the inadequacy of the simplified equations is eliminated. Indeed, as indicated by Fig. 3, the range of applicability is improved in the area where the graphical method is limited by the simplified equations. No other improvements were produced because the limiting conditions (kinetic content of data, shallowness of minima, etc.) are equally applicable to both data-evaluation methods. Therefore, the limiting effects of Fig. 3 are the same as those of Fig. 2, with the exception of the limitation resulting from the use of simplified equations for the graphical data evaluation. On the other hand, a further benefit of the curve-fitting evaluation method is the generally higher accuracy of the exchange current density determination. The error of the exchange current density is equal to or less than that resulting from the graphical method everywhere within the field of applicability. The error of the curve-fitting method can be as much as one order of magnitude less than that of the graphical method. The field of applicability shown on Fig. 3 is, however, subject to the following caveats.

In the computer curve-fitting method, there is no need for a fixed relation between t_l and t_m, since only one measurement is used rather than the series of measurements needed for the graphical case. Therefore, one cannot distinguish between the cases of $t_m = t_l + \Delta t$ and $t_m = qt_l$. However, to assure that the double layer is precharged, the technique still requires that $t_l < t_m$ and that the minimum in the overpotential-time curve be observable.

The method was found to be very sensitive to the risetime of the galvanostat when using the equation assuming ideal pulses; this effect can be diminished, however, by using an extended equation assuming linearly rising pulses (7). To achieve the field of applicability shown on Fig. 3, the extended equation was used; in this case, risetimes up to 50 nsec were examined and were found to have no effect on the results. In these evaluations, the rise and fall of the prepulse were assumed to be linear (7), which is a good approximation of the pulses produced by modern pulse generators. Any deviation from this assumed linearity will introduce some error in the determination of the exchange current density; this error was not evaluated, but is expected to be considerably less than the error caused by the complete neglect of the risetime. This latter case is illustrated in Fig. 4. For this graph, the synthetic data were generated with the equation that takes into consideration the finite rise of the pulses (7), whereas the data evaluation was carried out with the equation assuming zero risetime (6). A comparison with Fig. 3 reveals that a risetime even as short as 5 nsec has a deleterious effect on the accuracy of the determination of the exchange current density and decreases the field of applicability. Of course, if zero risetime data had been used in conjunction with the zero risetime equation in the curve-fitting program,

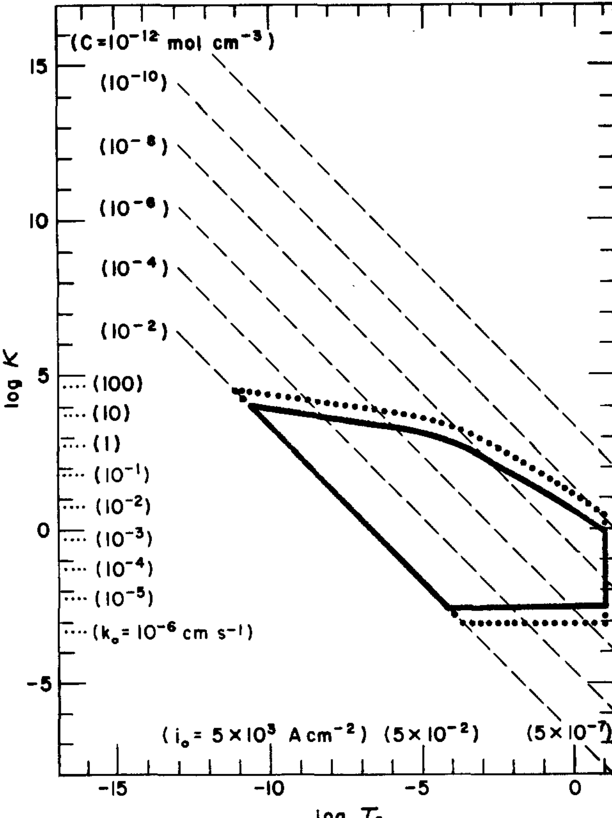

Fig. 3. Applicability diagram of the galvanostatic double pulse technique with computer curve-fitting data evaluation. The solid line marks the field of applicability for measuring the exchange current density with a maximum error of ±20%, with an accuracy of overpotential measurement of ±50 μV. The dotted line extends the field for the ±5 μV accuracy case.

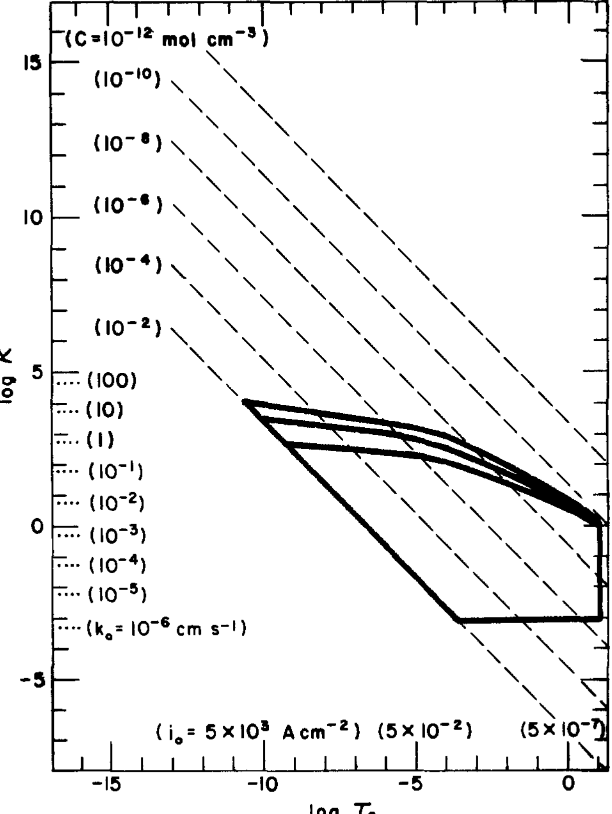

Fig. 4. Effect of the risetime of the galvanostat on the field of applicability of the curve-fitting method, with 5 μV overpotential accuracy. The upper limits represent, in decreasing order, a risetime of 5, 15, and 50 nsec.

the field of applicability in Fig. 3 would have been duplicated.

The method was also found to be sensitive to errors of the measurement of the overpotential and current density. Similar accuracies were assumed for the two measurements; for the case of the 50 μV potential error, the maximum current density error was set to $\pm 1\%$; and for the 5 μV case, the current error was limited to $\pm 0.1\%$. The combined effect of these errors is shown in Fig. 3.

In the calculations leading to Fig. 3 and 4, the number of data points was always 50, with the points being uniformly spaced during the measuring pulse. The first point was always taken at 0.1 μsec after the end of the prepulse to assure that all initial distortions of the potential, due to induction effects and ringing, are avoided in the data. Fifty is probably the maximum number of points obtainable with an analog oscilloscope, while thousands could be obtained with a digital oscilloscope or transient recorder. Increasing the number of data points can decrease the error of the determination of the exchange current density, at the price of longer computation times, but will not significantly change the field of applicability. The use of as many as 2000 data points can decrease the error by one order of magnitude. The computation time for 50 data points averages around 30 sec, and it increases approximately in proportion to the number of points.

To start the calculation, the curve-fitting program requires a set of initial guesses for the three parameters to be determined, (i_o/ν, the diffusion parameter, and the double layer capacitance). It is desirable to start with guesses that are close to the actual values. Figures 3 and 4 are valid for guesses that do not deviate by more than a factor of three from the actual values. A factor of two will produce very similar results. The field of applicability will start to shrink considerably when the factor is four or larger. This is not a serious limiting effect since the initial guess for the exchange current density can be obtained within the desired limits by the graphical data evaluation method of the double pulse technique. The required values of the diffusion parameter and the double layer capacitance can be obtained within the desired limits from the long-time and short-time slopes of galvanostatic transients.

The computer curve-fitting data-evaluation method permits one to calculate the diffusion parameter ($1/D_O^{1/2}C_O + 1/D_R^{1/2}C_R$), and the capacity of the double layer, in addition to the exchange current density. The fields of applicability, of course, are not necessarily the same for these parameters as for the exchange current density, and these limits were not examined in this work. However, the following observations are relevant. The field of applicability of the diffusion parameter is larger than that of the exchange current density, and its field of applicability completely overlaps that of the latter. Within the field of applicability shown on Fig. 3, the diffusion parameter can be determined with an error that is much less than that of the exchange current density. The fields of applicability for the determination of the capacity of the double layer and the exchange current density overlap only partially. The capacity can be determined with an error less than $\pm 20\%$ on the right-hand side of the field shown in Fig. 3; but on the left-hand side, the field is limited approximately by the $\tau_c = 10^{-8}$ line. This is probably due to the fact that at small values of τ_c the usual prepulse length is much longer than τ_c.

Conclusions

A comparison of the unmodified and modified techniques, coupled with graphical evaluation, reveals the general superiority of the modified technique. This is caused by the fact that the simplified equation needed for the graphical evaluation is a better approximation for the modified case. In general, the field of applicability is enlarged by about one-half order of magnitude of κ, and for very fast reactions it is enlarged by about two orders of magnitude.

The computer curve-fitting data-analysis method further extends the field of applicability of the technique because this method uses the full overpotential-time equation as the basis of the data evaluation and the approximation errors of the simplified equations are eliminated. This extends the field of applicability by about one order of magnitude of κ at τ_c values around 10^{-8}. At smaller and larger τ_c values, the curve-fitting method is approximately equivalent to the modified graphical method because they are both limited by the same experimental factors. Further advantages of the computer curve-fitting method are that the error of the determination of the exchange current density will generally be smaller, and that, in most cases, the values of the diffusion parameter and the double layer capacitance can also be obtained from the same measurement.

A comparison of the field of applicability of the galvanostatic single pulse technique (3) with that of the double pulse technique shows that at large κ values (fast reactions) the exchange current density can be measured with smaller error using the double pulse technique, but for slower reactions only the single pulse technique is applicable. Comparing the graphical evaluation methods of both techniques, one can conclude that the modified double pulse technique can be used to measure the exchange current density of reactions that are up to one and a half order of magnitude faster than those measurable with the single pulse technique. The unmodified double pulse technique is applicable to reactions about one order of magnitude faster than the single pulse technique at τ_c values larger than 10^{-6}, but it is worse at smaller τ_c values. Furthermore, using the criterion of maximum measurable κ at any τ_c, the unmodified double pulse technique is indeed inferior to the single pulse technique, as has been predicted by Sluyters and co-workers (21-23). The application of computer curve-fitting data evaluation increases the field of applicability of both the single pulse and the double pulse techniques but the double pulse technique remains equal to or better than the single pulse technique, with the improvement being up to one order of magnitude in measurable κ.

Mass Transfer in a Porous Trielectrode Reactor under Steady-State and Recirculating Conditions

Patrick K. Ng*

GM Research Laboratories, Electrochemistry Department, Warren, Michigan 48090

ABSTRACT

A porous electrode sandwiched between two counterelectrodes was investigated for the recovery of silver from dilute silver cyanide solution. Both single-pass steady-state and recirculating experiments were conducted with this trielectrode reactor, and the results were compared with those of a traditional bielectrode reactor containing only one counterelectrode. A more uniform potential distribution was observed in the cathode of the trielectrode reactor, and a higher volumetric reaction rate is thus possible. A model was developed to derive an overall mass transfer coefficient (K_m) from the results of recirculating experiments. The correlation is in good agreement with the one calculated from steady-state experiments and is best represented by $K_m = 4.1 \times 10^{-4} \text{Re}^{0.48}$.

Flow-through porous electrodes in which the flows of current and solution are parallel to each other have been studied to a great extent both experimentally and theoretically. The merits of such electrodes lie in the fact that they can provide a substantial amount of surface area and a high mass transfer rate. An extensive literature survey of porous electrodes can be found in review papers by Newman and Tiedemann (1, 2). Data furnished by Houghton and Kuhn (3, 4) indicated that porous flow-through electrodes have the highest volumetric reaction rate among electrodes, including planar, rotating cylinder, and fluidized bed. This high volumetric reaction rate makes porous electrodes a suitable candidate, under the present stringent environmental regulations, for treating dilute effluents from electroplating rinsing waste waters.

* Electrochemical Society Active Member.
Key words: cathode, current efficiency, mass transfer, transient.

The performance of a porous electrode is considered at its optimum if the whole electrode is operated under diffusion control, or is limited by the transfer rate of reactants to the electrode surface. This condition can be sustained only with a reasonably uniform potential distribution in the electrode. The low conductivity associated with dilute electrolytes makes this condition difficult to maintain and, as a result, the electrode is not performing up to its full capacity. A great deal of work has been done on predicting and measuring the potential distribution (5-11), and the mass transfer characteristics of the electrode (12, 25, 26). In general, an optimum design involves an electrode that is thin in the direction of current flow to maintain the necessary diffusion-limiting condition in the electrode. This design has a very short contact time for the solution and is not practical for application. One of the proposed remedies for the problem has been to flow the electro-

lyte perpendicular to the current field (13-16), and this is best represented by the "Swiss-roll" cell (14, 17). With this variation, the electrode can be constructed such that it is thin in the direction of current flow and is long in the direction of solution flow. A separator, however, is necessary and the fabrication of such an electrode can be cumbersome.

To maintain a high recovery efficiency in once-through systems, the electrolyte has to be pumped very slowly through the electrode. Sioda (18) gave an equation for the calculation of this critical velocity. Too low a flow rate, however, is also not practical when thousands of gallons of effluents have to be treated. A recirculating operation is thus more applicable and its behavior has been investigated theoretically (19-21) by considering the porous electrode as the analog of a chemical reactor. Experimental work has also been carried out for treating dilute solutions of copper (22, 23, 25) and antimony (24).

The purpose of this work was to develop an improved reactor design that is easy to fabricate and, at the same time, ensures diffusion-control condition over the whole electrode. This design consists of a porous working electrode (cathode) sandwiched between two porous counterelectrodes (anodes), and is referred to as the trielectrode reactor. With the current penetrating from both sides of the working electrode, the potential distribution is more uniform, and a higher volumetric reaction rate is possible. This reactor is useful when products from the counterelectrodes would not interfere with reactions on the working electrode. The behavior of the trielectrode reactor was examined and its performance was compared with that of a traditional bielectrode reactor. Mass transfer correlations were obtained and compared under both steady-state and recirculating conditions. Recovery of silver from a dilute alkaline silver cyanide solution was chosen for study because of the environmental toxicity and the escalating value of silver.

Experimental

Apparatus.—The reactor was fabricated from acrylic tubing (5.7 cm ID) and is shown schematically in Fig. 1. The cathode working electrode was constructed by pressing together silver-plated brass spheres (0.45 cm diam) to a height of 5 cm between two silver screens on which silver wire was welded for electrical contact. Its porosity and specific surface area (a) were calculated to be 0.39 and 8.05 $(cm)^{-1}$, respectively. Each anode was made of stainless steel balls (0.3175 cm diam), also packed between two stainless steel screens to a height of 5 cm. A stainless steel rod (0.635 cm diam) was inserted into each anode for electrical contact. The cathode was insulated from each anode by a plastic screen. Glass beads (0.23 cm diam) were packed at both the entrance and exit regions to ensure uniform flow. Only the bottom anode was connected when experiments for the bielectrode reactor were conducted. The electrolyte was prepared by diluting the silver plating bath solution to a concentration approximately 40 g/liter in KCN and 4 g/liter in KOH. Two initial silver concentrations, 150 and 250 ppm, were used during the experiments. Table I illustrates the physical properties of the solution. Three mercuric oxide reference electrodes were used for measuring the overpotential of the cathode via a capillary at three different positions, *i.e.*, the inlet, the middle, and the outlet.

Flow rates were controlled by a tubing pump and were calibrated with electrolytes by precision rotameters. The potential between the working cathode and the inlet reference electrode was kept constant by a potentiostat. Current flowing through each anode was obtained by measuring the potential across a shunt (0.1Ω) connected in series with anode. A 4-pen recorder was employed for continuous tracing of the currents, and a data logger was used for recording measurements on the cell voltage, the cathode overpotentials, and the anode overpotentials.

Table I. Physical properties of silver cyanide electrolyte

Viscosity (μ)	1.036×10^{-2} g/(cm-sec)
Density (ρ)	1.033 g/cm^3
Conductivity (κ)	0.07 $(\Omega\text{-cm})^{-1}$

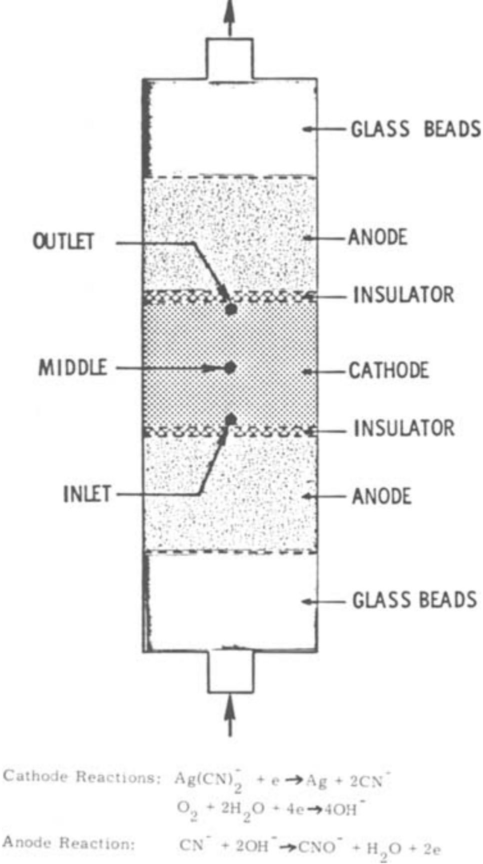

Fig. 1. Schematic diagram of the reactor

Procedures.—For single-pass (steady-state) experiments, the electrolyte was pumped from a 113.5 liter reservoir upward through the reactor. The electrolyte was deaerated for at least 4 hr before each experiment with N_2 gas at a flow rate of 1500 cm^3/min. After a constant electrolyte flow rate was maintained, the electrical circuit was then switched on. Steady state was usually attained in four to five residence times, and an outlet sample was collected for Ag analysis by an atomic absorption spectrophotometer. The applied potential was then increased and the procedures repeated. Caution was taken not to increase the applied potential to a level where the undesired hydrogen gas starts evolving. Another flow rate was then chosen and the entire process repeated.

For the recirculating experiments, the deaerated electrolyte was pumped from a solution volume of 1.5 liter. Samples from the reservoir were taken at predetermined time intervals. In order to minimize the effect of changing volume, only a small amount (2 or 3 ml) of solution was sampled, keeping the overall volume change at less than 2% for all experiments. The applied potential between cathode and inlet reference electrode was kept at 1.2V, under which limiting current condition prevailed over the whole cathode of the trielectrode reactor.

Results and Discussion

Single-pass (steady-state) systems.—Polarization curves obtained from single-pass experiments are shown in Fig. 2 for both the trielectrode and bielectrode reactors. Typical outlet silver concentrations in ppm are also shown in the parentheses. The trielectrode

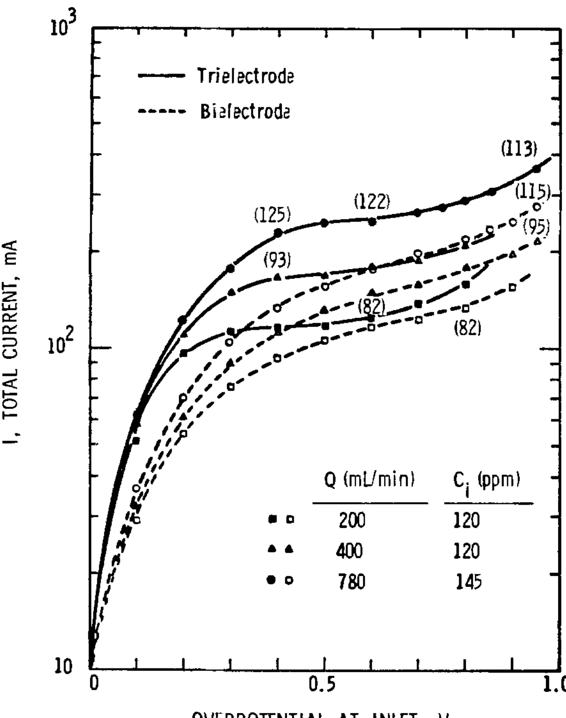

Fig. 2. Polarization curves at steady state.

reactor shows a definite limiting current plateau for all flow rates, indicating a mass transfer limiting condition over the whole cathode. This plateau falls in the potential range of 0.3 to 0.6V and shrinks with increasing flow rate. Hydrogen bubbles have been observed at overpotentials higher than 0.6V. The bielectrode reactor, on the other hand, indicates no plateau even at slow flow rates. Limiting current condition is not maintained and the reacting zone is confined near the inlet due to a highly nonuniform potential distribution. Current efficiencies for both reactors remained high (95-100%) until hydrogen gas started evolving. In general, the trielectrode reactor has a higher volumetric reaction rate than the bielectrode reactor, based on the outlet silver concentrations. Figure 3 shows typical potential distributions within the cathode when the overpotential between the cathode and the inlet reference electrode was maintained at 0.5V. It must be pointed out that each curve is only an approximation of the actual potential distribution. The overpotential in a bielectrode reactor is highest near the inlet and decreases rapidly, whereas the overpotential is relatively more uniform in the trielectrode reactor, particularly at low flow rates. With the additional anode, the potential near the outlet reaches about the same value as the inlet, and a minimum in potential exists near the middle of the cathode. The gain in overpotential or volumetric reaction rate, by the trielectrode reactor is obvious. At high flow rates, even the trielectrode reactor cannot maintain a sufficiently high overpotential near the middle portion of the cathode.

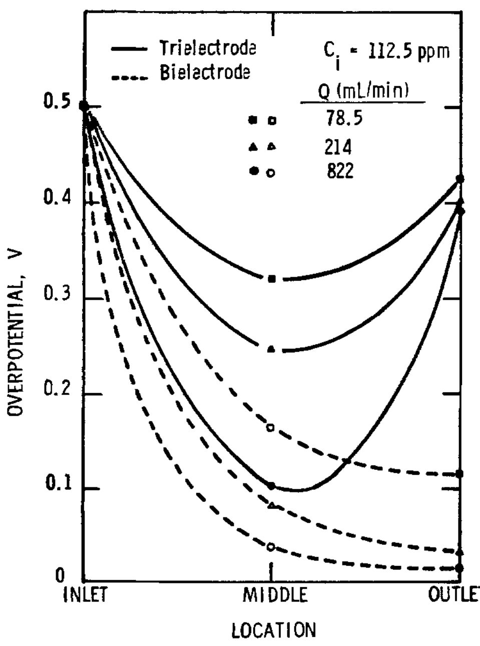

Fig. 3. Steady-state potential distribution in the cathode

Since the electrode is limited by mass transfer, the measured current is related to the mass transfer coefficient by the following equation

$$I = nFaV_TK_mC_i/10^3 \quad [1]$$

Equation [1] assumes a flat velocity profile in the electrode and a velocity such that $v >> aK_mL$, where L is the electrode length. A correlation between the calculated K_m and the Reynolds number (Re) is generally in the form of

$$K_m = B\,\mathrm{Re}^m \quad [2a]$$

where B is a constant containing system parameters. Figure 4 shows the plot of K_m *vs.* Re for both reactors. A least square fit to the trielectrode reactor gives the following correlation

$$K_m = 4.1 \times 10^{-4}\,\mathrm{Re}^{0.48} \quad [2b]$$

in which the exponent is in reasonable agreement with values obtained by other workers (10, 26). The bielectrode reactor follows closely the same correlation but deviates significantly at large Reynolds numbers where limiting current condition cannot be maintained.

The above polarization curve measurements established the proper control potential for the recirculating experiments. A value of 1.2V was subsequently chosen between the porous cathode and the inlet reference electrode, and is equivalent to a cathodic overpotential of about 0.45V.

Recirculating systems.—Previous work (22-25) on recirculating experiments has indicated that the reservoir concentration varied exponentially with time. This work also suggested this simple relationship and typical results are shown in Fig. 5 and 6 for both reactors. Referring to the flow circuit in Fig. 7, the reservoir silver concentration can be represented by

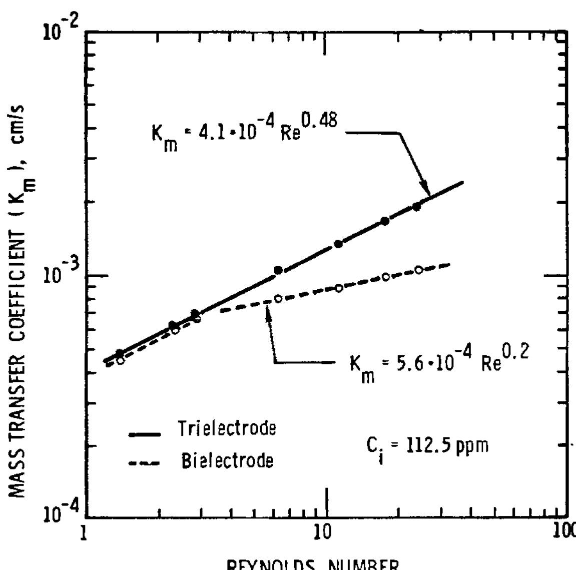

Fig. 4. Mass transfer correlation under once-through conditions

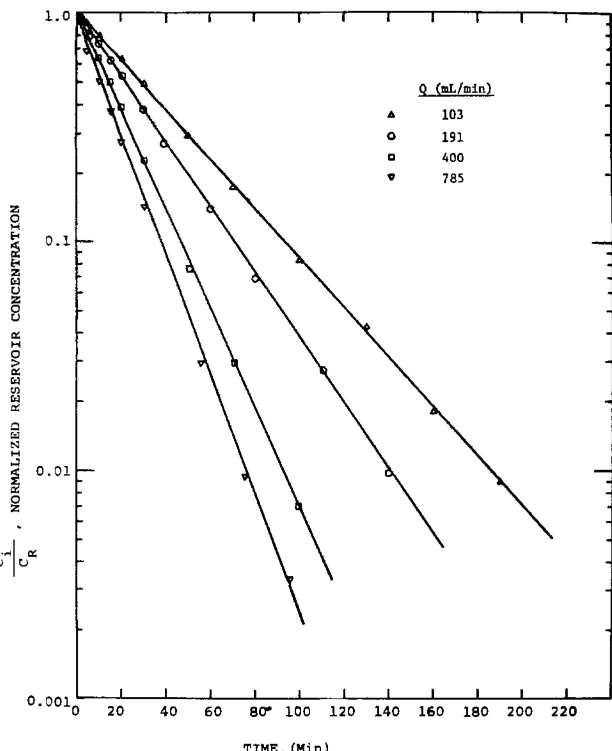

Fig. 5. Concentration transients for trielectrode reactor, V_R = 1.5 liters, C_R = 150 ppm.

$$C_i = C_R e^{-Ht} \quad [3]$$

where H is the slope of the straight lines in Fig. 5 and 6. The reservoir can thus be considered as a reactor with a first-order reaction, and H is the rate constant. For initial concentrations (150 and 250 ppm) studied in this work, the trielectrode reactor gives only one slope, whereas the bielectrode reactor has two. This is consistent with the fact that the trielectrode reactor has a more uniform potential distribution. Figure 8 illustrates a transient variation of overpotential at different locations of the cathode. For the trielectrode reactor, the middle position reaches the limiting current condition (above 200 mV) in a very short time (about 10 min), and the whole cathode is recovering silver effectively. On the other hand, the cathode of the bielectrode reactor has only the inlet region reacting for as long as 40 min before the middle and the outlet positions reach the same limiting condition. The reservoir rate constant is thus a measure of the performance of the reactor, and a close scrutiny of the rate constant would lead to the characterization of mass transport in the porous cathode under recirculating condition.

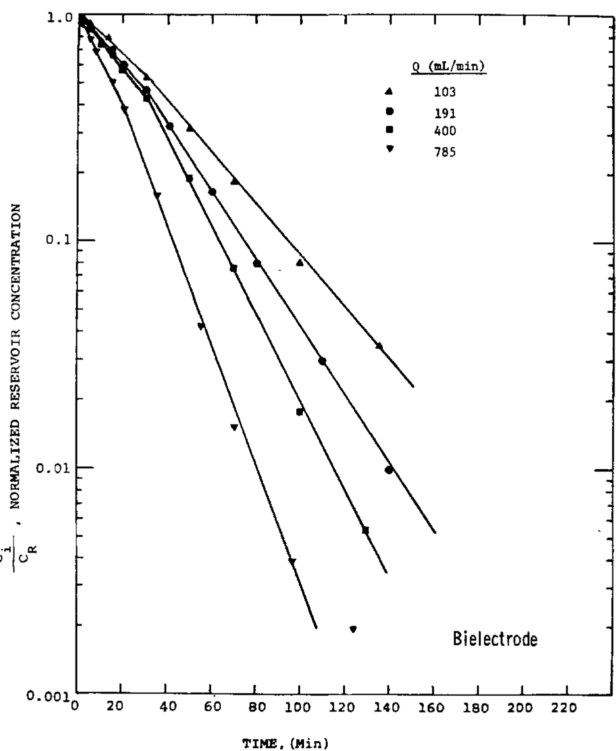

Fig. 6. Concentration transients for bielectrode reactor, V_R = 1.5 liters, C_R = 150 ppm.

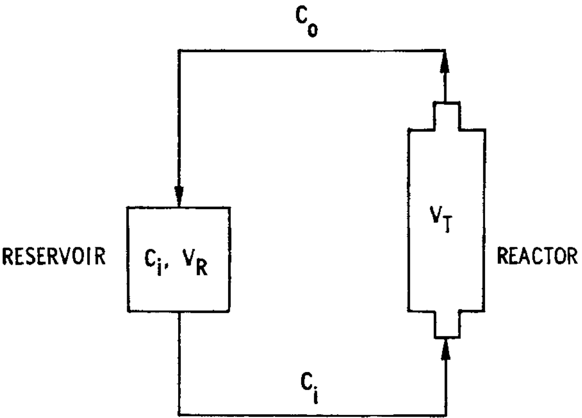

Fig. 7. Flow circuit for recirculating experiments

Figures 5 and 6 can be used to obtain two volumetric reaction rates, namely, an instantaneous (J_t) and an overall (J_T). Instantaneous volumetric reaction rate is the rate at a particular inlet concentration (C_i) and is best calculated by the following equation

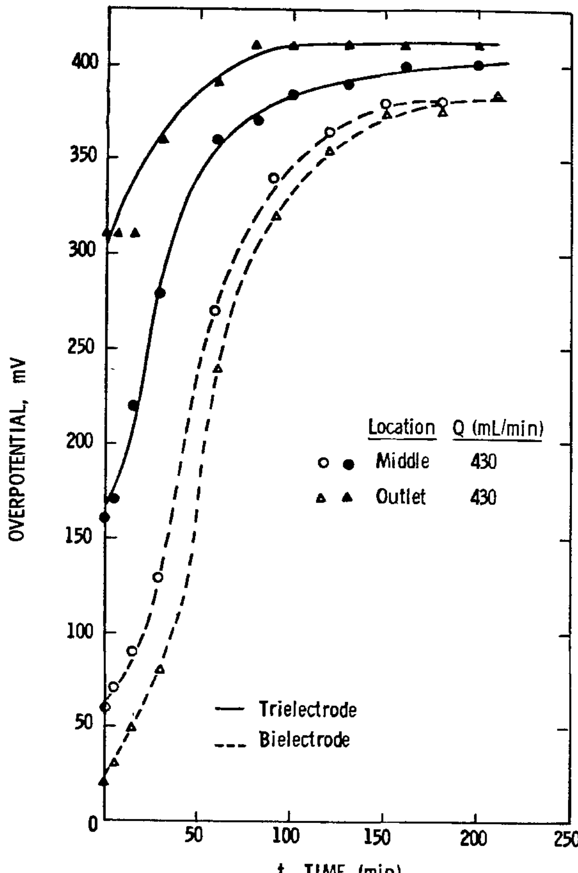

Fig. 8. Overpotential transients at different locations, V_R = 1.5 liters, C_R = 150 ppm.

$$J_t = -\frac{V_R}{V_T}10^3\frac{dC_i}{dt} = 10^3 C_i H \frac{V_R}{V_T} \qquad [4]$$

At the beginning of experiments, the trielectrode reactor definitely has a much higher J_t because of a higher rate constant (H). The bielectrode reactor has the same rate constant after about 40 min and starts having a higher J_t due to a higher C_i in the reservoir. However, the overall volumetric reaction rate (J_T), which is the overall rate calculated over any time interval starting from $t = 0$, remains high for the trielectrode reactor, as illustrated in Fig. 9. The trielectrode reactor can also reduce the problem of plugging by extending the reacting zone over the whole cathode.

Two current efficiencies can be defined: instantaneous (η_t) and overall (η_T). Instantaneous current efficiency is the efficiency at a particular inlet concentration (C_i) and can be estimated from experimental data. This was done by calculating the current efficiency between two sampling points and assigning it as the η_t at the midpoint. One of these results is shown in Fig. 10 in terms of concentration. The error of calculation is greatest at the beginning of the experiment where η_t has to jump from 0 to almost 100%, causing the scattering of data. In general, η_t is high at the beginning when silver ions [in the form of $Ag(CN)_2^-$] are plentiful. As the silver concentration drops with time, η_t decreases drastically, and oxygen reduction becomes the major reaction. For example, η_t is only 50% when 90% of the silver is deposited. The overall current efficiency (η_T), which is the current efficiency over the period of each experiment, remains at about 60% due to a high η_t at the beginning.

An overall mass transfer coefficient (K_m) of the trielectrode reactor under recirculating condition can also be obtained by mass balance equations of the cathode and the reservoir. The porous electrode is assumed to be pseudo-homogeneous with a uniform velocity profile (plug flow). In the recirculating experiments, the inlet silver concentration varied with time, and during each passage of electrolyte through the electrode, the silver concentration changed only slightly. It is assumed that, at any particular time, the bulk silver concentration in the electrode is uniform and equal to the outlet concentration (C_o). The experimental current is then related to C_o by an equation similar to Eq. [1], or

$$\eta_t I = nFaV_T K_m C_o / 10^3 \qquad [5]$$

where η_t is the instantaneous current efficiency. The value of C_o can be calculated by considering an overall mass balance of the cathode, that is

$$Q(C_i - C_o) = 60 K_m a V_T C_o \qquad [6]$$

Thus

$$C_o = C_i \frac{Q}{Q + 60 K_m a V_T} \qquad [7]$$

Substituting Eq. [7] into Eq. [5], one has

$$\eta_t I = \frac{anFV_T K_m C_i}{10^3} \frac{Q}{Q + 60 K_m a V_T} \qquad [8]$$

A plot of $\eta_t I$ *vs.* C_i yields a slope in which K_m can be calculated. The effect of the reservoir, or the rate constant H, is included in C_i which varied according to Eq. [3]. The correlation between K_m and Reynolds number is given in Fig. 11 and can be represented by

$$K_m = 4.0 \times 10^{-4}\, Re^{0.45} \qquad [9]$$

Equation [9] compares remarkably well with Eq. [2], considering the complexity and uncertainty in calculating η_t. This not only justifies the assumptions of the model, but also confirms the belief that K_m obtained from steady-state condition can be confidently used in recirculating condition. Equation [2] is probably the better representation of the mass transfer in the cathode.

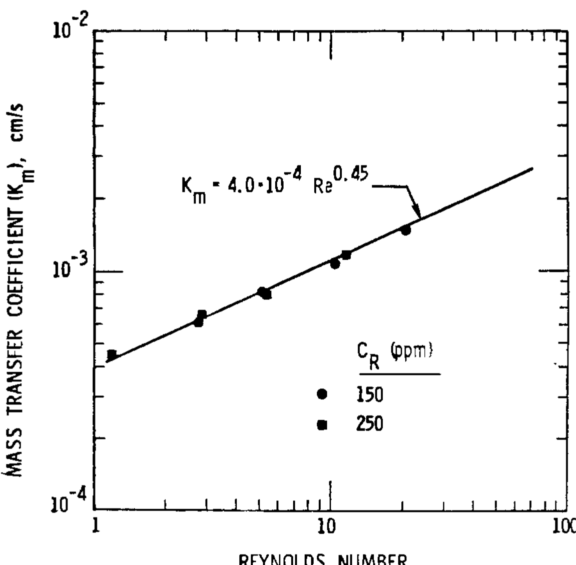

Fig. 11. Mass transfer correlation for trielectrode reactor under recirculating conditions.

Conclusions

Porous electrodes, although they can provide high volumetric reaction rate, are vulnerable to potential variation due to high solution resistivity. An optimum design includes a very thin electrode and a very slow solution flow rate, neither of which is practical. A trielectrode reactor can attenuate these drawbacks by placing the porous working electrode between two counterelectrodes. The additional counterelectrode greatly improves the uniformity of potential and expands the diffusion-control regime over the whole working electrode. As a result, a substantial increase in volumetric reaction rate can be expected, and experimental results substantiate this advantage of the trielectrode reactor. Furthermore, a more uniform reaction rate can extend the operating lifetime of the reactor, reducing maintenance requirements. This is particularly true when using the more practical continuously recirculating system for treating a large amount of solution.

Correlations for the overall mass transfer coefficient were obtained for the trielectrode reactor under recirculating and steady-state conditions. The results indicate that both conditions provide the same correlation. Literature correlations from steady-state experiments can thus be confidently applied to recirculating processes.

The Electrochemical Production of Organic Hypochlorite Compounds

Ronald L. Dotson* and Richard W. Lynch

Olin Corporation, Charleston Technology Center, Charleston, Tennessee 37310

ABSTRACT

The electrochemical synthesis of organic hypochlorite compounds is important as a process for direct production of reactive halofunctionalization agents (1, 2). These materials are useful as intermediates which contain a halogen in the plus one valence state, and applicable to the manufacture of industrial chemicals such as propylene oxide (2) and calcium hypochlorite (3-5). This electroorganic synthesis requires a raw material feed of aqueous brine, organic alcohol, and organic solvent in an undivided cell without separator, and no solvent in a second multi-chambered cell having a membrane. For example, tertiary butyl hypochlorite can be prepared by the electrolysis of aqueous sodium chloride brine and tertiary butyl alcohol. High product yield, current density, and current efficiency is achieved by the proper choice of anode-cathode or anode-membrane gap, proper control of the pH, and cell temperature control. The addition of an organic solvent such as carbon tetrachloride can be used in the "gap-cell" to extract the organic hypochlorite formed within the aqueous brine phase during or after the electrolysis step, according to the following overall reaction

$$NaCl + H_2O + ROH \rightarrow NaOH + H_2 + ROCl$$

The objectives of this research were: (*i*) to evaluate the use of electrochemical gap and membrane type cells for the manufacture of tertiary butyl hypochlorite from tertiary butyl alcohol and sodium chloride, and (*ii*) to optimize cell performance with respect to the operating conditions. This product is useful as a source of pure hypochlorous acid and can be used for the preparation of propylene oxide and calcium hypochlorite (6-8).

Experimental

Tertiary butyl hypochlorite was produced electrochemically in bench scale gap and membrane electrochemical cells.

Gap cell studies.—The test system used is shown in Fig. 1. All tests were run batchwise in a 2000 ml glass reaction flask produced by Tudor Scientific Glass Company. To this cell were added 1500 ml of saturated sodium chloride solution, 50 ml of t-butyl alcohol, and 350 ml of carbon tetrachloride. The cell contained an anode made up as a length of 5/16 in. diam titanium rod coated with ruthenium oxide at the standard firing temperatures. These anodes were prepared by sequentially painting on seven thin coatings from an aqueous solution of $RuCl_3$ dissolved in acidified o-butyl titanate and butanol, then fired in a muffle furnace for 1 hr at 520°C after each coating. This 5/16 in. diam titanium rod was masked down to an exposed length of 3 in. in each case. The cathode of this cell was formed of 1/32 in. thick 316 stainless steel plate rounded in a semi-circular shape with an exposed length of 3 in., as seen in Fig. 1.

All of the studies in the gap cell were made at a constant current of 3.4A, with a current density of 1.6 kA/m^2, based on the entire exposed anode area. The d-c power was supplied from two Heath SP-2730 Power Supplies. The cell voltage was measured with a digital Weston Voltmeter.

The experimental sequence is illustrated by the following example. The cell had a ⅛ in. anode-cathode gap and subtended angle cathode concentric about the anode rod. To the cell was added a volume of 1500 ml of saturated brine at a *p*H of 7.5. The brine was electrolyzed and stirred for 1 hr at ambient temperature. A 10 ml sample of the electrolyzed brine was then analyzed for the available chlorine using 7.6 ml of 0.1*N* sodium thiosulfate in an iodometric titration. To the remaining 1490 ml of electrolyzing brine was added 50 ml of t-butyl alcohol and 350 ml of carbon tetrachloride, and then electrolysis with mechanical stirring resumed at room temperature. The solution *p*H was constantly regulated to a *p*H of 7.5 by adding HCl at regular intervals. A nitrogen purge of the top section of the cell prevented the buildup of an explosive mix-

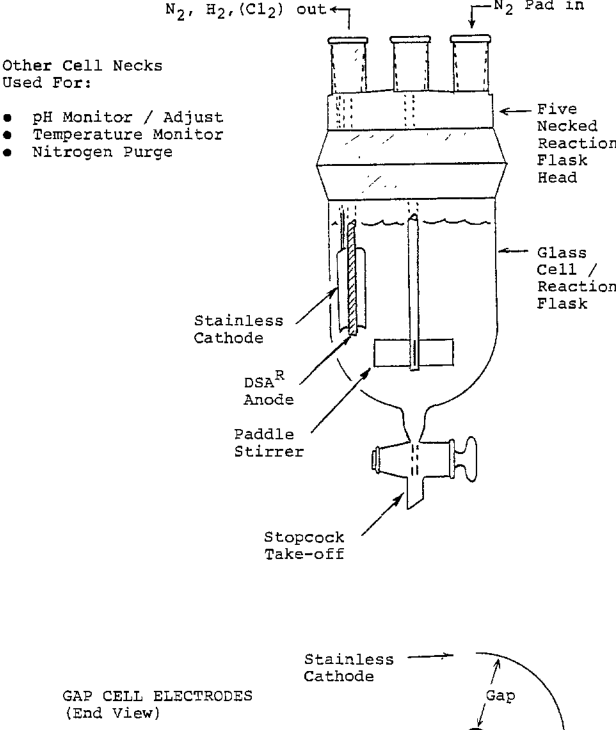

Fig. 1. Batch gap cell (empty)

* Electrochemical Society Active Member.

Key words: organic, industrial chemicals, electrolysis.

ture of hydrogen, chlorine, and oxygen. After line-out at a constant load, the cell voltage was observed to be about 3.2V in all cases. The electrolyte mixture in the cell became progressively more yellow in color as time passed until electrolysis was terminated after the passage of 6.8 A-hr of electricity. After mechanical stirring was stopped, the electrolyte was allowed to stand and to phase separate into a dense yellow organic layer and a clear aqueous layer. A 20 ml sample of the total 370 ml organic layer required 160.6 ml of 0.1*N* sodium thiosulfate for the total available chlorine titration. A 10 ml sample from the corresponding 1500 ml aqueous layer required 2.2 ml of 0.1*N* sodium thiosulfate for the available chlorine titration. This typical result of 92% anode current efficiency was determined after considering the available chlorine control of the initial electrolyzed brine layer and the final aqueous layer. The yellow-green product formed in the organic layer was t-butyl hypochlorite, C_4H_9OCl (9).

Membrane cell studies.—A block diagram for the membrane test cell is shown in Fig. 2. All runs were made batch-wise using a flow-through membrane cell constructed from du Pont Teflon®. The glass anolyte vessel was a 2000 ml reaction flask. The anolyte volume was 2000 ml and contained 1700 ml of brine along with 300 ml of alcohol. The anode of this cell was made from a 2.75 × 5.75 in. sheet of expanded titanium mesh coated with ruthenium dioxide; and the cathode was of the same dimensions but made of stainless steel. The membranes used were composed of the 427 and 295 du Pont Nafion® fluorocarbon cation exchange materials. The cell was designed to provide adjustable electrode-membrane gaps. The cell voltage varied with electrode-membrane gaps, and also both anolyte and catholyte solutions were circulated with inert pumps.

The membrane cell was normally operated at constant current of 20.5A, or 2 kA/m^2 current density. The cell voltage varied with electrolyte gap between membrane and electrode, and current density.

The experimental sequence is illustrated in the following example. This example uses an anode-membrane gap of ½ in. a cathode-membrane gap of ⅛ in., a Nafion® 427 membrane, a volume of 1700 ml of saturated brine at a pH of 7.5, and 300 ml of t-butanol added to the anolyte storage vessel. The electrolyte was circulated through the anode chamber of the cell and back into the anolyte storage vessel by an anolyte pump at a rate of 200 ml/min. A 500 ml volume of NaOH solution of 207 g/liter concentration was added to the catholyte storage vessel, and circulated through the cathode chamber of the cell and back again to the catholyte storage vessel. It was started circulating through the cathode chamber of the cell and back to the catholyte storage vessel by the circulating pump at a flow rate of 50 ml/min. Electrolysis was started and

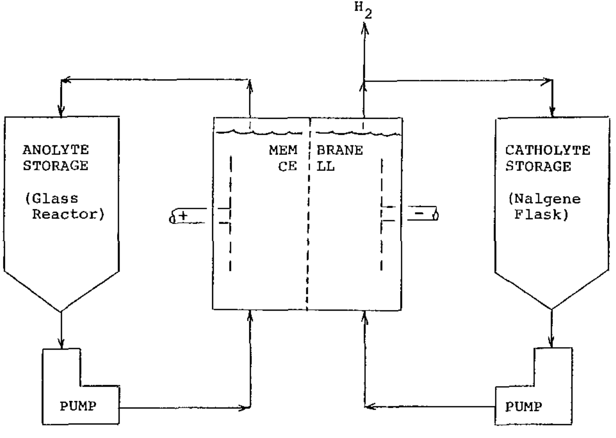

Fig. 2. Membrane cell system block diagram

the cell voltage determined to be 5.2V throughout the run. The anolyte pH was held at 7.5 by addition of 50% caustic at regular intervals, and the anolyte became progressively more yellow with time of run. After 2 hr, 41 A-hr of charge passed, and then the electrolysis was stopped and both anolyte and catholyte solutions collected in separate vessels. A volume of 750 ml of carbon tetrachloride was added to the anolyte in order to ease separation of the concentrated t-butyl hypochlorite product after each run. The inclusion of this step is thought to be safer, but not essential (10, 11).[1] The anolyte was separated into a 750 ml yellow organic phase and 1670 ml clear aqueous phase. A 10 ml sample of the organic phase used 178 ml of 0.1*N* thiosulfate for the available chlorine titration, while a 20 ml sample of the aqueous phase required 0.8 ml of 0.1*N* thiosulfate, and thus showed little hypochlorite remaining. A total volume of 570 ml of NaOH coproduct was collected, and analyzed as 257 g/liter or 21% caustic.

A current efficiency of 85% was determined for the anode portion of the cell, taking into account the small amount of available chlorine present in the final aqueous phase. The current efficiency for the cathode part of the cell was determined to be 68%. A minor amount of t-butanol was found in the catholyte solution, about 0.1% plus a small amount of NaCl, of 0.1%.

Results and Discussion

These studies in this work are unique and present viable commercial approaches to direct electro-synthesis of hypochlorite compounds from alcohols in one step in an electrochemical cell (12, 13).

Gap Cell Studies

Organic solvent.—The kinetics at the anode are thought to be the same for the membrane and gap cell studies. The major difference becomes apparent in the case of the gap cell where carbon tetrachloride is added before electrolysis. The current efficiency of the gap cell experiment was improved from 27 to 95% by solvent addition. This large difference results from the extraction of the very organic-soluble t-butyl hypochlorite moiety into the organic liquid phase where it can become insulated from the cathode surface thereby preventing its electrochemical reduction.

Electrode gap.—A series of identical experiments were run varying only cathode to anode gap distance. These runs showed the cell current efficiency reached a maximum of 93% at ⅛ in. electrode gap. Note in Fig. 3, where at a gap of inches/16 *vs.* cell voltage, the voltage coefficient, V/kA/m^2, and the current efficiency are described and calculated

$$\% \text{ Current Efficiency} = [m/EW/Q/\mathbf{F}] \times 100$$

where m is the mass of the product in grams, EW is the equivalent weight in grams per equivalent, Q is the quantity of electricity consumed, and $\mathbf{F}$ is the Faraday constant.

Electrolyte pH.—The pH of the electrolyte of the gap cell is important in determining the cell current efficiency and the resulting yield of t-butyl hypochlorite obtained. The theoretical optimum point of pH is 7.49, which is the pK_a for hypochlorous acid. Figure 4 provides the data from a series of experiments run at different pH's and electrode gaps at 27°C in a gap cell. The optimum pH is 7.5 and optimum at an electrode gap of ⅛ in. for a 93% current efficiency, in the pH range of 5.8-9.2 and electrode gaps of 1/16 to 1/2 in. Acidic conditions cause decomposition of the t-butyl hypochlorite with liberation of chlorine in the pres-

[1] Bradshaw and Nechvatal (11) reported that during the preparation of t-butyl hypochlorite an explosion occurred during the chlorination step of t-butyl alcohol due to lack of temperature control. They recommend that the temperature of the reaction never exceed 20°C; however, our runs were made at over 27°C with no problems in the electrochemical cells.

chlorite. Both routes lead to undesirable by-products, such as chlorates and chlorinated organics.

Membrane Cell Studies

Anode-membrane gap.—The best anode current efficiency obtained with the membrane cell was found to be 85% for t-butyl hypochlorite formation. During the membrane cell operation, the anode current efficiency depends on the anode-membrane gap, since efficiency increases with increasing gap and then levels as seen in Fig. 5. There appears to be an optimum gap at ½ in. giving maximum efficiency, and Fig. 6 shows the cell potential to rise more rapidly above ¼ in.

ELECTROCHEMICAL FORMATION OF t-BUTYL HYPOCHLORITE IN BENCH SCALE MEMBRANE CELL

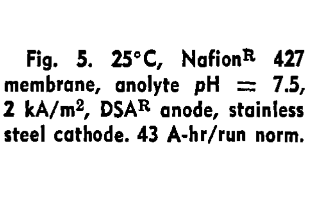

Fig. 5. 25°C, Nafion[R] 427 membrane, anolyte pH = 7.5, 2 kA/m², DSA[R] anode, stainless steel cathode. 43 A-hr/run norm.

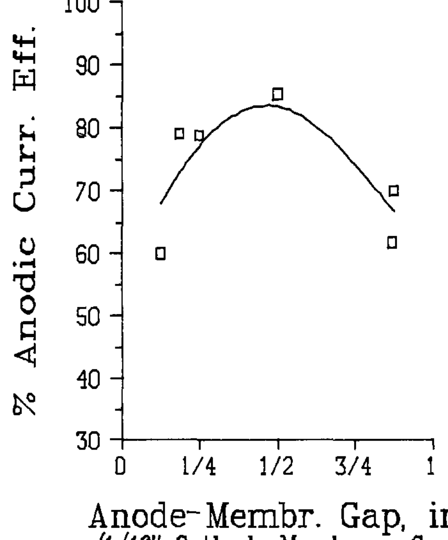
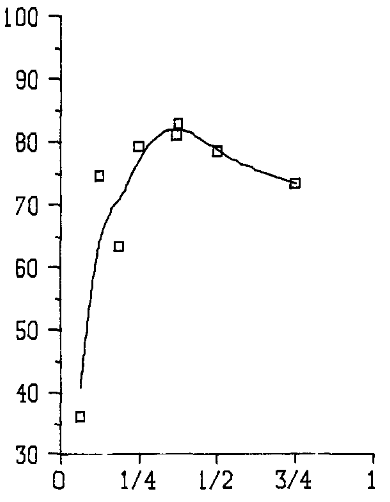
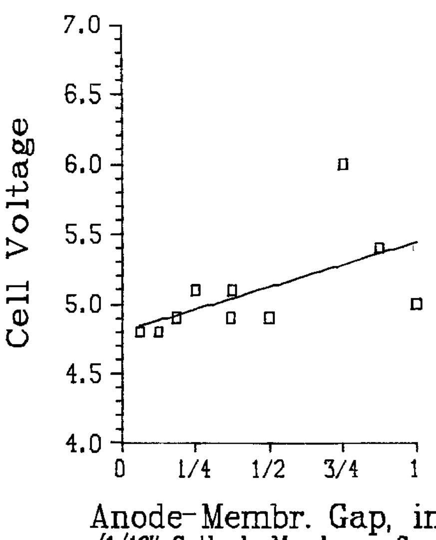




ELECTROCHEMICAL FORMATION OF t-BUTYL HYPOCHLORITE IN BENCH SCALE MEMBRANE CELL



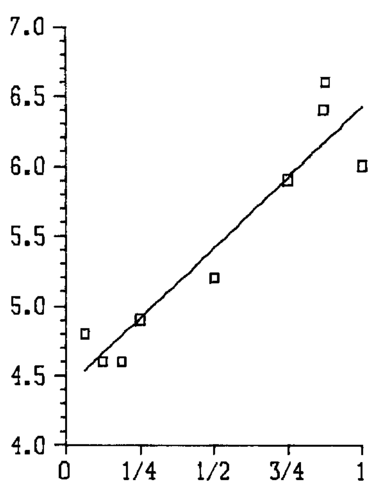


Fig. 6. 25°C, Nafion[R] 427 membrane, anolyte pH = 7.5, 2 kA/m^2, DSA[R] anode, stainless steel cathode.

Cathode-membrane gap.—The cathode-membrane gaps have little effect on the anode current efficiency, and the plots are shown in Fig. 5 nearly the same for 1/16 and 1/8 in. cathode-membrane gaps. Cathode current efficiencies do not have any clear-cut relationship to anode-membrane gaps or the cathode-membrane gaps, as seen from the large scatter of points in these cases. During the entire series of tests run producing t-butyl hypochlorite, cathode current efficiencies averaged 65-70% for the Nafion® 427 membranes.

Membrane type.—An alternate membrane, Nafion® 427, was used in some of these experiments and compared to the Nafion® 295 membrane. The anode current efficiency for this membrane was dependent on gap as was the 295; however, the cathode current efficiency increased dramatically to 85-90% for the 295. The Nafion® 295 membrane appears to be the best membrane for this application.

Conclusions

In this study bench scale gap and membrane cells were operated to produce organic hypohalites safely, economically, and pollution-free in highly pure form. The gap cell synthesis of t-butyl hypochlorite requires an inert organic liquid to dissolve the product as it is formed, but the membrane cell does not require any solvent.

The membrane cell production of t-butyl hypochlorite is safer than the gap cell production and in addition gives pure product. However, the explosive mixtures of hydrogen, chlorine, and oxygen must be purged from the gap cell system.

Electroreduction of 1-Methyl-2-, 3-, and 4-Carbomethoxypyridinium Ions

S. Kashti-Kaplan, J. Hermolin, and E. Kirowa-Eisner

Department of Chemistry, Tel-Aviv University, Ramat Aviv, Israel

ABSTRACT

The character of both polarographic waves of the three isomers 1-methyl-2-, 3-, and 4-carbomethoxypyridinium ions (2^+, 3^+, and 4^+, respectively) has been studied in acetonitrile and in methanol. The first wave is due to a one-electron reduction under DC and normal pulse polarographic (NPP) conditions. Whereas a stable free radical 4· is reversibly formed in the reduction of 4^+ and a dimer is irreversibly formed in the reduction of 3^+, the 2^+ reversibly forms radical 2· at low concentration and short pulse width and a dimer under DC conditions. The equilibrium constant and the rate constants for the dimerization reaction 2· $\rightleftharpoons$ ½ dimer have been determined by the reverse-pulse polarographic method (RPP). The radicals 2· and 4· have been identified by RPP, and the formal potentials of the couples 2^+/2· and 4^+/4· are reported. The second reduction wave of the three compounds is diffusion controlled in protic media (methanol) and yields dihydropyridine as a product. In acetonitrile, the pyridinium salts (n^+) exhibit quite complicated behavior, which is dependent on the nature of the pyridinium ion (position of the carbomethoxy group on the ring) and its concentration, the nature of the cations present in the solution, and the time scale in which the electrochemical method is applied. The 3^+ isomer does not undergo a second reduction step in this solvent. The anions 2^- and 4^- react with the cations to form nH (dihydropyridines), nLi, nNa, or the corresponding dimers n-n (reaction with the starting material n^+). The latter reaction causes a decrease in the amplitude of the second wave and is the most favored reaction in the presence of the indifferent bulky tetrabutylammonium cation, under which conditions the anions (2^- and 4^-) are most stable and are easily detected. The formal potential of the couples 2·/2^- and 4·/4^- are reported.

The observation that NAD^+ and NADH participate in biological oxidation/reduction reactions was made quite long ago (1), but the debate about the exact mechanism of this reaction, namely, hydride transfer (2) *vs.* stepwise electron-proton transfer (3), still continues (4, 5). The implication that radicals may be involved in this important reaction and also the search for the mechanism by which paraquat, a common and important herbicide, acts on the plants (6) have given rise to considerable research on the properties of pyridinyl radicals. Electrochemical techniques have been used in the systematic investigation of chemical phenomena involving NAD^+ and model molecules (7-9). Most pyridinyl radicals formed by electroreduction follow the reaction scheme (8-10)

$$\text{Py}^+\text{-R} + e \rightleftharpoons \text{Py}^\cdot\text{-R} \quad [1]$$

$$\text{Py}^\cdot\text{-R} \longrightarrow \tfrac{1}{2}\ \text{dimer} \quad [2]$$

However, Kosower and collaborators (11) were able to show that withdrawing substituent groups on the γ-position of the pyridinium ring may limit the above mechanism to the formation of the stable free radicals in equilibrium with the pyridinium ion (Eq. [1]), with no subsequent chemical reaction (Eq. [2]). Reversible dimerization processes are common features in radical chemistry (12) and are usually accompanied by marked changes in color. Reversible π-merization[1] of Wurster's blue cation radical, which is usually revealed by the appearance of spectacular colors, was detected by Hausser and Murrell (13) and later for pyridinyl radicals by other investigators (14, 15). Reversible dimerization of 1-trimethylsilyl and 1-trimethylgermyl-pyridinyl radicals (Eq. [3]), which gave rise to a covalent bond between the reacted species has been reported by Neumann and collaborators (16-18)

$$\text{Py}^\cdot\text{-R} \rightleftharpoons \tfrac{1}{2}\ \text{dimer} \qquad R = Si(CH_3)_3;\ Ge(CH_3)_3 \quad [3]$$

Earlier reports (19) on reversible dimerization of pyridinyl radicals based on color changes proved later to be incorrect (20).

Recently Kosower and collaborators (21-23) were able to show that 1-alkylpyridinyl radical, suitably substituted, can also undergo reversible dimerization to form covalent dimers. The behavior of 1-methyl-2-carbomethoxypyridinyl radical, 2·, in acetonitrile and in 2-methyltetrahydrofuran indicated beyond any doubt that reversible dimerization to yield covalent dimers takes place in solution over a considerable temperature range (21). π-mers of 2· were obtained only under special conditions, which were described in detail (22).

In this article we would like to report on the detailed electrochemical behavior of 1-methyl-2-carbomethoxypyridinium salt (2^+) in comparison to its two isomers, 1-methyl-3- and 4-carbomethoxypyridinium salts (3^+ and 4^+, respectively), and also in comparison to results obtained previously (6-11, 21-24). Employing DC, normal-pulse (NP), and reverse-pulse (RP) polarography it was possible to detect intermediate stability radical species and to determine some of their thermodynamic and kinetic constants

Key words: polarography, dimerization, carbonethoxypyridinium salts.

[1] Denotes a π-type charge transfer complex formation between two radicals. The products, π-mers, exhibit spectacular colors (6).

(2^+) (3^+) (4^+)

Experimental

A modified PAR 174 polarographic analyzer (25) with pulse width 0.8-90 msec, sampling time 0.6 msec, and memory time constant of 0.04 msec was used for DC, NP, and RP polarography. The current-potential curves were recorded on a Yokagawa XY Recorder, Model 3077. A 3.5 digit voltameter was used for setting the initial potential. All experiments were performed at 22°C. Potentials were corrected for iR drop according to the spherical symmetry calculations for a three-electrode system (26), where $V_{iR} = i\rho/4\pi r_0$ (ρ, the specific resistivity of the solution; r_0, the radius of the mercury drop; and i, the current at a given part of the polarogram). This correction is necessary for polarograms for which limiting currents are larger than 10 μA ($\rho \sim 50$ Ωcm). The flow rate of the dropping mercury electrode was 1.08 mg/sec.

An Ag/Ag^+ (0.01M), $LiClO_4$ (0.25M), CH_3CN reference electrode (27) was used both in acetonitrile and in methanol. The reference electrode compartment was a glass tube on the end of which a "thirsty glass" plug (Corning Type 7930 glass) was sealed with epoxy glue. The solution in this compartment was renewed every day. The liquid junction stability of this electrode in methanol was very good (drifts smaller than 1 mV/day were observed).

Mercury and nitrogen were purified by standard techniques. The nitrogen was bubbled through acetonitrile or methanol before entering the cell.

Acetonitrile (Merck, Uvasol) and methanol (Merck, proanalysi) were used. Freshly purified[2] acetonitrile was used for comparison with the commercial grade; no difference in the electrochemical behavior was observed. $LiClO_4$ (anhydrous, Fluka-purum) and tetrabutylammonium perchlorate (G. Frederick Smith Chemical Company) were used as electrolytes. 1-Methyl 2-, 3-, and 4-carbomethoxypyridinium perchlorates (mp = 112°-113°C, 88°-89°C, 110°-111°C, respectively) were prepared from the corresponding iodides by treatment with $AgClO_4$ [in methanol, followed by crystallization from methanol-ether (4)]. 1-t-Butyl-4-carbomethoxypyridinium perchlorate was prepared according to Ref. (28).

For large scale electrolytic preparation of the dimer, a mercury pool cathode ($A \sim 7$ cm²) was used. Its potential was controlled against an Ag/Ag^+ reference electrode. The platinum counterelectrode was separated by a Quickfit rotaflow stopcock. During the electrolysis the solution was stirred with a magnetic stirrer and deaerated with nitrogen. The electrochemical behavior of the dimer was tested with a DME inserted in the electrolysis cell itself.

Results and Discussion

We have investigated the electrochemical reductions of 1-methylpyridinium salts substituted with a carbomethoxy group at position 2, 3, or 4. The substituent is an electron-withdrawing group which stabilizes the radical species in the order 4 > 2 > 3, thus giving rise to fundamental differences in their chemical and electrochemical behavior. In both acetonitrile and methanol, all isomers yield two polarographic waves except the 3-carbomethoxypyridinium ion in acetonitrile which displays only wave (Fig. 1a-3a, 5a).

The electrochemical studies were carried out by conventional electrochemical methods, such as DC and normal-pulse polarography (NPP) and the recently introduced reverse-pulse polarographic (RPP) technique (29, 30). RPP is a pulse-polarographic technique that has the quantitative merits of the double-potential-step method and the diagnostic strength of cyclic voltametry. RPP has advantages over cyclic voltametry, since the capacitance currents are much smaller and thus faster reactions can be studied; mathematical treatment is easier and there are no complications due to simultaneous accumulation of products from different potential regions.

The principle of RPP is that during almost the entire life of the mercury drop, $\tau - t_p$, (seconds) a constant potential is applied at which the reaction of interest takes place. Products and intermediates are accumulated in the diffusion layer and their electroactivity is displayed during the application of a short anodic or cathodic potential pulse (milliseconds) during which the resulting current is measured. Examples of uses of RPP in electrode kinetics have been given elsewhere (29, 30).

First Wave

1-Methyl-3- and 4-carbomethoxypyridinium (3^+ and 4^+) ions.—The electrochemical behavior of the two isomers 3^+ and 4^+ at the first wave is well understood (9, 11). We only briefly describe our results to facilitate the comparison of their electrochemical behavior with that of 1-methyl-2-carbomethoxypyridinium (2^+) ion.

Reduction of 4^+ under polarographic conditions yields a one-electron reversible wave with the formation of the corresponding radical

$$4^+ + e \rightleftharpoons 4\cdot \qquad [4]$$

in acetonitrile (Fig. 1a) or in methanol as solvents and $LiClO_4$ or TBAP as supporting electrolytes. The radical is directly observed by its oxidation wave in the RP mode (Fig. 1c wave with $E_{1/2} = -1081$ mV). The reversibility of the charge transfer was proved by the Nernstian behavior of the DC, NP, and RP waves. The half-wave potentials are a good estimate for the formal potential $E^{\circ\prime}$ of the redox couple $4\cdot/4^+$.

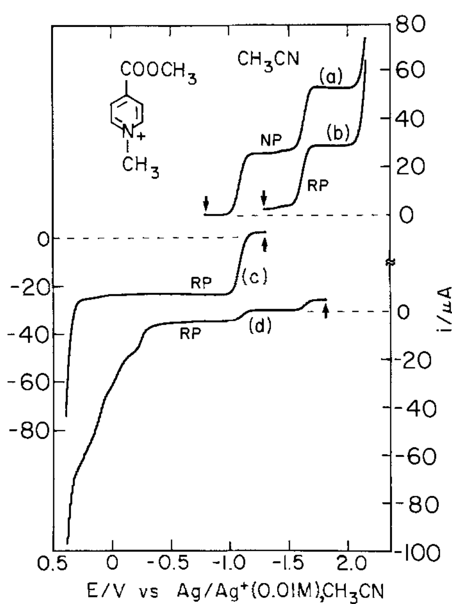

Fig. 1. NPP and RPP (constant E_{in} mode) of 0.65 mM 4^+ ClO_4^- in 0.25M $LiClO_4$-CH_3CN. $\tau = 1.1$ sec, $t_p = 3.1$ msec. Arrows indicate E_{in}. E_p is plotted on the X-axis.

[2] The acetonitrile was dried over a molecular sieve (4A) 24 hr and then stored over Mg turnings and 1,1'trimethylene-bis-(4-carbomethoxypyridinium)iodide, effectively removing oxygen and other reactive impurities. Samples of distilled solvent were collected under high vacuum (~10^{-6} mm Hg) and used immediately.

RP measurements reveal that the radical is the only product at short pulse duration as well as in DC measurements (up to 8 sec) in both methanol and acetonitrile (11). Because of the short times involved, the slow reaction of 4· with methanol (6) does not interfere.

The reduction of 3^+ results in a one-electron wave, the limiting current of which is diffusion-controlled under DC and NP conditions. The shape of the wave and the dependence of $E_{1/2}$ on time and concentration (Table I) corresponds to a reversible one-electron step followed by irreversible dimerization (Eq. [5])

$$3^+ + e \rightleftharpoons 3^\cdot; \quad 3^\cdot \xrightarrow{k_d} \tfrac{1}{2}\text{ dimer} \qquad [5]$$

Semilogarithmic analysis (31) (Eq. [6]), corresponding to reaction scheme [5]

$$E = E_{1/2} + \frac{RT}{\mathbf{F}} \ln \frac{2^{1/3}(i_{NP} - i)}{i^{2/3} \cdot i_{NP}^{1/3}};$$

$$E_{1/2} = E^{\circ\prime} + \frac{RT}{3\mathbf{F}} \ln(4.2 k_d t C_{2+}) \qquad [6]$$

was carried out with data from DC polarograms (drop time 1-5 sec) in the presence of Triton X-100 (required for the suppression at the maximum) and yielded the expected slope (Table I). The dimer formed during the electroreduction of 3^+ was directly observed by the RP technique. RP carried out with an initial potential in the plateau region of the first wave displays a well-defined two-electron wave of the dimer oxidation in both acetonitrile (Fig. 2c, $E_{1/2} = -400$ mV) and methanol (Fig. 3c, $E_{1/2} = -330$ mV).

The characteristic experimental parameters are reported in Tables I, II, and Fig. 1-4.

1-Methyl-2-carbomethoxypyridinium (2^+) ion.—The behavior of 2^+ is more complex than that reported previously (24) and offers a special case in which both the pure charge transfer process

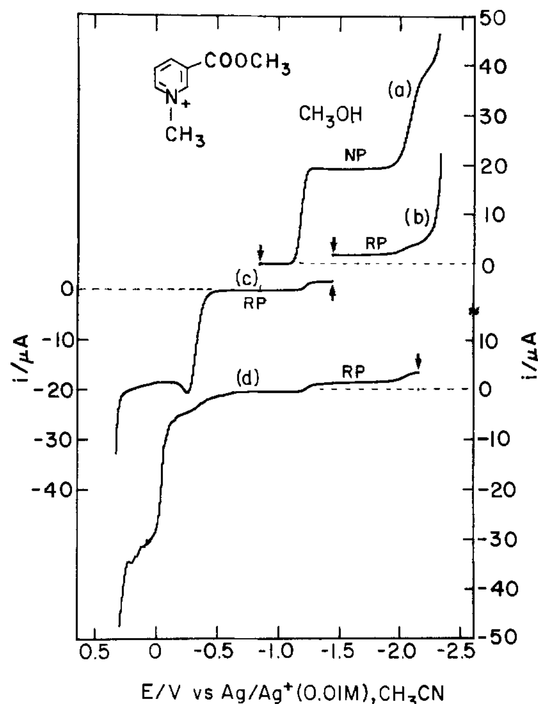

Fig. 3. NPP and RPP (constant E_{in} mode) of 0.54 mM 3^+ ClO_4^- in 0.25M $LiClO_4$-CH_3OH. $\tau = 1.1$ sec, $t_p = 3.1$ msec. Arrows indicate E_{in}. E_p is plotted on the X-axis.

$$2^+ + e \rightleftharpoons 2^\cdot \qquad [7]$$

and the dimer formation

$$2^+ + e \rightleftharpoons \tfrac{1}{2}\text{ dimer} \qquad [8]$$

can be observed separately by merely choosing the proper time scale. In the millisecond range, only the reversible formation of the 2· radical (Eq. [7]) is observed, while at much longer times (seconds) the reversible dimer formation (Eq. [8]) takes place. In an intermediate time range the dimerization process of 2· radical following the charge transfer step (Eq. [9]) is irreversible

$$2^+ + e \rightleftharpoons 2^\cdot; \quad 2^\cdot \rightarrow \tfrac{1}{2}\text{ dimer} \qquad [9]$$

The experimental data concerning the behavior described above are summarized in Table I.

Pathway of Dimerization

Dimerization can proceed in different pathways. Those proposed by Bard *et al.* (32) will be discussed

$$\text{I.}\quad 2^+ \overset{e}{\rightleftharpoons} 2^\cdot;\quad 2^\cdot \underset{k_m}{\overset{k_d}{\rightleftharpoons}} \tfrac{1}{2}\ \text{dimer} \qquad [10]$$

$$\text{II.}\quad 2^+ \overset{e}{\rightleftharpoons} 2^\cdot;\quad 2^\cdot + 2^+ \underset{k_m}{\overset{k_d}{\rightleftharpoons}} \text{dimer}^{\overset{+}{\cdot}};$$

$$\text{dimer}^{\overset{+}{\cdot}} \overset{e}{\rightleftharpoons} \text{dimer} \qquad [11]$$

$$\text{III.}\quad 2^+ \overset{2e}{\rightleftharpoons} 2^-;\quad 2^- + 2^+ \underset{k_m}{\overset{k_d}{\rightleftharpoons}} \text{dimer} \qquad [12]$$

At short time/low concentration measurements, the contribution of the dimerization reaction is negligible ($tC_{2^+} < k_d^{-1}$). One electron reduction wave was observed (cf. Table I) excluding II as a possible mechanism.

Distinguishing between mechanism I and II was based on measurements of the ratio of RP current of radical to RP current of dimer at varying initial potentials along the DC polarographic wave of 2^+. This ratio decreases with increasing DC for mechanism I and increases for mechanism II. The experimentally measured ratios indicate unequivocally that mechanism I is operative in the reduction at the first wave.

It will be shown later in this work that mechanism III is operative at the second-reduction wave and may become dominant under proper conditions.

The Reverse Pulse Method for Characterization of the Redox Couple $2^\cdot/2^+$

NPP in a limitingly low concentration range of 2^+ (8-17 μM) and short times (0.8-1.8 msec), corresponds to a one-electron reversible wave (without dimerization) as manifested by constancy of $E_{1/2}$ (Table I). The reversibility under these conditions could not be supported by a semilogarithmic analysis of the NPP wave (because of charging-current distortion), but was unambiguously proved by analyzing the RPP waves as will be shown later.

By applying RPP (potentiostating the DME at the plateau of the first wave for $\tau \geq 1$ sec, and sampling the current at $t_p \leq 3$ msec and $C_{2^+} \leq 2$ mM), the following observations were made: (*i*) the mixed cathodic-anodic wave ($E_{1/2} = -1.166V$, Fig. 5c) has Nernstian behavior for a simple one-electron charge transfer process; (*ii*) $E_{1/2}$ is independent of pulse

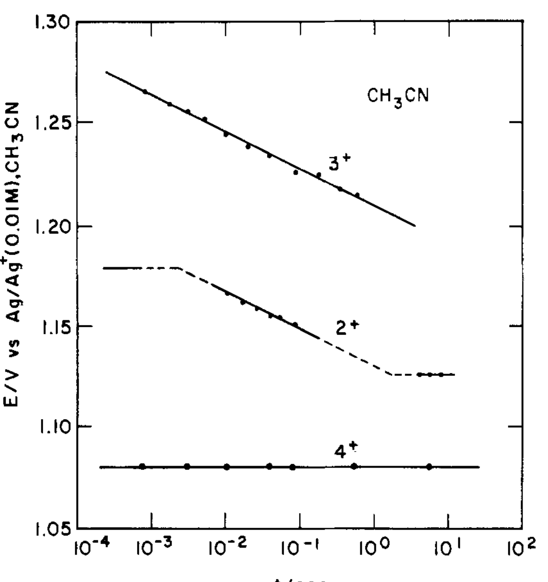

Fig. 4. Half-wave potential/time dependence for the first reduction wave of 2.5 mM 2^+, 3^+, and 4^+ in 0.25M $LiClO_4$-CH_3CN. Data derived from NP, RP, and DC polarography.

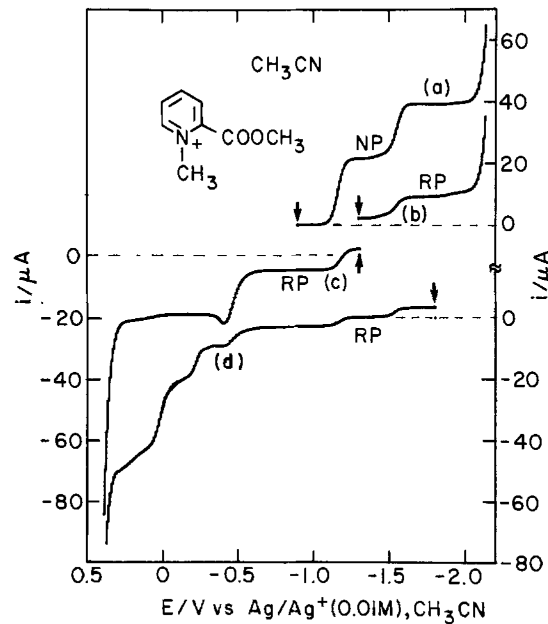

Fig. 5. NPP and RPP (constant E_{in} mode) of 0.57 mM 2^+ ClO_4^- in 0.25M $LiClO_4$-CH_3CN. $\tau = 1.1$ sec, $t_p = 3.1$ msec. Arrows indicate E_{in}. E_p is plotted on the X-axis.

width and concentration; and (*iii*) $i_{RP,D}/i_{RP,R}^2$ is independent of pulse width.

We thus conclude that the chemical reactions (monomerization and dimerization) are frozen and the simple charge transfer [7] is observed.

The main difference between the NP and RP modes stems from the fact that under RPP, the radicals have been allowed to dimerize over a long enough time ($\tau \geqq$ 1 sec), thus diminishing substantially the contribution of the dimerization process during the pulse.

The observation that at the same pulse width, monomerization is frozen at RPP, while dimerization is not frozen at NPP, indicates that $k_m < k_d C_{2^+}$ (0.1 mM $\leqq$ $C_{2^+} \leqq$ 2 mM).

The RP mixed cathodic-anodic wave is a good estimate for the formal potential of the couple $2^{\cdot}/2^+$: $E^{\circ\prime}_{2^{\cdot}/2^+}$(AN) $= -1166$ mV and $E^{\circ\prime}_{2^{\cdot}/2^+}$(MeOH) $= -1111$ mV.

Products of the Dimerization Process

RPP proved to be a useful tool to analyze the reduction products of 2^+ at the electrode. The RPP of 2^+ (Fig. 5c) includes two waves, one with cathodic and anodic components ($E_{1/2} = -1.166$ V, represents the reduction-oxidation process [7]) and the other, the anodic wave at -0.48V. The following facts indicate that the anodic wave represents the oxidation of only one product

(2-2)

1,1′-dimethyl-2,2′-dicarbomethoxy-4,4′-tetrahydrobipyridine: $\lambda_{max}(\epsilon)$ = 332 nm(2000); 245 nm(10000)sh (*i*) The reduction products of 2^+ in CH_3CN-$LiClO_4$ [obtained by Na-Hg reduction or by macroscale reduction on Pt or Hg electrodes (21)] exhibit the same oxidation wave at -0.48V. RPP of this solution indicates that the 2^+ is the product of the electrochemical process taking place at -0.48V. (*ii*) Introduction of oxygen into the system causes a decrease in the oxidation wave at -0.48V and a subsequent increase in the reduction wave of the starting material, (2^+). The formation of 2^+ is also revealed by the appearance of the absorption band at 270 nm and the disappearance of the absorption spectrum of the dimer, (2-2) [cf. (21)]. (*iii*) The photodissociation spectrum of the electroreduction products of 2^+, measured by RPP technique (33), corresponds very well to the absorption spectrum of the dimer (2-2) in this solution (21). A detailed discussion on the assignment of the structure of (2-2) is given elsewhere (21).

Determination of K_d, k_d, and k_m

The progress of the reaction

$$2^{\cdot} \underset{k_m}{\overset{k_d}{\rightleftharpoons}} \tfrac{1}{2}\,\text{dimer} \quad K_d = \frac{\text{dimer}}{[2]^2} \qquad [13]$$

can be followed by RPP. Under conditions at which the dimerization and monomerization processes are frozen, the RP limiting anodic currents for the radical ($i_{RP,R}$) at -1.166V and of the dimer ($i_{RP,D}$) at -0.48V are proportional to the concentration of these species in the diffusion layer at time τ, prior to the application of the pulse. The ratio $i_{RP,D}/i^2_{RP,R}$ reflects the progress of reaction [13] during the time τ at which E_{in} is applied. Therefore we define a kinetic parameter K_d'

$$K_d' = \frac{\overline{C}_D}{\overline{C}_R^2} = \frac{1}{2}\,\frac{i_{RP,D}}{i^2_{RP,R}} \cdot \frac{i_{NP,1}}{C_{2^+}} \qquad [14]$$

where $\overline{C}_R$ and $\overline{C}_D$ are the average concentrations of the radical and the dimer, respectively, in the diffusion layer at the time of pulse application.

A typical set of results obtained for 1.0 mM 2^+ in 0.25M $LiClO_4$-TBAP, 5×10^{-3}% Triton X-100, exemplifies the dependence of K_d' on τ:

log K_d'	3.42	3.57	3.78	3.99	4.12	4.16
τ (sec)	0.36	0.57	1.12	2.24	3.35	5.47

Since log K_d' approaches constancy at large τ, the value 4.2 is a first approximation for the equilibrium constant. A simulation technique, treating a second order following reactions with diffusion taken into account, has been elaborated (30) and applied on the 2^+ reduction process, yielding values for K_d, k_d, and k_m.

The equilibrium and rate constants in acetonitrile were determined in two different supporting electrolytes, $LiClO_4$ and TBAP, in order to examine the effect of the cations on the dimerization reaction. [The effect of cations on the stability of various pyridinyl radicals has been discussed recently (34).] No effect was observed in the concentration range of supporting electrolytes used (25-250 mM).

To exclude the possibility of adsorption of the dimer at the electrode surface with subsequent dissociation into radicals (33), measurements were carried out also in the presence of 0.01% Triton X-100, but only a small increase (0.1 log units) in K_d was observed. In acetonitrile (with $LiClO_4$ or TBAP): log $K_d = 4.8 \pm 0.1$; log $k_d = 4.1 \pm 0.1$; log $k_m = -0.7 \pm 0.05$. In methanol-0.25M $LiClO_4$: log $K_d = 4.8 \pm 0.1$; log $k_d = 4.4 \pm 0.1$; log $k_m = 0.4 \pm 0.05$.

A value of log $K_d \simeq 5$ in acetonitrile, obtained by a titration method, is reported elsewhere (21).

k_d was also estimated from NPP carried out at intermediate pulse widths, 10 msec $< t_p <$ 90 msec. As shown above, reversible electronation is observed at shorter pulse durations, while reversible electrodimerization is approached at $\tau \geqq 4$ sec. At pulse widths ranging from 10-90 msec and $C_{2^+} > 1$ mM, the current-potential relationship according to Eq. [6] is followed up to $i \sim \tfrac{1}{2} i_d$.[4] $E_{1/2}$ is shifted in this time range by 20 mV per decade of time (Fig. 4). Based on the value of $E^{\circ\prime}$ obtained earlier, k_d was calculated: log k_d(AN) $= 4.2 \pm 0.1$; log k_d(MeOH) $= 4.4 \pm 0.1$; these values are in good agreement with those obtained by the simulation method (30).

Second Wave

The second wave of 2^+, 3^+, and 4^+ is strongly dependent on the type of solvent (protic or aprotic), the type of supporting electrolyte (size of cation), the concentration of depolarizer, and the timing of the experimental measurement (τ, t_p).

In methanol, independent of the type of electrolyte, the amplitude of the second wave of the isomers equals that of the first wave, and its limiting current is diffusion controlled (with the exception of a small deviation in the case of 3^+).

In acetonitrile, with $LiClO_4$ as supporting electrolyte, the amplitude of the second wave of 4^+ is equal to that of the first wave, while with TBAP, the amplitude of the DC, but not the NP wave, is smaller in comparison of the first wave. The 2^+ isomer exhibits a slightly decreased amplitude in the second wave (in both DC and NP modes) in $LiClO_4$ with a more pronounced decrease in TBAP. No second wave for the 3^+ isomer was detected up to -2.5V.

Reacting Species of the Second Wave

RPP has been used to identify the reacting species of the second wave. The principle is similar to that of exhaustive electrolysis at the plateau of the first wave, where the electroactivity of the products is tested

[3] At very short τ, K_d' will be determined mainly by k_d; at very long τ, at which equilibrium conditions are approached, it will be determined by k_d/k_m.

[4] Simulated NPP curves using K_d and k_d values obtained above agreed with the measured curves (35).

in the potential region of the second wave. The difference between the exhaustive electrolysis method and the RPP method is that in RPP the products of the first wave are prepared in the diffusion layer only (1-5 sec electrolysis) so that no separation is needed between anode and cathode. The electroactivity of the products is displayed by applying short potential pulse (milliseconds) in the potential region of the second wave. The advantages of the RP method are due to the short time scale electrolysis in which even unstable products of the first wave can be detected as plausible reactants of the electrode process at the second wave; at long-term electrolysis the products may undergo chemical changes and thus are not necessarily identical to those of DC or NP polarography.

The diagnostics of the RPP display are based on the following: (*i*) If the product formed at the first wave is the reactant at the second wave, the limiting RP current is identical to the limiting current of the starting material under NP conditions (in both cases the total amount of species in the diffusion layer able to react is identical)

$$ {}_{1}i_{RP,2} = i_{NP,2} \qquad [15] $$

${}_{1}i_{RP,2}$ depends inversely on the square root of pulse width. (*ii*) If the product formed at the first wave is not the reactant of the second wave the RP current ${}_{1}i_{RP,2}$ will result only from the relatively small amount of starting material diffusing toward the electrode from the bulk of the solution. The rate of diffusion is equivalent to the DC limiting current at second wave. Thus

$$ {}_{1}i_{RP,2} = i_{DC,2} \qquad [16] $$

where ${}_{1}i_{RP,2}$ is independent of pulse width.

Such a test has been carried out on the compounds of interest 4^+, 3^+, and 2^+ with $LiClO_4$ as supporting electrolyte (Fig. 1b, 3b, 5b). 4^+ behaves according to Eq. [15] in both acetonitrile and methanol in the pulse width range 1-90 msec. The conclusion is that the product of the first wave ($4^\cdot$) is further reduced along the second wave and does not undergo any chemical changes preceding the second charge transfer.

3^+ yields a second DC and NP wave in methanol, but not in acetonitrile. The RP limiting current ${}_{1}i_{RP,2}$ in methanol behaves according to Eq. [16] in the time range 1-90 msec. This indicates that the dimer, which is the product of the first wave of 3^+, is not further reduced at the potential range of the second wave. The appearance of the second wave under DC and NP conditions, at potentials where the dimer is stable to reduction, indicates that the second electron transfer is very rapid compared to the dimerization reaction of radicals formed at the first wave. It must then be the radical $3^\cdot$ which is reduced along the second wave. The same conclusion has been reached for the reduction of NAD^+ and related compounds (8, 9) on the basis of exhaustive electrolysis.

The RPP of 2^+ is somewhat more complicated than those of 4^+ and 3^+ (Fig. 5b). The value of the RP limiting current is somewhere between i_{NP} and i_{DC} of the second wave in both acetonitrile and methanol. We have already shown that in the case of 2^+ substantial fractions of both $2^\cdot$ and the dimer exist as final products of the first wave on the time scale of the experiment. If, as with the two other compounds, the radical is the reacting species, the limiting RP current of 2^+ should be higher than that of 3^+ and lower than 4^+. The RP current ${}_{1}i_{RP,2}$ for such a case will be the sum of (*i*) the reduction of $2^\cdot$ present in the diffusion layer, which is expressed by the absolute value of the RP anodic current, ${}_{1}i_{RP(R)}$ and (*ii*) the reduction of 2^+ diffusing toward the electrode at the time of the pulse, which is expressed by $i_{DC,2}$

$$ {}_{1}i_{RP,2} = i_{DC,2} + |{}_{1}i_{RP,R}| \qquad [17] $$

The RP polarograms at different pulse widths gave currents in agreement with the calculated values from Eq. [17]. Thus the reacting species of the second wave is the radical.

In conclusion, the reacting species of the three carbomethoxypyridinium compounds at the second wave is the corresponding pyridinyl radical.

Intermediate Species and Products at the Second Wave

CH_3CN-TBAP.—In CH_3CN containing TBAP the NPP and RPP waves of 4^+ have Nernstian slopes according to Eq. [5] and [6] and the $E_{1/2}$ is independent of pulse width in the time range of 1-40 msec (Fig. 6). Thus, under such conditions, simple charge transfer is observed

$$ 4^\cdot + e \rightleftharpoons 4^- \qquad [18] $$

with a formal potential $E^{\circ\prime}{}_{4^-/4^\cdot} = -1.910$V. The $E_{1/2}$ of the DC wave is shifted to more anodic potentials with the increasing τ, and the ratio of the limiting currents $i_{DC,2}/i_{DC,1}$ is smaller than unity (while under NP conditions it is equal to unity). An explanation of this phenomena is given below in the discussion of dimerization processes at the second wave.

An attempt was made to determine the formal potential of the $2^-/2^\cdot$ couple at low concentrations of 2^+ (necessary to avoid dimerization, Eq. [23]). However, the relatively low concentration of 2^+ and the large background currents did not allow an accurate semilogarithmic analysis of the wave. Thus, a rough estimate of the formal potential yields a lower limit of $E^{\circ\prime}{}_{2^-/2^\cdot} \sim -1.83$V.

CH_3CN-TBAP-Li^+.—Addition of Li^+ to CH_3CN-TBAP solutions containing 2^+ or 4^+ has the following effects on the second wave: (*i*) At molar ratios $[Li^+]/[4^+] = 0$-1 the wave splits; a new wave at more anodic potentials is formed at the expense of the original wave, reaching full height at a molar ratio of unity (Fig. 7). Further addition of Li^+ (molar ratios 10-100) shifts the $E_{1/2}$ by 30 mV per decade of $[Li^+]$, and by 30 mV per decade of time (in the time range of 1-100 msec).[5] (*ii*) The addition of Li^+ restores the amplitude of the second wave to its full diffusion controlled height. (*iii*) The amplitude of the RP wave (E_{in} set on the plateau of the second wave) in the presence of Li^+ is considerably smaller than that measured with TBAP alone (Fig. 6). (*iv*) The reduction wave of Li^+ at $E_{1/2} = -2.3$V makes its appearance only at molar ratios larger than unity. Plots of the amplitude of the Li^+ wave as function of $[Li^+]$ have the shape of an

[5] For a EC scheme of reversible charge transfer followed by irreversible chemical reaction, $E_{1/2} = E^{\circ\prime} + \frac{RT}{F} \ln 0.89 \left(\frac{D_O}{D_R} C_M k t\right)^{1/2}$, where C_M is the concentration of the metal ion (31).

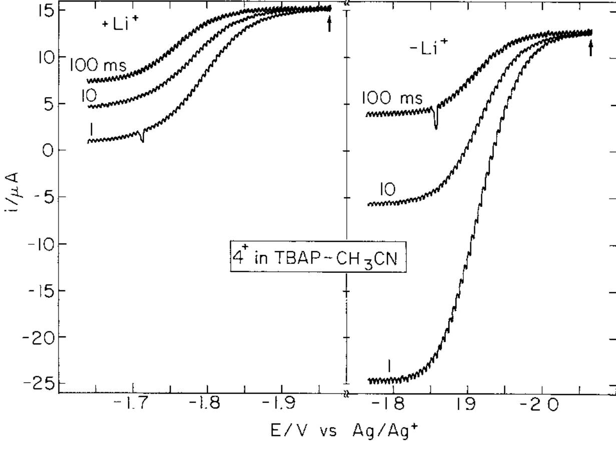

Fig. 6. RPP (constant E_{in} mode) of 2.3 mM 4^+ ClO_4^- in 0.25M TBAP-CH_3CN at different pulse widths. Right: no Li^+ added; left: +4.08 mM $LiClO_4$. τ = 0.5 sec. Arrows indicate E_{in}. E_p is plotted on the X-axis.

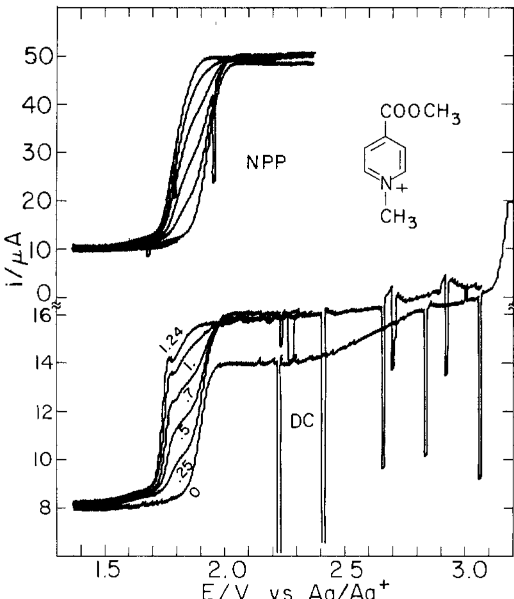

Fig. 7. Polarograms of 2.3 mM 4^+ ClO_4^- in 0.25M TBAP-CH_3CN with additions of $LiClO_4$. The values of the molar ratio $[Li^+]/[4^+]$ are marked on bottom curves. $\tau = 0.5$ sec, $t_p = 10$ msec.

amperometric titration with an increase of current starting at the equivalent point (molar ratio unity). (*v*) The electrochemical behavior of the system is independent of the presence of TBAP, which acts as an indifferent electrolyte. The effect of tetrabutylammonium ion was tested in acetonitrile, which contained no other electrolyte, under conditions in which the current ratio $i_{DC,2}/i_{DC,1}$ is considerably smaller than unity (4 mM 4^+). A gradual increase of TBAP concentration did not change the ratio and had the expected effect of decreasing the *iR* drop and the migration current. (*vi*) In solutions containing $LiClO_4$ alone, the anions 2^- and 4^- were also detected, although to a much smaller extent than in TBAP.

CH_3CN-TBAP-Na^+.—Addition of Na^+ to CH_3CN-TBAP solutions shifts the reduction wave to more positive potentials and restores the amplitude of the second wave to its full diffusion-controlled height. The shift of the wave is less pronounced than in the case of Li^+ at the same molar ratios, and the reduction wave of Na^+ ($E_{1/2} = -2.2$V) appears at molar ratios smaller than unity, depending on time (t_p or τ).

CH_3CN-TBAP-proton donor.—Addition of methanol as proton donor has an effect similar to that of Li^+, with, however, molar ratios much larger than unity ($\sim 5 \times 10^3$ in the case of 4^+) being required for full development of the new wave.

In the case of 1 methyl-4-cyanopyridinium ion, the behavior of which is similar to that of 4^+, acetic acid was used as proton donor. Only a 1:1 molar ratio of $[HAc]/[4^+]$ was required for the new wave to reach full height.

CH_3OH.—The electrochemical behavior in methanol is similar to that of acetonitrile solutions containing at least 20% (V) of methanol. The type of electrolyte does not affect the amplitude of the second wave or its location (differences of few millivolts are related to liquid junction potential).

The above experimental facts undoubtedly prove that the anions 2^-, 3^-, and 4^- are involved in a fast irreversible reaction with cations (Li^+, Na^+, H^+) present in solution.

Dimerization Processes at the Plateau of the Second Wave

The observation of a decrease of the current ratio ($i_{DC,2}/i_{DC,1}$ or $i_{NP,2}/i_{NP,1}$) is concurrent with the appearance of a dimer oxidation wave in the RPP mode (E_{in} set on the plateau of the second wave). In CH_3CN-TBAP solutions, the decrease is most pronounced with 2^+ ($i_{DC,2}/i_{DC,1} \rightarrow 0$ for C_2+, 3 mM; $i_{NP,2}/i_{NP,1} < 1$ and depends on t_p). With 4^+ only the DC ratio is decreased (*i.e.*, $i_{DC,2}/i_{DC,1} \sim 1/2$ at 3 mM). In CH_3CN-$LiClO_4$ solutions only the 2^+ exhibits this behavior (Fig. 5d), but a lesser degree than in CH_3CN-TBAP.

The identification of the dimer of the 2^+ isomer, formed at the plateau of the second wave, was made by comparing $E_{1/2}$ of its oxidation wave (Fig. 5d) with that of the dimer produced at the first wave (wave with $E_{1/2} = -0.48$V in Fig. 5c). Such comparison could not be carried out for the 4^+ isomer, since no dimer formation takes place at the first wave. In all cases in which the current ratios were smaller than unity the following behavior was observed: (*i*) The current ratio increases with decreasing depolarizer concentration, reaching unity at low concentrations. For example, the DC and NPP ratio for 2^+ in 0.25M $LiClO_4$-CH_3CN is:

$[2^+]$, mM	2.60	1.15	0.61	0.06
Current ratio	0.72	0.87	0.98	1.00

(*ii*) For a given isomer, the current ratio in acetonitrile is lowest with TBAP as electrolyte and increases with additions of equimolar amounts of small cations (H^+, Li^+, Na^+, Mg^{++}) or larger amounts of a proton donor such as CH_3OH. (*iii*) The second wave of 4^+ recorded in a pulse mode with E_{in} set on the plateau of the first wave has a considerably larger amplitude than with E_{in} set at a potential region in which no reduction takes place (NPP). (*iv*) In methanolic solutions ($LiClO_4$ or TBAP as electrolytes), only 3^+ yields a small amount of dimer with the potential set on the plateau of the second wave (Fig. 3d) (this accounts for the small decrease in the amplitude of the second wave).

Summary of the Electrode Processes at the Second Wave

From the results described above we conclude that the anions n^- (2^-, 3^-, or 4^-) formed in a reversible charge transfer reaction [19] (at the potential region of the second wave)

$$n^{\cdot} + e \rightleftharpoons n^- \qquad [19]$$

react irreversibly with cations or abstract protons from the solvent as follows

$$n^- + HB \rightarrow nH + B^- \qquad [20]$$

$$n^- + Li^+ \rightarrow nLi \qquad [21]$$

$$n^- + Na^+ \rightarrow nNa \qquad [22]$$

$$n^- + n^+ \rightarrow \text{dimer} \qquad [23]$$

The general idea that pyridinium cations may react with anions has been extensively discussed in the literature [*i.e.*, Ref. (36, 37)]. Dimerization of tropylium cation with its anion, formed by electrochemical reduction, (reaction similar to [23]) was observed by Breslow and Drury (38).

Reaction [20] dominates in protic solvents. The product, dihydropyridine, nH, is revealed by the RPP oxidation waves at about 0V (*i.e.*, see Fig. 3d for 3^+).

In acetonitrile solutions, n^- reacts with the cations of the electrolyte (reactions [21], [22]) or with the corresponding pyridinium cation, n^+ (reaction [23]).

The rate of the reaction with Li^+ is higher than that with Na^+.

No reaction between n^- and the bulky tetrabutylammonium cation takes place on the polarographic time scale. Thus, CH_3CN-TBAP solutions offer the most favorable conditions for the observation of anions, n^-, and dimers, n-n, formed according to reaction [23]. Whenever the dimerization process takes place, the amplitude of the second wave is decreased (as described above), since the net number of electrons involved in this wave is less than one.

The dimer formed on the plateau of the second wave results from a reaction between n^- and n^+ (reaction [23]), while along the wave, its formation from radicals also takes place

$$n^\cdot \rightleftharpoons \tfrac{1}{2}\ \text{dimer} \qquad [24]$$

To exemplify this point, the formation of the dimer (2-2) at the second wave is followed by measuring the RP current at a potential set on the plateau of the oxidation wave of the dimer (−0.36V), with the initial potential making excursions into the range of interest (Fig. 8c). The contribution of the oxidation currents of $2^\cdot$ and 2^- are evaluated by recording a reverse pulse polarogram as above, but the potential of the pulse is set at the plateau of the oxidation of the radical (∼ −0.80V) at which $2^\cdot$ and 2^-, but not the dimer are oxidized (Fig. 8b). Subtraction of curve 8c from 8b yields the oxidation current of the dimer, which is proportional to its amount generated at different initial potentials.

The formation of (4-4) dimers at the second wave (Eq. [23]), is most interesting, since no (4-4) dimers are formed under the conditions of the polarographic first wave (Eq. [24]). Dimerization of $4^\cdot$ radicals has only been observed in thin films (22b) or in the case of 1,1′-dimethylene or trimethylene-bis (4-carbomethoxypyridinyl) radicals (34, 39). The (4-4) dimers are very unstable in solutions and dissociate immediately into the $4^\cdot$ radicals. On the polarographic time scale, dimers are formed only according to reaction [23], but not according to reaction [24], leading us to the conclusion that the respective dimerization rate constants are substantially different.

Experiments performed with 1-t-butyl-4-carbomethoxypyridinium ion gave rise to greater amount of the respective anion and smaller amount of the dimer compared to 4^+ under similar conditions. Considering steric effect, we assume that the dimerization takes place at the 2-position of the ring, at least, for one of the participants of reaction [23].

From the thermodynamic point of view, it is of interest to calculate the equilibrium constant of reaction [25]

$$4^- + 4^+ \rightleftharpoons 4^\cdot + 4^\cdot \qquad [25]$$

$\log K = (E^{\circ\prime}_{4^\cdot/4^+} - E^{\circ\prime}_{4^-/4^\cdot})/(2.3\,RT/F) = 13.8$, was calculated with values of $E^{\circ\prime}$ determined in CH_3CN-TBAP (Tables II and III). Reaction [25] has been discussed by Mohammad *et al.* (40).

The processes along the second wave are summarized in Table III.

Acknowledgments

The authors would like to thank Professors E. Gileadi and E. M. Kosower for their interest in this work. The contribution made by D. Talmor with the simulation calculations is appreciated.

ABSTRACT

Varying amounts of metallic Ag are detected by x-ray diffractometry at the surface of Ag/Ag$_2$S electrodes that have been exposed to alkaline-ascorbic acid solutions. These electrodes give a voltammetric response to redox couples in solution and this response is interpreted as providing further proof of the presence of Ag metal at the electrode surface. The metallic Ag accumulates at the electrode surface primarily as a result of redox reactions between the Ag$_2$S and the ascorbic acid present in the solution in which the electrode is used.

Solid-state Ag$_2$S membrane electrodes that have an internal silver metal contact (Ag/Ag$_2$S) may give rise to negative deviations from Nernstian response (super-Nernstian response) at sulfide concentrations less than 10^{-6} mole/liter in an alkaline-ascorbic acid solution (1). A deposit or film that had appeared on the surface of one such electrode was previously studied in a scanning electron microscope (SEM), and deposits that were rich in silver but depleted in sulfur were observed; it was concluded that these could be deposits of metallic silver, thereby giving rise to the super-Nernstian response because of the measurement of mixed potentials (1). The internal silver metal contact was proposed to be the primary source of the metallic silver (1). This paper presents results from x-ray diffractometry (XRD) studies that show varying amounts of metallic Ag to be present at the outer Ag$_2$S surface of other Ag/Ag$_2$S electrodes that had been exposed for varying periods of time to alkaline-ascorbic acid solutions.

However, the presence of metallic silver at the electrode surface should not in itself cause interference with the Nernstian response of the electrode to low levels of sulfide ion in solution; the solid-state Ag$_2$S membrane electrode can be regarded as an electrode of the second kind (2), and the potential of the latter electrode is not affected by the extent of coverage of the silver wire by the silver salt (2, 3). The potential of an electrode of the second kind may be sensitive to the presence of redox couples in solution since bare silver metal may be exposed to the solution either directly or through the pores in the relatively thin layer of salt deposited on its surface (2, 3); the potential of the solid-state Ag$_2$S membrane electrode, however, is claimed to be insensitive to the presence of redox couples (4-6), since the metallic silver is isolated from the solution by a thick nonporous polycrystalline pressed pellet membrane. Metallic silver present at the outer surface of the solid-state membrane electrode may interfere with the Nernstian response of this electrode if the silver can alter sufficiently the electronic conductivity of the membrane electrode such that the latter can respond to the presence of redox couples in solution, *i.e.*, measure mixed potentials (1).

At room temperature, Ag$_2$S is both an ionic and electronic conductor. The ionic conductivity is high, $\sigma_i = 0.36 \times 10^{-3}\ \Omega^{-1}\ \text{cm}^{-1}$, both in cell I, Ag/Ag$^+$(aq)/Ag$_2S/Ag^+$(aq)/Ag and cell II, Ag/Ag$_2$S/Ag$^+$(aq)/Ag, and is attributed to the presence of Frenkel defects, silver vacancies, and silver interstitials (4). The electronic conductivity σ_e, however, varies strongly with the nature of the contact to the Ag$_2$S membrane; for a liquid contact as in cell I, $\sigma_e = 0.004 \times 10^{-3}\ \Omega^{-1}\ \text{cm}^{-1}$ while for a silver metal contact, cell II, $\sigma_e = 2.5 \times 10^{-3}\ \Omega^{-1}\ \text{cm}^{-1}$ (4). The high electronic conductivity of an Ag$_2$S electrode in contact with metallic Ag, Ag/Ag$_2$S, is attributed to the presence of excess silver in the crystal which acts as an electron donor (4); despite this, it has been claimed that the presence of redox couples in solution has little or no effect on the measured potential at an Ag/Ag$_2$S electrode because of the high resistance at the Ag$_2$S/solution interface to the transfer of electrons to redox species in solution (4, 5). However, the results presented in this paper show that our used Ag/Ag$_2$S electrodes give a well-defined voltammetric response to redox couples in solution, similar to the response observed at an Ag wire electrode; these voltammetric results provide further indirect evidence that metallic Ag is present at the outer surface of these used Ag$_2$S electrodes. It is proposed that the metallic Ag alters the electronic conductivity of the Ag$_2$S membrane to the extent that the electrode can measure mixed potentials.

From the results of the voltammetric and surface studies, it is concluded that the metallic silver accumulates at the electrode surface primarily as a result of the redox reaction between the Ag$_2$S and the ascorbic acid present in the solution in which the electrode is used.

Experimental

All Ag$_2$S membrane electrodes were obtained from Orion Research Incorporated; metal-contacted (Ag/Ag$_2$S) electrodes were purchased (Orion 94-16A) while the graphite-contacted (C/Ag$_2$S) electrodes were kindly provided by Orion. The Ag/Ag$_2$S electrodes were labeled alphabetically to identify them during use.

The surfaces of the Ag/Ag$_2$S electrodes were examined by x-ray diffractometry and scanning electron microscopy, using equipment described previously (7). X-ray reference data were obtained from Joint Committee for Powder Diffraction Standards (Swarthmore, Pennsylvania) file cards 4-0783 (Ag), 14-72 (Ag$_2$S), and 12-793 (Ag$_2$O).

The voltammetric studies were done at room temperature in solutions prepared from reagent grade chemicals using deionized-distilled water and deaerated with N$_2$. Stock (0.1 mole/liter) iron solutions were prepared by dissolving $(NH_4)_2Fe_2(SO_4)_3$ in 0.1 mole/liter HClO$_4$, and FeCl$_3$ in distilled water; microliter portions of these stock solutions were added to the deaerated electrolytes as required. Key words: membrane, electrode, x-ray, voltammetry.

(PAR) Model 174 Polarographic Analyzer was used, together with a conventional single-compartment cell (PAR Model K60). A Pt wire was used for the counterelectrode, while a saturated calomel electrode, separated from the test solution by a 0.1 mole/liter KNO_3 solution, was used as the reference electrode. A Moseley Model 2D-2 X-Y recorder and an HP Moseley 7100B X-t recorder were used to record the voltammetric and chronoamperometric results, respectively.

Results

Surface analyses.—Initially, electrodes J and M were examined by XRD. Electrode M had failed to give Nernstian response after continuous use for approximately one month in an H_2S-in-water monitor (8); on removing it from the monitor, a coarse crystalline deposit was present on its surface. Electrode J had been used extensively in the laboratory to study response to sulfide ions in alkaline-ascorbic acid solutions; it would rapidly acquire a surface film during use. After J had been stored for 3 weeks in an alkaline-ascorbic acid solution, a coarse granular deposit was present on its surface. X-ray diffractometry showed that Ag metal was the major component of the surface deposits on both electrodes. After the deposit was scraped from the surface of M, the Ag_2S counts were enhanced threefold while the Ag counts were reduced by ~60%; x-ray powder diffraction photographs showed that the scraped material contained both Ag and Ag_2S. After electrode J was scraped, the Ag counts from the surface were reduced by ~20% and the Ag_2S counts increased by ~50%; the scraped material in this case was essentially Ag with no detectable Ag_2S. Silver oxide, Ag_2O, was not detected at either electrode.

Further XRD and SEM analyses of other Ag/Ag_2S electrodes are summarized in Table I. Electrode H, used and treated similarly to electrode J, also had acquired a thick coarse layer on its surface during its 4 week storage in an alkaline-ascorbic acid solution. This layer was pitted and consisted almost entirely of Ag. The Ag layer was removed by polishing the electrode on 600 grit paper; the resultant exposed surface contained only Ag_2S and was porous and pitted. Another layer of Ag was subsequently grown on the surface of electrode H on re-exposure to alkaline-ascorbic acid, and this again could be removed by polishing. Electrode D had also been used extensively in the laboratory but had been stored dry, in air. The surface of D contained numerous large visible pits and consisted primarily of Ag_2S with some Ag, but Ag was not detected at electrode Z.

It had been previously presumed that the Ag diffused to the electrode surface from the internal silver metal contact (1); attempts to observe this diffusion process by heating an Ag/Ag_2S electrode in air were unsuccessful. Electrode T was a new electrode that gave Nernstian response to 3×10^{-7} mole/liter sulfide; metallic Ag was not detected by XRD at its surface neither before nor after heating for 102 hr at 371 K, nor after a further 380 hr at 398 K, despite a two-fold decrease in electrode thickness caused by polishing of the electrode during periodic examination while being heated.

Silver oxide was again not detected at any of the electrode surfaces.

Table I. XRD, SEM study of Ag/Ag_2S electrodes

Electrode	XRD*	SEM	Comments
C	—	Ag, Ag_2S pitted	Used in H_2S monitor
M	Ag, Ag_2S	—	Used in H_2S monitor
J	Ag, Ag_2S	—	Lab use Stored in alkaline-ascorbic acid
H	Ag, Ag_2S	Pitted	Lab use Stored in alkaline-ascorbic acid
H (polished)	Ag_2S	Porous	—
T	Ag_2S	—	No Ag after heating
Z	Ag_2S	Pitted	Lab use Air storage
D	Ag, Ag_2S	Pitted	Lab use Air storage

* Major surface component underlined.

Electrochemical Studies

Ag/Ag_2S electrode.—Numerous Ag/Ag_2S electrodes that had undergone "normal use" gave a voltammetric response to electroactive species in solutions. These electrodes had been used to measure sulfide in alkaline-ascorbic acid solutions, but were stored in air between use and were polished occasionally. There were no visible deposits or films on their surface. In an oxalate electrolyte (*p*H 4) containing Fe(II), a well-defined oxidation peak was observed at −50 mV as the electrode was scanned from negative to more positive potentials, Fig. 1A; a corresponding reduction peak for Fe(III) was not observed on the reverse scan even in the presence of added Fe(III), prior to the reduction of the Ag_2S at potentials more negative than −500 mV. The anodic peak current increased linearly with Fe(II) concentration over the range 0.1-4 $\times$ 10^{-3} mole/liter, Fig. 2, and also with the square root of the scan rate (ν),

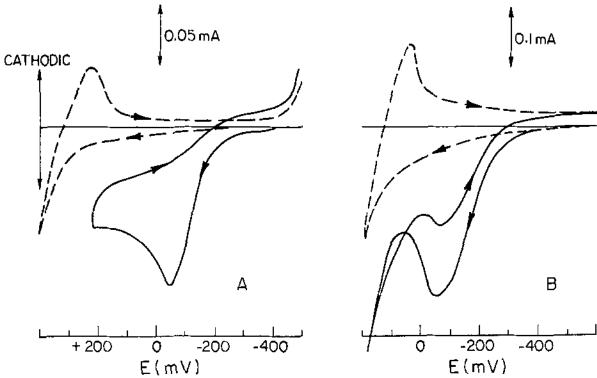

Fig. 1. Voltammetric response of Ag/Ag_2S electrode at 50 mV/sec to solutions of: (A) 2 $\times$ 10^{-3} mole/liter Fe(II) in 0.2 mole/liter $Na_2C_2O_4$ (*p*H ~ 4); (B) 2 $\times$ 10^{-3} mole/liter ascorbic acid in 1 mole/liter NaOH; - - - - - electrolyte only, ——— electrolyte plus electroactive species.

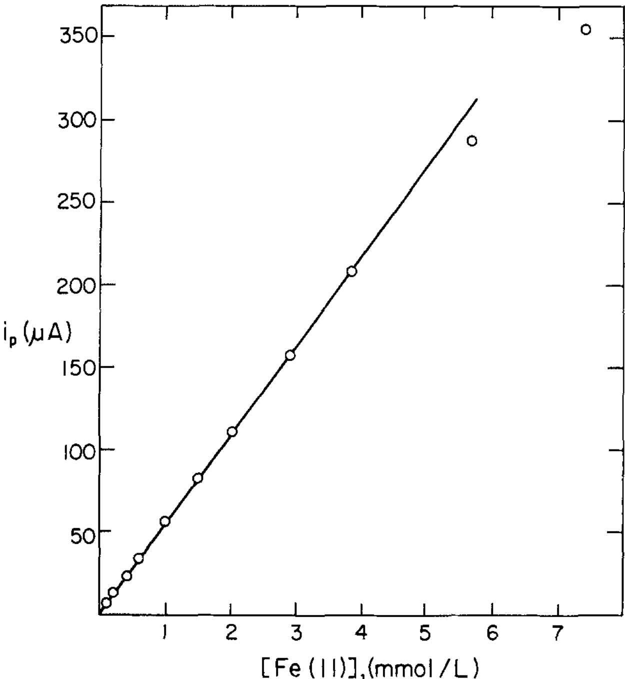

Fig. 2. Variation of peak current at Ag/Ag_2S electrode with Fe(II) concentration at 50 mV/sec in a 0.2 mole/liter $Na_2C_2O_4$ (*p*H 4) solution.

Fig. 3; deviations from linear response were observed at Fe(II) concentrations $>4 \times 10^{-3}$ mole/liter and at scan rates >50 mV/sec. At a given scan rate, the peak potential for the oxidation of Fe(II) varied by 100-200 mV from one electrode to another, and with the condition of the electrode surface. The anodic peak potential also shifted to more positive values with increasing scan rate; some electrodes appeared to follow an Ep-$\nu^{1/2}$ relationship while others appeared to follow an Ep-ln ν relationship ($1 \leq \nu \leq 200$ mV/sec). Both in the absence and in the presence of Fe(II), large anodic currents were observed at potentials more positive than +300 mV on the forward scan, and a corresponding reduction peak was observed on the reverse scan at +200 mV, Fig. 1A.

Similar results were observed in alkaline solutions containing ascorbic acid: an oxidation peak was observed at −100 mV on both the forward and reverse scans, Fig. 1B. The anodic peak current on the forward scan increased linearly with ascorbic acid concentration over the range $0.1\text{-}1 \times 10^{-3}$ mole/liter; the peak current $-\nu^{1/2}$ dependence in the ascorbic acid system was nonlinear, Fig. 3.

If the Ag/Ag_2S electrode was scanned to potentials more negative than −800 mV in the alkaline solution, the cathodic current increased markedly, Fig. 4; a well-defined anodic peak was observed on the reverse scan and the anodic peak current increased either as the switching potential became more negative or as sulfide ions were added to the solution. When the electrode was scanned to positive potentials, large oxidation currents that increased linearly with time (voltage) were observed. The well-defined reduction peak observed at +100 mV on the reverse scan increased in height as the switching potential for the forward scan was made more positive.

Potential-step chronoamperometry provided further information on the nature of the processes occurring at the positive potentials in the alkaline solutions. The oxidation current at +300 mV remained constant or decreased only gradually, Fig. 5; a dark deposit formed on some electrodes during this oxidation step. When the potential was stepped to −300 mV, the reduction current first increased with time, then decreased gradually, and finally decreased very rapidly; the black deposit was removed from the electrode surface during the reduction step. Equal amounts of charge were consumed by the anodic and cathodic processes.

The voltammetric responses of numerous Ag/Ag_2S electrodes to the oxalate-Fe(II) solution and to the alkaline-ascorbic acid solution were qualitatively similar, regardless of whether the electrodes gave good or poor Nernstian response to low levels of sulfide.

C/Ag_2S electrode.—Voltammograms obtained with the C/Ag_2S electrode, Fig. 6, were considerably different from those obtained with the Ag/Ag_2S electrode. Much lower background currents were observed and the oxidation processes, when Fe(II) was present,

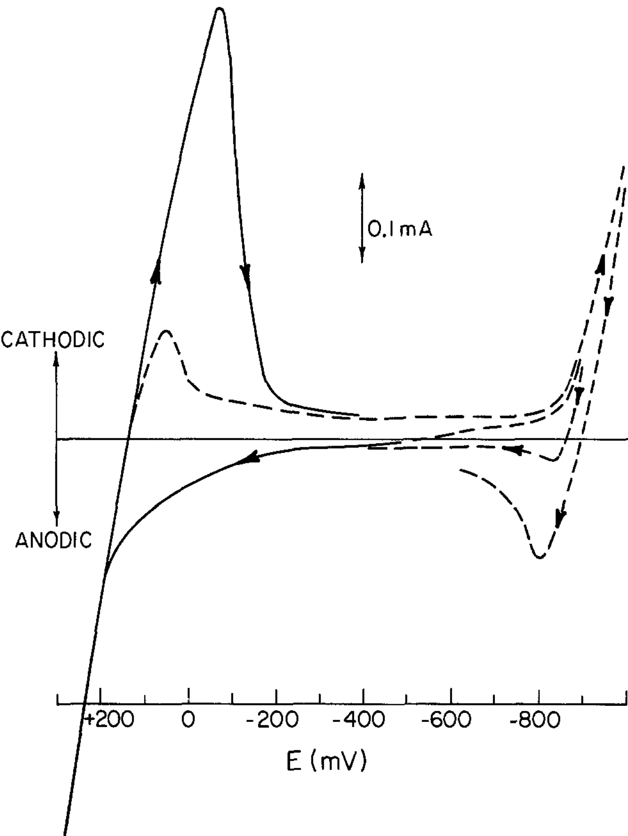

Fig. 4. Voltammetric response of Ag/Ag_2S electrode at 50 mV/sec in 1 mole/liter NaOH. Electrode was scanned: ——— from −500 to +300 to −400 mV; - - - - - from −500 to −900 to +300 to −1000 to −600 mV.

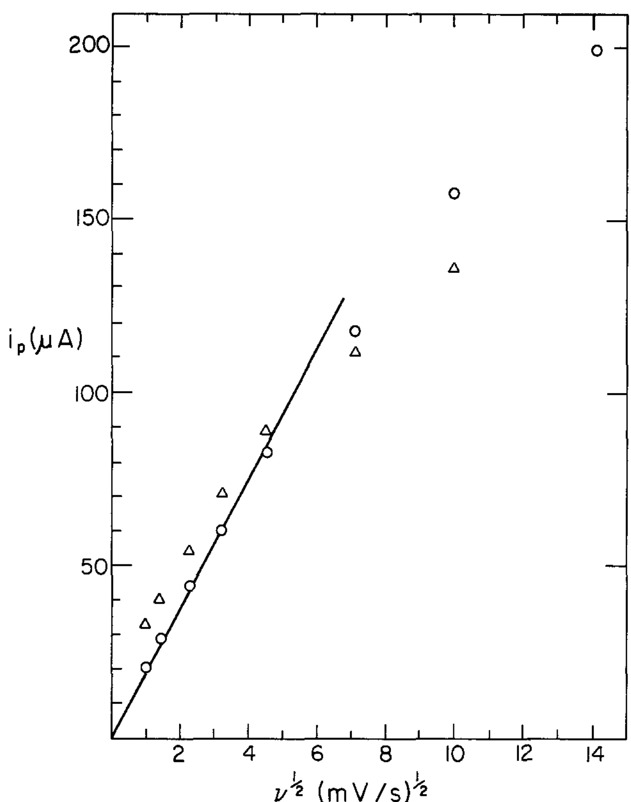

Fig. 3. Variation of peak current at Ag/Ag_2S electrode with square root of scan rate; ○, 2×10^{-3} mole/liter Fe(II) in 0.2 mole/liter $Na_2C_2O_4$ (pH ~ 4); △, 2×10^{-3} mole/liter ascorbic acid in 1 mole/liter NaOH.

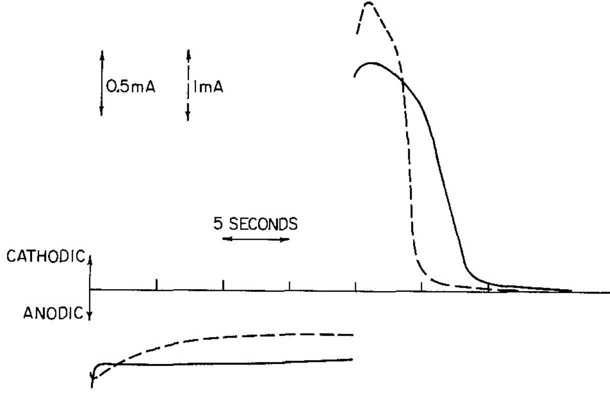

Fig. 5. Chronoamperometry at different Ag/Ag_2S electrodes in 1 mole/liter NaOH; anodic step at +300 mV, cathodic step at −300 mV.

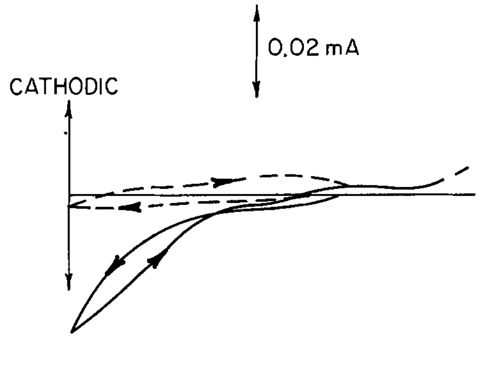

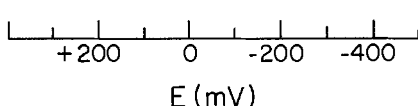

Fig. 6. Voltammetric response of C/Ag_2S electrode at 50 mV/sec; - - - - - 0.2 mole/liter $Na_2C_2O_4$ (pH ~ 4), ——— 2 × 10^{-3} mole/liter Fe(II) added.

occurred at considerably more positive potentials (+300 mV) and appeared to be ill-defined (hysteresis).

Ag electrode.—The voltammetric response of an Ag electrode to the redox species studied was qualitatively similar to the response of the Ag/Ag_2S electrode. A well-defined anodic peak for the oxidation of Fe(II) in the oxalate electrolyte was observed at −200 mV on the forward scan, and a corresponding reduction peak for the Fe(III) formed at the electrode surface was observed on the reverse scan, Fig. 7A. An anodic peak for the oxidation of ascorbic acid in an alkaline solution was observed at −300 mV, Fig. 7B.

Discussion

Surface studies.—The XRD results show that metallic silver had accumulated at some Ag/Ag_2S electrode surfaces. The layer of metallic silver present on the surface of electrodes H, J, and M could be removed by polishing or scraping, thereby renewing the surface. In the case of the scraped electrodes, surface roughening may also partially account for the variation in the x-ray counts. A small amount of metallic silver is detected at the surface of electrode D, presumably in the readily visible pits; metallic Ag is not detected by XRD at the surface of electrodes Z and T, despite the fact that the latter has undergone prolonged heating. Because the detection limit for XRD is ~5%, small but significant amounts of metallic silver may nonetheless be present at these electrode surfaces. These XRD results confirm our previous proposal, which was based on SEM results (1), that metallic silver accumulates at the Ag_2S/ solution interface.

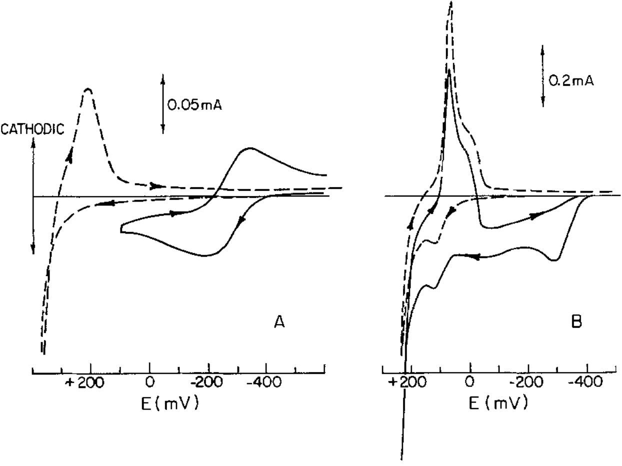

Fig. 7. Voltammetric response of Ag electrode at 50 mV/sec to solutions of: (A) 2 × 10^{-3} mole/liter Fe(II) in 0.2 mole/liter $Na_2C_2O_4$ (pH ~ 4); (B) 2 × 10^{-3} mole/liter ascorbic acid in 1 mole/liter NaOH; - - - - - electrolyte only, ——— electrolyte plus electroactive species.

Electrochemical studies.—Further evidence that Ag metal is present at the surface of the Ag/Ag_2S electrodes is provided by the fact that the voltammetric response of the Ag/Ag_2S electrodes is qualitatively similar to the response of an Ag wire electrode, both in the presence and absence of electroactive species. In the absence of electroactive species, both electrodes undergo oxidation at the same positive potentials and give rise to the same well-defined reduction peak on the reverse scan, Fig. 1 and 7. For the Ag electrode in alkaline solutions, the anodic processes occurring at potentials more positive than +100 mV have been ascribed to the formation and reduction of Ag_2O (9, 10); the reactions can be represented as

$$Ag + OH^- \rightarrow Ag(OH) + e \quad [1]$$

$$2Ag(OH) \rightarrow Ag_2O + H_2O \quad [2]$$

$$Ag_2O + H_2O + 2e \rightarrow 2Ag + 2\ OH^- \quad [3]$$

These reactions can also be applied to explain the response of the Ag/Ag_2S electrodes in alkaline solutions, Fig. 4 and 5. The oxidation of metallic silver, Eq. [1], gives rise to the large anodic currents observed at potentials more positive than +100 mV, while the cathodic peak present on the reverse scan is due to the reduction of Ag_2O to Ag, Eq. [3]. During the chronoamperometric measurements at +300 mV, the oxidation of metallic Ag to Ag_2O, Eq. [1] and [2], gives rise to the black deposit of Ag_2O on the electrode surface; during the subsequent reduction step at −300 mV, the black deposit is removed as the Ag_2O is reduced to Ag, Eq. [3]. The electrodeposition of metallic Ag is controlled by the rate of nucleation and growth of overlapping two-dimensional centers of silver metal on the electrode surface (11); this electrodeposition process is characterized by current-time curves (11) that are very similar to the ones observed in the chronoamperometric reduction process at −300 mV, Fig. 5.

Reduction of the Ag_2S to metallic Ag occurs at potentials more negative than −900 mV in alkaline solutions, Fig. 4

$$Ag_2S + 2e \rightarrow 2Ag + S^{2-} \quad [4]$$

The sulfide ion released at the electrode surface is consumed during the oxidation of Ag metal to Ag_2S in the reverse scan, giving rise to the anodic peak at −800 mV. The same reaction occurs at −400 mV in the pH 4 oxalate solution.

Species such as Fe(II) or ascorbic acid are oxidized at both the Ag and Ag/Ag_2S electrodes; the oxidations occur at slightly more positive potentials (by 250 mV) at the latter electrode, Fig. 1 and 7. At the Ag/Ag_2S electrode, these oxidations are diffusion controlled over a limited range of concentrations, Fig. 2, and scan rates, Fig. 3. The variation in the peak potential with scan rate indicates that factors such as charge-transfer kinetics (12) and/or electrode membrane resistance (13) are also limiting the current at this electrode.

The voltammetric behavior of ascorbic acid on Ag_2S appears similar to that observed at Pt (14). The nonlinear i_p-$\nu^{1/2}$ behavior, Fig. 3, suggests adsorption of ascorbic acid while the increased anodic currents observed on the reverse scan, Fig. 1, suggest that the oxidized product, dehydroascorbic acid is being desorbed. The following overall mechanism appears plausible (15)

$$Ag_2S + C_6H_6O_6^{2-} \rightarrow Ag_2S\text{-}(C_6H_6O_6)_{ads}^{2-} \quad [5]$$

$$Ag_2S\text{-}(C_6H_6O_6)_{ads}^{2-} + H_2O \rightarrow 2Ag + S^{2-} + 2H^+ + C_6H_6O_7^{2-} \quad [6]$$

Ascorbic acid is adsorbed at a silver ion site on the surface and electron transfer is assumed to occur via the adsorbed complex; the desorption of the dehydroascorbic acid allows the nucleation and growth of the Ag centers on the electrode surface.

Other workers have previously concluded that Ag/Ag_2S electrodes do not respond to the presence of redox couples in solution (4-6), in direct contrast to our results. The presence of Ag metal on our electrode surfaces as a result of their exposure to alkaline-ascorbic acid solutions may explain this discrepancy. Koebel *et al.* (4) measured the resistance to charge transfer in the cells $Ag/Ag_2S/Fe^{2+}$-Fe^{3+}/Pt and Pt/Fe^{2+}-Fe^{3+}/Ag_2S/Fe^{2+}-Fe^{3+}/Pt to be $4 \times 10^3 \Omega$ and $1 \times 10^6 \Omega$, respectively, by using a 10^{-2} mole/liter Fe(II)-5×10^{-3} mole/liter Fe(III)-0.5 mole/liter H_2SO_4 solution and by applying a square wave current. They concluded that this large resistance to electron transfer was located at the Ag_2S/solution interface and attributed it to the semiconductor properties of Ag_2S (4): a specific redox reaction usually requires a larger overpotential at a semiconductor electrode than at a metal electrode [(4, 16) and references therein]. Although the difference between the formal potentials of the redox couples used in our and Koebel's work may have some influence on the electron transfer kinetics at the semiconductor surface (16), we conclude that the facile electron transfer observed at our electrodes is primarily due to the Ag metal on our electrode surface, *i.e.*, the surface is heterogenous. The Ag/Ag_2S electrodes used by others (4, 5) presumably had not been exposed to a reducing environment and thus did not have Ag at their surface.

Further support for this conclusion of a heterogeneous surface is provided by a comparison of our voltammetric results with those of Van de Leest. Van de Leest observed (17) the anodic dissolution of an Ag/Ag_2S electrode in a nitrate electrolyte only at potentials more positive than +800 mV, while on the addition of bromide ions a new anodic peak was observed at +650 mV and ascribed to AgBr formation. These potentials are considerably more positive than the standard potentials for Ag metal and are also more positive than the potentials we observe at our Ag/Ag_2S electrodes in a nitrate electrolyte (anodic dissolution occurs at +400 mV as in the oxalate solution, Fig. 1A).

Redox reactions at a heterogeneous surface.—If the electrode surface is in fact heterogeneous, the current attributed to the redox couples can flow via different cells

cell A $Ag/Ag_2S/Fe^{2+}{}_{(aq)}/Pt$

cell B $Ag/Ag_2S/Ag/Fe^{2+}{}_{(aq)}/Pt$

cell C $Ag/Fe^{2+}{}_{(aq)}/Pt$

Cell B is considered to have isolated patches of Ag metal at the electrode surface, while in cell C it is considered that there are continuous "threads" of metallic silver extending from the silver metal contact at the back of the electrode through the Ag_2S crystal to its outer surface, *i.e.*, a pure Ag electrode exposed to the solution. The current flowing through each cell is governed primarily by the total interfacial area (A_j) of each cell and the exchange current density at each surface, i_j; the net observed current is the sum of the individual cell currents. On the basis of the XRD results of "normal" electrodes, *i.e.*, those that have not been stored or used for prolonged periods in an alkaline-ascorbic acid solution, it can be assumed that $A_A >> A_B \simeq A_C$. Despite the larger surface area of cell A, the exchange current density at a semiconductor/solution interface is usually several orders of magnitude smaller than at a metal electrode (16, 18, 19); we thus conclude that the current in cell A will be considerably smaller than cell B or cell C. The heterogeneous rate constant for the oxidation of Fe(II) ions in an oxalate electrolyte at an Ag electrode is 1×10^{-3} cm/sec (20), and thus the exchange current density at the Ag/Fe^{2+}(aq) interface for both cell B and cell C should be large.

Cell B, however, is expected to have a higher resistance than cell C; the electrical conductivity of Ag/Ag_2S at room temperature, $\sigma_e = 2.5 \times 10^{-3}\ \Omega^{-1}\ cm^{-1}$ is orders of magnitude smaller than that of Ag metal, $\sigma_e = 6.25 \times 10^5\ \Omega^{-1}\ cm^{-1}$ (21). In addition, cell B contains two separate solid/solid contacts and it has been concluded that the Ag/Ag_2S interface not only has a small exchange current density but also becomes strongly polarized under conditions of current flow (5). Koebel *et al.* (4) also noted that the nature of the Ag/Ag_2S contact was very important, as certain contacts were highly polarizable and irreproducible, giving high resistances; Buck has recently observed similar effects (22). The "patches" of metallic silver in cell B can arise because of redox interactions between the Ag_2S membrane and reducing agents in solution (*vide infra*); it is very probable that these "patches" have a large contact resistance, as it has been shown that silver films, produced by the interaction of various reducing agents with silver ions or complexes in solution, can have variable resistivities and compositions (23). We thus conclude that the observed redox currents are measured primarily via cell C, *i.e.*, the continuous "threads" of metallic Ag through the Ag_2S membrane.

Ag accumulation at electrode surface.—We had previously proposed that the primary means of metallic Ag accumulation at the outer Ag_2S surface resulted from the diffusion of Ag from the silver metal contact at the inner membrane surface (1). Attempts to observe this diffusion process by heating an Ag/Ag_2S electrode and examining the Ag_2S surface for the appearance of Ag by XRD were unsuccessful, perhaps because of the detection limit of XRD or because the conditions of our experiment were not optimal. However, it is well documented that Ag has a high interdiffusion coefficient in the system Ag/Ag_2S (2, 5, 24, 25) and diffusion of metallic silver through the membrane to the outer surface should occur.

We had also proposed previously that Ag could be formed at the electrode surface as a consequence of redox interactions between the Ag_2S membrane and reducing agents in solution (1). This mechanism now appears to be of primary importance; the XRD results show that those electrodes that had been either stored or used for a prolonged period in an alkaline-ascorbic acid solution had a surface deposit whose major component was metallic silver, and that the silver layer could be removed by polishing. The voltammetric results support this conclusion and provide a mechanism for this redox interaction; the voltammetric results indicate that ascorbic acid is adsorbed onto the Ag_2S surface prior to the electron-transfer step, Eq. [5], and that after the electron transfer the dehydroascorbic acid is desorbed from the surface, Eq. [6], to permit the nucleation and growth of the Ag centers. The silver deposited in this manner would also tend to diffuse inward into the Ag_2S membrane and could thus meet the silver diffusing outward from the back of the membrane to give rise to the continuous "threads" of metallic silver proposed in cell C.

Potentiometric vs. voltammetric response.—We are puzzled by the fact that there is no apparent correlation between the potentiometric and voltammetric response of these electrodes; all Ag/Ag_2S electrodes gave qualitatively the same voltammetric response, regardless of whether they gave good or poor Nernstian response to low levels of sulfide. A possible explanation may be the fact that the potentiometric response is much more sensitive to electrode surface effects (changes in composition and conductivity of the surface) than the voltammetric response where changes in

the electrode itself may have occurred, or are continuously occurring, because of the measurement process. Although the C/Ag_2S electrodes do not appear to give a well-defined voltammetric response to Fe^{2+}, we have observed (26) that on some occasions these electrodes give a Nernstian potentiometric response to varying concentration ratios of Fe^{3+}/Fe^{2+} in the oxalate electrolyte. The reproducibility of this potentiometric response for the C/Ag_2S electrodes is poor, however, as on other occasions they give no response; the reproducibility of the potentiometric response to varying ratios of Fe^{2+}/Fe^{3+} for the Ag/Ag_2S electrodes is generally better, but also varies from one electrode to another, and from time to time. Further work is required to understand this response.

Minimizing interference to Nernstian response.—On the basis of the foregoing results and discussion, it is evident that metallic Ag is present at the electrode surface and that the heterogeneous surface responds to, or senses, redox species in solution; the resulting mixed potentials interfere with the Nernstian response. Interference from mixed potentials could be minimized by the following:

1. Use of C/Ag_2S electrodes. These electrodes do not appear to be as sensitive to redox couples as the Ag/Ag_2S electrodes because of their lower electronic conductivity (4, 25). However, the electronic conductivity (4) and the standard potential of these electrodes (25) varies with the stoichiometry of the Ag_2S. Use of these electrodes in an alkaline-reducing environment would result in the deposition of metallic silver on the electrode surface, leading to gradual changes in the stoichiometry and hence conductivity and standard potential of the electrode.

2. Elimination of reducing agents. Since the reducing agents in solution not only give rise to the metallic silver deposit on the electrode surface but also are sensed by the silver on the electrode, it may be advantageous to eliminate them. Problems in the measurement of low concentrations of sulfide in alkaline solutions would result, because the reducing agents are required to maintain anaerobic conditions to prevent the rapid oxidation of sulfide in the alkaline solution by traces of dissolved oxygen; bubbling an inert gas through the solution is not sufficient to overcome this problem (27).

3. Working in acidic media. The rate of oxidation of H_2S by dissolved oxygen is much smaller in acidic than in highly alkaline solutions (28); by using acidic conditions to measure the dissolved sulfide, the reducing agents could be eliminated thus minimizing interference. Due to the high volatility and toxicity of H_2S, problems in sample handling and storage may be encountered under acidic conditions; these problems, however, are not major. A new continuous H_2S-in-water monitor is now commercially available wherein the H_2S is measured in an acidic (pH 5) solution by a sulfide electrode/glass electrode system (29). This monitor has been evaluated and tested in a laboratory and is currently being tested in the field, where its performance over the past 12 months has been excellent; electrode failure has not been observed.

Summary

On the basis of the XRD and voltammetric results, we conclude that Ag metal is present at the outer surface of Ag/Ag_2S electrodes. The Ag metal accumulates at this outer surface as a result of redox reactions between the Ag_2S membrane and the ascorbic acid present in solution, and perhaps also by diffusion from the Ag metal contact at the inner membrane surface. The Ag metal interferes with the Nernstian response of these electrodes to low sulfide concentrations in alkaline-ascorbic acid solutions, by responding to the redox couples present in solution and generating mixed potentials. This interference can be minimized by working in acidic solutions in the absence of reducing agents.

A Rotating Ring-Disk Electrode Study of Soluble Lead (IV) Species in Sulfuric Acid Solution

Maria Skyllas Kazacos*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The rotating ring-disk electrode technique was used to detect the presence of soluble Pb(IV) species generated during the anodic charging of the lead dioxide electrode in H_2SO_4. By potentiostatting a gold ring at 0.2V *vs.* Hg/Hg_2SO_4 while scanning the lead disk between 0.8 and 1.7V, it was possible to observe a small cathodic ring current corresponding to the anodic current waves on the PbO_2 disk, and attributable to the reduction of Pb(IV) to Pb(II). This paper presents evidence for the generation of soluble Pb(IV) as an unstable intermediate during the charging of the $PbSO_4/PbO_2$ electrode. The effect of addition of small amounts of H_3PO_4 to the H_2SO_4 electrolyte is also illustrated.

The possible existence of soluble Pb(IV) species in sulfuric acid solution is important in the lead-acid battery, particularly with regard to their effect on the performance of the positive lead dioxide electrode. Although considerable research has been carried out in this area, there still remains a number of unsolved problems concerning the behavior of this electrode. An early hypothesis of Feitknecht and Gaumann (1) assumed the formation of intermediate lead (IV) compounds during the charging process which are not stable in the acid, but decompose spontaneously or are hydrolyzed

$$PbSO_4 + SO_4^{2-} + 2H_2O = [Pb(OH)_2(SO_4)_2]^{2-} + 2H^+ + 2e \quad [1]$$

followed by

$$[Pb(OH)_2(SO_4)_2]^{2-} = PbO_2 + H_2SO_4 + SO_4^{2-} \quad [2]$$

or

$$PbSO_4 + SO_4^{2-} = Pb(SO_4)_2 + 2e \quad [3]$$

followed by

$$Pb(SO_4)_2 + 2H_2O = PbO_2 + 2H_2SO_4 \quad [4]$$

Another proposed mechanism assumes that at a certain overpotential applied to the $Pb/PbSO_4$ electrode, the *p*H of the solution in the pore volume will reach the value where the reaction

$$Pb^{+2} + 2H_2O = Pb(OH)_2 + 2H^+ \quad [5]$$

becomes possible. The $Pb(OH)_2$ formed is immediately oxidized further by solid-state reaction to PbO_2 (2).

β-PbO_2 has been reported to dissolve to the extent of approximately 0.2 mM in 33 weight percent (w/o) H_2SO_4; however, it is generally believed that soluble Pb(IV) species are not detected in sulfuric acid solution (3). The existence of two relatively stable tetravalent lead phosphate species, $2PbO_2 \cdot P_2O_5 \cdot nH_2O$ and $PbO_2 \cdot P_2O_5 \cdot nH_2O$, has been reported in phosphoric acid-containing sulfuric acid solutions (4-7). Polarographic measurements by Amlie and Berger (8) have confirmed the presence of soluble lead(IV) phosphate species produced both chemically and electrochemically in sulfuric/phosphoric acid solutions. They also developed an amperometric titration technique to determine quantitatively the Pb(IV) species concentration in these solutions. They could not, however, generate either chemically or electrochemically, any detectable soluble Pb(IV) species in pure 35% sulfuric acid solutions.

* Electrochemical Society Active Member.
Key words: metals, potential, voltammetry.

If soluble Pb(IV) species are formed during the charging process in the sulfuric acid battery, they would be unstable and decompose spontaneously (3). Since a rotating ring-disk electrode (RRDE) (9, 10) can be used for the detection at the ring of soluble species discharged by the disk, such an experiment was set up to study the generation of any soluble lead species at the lead dioxide electrode.

This technique is particularly useful in the study of unstable intermediates of the disk processes since it provides a virtually instantaneous quantitative analysis of the disk product (11).

Experimental

The RRDE construction and electronics employed here have previously been described by Miller (12). Ring disk measurements were made on a rotating Au ring-Pb disk electrode (disk area = 0.18 cm^2) which used lead of 99.999% purity. A two-compartment Pyrex electrolytic cell was used in all experiments and the counterelectrode consisted of lead rod, 99.999% pure.

The electrolyte consisted of 29 w/o H_2SO_4 which was prepared from analytical-grade sulfuric acid and deionized water. Before use, the solution was preelectrolyzed (2 liters) using two Pb electrodes with a current of 100 mA for 48 hr. All potentials were measured *vs.* an Hg/Hg_2SO_4 reference electrode containing the same electrolyte as used in the electrolysis cell. A thin Luggin capillary was mounted approximately 2-4 mm below the center of the disk electrode.

Unless otherwise specified, all measurements were carried out at a rotation speed of 2500 rpm and a potential scan rate of 10 mV sec^{-1}. Nitrogen gas was passed through the solution prior to electrolysis, as well as during the experiments to remove any O_2 generated at the PbO_2 electrode. All experiments were conducted at room temperature.

Results and Discussion

The curves of Fig. 1(a) show the typical behavior of a Pb disk electrode in H_2SO_4, when the potential is scanned between 0.8 and 1.7V *vs.* an Hg/Hg_2SO_4 reference electrode. The increase in faradaic current observed in the first scan [curve 1 of Fig. 1(a)] at potentials greater than 1.5V, corresponds to the coformation of O_2 and PbO_2. Although no current arrest corresponding to PbO_2 formation is observed on the initial scan, a definite black deposit corresponding to a PbO_2 film can be observed on the electrode surface. As sufficient PbO_2 forms on subsequent cycles to stabilize the $PbSO_4/PbO_2$ reversible electrode, a definite peak

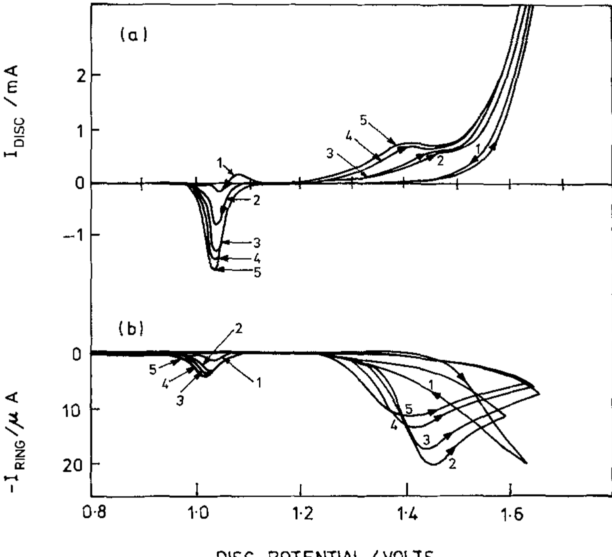

Fig. 1. (a) Consecutive controlled potential sweep cycles at a 0.18 cm^2 lead disk electrode in 29 w/o H_2SO_4. Potential range = 0.8 to 1.7V vs. Hg/Hg_2SO_4; sweep rate, ν = 10 mV sec^{-1}; rotation speed, ω = 2500 rpm. Numbers on curves refer to the cycle number. (b) Ring current traces for lead disk scans of Fig. 1(a). E_R = 0.2V.

corresponding to PbO_2 formation can be distinguished, as seen in curves 2-5 of Fig. 1(a). Reversal of the potential scan gives rise to the cathodic peak corresponding to the reduction of PbO_2 to $PbSO_4$.

If soluble Pb(IV) ions were being formed at the PbO_2 disk during charge or discharge, by potentiostatting the gold ring at the appropriate potential, it should be possible to observe a current at the ring for the reduction of Pb(IV) to Pb(II) or to Pb, depending on the potential of the ring electrode. Thus, if the ring is held at a potential less than approximately 1.0V but more positive than that required for Pb deposition a current corresponding to the reaction Pb(IV) + 2e → Pb(II) would be expected. It is also necessary to select a potential at which reduction of O_2 evolved at the disk will not interfere with, or mask, the reduction of interest at the ring. The ring was therefore potentiostatted at 0.2V *vs.* Hg/Hg_2SO_4 while the disk was scanned between 0.8 and 1.7V. The curves of Fig. 1(b) show the ring currents corresponding to the disk currents of Fig. 1(a). A reduction peak is indeed observed at the ring electrode during PbO_2 formation. In fact the ring peak closely follows the position of the PbO_2 peak as it moves to less positive potentials on successive cycles. The ring current decreases with each cycle, due to the increasing coverage of the ring with the insulating $PbSO_4$ layers. Furthermore, this ring peak is not present at a gold ring-gold disk electrode in the same solution, indicating that the species detected is peculiar to the reactions taking place at the lead electrode, and not to the reduction of oxygen evolved at the disk.

Reversal of the disk potential gives rise to a second smaller cathodic ring peak at potentials corresponding to $PbSO_4$ formation. Since the ring potential is too positive to detect Pb^{2+} in solution, the cathodic peaks observed at the ring electrode must be due to the reduction of soluble Pb(IV) species formed at the $PbSO_4/PbO_2$ electrode during charge and discharge.

If Pb(IV) ions are indeed reduced at the ring electrode at +0.2V, it should be possible to detect the presence of $PbSO_4$ on the surface of the ring. Previous workers (12) have shown, however, that during reduction of PbO_2, Pb^{2+} can also be detected at a gold ring. This is evidenced also by the considerable increase in the ring current during $PbSO_4$ formation, when the ring is potentiostatted at −1.1V (Fig. 2). The Pb(IV)

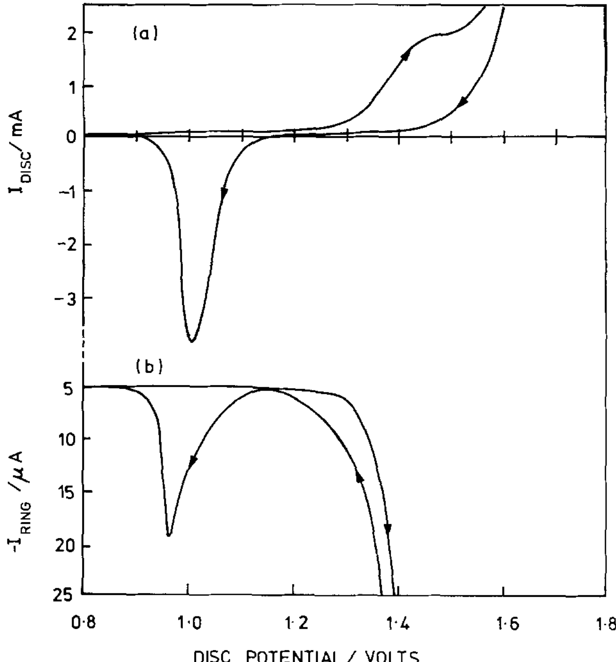

Fig. 2 (a) Controlled potential sweep cycle at a precycled lead disk electrode. Conditions as for Fig. 1. (b) Ring current traces at constant ring potential for the lead disk scan of Fig. 2(a). E_R = −1.1V.

ring peak at disk potentials corresponding to PbO_2 formation, however, can no longer be detected, due to O_2 interference. Since Pb^{2+} is generated during the reaction PbO_2 → $PbSO_4$, it would be expected that Pb^{2+} be precipitated by SO_4^{2-} and deposit on the ring. It is therefore important to ensure that any $PbSO_4$ on the ring is due to the reduction of Pb(IV) ions and not to precipitation of Pb^{2+} ions generated during the discharge reaction.

The electrode was repolished using 3 micron aluminum oxide paper to remove any $PbSO_4$ which may have been present from previous experiments. After immersing in the H_2SO_4, the ring was scanned negative from +0.2V to the potential for H_2 evolution and then reversed to the initial potential. Figure 3(a) shows the voltammogram obtained. No wave corresponding to $PbSO_4$ reduction or Pb reoxidation can be detected on the gold.

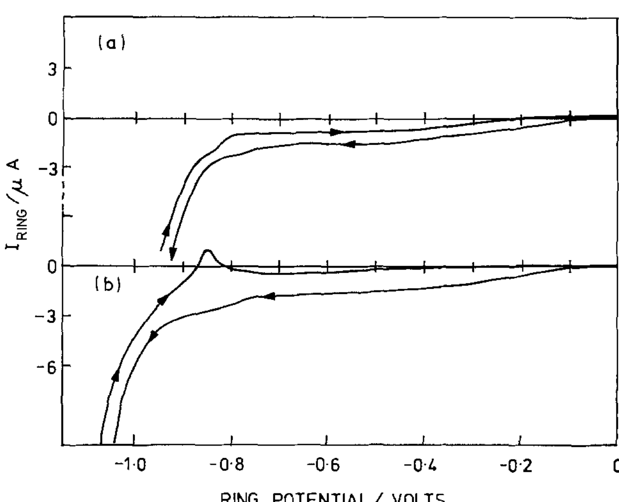

Fig. 3. (a) Potential sweep cycle of gold ring between 0.2 and −1.1V. Lead disk not previously cycled. (b) Potential sweep cycle of gold ring which had been previously potentiostated at 0.2V, while lead disk scanned between 0.8 and 1.7V in H_2SO_4.

The ring was then open-circuited while the disk was scanned from 0.8 to 1.7V and then back to 1.2V. Holding the disk at 1.2V and being careful not to allow PbO_2 reduction, the ring was then cycled negative from zero volts. A voltammogram, similar to Fig. 3(a) was again obtained showing that no $PbSO_4$ was present on the ring. Thus, scanning the disk from 0.8 to 1.7V does not lead to deposition of $PbSO_4$ on the ring from precipitation of Pb^{2+}.

The ring was then potentiostatted at +0.2V while the disk was scanned as above. When the ring was subsequently scanned negative from 0.2V and reversed after H_2 evolution, the voltammogram of Fig. 3(b) was obtained. Although no wave corresponding to the reduction of $PbSO_4$ can be distinguished due to the coevolution of H_2 on the gold, reversal of the potential gives rise to an anodic peak at a potential corresponding to the reaction $Pb \rightarrow PbSO_4$. Thus, as the ring potential was initially scanned beyond −1.2V, the $PbSO_4$ on the ring was reduced to Pb and on reversal a distinct peak for the reoxidation of Pb was obtained. This may be compared to Fig. 4 which shows the characteristic behavior of a lead electrode in sulfuric acid. This experiment thus verifies the presence of $PbSO_4$ on the ring electrode, the presence of which could only be due to the reduction of a Pb(IV) species generated at the disk during PbO_2 formation.

Previous workers (4-8) have demonstrated that the presence of H_3PO_4 increases the solubility of Pb(IV) in H_2SO_4 due to the formation of relatively stable Pb(IV) phosphate complexes. Addition of 0.5 w/o H_3PO_4 to the sulfuric acid effects the performance of the $PbSO_4/PbO_2$ electrode, as previously reported (13), and as seen from Fig. 5(a). Thus, the addition of small amounts of phosphoric acid results in the reduction peak shifting in the positive direction with a simultaneous decrease in height, as well as the appearance of a second more negative peak. The anodic peak is also seen to shift to a more positive potential in the presence of H_3PO_4, in agreement with other investigators (13, 14). The beneficial effect of phosphoric acid has been reported in the patent literature (15-19). However, higher concentrations can be detrimental to battery performance, as seen by excessive mossing at higher phosphate concentrations (16), probably related to the increased solubility of lead (IV) under these conditions. The ring current [Fig. 5(b)], corresponding to the disk scan of Fig. 5(a) shows a marked increase in the soluble Pb(IV) species on addition of H_3PO_4, as expected, again supporting the presence of Pb(IV) ions in solution during PbO_2 formation. This observation also rules out the possibility that the ring current may be due to colloidal PbO_2 particles which become detached from the electrode surface and are reduced at the ring, since such a phenomenon should not be affected by the presence of H_3PO_4 in the electrolyte.

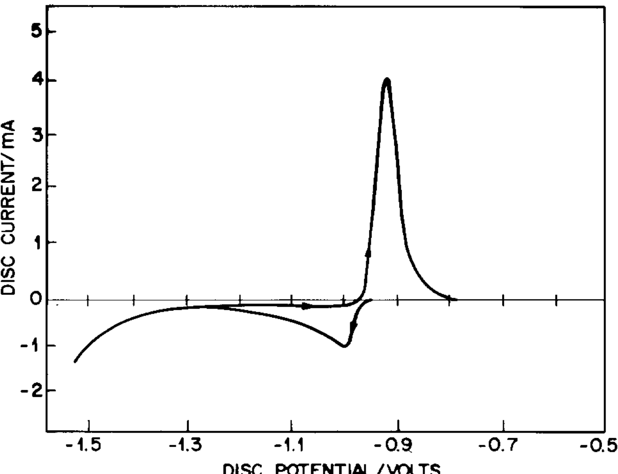

Fig. 4. Controlled potential sweep cycle at a 0.18 cm^2 lead disk electrode in 29 w/o H_2SO_4. Potential range −0.7 to −1.5V vs. Hg/Hg_2SO_4; ν = 10 mV sec^{-1}; ω = 2500 rpm.

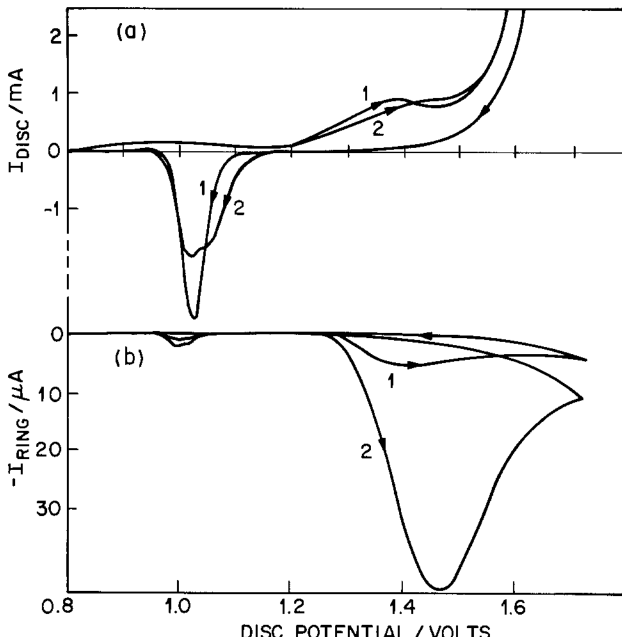

Fig. 5. (a) Curve 1: Potential sweep cycle at lead disk in H_2SO_4. Condition as for Fig. 1(a). Curve 2: Effect of addition of 0.5 w/o H_3PO_4 to H_2SO_4 solution. (b) Ring current traces corresponding to lead disk voltammograms of Fig. 5(a).

Further support for the existence of the soluble Pb(IV) species may also be obtained by comparing the magnitude of the ring currents at ring potentials of 0.2 and −1.1V. At the first potential, the Pb(IV) would be reduced to Pb(II), while at the more negative potential, Pb would be produced, resulting in an increase in the ring current by a factor of 2.

Before performing such an experiment however, two problems had to be overcome. Firstly, and as previously mentioned, at a ring potential of −1.1V, the Pb(IV) peak would be hidden by the oxygen reduction wave. To minimize this effect, the disk was precycled several times so as to stabilize the $PbSO_4/PbO_2$ electrode and increase the oxygen overpotential. The scans were also performed at lower sweep rates (2 mV/sec) to further separate PbO_2 formation from O_2 evolution.

The second difficulty arises from the low H_2 overpotential at a gold electrode which means that at a potential of −1.1V, the high H_2 evolution would prevent detection of a distinct wave corresponding to the reduction of Pb(IV) to Pb. This was overcome by first plating the gold ring electrode *in situ* with lead which has a much higher H_2 overpotential. The lead plating was accomplished by potentiostatting the ring at −1.1V while sweeping the disk between −0.8 and −1.4V. During this cycle, the disk electrode is charged, ($PbSO_4 \rightarrow Pb$) and discharged ($Pb \rightarrow PbSO_4$). During the discharge reaction, Pb^{2+} ions are generated at the disk (20) and swept across to the ring where they are reduced to Pb, thus plating the gold ring. As more and more Pb is deposited at the ring with continuous cycling of the lead electrode, the ring current decreased due to the increase in H_2 overpotential.

Using the lead-plated ring electrode which was potentiostatted at 0.2V, the disk was again scanned between 0.8 and 1.7V, with a sweep rate of 2 mV sec^{-1} [Fig. 6(a)]. Since this experiment required the use of a very slow sweep rate, a much lower current would be expected at the ring. In order to improve the sensitivity, therefore, 0.5 w/o H_3PO_4 was added to the sulfuric acid so as to increase the amount of Pb(IV) generated during the charge reaction. Figure 6(b),

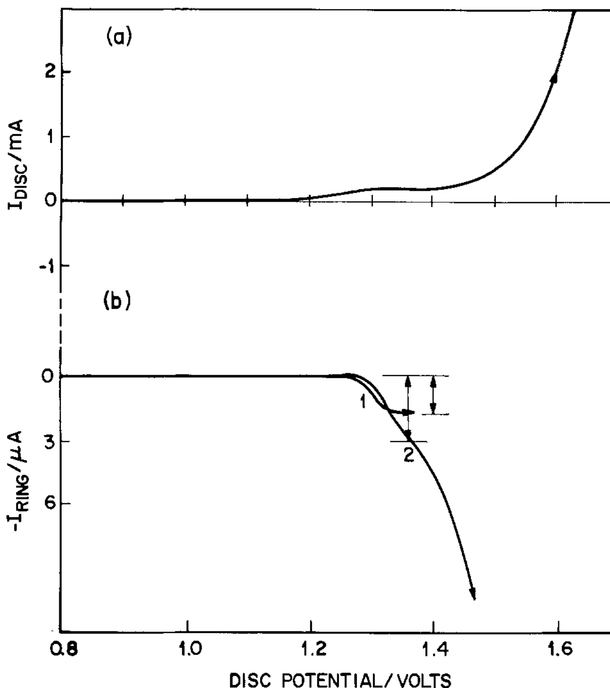

Fig. 6. (a) Voltammogram of lead disk in H_2SO_4 for $\nu = 2$ mV sec^{-1}. Other conditions as for Fig. 5(a). (b) Ring current traces at constant ring potential for lead disk scans of Fig. 6(a). Curve 1: $E_R = 0.2V$; curve 2: $E_R = -1.1V$.

curve 1 shows the characteristic Pb(IV) wave obtained at the ring at $E_R = 0.2V$. Setting the ring potential at $-1.1V$ and sweeping the disk as above, gave rise to the wave seen in Fig. 6(b), curve 2. A comparison of the ring currents at the two potentials does indicate that the ratio of the electrons transferred at -1.1 and 0.2V is approximately 2:1 as would be expected if the ring currents were due to the reduction of Pb(IV).

Conclusion

In this study, evidence has been presented for the generation and detection of soluble Pb(IV) ions in sulfuric acid solution during charge and discharge of the PbO_2 electrode. This was accomplished with the use of a rotating ring-disk electrode which is a particularly useful technique for the study of unstable intermediates of the disk reaction, as would be expected with Pb(IV) ions. This phenomenon could help to elucidate the mechanism of the reactions occurring at the positive electrode of the lead-acid battery which still presents a great deal of uncertainty and disagreement.

The Electrochemical Reduction of Molten Perchlorate and Chlorate Salts

M. H. Miles* and A. N. Fletcher*

Naval Weapons Center, Chemistry Division, China Lake, California 93555

ABSTRACT

The electrochemical reduction of molten $LiClO_4$ occurs much more readily on nickel electrodes than on platinum electrodes. This is likely related to the catalytic effect of the nickel oxide that forms on the electrode surface in oxidizing electrolytes. Both the thermal decomposition and the electrochemical reduction of molten chlorates and perchlorates require the rupture of Cl—O bonds. Such bond breaking processes appear to be catalyzed by the positive field of nearby cations and by p-type oxides. Cyclic voltammetric studies show that $LiClO_4$ is more readily reduced than $NaClO_3$ and that both form insoluble oxides as products. Potential *vs.* temperature measurements at a constant current density show nearly linear behavior between about 260°-380°C for the electrochemical reduction of $LiClO_4$ on nickel. Kinetic parameters calculated from these measurements yield 0.2 for the transfer coefficient, 15 kcal/mole for the activation energy, and 5×10^{-4} A/cm² for the exchange current density at 350°C. The transfer of the first electron accompanied by breakage of the Cl—O bond is postulated to be the slow step in the reduction reaction.

The melting points of $LiClO_3$ (129°C), $NaClO_3$ (263°C), $KClO_3$ (357°C), and $LiClO_4$ (247°C) are well separated from their thermal decompositions by temperature ranges of 100°-200°C (1). These molten oxychloride salts, therefore, may find use as oxidizing electrolytes in battery systems somewhat analogous to the use of thionyl chloride, $SOCl_2$ (2, 3). Electrochemical studies of fused $LiClO_4$ and $LiClO_3$ have been reported by other workers (4, 5), and electrochemical cells utilizing fused lithium chlorate with lithium anodes have been described (6). Mixtures of perchlorate salts with nitrate salts are also of interest due to their low melting temperatures and wide ranges of thermal stabilities. For example, an equimolar mixture of $LiClO_4$-$LiNO_3$ melts at about 160°C and appears to resist thermal decomposition up to about 450°C.

Previous studies of the electrode reduction of molten nitrates show that cations exert a major catalytic effect on the reaction (7, 8). Overvoltages for nitrate reduction increase with increasing size of the metal cation present, and the oxide ions produced by the reaction become more prone to oxidation to form peroxides or superoxides (8). Our interest in molten nitrate and oxyhalide systems is related to their possible use as oxidizing electrolytes in thermal battery cells (9).

Experimental

The electrochemical cell used in the cyclic voltammetric studies was constructed from Pyrex glass tubing with dimensions similar to the cell used previously (10). Uncompensated solution resistance was minimized by using a small working electrode ($A \sim 0.01$ cm²) positioned close to a Luggin capillary tip. The platinum and nickel working electrodes were constructed from wires sealed in glass with one end polished smooth. All potentials were measured against an $Ag/AgNO_3$ (0.1m) reference electrode as described previously (10). The counterelectrode generally consisted of a platinum wire spiral contained in fritted glass tubing that prevented any gaseous products from contacting the working electrode. The electrochemical cell was also equipped with a glass tube used for bubbling helium gas through the melt to remove residual water. The helium was passed through tubes of anhydrous calcium sulfate (indicating Drierite) and P_2O_5 prior to entering the cell. Despite using anhydrous $LiClO_4$ (J. T. Baker or G. F. Smith Reagent) that was dried in a vacuum oven at 130°C for several days, considerable water still remained in the salt. The water-wave on platinum in molten $LiClO_4$, similar to that observed in molten $LiNO_3$ (8), showed that the bubbling of dried helium gas through molten $LiClO_4$ at 300°-350°C for several hours was required to remove the final traces of water. The problem of water retention by $NaClO_3$, in contrast, was very minor. Temperature control was maintained within ± 5°C by the use of a fluidized sand bath (Tecam).

Potential *vs.* temperature measurements of the cathodic reaction at a selected constant current density were made on nickel electrodes ($A = 0.32$ cm²) using the electrode arrangement in an open pan as described previously (7). The only difference was that a platinum pan was used in place of nickel to minimize both the catalytic decomposition of molten $LiClO_4$ and the corrosion of the pan. A fiberglass filter served as a separator and contained most of the molten salt in these thin cells that used calcium as the anode to approximate conditions in thermal battery cells. Galvanostatic studies of the cathodic reaction at a fixed temperature were also made in these same cells.

Constant current measurements were obtained using a PAR Model 173 potentiostat/galvanostat and results were plotted using a strip chart recorder (HP 7100B). For cyclic voltammetric measurements, a PAR Model 175 programmer was also used and results were displayed with an X-Y recorder (HP 7047A).

Results

The electrochemical reduction of molten $LiClO_4$ occurs much more readily on nickel electrodes than on platinum electrodes. This is in sharp contrast to the electrochemical reduction of molten nitrates that occurs at about the same potential on both electrodes (7, 8). Figure 1 shows a cyclic voltammetric trace for the reduction of molten $LiClO_4$ at 300°C on nickel. The cathodic reaction begins at about −0.5V on nickel and at about −1.1V on platinum (Fig. 2). Although a reduction peak was observed on both metals, the peak was usually rather irregular on nickel and is not shown in Fig. 1. At a potential sweep rate of 100 mV/sec, typical peak potentials were about −0.8V on nickel and −1.5V on platinum. By varying the cathodic sweep limit, the following anodic peak was found to be directly related to the reduction reaction. Comparisons with previous results in molten $LiNO_3$ indi-

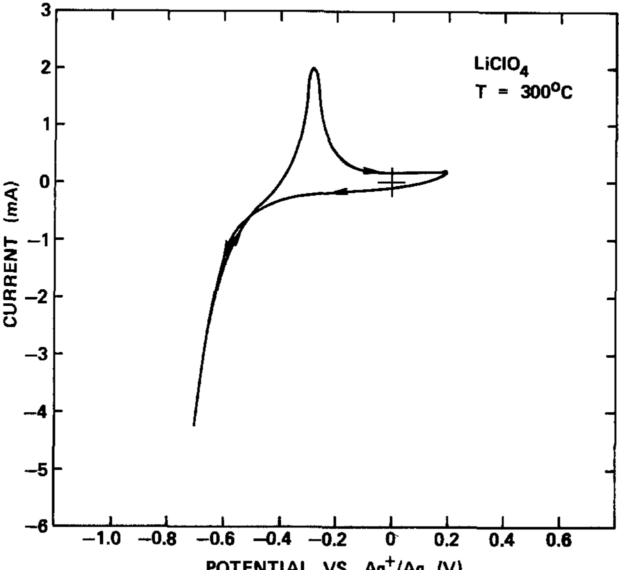

Fig. 1. Cyclic voltammetric study on nickel at 100 mV/sec. Results are for molten $LiClO_4$ at 300°C. Potential sweep was begun at 0.0V and swept first cathodically, then anodically, and finally cathodically to the starting potential.

cates that the anodic peak is due to the oxidation of insoluble Li_2O to form Li_2O_2 (8). Slight gas evolution observed immediately following the anodic peak suggests the decomposition of the unstable peroxide formed. Similar gassing was also observed following the anodic peak on molten $NaClO_3$ (Fig. 2).

Cyclic voltammetric studies of molten $LiClO_4$ at 300°C on platinum are shown in Fig. 2 at four potential sweep rates. For comparisons, a similar cyclic voltammetric trace at 100 mV/sec on platinum in molten $NaClO_3$ is also shown. Although molten $LiClO_4$ reduction begins at quite different potentials on nickel and platinum electrodes, the Li_2O oxidation peak remains at about the same potential. The water-wave on platinum in molten $LiClO_4$ occurs prior to the $LiClO_4$ reduction peak (4) and, as found in molten $LiNO_3$ (8), is not detected on nickel electrodes.

Figure 2 indicates that molten $NaClO_3$ is much more difficult to reduce than molten $LiClO_4$ and that insoluble Na_2O is produced by the electrode reaction. Oxidation of the Na_2O to the peroxide apparently occurs on the anodic sweep similar to previous studies in molten $NaNO_3$ (8). The different areas of the reduction and oxidation peaks in Fig. 2 likely reflect the partial dissolution of the oxide product. The extended cathodic sweep in molten $NaClO_3$ shows the reduction of sodium ions to metallic sodium at about $-3.1V$ *vs.* Ag^+/Ag. This metallic sodium likely reacts quickly with molten $NaClO_3$ to form sodium oxide. The solubilities of both Li_2O and Na_2O at 300°C, as determined from acidimetric titrations, were 0.2 mole percent (m/o) in molten $NaClO_3$ and 0.8 m/o in molten $LiClO_4$.

Studies of the $LiClO_4$ reduction peak were often complicated by rather irregular traces caused by gas bubbles forming at the working electrode. This effect was much greater with nickel electrodes than with platinum electrodes and persisted even at open circuit, suggesting the catalytic decomposition of $LiClO_4$. Although smooth cyclic voltammetric traces were often difficult to obtain, the potential sweep studies of $LiClO_4$ reduction on both platinum and nickel electrodes generally showed that the peak current was proportional to the square root of the sweep rate while the peak potential becomes more negative with increasing rate of potential change. It should be noted, however, that the peak currents are likely due to blockage of the electrode surface by insoluble oxides rather than by diffusion limitations of the reactants. Similar reduction peaks due to oxide blockage are obtained in molten $LiNO_3$ and $NaNO_3$ (8, 11, 12).

Figure 3 presents a cyclic voltammetric study of an equimolar mixture of $LiClO_4$-$LiNO_3$. On platinum, reduction of the $LiNO_3$ occurs more readily than the reduction of $LiClO_4$ and gives a peak potential of about $-0.95V$. The reduction of molten $LiClO_4$ beginning at about $-1.1V$ (see Fig. 2) gives an unsymmetric shape to the reduction peak. Insoluble Li_2O is produced by the reduction of both $LiNO_3$ and $LiClO_4$, hence a single oxidation peak is observed on the following anodic sweep. Preliminary studies of equimolar mixtures of $KClO_3$-$LiNO_3$ and $NaClO_4$-$LiNO_3$ at 350°C indicated less satisfactory performance than the $LiClO_4$-$LiNO_3$ mixtures. In particular, gassing was a serious problem. Differential scanning calorimetry studies of the $KClO_3$-$LiNO_3$ mixture gave thermal decomposition characteristics that related more closely to molten $LiClO_3$ than to $KClO_3$. Thermogravimetric experiments indicate that $LiClO_3$ decomposes more readily than $LiClO_4$ (1). These results suggest that the use of molten $LiClO_3$ as the oxidizing electrolyte might be less satisfactory than the use of $LiClO_4$ in the temperature range of 250°-400°C.

The analyses of potential *vs.* temperature measurements at constant current densities can yield various

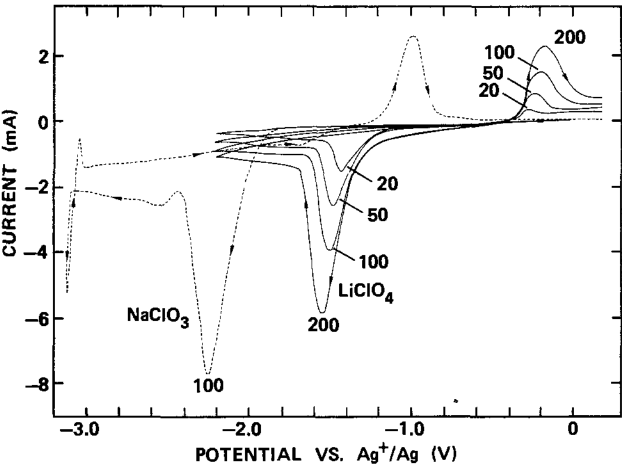

Fig. 2. Cyclic voltammetric studies on platinum in molten $LiClO_4$ and $NaClO_3$ at 300°C. The studies in $LiClO_4$ (solid lines) were made at potential sweep rates of 20, 50, 100, and 200 mV/sec. All potential sweeps began at 0.0V and were swept first cathodically and then anodically.

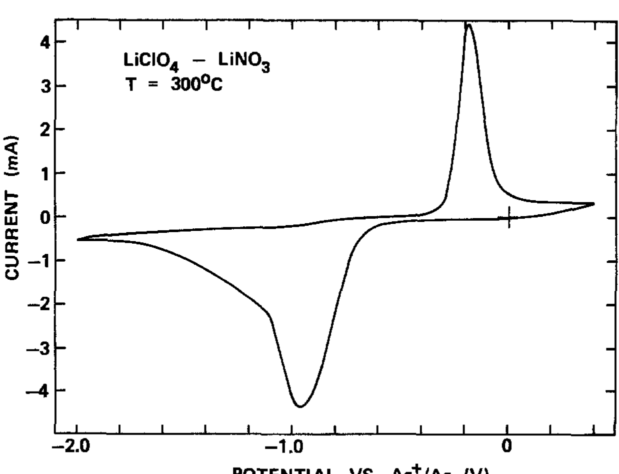

Fig. 3. Cyclic voltammetric study on platinum in equimolar $LiClO_4$-$LiNO_3$ at 300°C. Potential sweep rate was 100 mV/sec.

kinetic parameters since the constants in the empirical equation

$$E_c = a + (b_1 + b_2 \ln i)T \quad [1]$$

can be theoretically related to these parameters (7). Typical results for such experimental measurements on nickel electrodes in molten $LiClO_4$ and $LiNO_3$ are presented in Fig. 4. Both studies show an approximately linear potential change with temperature as predicted theoretically (7); however, for molten $LiClO_4$, the linear range is limited to about 280°-380°C. The upper limit is likely related to the thermal decomposition of molten $LiClO_4$ that begins at about this temperature (1). Table I presents the average values for the empirical constants obtained from nine separate studies in molten $LiClO_4$ as well as the kinetic parameters calculated from these constants. For comparisons, average results from similar studies of molten $LiNO_3$ reduction are also shown. For molten $LiClO_4$ reduction, the transfer coefficient (α_c) is calculated to be 0.20, the free energy of activation ($\Delta G^{\circ\ddagger}$) is about 15 kcal/mole, and the exchange current density (i_o) is 5×10^{-4} A/cm². The calculations of the $\Delta G^{\circ\ddagger}$ and i_o values involved the assumption that the equilibrium potential at 350°C is 0.2V for $LiClO_4$ reduction and 0.0V *vs.* Ag^+/Ag for $LiNO_3$ reduction (7). These values are supported by both thermochemical calculations and experimental observations. The i_o values presented are based upon the apparent electrode area that may vary from the real surface area depending upon the relative effects of electrode blockage by insoluble Li_2O and the roughness of the electrode surface. Similar studies on platinum electrodes gave poor results; this could likely be due to interference from the water-wave that occurs on platinum but is not detected on nickel (8).

Table II presents average Tafel and kinetic parameters obtained galvanostatically at 350°C from potential *vs.* current density measurements. Linear Tafel regions were generally observed between about 1-10 mA/cm². The α_c and i_o values show reasonable agreement with those obtained from the potential *vs.* temperature measurements under galvanostatic conditions (Table I). The parameters for molten $LiNO_3$ reduction obtained in these thin cells containing a calcium anode and exposed to the atmosphere also agree favorably with previous results obtained potentiostatically in stirred solutions under a helium atmosphere (8).

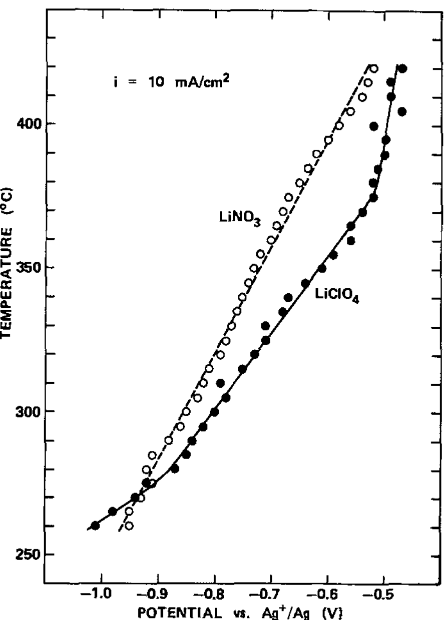

Fig. 4. Potential *vs.* temperature measurements for the electrochemical reduction of molten $LiClO_4$ and $LiNO_3$ salts on nickel electrodes at a constant current density of 10 mA/cm².

Table I. Average empirical constants and kinetic parameters for the electrochemical reduction of molten $LiClO_4$ and $LiNO_3$ salts on nickel electrodes. These values were obtained from potential vs. temperature measurements at constant current densities in thin cells that used calcium as the anode

Salt	a (V)	b_1 (V/K)	b_2 (V/K)	α_c	$\Delta G^{\circ\ddagger}$ (kcal/mole)	i_o* (A/cm²)
$LiClO_4$	−2.84	1.57×10^{-3}	-0.43×10^{-3}	0.20	15	5×10^{-4}
$LiNO_3$	−2.78	1.99×10^{-3}	-0.22×10^{-3}	0.39	25	3×10^{-6}

* At T = 350°C.

Table II. Average Tafel and kinetic parameters for the electrochemical reduction of molten $LiClO_4$ and $LiNO_3$ salts on nickel electrodes. These values were obtained from steady-state galvanostatic measurements at 350°C in thin cells that used calcium as the anode

Salt	b (V)	α_c	i_o (A/cm²)
$LiClO_4$	0.45	0.27	3×10^{-4}
$LiNO_3$	0.28	0.44	4×10^{-5}

Figure 4 and Tables I and II show that on nickel electrodes, the reduction of molten $LiClO_4$ occurs more readily than the reduction of molten $LiNO_3$. This is reversed from the observations on platinum electrodes.

The stability limit with respect to electrochemical oxidation was investigated for molten $NaClO_3$ and $LiClO_4$ at 300°C on platinum electrodes, and the cyclic voltammograms (Fig. 5) show that $NaClO_3$ oxidizes more readily than $LiClO_4$. The major anodic wave begins at about 0.8V in $NaClO_3$ and at about 1.7V in $LiClO_4$. On nickel electrodes, the major anodic wave begins at about 0.7V in molten $NaClO_3$ and at about 1.5V in molten $LiClO_4$ at 300°C. The oxidation reactions

$$2\,NaClO_3 \rightarrow 2\,Na^+ + Cl_2 + 3\,O_2 + 2\,e^- \quad [2]$$

$$2\,LiClO_4 \rightarrow 2\,Li^+ + Cl_2 + 4\,O_2 + 2\,e^- \quad [3]$$

likely involve the loss of an electron by the oxychloride anion followed by decomposition of the resulting radical (13). Mass spectrometric analysis of the gases produced at the anode during electrolysis of pure $LiClO_4$ showed no fragments containing Cl—O bonds (4). The slowly rising anodic current in the molten $LiClO_4$ study suggests the presence of small amounts of the more readily oxidized chlorate compound.

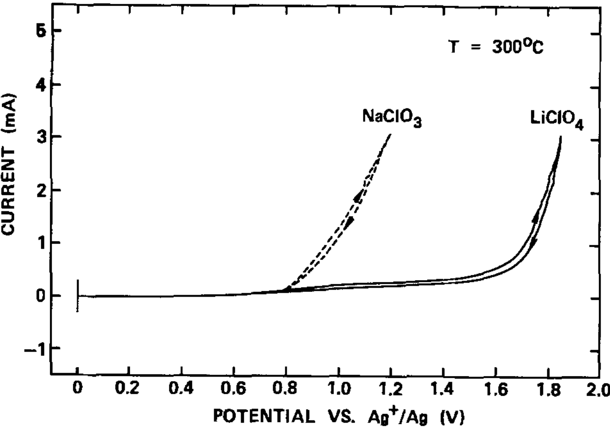

Fig. 5. Cyclic voltammetric studies of the electrochemical oxidation of molten $NaClO_3$ and $LiClO_4$ at 300°C. Potential sweeps began at 0.0V and were swept first anodically and then cathodically. Potential sweep rate was 100 mV/sec.

Discussion

Anders and Plambeck (4) have presented evidence that the reduction peak observed in molten $LiClO_4$ is due to the net reaction

$$LiClO_4 + 2\,Li^+ + 2e^- \rightarrow LiClO_3 + Li_2O\downarrow \quad [4]$$

The expected electron:oxide ratio was obtained but not the expected electron:chlorate ratio. This is not surprising considering the various decomposition and disproportionation reactions that may occur in molten chlorates and perchlorates (1). The Li_2O produced in the electrode reduction reaction can have a large catalytic effect on the decomposition reaction (1, 4). For example, we observed that 20g of molten $LiClO_4$ at 350°C in a quartz container was quite stable until 0.1g of Li_2O was added that produced immediate gassing and complete decomposition of the melt to a white solid (LiCl) within 30 min. The presence of $LiClO_3$ as an intermediate in the decomposition reaction or the reaction of chlorate with the oxygen produced, $LiClO_3 + \frac{1}{2}\,O_2 \rightleftharpoons LiClO_4$, could account for variable electron:chlorate ratios. Constant current exhaustive electrolysis experiments involving small amounts of $LiClO_4$ and $LiNO_3$ added to LiCl-KCl melts at 390°C indicated that both $LiClO_3$ and $LiNO_2$ reduction products react readily with oxygen to regenerate the reactants.

The chemistry of alkali metal nitrates depends greatly upon the nature of the metal cation that is present (7, 8). Increase of the electric field strength (polarizing power) of the cation results in a decrease in overvoltage for the electrochemical reduction. Although the rather high melting points of some of the alkali metal chlorates and perchlorates prevented a systematic investigation of cation effects in these molten oxyhalides, cation effects similar to those observed for molten nitrate reduction are to be expected. For example, the observation that fused $NaClO_3$ is more difficult to reduce than $LiClO_4$ (Fig. 2) may be largely due to the weaker electric field of the sodium ion since the electrochemical reduction of molten $LiClO_3$ apparently occurs readily even at 140°C (5, 6).

For alkali metal chlorates and perchlorates, it is generally observed that the greater the electric field strength of the cation, the lower the temperature at which the compounds begin to decompose (1). Both the thermal decomposition and the electrochemical reduction of molten chlorates and perchlorates require the rupture of Cl—O bonds; thus the positive electric field of a nearby cation apparently weakens such bonds via strong electron withdrawing effects. The equations

$$LiClO_4 + Li^+ + e^- \rightarrow (ClO_3)_{ads} + Li_2O\downarrow \quad \text{(slow)} \quad [5]$$

$$(ClO_3)_{ads} + e^- \rightarrow ClO_3^- \quad \text{(fast)} \quad [6]$$

represent a mechanism for $LiClO_4$ reduction that is consistent with the kinetic parameters obtained (Tables I and II) and similar to the mechanism proposed for the reduction of molten $LiNO_3$ (7). A possible mechanism for chlorate reduction similar to that for perchlorate would involve formation of $(ClO_2)_{ads}$ in the slow step followed by reduction to chlorite. Since any chlorite formed in the reduction process would tend to disproportionate with chloride being the final product (1)

$$3MClO_2 \rightarrow 2MClO_3 + MCl \quad [7]$$

the reduction of $LiClO_4$ could conceivably yield a total of eight electrons per molecule. A six electron reaction has been proposed for the reduction of $LiClO_3$ (5).

Various metal oxides in addition to Li_2O are capable of increasing the rates of decomposition of chlorates and perchlorates to a considerable extent, and the p-type oxides (MnO_2, CuO, and NiO) tend to be among the most effective catalysts (1, 14, 15). It has been proposed that the mechanism for the catalytic decomposition of oxyhalides on p-type oxides involves the transfer of an electron from the adsorbed oxyhalide anion to a positive hole in the oxide (1). After rupture of the Cl—O bonds to form oxygen, the electron is transformed back to the chlorine atom to form Cl^-. Nickel undergoes spontaneous passivation in nitrate melts due to formation of a nickel oxide film (16). Since nickel electrodes also form a dark oxide film in the molten oxyhalide salts (4), the observed gas bubbles formed at the nickel electrode even at open circuit suggests the catalytic decomposition of molten $LiClO_4$ and $NaClO_3$ by nickel oxide. On platinum electrodes, the irregular cyclic voltammetric traces produced by gas bubbles seemed to be related to the presence of insoluble Li_2O since the removal of Li_2O from the electrode surface resulted in less gassing and smoother traces.

The effectiveness of nickel electrodes in the electrochemical reduction of molten $LiClO_4$ is likely related to the catalytic properties of nickel oxide. Both the positive hole of the nickel oxide and the positive electric field of the Li^+ ion could contribute to the weakening of the Cl—O bond of the adsorbed perchlorate. The observation that platinum electrodes are much less effective than nickel electrodes in catalyzing the reduction of molten $LiClO_4$ is likely related to the noble behavior of platinum with respect to oxide film formation in fused $LiClO_4$ (4). Studies in condensed phosphates indicate a strong cation effect in the form of —P—O—P— bond weakening by induction (17, 18). The strong polarizing power of the lithium ion probably plays an important role in the oxidation of nitrite ions in molten $LiClO_4$ (19).

Explosive reactions may occur following the deposition of lithium metal at the cathode in molten $LiClO_4$ (4, 20). In our studies, the deposition of lithium metal at a nickel electrode in molten $LiClO_4$ at 350°C resulted in a sharp explosion shortly after switching the cell to open circuit. However, no explosive reactions were observed in the use of calcium anodes in molten $LiClO_4$ over a variety of conditions. A passive oxide film offers protection to the solid calcium (mp = 838°C) and isolates it from the molten $LiClO_4$, however, stable film formation is not possible with the liquid lithium (mp = 181°C) metal and its contact with the molten perchlorate gives a very unstable condition. Explosion hazards in the handling of sodium chlorate should also be noted (21).

Manuscript submitted Aug. 27, 1980; revised manuscript received Nov. 19, 1980. This was Paper 523 presented at the St. Louis, Missouri, Meeting of the Society, May 11-16, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by the Naval Weapons Center.

Solid Electrolyte Interphase (SEI) Electrode

II. The Formation and Properties of the SEI on Magnesium in $SOCl_2$-$Mg(AlCl_4)_2$ Solutions

A. Meitav and E. Peled*

Institute of Chemistry, Tel-Aviv University, Ramat Aviv, Tel Aviv, Israel

ABSTRACT

Magnesium metal immersed in thionyl chloride solutions becomes covered by a passivating layer which has properties of solid electrolyte. The buildup and the electrochemical properties of this layer were studied. Tafel slopes measured on freshly immersed Mg electrodes depend linearly on the apparent thickness of the SEI. The reaction resistance and the differential capacitance, on Mg and W electrodes, were measured by several methods. Values of the electrochemical parameters depend on the bias potential. The metal/solution interfacial capacitance of W electrode is higher by an order of magnitude than that of Mg electrode. This higher capacitance decreases markedly, under cathodic polarization.

The alkali and alkaline-earth metals show no significant corrosion in many strong oxidizing solvents (1). This apparent stability is explained by the existence of a passivating layer (PL), which is formed instantly by the contact of the metal with the solution. This layer consists of some insoluble products of the reaction of the metal with the solution (2-13). It acts as an interphase between the metal and the solution and has the properties of solid electrolyte, through which electrons are not allowed to pass. Therefore, it is called "solid electrolyte interphase (SEI)" (8). The electrochemical behavior of SEI electrodes are primarily governed by the properties of the SEI (8-13). Therefore an understanding of the SEI buildup and the conduction mechanism through it, is of practical and theoretical importance.

It was found that the PL of lithium immersed in thionyl-chloride (TC) solutions consists of lithium chloride crystals (7). The electrochemical properties of lithium in TC were recently investigated (10-11). The resistivity of this layer was found to be *ca.* 10^8 Ωcm and the apparent resistance was proportional to the SEI thickness. In aged electrodes the linear portion of the polarization (I/V) curves expanded up to 0.5V, indicating Tafel slope greater than 3V. On the basis of these and other results, it was concluded that the rate-determining step (rds) for the deposition-dissolution process of lithium in TC solutions is the migration of lithium cations through the SEI.

The behavior of pure magnesium and magnesium alloys has been reported in Ref. (6, 9, 12, 13). The investigations deal with TC solutions employing two electrolytes: $AlCl_3$-$MgCl_2$ and $FeCl_3$-$MgCl_2$. It was found that magnesium rapidly corrodes in $AlCl_3$-TC solution, being completely dissolved. However, in solutions saturated with $MgCl_2$ it practically does not corrode. Magnesium was electrodeposited on a nickel wire in $Mg(FeCl_4)_2$ solution (12). However, the electrolysis does not occur according to a simple electrodeposition mechanism. The magnesium deposits only after the nickel cathode has been coated by a PL. This layer is formed during the first period of the electrolysis by electroreduction of TC. The reduction products of TC precipitate on the cathode surface and inhibit the farther electron transfer through the interface. In experiments employing magnesium alloys it was found that the alloying elements affect the growth rate of the SEI, but not the resistivity of the SEI (13).

All these electrochemical measurements employing magnesium and magnesium alloys were taken near the OCP only. The primary goal of this work was to investigate in more details the formation and properties of the PL on magnesium, at OCP and during anodic and cathodic polarization; as well, to study the influence of the surface pretreatment on the electrochemical behavior of the magnesium metal in TC solutions. The second goal was to investigate the metal-solution interfacial properties. As the PL on alkali and alkaline-earth metals in TC forms spontaneously and immediately; the double layer (DL) capacitance of the metal-solution interface cannot be obtained. Therefore an inert tungsten electrode was used and its electrochemical behavior, at OCP and under cathodic polarization, was studied.

Experimental

All solutions were prepared and cells were assembled inside an argon-filled glove box. The Merck zur synthesis TC was twice distilled under vacuum. Fluka puriss $AlCl_3$ was vacuum sublimed at 120°-140°C and dissolved in distilled TC. Roc/Ric $MgCl_2$ (98%) was vacuum dried at 80°-120°C for 24 hr and dissolved (in 5% excess) in the $AlCl_3$-TC solution. Then the TC was pumped out of the solution and another volume of twice-distilled TC was added to the residual electrolyte, to form 0.6M Mg $(AlCl_4)_2$ solution. The experimental cell was constructed of three magnesium electrodes or of a tungsten working electrode and magnesium reference and counterelectrodes. A detailed construction of the cell is described in Ref. (12). The standard pretreatment of the magnesium consists of etching the metal (for about 10 sec at room temperature) in 5% HNO_3 (A.R.) and rinsing in distilled water. Then the electrode is fitted into the electrochemical cell, which is evacuated and transferred to the glove box. There, the cell is filled with the solution and the desired experiments are performed. All experiments, with saturated solutions, were carried out in 0.6M Mg $(AlCl_4)_2SOCl_2$.

The reaction resistance was calculated from galvanostatic micropolarization curves at steady state and from a-c measurements. The galvanostatic measurements were performed by a homemade pulse galvanostat with a rise time of about 1 μsec. The a-c measurements were performed with the use of a lock-in analyzer (PAR Model 5204), attached to a PAR Model 173 potentiostat. An *IR* correction was made in all experiments. All experiments were carried out at room temperature.

The differential capacitance of the magnesium-solution interphase was determined by an a-c method and from the initial slope of the η *vs.* t transients, using the equation

$$C = \frac{i}{(dv/dt)t \rightarrow 0} \qquad [1]$$

The minimum apparent thickness of the SEI (d) was calculated according to the measured differential capacity with the use of the equation for a parallel-plate capacitor and under the assumption that the dielectric constant is 5 (12). The dielectric constant of many calcium and magnesium compounds is about 5-10. The dielectric constant (ϵ) of $MgCl_2$ was not found in the literature. Moreover, these values of solid-state dielectrics are probably correct for single crystals. The true ϵ value of the polycrystalline $MgCl_2$ in the SEI may differ from that for a single crystal and should depend on many other parameters. As we have no ways to precisely determine ϵ, it was assumed, as a first approximation, that its value is constant in all experimental conditions. Therefore this calculation gives the minimum apparent thickness of the SEI.

Results

Electrochemical Properties of Magnesium Electrode

Unsaturated solution.—The reaction resistance (Rr) and the calculated thickness of the SEI (d) of a magnesium electrode immersed in a solution unsaturated with $MgCl_2$ are presented in Fig. 1. The composition of the solution was 1.2M $AlCl_3$ + 0.3M $MgCl_2$. A comparison of the calculated resistivity (Rr/d) of a magnesium electrode in a saturated and unsaturated solution *vs.* the immersion time is shown in Fig. 2. The magnesium electrode in the unsaturated solution disintegrated almost completely after about 70 hr of immersion in the electrolyte.

Surface pretreatment.—Under the described experimental conditions, the magnesium electrode introduced into the cell is covered by a thin oxide film. In order to investigate the possible dependence of the electrochemical properties of the magnesium on the primary

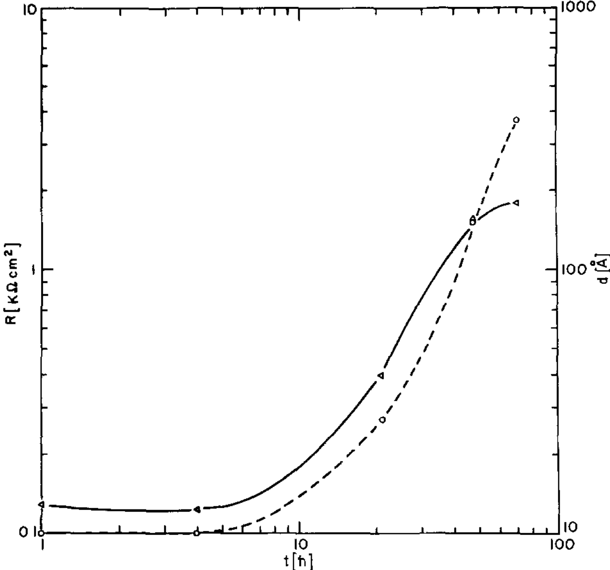

Fig. 1. Reaction resistance and calculated thickness of the SEI of magnesium electrode in acidic solution (1.2m $AlCl_3$-0.3m $MgCl_2$-$SOCl_2$) *vs.* the immersion time. △, Thickness; ○, resistance.

layer which coats it prior to its immersion in the TC solution, three sets of differently pretreated magnesium electrodes were examined: (*i*) standard pretreated electrodes, (*ii*) electrodes pretreated as in (*i*), followed by 50 hr of immersion in distilled water, (*iii*) electrodes degreased only. Scanning electron micrographs of the three magnesium electrodes after these pretreatment procedures are shown in Fig. 3-5. The white zones seen in Fig. 4 are the areas from which the hydrogen bubbles were evolved during immersion in water. The SEI resistivity-time plot of these electrodes, immersed in 0.6M $Mg(AlCl_4)_2$ solution, are presented in Fig. 6.

A-C measurements.—The differential capacity of magnesium electrode was measured as a function of time by an a-c technique, while constant anodic or cathodic overvoltages were applied. The a-c frequency was 100 Hz and rms amplitude was 30 mV. The d-c

Fig. 3. SE micrograph of a magnesium electrode pretreated by standard procedure. Magnification 500×. The line drawn on the picture presents length of 20 microns.

current and the differential capacitance during anodic polarizations of 50, 100, 200, and 300 mV are presented in Fig. 7 and 8. Figure 9 shows a-c differential capacity and d-c currents for cathodic overvoltages of 100, 200, 300, 800 mV. Passage of high cathodic currents is possible only if the cathodic polarization follows a previously applied anodic macropolarization. Under these experimental conditions the cathodic currents are much higher and a rapid gas evolution and a yellow precipitate on the cathode are observed. A marked increase in resistance and decrease in capacity are observed after such a polarization.

mersed in 0.6M $Mg(AlCl_4)_2$ solution, for up to 40 hr. The plots are shown in Fig. 10. The plots were obtained after different times of immersion: 1, 20, and 40 hr. The Tafel slopes are 280, 350, and 430 mV, respectively. On polarizing magnesium electrodes immersed for longer periods of time, the Tafel plots deviate from linearity (on a semilogarithmic scale). The linear portion of the η *vs.* i curves measured for electrodes immersed for longer periods of time reaches up to 300 ± 100 mV.

Electrochemical Properties of Tungsten Electrode

The OCP of tungsten in 0.6M $Mg(AlCl_4)_2$ TC solutions is about 1.9V *vs.* Mg reference electrode (RE). The differential capacitance and the reaction resistance of the tungsten electrode were measured by an a-c technique, in the frequency range of 40-1500 Hz. In this frequency range the differential capacitance did not depend significantly on the frequency, its value at OCP being about 30 μF/cm^2. Figure 11 shows two successive cyclic voltammograms at 500 mV/sec sweep rate. It should be noted that the cathodic current maximum of the first sweep disappears on the succeeding one. However, a current maximum does appear on the succeeding sweep when the sweep rate is decreased (smaller than 0.3 V/sec).

The current maximum observed on the first potential sweep rises as the sweep rate is increased. However, when the sweep rate is reduced a new cathodic

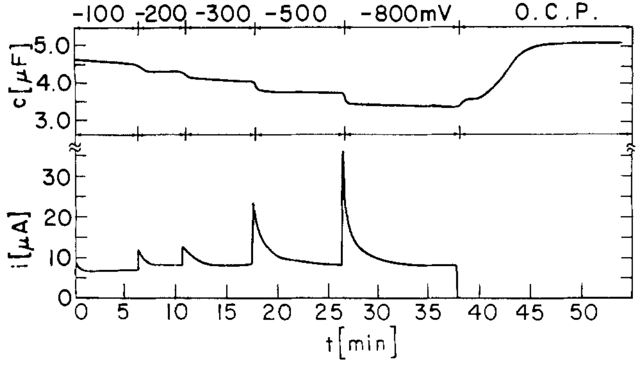

Fig. 9. D-C current and differential capacitance during application of cathodic overvoltages of 100, 200, 300, and 800 mV on magnesium electrode. Electrode area 2.2 cm^2.

current peak is detected on the backward potential scan (*i.e.*, going from 0 to 1.8V *vs.* MgRE). This is peak B in Fig. 12. Figure 12 shows cathodic d-c current (dashed line) and the interfacial capacitance as a function of an applied potential scanned at a rate of 2 mV/sec. It should be noted in Fig. 12 that the decrease of the cathodic current (after passing the peak) is associated with a sharp decrease of the electrode capacitance.

Supplementary to the a-c technique, the differential capacitance, at the tungsten-TC interface, was calculated from the *I-V* plots which were obtained at high sweep rates, in the potential range 2.0-1.8V *vs.* Mg RE. In this range the currents are mainly capacitative, Fig. 13.

The capacity values obtained at different sweep rates are presented in Table I.

Discussion

Formation and properties of the SEI.—It should be emphasized that the system investigated is thermodynamically unstable and the apparent stability is due to the kinetic properties of the system. These properties are directly dependent on the SEI features which are determined by: (*i*) thickness, porosity, and adhesion; (*ii*) electronic and ionic transference numbers (t_{e^-}, $t_{cath.}$, t_{anodic}); and (*iii*) ionic mobility. The main factors determining the ionic conductivity are the type of the structural defects (Frenkel, Schottky) and their concentration.

According to this work it seems that it is possible to define two different states of the magnesium SEI

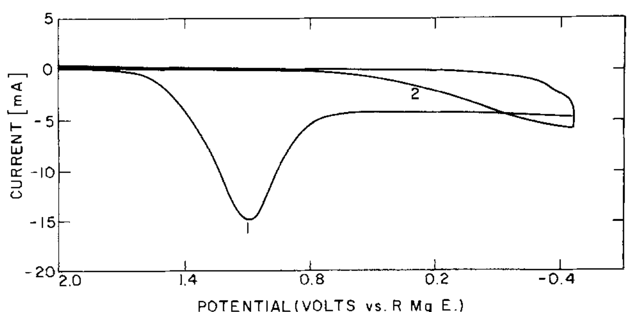

Fig. 11. Two successive voltammograms on tungsten electrode. Sweep rate 500 mV/sec. Electrode area 1.7 cm^2.

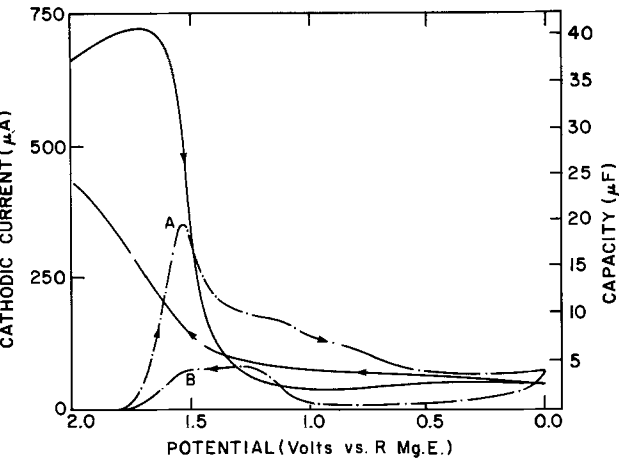

Fig. 12. Current and a-c capacitance vs. potential applied on tungsten electrode. Potential sweep rate 2 mV/sec. Electrode area, 1.7 cm². —·—·— current, ——— a-c differential capacitance.

electrode: (*i*) Electrodes that are held under OCP condition for sufficiently long durations (50 hr or more). Under these "steady-state" conditions, the SEI would have the relatively highest integrity and compactness. Consequently, the ionic and electronic conductivities will have the minimum intrinsic value. (*ii*) Electrodes handled under nonsteady-state conditions, such as: (*a*) acidic solutions, (*b*) freshly immersed electrodes, and (*c*) continuous heavy anodic polarization.

In all these circumstances the SEI is relatively thinner and may have a highly disordered structure, which leads to high ionic and electronic conduction.

In acidic solutions (excess of $AlCl_3$), the corrosion rate of magnesium is much higher than in neutral solutions (saturated with $MgCl_2$). Accordingly, the apparent electrode resistance and the calculated resistivity (Fig. 2) are smaller by an order of magnitude than their values in neutral solutions. This may result from the continuous process of redissolving of the precipitated corrosion product ($MgCl_2$).

The behavior of magnesium in saturated solution during the first hours of immersion is very similar to its behavior in the unsaturated solution. The resistivity, during the first 3 hr, does not differ much from the values in the unsaturated solution. It seems that in both cases the same process of dissolution of the PL establishes these relatively low values. It is possible that these lower values are accompanied by a high rate of corrosion. During this process there is a rearrangement of the surface layer on the immersed electrode. The oxide layer dissolves and a new (most likely $MgCl_2$) layer is built up. The formation of the $MgCl_2$ is thermodynamically preferred over MgO by 35 kcal/mole ($MgO + SOCl_2 \rightarrow MgCl_2 + SO_2 - 35$ kcal/mole).

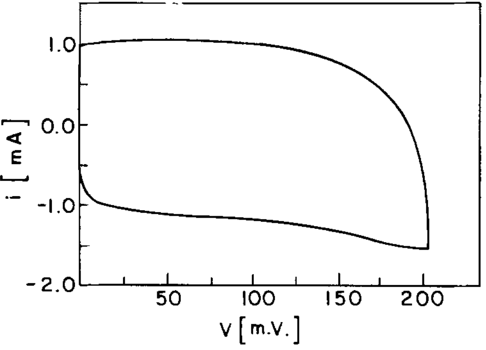

Fig. 13. *I-V* curve on tungsten electrode, obtained at sweep rate 20 V/sec in the potential range 2-1.8V vs. MgRE (Recorded on oscilloscope.)

Table I. The differential capacitance calculated from double layer charging currents, at different potential-sweep rates

Sweep rate (V/sec)	0.2	20	100	200	500	Average
Capacity ($\mu F/cm^2$)	24	29	26	24	24	25 ± 1

This exchange process causes a very defective interphase, which has a highly disordered structure. However, with the growth of the $MgCl_2$ layer, the corrosion ceases, the layer becomes more compact and ordered, and the resistivity reaches its steady-state value. This proposed mechanism of film exchange, on freshly immersed electrodes, is also supported by several other experimental results:

1. The original state and composition of the magnesium surface film has no influence on the SEI properties after 30-50 hr of immersion.
2. The resistivity of magnesium electrodes which are covered by a thick oxide layer (Fig. 4) falls by almost an order of magnitude during the first 2-5 hr of immersion. Then it passes through a minimum and increases slowly for 40-60 hr, until it reaches an almost steady-state value of $(1.8 \pm 0.2) \times 10^{10}$ Ωcm.
3. The OCP of magnesium *vs.* tungsten increases by about 0.2V, within the first few days. The lower OCP during this time may be caused by the high corrosion rate.

Deposition-dissolution mechanism of the SEI magnesium electrode.—From the significantly different electrochemical behavior of the magnesium electrode during cathodic and anodic macropolarization, it appears that the anodic and cathodic processes are essentially different. In the anodic process, the dissolution of the metal beneath the PL causes a process of breakdown and repair of the SEI. This process becomes faster as the dissolution current is increased. As a result, a very disordered SEI is formed which has a high ionic (and probably electronic) conductivity. However the SEI cannot be completely removed by anodic dissolution. It was found that a current density of 5 mA/cm² passed for 1 hr (which removed about 13 microns of magnesium) did not have significant influence on the differential capacity. It does not exceed 2 $\mu F/cm^2$ during the anodic-dissolution and does not exceed 4 $\mu F/cm^2$ immediately after turning off the current. The calculated thickness of the SEI during this polarization was *ca.* 25Å. These capacitance values are much lower in comparison with 25-30 $\mu F/cm^2$, the tungsten-solution interfacial capacitance.

As opposed to anodic-dissolution experiments, under cathodic polarization, the d-c current and the electrode capacitance remain almost unchanged as the cathodic overvoltage is increased up to −800 mV vs. Mg RE. On stepping the potential more cathodically there are some transient phenomena which are not observed on anodic polarization (Fig. 9). These indicate that under prolonged cathodic polarizaton there is some kind of blocking mechanism. The relatively low cathodic currents measured prove that the SEI remains quite a good electronic insulator even under such high electric fields (10^6 V/cm). Only a previously applied anodic macropolarization enables passage of relatively high cathodic currents, which are accompanied by a rapid gas evolution and a yellow precipitate (probably SO_2 and S) on the electrode. A possible explanation for these phenomena is as follows: the pre-applied anodic macropolarization decreases markedly the thickness of the SEI and enhances its electronic and ionic conductivity. Under these conditions, in a subsequent high cathodic polarization, a direct reduction of the TC solvent can take place. Supplementary to this, under high electric field, the magnesium cations may be reduced within the SEI, without reaching the metal-solid electrolyte interface. The precipitated metallic magnesium may cause a short-circuit through the SEI thus markedly enhancing the direct reduction of TC.

Tafel slopes.—High Tafel slopes are a well-known phenomena in literature dealing with oxide films (14, 15). The explanation for these phenomena involves the basic assumption that a major fraction of the applied metal-solution overpotential falls across the PL. The same may be expressed differently by saying that the rds of the redox reaction is the migration of the ions through the SEI. Accordingly the current-voltage relation should obey the law of migration of ions in a solid electrolyte, while the Tafel slope (b) depends on thickness (d) of the SEI according to Eq. [2]

$$b = \frac{2.3RT}{az\mathbf{F}} \cdot d \qquad [2]$$

where $2a$ is the jump distance of the mobile ion and z is the valence of the mobile ion.

In this work it was found that for aged magnesium electrodes there is a linear relationship between the overpotential and the current, up to 300-400 mV. This indicates that the Tafel slope is higher than 2V. However to reach the Tafel region it was possible only for freshly immersed electrodes. In these cases Tafel slopes depend on immersion time. These results support a previous conclusion that the rds is the migration of Mg^{2+} ions in the solid electrolyte. The SEI thickness calculated from the Tafel slopes correlated well with the thickness calculated from the differential capacity (Table II). However, good correlation was observed only on freshly immersed electrodes. Tafel curves obtained on electrodes immersed for longer times deviate from linearity. This occurs as a result of the necessity to pass higher currents in order to reach the Tafel region. These currents partially destroy the SEI structure.

Tungsten Electrode

The interpretation of the electrochemical measurements performed on active metal electrodes coated by a passivating layer, which is a poor electronic conductor, is based on the following assumptions: (*i*) the rds of charge transfer is the ion migration through the SEI and (*ii*) the double layer capacities of the two interfaces, metal-SE and SE-solution, are much higher than the SEI capacity. Only under these conditions would the apparent resistance and capacity represent the properties of the SEI.

The spontaneous formation of PL on alkaline-earth metals prevents the possibility of carrying out any electrochemical measurements at the metal-solution interface. Employing the "inert" tungsten electrode permitted the determination of the DL capacitance of the metal-TC interface. With the use of an a-c technique the differential capacity of the metal-solution interface at OCP was found to be about 30 μF/cm^2. The values of the DL capacity calculated from DL charging currents are in perfect agreement with the values obtained in the a-c measurements. The small increment of the capacity in the first 200 mV of the cathodic overvoltage (Fig. 12) may result from specific adsorption, since in this potential range the faradaic current is negligible. Comparison of these values with the differential capacity measured for magnesium (2-0.1 μF cm^{-2}) clearly indicates the existence of the PL on magnesium and underlines the basic difference between the "bare" tungsten electrode and the "covered" magnesium. In $Mg(AlCl_4)_2$ solution saturated with $MgCl_2$, the chloride produced by the reduction of TC ($2SOCl_2 + 4e \rightarrow SO_2 + 4Cl^- + S$) may precipitate as $MgCl_2$ on the tungsten electrode and form a PL. This PL has a low electronic conductivity and so it slows further reduction of the solvent. The significant decrease of the capacitance [to 1.6 μF cm^{-2} (Fig. 12)] and the appearance of a current maximum are due to the above-mentioned process. When potential returns to the OCP, the capacitance rises to about its initially high value (Fig. 12). It would appear that a slow chemical dissolution of the PL occurs in parallel with the reduction of the solvent. These two opposing processes (formation and dissolution) determine the dependence of the reduction current on the sweep rate. If two consecutive voltammograms are performed at high sweep rates, the PL formed is not dissolved at the end of the first sweep. Consequently, it completely inhibits a further solvent reduction on the second sweep (Fig. 11). However, on slow scanning of the potential the PL has enough time to dissolve, thus enabling further solvent reduction in the second sweep, or even in the reverse direction of the first one. The small cathodic current peak on the reverse branch (Fig. 12) is due to this process.

The apparent resistivity of the PL on tungsten is (0.5-1) $\times 10^{10}$ Ωcm (assuming the same ϵ as for magnesium electrode). These values correlate quite well with the steady-state resistivity of the SEI on magnesium (1-2) $\times 10^{10}$ Ωcm.

The thickness of the PL on tungsten was calculated by two independent methods: (*i*) from the reduction charge, passed during the cathodic sweep and (*ii*) from the differential capacitance.

Because of the chemical dissolution of the PL, the "efficiency" of the PL formation depends on the sweep rate. Figure 14 shows the thionyl chloride reduction charge *vs.* the sweep rate. The two curves show the charge passed up to the peak of the reduction current and up to the plateau (0.5 *vs.* Mg RE). It can be seen that the charge reaches a constant value at high sweep rates. It was found that the solvent reduction is inhibited by the formation of a PL of 30-40Å thickness (1.5-2 mcoulomb/cm^2). This value corresponds quite well with the electron-tunneling path in insulators (16), the thickness of passivating oxides (at Vp) in aqueous solutions (17), and with the minimum thickness of the SEI on magnesium. The reduction ceases almost completely as the thickness reaches 80-90Å (4-4.5 mcoulomb/cm^2).

The thickness of the PL on tungsten electrode, which is calculated according to the interfacial capacitance assuming $\epsilon = 5$, do not differ significantly from that calculated according to the cathodic charge (Fig. 14).

Table II. The SEI thickness calculated from Tafel and capacity data

Immersion time (hr)	1	20	40
Tafel slope (mV)	280	350	430
Thickness [Å]* based on Tafel data	19	23	29
Thickness [Å]** based on capacity data	17	24	30

* The thickness was calculated according to Eq. [2], where it was assumed that $a = 2$Å and $z = 2$.
** The dielectric constant was assumed to be 5.

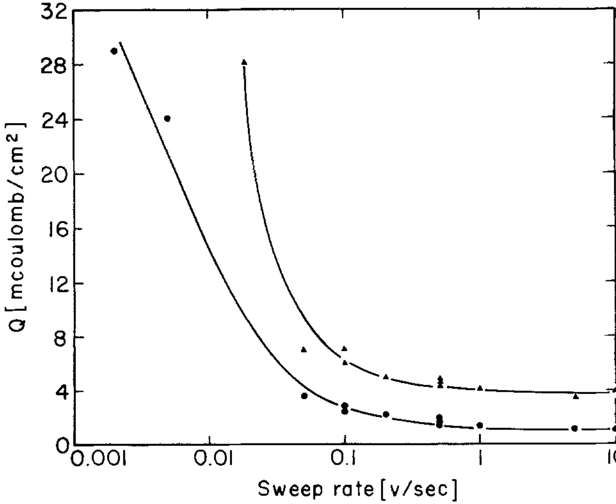

Fig. 14. Reduction charge passed during cathodic potential sweep vs. the sweep rate. ● Charge passed up to the peak of the reduction current. ▲ Charge passed up to the plateau.

The corresponding values are 30 and 80-90Å, respectively. The discrepancy of these values is attributed to the two different experimental methods. SEM studies pointed out that the surface of the PL on magnesium is very rough. The PL formed on tungsten may be rough too. The interfacial capacitance is mainly contributed by the thinner parts of the layer. Consequently, the calculated thickness, according to the interfacial capacitance, is smaller than the geometric average value [for details see Ref. (11)], which is calculated from the passivating charge. So, the above-mentioned experimental discrepancy seems quite reasonable. Moreover, in addition to the results of Tafel experiments, it points out that the assumed value of the dielectric constant is quite suitable for these systems.

Acknowledgments

Ohmic Potential Drop in Flow-Through and Flow-By Porous Electrodes

Peter S. Fedkiw*

Department of Chemical Engineering, North Carolina State University, Raleigh, North Carolina 27650

ABSTRACT

The limiting current analysis has been applied to the flow-through and planar flow-by porous electrodes using a recently developed low flow rate mass transfer coefficient correlation. At the limiting current, the maximum ohmic drop in the solution is developed. The flow-through electrode analysis is identical to that first given by Bennion and Newman. In the flow-by electrode, the two-dimensional structure of the potential field is taken into account. It is shown that given a maximum solution ohmic potential drop and reactant conversion, a flow-by electrode with an aspect ratio $L/d > 5$ is superior to a flow-through electrode in that the maximum processing rate will always be higher for the range of parameters presented in this work. If the aspect ratio L/d (length-to-width) of the flow-by electrode is large, it is reasonable to assume that the potential field is governed by a one-dimensional Laplace equation. This simplifying assumption has been examined and shown to overestimate the maximum ohmic potential drop. Given the two constraints mentioned above, a flow-by electrode will have an optimum aspect ratio L/d which is determined by an economic balance between greater current-volume of the bed as L/d increases *vs.* greater pumping and separator (if required) costs which also increase with L/d.

Packed bed electrodes (three-dimensional) have the major advantage of large surface area available for reaction per unit volume of the reactor in comparison to the more conventional flat (two-dimensional) electrode configuration. The reaction distribution in packed beds can vary significantly, however, because of ohmic, geometric, and mass transfer effects; this can become an undesirable problem. The spatial variation in reaction rates is accompanied with a consequential variation in the potential difference between the electrode and adjacent electrolyte. The reaction selectivity and and reactant conversion may become significantly affected in a multiple step (parallel or series) reaction network (1-5).

An upper bound can be determined on the solution phase potential variation by analyzing the current distribution in a bed with a single reaction taking place under mass transfer controlled conditions. An upper bound is established because the rate of any reaction cannot exceed the rate of its reactant supply.

The purpose of this paper is to examine the solution phase potential variation in a packed bed electrode

* Electrochemical Society Active Member.

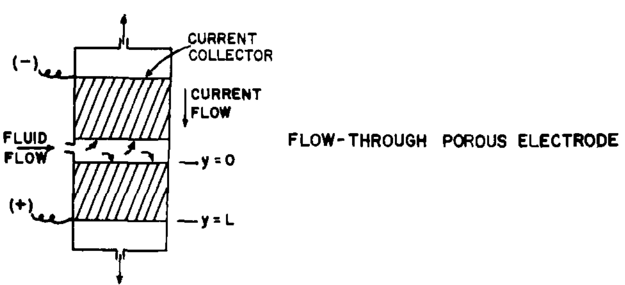
Key words: current, flow-by electrode, potential.

operating with a single reactant under mass transfer controlled conditions. Two configurations of the packing of the electrode are considered and compared (Fig. 1): (*i*) the flow-through electrode where the current and fluid flow are parallel (fluid flows through the current collector) and (*ii*) the flow-by electrode configuration where the current and fluid flow are approximately perpendicular (fluid flows by the current collector). Focus is fixed on a single packed bed electrode in the cell, that is, it is assumed that the counterelectrode effects can be ignored.

The limiting current analysis as outlined here cannot, of course, determine absolute electrochemical driving potentials at any position in the bed. Other information such as the specific kinetics of the reaction (or reaction sequence) must be known. To incorporate such effects into an analysis of the electrode adds complexity to the resulting model equations. (A short review of previous detailed analysis is presented in the following paragraph.) The limiting current analysis is useful because of its simplicity, and it enables a first-order engineering design of the reactor to determine maximum permissible flow rate and packing depth (parallel and/or perpendicular to current flow) as was shown by Newman and Tiedemann (6) for the flow-through electrode.

Bennion and Newman (7) first analyzed the flow-through configuration using the limiting current deposition of Cu^{++} as a test reaction. They derived an analytical expression (assuming convective transport of reactant only) which related the solution phase ohmic potential drop to the physical and operational parameters. [Other workers have rederived this result as reviewed in Ref. (6). In this same reference, Newman and Tiedemann expanded the earlier work to account for axial dispersion.] Alkire and Ng (8, 9) have studied extensively the flow-by electrode configuration. These publications were mostly concerned with calculating the spatial reaction distribution and reactant conversion with a single electrode reaction. Some attention was directed at evaluating the maximum potential variation under limiting current conditions (9). However, it was assumed that the potential varied strongly in the direction perpendicular to the fluid flow only.

A recently developed correlation (10) for low Reynolds number mass transfer coefficients will be applied in the governing equations in this work in order to calculate the solution phase potential drop. The results are expressed in terms of the relevant dimensionless parameters of the system. In addition, the two-dimensional Laplace equation is solved to describe the potential variation in the flow-by electrode. The conditions under which the one-dimensional approximation used by Alkire and Ng is valid is also examined. It is shown that neglect of the two-dimensional structure will overestimate the solution phase potential drop.



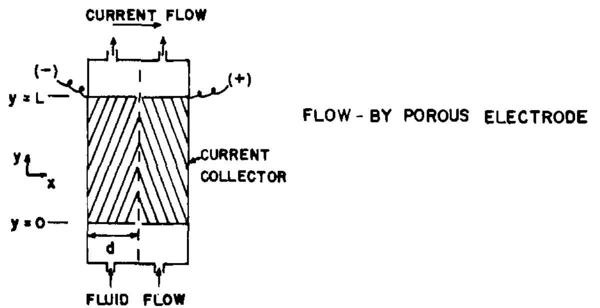


Fig. 1. Flow-through and planar flow-by electrode configurations with both packed bed working and counterelectrodes.

Model Formulation

It is assumed that the packed bed can be modeled as a superposition of two continuum. The reaction rate term then appears as a pseudo sink or source term in the species and charge conservation equations (11). It is also assumed that a single reaction takes place in a well-supported electrolyte at the limiting current under steady-state conditions. This reaction is written in a general form as

$$\Sigma s_i M_i^{z_i} \rightarrow ne^- \quad [1]$$

The reactive species of molar concentration C is transported through the electrode by convective means only. The dispersive flux is assumed negligible. Under the above conditions the equations which govern the concentration and potential are

$$v \frac{dc}{dy} = -ak_m C \quad [2]$$

$$-\kappa \nabla^2 \phi_2 = \frac{n\mathrm{F}}{s_R} ak_m C \quad [3]$$

Both equations apply to the flow-through and flow-by electrodes. The conductivity κ has been corrected from its free stream value κ_0 and is assumed to be much less than the matrix conductivity, thus the matrix is isopotential. The mass-transfer coefficient k_m depends on the velocity v, the diffusivity of the reactive species, and the packing geometry. For both electrode geometries, we shall examine the solution to each of these equations under appropriate boundary conditions.

Flow-Through Electrode

The solutions to Eq. [2] and [3] for this geometry have been given by Bennion and Newman. They assumed that the potential varies only in the streamwise direction and hence, only second-order derivatives of the potential with respect to the streamwise coordinate appear on the left-hand side of Eq. [3]. The boundary conditions on the potential depend on the placement of the counterelectrode which can be placed upstream or downstream of the fluid inlet to the bed. Assume an upstream counterelectrode with the reference potential set at the solution phase entrance to the bed; the boundary conditions become

$$y = 0 \text{ (fluid inlet) } C = C_F,\ \phi_2 = V \quad [4a]$$

$$y = L \text{ (fluid exit) } \frac{\partial \phi_2}{\partial y} = 0 \quad [4b]$$

In dimensionless form the solution to Eq. [2], [3], and [4] for the concentration and potential can be written

$$\frac{C}{C_F} = \exp\left(-\frac{aL}{\epsilon}\frac{\mathrm{Sh_B}}{\mathrm{Pe_B}}\frac{y}{L}\right) \quad [5]$$

$$\Delta\Phi_2 \equiv \frac{\phi_2 - V}{\dfrac{-\epsilon n\mathrm{F}D_0C_F}{\kappa s_R}} = \left\{ \frac{\mathrm{Pe_B}^2}{\mathrm{Sh_B}} + \frac{aL}{\epsilon}\mathrm{Pe_B}\frac{y}{L} \exp\left[-\frac{aL}{\epsilon}\frac{\mathrm{Sh_B}}{\mathrm{Pe_B}}(1 - y/L)\right]\right\} \exp\left[-\frac{aL}{\epsilon}\frac{\mathrm{Sh_B}}{\mathrm{Pe_B}}\frac{y}{L}\right] - \frac{\mathrm{Pe_B}^2}{\mathrm{Sh_B}} \quad [6]$$

In order to calculate accurate conversions and potential drops, it is necessary to have accurate values for the dimensionless mass transfer coefficient Sh_B (bed Sherwood number).

Equation [6] is a special case of the more general relationship derived by Newman and Tiedemann (6) who did not neglect the axial dispersive term for the reactant in Eq. [2]. However for most cases of practical importance, inclusion of dispersion only adds a minor correction.

The concentration profile (Eq. [5]) is independent of the counterelectrode placement at the limiting current. However, the solution phase potential drop is highly sensitive to the counterelectrode placement. When the counterelectrode is placed downstream of the fluid exit at the limiting current, it can be shown that the potential drop across the solution from the front to the back of the electrode asymptotically increases linearly with the packing depth (6). [Trainham and Newman (12) have recently analyzed the effect of counterelectrode placement on reaction rate distribution below the limiting current.] Since the potential drop continually increases with an increase of bed length, we shall concentrate on the flow-through electrode with an upstream counterelectrode placement.

Flow-By Electrode

Because the fluid and current flow are not parallel in this electrode configuration, the analysis of the potential field is more complex than that in the flow-through electrode. We shall assume that $L/d \geqq 1$ and furthermore that the bed shown in Fig. 1 is of infinite extent in the direction which is mutually perpendicular to the current and fluid flow. The potential will vary only in the x and y coordinates. The concentration profile within the reactor will be a function only of the streamwise coordinate, a direct consequence of the limiting current assumption. (Below the limiting current the concentration will vary in the x direction.) If the dispersive flux of reactant is neglected, the concentration profile is still given by Eq. [5]. The potential will satisfy

$$\frac{\partial^2\phi_2}{\partial x^2} + \frac{\partial^2\phi_2}{\partial y^2} = -\frac{nFak_mC_F}{s_R\kappa} e^{-\frac{ak_m}{v}y} \quad [7]$$

subject to the assumed boundary conditions

$$y = 0, \ \frac{\partial\phi_2}{\partial y} = 0 \quad [8a]$$

$$y = L, \ \frac{\partial\phi_2}{\partial y} = 0 \quad [8b]$$

$$x = 0, \ \frac{\partial\phi_2}{\partial x} = 0 \quad [8c]$$

$$x = d, \ \phi_2 = V \quad [8d]$$

Any packing material must be physically supported at the bottom of the bed ($y = 0$). A compression-type support at the top of the bed ($y = L$) is usually used to restrain the bed from expanding under the stress of the flowing fluid and to ensure good interparticle contact. Both of these supports must be porous for the fluid to pass through. It assumed that the effective conductivity of the fluid in these porous supports is much less than the effective conductivity of the fluid in the bed. Under these circumstances, little current can flow through these supports which accounts for boundary conditions [8a] and [8b]. No current leaks out the back side (farthest away from the counterelectrode) which gives Eq. [8c]. The final boundary condition [8d] assumes that either the conductivity of the counterelectrode compartment is much larger than that of the working electrode, or that the counterelectrode is very near the separator. Under these conditions the potential on the counterelectrode side of the electrode will be uniform. The Appendix examines this assumption in more detail. For a bed of large aspect ration L/d, it is shown that the potential at $x = d$ is not constant in the streamwise direction. Since more current flows to the region of the bed near $y = 0$, the potential along $x = d$ must be less than V due to the ohmic drop. However, the solution potential drop across the working electrode is seen to be independent of the counterelectrode separation.

Equations [7] and [8] have been solved by superposition of a particular solution and three Fourier-series type homogeneous solutions. In a dimensionless form the potential can be written

$$\frac{\Phi_2 - \mathcal{V}}{Sh_B\left(\frac{aL}{\epsilon R}\right)^2} \equiv \frac{\phi_2 - V}{\frac{-\epsilon nF}{s_R}\frac{D_oC_F}{\kappa}Sh_B\left(\frac{aL}{\epsilon R}\right)^2} = \frac{R^2e^{-\gamma Ry/L}}{(\gamma R)^2} + \Phi_2^a + \Phi_2^b + \Phi_2^c \quad [9]$$

where

$$\Phi_2^a = \sum_{n=1}^{\infty}\left[\frac{(-1)^n 2R}{\gamma R\lambda_n^2 \sinh\lambda_n R}\right]\cosh\lambda_n(Y - R)\cos\lambda_n X$$

$$\Phi_2^b = \sum_{n=1}^{\infty}\left[\frac{(-1)^{n+1}2Re^{-\gamma R}}{\gamma R\lambda_n^2 \sinh\lambda_n R}\right]\cosh\lambda_n Y\cos\lambda_n X$$

$$\Phi_2^c = \sum_{n=0}^{\infty}\left[\frac{2R^2/(\gamma R)}{(1 + \delta_{n,o})\cosh\lambda_n} \cdot \frac{(-1)^n e^{-\gamma R} - 1}{(\gamma R)^2 + (n\pi)^2}\right]\cosh\hat{\lambda}_n X\cos\hat{\lambda}_n Y$$

where

$$\gamma R = \frac{Sh_B}{Pe_B}\frac{aL}{\epsilon}, \ \lambda_n = \left(n - \frac{1}{2}\right)\pi$$

$$\hat{\lambda}_n = \frac{n\pi}{R}$$

$$X = x/d$$

$$Y = y/d$$

Alkire and Ng solved Eq. [7] in the limit of $R \rightarrow \infty$ where it is anticipated that all derivatives of potential with respect to the streamwise direction will be zero. Equation [7] with the y derivatives neglected can be solved subject to [8c] and [8d] to yield

$$\Phi_2 - \mathcal{V} \equiv \frac{\phi_2 - V}{\frac{-\epsilon nFD_oC_F}{s_R\kappa}} = Sh_B\left(\frac{aL}{\epsilon R}\right)^2\left(\frac{X^2}{2} - \frac{1}{2}\right)e^{-\gamma Ry/L} \quad [10]$$

Maximum Potential Drop

Equations [6] evaluated at $y = L$ indicates the maximum potential drop for the flow-through electrode. In the flow-by electrode the maximum potential drop will occur at the fluid inlet to the bed where the largest current is flowing. Equation [9] evaluated at $X = 0$, $Y = 0$ gives the maximum potential drop. One may be suspicious of the appropriateness of applying Eq. [10] near the bed inlet due to the validity of its assumptions. Near $y = 0$ we anticipate the existence of a region wherein the streamwise derivatives cannot be neglected, but this is exactly the region in which we are interested in calculating the potential drop. Equation [10] was derived by neglect of all y derivatives. It can be shown by a singular perturbation solution to

Eq. [7] and [8] that the maximum dimensionless potential drop is given as

$$\left[-\frac{1}{2}+0\left(\frac{1}{R}\right)\right] \mathrm{Sh_B}\left(\frac{aL}{\epsilon R}\right)^2$$

in the limit of $R \rightarrow \infty$ which conforms to Eq. [10]. Three regions were delineated in the singular perturbation analysis: two inner regions, one near the fluid inlet and the other near the fluid exit of the bed; and a common outer region which encompasses the remainder of the bed.

Mass-Transfer Coefficient

The maximum potential drop will depend on the mass-transfer coefficient. It is important to have an adequate estimate of this quantity in order to calculate both the total reactant consumption and the potential drop.

Packed bed electrodes are usually operated at low fluid velocities. This is particularly true for the flow-through configuration. A recent extensive review (10) of the chemical engineering literature for low velocity, liquid phase mass transfer coefficients showed a sparcity of data and a large variation in the few reported results. Sometimes even conflicting asymptotic trends of the data were reported. An experimental and theoretical program was undertaken to develop a mass transfer coefficient correlation which would be useful for the low Reynold's number regime. Figure 2 is a plot of the resulting correlation in comparison to experimental data. The correlation related $\mathrm{Sh_B}$ at creeping flow to the Péclet number and the dimensionless streamwise depth (aL) of the bed. The correlating equation and further details may be found in Ref. (10). This Sherwood number correlation was used in Eq. [6], [9], and [10] to generate the results given in this paper.

Results and Discussion

When comparing the performance of a flow-by electrode to a flow-through electrode, a common basis for the evaluation must be established. Consider the two-electrode configurations with a given equal cross-sectional flow area and volume. Under these two constraints, at a set flow rate, the consumption rate (conversion) of reactant is identical in both reactors. It might seem that the current must traverse a longer path in the flow-through electrode than in the flow-by electrode (recall $L/d \geq 1$), hence a larger ohmic drop must occur in the flow-through configuration. The results of this work demonstrate quantitatively, however, that this is not true for all L/d values. There is a lower limit to this ratio below which it becomes more advantageous to use the flow-through configuration. Table I lists a comparison between the calculated solution phase ohmic potential drop in the flow-through and flow-by reactors at three values of conversion each at two Péclet numbers. It is seen from this table that a lower limit for L/d exists below which the ohmic potential drop in the flow-through electrode is less than that in the flow-by electrode. It is also seen that this lower limit decreases as the conversion decreases at a given Péclet number. However, for all L/d greater than five in the range of parameters varied in this study, the flow-by electrode was always the preferred choice over the flow-through electrode. This conclusion is expanded on below.

Figure 3 is a plot of the maximum dimensionless ohmic drop in a flow-through electrode as a function of the conversion and Péclet number. Figures 4a, 4b, and 4c are similar to Fig. 3, but are for the flow-by elec-

trode of L/d ratio 5, 10, and 40, respectively. Also indicated by the dotted lines on Fig. 4 is the ohmic drop predicted by Eq. [10]. The lower limit of 10 for the Péclet number was chosen so that axial dispersion does not become important in any of the calculations. A comparison between Fig. 3 and 4 shows that at a given conversion and maximum permissible voltage drop, the flow-by electrode will permit a larger Péclet number (processing rate) than the flow-through electrode. The flow-by electrode is inherently the better of the two arrangements from ohmic considerations for $L/d \geq 5$. We shall focus our attention in the remainder of this paper on the more promising flow-by electrode.

The dimensionless streamwise depth of the packing will vary along each curve of Fig. 3 and 4. The specification of the conversion and Péclet number permits

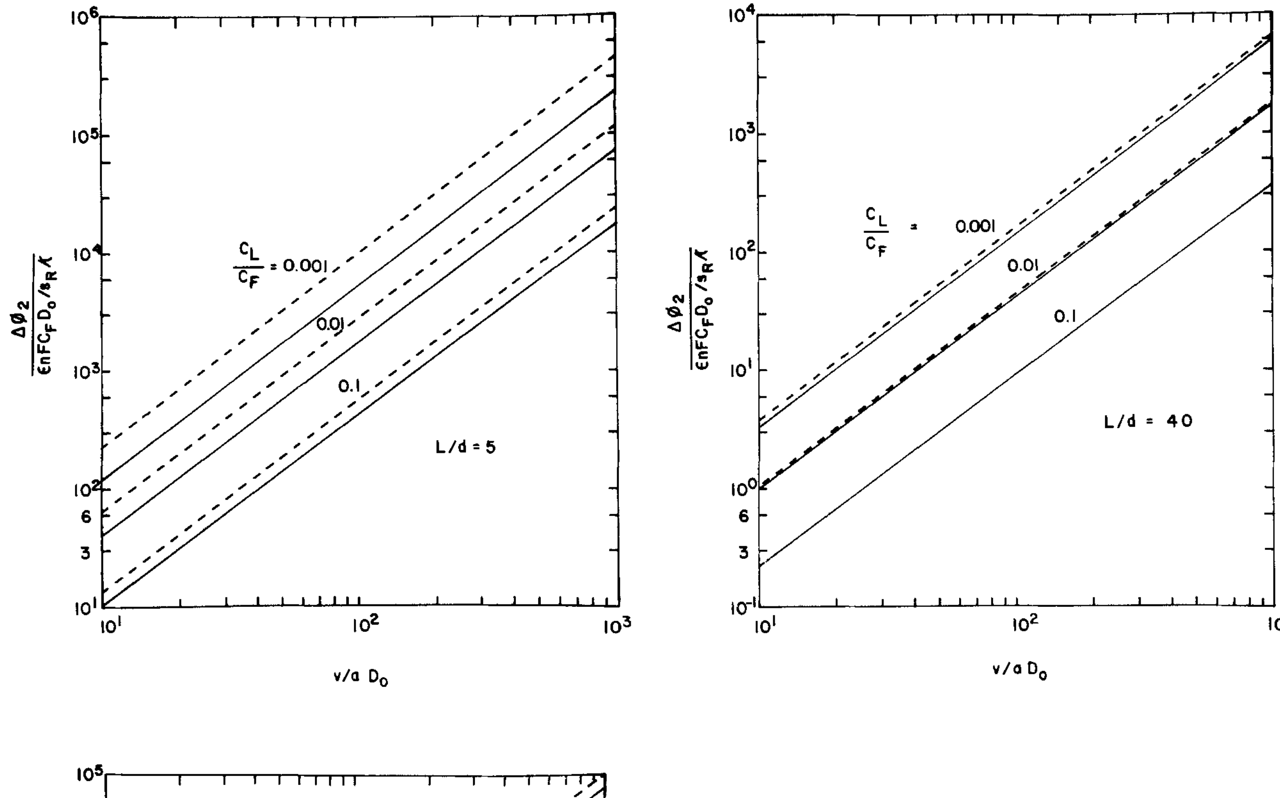

Fig. 4a-c. Maximum solution phase ohmic drop in a planar flow-by electrode at the limiting current for various aspect ratios: (a) $L/d = 5$, (b) $L/d = 10$, (c) $L/d = 40$. Solid line: solution of two-dimensional Laplace equation. Dotted line: solution of one-dimensional Laplace equation.

the use of Eq. [5] (evaluated at $y = L$) along with the Sherwood number correlation to calculate the resulting value of aL. Table II lists these packing depths for selected values of conversion and Péclet number.

Figure 4 is a log-log plot and consequently it is difficult to appreciate the difference between the potential drop predicted by Eq. [9] and that by Eq. [10]. Figure 5 illustrates more clearly the error associated with assuming that a one-dimensional approximation for the limiting current potential field is valid. This is a plot of Eq. [9] and the ordinate which is proportional to the maximum solution potential drop has been normalized such that it is one when the one-dimensional approximation is valid. The curves are for three different Péclet numbers (conversions). As $L/d \rightarrow \infty$ all lines converge to the common ordinate value of one. We note, however, that at a given Péclet number and identical ordinate, a larger value of L/d is required for the deeper bed ($aL = 100$, Fig. 5b) than for the shallower bed ($aL = 30$, Fig. 5a). Also note that the larger the Péclet number (or equivalently, C_L/C_F), a smaller L/d ratio is required to ensure that the one-dimensional approximation is valid. These results are also reflected in Fig. 4 and they can be interpreted physically As the C_L/C_F ratio increases, the more uniform will be the reaction distribution in the streamwise direction; the scaled potential field will consequently vary weakly in the y direction and more dominantly in the x direction which is the basis for the one-dimensional approximation. Also, as aL increases for a given Péclet number (or equivalently, as C_L/C_F decreases), the reaction distribution becomes highly nonuniform with most of the reactant consumed near the entrance of the bed. However, it is precisely this region which is ignored in the one-dimensional approximation. Therefore, the one-dimensional simplification is not a good approximation in this circumstance.

In all situations it is seen that Eq. [10] overestimates the maximum potential drop. A designer who utilizes Eq. [10] will construct a conservative design for a packed bed electrode. In the proper set of circumstances this conservative design will not permit the full utilization of the bed. Consider as an example a flow-by electrode which is to have an L/d ratio of 10 (Fig. 4b) and C_L/C_F equal to 0.001. A typical value for the ordinate of Fig. 4 is 10^3. Equation [10] (dotted line) predicts that the maximum permissible Péclet number is 55. However, the full solution to the Laplace equation (solid line) predicts a maximum Péclet number of 72. For the conditions of this particular bed, a maximum production rate 31% larger is predicted when no approximations are made in solving Laplace's equation.

In order that Eq. [9] be a better approximation than Eq. [10] to the actual solution phase potential distribution in a flow-by electrode, the no-current boundary conditions (Eq. [8a], [8b]) imposed at the bottom and top of the bed must be a good approximation to reality. If the bed support at $y = 0$ does permit an appreciable current to enter through its bottom face from the counterelectrode compartment (and likewise for the support at the top), Eq. [8a] and [8b] must be replaced with a more complex boundary condition that

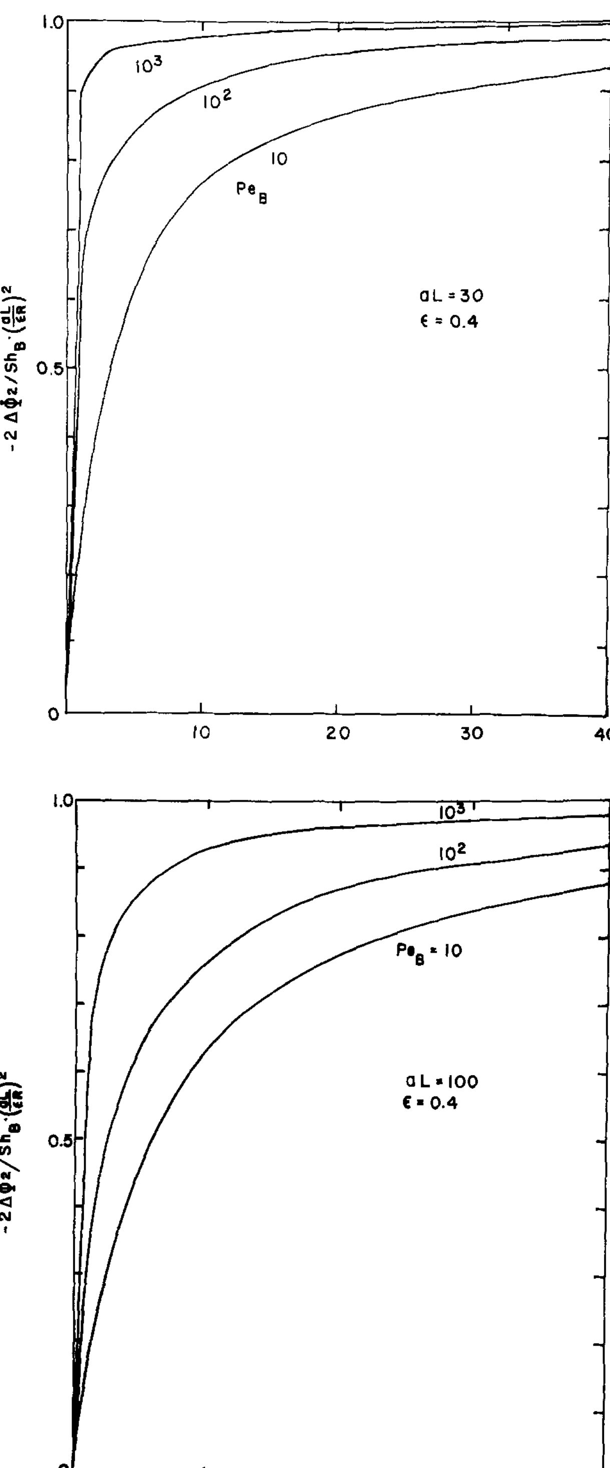

Fig. 5a-b. Normalized maximum solution phase ohmic potential drop in a flow-by electrode at the limiting current for (a) $aL = 30$ and (b) $aL = 100$.

cannot be stated independent of considering the counterelectrode placement and total cell geometry. Truly, this is a more complex problem and is not considered quantitatively here. However, qualitatively we can extrapolate from the results obtained here and state that the maximum solution phase ohmic drop with a given flow-rate will be less with a "leaky" support than with an insulator. Hence a higher maximum processing rate is possible for a specified $\Delta\Phi_2$.

The example of two previous paragraphs arbitrarily chose a value for the L/d ratio. As part of the cell design, however, this number must be determined from

Table II. Dimensionless packing depth (aL) required to obtain the specified conversion at various Péclet numbers in a flow-by or flow-through porous electrode at the limiting current

a total system economic analysis. From ohmic considerations it would be beneficial to make L/d as large as possible. Figure 4 indicates that the maximum Péclet number will increase as L/d increases. However, in order to meet the design criteria, other variables must also change. In the following discussion a simple qualitative analysis of the factors to be considered in determining an L/d ratio is presented. As a specific example suppose that the conversion has been set at 99% and the maximum ohmic drop corresponds to an ordinate value on Fig. 4 of 10^3. Let us also assume that the packing material has been chosen which specifies a and that a bed of unit width is under consideration. An optimal value of L/d can be found with a corresponding maximum production rate as shown below.

Table III presents for selected L/d ratios the Péclet number and corresponding aL value calculated from Eq. [5] and [9] which satisfies the given conversion and ohmic constraints. The bed height must increase with L/d to obtain a given conversion (line 2), but the maximum processing rate will also increase (line 1). The bed height can become so great that a purely mechanical constraint may determine the maximum packing depth. Entry 3 of this table is proportional to the volume of the bed which increases proportionally with L/d. The total current through the electrode is proportional to the entry of line 4. It also increases with L/d but at a greater rate than the volume such that the current/volume (line 5) of the bed also increases with L/d. Since the current/volume is directly proportional to the amount of product produced per capital cost of the reactor, this ratio should be as large as possible for an operating reactor. As L/d increases the pumping cost will increase because of both the higher flow rate and narrower flow area and eventually overtake the positive benefit of a greater current/volume of the reactor. If a separator is required, its cost will also increase with L/d and must also be considered. The optimum L/d is thus seen to be determined by minimizing the total cost of running the electrochemical reactor which is a sum of the depreciated capital equipment costs which decrease with L/d and the operating costs which increase with L/d.[1]

Summary

The limiting current analysis has been applied to a flow-through and flow-by porous electrode. The two-dimensional nature of the potential distribution within the flow-by electrode was taken into consideration. It is shown that the maximum processing rate obtainable in a flow-by electrode ($L/d \geqq 5$) is always greater than that in a flow-through electrode given a conversion and maximum solution phase potential drop. The one-dimensional approximation to the solution of Laplace's equation in a flow-by electrode was compared to the two-dimensional solution and was found to give conservative estimates for the maximum reactant processing rates. A procedure for choosing an optimum L/d ratio in a flow-by electrode was qualitatively outlined.

[1] In the review process of this manuscript, it was pointed out to the author that an M.S. thesis exists (13) which utilizes a similar optimization procedure as outlined here.

APPENDIX

Comments on the Potential Boundary Condition for a Flow-By Electrode

Let us consider the correct boundary condition for the electrical potential along the face $x = d$ in a flow-by electrode as shown in Fig. 1.

Suppose that the counterelectrode (anode for sake of argument) is a planar electrode and is separated a distance d_A from the back face of the cathode. At the limiting current, the potential in the anode and cathode compartments obey, respectively

$$\nabla^2\phi_2{}^A = 0 \quad \text{[A-1]}$$

$$\nabla^2\phi_2{}^C = -\frac{n\mathbf{F}ak_mC}{s_R\kappa} \quad \text{[A-2]}$$

subject to the boundary conditions

$$\phi_2{}^A = V \quad \text{at} \quad x = d_A$$

$$\frac{\partial\phi^C}{\partial x} = 0 \quad \text{at} \quad x = 0 \quad \text{[A-3]}$$

$$\frac{\partial\phi_2{}^{A(\text{or } C)}}{\partial y} = 0 \quad \text{at} \quad y = 0, L$$

Here V is the applied cell voltage.

If the length to width ratio L/d is $>> 1$ Eq. [A-1] and [A-2] reduce to

$$\frac{\partial^2\phi_2{}^C}{\partial x^2} = \frac{-n\mathbf{F}ak_mC_F}{s_R K}\cdot e^{-\gamma y} \quad \text{[A-4]}$$

$$\frac{\partial^2\phi_2{}^A}{\partial x^2} = 0 \quad \text{[A-5]}$$

Equation [A-4] and [A-5] can be solved subject to [A-3] and requiring the continuity of potential and current between the anode and cathode compartment at $x = d$.

In a nondimensional form the two solutions may be written

$$\frac{\Phi_2{}^C - \mathcal{V}}{\left(\frac{aL}{\epsilon R}\right)^2 \mathrm{Sh_B}} = \left(\frac{X^2-1}{2} + \frac{1-X_A}{r}\right) e^{-\gamma Ry/L} \quad \text{[A-6]}$$

$$\frac{\Phi_2{}^A - \mathcal{V}}{\left(\frac{aL}{\epsilon R}\right)^2 \mathrm{Sh_B}} = (X - X_A)\frac{e^{-\gamma Ry/L}}{r} \quad \text{[A-7]}$$

where r is the ratio of the anode compartment conductivity κ_A to that of the cathode κ and X_A is d_A/d. For convenience sake, it has been assumed that the separator is of negligible thickness and resistance. Equation [A-6] demonstrates that the potential along $X = 1$ is not uniform unless X_A is near one or r is large. However $\Delta\Phi_2{}^C$ is unaffected by these parameters.

The Hydrogen Evolution Reaction on Electrodeposited Gold, Nickel, and Zinc Rotating Disk Electrodes

P. C. Andricacos* and H. Y. Cheh*

Department of Chemical Engineering and Applied Chemistry, Columbia University, New York 10027

Consider a first-order irreversible cathodic reaction occurring on a rotating disk electrode (RDE) to which a step potential has been applied. The relation between the steady-state current density under mixed diffusion-kinetic control, i, and the rotation speed, ω, of the RDE is given by the following equation (1)

$$i^{-1} = i_k^{-1} + (0.620\ nFc^bD^{2/3}\nu^{-1/6})^{-1}\ \omega^{-1/2} = i_k^{-1} + i_l^{-1} \quad [1]$$

where i_k is the purely kinetic current density, i_l is the diffusion-limiting current density, D is the diffusion coefficient of the reacting ion, ν is the kinematic viscosity of the electrolyte, and c^b is the bulk concentration of the reacting ion. Equation [1] predicts that i^{-1} is a linear function of $\omega^{-1/2}$ for a fixed potential; the slope is proportional to $D^{2/3}$, $(c^b)^{-1}$, and $\nu^{-1/6}$, and the intercept is the reciprocal of i_k. If the i^{-1} *vs.* $\omega^{-1/2}$ line is plotted for various values of the potential, parallel lines should result. The value of the Tafel slope can then be extracted from the intercepts of these lines. Equation [1] was used by Frumkin and Tedoradze (2, 3) for the study of Cl_2 reduction and by Zurilla *et al.* (4) for O_2 reduction. It was augmented by Jahn and Vielstich (5) to include the reverse (anodic) reaction. The augmented form was experimentally verified by these authors and later by Viswanathan and Cheh (6).

In the present note, Eq. [1] is applied to interpret data obtained for the hydrogen evolution reaction (HER) on electrodeposited Au, Ni, and Zn RDE's. It offers the advantage that data obtained at high overpotentials and/or electrolytes with low H^+ concentrations can be treated despite diffusion limitations. Such experimental conditions are necessary if the HER occurs on substrates which corrode in the electrolyte. Its disadvantage in the particular case of the HER is that it applies only to those mechanisms which have a first-order dependence on the surface concentration of H^+. Furthermore, the surface coverage with adsorbed hydrogen must be constant over the entire potential and current density regions studied. Such mechanisms are those involving a charge transfer or electrochemical desorption steps as rate determining, the former proceeding at low coverage and the latter at high coverage (7).

Experiments were conducted on electrodeposited Au, Ni, and Zn RDE's. Table I summarizes plating condi-

Key words: electrodeposition, electrolyte, diffusion.

tions for each metal. Single or two step galvanostatic pulses were used throughout. A two step pulse was employed in the deposition of Ni to cathodically protect the deposit during the relaxation period (11). Typically 4-5 layers of deposit were necessary to produce a satisfactory surface as judged by the metal under investigation. This was established by separate cyclic voltammetric tests. The duration of plating each layer was approximately 1 hr, followed by mechanical polishing to produce a mirror-like surface. Current densities used are shown in Table I. The deposit thickness cannot be calculated because of the polishing procedure.

Measurements were conducted in a conventional three compartment cell. The counterelectrode was a Pt spiral and the reference electrode was an SCE. A glass electrode was also immersed for pH control together with the SCE. The electrolyte was a 0.25M Na_2SO_4 solution acidified to a pH of 3.2 by the addition of 9.1 ml of a 1% (by volume) solution of H_2SO_4. It was prepared from triply distilled H_2O and analytical grade reagents without further purification, and was continuously saturated with H_2.

The i^{-1} *vs.* $\omega^{-1/2}$ plots for the three metals are shown in Fig. 1-3. Figure 4 is a Tafel plot, where i_k are the reciprocals of the intercepts in Fig. 1-3. The Tafel slopes in Fig. 4 and the exchange current densities calculated by extrapolation to zero overpotential are reported in Table II. The equilibrium potential was calculated from the measured pH value. The fourth column is the reciprocal of the slope of the i^{-1} *vs.* $\omega^{-1/2}$ plots, which is equal to the slope of a Levich plot, *i.e.*, i_l *vs.* $\omega^{1/2}$. Its value depends on ν, D, and c^b. If the latter is not known exactly, one can still check for consistency by measuring limiting current densities directly, constructing a Levich plot, and then comparing its slope with the reciprocal of the i^{-1} *vs.* $\omega^{-1/2}$ slope. Such experiments were performed for the limiting current densities of the HER on a commercial (Pine Instruments, DT6) Pt RDE of a different geometrical area in the same solution. The slope of the Levich plot was 3.78×10^{-4} A/cm² sec$^{1/2}$, which is within 11% of the values reported in Table II. The discrepancy might be attributed to surface area variations caused by the polishing procedure.

The values of the Tafel slope and the first-order dependence on the surface concentration of H^+ for both Au and Ni are consistent with a mechanism in which the electrochemical desorption step is rate determining and proceeds at high coverages. Since the H^+ concentration is not known exactly, one cannot compute the

exchange current density that the present measurements would predict for acid strengths typically reported in the literature. However, assuming complete dissociation of H_2SO_4, the predicted value for 1M acid is about 10 μA/cm², which is in agreement with the literature values (12, 13).

Results in Fig. 3 and 4 indicate that the Tafel slope of the HER on Zn is considerably higher than the one predicted for a charge transfer rate-determining step (14) and consequently, the value of the exchange current density is also abnormally high. Zn data were difficult to reproduce; however, the increase of the i^{-1} *vs.* $\omega^{-1/2}$ slope with decreasing cathodic potentials was a common feature in all runs. If one assumes a simultaneous anodic dissolution with a first-order overall dependence on the concentration of Zn^{+2}, such discrepancies are expected (5). However, they cannot be taken into account quantitatively, since both Zn^{+2} concentration and anodic overpotential are unknown. The possibility of substrate dissolution was also evidenced by an increase in the net cathodic current from the initial to the steady-state value, as opposed to Au and Ni for which the initial HER current was higher than the steady-state value. Initially, there is an infinite tendency for Zn corrosion, since no Zn^{+2} ions exist in the electrolyte. As the Zn^{+2} concentration increases, the corrosion current decreases, and the net current increases.

To summarize, our results indicate that hydrogen evolution on Au and Ni in the electrolytes studied proceeds at high coveragees of H^+ with electrochemical desorption as the rate-determining step, whereas hydrogen evolution and Zn dissolution occur simultaneously.

Manuscript submitted July 9, 1980; revised manuscript received Nov. 17, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Electrochemical Reduction of 4b,9b-Dihydroindeno[2,1-a]indene-5,10-diones

Stanley Wawzonek*

Department of Chemistry, The University of Iowa, Iowa City, Iowa 52242

The electrochemical reduction of 4b,9b-dihydroindeno[2,1-a]indene-5, 10-dione (1a) in dimethylformamide was investigated as a possible method for simplifying the preparation of 3,4,7,8-dibenzocycloocta-1,5-dione which originally was prepared (1) from this diketone **1a** by a lengthy three step synthesis in a 30% overall yield. This research was predicated on

1a R=R′=H

b R=CH_3; R′=H

c R=R′=CH_3

2

the report that the electrochemical reduction of cyclohexan-1,4-dione gave a 1,4-diradical which cleaved to hexane-2,5-dione. The yield of the latter was only 6% but 63% of the starting material was recovered (2).

In the present work it was hoped that a 1,4-diradical would be formed by generating anion radical moieties at each of the carbonyls in **1a** and that cleavage would then occur between the 4b and 9b carbons and form 3,4,7,8-dibenzocycloocta-1,5-dione.

The formation of such a 1,4-diradical was prevented by an unexpected reaction which is described in the present paper.

Experimental

Melting points are uncorrected. Infrared spectra were recorded on a Perkin-Elmer Infracord Model 137B spectrophotometer. NMR spectra were obtained with a Bruker HX-90 Fourier transform NMR spectrometer.

Electrochemical reduction of 4b,9b-dihydroindeo[2, 1-a]-indene-5,10-dione (**1a**) *(5)*.—A solution of the diketone **1a** (5) (4.68g, 0.02 mole) in dimethylformamide (320 ml) containing tetrabutylammonium bromide (20.6g) was degassed for 1 hr with nitrogen and then reduced at a mercury cathode (area: 63 cm²) under nitrogen. The anode compartment was a porcelain cylinder (5 cm in diameter and 2 cm high) and

* Electrochemical Society Active Member.

Key words: pinacols, self-protonation, dimethylformamide.

contained 0.2*M* tetrabutylammonium bromide in dimethylformamide and a platinum gauze anode. The reference electrode was mercury in a dimethylformamide solution containing 0.2M tetrabutylammonium bromide and was separated from the cathode compartment with a porous glass disk. The electrolysis was carried out at a potential of −1.2V using a PAR Model 371 Potentiostat. Polarographically **1a** shows two one-electron waves at −1.03 and −1.38V (*vs.* Hg pool). The large scale reduction results were similar to those obtained at −1.2V if an applied potential between −1.4 and −1.7V was used in the electrolysis. The initial current of 0.05A decreased to 0.01A after 11 hr. The resulting solution which contained a red solid was treated with excess methyl iodide and stirred until the red color disappeared. Removal of the dimethylformamide under reduced pressure was followed by the addition of water. The resulting solid was dissolved in methylene chloride and the solution was dried and the solvent was removed. Addition of ethyl acetate resulted in the precipitation of the tetrabutylammonium iodide formed in the reaction. The filtrate gave an oil which was taken up in benzene and chromatographed on alumina using benzene as an eluant. The first fraction after fractional crystallization using petroleum ether (bp 60°-68°) gave *cis*-4b-methyl-4b, 9b-dihydro-indeno [2,1-a]indene-5,10-dione (**1b**) (1.74g) and the starting material (**1a**) (0.08g). *cis*-4b-Methyl-4b,9b-dihydroindeno[2,1-a]indeno-5,10-dione (**1b**) melted at 93°-95° after two crystallizations from petroleum ether (bp 60°-68°). This compound (**1b**) has been prepared by the methylation of **1a** in ethanolic potassium hydroxide and is reported to be a viscous oil (3). Repetition of this method gave the same crystalline solid. Its spectral properties were identical to those reported for the oil (3). *Anal.* Calcd. for $C_{17}H_{12}O_2$: C, 82.26; H, 4.84. Found: C, 82.30; H, 4.96.

Further elution of the alumina with benzene and with chloroform gave a mixture of pinacols (2) (1.14g) which could be separated by fractional crystallization from benzene and from ethanol. One isomer after crystallization from benzene melted at 180° with gas evolution; IR(Nujol) 2.91(OH), 5.88 μ(CO); NMR ($DCCl_3$) δ 3.00(s, 2H, OH), 3.92(d, 2H, 11-H (J = 6.65 Hz)), 4.14(s, 2H, 10-H (J = 6.65 Hz)), 7.11-7.88 (m, 16H, aromatic Hs). *Anal.* Calcd. for $C_{32}H_{22}O_4$: C, 81.70; H, 4.68. Found: C, 82.11; H, 4.99.

The second isomer after crystallization from benzene melted at 240°-255° with decomposition; IR(Nujol) 2.87(OH), 5.83 μ(CO); NMR($DCCl_3$) δ 2.83(s, 2H, 20 Hs), 3.99(d, 2H, 11-Hs (J = 6.59 Hz)), 7.13-7.66(m, 16H, aromatic Hs). *Anal.* Calcd. for $C_{32}H_{22}O_4$: C, 81.70; H, 4.68. Found: C, 82.33; H, 5.07.

Further elution using ethyl acetate gave a solid (0.4g) melting at 285°-290°C with decomposition and resembling the high melting product obtained from the diketone **1a** with alkali (5).

cis-4b,9b-Dimethyl-4b,9b-dihydroindeno[2,1-a]indene-9,10-dione (**1c**).—*cis*-4b-Methyl-4b,9b-dihydroindeno[2,1-a]indene-9,10-dione (**1b**) 2.54g) was dissolved in dimethylformamide (50 ml) and treated successively with 0.1*M* tetrabutylammonium hydroxide (23 ml) in methanol and methyl iodide (2 ml) until no more red color was produced by the base. The resulting pale yellow solution was treated with water and the solvent was removed under reduced pressure. The resulting solid was taken up in ethyl acetate and the precipitated tetrabutylammonium iodide was filtered. The filtrate was evaporated to dryness and the resulting solid was dissolved in benzene and the resulting solution was passed through an alumina column. Removal of the benzene gave **1c** (1.78g) melting at 128°-30°C. One crystallization from petroleum ether (bp 60°-68°C) gave white crystals melting at 130°-132°C [lit. 3) 126°-128°C]. The infrared and NMR spectra were identical to those reported (3).

Electrochemical reduction of cis-4b-9b-dimethyl-4b,9b-dihydroindeno[2,1-a]indene-5,10-dione (**1c**).—A solution of **1c** (1.57g) in dimethylformamide (100 ml) containing 0.2*M*-tetrabutylammonium bromide was electrolyzed under nitrogen at a mercury cathode at a constant potential of −1.8V. The anode was a platinum gauze electrode and the reference electrode was mercury in a dimethylformamide solution of 0.2*M* tetrabutylammonium bromide. Polarographically **1c** shows two one-electron waves at −1.09 and −1.65V (*vs.* Hg anode) in a dimethylformamide solution of 0.2*M* tetrabutylammonium bromide. The current observed was 0.2A which slowly dropped to 0.1A in the course of 2 hr. The solution during the electrolysis turned a dark green. Acidification with dilute acetic acid gave a pale yellow solution. Removal of the solvent gave a solid which was dissolved in benzene and chromatographed on silica. Using benzene as an eluant gave as the first fraction the starting diketone (**1c**) (0.51g). The second fraction (0.28g) gave **4** melting at 175°-180°. Recrystallization from benzene gave a sample melting at 179°-180°. IR(Nujol) 2.79(OH), 5.89 μ(CO), NMR($DCCl_3$) δ 1.48(J, 3H, 10-CH_3), 1.57(s, 3H, 11-CH_3), 1.85(broad s, 1H, OH), 5.21 (broad s, 1H, 9-H), 7.23-7.82(m, 8H, aromatic H). Addition of D_2O sharpened the singlet at δ 5.21 and eliminated the singlet at δ 1.85. *Anal.* Calcd. for $C_{18}H_{16}O_2$: C, 81.82; H, 6.06. Found: C, 81.63; H, 6.03.

Results

The electrochemical reduction of **1a** did not proceed as planned but gave results which were considered to be important enough to report.

Reduction of **1a** (under nitrogen) in dimethylformamide containing 0.2*M* tetrabutylammonium bromide proceeded with the formation of a deep red colored compound. Acidification of the solution caused decolorization and gave a mixture of pinacols 2 and the starting material (**1a**). Repetition of the electrolysis followed by treatment with methyl iodide instead of acid gave the same mixture of pinacols and *cis*-4b-methyl-4b,9b-dihydro-indeno[2,1-a]indene-5,10-dione (**1b**) (3) in place of **1a**.

These results indicate that the anion radical formed from **1a** is protonated by another molecule of **1a** and dimerizes to the pinacols **2**. The red colored compound formed is therefore the mono-tetrabutylammonium salt of the enolate (3). The di-tetrabutylammonium salt was eliminated as a possible structure since

3 **4**

none of the *cis*-4b,9b-dimethyl-4b,9b-dihydroindeno [2,1-a]indene-5,10-dione (**1c**) was isolated. This salt would be expected to react stepwise with methyl iodide and form first the enolate of **1b** and then the dimethyl derivative **1c**. The plausibility of the second step was demonstrated chemically; treatment of **1b** in dimethylformamide with tetrabutylammonium hydroxide and methyl iodide gave **1c**.

The possibility of an anion-radial structure for **3** was eliminated by the reaction of the diketone **1a** with tetrabutylammonium hydroxide in dimethylformamide; a similar colored species was formed.

The unusual proton donor capability of **1a** in dimethylformamide was verified by its effect on the polarographic reduction of azobenzene in dimethylformamide containing 0.2*M* tetrabutylammonium bromide. In this medium azobenzene gave two reduction waves at −0.6 and −1.28V (*vs.* Hg pool), with a ratio of wave heights of 1:0.96. Addition of 1.11 mmoles of **1a** to 0.66 mmoles of azobenzene changed the ratio of the two waves to 1:0.196. The decrease in height of the sec-

ond wave indicated that 80% of the initial anion radical formed from azobenzene is diprotonated by a CEC mechanism and that 1.06 mmoles of protons are involved. Since 1.11 mmoles of **1a** were added originally, its (**1a**) utilization as a proton source is 95% efficient.

The benzyl ketone moiety present must be responsible for the proton capability of **1a** since dibenzylketone had the same effect upon the polarographic behavior of azobenzene in dimethylformamide. Acetophenone and cyclohexanone which do not have this grouping, had no effect on the polarographic behavior of either azobenzene or benzophenone in dimethylformamide.

To circumvent the possibility of enolization *cis*-4b-9b-dimethyl-4b,9b-dihydroindeno[2,1-a]indene-5,10-dione (**1c**) was electrolyzed in dimethylformamide containing tetrabutylammonium bromide at a mercury cathode at a potential of −1.80V. The resulting deep green anion radical (**3**) produced gave upon acidification a mixture of the alcohol **4** and the starting material (**1c**). No products corresponding to the eight-membered ring diketone or its reduction products were isolated.

The alcohol **4** could be formed in two ways. The anion radical from **1c**, which is a mixed valence anion radical (**3**), is an intermediate in the 2-electron reduction and could be formed under the large scale reduction conditions used. Treatment with dilute acid would convert this species into the alcohol **4** and the diketone **1c** in a similar fashion to that reported for the ketyl of benzophenone (4). The second possibility is the reduction of the anion radical to an unsymmetrical dianion which on protonation forms **4**.

The Role of Defects in the Fracture of Oxide Films on Metals

D. R. Arnott,[1] W. J. Baxter, and S. R. Rouze

General Motors Research Laboratories, Physics Department, Warren, Michigan 48090

ABSTRACT

The extent of fracture of anodic oxide films during tensile deformation of aluminum is shown to be controlled by the density of defects in the oxide. The density of defects was monitored by the "leakage" resistance of the film, while the extent of fracture of the oxide was obtained from measurements of reanodization current transients. Other experiments in a photoelectron microscope showed that these oxides are ruptured at emerging slip steps. This provided the basis of a simple model for oxide fracture, which requires the presence of a defect in the oxide at the site of an emerging slip step. A relationship between the leakage resistance and fracture susceptibility of the oxide was derived and confirmed by experiment, showing that both properties are controlled by the same type of defect. The density of these defects may be controlled by the surface preparation prior to anodization. If the density of defects is greatly reduced, even a thin (28 nm) oxide becomes strong enough to suppress slip step formation during tensile deformation.

Various properties of oxide films on metals are often ascribed to the presence of imperfections or flaws. For example, defects in the oxide are held responsible for: (*i*) the finite conductivity (leakage currents) of these oxide films (1, 2); (*ii*) the occurrence of pitting in a corrosive environment (3); and (*iii*) the initiation of mechanical failure of the film during deformation (4, 5).

The precise nature of the defects is usually indeterminate, particularly for thin oxide films. However, the development of pores in aluminum oxide has been well documented by electron microscopy and demonstrated to be responsible for an increase of leakage current (1, 2, 6). On the other hand, defects are often attributed to surface contamination of the metal or the presence of inclusions in the metal. For example, it has been reported that impurities decrease the ductility of anodic oxide films formed on the surface of tantalum (4).

In this study of thin barrier layer anodic oxide films on aluminum, it is shown that there is a systematic relationship between the conductivity and the strength of thin (<30 nm) anodic films, indicating that, in this case at least, the same defect controls both properties. These oxides are shown to rupture at emerging slip steps provided that defects are present in the oxide. If the density of defects in the oxide is reduced sufficiently, even a very thin oxide (28 nm) becomes strong enough to suppress slip step formation during tensile deformation of aluminum.

Experimental

The present series of experiments was centered upon the influence of chromic acid cleaning treatment on the properties of anodic films formed on 1100-0 aluminum.

Specimens of 1100 aluminum were degreased with acetone and cleaned further by immersion for 10 min or less in chromic acid solution[2] at 70°C. After rinsing with water and alcohol, the oxide film was then grown by anodization in a solution of 3% tartaric acid, adjusted to pH = 5 with NH_4OH. To obtain oxides of well-controlled thickness, the current density during anodization was limited to ~1 mA/cm^2 until the required voltage (V) was attained, and then allowed to decay for a period of 10 min. The specimens were then removed from the electrolyte, rinsed with water and alcohol, and blown dry. Auger sputter profiling of a few samples confirmed that the oxide thickness was essentially constant and independent of the precleaning treatment.

The leakage currents through the anodized film were measured by reimmersing the anodized specimen in the tartaric acid solution, then applying a potential ½V. This procedure ensured that the measured current was primarily due to leakage processes and not a continued growth in oxide thickness.

The mechanical properties of the anodic films were examined with the following techniques.

1. The extent of fracture of the oxide produced by known amounts of tensile deformation was measured quantitatively by the reanodization current transient method described previously by Baxter and Gifford (7). Briefly, after tensile deformation the microcracks produced in the 28 nm oxide (formed at 20V) were reanodized at a lower voltage (10V), and the current transient recorded on a digital oscilloscope. The decay time (τ) of this current transient is directly proportional to the area of metal being reanodized, *i.e.*, the total area of the microcracks produced in the 28 nm

[1] Present address: Capricornia Institute of Advanced Education, Rockhampton, Queensland, Australia.

Key words: defects, films, oxide fracture.

[2] 7g Cr_2O_3, 20 ml H_2SO_4, 200 ml H_2O.

oxide over the deformed gauge section of the sample. The results are expressed as τ/A, where A is the surface area of the entire specimen gauge section.

2. The mode of fracture of the oxide was observed directly and continuously during tensile deformation of small samples in the photoelectron microscope (PEM) (8). These samples were all mechanically polished, prior to the chromic acid and anodization procedure, to improve the resolution of the image obtained in the microscope. In these experiments, any microcracks produced in the oxide appear as regions of much stronger photoelectron emission, often referred to as photostimulated exoelectron emission (9, 10). Such observations provide both a measure of the strain required to fracture the oxide as well as defining the mode of fracture. These specimens were also examined subsequently by conventional optical and scanning electron microscopy.

Leakage Current

The leakage current through the oxide, at ½V after anodizing at V, decreases dramatically with increase of precleaning time in chromic acid. As shown in Fig. 1 for a 14 nm oxide, a period of 5 min was sufficient to reduce the leakage current by two orders of magnitude. Thus it may be concluded that the precleaning of the aluminum substrate in chromic acid greatly reduces the concentration of flaws in the subsequently formed oxide film. This simple result provided an opportunity to compare the mechanical properties of aluminum oxide films of the same thickness, but with widely different concentrations of defects.

Reanodization Current Transients

Two sets of measurements are shown in Fig. 2. One series of specimens were deformed to a tensile strain of 6×10^{-2}. The decay time of the current transient for these specimens decreases rapidly with increasing duration of the chromic acid treatment. In fact, the form of this curve provides an interesting comparison with that in Fig. 1, the reduction of both leakage current and reanodization time constant being essentially

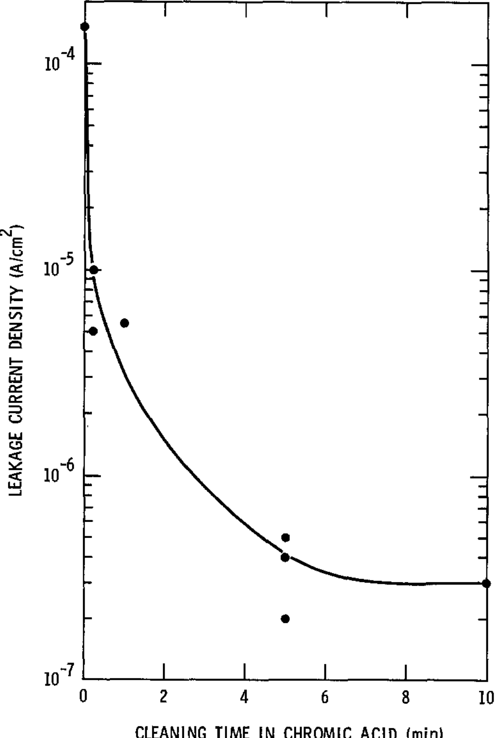

Fig. 1. Effect of duration of precleaning of aluminum in chromic acid on the leakage current density of a subsequently deposited 14 nm anodic oxide film. Leakage current measured at 5V with specimen immersed in anodizing electrolyte.

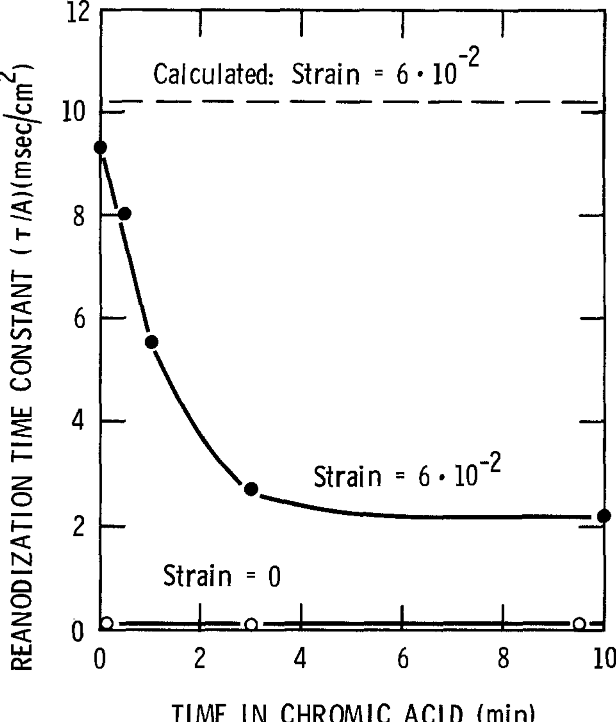

Fig. 2. Effect of duration of precleaning of aluminum in chromic acid on the time constant for reanodization after tensile deformation. Samples coated initially with 28 nm oxide (at 20V), and reanodized at 10V. Tensile strain as indicated in figure.

completed by a 5 min treatment. By contrast the decay time for undeformed specimens is very small and independent of the chromic acid treatment. This transient is simply that required to charge up the oxide film and the time constant is controlled by the oxide thickness, which has a constant value for all specimens.

The calculated curve shown in Fig. 2 is for a perfectly brittle oxide film. This value of τ/A was calculated on the following basis.

1. A series of calibration measurements on small samples of known area showed that

$$\tau = K\delta A \quad [1]$$

where δA is the area of metal being anodized, and K, for our experimental arrangement, had a value of 300 msec/cm².

2. For a perfectly brittle oxide, the area of fresh metal revealed by the microcracks is equal to the geometrical increase of surface area of the specimen (δA). The value of δA may be calculated for a given tensile strain (ϵ_1) on the basis of constant specimen volume, *i.e.*

$$\epsilon_1 + \epsilon_2 + \epsilon_3 = 0 \quad [2]$$

where ϵ_1, ϵ_2, and ϵ_3 are the strains in the three principal directions. Also it is known empirically that the changes in width and thickness of the sample are simply related by

$$\epsilon_2 = R\epsilon_3 \quad [3]$$

where $R \simeq 0.7$ for this material (11). From these relationships it is easily shown that for our specimen geometry

$$\frac{\delta A}{A} = 0.57\,\epsilon_1 \quad [4]$$

Combining Eq. [1] and [4], the value of $\tau/A = 170\,\epsilon_1$ msec/cm². Thus for a tensile strain of 6×10^{-2}, $\tau/A = 10.2$ msec/cm². This value is only slightly greater than that observed experimentally for the oxide film formed without any prior chromic acid treatment. The small difference can be accounted for simply by assuming that the oxide behaves elastically

until attaining a strain of 6×10^{-3}, whereupon fracture is initiated. This value of the fracture strain is in fact in the range of values reported by other investigators (5, 10, 12-14).

The difference between the calculated and the experimental curves for a tensile strain of 6×10^{-2}, may be regarded as a measure of the effective ductility of the oxide film. The precleaning in the chromic acid can apparently reduce the concentration of flaws in the oxide sufficiently to produce a fivefold reduction in the extent of rupturing of the oxide. For example, the saturation level of $\tau/A = 2.2$ msec/cm^2 could be interpreted in terms of most of the strain (4.7×10^{-2}) being accommodated elastically by the oxide. This dramatic difference in the fracture resistance of these oxide films merited further investigation on a more microscopic level as outlined below.

Photoelectron Microscopy

Two types of specimens were examined; one was precleaned with chromic acid for 20 min while the other received no chromic acid treatment. Both were anodized to form a 28 nm oxide. The tensile strain required to initiate the fracture of these oxides, as determined by the onset of exoelectron emission, was essentially the same irrespective of the chromic acid treatment. The onset of oxide rupture always occurred at strain levels of 5×10^{-3} to 1×10^{-2}. By contrast, however, the total extent of cracking of these oxides differed markedly. This is illustrated by the photoelectron micrographs in Fig. 3 which show the sources of exoelectron emission produced after a tensile strain of 4×10^{-2}. The sample which was not precleaned with chromic acid has developed many sources of exoelectron emission, *i.e.*, microcracks in the oxide (Fig. 3a), while there are only a few in the oxide on the sample which had been treated with chromic acid (Fig. 3b). The mode of fracture appears to be the same in the two cases, namely the microcracks are in grain confined arrays and are associated with slip step emergence.

Thus the major effect of precleaning with chromic acid is that the subsequently formed anodic oxide film is considerably more difficult to rupture. A number of explanations could be proposed to account for this effect. For example, it could be argued that the chromic acid treatment actually etched away the work hardened layer near the surface, so that during subsequent deformation the slip steps would develop on a much finer scale and not be large enough to rupture the oxide. However an explanation along these lines is refuted by similar experiments in the PEM, where only the very thin natural oxide had been allowed to form after the initial cleaning of the specimens. As shown by the photoelectron micrographs in Fig. 4, the natural oxide develops numerous arrays of microcracks irrespective of the chromic acid treatment.

Another possible explanation could be formulated in terms of the chromic acid treatment leaving a contaminating film, perhaps only a monolayer, so that the anodic oxide film is not as well bonded to the metal substrate. If this were the case, the oxide film might tend to peel rather than rupture, as outlined analytically by Grosskreutz and McNeil (15) several years ago. Peeling of thicker oxides during tensile deformation has in fact been reported by several authors (4, 16,

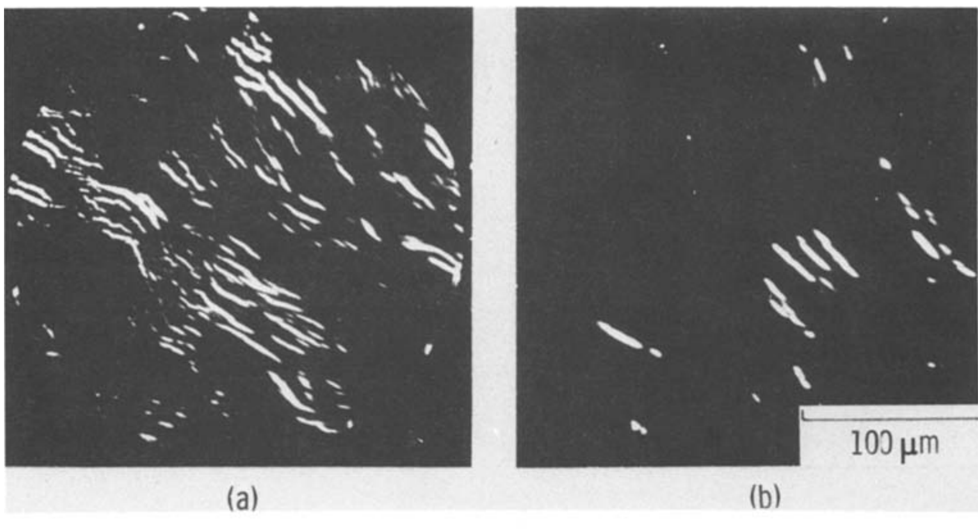

Fig. 3. Photoelectron micrographs of 1100 aluminum coated with 28 nm anodic oxide, showing sources of exoelectron emission after a tensile strain of 4×10^{-2}. (a) Precleaned with acetone, (b) precleaned with chromic acid for 20 min, prior to anodization.

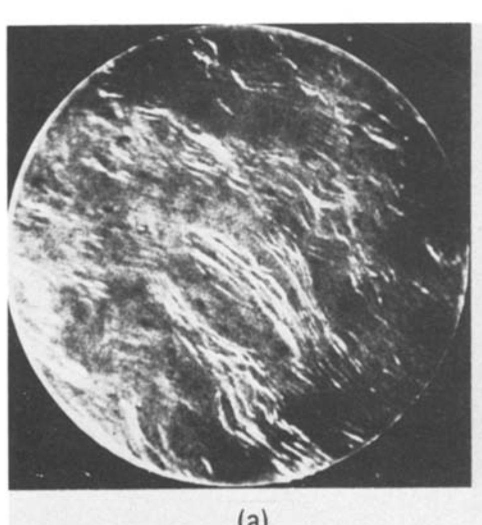

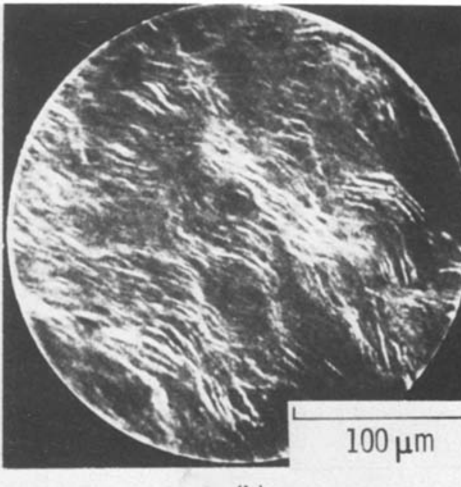

Fig. 4. Photoelectron micrographs of 1100 aluminum coated with thin natural oxide, showing sources of exoelectron emission after a tensile strain of 4×10^{-2}. (a) Precleaned with acetone, (b) precleaned with chromic acid.

17), but in our experiments we have not detected any evidence of peeling even for oxides as thick as 200 nm.

The 28 nm oxide formed after chromic acid treatment behaves quite differently from the oxides formed under the other three conditions considered above. Subsequent examination of these specimens with an optical microscope showed that in the case of the three oxides exhibiting a similar and high degree of susceptibility to fracture, the specimens had developed the usual multitudinous arrays of slip lines. On the other hand hardly any slip lines were visible on specimens which had been coated with the more fracture resistant 28 nm oxide. Closer examination of the latter, at higher magnification in a scanning electron microscope, did reveal a few isolated arrays of what appear to be microcracks in the surface oxide (Fig. 5a). But these are quite different in character from the strongly defined slip steps which always develop on specimens with the other less fracture resistant oxides (*e.g.*, Fig. 5b).

Thus of the four surface oxides under consideration here, the 28 nm oxide with low leakage current is unique in that it is apparently strong enough to suppress slip step development during tensile deformation. The other three oxides are much weaker, are apparently of similar strength, and are much more easily ruptured by the relatively freely emerging slip steps.

Flaw Controlled Fracture of Oxide Films

The above experiments show that the extent of fracture of surface oxides during tensile deformation of the metal substrate is closely related to the concentration of flaws initially present in the oxide film. This conclusion is consistent with the observations of oxide fracture by photoelectron microscopy. as well as the quantitative measurements of the extent of fracture by the reanodization current transient technique. On the other hand, the experiments in the PEM also showed that the tensile strain required to initiate oxide fracture was approximately independent of the concentration of flaws in the oxide (as measured by the leakage current). Thus we conclude that the fracture process is a highly localized phenomenon and requires only the presence of a flaw at the site of an emerging slip step.

Thus the following picture of the process emerges. During the early stages of tensile deformation slip steps are initiated over the entire surface of the sample, producing highly localized stress concentrations in the strongly bonded oxide film. In the model of Grosskreutz and McNeil (15) the oxide film is regarded as having two choices, either fracture or peel, depending upon the strength of the film and the strength of the bond to the substrate. In the metal-oxide system studied here we have never observed peeling of the oxide. Instead the two alternatives are that either the oxide fractures or the slip step is suppressed, *i.e.*, the oxide acts as a barrier to slip step development. This was clearly demonstrated for the 28 nm oxide (Fig. 3 and 4), but was not observed for the much thinner natural oxide. The latter may simply not be strong enough to withstand the stresses produced by an emerging slip step, so always fractures. On the other hand, the 28 nm oxide may either fracture or suppress the slip. The degree to which these two alternatives occur is dependent upon the strength of the oxide in the immediate vicinity of the emerging slip steps, *i.e.*, on the probability of the presence of a debilitating flaw in the oxide.

Let us consider in more detail the implications of this model for the more interesting case of the 28 nm oxide. The nature of the flaws controlling the leakage current and the fracture strength of this oxide is not clear. Let us simply assume that they are point defects when viewed perpendicular to the surface, such as for example the pores which have been reported to form in similar anodic films even during the first 10 min of anodization (6). The leakage current density of such an oxide film will be

$$I_l = \alpha N \quad [1]$$

where N is the concentration of defects and α is a constant.

If these defects are randomly distributed with an average spacing d, then

$$Nd^2 = 1 \quad [2]$$

The occurrence of oxide fracture is determined by the probability (P) of an emerging slip line of length D (and negligible but finite width) encountering a defect. There are three regimes to consider.

I. If $D >> d$, $P \sim 1$. This is the case of a high density of defects so all slip steps will rupture the oxide with ease. The reanodization time constant (τ/A) for a given value of tensile strain will be independent of I_l

$$i.e., \ \tau/A = \text{constant} \quad [3]$$

II. $D \sim d$. In this regime of intermediate flaw density

$$P \sim \frac{D}{d} \sim DN^{1/2} \quad [4]$$

Thus the reanodization time constant (τ/A) for a given tensile strain will depend upon $N^{1/2}$, or

$$\tau/A \sim I_l^{1/2} \quad [5]$$

III. If $D << d$, $P \sim N$. Thus for a low density of flaws

$$\tau/A \sim I_l \quad [6]$$

The experimental relationship between I_l and τ/A can be obtained from the results in Fig. 1 and 2. Values of I_l and τ/A, for equal periods of cleaning time in chromic acid, were taken from the curves drawn through this original data. The relationship between these values of I_l and τ/A are shown in Fig. 6. The regimes of high defect density (I), and intermediate defect density (II) are clearly apparent and in good

agreement with Eq. [3] and [5]. The third regime of low defect density was apparently not achieved in these experiments.

This analysis, particularly the confirmation of Eq. [5], provides further support for our contention that the same defects control both the leakage current and the fracture strength of the oxide film. These defects were present in a high concentration since the analysis of Fig. 6 shows that $d \leq D$. The length of a slip line D approximates the average grain diameter, so the defects apparently reside in regions corresponding to the interior of the grains of the substrate metal. Presumably they form around pre-existing defects in either the very thin initial natural oxide film and/or in the surface layers of the substrate metal.

Summary

During tensile deformation of aluminum, the extent of fracture of anodic oxide films on the surface is controlled by the density of defects initially present in the oxide. For oxide thicknesses ≤30 nm, the fracture occurs at slip steps emerging from the underlying metal, provided that the oxide contains debilitating defects in the immediate vicinity of the step. In these experiments the same defects controlled both the susceptibility to fracture as well as the leakage current, or effective resistivity, of the oxide film. In fact these two properties can be related in terms of a simple model involving only the probability of a defect in the oxide being located in the path of an emerging slip step.

The density of defects in these thin barrier layer type of anodic oxides is determined by the condition of the aluminum surface prior to anodization. Thus the defects originate either from flaws in the initial natural oxide upon which the anodic film grows, or from impurities or inclusions in the substrate metal. The density of defects can be greatly reduced by cleaning the surface with chromic acid prior to anodization. This increases the strength of the oxide film, so that even a thin (28 nm) oxide suppresses slip step formation during tensile deformation.

ABSTRACT

Epitaxial layers were grown by melting the surface of a polysilicon/silicon structure with a scanning cw argon laser beam. Topographical features and crystalline perfection associated with the laser-induced recrystallization were investigated by transmission electron microscopy (TEM) and optical microscopy. The regrown layers obtained were relatively free of defects, as revealed by TEM analysis. Large concentrations of dislocation lines and twinning zones were not detected in these studies; however, dense dislocation networks were observed in the substrate beneath the epitaxial layer.

Laser annealing, particularly by cw laser scanning, has been used in a variety of experiments to grow thin layers of silicon crystal. Recrystallization of an ion-implanted amorphized layer (1-4), grain growth of both poly and single crystal silicon on an insulating layer (5, 6), and graphoepitaxy (7, 8) are the major achievements obtained to date.

However, epitaxial growth from the polysilicon/single crystal silicon structure, utilizing cw laser scan techniques has not been reported, although epitaxial growth (9-12) and bridging epitaxial growth (13) are known to occur by melting the surface with a high energy density ($10^7 \sim 10^8$ W/cm^2) laser pulse.

This paper describes the grain growth obtained when a poly-Si/Si structure is scanned by a separated single beam of a cw Ar laser, with an energy density high enough to melt the surface. Under appropriate conditions, epitaxial growth of silicon is obtained.

Key words: semiconductor, epitaxy.

Experimental

The scanning laser setup has been described elsewhere (14). It consists of a 25W cw Ar laser operated in a multiline mode, an X-, Y-beam deflection system implemented with galvanomirrors, a heated vacuum-chuck sample holder, and control electronics.

The samples were prepared by depositing 2000Å polysilicon layers on (100) Si wafers using the hydrogen reduction of silane at 630°C at 0.8 Torr (LPCVD). The grain size was on the order of 500Å or less as measured by transmission electron microscopy (TEM).

The scanning speed of the laser beam was 12 cm/sec. In area scan experiments, the separation between the two successive scanning lines was set to about 11 μm so that the melted zones were well overlapped to assure the occurrence of uniform growth over the total area scanned. This assures overlap of more than 50%

of the laser traces. The substrate temperature was 350°C in all anneal experiments. Bevel polishing was done at an angle of 1°9′ on a Plexiglas plate with Metadi grits. The etchant used to delineate the polysilicon/silicon substrate boundary was a diluted Sirtl etch with the composition $CrO_3:H_2O:HF = 5g:10$ ml: 1 ml.

Results

The samples were annealed under various output powers in the single line scan mode. The development of surface topographic features with the output power of the cw laser is shown in Fig. 1. At low power, the trace of a laser beam shows a dotted surface structure [Fig. 1D)], which was found to be a result of the grain growth of polycrystalline silicon when examined by TEM. Increasing the laser power to a threshold value turned the center portion of the beam trace band into a ripple pattern [Fig. 1(C)]. Further increase in laser power smeared out the ripples into a rather coarse and irregular pattern [Fig. 1(A) and (B)]. Although the dotted and ripple structures have already been reported in pulse experiments (12), the latter irregular feature was not known. It did not disappear even at an output power level as high as 15W which is the maximum output of the cw laser used in this experiment. This can be associated with the longer melt duration in the cw laser irradiation than that in the short pulse case.

The bevel polish and etching show the existence of the polysilicon/single silicon substrate boundary in samples annealed at low laser powers. However, the boundary disappeared under the ripple pattern indicating that melting occurred into the substrate and suggesting the epitaxial regrowth of the polysilicon layer (Fig. 2). The beveling also shows the minute variation of the cross-sectional height of the beam trace as illustrated in Fig. 3(c). TEM examination of these single line scanned samples was employed to study the possible occurrence of epitaxial growth.

The change in the crystal structure brought about by cw laser anneal is shown in Fig. 3(a) for an 8W annealed sample with the ripple structure. The grain size of polycrystals increases from the edge toward the center of the laser beam trace and turns into single crystal epitaxial layer at the onset front of the ripple structure. The quality of the epitaxial layer is good as judged by the (100) transmission electron diffraction pattern, and by the absence of twin boundaries or dislocation lines. However, the electron micrograph of the epitaxial layer shows a periodic contrast associated with surface undulations, thereby duplicating the characteristic ripples observed on the surface of the regrown layer. This periodic ripple (thickness) contrast can probably be ascribed to the periodic change of stress accompanying crystal regrowth. The regularly defined (thickness) contrast variations disap-

peared in the sample annealed at 10W. The layer grown at 10W was also shown to be single crystal by diffraction, with no structural irregularity observed by TEM.

Another feature revealed by the TEM observation is the dislocation network which appeared in the substrate crystal below the epitaxial layer [Fig. 3(b)]. From micrographs obtained on a large number of samples, we observed that the dislocation lines extend from the epitaxial layer to the transition region where polycrystals develop, depending on the laser energy they receive. Since no periodic variation in contrast is observed for long dislocation lines, with the foil oriented at the exact Bragg condition ($S_g \simeq 0$), these lines are believed to lie on (100) planes extending in <110> directions. All these results are summarized in Fig. 3(c), which schematically shows the crystallographic changes when a surface of a polysilicon/silicon structure is swept by a laser beam.

Area scanning was used in an attempt to obtain large epitaxial layers. Scan conditions were chosen as stated in the Experimental section, using the results obtained for single line scan experiments. The surfaces of the area scanned sample are seen to reflect the topographical features of single line scans. One example is shown in Fig. 4, which retains the ripple structure observed in a single line sample. Electron diffraction demonstrates that the polysilicon layer was regrown as an epitaxial layer by area laser beam scanning.

Discussion

A lower bound on the propagation velocity of the recrystallization front along the direction of scan can be estimated, postulating that the ripples are generated by standing waves from interference of laser beam on crystal surface (12, 16, 17).

This propagation velocity should be an order of magnitude faster than the scan speed, because the crystal growth pattern (the ripples) caused by the variation of laser power distribution by interference is not smeared out by scanning. Therefore, the lower limit of this velocity is estimated to be around 1 m/sec in the ripple growth condition. This value is well within a reasonable range for the laser-induced liquid phase epitaxial growth, from the discussion on the crystal growth velocity in a previously published paper (15).

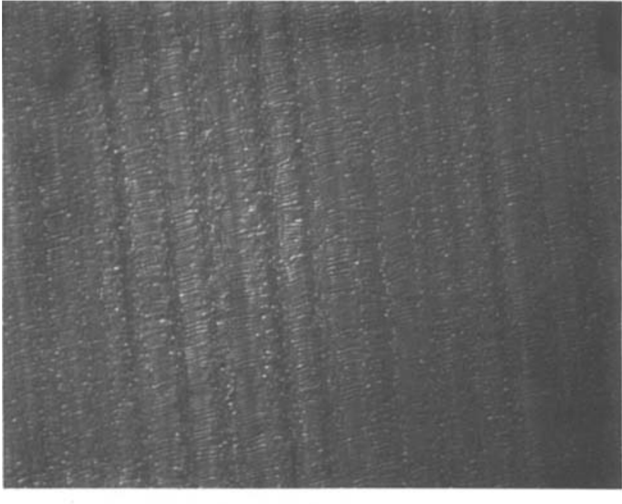

Fig. 4. An optical micrograph showing the surface topography of an epitaxial layer grown by overlapping laser scans (8W).

Conclusion

Liquid phase epitaxial growth from polysilicon/single crystal structures utilizing a cw Ar laser was demonstrated. The epitaxial layer was of relatively good crystal perfection in that the layer included few dislocations and twins. However periodic pile up of stress at some power levels, surface roughness, and high density dislocations under the epitaxial layer indicate the need for further study.

Comparison of Aluminum Etch Rates in Carbon Tetrachloride and Boron Trichloride Plasmas

K. Tokunaga,* F. C. Redeker,* D. A. Danner, and D. W. Hess*

Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

Etch rates of aluminum and "native aluminum oxide" films were studied as a function of substrate temperature in a parallel plate plasma etcher using CCl_4 and BCl_3 plasmas. Differences in the inhibition period for CCl_4 *vs.* BCl_3 etching were attributed to the relative abilities of these etchants to scavenge oxygen and water vapor and to etch native aluminum oxide. The temperature dependence of the etch rates suggested basic differences in the rate-controlling steps for CCl_4 *vs.* BCl_3 plasma etching. The surface chemistry of the electrode materials played an important role in the etch rates observed with CCl_4 and BCl_3.

Plasma or reactive ion etching of aluminum and aluminum alloys is vitally important to the VLSI effort. A number of papers have appeared recently describing the etching of aluminum films in carbon tetrachloride or boron trichloride plasmas using parallel plate plasma etch systems (1-10). However, these publications have not directly compared etch rate results for carbon tetrachloride and boron trichloride in the same etch system. In this paper we investigate the etch rates of aluminum films in carbon tetrachloride and boron trichloride as functions of substrate temperature in a parallel plate plasma etcher.

Experimental Procedure

The detailed operation of the parallel plate plasma etcher used in this study has been described previously (10), so only a brief description will be given here. Filament-evaporated or S-gun sputtered aluminum films on either Pyrex cover slips or on oxidized 2 in. diam silicon wafers were placed on the grounded lower electrode, which was temperature controlled. Power from a 13.56 MHz rf generator was supplied to the upper electrode, which was separated from the lower electrode by a distance of 2.5 cm. Etch gases entered the system through holes in the hollow upper electrode, and were exhausted through the lower electrode support column.

The etch runs described below were carried out at 100W rf power (0.3 W/cm^2) and 13 Pa (0.1 Torr) pressure. Since etching proceeded from the substrate edge to the center, the etch time was taken as the time required to completely remove the aluminum film.

Results

Many investigators have noted that the native aluminum oxide film present on aluminum surfaces etches slowly (compared to aluminum) in chlorine-containing etch gases (2-6, 10, 11). By utilizing both a thin (30-40 nm) and a thick (>500 nm) aluminum film during each etch run, an estimate of the etch rates of aluminum and of native aluminum oxide has been made as shown in Fig. 1 (10). Of course, this etch rate analysis assumes that the native aluminum oxide coating is the sole cause of the slow initiation step in aluminum etching. As indicated previously (10), this assumption is not entirely correct, since water vapor or oxygen in the etching chamber also inhibit aluminum etching (8, 9, 12). Nevertheless, such an analysis allows comparisons to be made between the ability of different etch gases to minimize or control oxygen or water vapor effects, and to etch native aluminum oxide.

* Electrochemical Society Active Member.

Key words: aluminum plasma etching, boron trichloride plasma, carbon tetrachloride plasma, oxygen scavenging, water vapor scavenging.

CCl_4 etching.—Using anodized aluminum electrodes (10), controllable aluminum etching was achieved in pure CCl_4 plasmas as shown in Fig. 1. However, Fig. 1 indicates that a large discrepancy (approximately a factor of 100) is observed between the etch rate of the "oxide" (which is composed of oxygen and water vapor scavenging, and native aluminum oxide etching) and the etch rate of the aluminum.

In an attempt to determine an order-of-magnitude estimate of the etch rate of native aluminum oxide, aluminum oxide was sputtered onto silicon wafers using a Model 304 Randex rf sputtering system. The sputtering atmosphere was 20% O_2/80% Ar, at a pressure of 0.01 Torr, which resulted in an aluminum oxide film with a refractive index of 1.60. At 100°C substrate temperature, the sputtered aluminum oxide etch rate was ~0.1 nm/sec, which is approximately a factor of two higher than that indicated in Fig. 1 for "oxide." This difference is no doubt related to the fact that native aluminum oxide has a different composition than

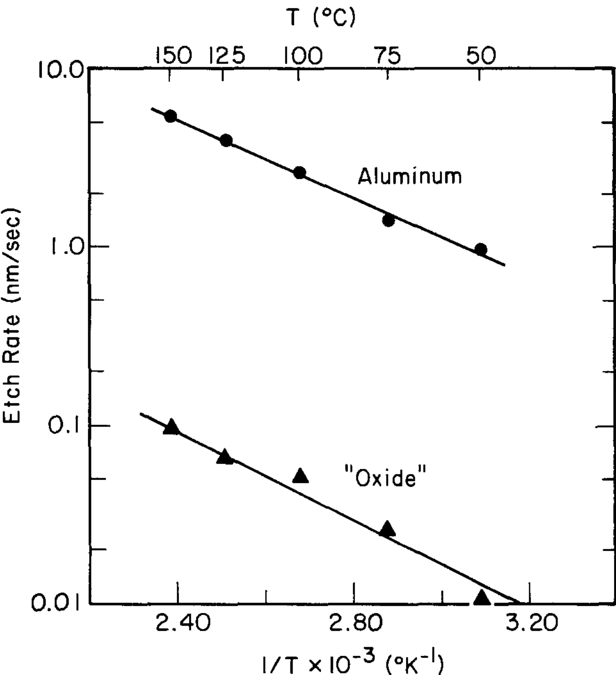

Fig. 1. Etch rate of aluminum and "oxide" (composed of oxygen and water vapor scavenging plus native aluminum oxide etching) films in CCl_4 as a function of electrode temperature on anodized aluminum electrodes.

sputtered aluminum oxide, since scavenging effects should be similar in both cases.

The etch rate data of Fig. 1 also indicate that the activation energies for aluminum and "oxide" etching are nearly equal (~0.2 eV/mole). The meaning of the equality of the activation energies is not clear, since the "oxide" etch rate is composed of oxygen and water vapor scavenging, along with native aluminum oxide etching. All that can be said at present, is that under the conditions used in this study, the overall inhibition period displays an activation energy of ~0.2 eV/mole.

A few comments can be made in regard to the portion of the inhibition period due to native aluminum oxide etching. Atomic chlorine appears to be the etchant for aluminum, while a chlorocarbon species is believed to be the primary etchant for aluminum oxide (2, 6). Indeed, this is in agreement with results in our system as well as others (2), that demonstrate the inability of Cl_2 plasmas to effectively and uniformly etch aluminum. However, if substrate bombardment is enhanced, as in the case of RIE, aluminum oxide can be etched successfully in Ar/Cl_2 atmospheres (6, 13).

BCl_3 etching.—An Arrhenius plot of the etch rate of aluminum and "oxide" films in BCl_3 using anodized aluminum electrodes, is shown in Fig. 2. Unlike the results obtained with CCl_4, BCl_3 displays little temperature dependence of the etch rates-activation energy ~0.02 eV/mole for aluminum, and ~0.03 eV/mole for "oxide." These observations suggest basic differences in the rate-controlling steps for BCl_3 *vs.* CCl_4 plasma etching of aluminum.

BCl_3 was also used to etch sputtered aluminum oxide. At a substrate temperature of 100°C, the etch rate was ~0.01 nm/sec, which is a factor of two lower than that determined via our analysis on "oxide" films.

Discussion

One of the primary differences between CCl_4 and BCl_3 etching of aluminum involves the ability of CCl_4 to form unsaturated chlorocarbons, and thus polymer films in a glow discharge. With CCl_4, and an active surface as stainless steel (SS), chlorine atom recombination, chlorocarbon recombination, and reaction of chlorine with the electrode material are all likely processes, and contribute to the concentration of unsaturated chlorocarbons and thus to polymerization (10). Under the high pressure and low power conditions utilized in our previous study (10), polymerization of CCl_4 on SS electrodes was difficult to avoid, although at lower pressures, where ion and electron energies are higher, polymerization can be minimized, and etching can proceed, even with low power densities. For instance, at 0.1 Torr, both BCl_3 and CCl_4 exhibit aluminum etch rates approximately a factor of two lower with SS than with anodized aluminum electrodes.

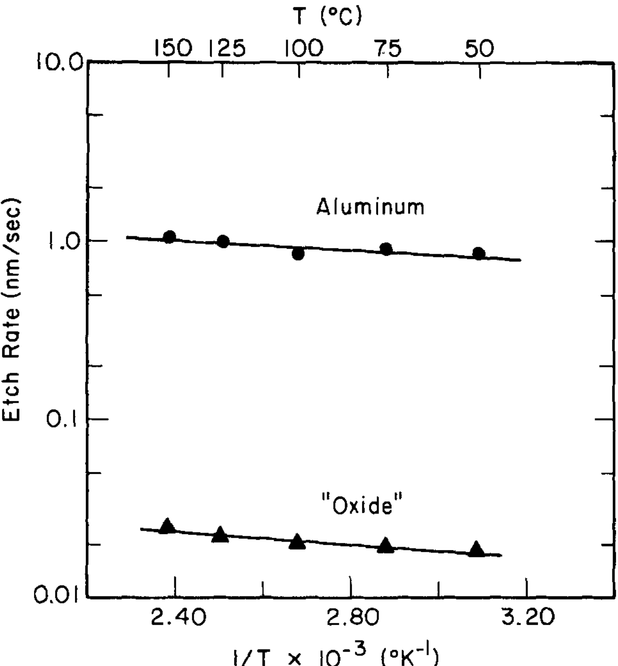

Fig. 2. Etch rate of aluminum and "oxide" (composed of oxygen and water vapor scavenging plus native aluminum oxide etching) films in BCl_3 as a function of electrode temperature on anodized aluminum electrodes.

Since boron does not form the same type of polymer structures as does carbon, no polymer is observed on the samples or on the electrodes with BCl_3 using SS or anodized aluminum electrodes. Boron compounds (possibly a combination of BCl_3 and boron oxychlorides) do condense or adsorb on the bell jar walls with anodized aluminum or SS electrodes, because when the etch chamber is vented to the atmosphere, a white deposit ($B(OH)_3$) forms immediately. Such deposits are never observed with CCl_4.

Aluminum oxide etching and oxygen scavenging.—Under the present plasma conditions, the etch rate of sputtered aluminum oxide is an order of magnitude higher with CCl_4 than with BCl_3 as discussed previously. Thus, if native aluminum oxide etching is the primary cause of the inhibition period for aluminum etching, the inhibition period should be shorter for CCl_4 than for BCl_3, at least to the extent that the etch rate of native aluminum oxide can be equated to that of sputtered aluminum oxide. Indeed, the inhibition period is slightly shorter for CCl_4 etching than for BCl_3 etching, at higher temperatures (100°C), but the difference is less than expected on the basis of sputtered aluminum oxide etch rates. However, the inhibition period is always more variable with CCl_4 than with BCl_3.

In order to compare the abilities of CCl_4 and BCl_3 to scavenge oxygen and water vapor from the chamber atmosphere, and thereby to estimate the relative importance of scavenging in the inhibition period, the effluent gases from 1% mixtures of oxygen in CCl_4 and in BCl_3 were monitored with a UTI Model 100 C quadrupole mass spectrometer. Figure 3a demonstrates that when a plasma is ignited in the O_2/CCl_4 mixture, the intensity of the O_2^+ peak decreases as expected, due to the reaction of carbon-chlorine fragments with O_2, but O_2 is still present in the plasma effluent. However, when an O_2/BCl_3 plasma is struck, the intensity of the O_2^+ peak goes to zero, and remains there until the plasma is extinguished (Fig. 3b). Further, with BCl_3, the O_2^+ peak intensity is zero with an O_2 content in the inlet of approximately 5 volume percent.

In addition, the H_2O^+ peak intensity decreases when a plasma is ignited in either a BCl_3 or a CCl_4 plasma, but does not go to zero in either case. Nevertheless, the inhibition time is more reproducible in a BCl_3 than in a CCl_4 plasma. These results indicate that BCl_3 is a more efficient oxygen and possibly water-vapor scavenger than is CCl_4. As a result, etch reproducibility should be improved with BCl_3 compared to CCl_4, since etching should not be as critically dependent upon residual oxygen and water vapor in the etch chamber. Indeed, such conclusions have been demonstrated in our system, and these studies are consistent with the effects of oxygen and water vapor on CCl_4 etching (8, 9, 12).

Additional evidence for the scavenging differences between BCl_3 and CCl_4 arises from consideration of the reflected power observed in CCl_4 and BCl_3 plasmas. The reflected power for a CCl_4 plasma is shown as a function of time in Fig. 4. Approximately 1 min is required from plasma ignition until the reflected power reaches a minimum value. However, only 15 sec is required when BCl_3 is used (Fig. 4). The exact time

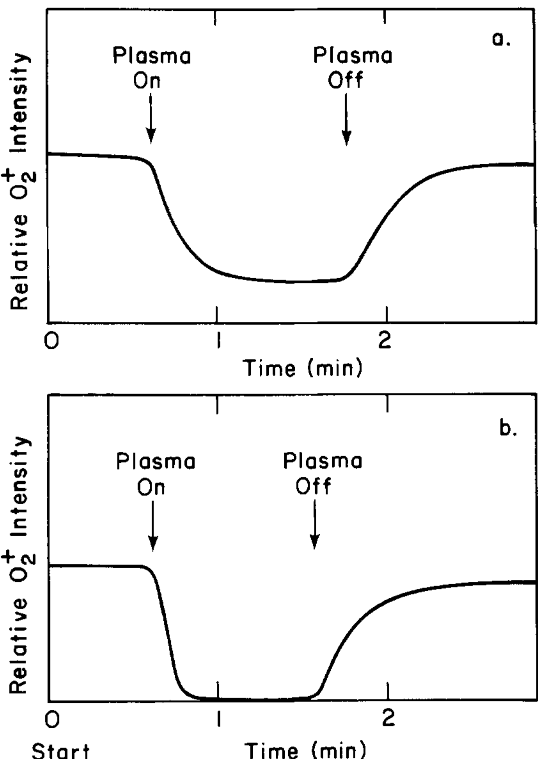

Fig. 3. (a) Relative O_2^+ peak intensity in a 1% O_2/99% CCl_4 plasma as a function of discharge time. (b) Relative O_2^+ peak intensity in a 1% O_2/99% BCl_3 plasma as a function of discharge time.

required to reach a minimum varies slightly (apparently due to water concentration); however, the trend is always the same. Further, the minimum reflected power is less with BCl_3 than with CCl_4, and this observation apparently depends upon water concentration also. These results are consistent with the mass spectrometer studies shown in Fig. 3, in that oxygen is still present in the plasma effluent when a plasma is ignited in a 1% O_2/CCl_4 mixture, but is absent with a 1% O_2/BCl_3 mixture. Also, Fig. 3 and 4 demonstrate a more rapid change in O_2^+ peak intensity and reflected power, respectively, for BCl_3 as compared to CCl_4. Thus the reflected power may indicate the portion of the inhibition period due to oxygen and water vapor scavenging. In fact, in aluminum etch runs, the aluminum has not begun to etch at the point in time where the reflected power reaches a minimum. Rather, it begins to etch after approximately one additional minute of plasma exposure.

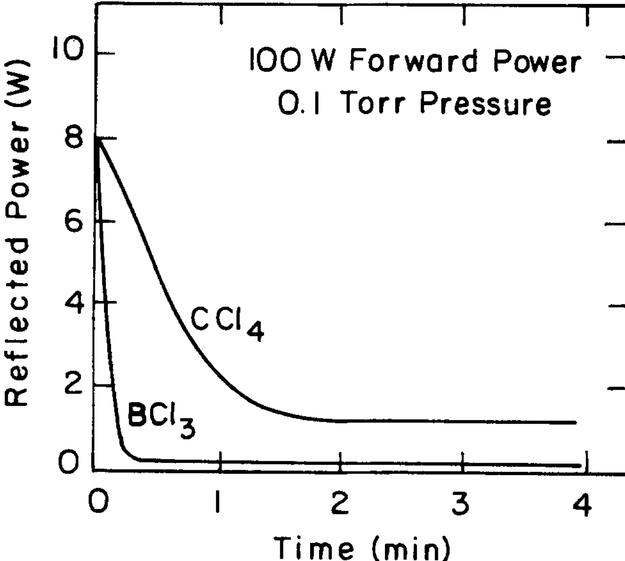

Fig. 4. Reflected power in BCl_3 and CCl_4 plasmas as a function of discharge time.

The above results are consistent with discharge impedance monitoring of CCl_4 plasmas during aluminum etching using RIE (14). In that study, a gradual decrease (over ~1 min) of electrode voltage was observed after ignition of the CCl_4 plasma. Thus, it is quite likely that oxygen or water vapor scavenging was in part responsible for the impedance changes observed at the start of the etch process.

Since BCl_3 is a reasonably efficient scavenger of oxygen and water vapor, one can assume that the inhibition period for BCl_3 etching is primarily due to native aluminum oxide etching. However, the etch rate estimate from aluminum samples is ~2 times higher than that observed for sputtered aluminum oxide. This discrepancy is no doubt related to the heavily hydrated nature of native aluminum oxide surfaces (15). Since BCl_3 reacts readily with water, the native oxide is probably more reactive toward BCl_3 than is sputtered aluminum oxide.

CCl_4, on the other hand, displays an "oxide" etch rate that is ~2 times lower than that of sputtered aluminum oxide. Again, this is probably due to the high moisture content of the native oxide surface, since CCl_4 plasmas are not efficient oxygen and water vapor scavengers, and, in fact, these species tend to inhibit aluminum etching. Currently, it is not clear why CCl_4 plasmas can etch sputtered aluminum oxide more rapidly than BCl_3 plasmas. However, such results may be related to differences in the plasma and electrode potentials between CCl_4 and BCl_3, or to different concentrations of etchant species generated by the two etch gases.

Chemistry of BCl_3 and CCl_4 etching.—Etch rate studies with BCl_3 and CCl_4 have indicated that the aluminum etch rate is higher on anodized aluminum than on SS electrodes. This difference may be partly due to higher recombination and/or reaction rate of chlorine free radicals, which have been proposed to be the etchant species for aluminum, on SS surfaces. Such conclusions are consistent with studies of fluorine atom recombination on steel *vs.* alumina surfaces (16). These latter studies have shown that steel is a better recombination surface for fluorine atoms than is alumina.

Another consideration with regard to electrodes involves the effect of oxygen from the electrode material (10, 23). Oxygen could promote the removal of boron from the aluminum surface if boron oxychlorides are formed, and in addition can generate additional chlorine atoms by reaction with boron-chlorine fragments. Thus, enhanced aluminum etch rates may be expected.

Comparison of Fig. 1 and 2 suggests that under the plasma conditions investigated in this study, basic differences exist in the rate-limiting steps for BCl_3 *vs.* CCl_4 etching of aluminum. A possible reaction sequence for the etching of aluminum in BCl_3 plasmas can be written as follows

$$BCl_3(g) + e \rightarrow BCl_2(g) + Cl(g) + e \quad [1]$$

$$Cl(g) \rightarrow Cl(ads) \quad [2]$$

$$Cl(ads) + Al \rightarrow AlCl(ads) \quad [3]$$

$$AlCl(ads) \rightarrow AlCl(g) \quad [4]$$

The dissociation of BCl_3 via electron collisions into BCl_2 has been indicated previously, since rf glow discharge dissociation of BCl_3 represents a high yield pathway for the formation of B_2Cl_4 (17). Also, the adsorption of chlorine gas and/or chlorine atoms onto clean aluminum surfaces has been reported (18). Clearly, gas phase species other than Cl_2 or Cl might

adsorb onto aluminum surfaces (for instance, CCl_x or BCl_x), but for the purpose of the following discussion, these possibilities need not be considered. AlCl has been observed by emission spectroscopy of CCl_4 plasmas (19). Of course, AlCl(ads) can further react on the aluminum surface, the electrode surface, or in the gas phase, to form $AlCl_2$ and/or $AlCl_3$ as the final reaction product. The above mechanism (Eq. [1]-[4]) is in principle similar to that proposed for the etching of silicon in CF_4 plasmas (20). The present mechanism, however, considers the adsorption of Cl atoms on the aluminum surface, as well as the possibility of desorption of various aluminum-chlorine fragments in addition to $AlCl_3$. Indeed, fragment desorption has been demonstrated for the etching of silicon with fluorine-containing gases (21).

Since reactions [2]-[4] are surface reactions, a temperature dependence is expected for these steps. On the other hand, reaction [1] represents a gas phase generation of chlorine free radicals, which is independent of substrate temperature. Thus, the rate-determining step for BCl_3 etching of aluminum on anodized aluminum or stainless steel electrodes is probably the gas phase generation of etchant species. Such conclusions are consistent with previous aluminum etch studies using BCl_3 on stainless steel electrodes (2).

A similar reaction sequence for CCl_4 etching can be written by replacing reaction [1] with [1a]

$$CCl_4(g) + e \rightarrow CCl_3(g) + Cl(g) + e \qquad [1a]$$

Indeed, mass spectrometric studies have shown that CCl_3 is prevalent in CCl_4 discharges (22). Since a substrate temperature dependence is observed for CCl_4, one (or more) surface reactions of the type [2]-[4] control the etch rate.

Reactions similar to [1]-[4] can be written for the etching of native aluminum oxide. However, the composition of this layer is uncertain, and so no specific reactions are proposed. Nevertheless, if it is assumed that oxygen assists the removal of boron or carbon species, the chlorine is left to react with aluminum. Indeed, carbon oxides and oxychlorides are well known, and gas-phase oxychlorides of boron have been reported (24). These considerations are consistent with the improved etching characteristic of CCl_4 and BCl_3 on anodized aluminum electrodes compared to stainless steel electrodes. On stainless steel, an efficient means of removing carbon and boron is not available after the native aluminum oxide coating has been removed. However, with anodized aluminum electrodes, small concentrations of oxygen are present to assist removal of carbon (23) or boron species but the concentrations are sufficiently low to prevent inhibition of aluminum etching by aluminum oxide formation.

The scavenging studies discussed above indicate that the relative reactivity of oxygen with aluminum *vs.* CCl_x or BCl_x is an important aspect of aluminum plasma etching. Apparently, in the competition for oxygen between BCl_x and Al, BCl_x is the preferred reactant, whereas with CCl_x, aluminum may be the better scavenger. Certainly, the etch rate of aluminum samples decreased when oxygen was added to CCl_4 (10), and our analysis indicated that both the "oxide" and the aluminum etch rates decreased. However, small additions ($\sim$1%) of oxygen to BCl_3 resulted in a decrease in the "oxide" etch rate, but an increase in the aluminum etch rate, such that the overall etch rate increased. Higher oxygen concentrations result in boron oxide deposition. These results are consistent with previous studies which report an increase in overall aluminum etch rate with oxygen addition to BCl_3 plasmas (7).

In CCl_4 etching, oxygen reacts with aluminum or carbon species, while with BCl_3, oxygen reacts preferentially with boron to form oxides or oxychlorides, thus generating additional chlorine atoms, which enhance the aluminum etch rate. This latter reaction is analogous to that observed when oxygen is added to CF_4 during silicon etching (25).

If CCl_4 is a better etchant for aluminum films than is BCl_3, and if BCl_3 is a better scavenger for oxygen and water vapor than is CCl_4, then an improved etchant for aluminum may be some mixture of the two. Indeed, preliminary studies in our laboratory indicate that such mixtures display higher etch rates and better reproducibility than either CCl_4 or BCl_3 individually. However, boron residues may preclude their usefulness.

Summary

The etch rates of aluminum and "native aluminum oxide" (composed of native aluminum oxide etching and oxygen and water vapor scavenging) in CCl_4 and BCl_3 plasmas were investigated as functions of substrate temperature in a parallel plate plasma etcher. Oxygen and water vapor scavenging appeared to be the most important process in initiating aluminum etching in CCl_4 plasmas, while aluminum oxide etching was the primary factor in the inhibition period with BCl_3 plasmas. These results suggest a chemical competition for oxygen or water vapor between aluminum and either boron-chlorine or carbon-chlorine fragments, with boron compounds being the better scavengers.

The etch rates of aluminum in CCl_4 plasmas on anodized aluminum electrodes were critically dependent upon temperature, indicating that surface reactions were rate controlling. However, BCl_3 etching on anodized aluminum or on SS electrodes showed little or no temperature dependence, suggesting that the rate-controlling step(s) involved gas phase generation of etching species.

The etch rate of aluminum using BCl_3 was dependent upon the electrode material, with the etch rate being greater by a factor of 2 with anodized aluminum than with SS electrodes. The differences observed are believed to be due to increased chlorine atom recombination on SS electrodes and/or to the ease of surface boron removal and additional chlorine atom generation when oxygen is available from the electrode material.

ABSTRACT

Indium phosphide, a direct gap semiconductor with a room temperature energy gap of 1.35 eV, is a promising photovoltaic material for thin film devices. Thin films of indium phosphide have been deposited on tungsten-coated graphite substrates by the reaction of indium, hydrogen chloride, and phosphine in a gas flow system. Without intentional doping, the deposited films are n-type with a carrier concentration of about 10^{17} cm^{-3}. Schottky barriers prepared from these films have been found to exhibit low rectification ratios, high dark currents, and poor photovoltaic response due to the shunting effects of grain boundaries. The grain boundary effects can be partially reduced by heat-treatment in an ammonia atmosphere, converting the surface of grains into indium nitride. The formation of indium nitride has been verified by Auger electron spectroscopy and x-ray photoelectron spectroscopy.

Direct gap semiconductors with bandgap energy of 1.3-1.8 eV are most promising materials for thin film photovoltaic devices. Because of their sharp optical absorption edges and large absorption coefficients, solar radiation with energy in excess of the bandgap energy are essentially all absorbed within 2-3 μm of the surface. Thus, the grain size and minority carrier diffusion length requirements are less stringent than those required of indirect-gap materials. Among III-V compounds, gallium arsenide with a room temperature energy gap of 1.43 eV and indium phosphide with a bandgap energy of 1.35 eV are considered as most promising. For example, gallium arsenide films deposited on graphite or tungsten-coated graphite substrates by the halide process have an average grain size of about 10 μm, and large area (10 cm^2) MOS solar cells have been fabricated from this type of polycrystalline films (1, 2). The AM1 efficiency of thin film gallium arsenide solar cells is higher than 8%; while their short-circuit current density is about 80% of that of single crystalline gallium arsenide solar cells, their open-circuit voltage is considerably lower. Indium phosphide films have also been deposited on foreign substrates such as carbon and molybdenum, and small area (3 mm^2) thin film solar cells of the configuration n-CdS/p-InP/p^+-GaAs/carbon fabricated. Although the photocurrent from thin film cells is similar to that from single crystalline CdS/InP cells, thin film cells have considerably lower open-circuit voltage and fill factor, resulting in a conversion efficiency of about 5.7%.

The considerably lower open-circuit voltage in thin film cells is due presumably to the high saturation current which arises from the poor grain structure or grain boundary effects. In this work, indium phosphide films have been deposited on tungsten-coated graphite substrates by the halide process. Schottky barrier devices prepared from these films exhibit excessive dark currents due to the shunting effects of grain boundaries. The grain boundary effects can be reduced sub-

stantially by the heat-treatment of indium phosphide films in an ammonia atmosphere, due to the formation of indium nitride at the grain surface. The experimental procedures and results are discussed in this paper.

Deposition of Indium Phosphide Films

Graphite is an economical substrate for large area solar cells. Several types of low-cost graphite, such as grade PLC graphite manufactured by POCO Graphite Incorporated, have a linear thermal expansion coefficient very similar to that of indium phosphide (4.5×10^{-6} $°C^{-1}$). Graphite is chemically inert under the conditions used for the deposition of indium phosphide. Also, graphite has high thermal and electrical conductivities and may be used as an ohmic contact to the solar cell. However, the density of low-cost graphite is 1.65-1.75 g/cm^{-3} (theoretical density of graphite: 2.2 g/cm^3), corresponding to a porosity of 20-25%. Consequently, the surface of graphite has a high concentration of pits, and uniform nucleation of indium phosphide cannot be expected. To provide a homogeneous surface, a thin layer (2-3 μm) of tungsten, an impervious material, was deposited on graphite substrates by the reduction of tungsten hexafluoride with hydrogen at 500°C.

The deposition of indium phosphide films on tungsten/graphite substrates was carried out by the reaction between indium, hydrogen chloride, and phosphine using the apparatus shown schematically in Fig. 1. A typical temperature profile with the positions of indium and substrate are also shown. The reaction tube was made of fused silica and was of 55 mm ID; the use of a relatively large diameter reaction tube facilitates the preparation of large area indium phosphide films of uniform properties. The reaction tube is held in a four-zone furnace with each zone separately heated and controlled. The temperature profile and the composition and flow rate of the reactant mixture are important factors affecting the deposition rate of indium phosphide.

To carry out the deposition of indium phosphide, an indium container and the substrate are placed in the appropriate temperature zones. A hydrogen-hydrogen chloride mixture is introduced into the reaction tube over the indium container, where indium is converted into volatile indium monochloride. At the same time, phosphine is introduced into the reaction zone near the substrate surface. The reaction between indium monochloride and phosphine on the substrate surface deposits indium phosphide. In the deposition experiments, the temperature of indium was maintained at 745°-755°C, and the flow rate of hydrogen was 0.5-1.5 liters/min. The substrate temperature was varied in the range of 500°-650°C, and the flow rates of hydrogen chloride and phosphine were 10-45 ml/min and 30-135 ml/min, respectively (a PH_3/HCl molar ratio of 3 or higher was always used to minimize any phosphorus deficiency in the deposit). The results of a number of deposition experiments indicate that the deposition parameters can only be varied over a limited range in order to obtain continuous films. During the initial stage of deposition, a high flux of reactant mixture, by using a relatively high flow rate of hydrogen through indium, for example, must be maintained at the substrate surface. Once a continuous film is formed, the deposition rate of indium phosphide may be reduced by reducing the flow rate of hydrogen chloride.

The microstructure of indium phosphide films on tungsten/graphite substrates were examined using optical microscope and scanning electron microscope on the as-deposited and fractured cross-section surfaces. One example is shown in Fig. 2 where the scanning electron micrographs of the as-grown and fractured cross-section surfaces of an indium phosphide film deposited on a tungsten/graphite substrate at 600°C using a hydrogen chloride flow rate of 45 ml/min are reproduced. The crystallites in these films are of random shape and size; x-ray diffraction examinations indicate that the films are essentially polycrystalline with no appreciable preferred orientations.

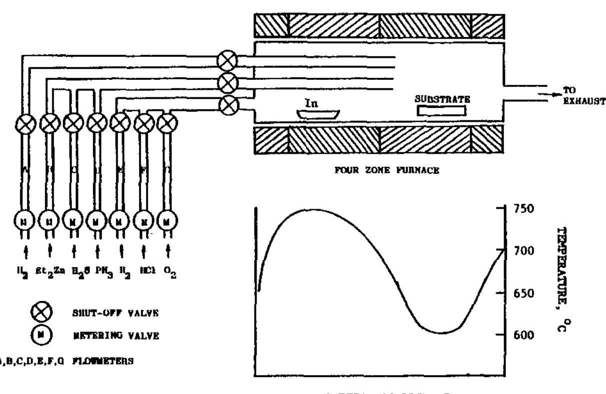

Fig. 1. Schematic diagram of the apparatus for the deposition of indium phosphide films and a typical temperature profile used in the deposition process.

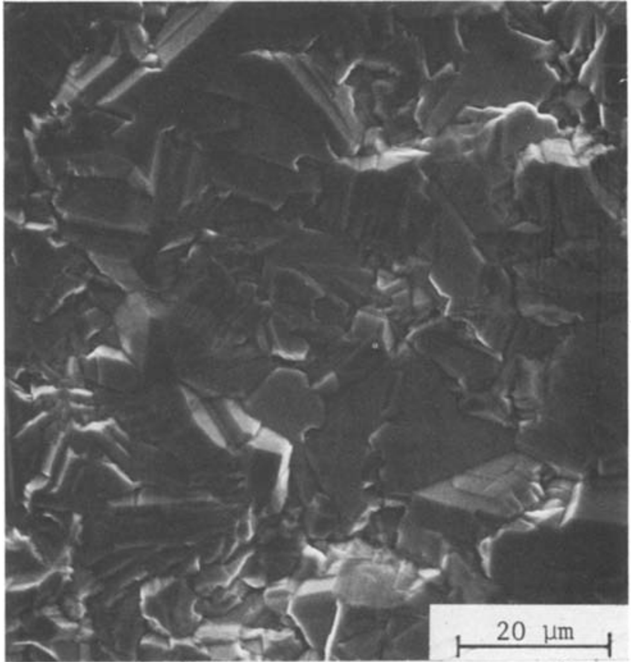

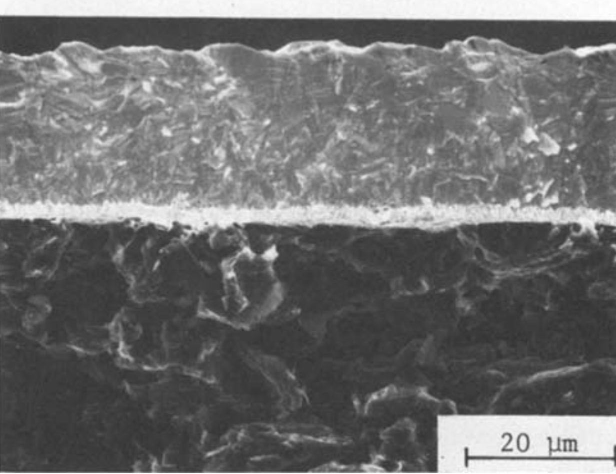

Fig. 2. Scanning electron micrographs of the as-grown and fractured cross-section surfaces of an indium phosphide film deposited on a tungsten/graphite substrate.

Electrical Properties of Indium Phosphide Films

Without intentional doping, indium phosphide films deposited on tungsten/graphite substrates are always n-type. The carrier concentration in indium phosphide films determined by differential capacitance method is in the range of (0.5-3) $\times$ 10^{17} cm^{-3}; lower carrier concentrations were obtained when the indium source was saturated with phosphine prior to the deposition process. The n-InP/W interface is ohmic with an interface resistance of less than 10^{-3} Ω-cm^2 at a current density of 10 mA/cm^2.

The electrical properties of indium phosphide films on tungsten/graphite substrates were evaluated by measuring the dark current-voltage characteristics of Schottky barriers prepared from these films. Schottky barriers were prepared by the evaporation of silver dots of 1-2 mm^2 area onto the specimen surface through a metal mask under a pressure of less than 10^{-6} Torr, and their dark current-voltage characteristics measured at room temperature. To evaluate the photovoltaic properties of indium phosphide films, Schottky barrier solar cells of 1 cm^2 area were prepared by the evaporation of a thin silver film (60-80Å thickness) and the grid contacts (10 lines per cm) onto the specimen surface, and their illuminated current-voltage characteristics measured under AM1 conditions. All Ag/n-InP/W/graphite devices were found to show excessive dark currents and poor rectification ratios. As an example, Fig. 3 shows the characteristics of an Ag/n-InP/W/graphite structure of about 1 mm^2 area, where the forward current density exceeds 1 A/cm^2 at 0.3V, the diode quality factor "n" is about 5, and the rectification ratio is less than 10. However, when a semispherical gold pressure contact is used instead of the evaporated contact, the current-voltage characteristic is often improved significantly. Figure 4 shows such a characteristic, where the diode quality factor is less than 2 and the rectification ratio at 0.3V exceeds 1000. This difference in characteristics between evaporated and pressure contacts is due presumably to the fact that the grains in indium phosphide films are not tightly packed and metals penetrate through grain boundaries during contact formation, causing shunting effects. Auger and SIMS studies on fractured cross sections have shown that the segregation of impurities,

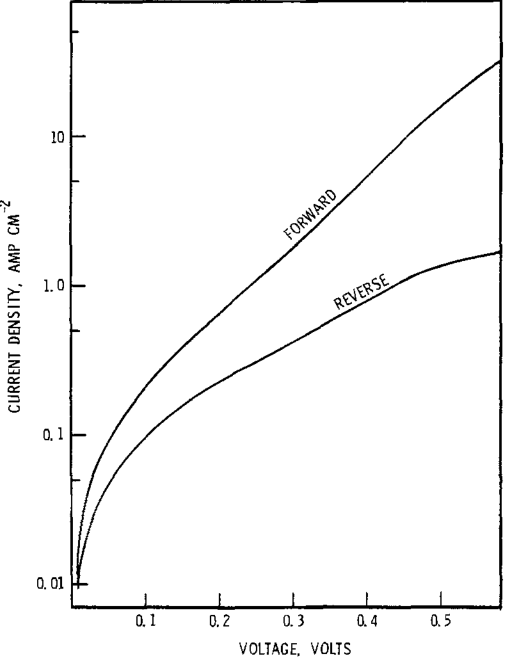

Fig. 3. Dark current-voltage characteristics of a silver Schottky barrier of about 1 mm^2 area prepared from an n-type indium phosphide film on a tungsten/graphite substrate.

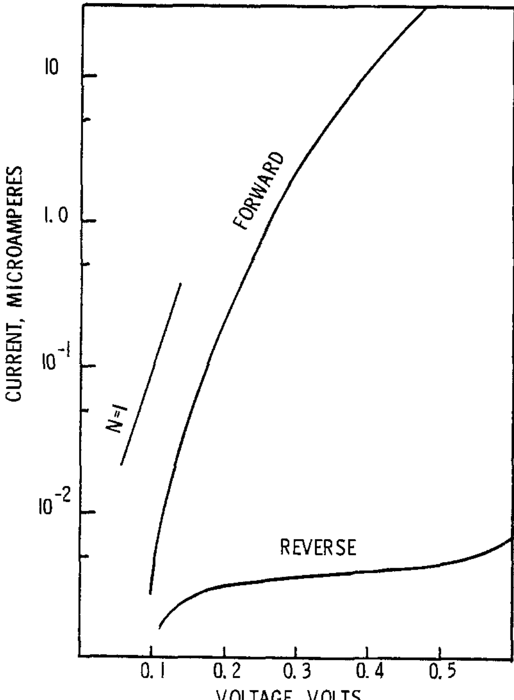

Fig. 4. Dark current-voltage characteristics of a semispherical gold pressure contact on an n-type indium phosphide film on a tungsten/graphite substrate.

such as sulfur, at grain boundaries is also a major factor contributing to the shunting effects.

Because of the high dark current, Schottky barrier solar cells of 1 cm^2 area exhibit poor photovoltaic characteristics. Under AM1 conditions, the open-circuit voltage and short-circuit current density are usually in the range of 5-10 mV and 1-3 mA/cm^2, respectively. Schottky barrier solar cells were also prepared from n-type indium phosphide films deposited on aluminum-coated graphite substrates; their characteristics were inferior to those on tungsten-coated graphite substrates. Auger and SIMS studies on fractured and cross sections have shown that aluminum from the substrate diffused into the indium phosphide film preferentially along the grain boundaries. The diffusion of aluminum into indium phosphide generates phosphorus vacancies, thereby increasing the donor concentration in, and electrical conductivity of, grain boundaries. Thus, impurity segregation at grain boundaries is a major factor contributing to the shunting effects.

Reduction of Grain Boundary Effects by Nitridation

The high dark current in Schottky barriers from indium phosphide films is contributed by the shunting effects of grain boundaries in the films. The electrical conductivity of grain boundaries dominates over that of the grains due to at least two factors: dopant segregation at grain boundaries and the presence of minute voids between grains in indium phosphide films. The shunting effects of grain boundaries associated with impurity segregation may be reduced by using a higher bandgap material at the grain surface. Indium nitride with a bandgap energy of about 3 eV appears to be a promising candidate; this material has been prepared by the reaction of indium (III) oxide with ammonia and is stable in air at temperatures up to 300°C (4).

Because of the greater stability of indium nitride, the surface of indium phosphide can be converted into indium nitride by treatment with ammonia at high temperatures. A number of indium phosphide films were heated in an ammonia flow at 500°-650°C for a period of 15 min to 2 hr. Subsequently, silver contacts

were evaporated onto the ammonia-treated surface, and the dark current-voltage characteristics of the resulting MNS structures were used to determine the effects of temperature and duration of the ammonia treatment. At temperatures of 550°C and below, the conversion of indium phosphide into indium nitride is negligible, and the decomposition of indium phosphide becomes apparent at 650°C. Ammonia treatment at 600°C for 20 min appears to be optimum for reducing dark currents without introducing a large series resistance. The *in situ* ammonia treatment of indium phosphide films immediately after the deposition process has produced the same results.

To determine the composition and chemistry of ammonia-treated indium phosphide films, high resolution scanning Auger electron spectroscopy (AES) and x-ray photoelectron spectroscopy (XPS) using a Physical Electronics Industries Model 590 SAM/SIMS and a Model 550 XPS/SAM were carried out. For AES, pulse counting with 10 nA currents and 5 kV beam voltages were used. For the XPS studies, the argon ion source was operated at 10 kV with a magnesium anode; the pass energy was 10 eV providing a 0.3 eV instrument resolution. Figure 5 shows an Auger depth-compositional profile for an ammonia-treated indium phosphide film. The surface layer of indium phosphide, about 50Å thickness, has been converted into a nitride, and an orderly transition from the nitride to the phosphide is observed. To determine the chemical composition of the ammonia-treated indium phosphide films, XPS data were obtained at two points, α and β shown in Fig. 5, during the depth profile. The positions of the indium $3d_{3/2}$ and $3d_{5/2}$ peaks in the XPS spectra are shown in Fig. 6. These peaks were compared to the $3d_{3/2}$ (451.2 eV) and $3d_{5/2}$ (443.6 eV) peaks from an indium standard. The spectrum taken at point β shows $3d_{3/2}$ and $3d_{5/2}$ peaks at 451.6 and 444.0 eV, respectively, which correspond to indium phosphide. The spectrum taken at point α shows $3d_{3/2}$ and $3d_{5/2}$ peaks at 452.6 and 445.0 eV, respectively, which correspond to indium nitride. No other signals over this binding energy range were observed.

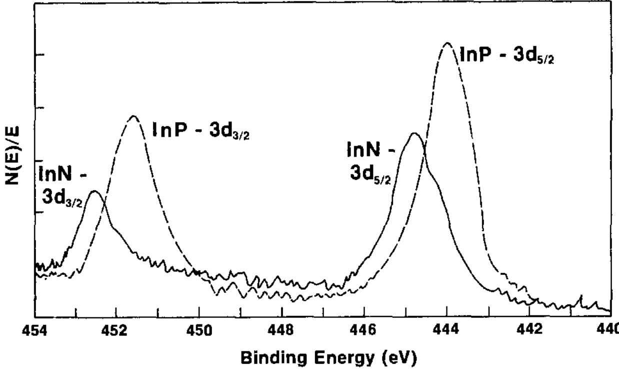

Fig. 6. XPS spectra taken at two points of the depth-compositional profile shown in Fig. 1: Dashed line—indium phosphide spectrum taken at point β in Fig. 1; Solid line—indium nitride spectrum taken at point α in Fig. 1. (Mg anode, 10 keV source; instrument resolution: 0.3 eV).

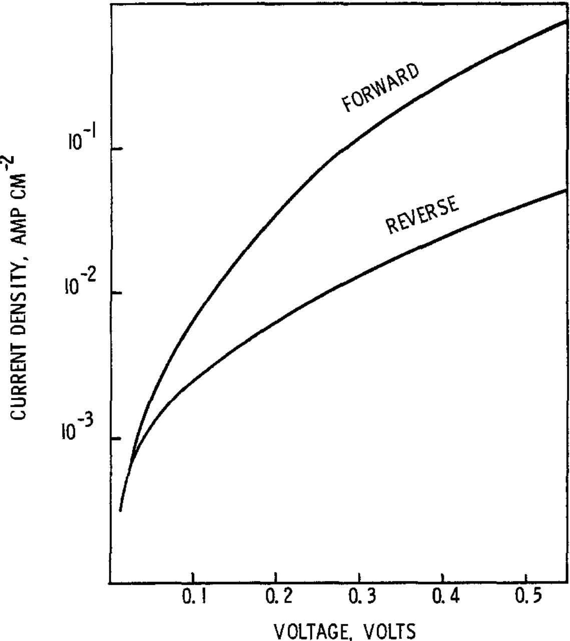

Fig. 7. Dark current-voltage characteristics of a Schottky barrier solar cell of 1 cm² area prepared from an ammonia-treated n-type indium phosphide film on a tungsten/graphite substrate.

Schottky barriers prepared from ammonia-treated indium phosphide films show considerably improved characteristics. Figure 7 shows the dark current-voltage characteristics of a solar cell of 1 cm² area with the configuration Ag/InN/*n*-InP/W/graphite. The dark current is reduced considerably as compared with the Schottky barrier structure (Fig. 3), and the rectification ratio is also improved. However, the dark current is still too high for efficient solar cells. Under AM1 conditions, the open-circuit voltage and short-circuit current density are 125 mV and 6.5 mA/cm², respectively.

Summary and Conclusion

Indium phosphide films have been deposited on tungsten-coated graphite substrates by the reaction of indium, hydrogen chloride, and phosphine. The electrical properties of these films are determined predominately by the shunting effects of grain boundaries due to at least two factors: (*i*) the segregation of dopants at grain boundaries, and (*ii*) the loose packing of grains in the films. The shunting effects may be reduced to some extent by converting the surface of indium phosphide into indium nitride; however, more efficient passivation techniques are necessary in order to produce efficient solar cells.

In Situ Semiconductor Heterostructure Arrays: Ge-GaAs

D. E. Holmes[1]

Hughes Research Laboratories, Malibu, California 90265

ABSTRACT

The experimentally determined microstructure of the directionally solidified Ge-GaAs eutectic, studied for the first time, was characterized as an aligned array of GaAs rods in a Ge matrix. Alignment occurred within facetted grains on the order of 100 μm wide. Possible causes of the grain structure are discussed. Based on these findings, the growth characteristics and properties of several new *in situ* semiconductor heterostructure materials (directionally solidified composites) containing group IV, III-V, and II-VI compounds were evaluated.

The potential for producing semiconductor heterostructures in a one-step process has been virtually overlooked. Heterostructures are conventionally grown layer by layer. Yet, aligned *in situ* composites of metals and oxides have been produced by techniques such as directional solidification of eutectics (1-4), eutectoid decomposition (5), and directional decomposition of noncrystalline solid single phase materials (6). Although a limited number of directionally solidified composites containing semiconductors have been grown (7-11), semiconductor-semiconductor composites containing group IV, III-V, and II-VI compounds have not been studied systematically.

This investigation concerned new *in situ* semiconductor composites with emphasis on the structure and properties of the internal phase boundaries. Attention was focused on the directional solidification of eutectics (12). The Ge-GaAs system was chosen for experimental study because (*i*) the pseudobinary phase diagram has been shown to contain a eutectic (13-15) and (*ii*) the difference between the lattice parameters of Ge and GaAs is very small (~0.004Å), providing an excellent lattice match at the phase boundaries.

Apparatus and Procedures

Mixtures of GaAs and Ge of the approximate eutectic composition (75 atomic percent Ge) were melted in 1-cm-diam graphite crucibles contained in evacuated quartz ampuls. The melt height was about 2 cm. The solution was solidified directionally in a vertical Bridgman apparatus by lowering the ampul through a heater at a rate of about 2 mm hr^{-1}. Although the measured vertical temperature gradient in the furnace was about 25°C cm^{-1}, the actual gradient in the melt during solidification could have been much lower because of the heat-leveling effect of the ampul. The ingots were cut parallel and perpendicular to the solidification direction and polished using Linde A and B.

The electrical properties of bulk samples were determined by Hall effect measurements. Compositional analyses and compositional microprofiles were obtained by energy dispersive x-ray analysis (EDAX Model 5-150), electron spectroscopy for chemical analysis (Perkin-Elmer ESCA-SAM Model 550), and scanning Auger microscopy (Perkin-Elmer SAM Model 590). Microstructures were determined by examination with the optical microscope and the SEM (Cambridge Stereoscan Model 150).

Results and Discussion

A characteristic feature of the microstructure of the material is facetted grains, as shown in Fig. 1. The grains were delineated by plasma (LFE-PDE 100 CF_4-O_2) and chemical [AB etch, Ref. (16)] etching. The grain size ranged from about 10 to 300 μm, and the larger grains were distributed toward the end of the ingot that was last to solidify.

A regular intragranular structure characterized by continuous bands of two alternating phases was revealed in several grains in unetched samples, as shown in Fig. 2. The phase of lower volume fraction occurred in 0.1-0.4 μm wide bands with an average separation of about 1.3 μm. The delineation of the structure apparently resulted from preferential polishing. The average concentration of Ga, Ge, and As in the regions depicted in Fig. 2, as determined by EDAX measurements, corresponded to the original composition of the melt. ESCA studies confirmed the presence of Ga and As in compound form and of elemental Ge (see Table I). The

spatial relationship between the structures revealed by the SEM (Fig. 2) and the actual distribution of the compounds was studied by making SAM compositional profiles across the aligned structures. The results (Fig. 3) showed that the Ge and GaAs phases did indeed alternate along the surface of the sample. Examination of regions depicted in Fig. 2 before and after chemical etching for 1 sec revealed that the regular structure extended continuously only within one grain; the relative orientation of the regular structure from grain to grain appeared to be random.

The intragranular structure of most of the grains in the plasma-etched samples was characteristic of a rod-matrix structure, where bundles of aligned rods in the different grains intersected the surface of the sample at random angles. The rods appeared to be aligned close to perpendicular to the sample's surface in several grains, as shown in Fig. 4. The projections corresponded in diameter and spacing to the GaAs phase depicted in Fig. 2.

The results above show that the Ge-GaAs eutectic can be grown with a regular structure over regions on the order of 100 μm wide. However, the question arises as to the cause of the facetted grains. This issue is discussed below in the light of prevailing theoretical models (18-25).

Hunt and Jackson (22) have treated the general problem of the microstructure of two-phase materials by extending Jackson's (26) original work describing single-phase materials in which he correlated the growth kinetics and morphology of the solid-liquid interface with the α-factor.[1] They found the following three guidelines to be generally consistent with experiment: (*i*) eutectics in which neither phase forms a facet ($\alpha < 2$ for both phases) have regular rod-matrix or lamellar structures; (*ii*) eutectics in which both phases form facets ($\alpha > 2$ for both phases) have irregular structures; (*iii*) eutectics in which one forms a facet ($\alpha > 2$) and the other does not ($\alpha < 2$) have complex-regular structures (regular structures extending over small distances).

The Ge-GaAs eutectic is a borderline case according to the criteria above (see Table II). This is because Ge and GaAs crystallize in the zincblende structure, which has possible values of ϵ ranging from 0.5 to 0.75. The precise value depends on the crystallography of the phase boundaries, which is unknown. As a result, the α-factor for compounds with entropies of melting between 2.7 and 4 are close to the critical value of 2.[2]

The facetted nature of the grains, taken with the regular structure within each grain, indicates complex-regular behavior overall. However, this assignment is not definitive for three reasons. First, although a crystallographic relationship is often observed between grains in a complex-regular structure (22), the orientation of sets of rods from grain to grain in Ge-GaAs appears to be random. Second, the experimentally determined average rod spacing is an order of magnitude smaller than expected. Atoms rejected into the

[1] $\alpha = \epsilon \Delta S/R$ where $\Delta S/R$ is the dimensionless entropy of melting and ϵ is the ratio of nearest neighbor coordination in the plane of the growth front to that in the bulk.

[2] More detailed calculations of the single-phase α-factors taking into account the effects of compound formation and solid-solid miscibility (25, 26) could not be made because the phase diagram is not known in sufficient detail to obtain the necessary thermodynamic parameters.

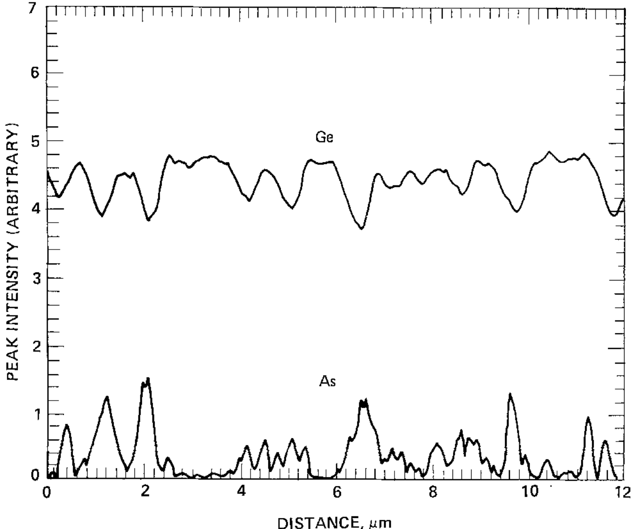

Fig. 3. Scanning Auger compositional microprofile taken across aligned structures depicted in Fig. 2. The experimental resolution was about 2000Å. As a result, the electron beam was always incident on some region of the Ge matrix.

melt at the growth interface ahead of one phase diffuse laterally and incorporate with the adjoining phase. The size and spacing of the microstructural features therefore decrease as the growth rate increases and the diffusion coefficients decrease. For comparison, the lamellar spacing of Pb-Sn (1) solidified at a rate corresponding to the present experiments was about 7 μm. Because the diffusion coefficients of Ga, Ge, and As are higher than Pb and Sn under the respective growth conditions (29, 30), rod spacings of at least 10 μm were anticipated for the Ge-GaAs system. Third, the gradation of the grain size along the ingots is inconsistent with a constant solidification rate.

One explanation consistent with these observations is that, in the present experiments, solidification occurred rapidly and uncontrollably from an undercooled melt. This situation was possible because the melts were not seeded. Solidification under these conditions could account for the facetted grain structure.

Further evaluation of the microstructure showed that, from a consideration of the surface energy of the phase boundaries (23), a rod-matrix structure is favored over a lamellar structure when the volume fraction of one phase is less than $1/\pi$. On this basis, the directionally solidified Ge-GaAs eutectic would be predicted to have a microstructure of GaAs rods in a Ge matrix (see Table II), which is in agreement with the present experimental results. A lamellar structure should be possible by adjusting the melt composition off the eutectic (1).

Hall measurements indicated that the Ge-GaAs composite is p-type with a free carrier concentration greater than 8×10^{19} cm^{-3}. The degenerate doping behavior probably results from mutual doping: Ge is an acceptor in GaAs; Ga, an acceptor in Ge with a distribution coefficient of about 0.1, is incorporated at a higher concentration than As, a donor with a distribution coefficient of 0.02.

Because our analysis of the directionally solidified Ge-GaAs eutectic showed that a regular structure was possible, a survey was conducted to find other potential *in situ* semiconductor heterostructure materials. Several pseudobinary phase diagrams of group IV, III-V, and II-VI materials have a eutectic, as shown in Table II. The microstructures predicted on the basis of volume fraction and single phase α-factor criteria are indicated. The properties of the composites were evaluated by comparing the relative properties of each phase: The application of heterostructures generally depends on the property variations across the heterointerface. The refractive index, optical bandgap, and electrical resistivity were compared for illustration (see Table II). The properties of the individual phases were used for comparison, and the effects of mutual doping could not be assessed quantitatively in the absence of detailed phase diagrams. The property difference, or property ratio, varied widely from composite to composite. Further, in the case of the GaAs-CrAs and InP-CrP composites, a high resistance ratio is anticipated because Cr, as a deep acceptor, would cause semi-insulating behavior in these compounds (32, 33).

Summary and Conclusions

This investigation shows that a two-phase, aligned array of Ge and GaAs can be produced by directional solidification. Alignment was observed to extend in grains over distances of up to 300 μm. We concluded that the small size of the microstructural features within the grains and the formation of the grains themselves could have resulted from rapid and uncontrolled solidification from a supersaturated melt. Future work with Ge-GaAs will include seeded growth experiments to prevent supersaturation and to determine whether or not rod alignment can be promoted over greater distances. An evaluation of potential *in situ* heterostructure materials containing group IV, III-V, and II-VI compounds indicates that regular structures could be achieved in many cases because the α-factors are similar to that of Ge and GaAs. Mutual doping was identified as a fundamental limitation to the control of the electrical and optical properties of some of these materials.

Acknowledgments

The author wishes to acknowledge the patient and skillful assistance of Merry Nell Colborn with the SEM analysis. The contribution of Dr. Marion Clark in making the plasma etching studies is deeply appreciated. Dr. John Moulder of Perkin-Elmer (Surface Science Division, San Jose, California) is gratefully acknowledged for conducting the ESCA and SAM analyses.

Manuscript received Oct. 3, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by Hughes Research Laboratories.

Ohmic Contacts to Lightly Doped n-AlGaAsSb

R. A. Milano, Raymond Chin, and Y. Z. Liu

Rockwell International Electronics Research Center, Thousand Oaks, California 91360

ABSTRACT

Two different metallization schemes, AuGe/Pt/Au and Sn/Ag/Ni have been used to fabricate ohmic contacts to lightly doped n-type $Al_xGa_{1-x}As_ySb_{1-y}$ ($x \sim 0.3$, $y \sim 0.01$). The electrical characteristics of each have been studied and the metallurgy has been examined using Auger electron spectroscopy (AES) sputter analysis. The results show that the AuGe/Pt/Au system is undesirable owing to the rapid diffusion of Au and Ge into the AlGaAsSb, even at very low temperatures (275°-300°C). The Sn/Ag/Ni system, however, forms a satisfactory ohmic contact and all of the constituents remain in a very shallow region near the semiconductor surface. The lowest specific contact resistance for this system is 1.3×10^{-3} Ω-cm² obtained at an alloy temperature of ~425°C.

The quaternary alloy AlGaAsSb is an important material for the fabrication of optoelectronic devices. To date, lasers (1), detectors (2), and solar cells (3) have been fabricated using AlGaAsSb. More recently, the observation of charge transfer (4) in this material has stimulated work on the fabrication of a heterojunction CCD imager to respond in the 1-2 μm spectral region. Ohmic contacts are an important component of all of the above listed devices. In order to optimize the device performance, it is necessary to fabricate contacts with the lowest possible contact resistance. The formation of ohmic contacts to a CCD channel layer is particularly difficult because of the doping and layer thickness requirements necessary for optimum performance. Typically $N_D - N_A \sim 1\text{-}3 \times 10^{16}$ cm^{-3} and $d \leqq 1.0$ μm. The constituents of the contact must form a shallow, heavily doped region. The use of a rapidly diffusing element may result in the formation of ohmic contacts; however, the *I-V* characteristics of the underlying p-n heterojunction will be degraded.

Ohmic contacts to p- and n-type AlGaAsSb are usually formed with Ag-Mn (1, 3) and Au (3), respectively. The contacts are made to relatively thick (> 2 μm, typically) layers of heavily doped material. The fabrication of an ohmic contact to a thin, lightly doped n-type layer using Au has been attempted without success. Two new metallizations, AuGe/Pt/Au and Sn/Ag/Ni, have been used to form ohmic contacts to AlGaAsSb. The diffusion of the various elements into the epilayer after alloying has been measured using AES and the electrical characteristics have been examined.

Experimental Procedure and Results

$Al_xGa_{1-x}As_ySb_{1-y}$ ($x \sim 0.3$, $y \sim 0.01$) layers were grown on n⁺ and p⁺ GaSb substrates by LPE using a slider boat apparatus (5). The initial growth temperature was 500°C and the cooling rate was 1.5°C/min. Te was used as the dopant. Differential *C-V* analysis was used to determine the doping and layer thickness. For all samples used in these experiments, $N_D - N_A \approx 2\text{-}5 \times 10^{16}$ cm^{-3} and $d \approx 0.5\text{-}1.0$ μm. Standard photolithographic techniques were used to define an array of dots on each wafer. The contact metals were deposited by E-beam evaporation at a pressure of $1\text{-}2 \times 10^{-6}$ Torr. Prior to deposition, the regions to be contacted were cleaned with solvents and etched with 10:1 DI:HF for 30 sec. After deposition the samples were alloyed in palladium-purified flowing H_2.

AuGe/Pt/Au Contacts

The AuGe/Pt/Au metallization consists of 2000Å AuGe (88%:12%), 150Å Pt, and 1000Å Au evaporated sequentially. Previous attempts to fabricate ohmic contacts to AlGaAsSb/GaSb n/p⁺ heterojunctions using this system have indicated that for alloy temperatures greater than 330°C the underlying heterojunction was no longer rectifying (6). The sample was, therefore, alloyed at 275°C for 2 min. The *I-V* characteristics between contact dots were measured using a curve tracer and found to be extremely nonlinear, as shown in Fig. 1. A subsequent heat-treatment at 300°C for 2 min resulted in no significant improvement. The nonlinearity of the *I-V* characteristics prevented a meaningful determination of the contact resistance.

In order to understand the nonlinear effects observed, the metallized regions were analyzed using AES sputter profiling to determine the depth of penetration of the contact constituents into the epitaxial layer. The sputtering rate used was ~1 Å/sec. The results of the analysis are shown in Fig. 2 where the Auger signal amplitude is plotted as a function of sputtering time. The Al peak defines the location of the epitaxial layer. A relatively high concentration of Ga is found at the surface. This behavior is characteristic of Au-based ohmic contacts on GaAs (7). The low concentration of Sb at the surface and its movement from the epilayer toward the surface indicates that a significant amount of Sb evolves from the surface during alloying. A similar effect is observed during Zn diffusion into GaSb (8). Both Au and Ge are present throughout the epitaxial layer and Au is found in the substrate as well. The Pt was contained in a region

between 0 and 4000 sec and has been omitted from Fig. 2 to preserve clarity.

The large Au and Ge signals located in the range of 3000-5000 sec, where a minimum in the Sb signal is located, provide a possible explanation for the observed behavior. At alloy temperatures below the AuGe eutectic temperature ($T_{eut} = 356°C$), significant movement of the constituents is not expected (7). However, if a large concentration of vacancies exist, generated by the movement of Sb towards the surface, then interstitial-substitutional diffusion due to the atom size of Au and Ge is possible. The *I-V* data shown in Fig. 1 are characteristic of field emission tunneling (9), indicating that the incorporation of Ge into the material has produced a heavily doped region to which the Au/Ga surface layer makes contact.

Sn/Ag/Ni Contacts

Ohmic contacts were formed by sequentially evaporating 100Å Sn/200Å Ag/500Å Ni. The sample was cleaved into nine pieces and each piece was alloyed for 5 min. An alloy temperature range of 275°-475°C was investigated in 25°C increments. The *I-V* characteristics between dots with varying center-to-center spacings were examined on a curve tracer. Samples that were alloyed at $\leq$350°C had nonlinear *I-V* characteristics and the resistance uniformity was very poor. For alloy temperatures $\geq$375°C, the uniformity and linearity improved significantly with the best results in the 400°-425°C range. A typical *I-V* characteristic of Sn/Ag/Ni contacts alloyed at 425°C is shown in Fig. 3. The total resistance measured between the contacts is independent of contact separation indicating that the resistance of the contact dominates the measurement. Specific contact resistance was calculated using the expression $R_c = (R_T/2)A$, where R_T is the total measured resistance between the contacts and A is the contact area (10). The minimum R_c was obtained for an alloy temperature of 425°C. At this temperature, $R_c \leq 1.3 \times 10^{-3}$ Ω-cm^2.

The results of the AES analysis of the contacts alloyed at 375° and 475°C are shown in Fig. 4(a) and (b), respectively. It is important to note that the sputtering times are 10× less than in Fig. 2. At 375°C, Ag remains localized in a region very near the surface of the semiconductor. Only a small amount of Sn has penetrated into the material. The relative positions of the Ag and Sn peaks indicate that at this temperature Sn is moving into the Ni cap layer. Alloying at 475°C produces a somewhat broader interface region; however, relative locations of Ag and Sn and the depth of penetration of each into the semiconductor is essentially unchanged. An Ni cap was originally chosen to prevent the contact metals from balling up for $T >$ 229°C (eutectic temperature of Ag-Sn). As shown in Fig. 4(a) and (b), it effectively stops the outdiffusion of Ga and Sb from the semiconductor. Very few vacancy sites are therefore available for the dopant atoms to occupy; consequently the contact resistance of this system is relatively high.

Discussion

As described by Rideout, a heavily doped region of semiconductor next to the deposited metal is necessary to form low resistance ohmic contacts (9). The heavy doping in the semiconductor allows tunneling to occur through the thin potential barrier which exists at the metal-semiconductor interface. Formation of a low resistance contact to lightly doped material then presents a problem. One possible solution is to deposit a eutectic metal(s) which has a dopant as one of its constituents. During the subsequent alloying process, the constituent which acts as the dopant diffuses into the semiconductor, thus allowing a selective ohmic contact to be formed while preserving the lightly doped material elsewhere.

Application of this technique to the quaternary AlGaAsSb requires special considerations. Owing to the low growth temperature (400°-600°C) of AlGaAsSb and hence lower bond strength, it is necessary to use alloys with low eutectic temperatures. Both AuGe and AgSn form low temperature eutectics; however, Ge is known to be a p-type dopant in solution grown AlGaSb (11) and AlGaAsSb (12), while Sn can be used to grow either p- or n-type GaSb (13).

In order to form an n-type contact, outdiffusion of Sb from the semiconductor must be prevented. This is not the case for the AuGe/Pt/Au contact, where the outdiffusion of Sb through the Pt barrier and the indiffusion of Au and Ge result in a p-type region. In the case of the Sn/Ag/Ni contact, severe Sb outdiffusion is prevented. The net effect is to create an n^+-type region at the metal-semiconductor interface. Since Sn is an amphoteric dopant (13) and a large Ga vacancy concentration is not readily available, a very heavily doped region cannot be formed. Therefore, the contact resistance is rather large.

Conclusions

In conclusion, it has been shown that Sn/Ag/Ni ohmic contacts can be formed to lightly doped ($N_D - N_A \sim 10^{16}$ cm^{-3}) n-type $Al_xGa_{1-x}As_ySb_{1-y}$ ($x \sim 0.3$, $y \sim 0.01$) epitaxial layers. Control of the column III and V vacancies must be maintained in order to allow

the desired substitution of the amphoteric doping such as Sn to occur in the proper vacancy. This can be achieved with the proper eutectic metals and alloying conditions, allowing either p- or n-type contacts to be made to AlGaAsSb.

Reduction of Defects in Ion Implanted Bipolar Transistors by Argon Back Side Damage

James A. Topich*

Tektronix, Incorporated, Beaverton, Oregon 97077

ABSTRACT

The effectiveness of argon backside implants on the reduction of defects in an implanted bipolar process has been investigated. Insertion of an argon backside implant at two places in the processing sequence has been found to be beneficial. A backside implant before initial oxidation of the wafers will minimize the density of epitaxial defects for both arsenic diffused or implanted buried layers. For diffused buried layers, the backside damage offers only minimum improvement in yield because of the gettering action of the diffused arsenic itself. For implanted buried layers, the backside damage allows for higher arsenic doses and shorter HCl etch-back prior to epi growth, resulting in lower sheet resistance while still maintaining acceptably low defect levels. Correlation of electrical parameters and crystal defects showed that small defects in the emitter, probably dislocations generated by the implanted emitter process are responsible for "piped" transistors, leaky base emitter junctions, and poor low current beta. An argon backside implant just prior to emitter processing will reduce the density of these small defects and improve device yield.

The reduction of emitter-collector shorts in bipolar integrated circuit processing is of critical importance as chip densities and circuit complexity increase. The shorts or "pipes" are caused by a number of processing-induced defects, among them epitaxial defects, oxidation induced stacking faults, slip lines, and dislocations (1). It is a well-established fact that backside damage due to ion implantation will getter metallics (2, 3) and that both MOS and bipolar circuit yield (4, 5) is improved by the inclusion of such a step in the processing sequence. The work reported here focuses on (*i*) the effect of argon backside implants on the reduction of epi defects for both arsenic diffused and arsenic implanted buried layers and (*ii*) the use of a pre-emitter argon backside implant for improving device yield.

Experimental

The test vehicle was a current production process for high frequency bipolar integrated circuits. The starting material was commercially obtained 2 in. silicon wafers, Czochralski grown, 10-50 Ω-cm resistivity, boron doped, with (111) surface orientation. The oxygen content of the wafers was not specified and the back surface was chem-mechanical polished. The nominal epi layer thickness which was grown over either the diffused or implanted buried layers was 3 microns. The active base and emitter were implanted using boron and arsenic, respectively. Resulting junction depths are approximately 0.2 microns for the base-emitter junction and 0.3 microns for the base-collector junction. Maximum f_T for the devices is in the range of 6-7 GHz.

In order to study the effects of the backside argon implants, the wafers were pulled from the normal processing sequence at various steps, stripped of all oxide and Wright etched (6) to delineate crystal defects. Some of the wafers were electrically probed after the contact openings were cut, and mapped for "piped" devices, leaky base-emitters, and poor low current beta. These wafers were subsequently Wright etched and observed defects correlated with electrical measurements.

No attempt was made to optimize or improve the overall yield by varying any of the processing parameters other than the insertion of the backside argon implant at various stages in the fabrication sequence. The only exceptions to this were the implant dose and energy for the implanted buried layer, and the HCl etch-back in the subsequent epitaxial growth step. These changes, however, were made in order to see how far the implanted buried layer process could be pushed to reduce the resulting sheet resistance while maintaining an acceptably low defect density.

Results and Discussion

Buried layer and EPI gettering.—For the diffused buried layer process, a significant reduction in overall defect density after epi growth resulted from a backside argon implant when the implant was done before initial oxidation. Figure 1 shows a comparison of two wafers processed identically except that wafer (b) was implanted on the backside with argon at a dose of 1×10^{16} cm^{-2} and an energy of 190 keV. Defect reduction for wafer (b) however, is primarily in the field region and not over the buried layer regions where the active devices will be subsequently fabricated. The lack of defects in the buried layer regions for both wafers (a) and (b) can be attributed to the gettering effect of high arsenic concentration diffusion which annihilates the small stacking faults formed during the initial silicon oxidation (7). These stacking faults, which show up as small saucer or S-pits when preferentially etched, act as nucleation sites for defects in the epitaxial layer. With the backside argon implant, epi defects are also eliminated in the field region due to dislocation networks generated in the backside by the implantation process. These dislocations getter metallics (8) which can precipitate and form the previously mentioned S-pits. The TEM photo in Fig. 2 shows the interference fringes of one of these small stacking faults and resulting strain contrast due to the precipitates.

During the initial gettering studies, rather high doses and energies were used for the backside implant. Further tests showed that these parameters could be reduced substantially while not only maintaining but improving gettering efficiency. The stacking fault density after epi growth as a function of argon dose implanted at 100 keV is shown in Fig. 3. The transition around a dose of 2×10^{14} cm^{-2} coincides quite closely with the argon dose needed to produce an amorphous layer in silicon. The decrease in gettering efficiency at the higher doses is believed to be due to precipitation of the implanted species around the dislocations, thus

reducing their effectiveness in gettering metallics (8). A dose of 5×10^{14} cm^{-2} at 100 keV is sufficient for producing the desired gettering effect. Since most of the experimental runs were started before the minimum argon dose and energy were determined, the results presented here are for higher doses and energies.

Fig. 2. TEM photo of small stacking fault formed during initial oxidation.

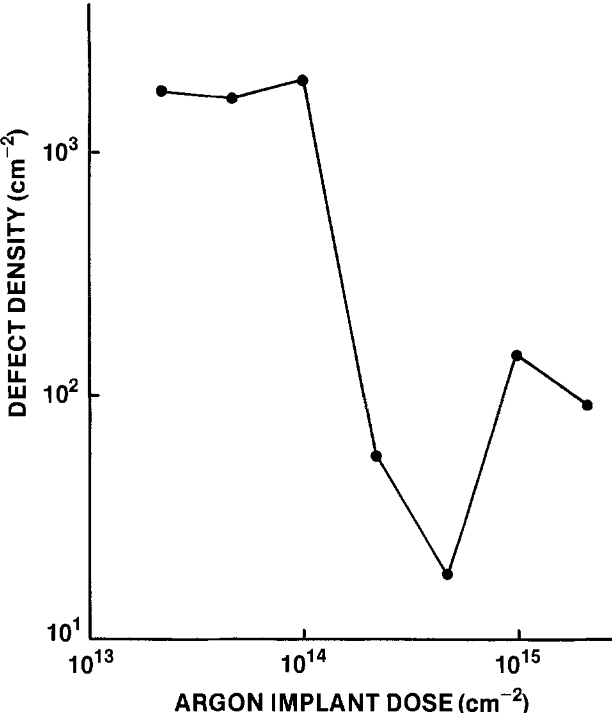

Fig. 3. Stacking fault density after epi growth as a function of argon backside dose.

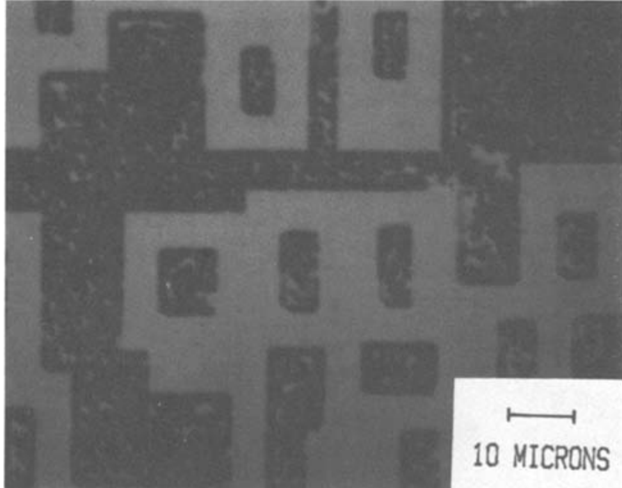
For arsenic implanted buried layers the defect problem is of a different nature than that of diffused buried layers. If drive cycles after a buried layer implant and HCl etch-back prior to epi growth are not optimized, a large number of defects can be generated over the buried layer regions. These defects, directly in the active device areas, are extremely detrimental to device performance and circuit yield.

Appropriate drive cycles for the implanted buried layer and epi growth conditions have been reported previously (9) and are only briefly outlined below. After a buried layer implant of 5.5×10^{15} arsenic ions per cm^2 at 50 keV, a two-step anneal is used. The first is a 600°C soak in dry oxygen for 1 hr. This is above the recrystallization temperature for silicon (550°C) and allows for the solid-state epitaxial regrowth of the amorphous layer. The second is a 30 min ramp from 1100° to 1250°C, a 1 hr soak at 1250°C, and slow ramp back to 1100°C. This process serves to fully activate and drive in the implanted arsenic ions as well as removing residual defects remaining after the low temperature anneal. This annealing cycle is also done in a dry oxygen ambient. A recent paper (10) reported that a low defect density could not be obtained for arsenic implanted buried layers if the drive-in is done in an ambient containing more than 10% oxygen. The anneals used in this work were conducted in 100% oxygen and essentially defect-free buried layers were obtained.

The depth of silicon removed by the HCl etch-back prior to epi growth was also found to be critical for obtaining low defect densities. It was determined experimentally that approximately 0.4 microns of silicon had to be etched away in order to achieve an acceptable low defect density in the epi layer.

The above-mentioned processing can be used to obtain epi layers with low defect densities even without the use of an argon backside implant. With the implant however, some processing constraints can be relaxed resulting in lower sheet resistance for the buried layer while still maintaining at low defect density. Figure 4 shows photomicrographs of two wafers, one with a backside implant and one without. The buried layer implant and epi parameters were not optimized for these samples in order to demonstrate defect reduction achieved with a backside argon implant. A significant



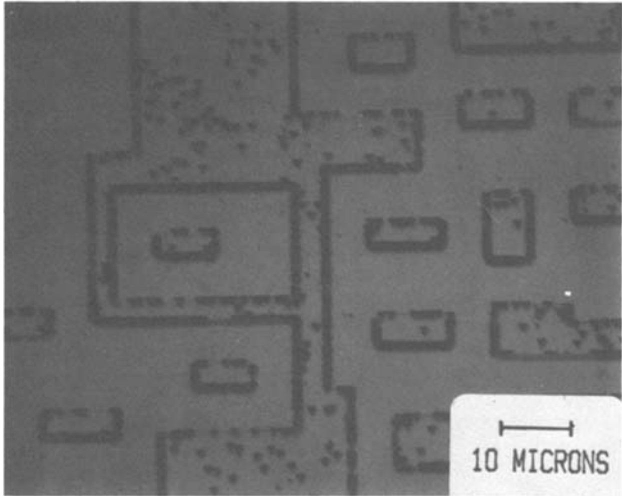


Fig. 4. Defect reduction for implanted buried layers (a, top) without backside damage (b, bottom) with backside damage.

improvement is evident with the backside implant, but it does not completely eliminate defects. Figure 5 shows defect densities observed after epi growth for various arsenic buried layer dose-energy products using optimized anneal and epi processing parameters and an argon backside implant of 1×10^{16} at 190 keV before initial oxidation. A reasonable correlation is shown between the buried layer dose-energy product and the defect density. For comparison, a buried layer implant with a dose energy product of 400×10^{15} keV-cm^{-2} (50 keV $\times$ 8 $\times$ 10^{15} cm^{-2}) and without the backside implant had a defect of over 1600 cm^{-2} which is well off the figure. The implant parameters used in the production process mentioned previously give a dose-energy product of 275×10^{15} keV-cm^{-2}, resulting in a defect density on the order of 100 per cm^2.

The use of a backside argon implant also permits a decrease in HCl etch-back prior to epi growth while still maintaining an acceptably low defect density. Figure 6 shows data from a number of tests where parameters such as HCl flow rate, etch-back time, and buried layer implant dose were varied. The two lines were fitted to data points from samples which received a backside argon implant, but were subjected to different HCl etch-back conditions. The 0.1 micron/min etch rate is used in our lab for arsenic diffused buried layers while the 0.4 micron/min etch rate is used for arsenic implanted buried layers. A 1 min etch time is typically used, but in these tests times of 20, 40, and 60 sec were used. For a given implant dose there were only small variations in defect densities for the three different etch times at each etch rate. These variations did not always correlate with the etch time, thus for the sake of clarity only the two solid lines corresponding to the data are shown without the data points. It can be said however, that an HCl etch-back which removes approximately 0.13 microns of silicon is sufficient for implant doses up to 7×10^{15} cm^{-2} on wafers which have previously had a backside argon implant, a similar set of HCl etch-back tests were conducted using the same buried layer implant doses but without the backside implant. Results from these tests are shown as the data points in Fig. 6. Again, there was no correlation between the etch time used and the observed defect densities, but the data spread was almost three orders of magnitude. It is obvious that without the argon backside implant the defect density is quite unpredictable. Some samples may have a very low defect density while others which underwent similar processing have unacceptably high defect densities.

The curves in Fig. 7 show the interrelationship between the arsenic implant dose, HCl etch-back time (at an etch rate of 0.4 microns per minute), and resulting buried layer sheet resistance prior to epi growth. Final sheet resistance is smaller than the pre-epi value due to increases in carrier mobility as the arsenic concentration per unit volume decreases due to diffusion. For the implanted buried layer process as originally developed, a dose of 5.5×10^{15} cm^{-2} and an HCl etch-back of 60 sec were used. This gives a sheet resistance of approximately 18 Ω/square. With the

Fig. 5. Defect density as a function of buried layer dose-energy product.

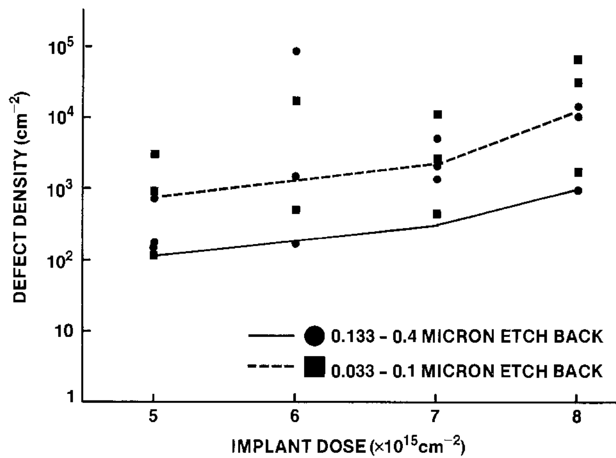

Fig. 6. Effects of HCl etch-back and implanted buried layer dose on epitaxial defects.

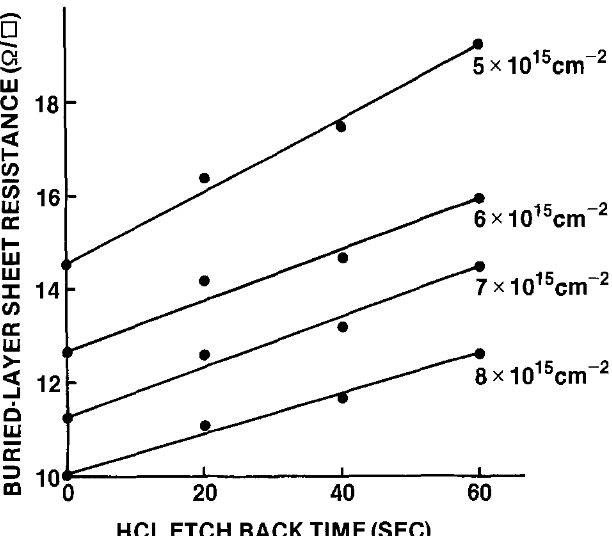

Fig. 7. Buried layer sheet resistance as a function of arsenic dose and HCl etch-back time at an etch rate of 0.4 microns per min.

argon backside implant, the buried layer dose could be increased to 7×10^{15} cm^{-2} and the HCl etch-back time decreased to 20 sec, with a subsequent drop in the buried layer sheet resistance to 12 Ω per square. Lower sheet resistance can be used to improve the high frequency performance of the resulting transistors.

When an argon backside implant was incorporated into the complete bipolar processing sequence using either diffused or implanted buried layers, no significant yield improvement or change in yield distribution was observed and the percentage of test transistors with emitter-collector shorts remained essentially the same. Such results were not unexpected since the diffused buried layer acts as a getterer itself, almost completely eliminating epi defects in the active regions. The argon backside implant serves only to reduce the defect density in the field regions away from the active devices as was shown in Fig. 1. The implanted buried layer process conditions (anneal, drive-in, and epi) had already been optimized for low defect levels (9), thus the argon backside implant was not expected to offer significant improvement.

Base and emitter gettering.—Poponiak, Nagasaki, and Yen (5) showed that an argon backside implant before emitted processing significantly reduced the number of "piped" devices. Because of that work a number of gettering techniques were incorporated into the bipolar process previously mentioned, and the resulting defects were studied at various stages of the processing sequence. The gettering techniques employed were backside argon implants (*i*) before initial oxidation, (*ii*) before base processing, or (*iii*) before emitter processing and phosphorus backside diffusion. Also included for comparison were wafers where no intentional gettering was used. (Phosphorus backside diffusion was done during deep collector processing early in the fabrication sequence and is not as effective as that done during a phosphorus emitter diffusion because of the many high temperatures processes still to be performed in which defects can be generated and impurities introduced.)

When samples were stripped of all oxide and Wright etched after emitter processing was completed, two types of defects were observed. One was large epi stacking faults which occurred primarily in the field region of those wafers which did not receive a backside implant before initial oxidation. The other was a small defect that occurred primarily in the P+ base contact and the emitter regions; these were called "shallow pits" because of their appearance. From our observations, these defects are not formed until base P+ contacts or emitters are implanted. They are most likely dislocations generated by the implant process and decorated with metallics.

Figure 8 shows defect densities for both epi stacking faults and shallow pits as observed after emitter processing, for each of the gettering techniques incorporated into the diffused buried layer process. The argon backside implant before initial oxidation is shown to be most effective in reducing epi stacking fault density; this is as expected considering the formation mechanism. The largest reduction in shallow pit density occurred for an argon backside implant just prior to emitter processing. This is most probably due to metallic contaminants being pulled to the backside, having been introduced and/or redistributed during various high temperature processing steps. No other gettering technique studied came close to the backside implant before emitter processing in reducing shallow pit defect density.

In order to correlate poor device performance with crystal defects in the silicon, a mask set was used which contained a 2000 μm^2 emitter test transistor on each chip. This large device area permitted electrical measurements to be made without the need of metallization. Thus it was possible to map the wafers for "piped" transistors, leaky base-emitter junctions, and poor low current beta and then remap for defects after Wright etching. In this way a direct correlation between electrical performance and crystal defects could be made. Many of the devices had both emitter-collector shorts and leaky base-emitter junctions but were put only in the "piped" transistor category for the statistical analysis.

For the processing runs from which the data in Table I was collected, only one epi stacking fault was found in any of the emitters after Wright etching. Shallow pits, however, were found in many of the emitter regions. Those wafers which received an argon backside implant before emitter processing had a much lower incidence of pits. The use of an argon backside implant before initial oxidation either alone or in conjunction with the pre-emitter backside implant did not of itself affect the shallow pit density.

Table I lists the results of the correlation between poor electrical performance and the presence of shallow pits in the emitter regions. It should be pointed out that when the term "gettered" is used in Table I it refers only to pre-emitter argon backside implant gettering. The results show that (*i*) pre-emitter argon backside implant reduces the incidence of shallow pits, (*ii*) piped transistors, leaky base-emitter junctions, and poor low current beta can be strongly correlated to the

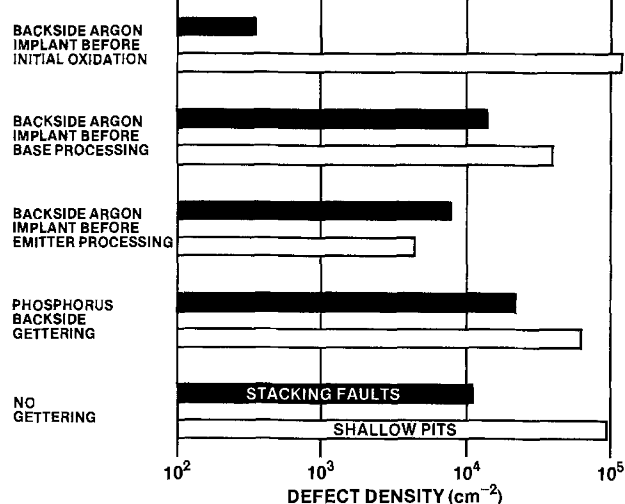

Fig. 8. Defect densities for both epi stacking faults and "shallow pits" for various gettering techniques observed after emitter processing.

Table I. Results of correlation between electrical parameters and "shallow pits" in the emitter

	Gettered	Ungettered
Number of devices tested	418	380
Number of devices with "shallow pits"	45	214
Number of "piped" devices	9	38
Number of "piped" devices with "shallow pits"	4	36
Number of leaky base-emitter junctions	0	52
Number of leaky base-emitter junctions with "shallow pits"	0	52
Number of devices with poor low current beta	0	8
Number of devices with poor low current beta and "shallow pits"	0	7

presence of these shallow pits, (*iii*) a shallow pit in the emitter is not always detrimental to performance as the 62% good devices with shallow pits indicates. Approximately 1% of the devices tested had poor electrical performance, but no defects were observed in the emitters. This may have resulted from the Wright etch washing out a very small pit since the etch consumed a quantity of silicon greater than the original active device depth, or there may in fact not have been a defect in those devices.

Some wafers which did not receive a pre-emitter argon backside implant were probed and mapped for electrical performance. There were appreciable numbers of piped devices, leaky base-emitter junctions, and devices with poor low current beta. The wafers then received a post-emitter argon backside implant and a 30 min anneal at 900°C in argon. The thermal cycle would not have a detrimental effect on the impurity profiles. When the wafers were reprobed after the gettering step only one spiked device remained. All others had normal transistor characteristics. When the wafers were Wright etched only 5% of the devices had shallow pits in the emitter. The "piped" device that remained had an epi defect in the emitter which was not affected by the post-emitter gettering. These results are contrary to the results of Barson, Klepner, and Seto (11) who found that the "pipes" in their relatively deep structures were not cured by a post-emitter gettering step even though the gettering did reduce the number of soft diodes. This apparent inconsistency can be reconciled by considering that the devices of this study were fabricated with very shallow junctions, and defects associated with shallow pits can be in many instances sufficiently long so as to traverse the entire base width. For the deep devices used in Ref. (11) it is quite possible that two different defects were responsible for "piped" devices and soft junctions, and only one was affected by the post-emitter annealing. The fact that the "piped" devices in this study could be cured by a post-emitter argon backside implant gettering step indicates that collector-emitter leakage is not due to enhanced diffusion of the arsenic from the emitter along the defect, but most likely it is due to metallic precipitates.

Conclusions

Use of an argon backside implant in silicon wafer processing can result in a reduction of crystal defects. The type of defect minimized and the ultimate effect on circuit performance depends on when the backside implant is incorporated into the fabrication sequence. A backside implant prior to initial oxidation can reduce epitaxial defects for both diffused and implanted arsenic buried layers. This will not necessarily improve circuit yield since both processes can be implemented so as to minimize epitaxial defects in the active device regions without a backside implant. For the implanted buried layer process however, use of an argon backside implant allows for an increase in the arsenic implant dose and/or a decrease in the HCl etchback prior to epi growth. Both of these changes provide lower buried layer sheet resistance while still maintaining low defect levels.

The defect found to be primarily responsible for the majority or "piped" transistors, leaky base-emitter junctions, and poor low current beta for the process described appears as "shallow pits" when Wright etched. These defects can be greatly minimized by an argon backside implant immediately prior to the arsenic emitter implant. Resulting reduction in "shallow pit" density correlates with the reduction in the percentage of "piped" transistors, leaky base-emitter junctions, and poor low current beta. These defects, associated with the implanted emitter, can be cured by a post-emitter gettering step using a backside argon implant, but the most logical procedure is to incorporate the backside implant prior to emitter processing and utilize the emitter drive cycle to activate the gettering action.

Conductivity Profiling of GaAs/(AlGa)As Multilayer Structures

J. L. Zilko and P. J. Anthony

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A simple method for profiling the conductivity of GaAs/(AlGa)As multilayer structures is presented. The technique consists of step etching the sample using a chemical etch while measuring sample resistance after each etch step. An annulus geometry is used for the electrical measurement with the contact metallization also serving as an etch mask. Sample preparation is simple so that the technique can be used as a routine process monitor. The results from profiling single and multilayer heterostructure (AlGa)As laser materials grown by liquid phase epitaxy (LPE) are presented. Of particular interest is the ability of this technique to measure the resistivity of underlying layers.

The electrical conductivity of the various layers of multilayer GaAs/(AlGa)As structures, such as those that make up heterostructure lasers, can strongly affect the performance of the devices. For example, a high resistance P-(AlGa)As confinement layer in heterostructure lasers can significantly increase the lasing threshold current and its temperature dependence (1-3). However, several investigators (4, 5) have noted that the measured conductivity of a liquid phase epitaxial (LPE) Ge-doped $Al_{0.4}Ga_{0.6}As$ layer in a multilayer structure can be substantially different from that of a similar single layer grown on a semi-insulating substrate. Thus, the ability to measure the conductivity of the actual multilayer structures including underlying epitaxial layers is of primary importance for the evaluation of crystal growth processes and device material. While the conductivity of single layers can be determined from capacitance (6) or Hall effect (7) techniques which are relatively straightforward and easily interpretable, this is not the case for layers buried within multilayer structures. The conductivity of moderately or highly doped layers is particularly difficult to profile due to the decrease in depletion layer width with doping level.

In this paper, we present a simple technique for measuring the conductance of multilayer structures as a function of depth using chemical etching of the layers. Several examples of the resulting conductance profiles are given for both single layer and multilayer structures and the sources of error in this measurement technique are discussed.

Experimental

Crystal growth was accomplished by conventional LPE techniques (8) using the source-seed method (9). The substrates were Si-doped n^+-GaAs which were degreased and etched immediately prior to insertion into the LPE reactor. Single layer (AlGa)As, 6-layer experimental structures, and 4-layer laser structures were grown. The laser structures consist of N-$Al_{0.4}Ga_{0.6}As$, p'-$Al_{0.08}Ga_{0.92}As$, P-$Al_{0.4}Ga_{0.6}As$, and p^+-GaAs layers grown sequentially on the n^+-GaAs substrate. The layer thicknesses ranged from 1.50 to 2.50 μm for the N layer, 0.1 to 0.2 μm for the p' layer, 0.8 to 1.8 μm for the P layer, and 0.4 to 0.8 μm for the p^+ layer.

The conductance profiling was carried out by incrementally chemically etching the sample, followed each time by a measurement of the sample resistance. The sample geometry consisted of an annulus as shown schematically in Fig. 1 with electrical contact made at the center and outer contact pads. This geometry was chosen in order to eliminate edge effects and minimize the effects of misalignment of the contacts on the measurement (10). Junction isolation confined the current to the p-type layers close to the surface. The inner diameter of the annulus was 0.15 cm, the outer diameter 0.30 cm, and typical sample dimensions were 0.4 by 0.4 cm. For a laterally homogeneous single layer with annular contacts, the measured resistance is

$$R_s = \frac{\ln r_2/r_1}{2\pi} \frac{1}{\int_0^t dx/\rho(x)} \quad [1]$$

where $\rho(x)$ is the depth dependent resistivity and r_2/r_1 is the ratio between the outer and inner radii of the annulus. In this expression we assume that the effective resistance of the layers under the contacts is negligible compared to the resistance between contacts. Equation [1] can be rewritten in a more useful form as

$$\frac{d(1/R_s)}{dx} = \frac{2\pi/\rho(x)}{\ln r_2/r_1} \quad [2]$$

The multilayer structures in general consist of a series of layers each with a constant value of resistivity so that, for example, as profiling is carried out through the p^+-GaAs layer, Eq. [1] becomes

$$\frac{d(1/R_{p^+})}{dx} = \frac{2\pi/\rho_{p^+}}{\ln r_2/r_1} \quad [3]$$

Similar expressions can be written as etching proceeds through subsequent layers. In addition, for controlled etching conditions, the distance etched into the sample

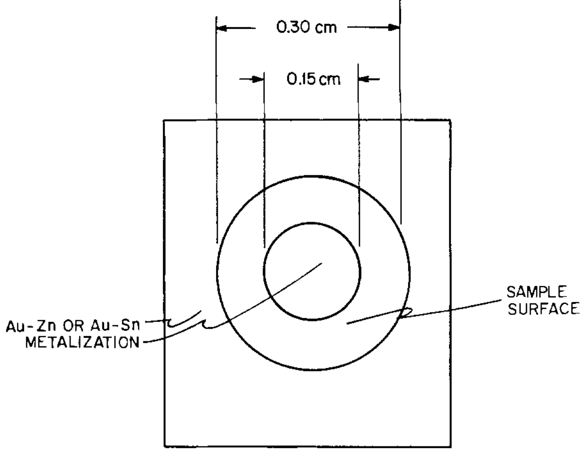

Fig. 1. Sample geometry for conductance profile measurements

Key words: heterostructure, resistivity, etching.

is proportional to time. Thus, a plot of $1/R_s$ *vs.* etch time for the entire sample should give a series of straight lines with slopes inversely proportional to the resistivities of each p-type layer.

Ohmic contacts were made to the P or p^+ surface by evaporating an Au-Zn alloy through a contact mask. These contacts also served as the etch mask. Simple press contacts were made to the metallization. The voltage applied between contacts was kept constant at 0.1V in order to maintain junction isolation of the p-type layers from the n-type layers, and the current flowing through the sample was monitored at each step.

The samples were etched with voltage applied to the sample contacts using a solution consisting of H_2SO_4, H_2O_2, and H_2O in volume ratios of 40:1:1 or 10:1:1 at room temperature. The 10:1:1 etch is faster than the 40:1:1 and proved useful in profiling samples with thick layers.

A controlled amount of the etch was applied to the sample surface for a time of 5 ± 0.5 sec after which the etch was washed away by $\sim 10^6$ Ω-cm deionized water. No evidence was found to suggest electrochemical etching. It was noted that careful degreasing of the samples prior to metallization prevented separation of the metallization from the semiconductor surface during etching.

The layer thickness and etch rate of each sample was measured after resistance profiling using scanning electron microscopy (SEM) of cleaved and stained sample edges. The etch rate of GaAs and (AlGa)As was generally found to vary spatially by less than 10%. In addition, the etch rate of each layer appeared to be time independent. Both the small lateral dimensions of the sample and the short time of each etching increment improve the controllability of the etch. Figure 2 is an SEM micrograph of the cleaved cross section of a profiled laser structure showing the edge of the etched region. In order to improve contrast, the sample was etched for 30 sec in a solution consisting of H_2O_2 and NH_4OH at a pH of 7.5 which preferentially attacks binary material (11). The four epitaxial layers as well as the metallization can be seen in this figure. Etching was carried out in this case through the p^+, P, and p' layers to the N-(AlGa)As layer.

Results

Figure 3 is a plot of sample conductance, $G \equiv 1/R_s$, as a function of etching time for a p-type Ge-doped $Al_{0.4}Ga_{0.6}As$ single layer grown on an n^+-GaAs substrate. The layer thickness was 4.0 μm. G varies approximately linearly with etching time indicating a constant value of ρ. The value of ρ obtained from the

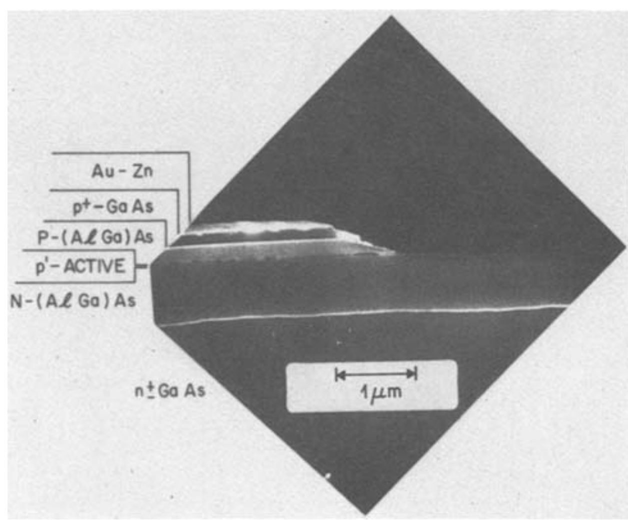

Fig. 2. SEM micrograph of the cleaved cross section of profiled heterostructure laser material.

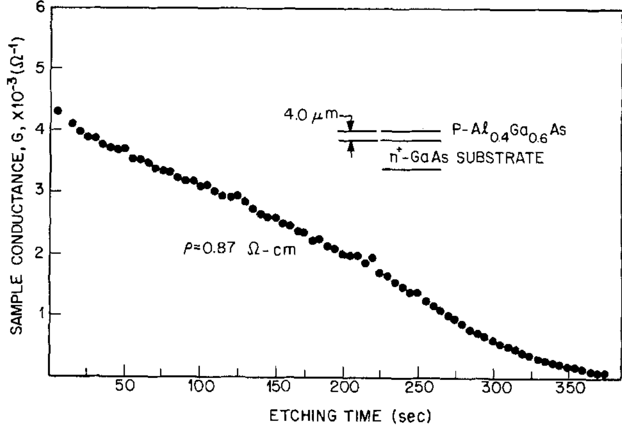

Fig. 3. Sample conductance as a function of etching time for a p-type $Al_{0.4}Ga_{0.6}As$ single layer grown on an n^+-GaAs substrate.

slope of the G *vs.* etch time curve in Fig. 3 and the layer thickness was 0.87 Ω-cm. We have generally found the value of ρ measured by the profiling technique to be within 20% of the value of ρ obtained from Hall effect measurements.

Figure 4 is a conductance profile of a typical laser structure obtained using the 40:1:1 etch. Only the p^+-GaAs and P-(AlGa)As layers can be distinguished. The thin (~1000Å) p' layer buried beneath the p^+ and P layers is partially inaccessible within the junction depletion width and is not identifiable in the measurements. Because most of the current is initially shunted through the high conductivity p^+-GaAs, the conductance decreases rapidly as etching proceeds through that layer. The lower conductivity of the P-(AlGa)As layer results in a less rapid decrease in G with etch time. The measured resistivity of the p^+ layer is 1.5×10^{-2} Ω-cm compared to 0.24 Ω-cm for the P layer. The measured value of ρ_{p^+} is thus a factor of 17 less than that of ρ_P for this sample. The conductance profile of a second similar standard laser structure is shown in Fig. 5. The profile in Fig. 5 has the same general appearance as the profile in Fig. 4 but with values of ρ_{p^+} and ρ_P of 1.6×10^{-2} Ω-cm and 0.55 Ω-cm, respectively. Conductivity profiling of a large number of wafers has indicated that the conductivity of the P layer can be perturbed by over a factor

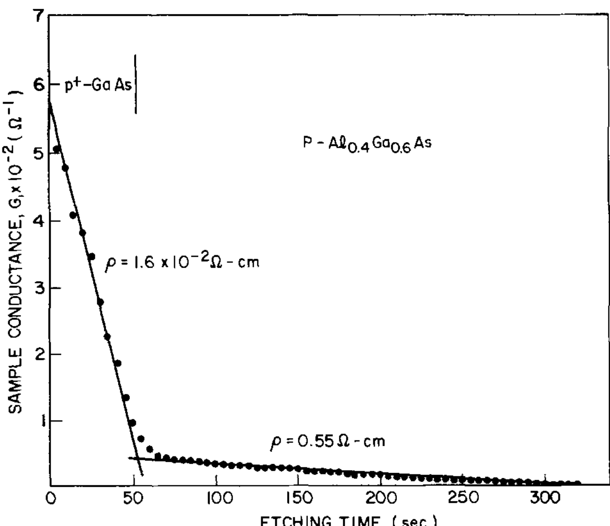

Fig. 5. Sample conductance as a function of etching time for heterostructure laser material from a second wafer.

of 5 by changes in LPE process variables and the profiling technique has been used as a primary analytical tool for this study. The results of this study will be discussed in detail in a future publication.

In order to demonstrate the depth resolution that can be achieved using this technique, a 6-layer structure consisting of N-$Al_{0.4}Ga_{0.6}As$ (2.5 μm), p'-$Al_{0.08}Ga_{0.92}As$ (0.1 μm), P_1-$Al_{0.4}Ga_{0.6}As$ (1.1 μm), p"-$Al_{0.12}Ga_{0.88}As$ (0.15 μm), P_2-$Al_{0.4}Ga_{0.6}As$ (0.6 μm), and p^+-GaAs (0.5 μm) layers was grown sequentially on an n^+ substrate. The doping levels for the P_1, P_2, and p" layers were chosen such that $\rho_{P_2} > \rho_{P_1} > \rho_{p''}$. The conductivity profile was obtained using 10:1:1 etch and is shown in Fig. 6. The p^+ layer has been eliminated for clarity. The profile indicates that $\rho_{P_2} > \rho_{P_1} < \rho_{p''}$ as predicted from the doping levels. More importantly, the 0.15 μm thick p" layer is observable in the profiles even at a depth of over 1 μm beneath the surface and even using the relatively fast 10:1:1 etch. This indicates that etching proceeds uniformly through the layers using the step etching technique and that thin layers beneath the surface can be adequately profiled.

Discussion

Using a simple step etching technique, the conductivity of a variety of single and multilayer structures can be measured. Of particular interest is the ability to measure the conductivity of buried layers that are difficult to measure using other techniques. A conductivity profile of a laser structure can typically be done in 30-40 min after contact formation so that this technique can be used as a routine process monitor for device material.

The principal errors of this measurement are: (*i*) spatial variations in layer thicknesses, (*ii*) spatial variations in the etch rate, (*iii*) errors in the time of each etch step, (*iv*) variations of the sample temperature during measurement, and (*v*) lateral inhomogeneities in the resistivity. It was found that spatial inhomogeneities in layer thickness were typically ~20% and that etch rate variations across a sample were typically less than 10%. The primary effect of these errors is to make the measured interface between the p^+ and P layers more diffuse. Errors in the length of each etch increment are estimated to be generally ±10% although the error can be greater than that for isolated data points. The effect of this source of error is diminished by the use of a large number of data points. Sample temperatures during the conductance measurements can have a large effect on the measured value of R_s but can be minimized by taking care to provide a constant temperature environment during the measurement. Lateral inhomogeneities in resistivity caused, for example, by metallic inclusions in the semiconductor layers affect both the accuracy of the resistivity measurement and the lateral uniformity of the etch rate.

In some extreme cases, for example in highly resistive layers, the resistance from the metal contacts to the edges of the etched region may be neither negligible nor constant. The measured resistivity of such a layer would then overestimate the actual layer resistivity. We have thus far studied no wafers of this type.

The primary advantages of this technique are: simplicity of experimental technique, the speed with which routine profiles can be taken, and the ability to measure the conductivity of buried layers. The primary disadvantages are that no information about carrier concentration or mobility separately can be obtained and such experimental errors as spatial inhomogeneity of etch rate can introduce errors in the profile that are difficult to subtract out.

In conclusion, we have demonstrated that useful information concerning the resistivity of buried layers in multilayer structures can be obtained by chemically etching the structure in short (5 sec) increments. The technique has proved to be useful in the evaluation of heterostructure laser structures grown by LPE. The major errors in measurement are nonuniform layer thicknesses and etching and errors in the etch increment. The technique is simple, the results easily interpretable, and the information can be obtained only with considerable difficulty using other techniques.

Localized GaAs Etching with Acidic Hydrogen Peroxide Solutions

Don W. Shaw*

Texas Instruments Incorporated, Dallas, Texas 75265

ABSTRACT

Control of the morphologies or profiles produced by localized etching of GaAs structures has assumed increasing importance with the current emphasis being placed on microdefinition and surface relief optimization for GaAs monolithic circuits. To obtain a better understanding of the complex anisotropic etching behavior observed in GaAs, the morphologies produced by various acidic hydrogen peroxide solutions were evaluated. The degree and nature of the anisotropy is shown to vary extensively and systematically with the etchant composition. Both highly anisotropic and essentially isotropic etching may be obtained by selection of the appropriate etchant composition.

Gallium arsenide semiconductor technology is progressing toward increasing levels of integration. Analog, monolithic integrated circuits for microwave applications and digital circuits for high speed logic are under development. However, integrated circuit development places new requirements on GaAs processing technology, particularly with respect to chemical etching. Unlike the elemental semiconductors, GaAs has a noncentrosymmetric crystal structure, which results in unusual etching characteristics. For example, in defining a step on the usual {100} GaAs wafer, chemical etching generally produces step profiles that are grossly nonequivalent for steps running in orthogonal <011> directions. An etched mesa with a rectangular shape and aligned with the cleavage directions will have two sides with gradually sloping walls, while the other two sides will have obtuse-angled walls that are unsuitable for metallization steps or crossovers. This phenomenon greatly complicates circuit design and layout, if chemical etching steps are required in subsequent processing.

As GaAs technology develops it becomes increasingly important to understand, control, and exploit these unique etching characteristics. For some device and circuit applications, highly anisotropic etchants are desirable, *e.g.*, formation of crystallographically defined "vee grooves." In other cases, isotropic etchants are required to obtain symmetrical structures in spite of the noncentrosymmetric nature of the GaAs crystal structure. This report describes one stage of a systematic evaluation of GaAs etchants. Included in the evaluation is an assessment of the profiles produced in etching, the degree of undercutting in the presence of an inert mask, the relative anisotropy, and the kinetics for room temperature etching. The results should provide guidance for efficient selection of requisite GaAs etchants and etching processes.

Etchants are generally composed of an oxidant and a solvent or solubilizing agent. The most common oxidants for GaAs are hydrogen peroxide and halogens, such as bromine. However, other agents such as $K_3Fe(CN)_6$, $Ce(SO_4)_2$, and $KMnO_4$ are also effective oxidants. The oxides produced in GaAs oxidation are amphoteric in nature and may be dissolved in either acidic or basic aqueous solutions or, in some cases, in organic solvents such as methanol. As will become evident, the different etchant compositions, although similar in principle, produce widely varying etching characteristics.

In the limiting cases the rate of etching may be determined by one of two basic events: the chemical processes that occur at or upon the semiconductor surface or the mass transport processes that occur within the liquid to supply fresh etchant species to the etching surface or to remove the reaction products. Etchants whose rates are limited primarily by mass transport are particularly useful for polishing. Surface protrusions have more favorable access to the incoming etchant species and tend to be etched more rapidly so that the surface becomes smoother. Mass-transport-limited etchants also tend to be more isotropic with respect to crystallographic orientation. Conversely, kinetically or surface-limited etchants tend to preserve the original configuration of an initially planar surface; and, since the etch rate is determined principally by the surface reaction rate, their etch rates are relatively insensitive to the nature and degree of agitation. Kinetically limited etchants are often highly anisotropic. *e.g.*, the orientation-dependent etchants that are highly coveted for producing precisely defined shapes or cross sections in semiconductor crystals. As will be subsequently shown, both types of behavior can be observed when etching gallium arsenide with acidic hydrogen peroxide solutions.

Experimental Approach

For each etchant composition included in the present study, the following parameters were evaluated: etch rate, cross-sectional morphology, undercutting, and relative anisotropy (as defined in a later section). Particular emphasis was placed on identification of the principal morphology-determining crystallographic orientations, since procedures are described in a related publication (1) for using this data to predict the shapes expected as a function of the wafer surface orientation and mask geometry.

All studies were performed on {100} GaAs slices, which were not intentionally doped. The measured carrier density was 1.5×10^{16} cm^{-3} (n-type). After being

* Electrochemical Society Active Member.
Key words: etching, dissolution, semiconductor, topography, kinetics.

chemically polished on both sides, the slices were coated with a plasma-deposited silicon nitride film, which served as an etch mask. The nitride film was patterned using photolithography to expose GaAs in the stripe and circle configuration shown in Fig. 1. The stripes, which were visually aligned with respect to the <110> cleavage planes of the slice, were used to evaluate the etch rate and cross-sectional anisotropy. The circular regions or rings allowed evaluation of the azimuthal anisotropy, particularly with respect to undercutting. In practice, a patterned slice would be incrementally etched for sufficient total time in a given etchant composition to produce a channel depth within the stripes of ~10 μm. Typically the time increments would be chosen to remove 2-3 μm in each stage; and, prior to beginning the next etch stage or increment, small pieces would be cleaved in each of the two fundamental <110> directions (two orthogonal directions). The depths were measured on each of the cross sections; and by plotting the depth as a function of time, the etch rates were obtained. Any variation in etch rate as a function of time could also be detected.

In each experiment the etching was performed with the slice in a rotating (135 rpm) beaker, which was inclined by 30° from an upright position. The rotation direction was reversed midway during each time increment. Unless otherwise specified, all etchant compositions were freshly prepared from reagent-grade or semiconductor-grade starting materials, and all etching experiments were performed at room temperature. When necessary, the etchant solutions were allowed to cool or warm to room temperature prior to etching. This took no more than 2 hr after solution preparation in any case.

The extent of undercutting was assessed by the ratio, w/d, where w is the lateral etch distance just below the nitride film measured parallel to the cleavage direction in question, and d is the channel depth. Angular measurements were made on micrographs of the cleaved cross sections or by use of an optical microgoniometer.

Results and Discussion

The characteristics observed for the thirteen etchant compositions selected for investigation are summarized in Table I. The compositions are expressed as volume ratios (of the concentrated reagents) and molar concentrations. Included in the tabulated experimental data are the undercut ratio as previously defined, the etch rate perpendicular to the {100} surface, and the relative anisotropy. The latter parameter is chosen to provide some measure of the degree of anisotropy of the etch rate with respect to crystallographic orientation. The relative anisotropy is estimated from the observed azimuthal variation in undercutting of the circular masked region on a {100} slice. It is arbitrarily defined as the difference between the maximum and minimum extents of undercutting (U_{max} and $U_{min.}$, respectively) normalized by the average of these two values, *i.e.*

$$\text{relative anisotropy} = \frac{U_{max} - U_{min.}}{\frac{1}{2}(U_{max} + U_{min.})}$$

Also shown in Table I are cross-sectional profiles for the two orthogonal cleavage sections. These profiles are drawn to scale from optical micrographs of the cross sections. The angles and relative dimensions (including the degree of undercutting) are correct as shown. To aid in comparison of the cross sections for various etchant compositions the sections have been drawn to the same etch depth (normalized with respect to depth).

Sulfuric acid based compositions.—Sulfuric acid is the most widely employed reagent for acidification of hydrogen peroxide based GaAs etchants. The nine H_2SO_4-H_2O_2 etchant compositions listed in Table I were chosen to represent systematic compositional variations such as dilution at fixed H_2O_2/H_2SO_4 concentration ratio, variations in H_2SO_4 concentration at constant H_2O_2 concentration, etc.

Consider first the effects of diluting a basic 1:8:1 etchant as represented by the first five compositions in Table I. As expected, the etch rate decreases as both the acid and H_2O_2 concentrations are diminished, with a nearly linear decrease in rate with dilution for the less concentrated solutions. However, the most interesting effect of dilution occurs with the cross-sectional profiles. Although the profiles produced by these etchants are given in Table I, it is instructive, at least with the first series, to refer to the actual micrographs of the orthogonal cross sections given in Fig. 2.

Two cross-sectional micrographs, representing portions of cleaves through both of the different, orthogonal cleavage directions ([011] and [01$\bar{1}$]) lying in the (100) plane, are shown for each composition. The (01$\bar{1}$) sections[1] (right-hand side of Fig. 2) reveal flat bottoms in the etched channels between the stripes. Connecting the channel bottoms with the upper surface are acute-angled walls, which, in the sections etched with the more dilute compositions, are sharply defined planar walls corresponding to {111} surfaces (55°). However, it is evident on closer inspection that the sidewalls of the two most concentrated compositions (1:8:40 and 1:8:1) are not planar but curved. Indeed the walls from the 1:8:1 etched section appear to be

[1] Assignment of polarities to the two orthogonal sections is made by assuming that the acute-angled walls, which make an angle of ~55° with the {100} surface, are the {111}A or {111}Ga orientation. These directions are generally known to be the slowest etching directions in GaAs.

composed of two basic surface orientations, making angles of 55° ({111}) for the portion of the wall nearest the upper surface, and ~40° for that nearest the channel bottom.

The effects of etchant composition are even more pronounced with the profiles obtained with the (011) sections (left side of Fig. 2). The most concentrated etchant composition (1:8:1) yields a section with obtuse-angled walls. These walls are inclined with respect to the upper surface by an angle of (90° + 65° = 155°). Note that this does not correspond to a {111} surface (145°) even though this is the configuration where the {111} orientation would be expected based on the results of the (01$\bar{1}$) sections. Later, this point will be discussed in detail, but at present, note that at the extreme lower portion of the walls of the 1:8:1 (011) section a small acute-angled surface exists. The relative portion of the walls made up of this acute-angled surface in comparison with the obtuse one increases progressively as the etchant composition is successively diluted. The lower, acute-angled surface yields projected angle of ~55° on the micrographs. This then represents a {$\bar{1}\bar{1}\bar{1}$}As or {111}B which is of opposite polarity to the acute-angled {111} surfaces on the (01$\bar{1}$) sections to the right. Evidently, as the etchant becomes more dilute the {$\bar{1}\bar{1}\bar{1}$} etch rate decreases relative to the rate for the orientation that forms the obtuse-angled surface.

As previously mentioned the noncentrosymmetric nature of GaAs crystals complicates fabrication of semiconductor devices. In etching mesas on the usual {100} GaAs wafers, if the mesa mask pattern is rectangular with the sides aligned parallel to the cleavage directions in the customary manner, then the mesa will have two opposing acute-angled sides with the other two sides being obtuse angled. The obtuse-angled sides are unsuitable for metallization and the device design is constrained. Silicon, on the other hand, yields equivalent mesas, with all four sides having the desirable acute-angled walls. Since, the extent of the lower, acute-angle wall increases with increasing dilution in the first four etchants in Table I (Fig. 2), it was hoped that even greater dilutions would result in symmetrical mesas with acute-angled walls similar to those obtained with silicon. With the 1:8:1000 solution this situation was approached, with only a small obtuse-angled wall at the top of the (011) section; however, at this dilution the etch rate had dropped to a very low value (0.038 μm min^{-1}). Thus, a completely symmetrical acute-angled mesa etch solution was not obtained with etch rates comparable to those commonly employed.

The angles of the various planar regions comprising the walls of these locally etched crystals may be analyzed using a graphical procedure (1). In this way the relative etch rates of the orientations yielding the various etched facets or portions of the etched walls may be ascertained and compared. The procedure yields the minimum permissible rates as a function of crystallographic orientation that are consistent with an observed cross-sectional morphology. Application to the cross sections shown in Fig. 2 yields the polar diagrams shown in Fig. 3 for each of the four etchants under discussion. These diagrams are not to be considered the actual rate *vs.* orientation diagrams, but rather the minimum rates as a function of orientation. Thus, minima present on these diagrams may result in etched facets; however, the intermediate orientations (angles on the diagram) between minima are merely

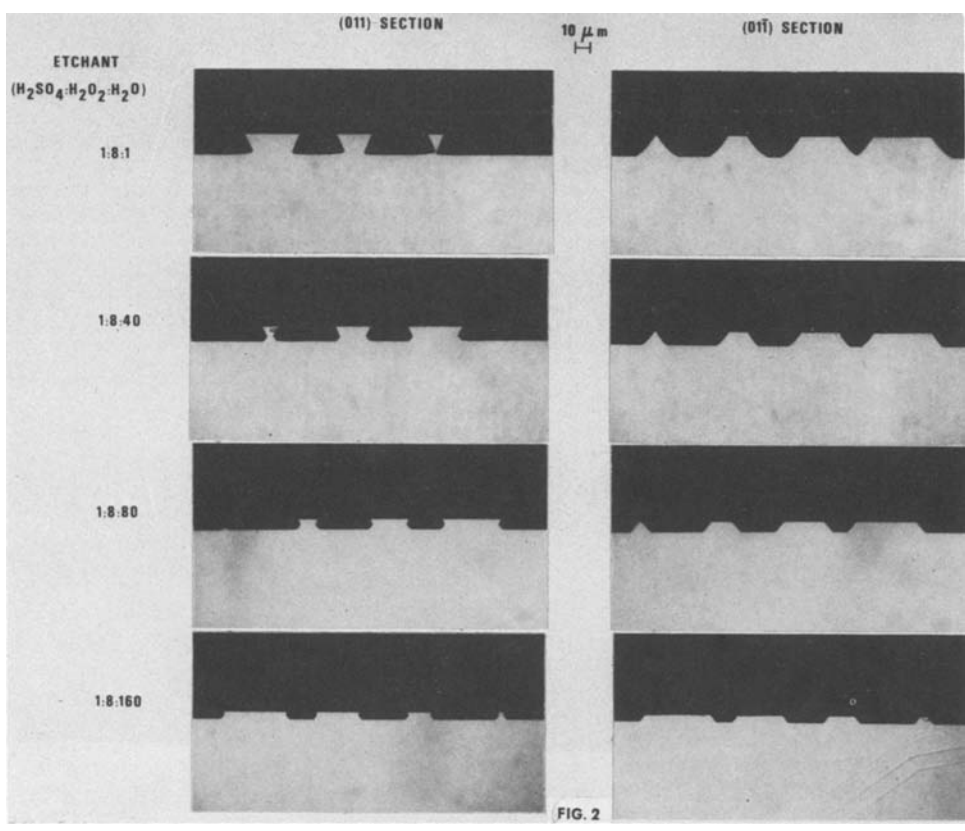

Fig. 2. Micrographs of orthogonal cross sections cleaved from slices etched in H_2SO_4:H_2O_2:H_2O solutions.

the minimum rates consistent with the observed cross sections, and the actual rates for intermediate angles will generally exceed these values. On the other hand, the etched morphologies are principally determined by the minima. The diagrams were constructed on the basis of measurements of the extent of undercutting just beneath the etch mask, the measured intersection angles between the planar regions (or their geometrical

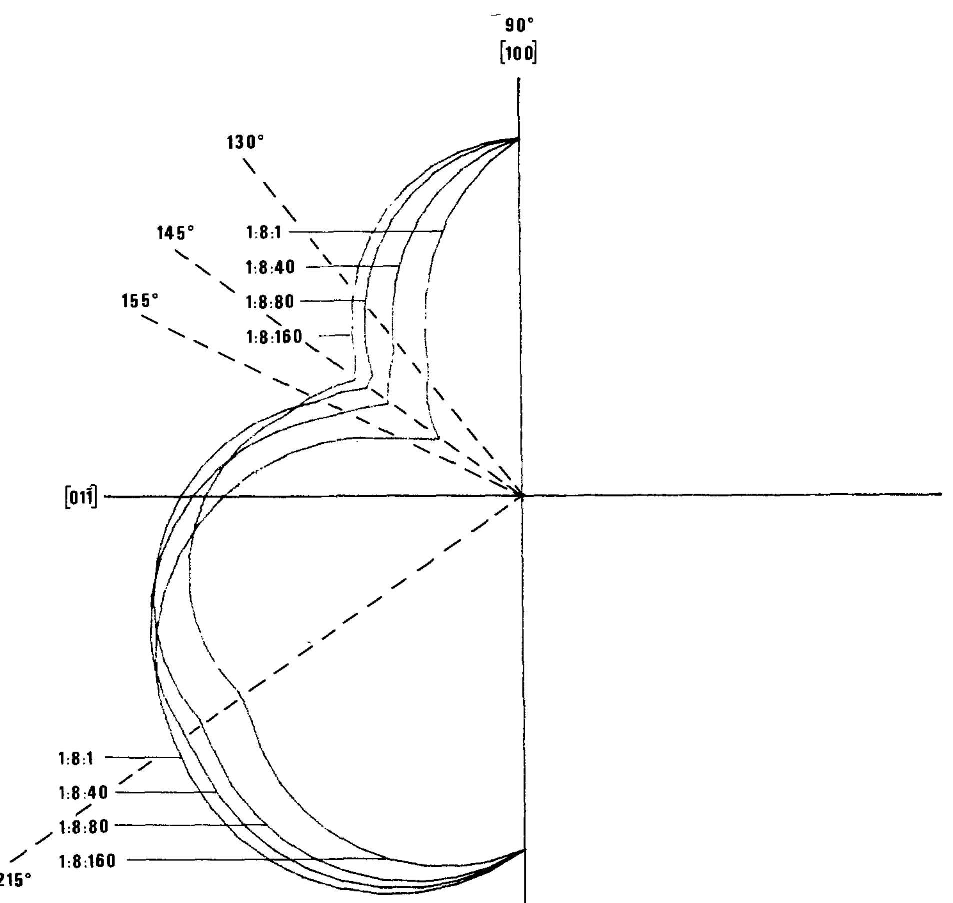

Fig. 3. Minimum-rate polar diagrams for GaAs etching with H_2SO_4:H_2O_2:H_2O solutions of the designated compositions (by volume of concentrated reagents).

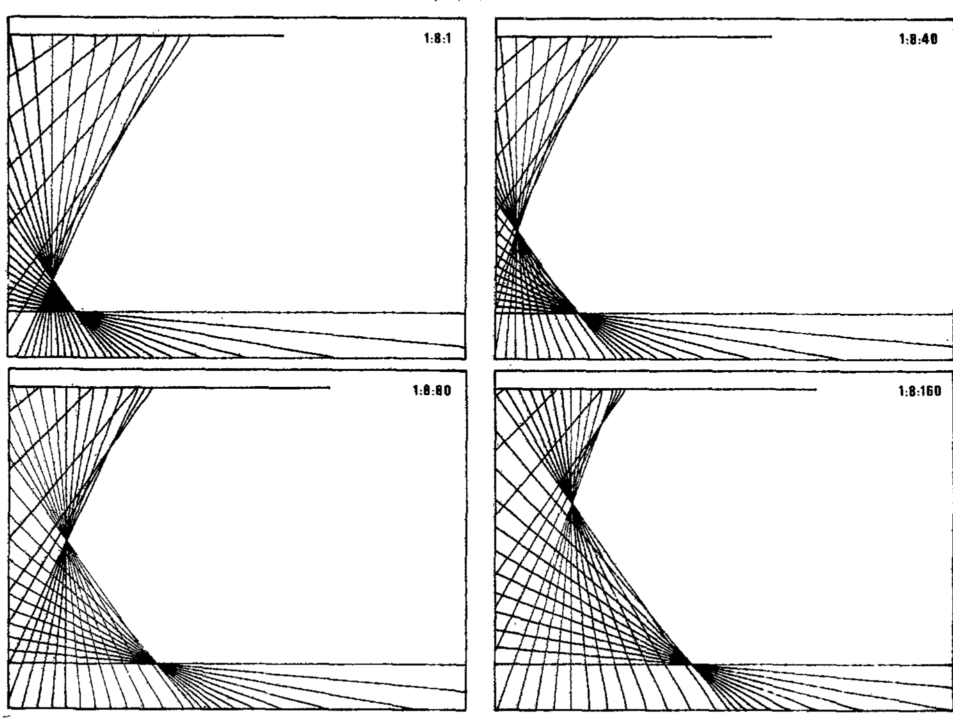
extensions) and the upper surface, and the etch rate or depth perpendicular to the surface in regions significantly distant from the mask edge that a planar etch front parallel to the original surface is evident.

The derived polar diagrams may be verified by comparison of the experimental cross sections in Fig. 2 with predicted cross sections geometrically constructed from the diagrams. This construction, which is discussed in detail in Ref. (1), consists of locating the origin of the polar diagram at a position representing the edge of the etch mask with the correct orientation normal to the slice surface. Radius vectors are then extended from the origin to their intersection with the polar diagram. Normals are drawn to the ends of these radius vectors, and the predicted cross-sectional profile is defined by an envelope-of-normals, which consists of all normals or portions of normals that may be reached from the origin without intersecting any others. The machine-drawn, predicted cross-sectional profiles for the four 1:8:X etchants under consideration are shown in Fig. 4 and 5. For purposes of comparison they are all normalized to a uniform etch depth.[2] Comparison of the predicted profiles with the actual micrographs in Fig. 2 supports the validity of the minimum-rate polar diagrams.

Consider the diagrams of Fig. 3. All four etchants have minimum etch rates at ~145°, which corresponds to the {111} orientation. As previously mentioned, this

[2] It should be noted that if the relative etch rates do not vary with time, the polar diagrams and hence the basic cross-sectional profiles will be independent of the extent of etching. This was confirmed experimentally with each etchant by observing that the cross-sectional shapes did not change with incremental etching. In other words with increased etching time the etched grooves or channels enlarged, but the basic cross-sectional profiles were invariant.



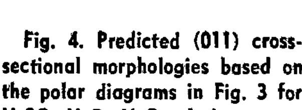


Fig. 4. Predicted (011) cross-sectional morphologies based on the polar diagrams in Fig. 3 for H_2SO_4:H_2O_2:H_2O solutions.

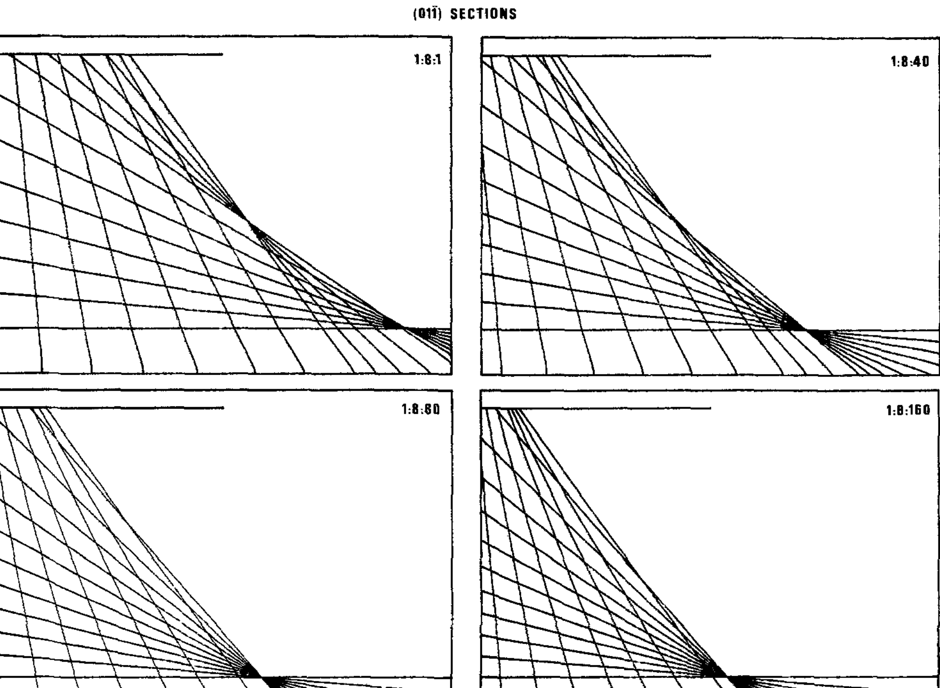

Fig. 5. Predicted (01$\bar{1}$) cross-sectional morphologies based on the polar diagrams in Fig. 3 for H_2SO_4:H_2O_2:H_2O solutions.

is assumed to be the {111}A, since the electron deficient, Ga-rich {111}A surface is resistant to chemical oxidation and generally is the slowest etching orientation for GaAs crystals. The {111}A etch rate is responsible for the acute-sloped facets near the upper surface of the $(01\bar{1})$ sections. Three other minima directions also contribute to the resulting shapes. First among these is the orientation occurring at 215° which corresponds to a {111}B or {111}As. Obviously the chemical properties of the surface atoms are not the sole factor determining etch rate, because the electron-rich character of the {111}B surface should make it one of the most rapidly etching orientations. Most likely the minimum at {111}B is due to the great packing density of the close-packed {111}B surface relative to the adjacent orientations. The most important criterion for faceting is not the absolute rate of a given orientation, but rather its rate relative to the adjacent orientations. Thus, the {111}B produces faceting even though it has a relatively high etch rate. The relatively minor perturbation to the polar diagrams at 215° results in the lower, acute-angled facets that appears on the (011) cross sections (Fig. 2 and 4).

The orientations corresponding to the other two minima (130° and 155°) are somewhat unexpected because no low index orientations lie at these angles. The angle, 155°, corresponds to the {332} orientation; however, this relatively high index orientation has been previously (2) associated with facet formation with a Br_2:CH_3OH etchant composition. The 130° minimum appears to be even more complex. Only a very high index surface would appear at 130° in the $[0\bar{1}\bar{1}]$ direction where the facet appears to be located on the $(01\bar{1})$ sections (lower acute facet notable in the sections for the 1:8:1 and 1:8:40 compositions in Fig. 2). However, lying close to the $[0\bar{1}\bar{1}]$ zone axis (within 12°) are two {332} orientations whose apparent facet angles if projected into the $(01\bar{1})$ viewing surface would be 130.3°. These {332} are the only likely orientations responsible for the clearly defined lower facets observed on some $(01\bar{1})$ cross sections.

From Fig. 3 it is evident that relatively minor local minima or perturbations, such as those at 130° and 155°, can be associated with pronounced effects on the morphology, primarily because of the angles where they occur. An interesting question concerns why local rate minima are found at {332}, but not at other high index planes lying in the zone, *e.g.*, {221}, {331}, {211}, etc. The other orientations in the immediate vicinity of {332} do not contribute significantly to the morphology or otherwise the sharply defined obtuse facet near the mask surface on the (011) sections would be more rounded than the very planar regions observed. Thus we are faced with the conclusion that {332} possesses unique characteristics that tend to resist etching by the etchants with higher H_2O_2 concentrations. Koszi and Rode (2) observed precisely defined {332} etched facets with a Br_2:CH_3OH etchant. Presumably the etch rate inhibition is due to either the chemical properties and/or the geometrical atomic arrangement of the {332} surfaces, surface steps, or kinks.

Since the polar etch rate diagrams in Fig. 3 are all normalized to the same [100] etch rate, the effect of etchant composition on the etch rate anisotropy is readily apparent. As the basic 1:8:1 etchant is successively diluted the etch rate becomes more isotropic with respect to orientation. This is evident from Table II where the relative rates (rate ratios) of the two polar {111} rates are displayed. It should be noted, however, that the decrease rate ratios in Table II result from a simultaneous increase in the {111}A etch rate and a decrease in the $\{\bar{1}\bar{1}\bar{1}\}$B etch rate (relative to {100}) with dilution. Of course, a truly isotropic etchant would exhibit an unperturbed, circular polar diagram. The decrease in anisotropy with dilution is also apparent in the "relative anisotropy" column in Table I. Note, however, that even on dilution to 1:8:1000 the anisotropy is still significant, having a value of 0.22 as compared with zero for an isotropic etchant.

Table II. Influence of etchant composition on etch rate anisotropy for polar {111} orientations

Etchant composition [conc. H_2SO_4:H_2O_2(30%):H_2O] (by volume)	Etch rate ratio $R\{\bar{1}\bar{1}\bar{1}\}B$ / $R\{111\}A$
1:8:1	4.2
1:8:40	2.6
1:8:80	2.1
1:8:160	1.5

Examination of the degree of undercutting (ratio of undercutting to etched depth) in Table I shows that the greatest undercutting occurs in the <100> azimuthal direction. Although only three directions are tabulated in Table I, examination of the patterned rings on the etched slices confirmed that the <100> direction is, indeed, the most susceptable to undercutting. This is due to the absence of slow-etching planes with {111} character in the <100> zone. Other trends are also evident from Table I. Consider the H_2SO_4-based series, 1:8:80, 1:1:8, 4:1:5, and 8:1:1, where the H_2SO_4 concentration is increased at nearly constant H_2O_2 concentration (~1.0 mole/liter). At low concentrations the etch rate increases as the H_2SO_4 concentration is raised, in a manner similar to that observed by Iida and Ito (3). Accompanying the increase in H_2SO_4 concentration is an increase in solution viscosity, which becomes particularly apparent with H_2SO_4 concentrations above ~4 mole/liter (4). Thus, whereas the H_2SO_4 may initially increase the surface dissolution kinetics, the high viscosities at elevated H_2SO_4 levels decrease the mass transport rates in the liquid to the degree that the overall etch rate decreases. This hypothesis is consistent with previous observations (3) that at high H_2SO_4 concentrations the etch rate becomes sensitive to stirring effects and the apparent activation energy decreases, effects generally associated with mass transfer control of the etch rate.

If the etch rate becomes mass transport limited, the etch rate anisotropy should decrease. This is evident from Table I where the relative anisotropy first increases and then decreases with increasing H_2SO_4 concentration in the same manner as the etch rate for the series 1:8:80, 1:1:8, 4:1:5, and 8:1:1. Note also the rounded profiles obtained with the (011) cross sections for the two highest H_2SO_4 compositions, 8:1:1 and 3:1:1. Of course, these etchants are not completely isotropic because some angular or faceted behavior is apparent near the mask surface on the (011) sections, and the $(01\bar{1})$ sections are clearly faceted.

The 8:1:1 and 3:1:1 compositions also provide a comparison of the effects of increasing H_2O_2 concentrations at high H_2SO_4 levels. The etch rate increases strongly as the H_2O_2 concentration is doubled from 1.0 to 2.0 moles/liter. However, the relatively anisotropy actually decreases, indicating that there is no simple relationship between the (100) etch rate and the relative anisotropy.

Hydrochloric acid based compositions.—All of the H_2SO_4-based etchants exhibited to a greater or lesser extent an obtused-angled facet on the (011) sections. Even etchants with apparent mass transfer limitations such as 8:1:1 and 3:1:1, [where the (011) section showed rounded, less-angular walls] still retained the small obtuse facet near the mask surface. Obtuse-angled walls are undesirable for many electronic device configurations. Fortunately, some HCl-based etchants yield significantly different profiles.

The etching characteristics of four HCl-based compositions are presented at the bottom of Table I. At high dilutions and/or low HCl concentrations, etchants

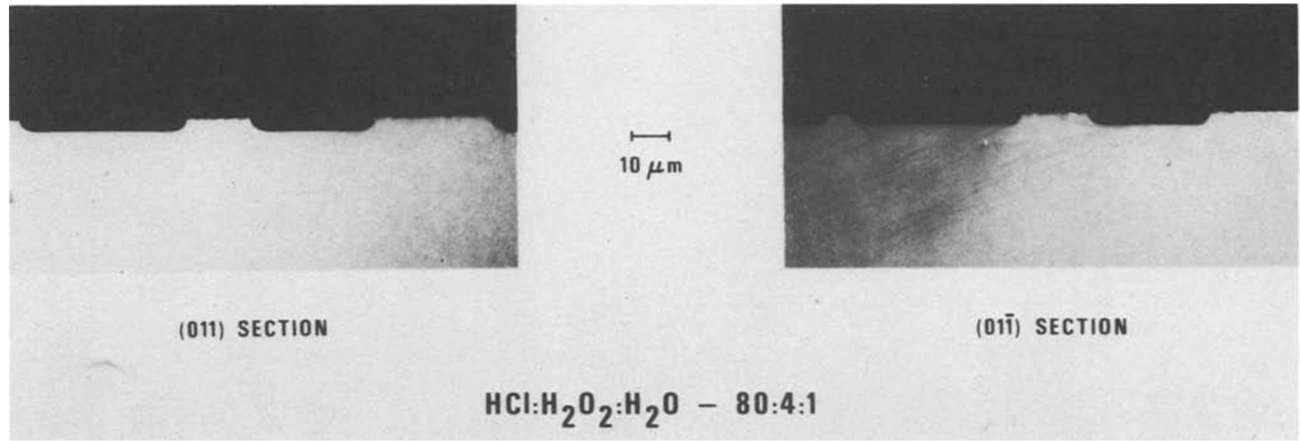

Fig. 6. Micrographs of orthogonal cross sections cleaved from GaAs slice etched in $HCl:H_2O_2:H_2O$-80:4:1 solution

exhibit orientation-dependent rate characteristics similar to the H_2SO_4-based solutions, although the lower acute-angled facet previously observed on the (011) sections is not evident with the 1:1:9 $HCl:H_2O_2:H_2O$ solution. If, however, the HCl concentration is increased to the neighborhood of 10 moles/liter, an unexpected effect is observed. The etchants become essentially isotropic. This is apparent from comparison of the (011) and (01$\bar{1}$) cross-sectional profiles for the last two compositions (40:4:1 and 80:4:1) given in Table I. Here the cross-sectional profiles are smoothly rounded, and essentially identical profiles are obtained for both orthogonal cross sections. The actual cross-sectional micrographs obtained from wafers etched in the 80:4:1 solution are shown in the lower part of Fig. 6. Unlike previous GaAs etchant compositions, the 80:4:1 $HCl:H_2O_2:H_2O$ solution produces virtually identical (011) and (01$\bar{1}$) cross-sectional profiles. Furthermore, the degree of undercutting was azimuthally uniform, both on the inside and outside perimeters of the ring pattern, as expected for an isotropic etchant.

More quantitative assessment of the isotropic character of some HCl-based etchants may be obtained from the relative anisotropy column of Table I. For low HCl concentrations the etchants are quite anisotropic. Indeed, the 1:4:40 composition yielded the highest anisotropy of all etchants tabulated in Table I. However, as the HCl concentration is increased, the relative anisotropy falls and becomes essentially zero for the last two compositions with HCl concentrations in excess of 10 moles/liter.

The isotropic, HCl-based compositions should be useful for any application where uniform orientation-independent etching is required. However, their isotropic rate characteristics are accompanied by a mass transfer controlled behavior, and the etch rates become particularly sensitive to the degree and nature of agitation employed during etching. The etch rates given in Table I for the 40:4:1 and 80:4:1 correspond to the particular agitation conditions employed, and significant deviations should be expected for other conditions. Likewise, it is necessary to provide very uniform agitation to obtain uniform morphologies.

Another interesting feature is the low degree of mask undercutting produced by the 1:1:9 composition. The ratio of undercut to etched depth for each azimuthal direction is lower for the 1:1:9 etchant than for any other composition in Table I.

Summary and Conclusions

The GaAs etch rates and morphologies produced by a wide range of acidic hydrogen peroxide etchants have been examined. Through analyses of the cross-sectional morphologies obtained from locally etched samples, the etch rate anisotropy with respect to crystallographic orientation can be assessed. The principal slow-etching and morphology-determining orientations are {111}Ga, {111}As, {332}Ga, and {100}. Sulfuric acid based etchants are generally anisotropic with respect to orientation; but, the degree of anisotropy decreases with high-H_2SO_4-concentration etchants, where mass transport rate limitations are encountered. Hydrochloric acid based etchants are also anisotropic if the HCl concentration is low. However, at higher HCl concentrations (*e.g.*, greater than 10 moles/liter), the etchants are essentially isotropic. Thus, $HCl:H_2O_2:H_2O$ compositions are identified, which, during localized etching, produce uniformly rounded etched profiles independent of the azimuthal crystallographic direction.

Delineation of Shallow Junctions in Silicon by Transmission Electron Microscopy

T. T. Sheng and R. B. Marcus

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A method has been developed for delineating arsenic implanted n^+p junctions in silicon by selective etching in 0.5% HF in HNO_3 and examination by transmission electron microscopy. This method is particularly applicable to shallow junction ($\lesssim 0.1$ μm) devices where conventional methods are no longer applicable. The n^+ region is selectively etched, and delineation occurs at a depth corresponding to a concentration of 1×10^{19} As/cm^3.

The trend in silicon VLSI MOS technology is toward smaller geometries with shallower junction depths and shorter gate lengths. As these dimensions approach 1 μm and below, traditional methods for measuring these distances are no longer useful. Angle lap-stain methods as normally applied are limited by the spacing of interference lines, which is 0.275 μm for Xe light. Samples cleaved through a junction, selectively etched and examined in the SEM offer an improvement in resolution as well as information on the lateral extent of the junction (1), but quantitative information is limited by the resolution of the SEM and uncertainty about the spatial relationship between the chemical delineation and the junction. Spreading resistance probing of a shallow angle-lapped surface (2) is limited in resolution due to the probe tip size. Auger electron spectroscopy (3) and Rutherford backscattering (4) methods are useful for depth measurements for shallow junctions, but give no information on the lateral extent of the junction.

In this paper a method is described for accurately and reproducibly determining junction profiles using transmission electron microscopy (TEM) on cross-section samples. This method has been demonstrated to provide a precision of ±45Å on a 1180Å junction depth sample and gives sharp delineation in both vertical and lateral directions.

Experimental

P-type, (100) oriented 6-8 Ω-cm 75 mm diam silicon wafers were used as starting material for these experiments. Two types of samples were processed as described in Table I. The test pattern samples were fabricated from a two-level mask set that produced a repetitive array of 1.0, 2.0, and 4.0 μm gates bounded by 2.0 μm source/drain regions; adjacent "IGFET's" were separated by 2.0 μm field oxide regions. In the orthogonal direction these features ran the length of the wafer. A very large number of cross-section preparations for TEM study could be made from each wafer. These preparations were primarily used to evaluate different chemical etchants to determine reproducibility and accuracy and to determine the doping level which corresponded with the delineation; most of the studies were performed on these test pattern samples. Unpatterned samples were also used to evaluate accuracy and to determine the location of the delineation.

The method for preparing cross-section samples has been described elsewhere (5). Each preparation for TEM study contained four to six specimens, all from the same wafer. In a typical case (for the test pattern samples) 5-10 gates could be examined in one sample, so 20-60 gates in one preparation could be examined by TEM.

Key words: junction delineation, pn junction, VLSI technology, electron microscopy.

Chemical etchants were examined in terms of their ability to produce reproducible and accurate junction delineations. Reproducibility was determined by using the following procedure:

1. Prepare TEM sample.
2. 5-60 sec buffered HF [34.6 weight percent (w/o) NH_4F, 6.8 w/o HF], rinse and dry, and treat in etchant.
3. Deposit calibrated latex balls (6) over TEM preparation for internal magnification standard.
4. TEM study and evaluation.
5. Ion mill (6.5 kV, 100 μA Ar^+ ions/gun) 5 min-2 hr and repeat steps 2-4.

The latex balls, nominally 0.312 μm diam, were calibrated against a replica of a diffraction grating with a known period of 0.715 μm.

The accuracy of the method was found by determining the doping level which corresponded to the etched delineation. This was done by comparing measurements with junction depths calculated from variation 3 of the SUPREM II diffusion model (7) (with clustering; $M = 4$), which in turn was calibrated against junction depths measured by Auger electron spectroscopy (3) and Rutherford backscattering (4).

The chemical etchants examined were a combination of HF and HNO_3 (8), and a copper plating solution (9), all at room temperature. A variety of etch times and concentrations (for the HF-HNO_3 system) were studied, including an evaluation of the effect of illumination. Vapor etching was also studied. In all cases the etching was preceded by 5-60 sec treatment in buffered HF (BHF) followed by a 1 sec rinse and quick dry by blotting. The HF-poor etchants produced very little thinning of SiO_2, and in order to produce a more uniform contrast in micrographs the SiO_2 was pre-thinned, in these cases, by exposure to 60 sec of BHF.

Table I. Description of samples

A. Test pattern samples

Source/drain doping:
Arsenic implant, 30 keV, 7×10^{15} ions/cm^2, 900°C, 35 min O_2 drive-in
Gate:
3500A undoped polysilicon on 250A SiO_2. Gate length = 1.0, 2.0, 4.0 μm
Field oxide:
3500A SiO_2. Oxide length = 2.0 μm

B. Unpatterned samples

n^+ doping:
Arsenic implant, 30 keV, 7×10^{15} ions/cm^2, 900°C 35 min. O_2 drive-in
Additional thermal treatments:
15 min 950°C Ar
30 min 950°C Ar
60 min 950°C Ar
120 min 950°C Ar

Results

A copper plating treatment has been reported to give clear pn junction delineation when examined by optical microscopy (9). Baths were prepared using 8

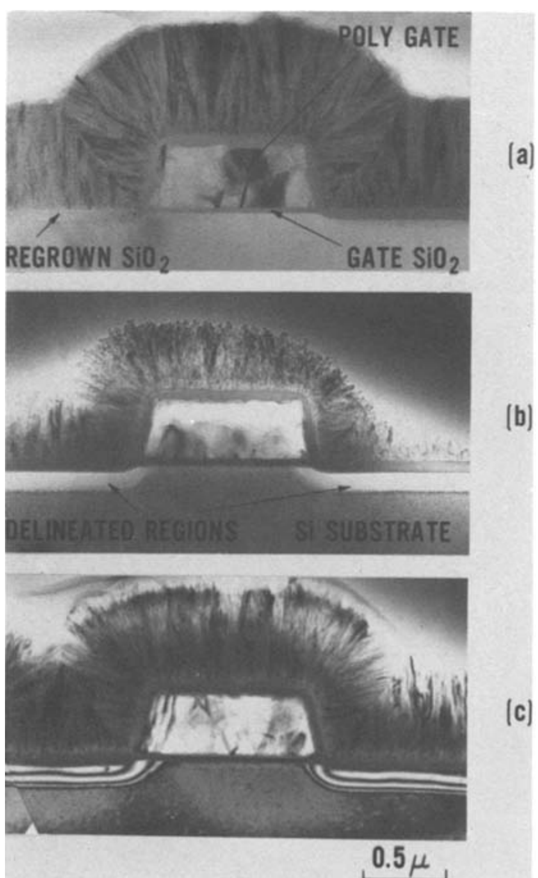

Fig. 2. TEM photographs of a vertical section through test pattern structure containing gate, source, and drain regions before etch (a) and after 9 sec etch in 0.5% HF-HNO_3 solution (b). Tilting the sample revealed thickness contours in the n^+ region (c).

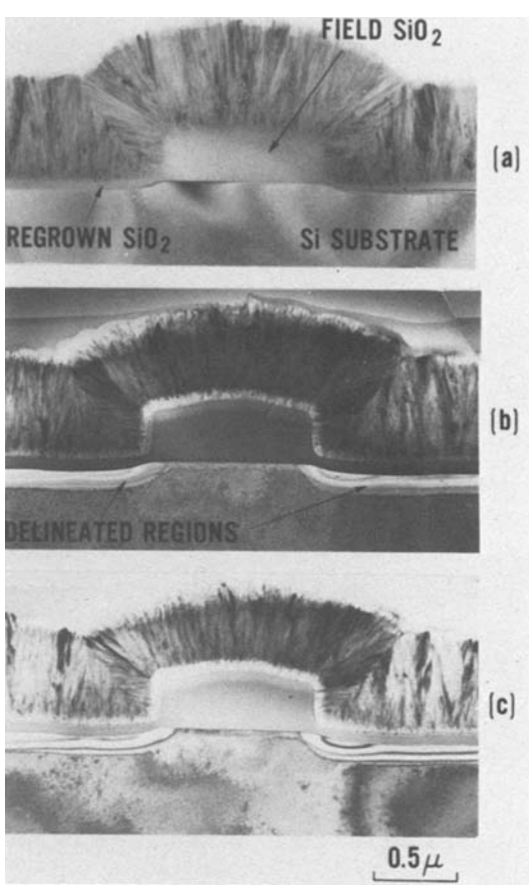

Fig. 3. TEM photographs of a vertical section through test pattern structure containing field oxide, source, and drain regions before etch (a) and after 9 sec 0.5% HF-HNO_3 etch (b). Tilting the sample revealed thickness contours in the n^+ region (c).

g/liter of $CuSO_4 \cdot 5H_2O$ and 10 ml/liter of concentrated HF. TEM test pattern preparations were etched using plating times of 5 sec. In one case strong illumination was used during plating and in another case plating was performed in the dark. In all experiments it was found that n^+ material was preferentially etched, but the plating overlay on the n region contained grains too large ($\sim$0.1 μm) to permit clear delineation. A micrograph of such a sample is shown in Fig. 1.

Various mixtures of HNO_3-HF were examined. Although HF-rich solutions tend to remove oxide at a fast rate thus destroying part of the structure of a sample under study, these solutions were examined since they are typically used for routine angle lap-strain procedures. Solutions of 0.25, 0.5, 1.0, 1.5, 2.0, and 4.0% HNO_3 in HF were used on TEM test pattern preparations for times of 1-8 sec, both with and without strong illumination. Results were variable, ranging from 1000 to 2400Å, with no clear correlation of measured delineation depth with any of the above variables.

Attempts have been made to delineate junctions by holding the TEM preparation in the vapor from a 33% HNO_3 in HF solution heated to boiling. Although junctions have been delineated by this method (5), reproducibility is poor.

The most successful results were obtained with dilute solutions of HF in HNO_3. Although 1% solutions gave delineations whose depths increased with increasing etching time, 0.5% solutions gave reproducible depth independent of etch time as shown in Table II. TEM preparations 1, 2, and 3 (Table II) were etched for 5, 9, and 7 sec, respectively, and each preparation contained 4-6 specimens. The average delineation depth measured from the test pattern samples (10 measurements on two preparations) was 995Å with a standard

Table II. Junction delineation using 0.5% HF in HNO_3

deviation of 45Å. Figures 2 and 3 show micrographs of TEM test pattern structures before (a) and after (b and c) etch in 0.5% HF in HNO_3. The micrographs in Fig. 2 and 3 are from polygate and field oxide regions, respectively. Delineations are sharp, and the magnitude of lateral junction penetration under a gate can be easily measured. The ratio of lateral to vertical delineation (c/a in Fig. 4, measured from the positions of the polysurface before reoxidation and the silicon surface after reoxidation) was found to range from 0.75 to 0.95 μm.

Discussion

The use of 0.5% HF in HNO_3 as a junction delineation etchant was found to give reproducible results, both for measurements on a number of samples within a preparation, and for measurements on different preparations. The determination of accuracy is not quite as easy to evaluate. At present we assume variation 3 of SUPREM II computation (with clustering; $M = 4$) to be correct, and Auger electron spectroscopy (3) and Rutherford backscattering (4) measurements confirm that the model is correct to within ~ 300Å for shallow junctions.

The doping concentrations which correspond to the delineated depths measured from the TEM photographs are calculated from the SUPREM II model and are shown in the last column of Table II. A profile calculated for the test pattern samples is shown in Fig. 5. These data indicate that the delineation occurs at a concentration of $\sim 1 \times 10^{19}/cm^3$. A plot of the measured delineation from the micrographs *vs.* the calculated depth which corresponds to 1.0×10^{19} As/cm^3 for the unpatterned samples is shown in Fig. 6. The curve passes through the origin and lends support to the argument that delineation corresponds to a concentration level of $\sim 1 \times 10^{19}$ As/cm^3.

The steepness of the profile for concentrations $< 10^{19}/cm^3$ for the test pattern samples (see Fig. 5) places the true junction only a short distance deeper than the delineations. With increasing junction depth the steepness of the concentration profile diminishes slightly, and for the 120 min unpatterned sample with a junction depth of 3510Å, the junction would be ~ 470Å deeper than the delineation; this trend can be seen in the fifth column of Table II. Although the precise location of the junction is subject to errors in the SUPREM II model, these errors are likely to have

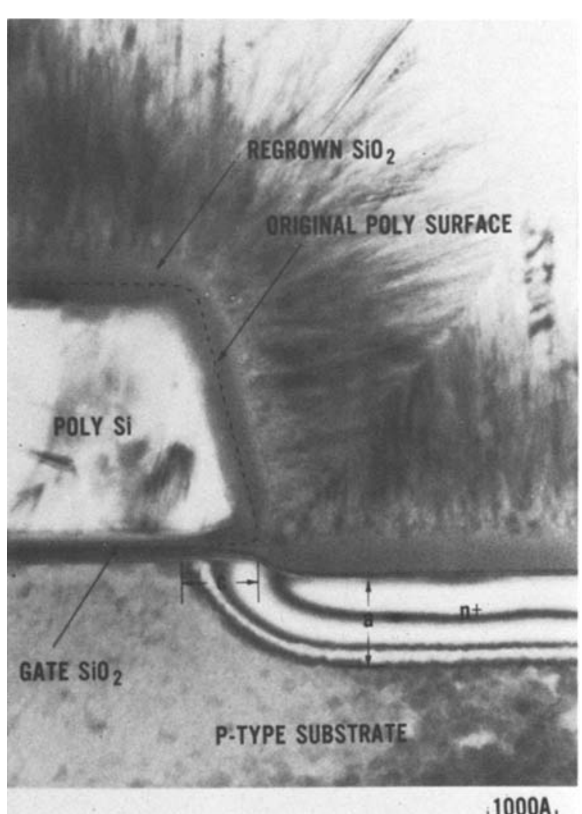

Fig. 4. TEM photograph of vertical section through test pattern structure at edge of gate after 9 sec. etch in 0.5% HF-HNO_3. The parameters a and c are, respectively, the junction depth and the lateral penetration of the junction from the position of the original edge of the implant (before reoxidation).

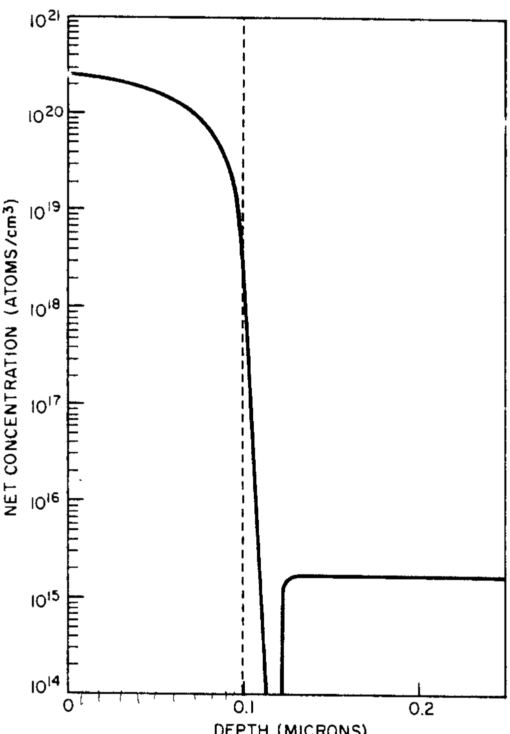

Fig. 5. Arsenic profile calculated for the test pattern samples using variation 3 of SUPREM II with clustering. The dotted line indicates the average depth measured from the TEM samples.

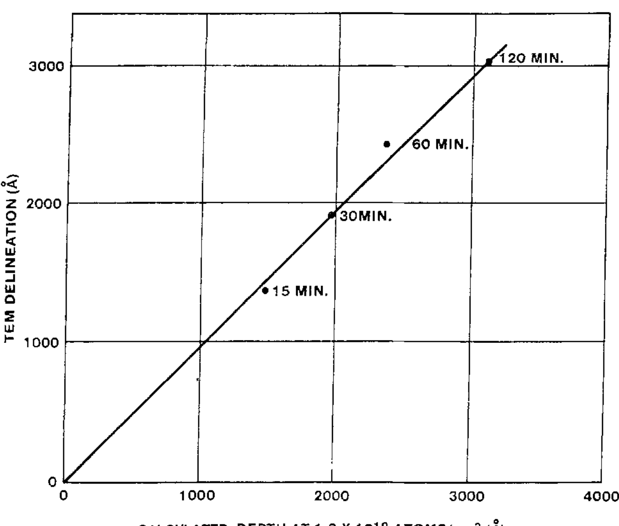

Fig. 6. Plot of delineation depth vs. calculated depth corresponding to {As} = 1×10^{19}. Data obtained from the unpatterned samples using variation 3 of SUPREM II.

no effect on the profile for the higher arsenic levels where Auger and Rutherford scattering measurements show little difference between the two variations of the SUPREM model.

It may be incidentally noted that oxide thickness on the sidewalls of the poly is 30-50% thinner than oxide on the poly surface. This is thought to be due to the higher As doping of the poly surface (due to the normal direction of incidence of the implantation) and the known faster oxidation of implanted poly. The extreme thinning of oxide sometimes seen at polycorners is a different phenomenon that is discussed elsewhere (10).

Conclusion

A method has been found for delineating arsenic implanted n^+p junctions in silicon with a reproducibility and resolution that has not been previously realized. The delineation method uses 0.5% HF in HNO_3 to selectively remove silicon with an arsenic concentration greater than $1 \times 10^{19}/cm^3$; the delineation is observed in the transmission electron microscope. Measurements were made on arsenic implanted and annealed samples with and without gate structures, and delineation data were correlated with junction profiles calculated from SUPREM II modeling with clustering. This method is particularly applicable to shallow junction arsenic implanted source/drain structures where the doping profile falls off sharply for concentrations below $1 \times 10^{19}/cm^3$. Ten measurements on samples which represent etch time of 5 and 9 sec gave an average delineation depth of 995Å with a standard deviation of 45Å.

ABSTRACT

The requirement to fabricate CCD imagers free of defects brings about the need to identify the origin of the defects in an effort to improve the imager technology. The following defects in the video display were commonly observed: vertical and horizontal lines, localized spots, and striations. Their origin was analyzed using a combination of optical microscopy, chemical etching, and EBIC. It was establishd that they are related to defects present in the oxide and polysilicon, defects introduced into the bulk silicon by processing, and defects present in the starting material. A detailed discussion of their relation to the starting material, device processing steps, and their appearance in the displayed output as a function of the device operating conditions is given.

One of the more challenging problems of VLSI technology is the fabrication of large area devices free of localized defects. This is particularly important for photosensitive mosaics such as CCD imagers intended for use as the image sensor of a television camera. The history of camera tubes, which spans some fifty years, has been dominated by the efforts to improve the image quality of each successive generation of devices. Silicon technology is the latest to be applied to this application, first in the diode array of the silicon vidicon and now in CCD's.

As has been previously reported (1-5), there are ample opportunities for defects to be present since a sensor area of 1.5 cm^2 contains between 1 and 3 $\times 10^5$ picture elements (pixels). Any defect producing a video signal anomaly in the order of 1%-2% of the peak signal, which corresponds to a current change in the order of 10^{-9}A, is observable in the video display of the sensor output.

A successful program to eliminate image blemishes must first identify the origin of each type of electrically active defect and then establish a correlation between a particular type and a specific part of the fabrication process. With this information the efforts to upgrade the device processing can proceed in a purposeful manner.

This paper reports the results of our investigation into the origin of electrically active defects found in the SID 52501 CCD imager (6) manufactured by the Electro-Optics Department of the RCA Solid State Division. We believe that the results presented here are typical of any frame transfer imager.

The majority of point and some line defects observed in the television display of the output signal from these devices have involved the malfunction of one or more pixels, failures which can be eliminated by improved control over processes such as mask fabrication, photolithography, etching, and ion implantation that are used in fabricating the CCD structure. Other defects arise from inhomogeneities and defects in the single crystal substrate which can originate during processing, but most frequently are present in the virgin wafer. Our analysis shows that defect densities can be minimized and increased yields of cosmetically pleasing CCD imagers are within the capability of present integrated circuit technology. Cost reductions resulting from improved yields will follow from further improvement in the state-of-the-art.

Experimental Approach

The SID 52501 CCD imager (Fig. 1) whose die size is 1.25 $\times$ 1.95 cm is fabricated on a 10 Ωcm float zone p-type silicon wafer. It uses a three-phase single level polysilicon gate structure and contains a parallel array of 320 surface channel linear CCD's each having 512 stages of 30 $\times$ 30 μm area. The array is subdivided into two identical areas of 320 $\times$ 256 stages, one part serving as the image sensing register, the other as a storage register. In the normal TV camera system the device is operated in the frame transfer mode. An optical image is focused on the image register where the photogenerated charges are integrated for 1/60 sec. The entire charge image is then transferred into the storage register during the 1.3 msec blanking interval in order that the next image integration cycle can be started. Simultaneously, the first charge image is transferred one line at a time out of the storage register and into a 320 stage buried channel CCD output register. Each successive line of charge is transferred through the output register and read serially by a floating gate output transistor amplifier. This readout is continued until a complete field has been removed from the storage register at which time the entire cycle is repeated.

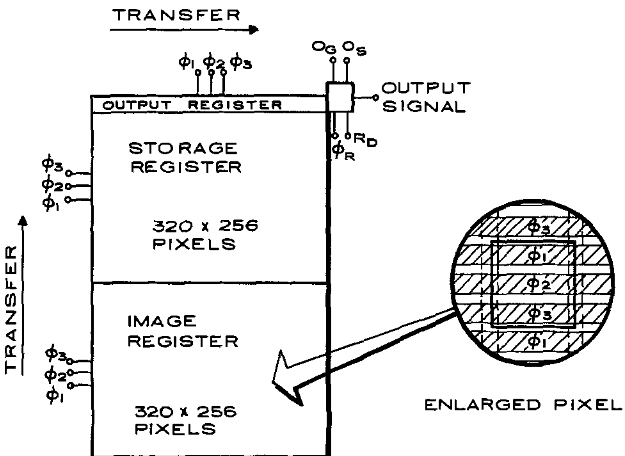

Fig. 1. Schematic diagram of a three-phase frame transfer CCD imager showing the image, storage, and output registers. In the diagram of the enlarged pixel the horizontal polysilicon gates are shown by the solid lines and the vertical channel stops by the dashed lines.

By forming the integrating wells under the $\phi 1$ gates for the odd numbered fields and under $\phi 2$ for the even, a display of two interlaced fields on the TV monitor produces a 512 line image (7). In a fully operational device, defective pixels in any of the 320 parallel CCD channels can introduce blemishes in the transduced image producing either a high signal (white) defect by the injection of spurious charge, or a low signal (black) defect because charge is lost before it reaches the output stage. Such a signal loss originates either from a localized region having low photosensitivity or a defective channel blocking the complete transfer of charge.

Because the camera system used for this study has the capability to vary the number of clock cycles used during transfer of the charge image from the image to the storage register, a simple means is available for distinguishing between defects in these two sections of the device. If the apparent location of the defect as observed in the displayed output changes as the number of cycles of the transfer clocks is altered, then the defect is within the area of the imaging register. Defects whose position is not altered are in the storage register area.

After having determined that a blemish seen in the displayed output was located in a particular register and could be classified by its electrical and optical characteristics, the next step was to determine its origin. The exact position was established by observing in the video display of the output from the operating device the coincidence of its signal with that generated by a stationary 5 μm diam light probe as the device was moved about on a microscope stage. A 500× microscope with a long focal length objective was used to examine the area surrounding the defect and also to guide the operator in scribing a square around the defective pixel using a micromanipulator probe as a stylus. As shown in Fig. 2 the CCD structure consists of a number of lamina formed on the silicon substrate. A defect can originate in any part of the superstructure or in the substrate itself and can rarely be found by optical examination of the top surface. Using either KOH or HF etching to strip each successive layer, the newly exposed lamina was examined by Nomarski microscopy to determine its mechanical integrity in the region of the defect. When the entire superstructure had been removed, the substrate was given a Dash etch followed by microscopic examination to determine if microdefects such as edge dislocations, saucer pits, and mounds were present. In addition, EBIC (electron beam induced current) scans (8) were made in the defect region to determine whether crystallographic defects were electrically active.

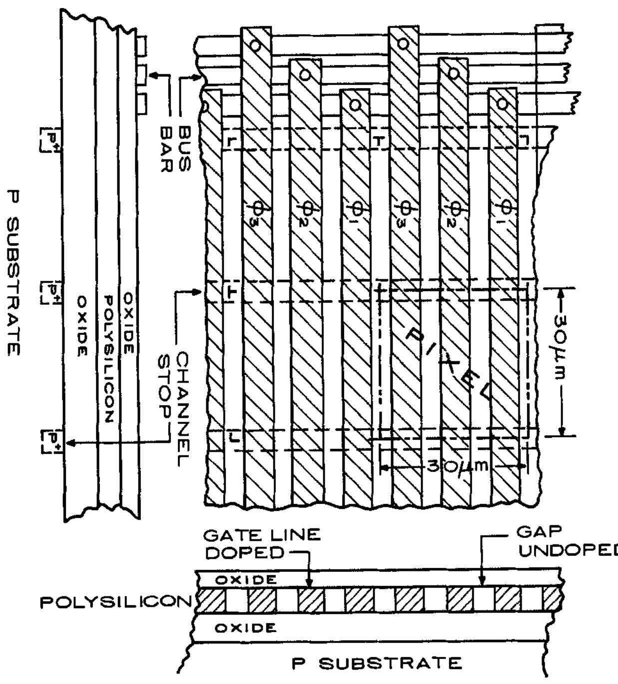

Fig. 2. Plan and cross-sectioned views of the CCD structure which was used for this study.

By repeating these analytical procedures for each type of blemish on many samples, a classification was made of the various electrically active defects and common origins for each class were established. Following each step of the fabrication process the presence or absence of the established origin for a particular defect was used to assess the need for a process change and as the means by which to compare the results from modified procedures. In this manner controls could be established over an improved processing schedule which either eliminates or reduces the number of electrically active defects of a particular class.

Classification of Defects and Their Origin

In the video display of the output signal from a CCD imager the contrast of a blemish can vary between the extremes of the full well charge storage capacity (white signal) to a zero signal charge (black). Typical examples of the various CCD image defects are shown in Fig. 3. Blemishes have been observed whose contrast with respect to the surrounding background varies with operating voltage, rate of charge transfers, illumination intensity, and illumination wavelength. Some exhibit voltage or illumination thresholds. Table I lists a variety of spurious signal defects along with their location and identifying characteristics. These are discussed more fully in the following paragraphs.

Striations.—The ring-type bands of varying contrast observed in the background of the displayed image produced by the SID imager are striations. Their contrast increases with both increasing wavelength of the incident illumination and with a change of the barrier gate bias from depletion (positive voltage) to accumulation (negative voltage). Although the contrast variations in the image associated with the striations ordinarily do not exceed 4% and are usually less than 1%, their coherent nature makes them cosmetically unacceptable (Fig. 3c).

It was established by an extensive study (9) that striations are caused by a combination of inhomogeneities in the distribution of recombination centers and localized resistivity variations in the as-grown wafers. These nonuniformities modulate the collection efficiency of photogenerated charges which must diffuse through a field-free region before reaching a charge storage well. Since material inhomogeneities form concentric rings in the wafer, the appearance of the stria-

tion pattern in the displayed image will depend on the location of a particular device on the wafer.

Slip.—The clusters of short horizontal and vertical line segments in the displayed CCD image of Fig. 4a are caused by crystallographic slip in that area of the substrate occupied by the image and/or storage registers of the SID device. The contrast of these bright lines is enhanced by increasing the voltage applied to the storage gates in the image register during the integration period. Figure 4 is an example of a device having slip lines in the displayed output image (Fig. 4a) which exhibit a one-to-one correlation with the crystallographic slip present (Fig. 4b) in the bulk silicon in the same part of the register. These substrate features were revealed by a Dash etch. In the present work it has been found that in order for the slip lines to be observed in the displayed image, the crystallographic slip has to be electrically active. The crystallographic slip observed after chemical etching, but not revealed by EBIC, did not give the slip lines in the displayed image. Although the means by which the crystallographic slip becomes decorated to make it electrically active is not clearly understood, it is known that the propagation of slip from the edge of the wafer into the central area occupied by the devices occurs during processing. The slip is introduced at the wafer edge (10) and is spread by the combined effects of the strain generated by fast heating and cooling cycles (11) and by the stresses produced by the formation of the silicon dioxide and polysilicon layers (12) of the device superstructure. Control over the heating and cooling rates during device processing and adjustment of the conditions under which the various lamina are formed so that stress is minimal has been shown to reduce crystallographic slip in the device areas by a significant amount.

Black vertical lines.—Black vertical lines in the displayed image from a frame transfer CCD imager (Fig. 3) can originate in either the image or storage registers and are the result of a defect which inhibits the transfer of charge along a channel. It has been determined that the defects were formed by an unintentional diffusion of p^+ dopants into the region between the channel stops (Fig. 5). If a complete bridge is formed between a pair of channel stops, no charge will be transferred beyond the defective pixel. If a partial blockage occurs then only a portion of the charge will be transferred, particularly during the high speed transfer of the charge image from the image to the storage register. A few examples have been observed where there is a combined blockage of a channel and a break in an adjoining channel stop. In such a case charge packets whose transfer is blocked in one channel can shift to the adjacent column and in the displayed image a black line is paired with a bright line beyond the defect site.

Unintentional p^+ diffusions are the result either of a poor quality masking oxide or problems encountered during photolithographic definition of the channel stop lines.

(b)

Fig. 4. Comparison between (a) slip (cross-hatched pattern) observed in the displayed image and (b) crystallographic slip in silicon substrate revealed by Dash etch. Lower left corner in Fig. 4a corresponds to lower left corner in Fig. 4b.

Black horizontal lines.—Black horizontal lines such as seen in the Fig. 3 image display result from a discontinuity in a transfer gate or a shorted pair of gates located in either the image or storage register. A gate in this part of the device consists of a 6 μm wide doped line in the polysilicon layer which extends across the full width of the device and is connected to a metal bus at each end. Figure 6 is a micrograph of a typical discontinuity or break in a gate line.

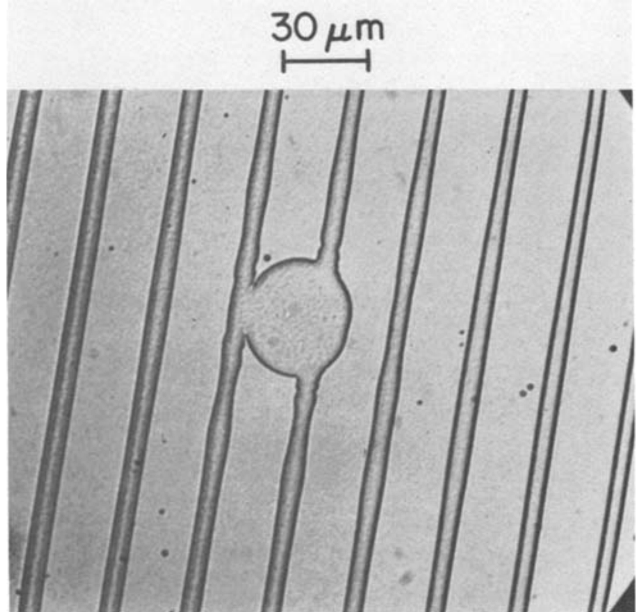

Fig. 5. An example of a defective channel stop diffusion which blocks the CCD channel. (Nomarski micrograph of a Dash etched crystalline substrate.)

Pixels located along the defective line are driven by clock pulses from one end of the line whereas the pixels in nondefective lines are driven from both ends so that the high frequency clock pulse encounters different attenuation along the open line than along nondefective lines. This leads to the distortion of the clock pulse shape and phase applied to those pixels situated under the defective line, which results in an incomplete transfer of charge. It has been established that the effect is the strongest for the breaks located in the vicinity of metal buses and that for breaks located in the center of the gate where no pulse distortion should take place the defect in the image is of minimum contrast. It has been observed that the contrast of the defects is enhanced by the increase of transfer speed and high signal level (peak illumination intensity). Similar incomplete charge transfer is also caused by shorts between the gates.

Shorts or breaks in the gate lines of the polysilicon layer are caused by defects in the patterned oxide mask which defines the regions to be doped by diffusion from a phosphorous glass overlayer and are the result of problems related to the photolithographic definition of the oxide pattern.

White spots and lines.—A single pixel size white spot or one column wide white vertical line is caused by a charge injecting defect at a given pixel site (Fig. 3). The amount of spurious charge added to any packet of photogenerated charge will depend on the amount of time it occupies a defective pixel site. In the image register during the integration period this amounts to 15.5 msec and the result is a single high signal charge packet which appears as a discrete spot in the displayed image. By comparison, other charge packets transferred through this defective pixel during the transfer from the image to the storage register will generally pick up an insignificant amount of spurious charge during the ≈ 1 μsec occupancy.

Defect sites in the image register having exceptionally high injection rates are capable of generating a low contrast vertical line in the displayed image because sufficient spurious charge is added to each packet during the image-to-storage register transfer to produce a visible image. In the display the bright

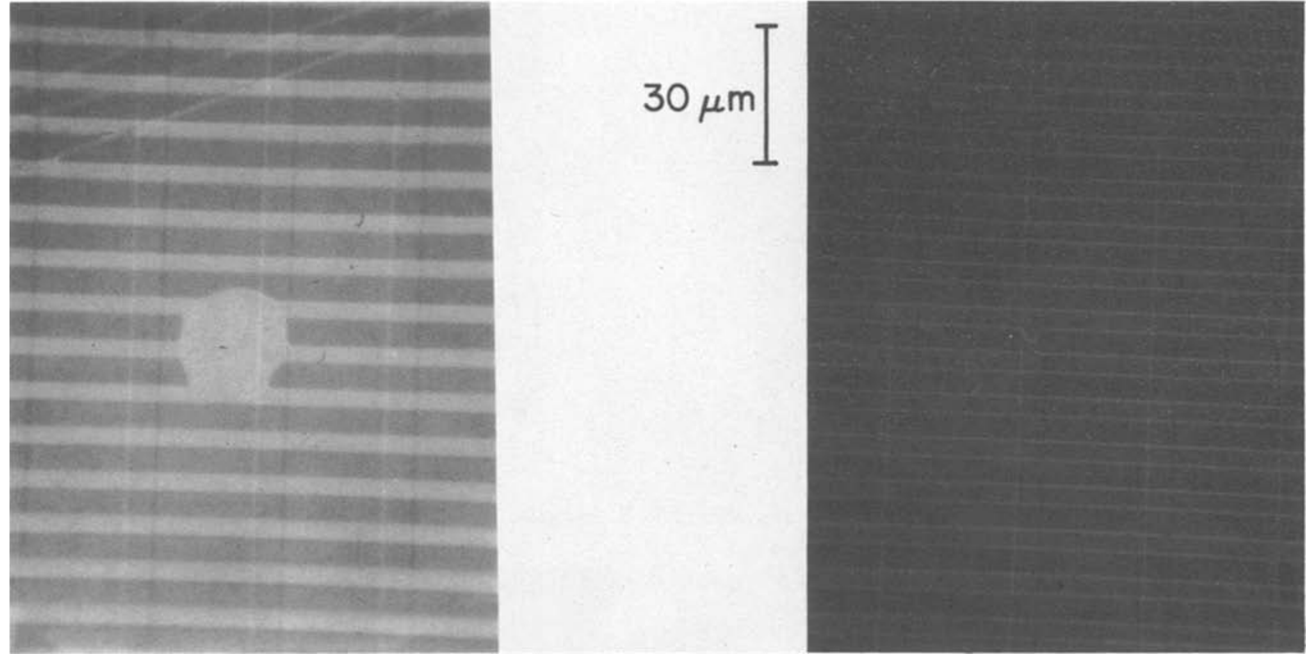

Fig. 6. Typical defects observed in the polysilicon gate structure. Highly doped regions are the darker lines

point image, which will have become enlarged by blooming, is trailed by a low contrast smear.

In the storage register each charge packet spends one line time (64 μsec) in each pixel site as it moves along a column on its way to the output register so there is ample time for a sufficient amount of spurious charge to be added to each packet transferred through a defective pixel to produce a high current vertical line in the displayed image which extends from the defect to the bottom edge of the display. The rate at which charge is injected in the storage register well of a defective pixel determines the contrast of the vertical line seen in the displayed image.

As shown in Table II six types of charge injecting defects have been identified which differ in their characteristic behavior as the result of changes in storage gate potential and illumination wavelength.

An electrical short between the polysilicon gate layer and the substrate through a pinhole in the channel oxide will produce a defective pixel whose injected charge amplitude is strongly dependent on both the maximum voltage applied to the gate and the rate of transfer. Such shorts form junctions between the n-doped polysilicon and the p-doped substrate which exhibit a reverse bias breakdown threshold. In the image register the peak gate voltage is applied during the rapid transfer of the charge image from the image to the storage register. Because the p-type substrate is patterned with p^+ channel stops and the intrinsic polysilicon layer is patterned with n^+ doped gate lines, the makeup of a substrate short can vary depending on its location, (p-i-n^+ or p^+-n^+) and each variant will have a somewhat different threshold and gate voltage dependence.

Another source of point defects are unintentional phosphorus diffusions through pinholes in the masking oxide used to define the source/drain sites. These can form small n^+-p^+ junctions at the edge of a channel stop. Such defects exhibit a breakdown above a critical gate bias voltage (usually about 8V) which produces a high signal point defect in the displayed image. An n^+ diffusion which does not contact a p^+ region will not act as an injection spot because the breakdown voltage of an n^+-p junction is much higher than those used in the CCD operation.

Damage to the wafer surface which can either be present in the virgin wafers or be introduced during processing will produce high current generation sites whose injection rate is usually independent of operating conditions. It should be noted that the residual surface damage responsible for this type of defect usually cannot be seen by optical examination of the original wafer prior to processing. The damage sites are revealed on the surface of a wafer only after etching or with EBIC scanning. However, the damage becomes visible when the wafer is oxidized because the oxide usually grows at a different rate in the damaged area.

The last three categories listed in Table II are crystallographic defects in the substrate which may be present in the as-grown crystals or be introduced during device processing. Dislocation networks introduced by diffusion of the dopant for the channel stops have been observed previously (13) and are caused by the strain resulting from the lattice mismatch between the doped and undoped regions of the crystal. The blemishes in the displayed image which are the result of this type of injecting defect do vary in contrast as the integrating voltages are altered. These dislocation networks can be eliminated by decreasing the dopant concentration in the channel stop region below a critical value.

Other crystallographic defects are the edge dislocations which are responsible for low contrast white spots in the displayed image whose intensity is critically dependent on the device operating conditions. A micrograph of the etch pits formed at one of these dislocation sites is shown in Fig. 7. The data on Table III indicate that when such defects are located in the

image register the contrast of the spots they produce in the displayed image can be changed by varying either or both the storage gate potential and the wavelength of the incident illumination. The mechanism of the edge dislocations formation during processing has been reviewed in Ref. (10).

The last category of defect listed in Table II is related to defects present in as-grown crystals and called here, for convenience, microprecipitates. They appear as hillocks [similar to those observed in CZ silicon (14)] when observed by Nomarski microscope examination of the surface of an etched sample. They can also be seen without etching on the surface of an oxidized wafer as shown in Fig. 8. Some of the white spots in the displayed image resulting from charge injection by these microprecipitates were observed to be independent of device operating conditions, while others exhibited the same dependence as those spots arising from edge dislocations. Usually the contrast of the spots related to microprecipitates is greater than that associated with edge dislocations.

Not all of the crystallographic defects in these last two categories are electrically active. Figure 9(a) shows an example of electrically active defects observed by EBIC scanning while Fig. 9(b) shows the edge dislocations present in the same area as revealed by a Dash etch. Only two of the four defects giving etch pits are electrically active. Similar data was obtained for microprecipitates.

It must be pointed out that the fraction of crystallographic defects which are electrically active increases during processing. For example, in a virgin wafer about 10% of the microprecipitate sites are electrically active. After initial oxidation about 30% have become active and after complete processing of the device the active fraction has increased to about 50%. During wafer processing the probability for a crystallographic defect to be electrically active has been found to increase just as the average concentration of recombination centers increases. Table IV shows the relationship between the average value of diffusion length, as measured by surface photovoltage (15), and those white spots in the

served that only in those wafers with the shorter diffusion length (higher concentration of recombination centers) could a correlation be established between edge dislocations and white spots in the displayed image. These data indicate that changes in the density of recombination centers as small as a factor of four can lead to substantial differences in the percentage of electrically active crystallographic defects.

Black spots.—Black spots in the displayed image fall into two categories, one being defects which cover several pixels, the other one pixel size blemishes of low contrast. The large spots were found to be associated with anomalies in the polysilicon layer. Defects such as hillocks or voids can affect either the light transmission through the polysilicon or the charge transfer through a given pixel (in much the same manner as an open gate line). The small spots are caused by a low photosensitivity region in the substrate. These result from the presence of a crystallographic defect under one pixel which produces a region with a higher than average concentration of recombination centers. The contrast of this type spot depends strongly on both the storage gate potential and the illumination wavelength.

As shown in Table III the same defect which appears in the displayed image as a black spot when the defective pixel is illuminated with infrared light can also appear as a white spot under short wavelength illumination. This is interpreted as indicating the presence of an electrically active crystallographic defect which acts as a generation center when it is located inside the depletion region and a recombination center when it is located outside the depletion region. Most of the charge generated by short wavelength light originates within the depletion region and a defective pixel collects both the photogenerated and the injected carriers. Alternatively, most of the photogenerated charge resulting from long wavelength light originates outside the depletion region where it is subject to recombination losses. The number of carriers which recombine before reaching the depletion region can be greater than the injected carriers with the result that the defective pixel will show a lower signal contrast than its neighbors. The depletion region contracts as the potential applied to the storage gate of a pixel is reduced, therefore, one can account for the observed decrease in the number of white spots and the increase in the number of black spots which occurs as the barrier gate voltage is switched from shallow depletion to accumulation (the anti-blooming mode of operation) (16).

Summary and Conclusions

The origin of cosmetic defects in CCD imagers and dependence of their contrast on operating conditions has been analyzed. It was established that all defects observed in the displayed image could be correlated with defects present in the superstructure (*e.g.*, pin holes in the oxide layer, defects in polysilicon) or with defects present in the substrate. The substrate defects could be divided into three categories: obvious defects introduced by processing such as nonintentional n+ or p+ diffusions, process-induced crystallographic defects such as dislocations networks, slip, or edge dislocations, and defects present in virgin wafers such as striations or microprecipitates. The process-dependent defects visible either in the superstructure or in the substrate are easily recognized and can be eliminated by attention to the techniques of LSI fabrication. Less well understood and more difficult to control are crystallographic defects, whether present in the virgin wafers or introduced by processing. Although processing steps responsible for the formation of crystallographic defects have been identified, an important unresolved issue still remaining is how nucleation and propagation of crystallographic defects, especially edge dislocations, can be prevented. At the completion of processing only a fraction of the crystallographic defects have become electrically active, the requirement for their producing cosmetic defects in the displayed image. Therefore, the mechanisms by which crystallographic defects become decorated should be investigated. The important issue to be solved is related to the sources of contamination; are they introduced from outside during processing or rather they are caused by redistribution and change of state of those defects which are already present in the original wafers (17, 18)? Only detailed understanding of these problems will provide the basis for process changes which will result in significant improvement of CCD imagers quality.

Bulk Impurity Charge Trapping in Buried Channel Charge Coupled Devices

M. J. McNutt* and W. E. Meyer

Rockwell International, Anaheim, California 92803

ABSTRACT

Buried channel charge coupled devices are particularly sensitive to the effects of bulk state impurities on such device characteristics as thermal leakage current, charge transfer efficiency, and noise. This paper reviews the statistics relevant to these effects and describes an improved application of the double pulse experiment for probing bulk impurities. This experiment found that the dominant impurity in our devices had an energy level 0.404 eV from one of the bandedges and determined a lower limit of 10^{13} cm^{-3} for the concentration. A close match with previously reported results suggests that this energy level is referenced to the valence band and represents iron. By eliminating the corrosive HCl gas used to getter sodium in the thermal oxides, the source of iron was removed and the affected device characteristics improved about two orders of magnitude.

Bulk impurities, especially in buried channel devices, give rise to several undesirable charge coupled device (CCD) characteristics. Among these are enhanced thermal leakage current, bulk state trapping, and bulk state trapping noise. Thermal leakage current generates charge internally and limits the time during which an empty charge packet can be stored. Bulk state trapping and subsequent emission smears charge into trailing charge packets, thus degrading the signal, and also gives rise to a partition-type bulk state trapping noise. The trapping noise can also dominate as a generation-recombination noise in the output circuit due to the proportionality of this noise power to the square of the bias current.

Mohsen and Tompsett (1) discussed the effects of bulk traps on the performance of buried channel CCD's and described the double pulse technique they used to determine the trap emission time constant. Our purpose in this paper is to review the trapping statistics that include the effects of both energy bands and to describe an efficient implementation of the double pulse measurement technique. We are also interested in identifying the appropriate impurities, and, in our example, we will find a large iron distribution and discuss its source and eventual elimination.

* Electrochemical Society Active Member.

Key words: iron, bulk impurities, charge coupled devices.

Bulk Impurity Statistics

Figure 1 is a band diagram describing the four possible Shockley-Read-Hall (2) trapping transitions assumed to dominate in the device. (*a*) and (*b*) are electron capture and emission rates, and (*c*) and (*d*) are hole capture and emission rates at a trap with energy, E_T. E_C and E_V are the conduction and valence band energies. The relevant statistics can be described by three rate equations

$$dn/dt = (b) - (a) = e_n n_T - c_n n p_T \quad [1]$$

$$dp/dt = (d) - (c) = e_p p_T - c_p p n_T \quad [2]$$

$$dn_T/dt = (a) - (b) - (c) + (d) = c_n n p_T - e_n n_T - c_p p n_T + e_p p_T \quad [3]$$

n and p are the electron and hole concentrations, and n_T and p_T are the filled and empty electron bulk state concentrations. c_n and c_p are the electron and hole capture coefficients, and e_n and e_p are the electron and hole emission coefficients.

At equilibrium

$$dn/dt = 0$$
$$n = n_o = N_C \exp[(E_F - E_C)/kT]$$
$$dp/dt = 0$$
$$p = p_o = N_V \exp[(E_V - E_F)/kT] \quad [4]$$

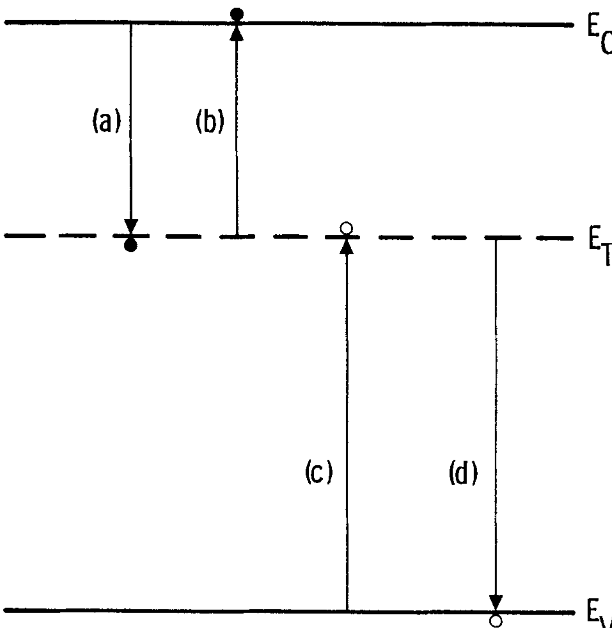

Fig. 1. Energy band diagram indicating bulk state trapping processes.

where N_C and N_V are the effective density of states at the two bandedges and E_F is the Fermi energy. Substituting Eq. [4] into [1] and [2] gives

$$e_n = c_n N_C \exp[(E_T - E_C)/kT]$$
$$e_p = c_p N_V \exp[(E_V - E_T)/kT] \quad [5]$$

To obtain this result we used the Fermi occupation factor in n_T and p_T such that

$$n_T = N_{TT}/(1 + \exp[(E_T - E_F)/kT])$$
$$p_T = N_{TT} \exp[(E_T - E_F)/kT]/(1 + \exp[(E_T - E_F)/kT]) \quad [6]$$

where $N_{TT} = n_T + p_T$ is the total bulk state concentration. Also in equilibrium

$$dn_T/dt = 0$$
$$n_T = N_{TT}(c_n n_o + e_p)/(c_n n_o + e_n + c_p p_o + e_p) \quad [7]$$

where Eq. [3] was substituted along with $p_T = N_{TT} - n_T$.

As noted by Sah (3), Eq. [5] are strictly valid only at thermal equilibrium where they are derived. However, for small deviations from equilibrium we can assume that the electric fields are not large enough to make the capture and emission coefficients field dependent. Also, we will be primarily interested in the temperature dependence of the emission cofficient rather than its absolute value, thus minimizing the effects of nonequilibrium on the measurement accuracy.

In depletion, we have $p = n = 0$, so the emission transitions, (*b*) and (*d*), dominate the capture events, (*a*) and (*c*), in Eq. [3] giving

$$dn_T/dt \simeq -e_n n_T + e_p p_T$$
$$= -(e_n + e_p)n_T + e_p N_{TT} \quad [8]$$

The solution to Eq. [8] is

$$n_T = \Delta n_T \exp(-t/\tau) + (\tau/\tau_p)N_{TT} \quad [9]$$

where $\tau^{-1} = e_n + e_p$ and $\tau_p^{-1} = e_p$. Let $t = 0$ be the time when the device is switched from equilibrium to depletion so that $n_T(0)$ is given by Eq. [7]. Then from [7] and [9] at $t = 0$ we get

$$\Delta n_T = N_{TT}[e_n c_n n_o - e_p c_p p_o]/[(e_n + e_p)(c_n n_o + e_n + c_p p_o + e_p)] \quad [10]$$

In some cases, [10] can be greatly simplified. For example, in N-type material $n_o >> p_o$, and, if the impurity level is near the middle of the bandgap, $c_n n_o >> e_n, e_p$ so that $\Delta n_T \simeq N_{TT} e_n/(e_n + e_p)$. Furthermore, if the energy level is in the upper half of the bandgap, we should have $e_n >> e_p$ and $\Delta n_T \simeq N_{TT}$.

Depending on the location of the impurity energy level, either e_n or e_p normally dominates in τ. For example, if E_T is closer to E_C than E_V, we expect $e_n >> e_p$ from Eq. [5] and so

$$\tau \simeq e_n^{-1} = \{c_n N_C \exp[(E_T - E_C)/kT]\}^{-1} \quad [11]$$

The capture coefficient, c_n, is proportional to $T^{1/2}$ since it contains the thermal velocity factor, and the effective density of states, N_C, is proportional to $T^{3/2}$ (4). Thus, there is a T^2 factor built into the $c_n N_C$ product. This factor can be eliminated by multiplying Eq. [11] by T^2. Then when we take the natural logarithm we get

$$\ln(\tau T^2) = \ln(T^2/c_n N_C) + (E_C - E_T)/kT \quad [12]$$

Now if $\ln(\tau T^2)$ is plotted against $(kT)^{-1}$, the slope of the straight line is $E_C - E_T$ which identifies the impurity energy level. In the other case, if $e_p >> e_n$ (*e.g.*, E_T closer to E_V), then

$$\ln(\tau T^2) = \ln(T^2/c_p N_V) + (E_T - E_V)/kT \quad [13]$$

and the data slope gives $E_T - E_V$.

Trapping occurs when a charge packet in the CCD is transported into a cell that has previously been empty or in depletion. This means that the exponential term in Eq. [9] has at least partially decayed. When the charge packet arrives, electrons fill these empty impurity states almost instantaneously due to the high capture rate caused by the large carrier concentration. However, when the charge packet is transported to the next cell, these electrons stay trapped in the impurity states. We are back to a depletion condition and these electrons are only emitted from the traps according to the exponential time term in Eq. [9]. As the electrons are emitted from the traps they are picked up by trailing charge packets. This total process tends to smear out the CCD signal in time.

The trapping process also gives rise to partition noise in the CCD charge signal due to the constant reapportionment of charge among adjacent cells. Also, there is substantial generation-recombination noise in any currents flowing in the device, particularly in the output circuit where the currents can be substantial. This noise is derived from the constant emission and capture of the current carriers even in a nearly equilibrium condition where the total concentration is constant.

Experimental Procedure

In order to obtain some direct quantitative information on these bulk states, we performed a double pulse charge transfer experiment similar to that of Mohsen and Tompsett (1). This experiment is illustrated in Fig. 2. The device is encased in a controlled temperature environment, and the analog signal charge transfer is driven by a four-phase clock driver. The driver also triggers a double pulse generator at a predetermined interval based on an integral number of clock periods. The double pulse generator puts out two pulses, one immediately following the trigger signal and a second pulse that is delayed from the trigger signal. The delay is manually adjustable, and the width of the two pulses is also adjustable, but the width is normally at least two clock periods. The double pulse output signal from the pulse generator is applied to the shift register input, which samples the signal every clock period and converts voltage to proportional charge. The sampled signal charge is transferred through the shift register where it loses charge to empty bulk state energy levels. Eventually, the diminished signal charge reaches the output where

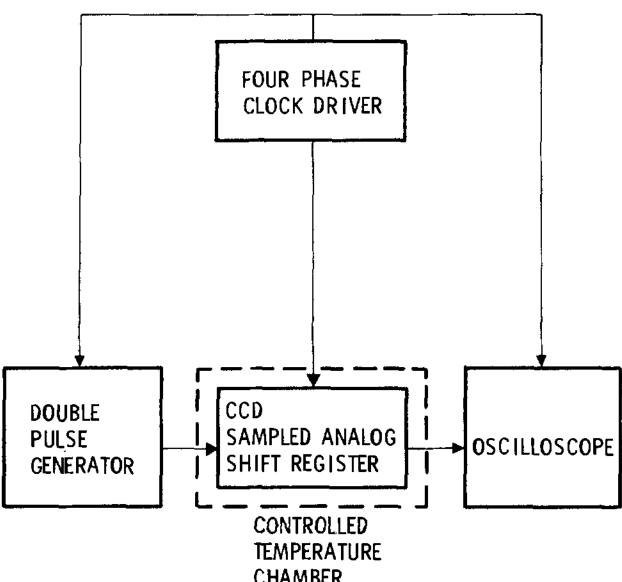

Fig. 2. Block diagram of CCD variable delay double pulse trapping experiment.

it is proportionally converted back to voltage and displayed on the oscilloscope. The oscilloscope uses the same trigger as the pulse generator. Figure 3 contains typical examples of the input and output signals, where, in this case, the output signal has been time shifted to eliminate the shift register delay that would normally occur. As shown in the figure, the pulses applied to the CCD input extend over two clock periods. For each input signal pulse, the resulting output then gives two sample pulses corresponding to the two charge packets that each input signal pulse forms. A more negative output corresponds to a larger charge packet of electrons.

As seen in the output circuit signal, the first charge packet or cell is greatly reduced during transfer down the CCD channel. This is due to trapping of charge by the bulk states. Since most of the traps are filled by the first charge packet, the second charge packet transfers through the CCD with very little loss. There is some loss, however, since the first charge packet is not exposed to all the traps in the channel because of decreases in the charge packet volume due to charge loss.

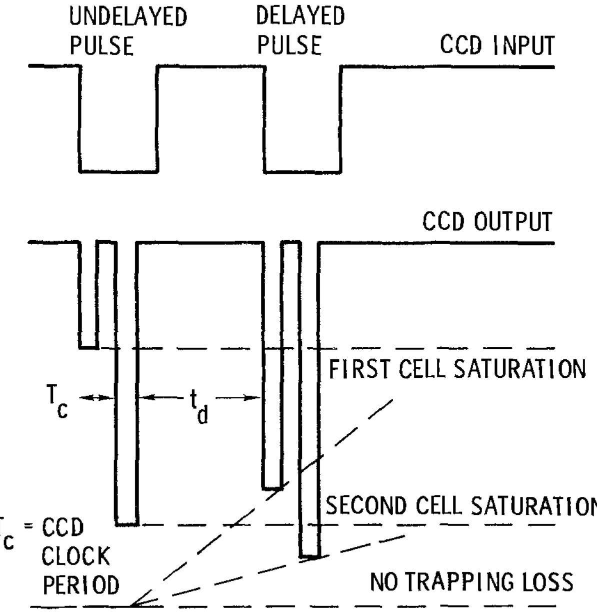

Fig. 3. Variable delay double pulse trapping experiment input and output signals.

These remaining traps are nearly all filled (in this example) by the second charge packet or the second sample of the first input signal pulse.

In the extreme case of a very large impurity concentration, more than two charge packets may be required to fill the trapping levels. This does not substantially affect the measurement technique as long as a sufficient number of charge packets is provided. This is accomplished by extending the signal pulse width over additional clock periods.

There is a delay, t_d, between the second charge packet from the first input pulse and the first charge packet from the second input pulse as shown in the figure. During this time electrons are emitted from the traps according to the depletion statistics of Eq. [9]. Then when the next charge packet comes along, it fills the recently emptied traps such that its trapping loss is equal to the emission that occurred in the t_d interval. If the emission of trapped charge is large, some of these traps may be missed by the reduced first delayed charge packet. These are then filled by the second delayed charge packet or any additional charge packets that may be required.

If $t_d = 0$, no significant emission from the traps occurs between the charge packet pairs so that no trapping loss occurs in the second pair. At the other extreme, if $t_d >> \tau$, where τ is the trap emission time constant, all the traps empty during t_d and the second charge packet pair experiences the same trapping loss as the first pair. For values of t_d in between these extremes, the second pair trapping loss follows the form

$$Q(t_d) = Q(\infty) + [Q(0) - Q(\infty)] [Q(t_d)/Q(0)] \exp(-t_d/\tau) \quad [14]$$

In Eq. [14], $Q(t_d)$ is the remaining charge at the CCD output in a charge packet delayed by t_d, while $Q(0)$ and $Q(\infty)$ are the remaining charge for charge packets with zero and infinite delays. The quantity $Q(0) - Q(\infty)$ is the charge potentially subject to trapping, and the exponential factor is that of the trap emission rate. As the charge packet moves along the CCD channel losing charge to trapping centers, its volume is reduced and it is exposed to a smaller volume of trapping centers. In a uniform buried channel, this is represented by the factor $Q(t_d)/Q(0)$ where the charge packet volume is assumed proportional to the amount of charge. Finally, we can isolate $Q(t_d)$ in [14] to get

$$Q(t_d) = Q(\infty)/\{1 - [1 - Q(\infty)/Q(0)] \exp(-t_d/\tau)\} \quad [15]$$

Of course the CCD output voltage is proportional to $Q(t_d)$. Thus, by varying t_d and observing the corresponding change in the output voltage, τ can be deduced.

Frequently if the trapping effect is not too large, we have $[1 - Q(\infty)/Q(0)] << 1$, and Eq. [15] can be approximated by

$$Q(t_d) \simeq Q(\infty) \{1 + [1 - Q(\infty)/Q(0)] \exp(-t_d/\tau)\} \quad [16]$$

This approximation becomes more accurate as the exponential factor decays. Since we now have a purely exponential time term in Eq. [16], the time constant, τ, can be determined without regard to the absolute values of $Q(\infty)$ and $Q(0)$. Sometimes the first sample of the delayed signal pulse experiences very large trapping losses such that $Q(\infty) \simeq 0$ and [16] cannot be used. In that case, a second or third sample will have less trapping loss and thus qualify for using Eq. [16]. Since we have to take as many samples of each signal pulse (*i.e.*, stretch the signal pulse over more clock periods) as necessary to get at least one undiminished sample, we can always apply Eq. [16] to one of the sample pulses.

Although the time delayed trapping data can be taken in the usual point-by-point manner, a more efficient technique gives a much faster result with an increase in accuracy. This technique uses the fact that the sampling nature of the CCD provides the same size charge packets at the same sample times even as the signal pulse is delayed up to one full clock period. However, when the signal pulse edge passes through the sample aperture time, the charge packet abruptly changes. Thus, when the time delay between pulses is continuously varied, the CCD output photographed by a time exposure clearly indicates the corresponding charge loss variation in the delayed charge packets. Each of the time delayed outputs is displayed for the time it takes to adjust the delay through one CCD clock period. If this time is long enough to expose the film and the delay is varied in a roughly uniform fashion, a good photograph will result. In practice, this typically requires opening the camera shutter for about 5 sec while turning the delay knob on a double pulse generator.

In performing the experiment, it is important to choose a CCD clock period that is much less than τ in order to get many samples of the exponential decay to match with Eq. [15]. Also, the time between the end of the delayed signal pulse and the start of the next signal pulse pair must be long enough to allow all the trapped carriers to be emitted. In other words, the signal pulse pair repetition period must be many τ time constants longer than the longest delay between the two pulses. The first signal pulse then provides the $Q(\infty)$ reference values.

The accuracy of the single photograph method can be better than the technique of recording each time delayed sample separately, even though the individual sample resolution may be less. This is because there is much less opportunity for calibration or temperature drift between t_d readings. Therefore, the relative accuracy between data points is excellent, which is most important in obtaining the time constant, τ, by matching experimental results with Eq. [15]. It should also be noted that this technique of probing bulk impurities by using CCD's is potentially more sensitive than normal capacitance transient methods (5) because the charge packet flows through a number of cells losing trapped charge in each one. In more traditional measurements, only the equivalent of one cell is used. Thus, sensitivity is multiplied by the number of CCD cells. However, to take advantage of this enhanced sensitivity, CCD noise sources such as transfer efficiency noise and output FET noise must be minimized.

Although the double pulse experiment does not by itself give the impurity concentration, N_{TT}, except in the special cases where $N_{TT} \simeq \Delta n_T$, it can give the impurity energy level by finding the slope of Eq. [12] or [13]. This can identify the impurity involved. Since the technique directly measures the adverse CCD characteristic, namely charge transfer trapping loss, it always identifies the impurity that is most injurious to the device, and the measurement can be made near the normal operating temperature.

Experimental Result

An example of the determination of the time constant, τ, at a single temperature is shown in the oscilloscope photo of Fig. 4. This photo is a long time exposure showing the first charge packet pair and a sequence of second charge packet pairs at various delays. The delay time was adjusted continuously from 0 to the edge of the oscilloscope scale while the camera shutter was open. The result is the two exponential decays vividly displayed for the first and second delayed charge packets. The two undelayed charge packet signals are also shown, somewhat bloomed due to the long exposure time. They indicate the long delay values of the delayed charge packets so that the time constant can be determined. They also define the reference time. Since the trapping loss is about 25% of the total first charge packet (the zero charge level is well above the top of the scope display), Eq. [16] approximates [15], and a simple exponential decay can be assumed.

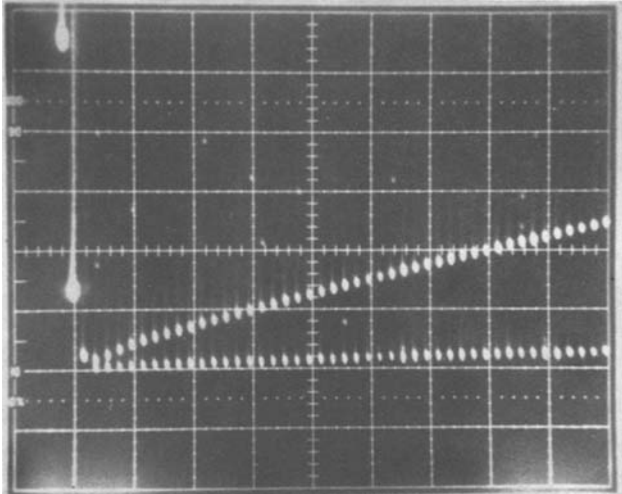

Fig. 4. Long exposure photo of CCD output during variable delay double pulse trapping experiment. Device 30338-1-4-37B; CCD Clock Rate = 50 KHz; Horizontal scale = 100 μsec/div.; Vertical scale = 0.1 V/div.; temperature = 55°F.

For example, let 0V be the top of the vertical scale as an arbitrary reference. The undelayed first charge packet signal is at −0.05V. The delayed first charge packet when the delay is zero (*i.e.*, no charge loss) is at −0.60V, giving a maximum charge loss equivalent to 0.55V. We see a charge loss equivalent to 0.20V at a delay of 700 μsec, so that

$$0.55 - 0.20 = 0.55 \exp(-700 \times 10^{-6}/\tau)$$

$$\tau = 700 \times 10^{-6}/\ln(0.55/0.35)$$

$$= 1550\ \mu\text{sec} \quad \text{at} \quad T = 55°\text{F}$$

Naturally, curve-fitting techniques could be used with Eq. [15] to get more precise values of τ if required. By repeating the experiment at several temperatures, we can plot $\ln(\tau T^2)$ *vs.* $(kT)^{-1}$, and from Eq. [12] and [13], we expect a straight line of slope $E_C - E_T$ or $E_T - E_V$. The experimental results are plotted for a single CCD device in Fig. 5 and they do in fact fall on a least squares fit straight line of slope 0.404 eV $\simeq$ $E_C - E_T$ or $E_T - E_V$. This is an energy level that lies near the midgap of silicon, where we know it can give rise to the most thermal leakage current. The reported energy level closest to this number in silicon is $E_T - E_V$ $\simeq$ 0.40 eV for iron (6-8). Iron is known to have one of the highest diffusion coefficients of any impurity in silicon, and its solid solubility is larger than 10^{15} cm^{-3} at our lowest furnace temperatures. An obvious source of iron is the stainless steel plumbing for the gas flow systems and the gas storage tanks. The potentially corrosive HCl gas system used to getter mobile sodium ions from the gate oxides was particularly suspect. By eliminating the HCl gas flow and relying on clean processing and gettering of sodium by our phosphorus-doped polysilicon gates, we obtained an immediate reduction of about two orders of magnitude in thermal leakage and charge trapping in finished devices.

The concentration of trap states from which carriers are emitted after a certain time is given by the first term in Eq. [9], and the concentration of emptied traps after steady state is achieved is represented by the factor Δn_T. As seen in Eq. [10], Δn_T is only a fraction of the total impurity concentration, N_{TT}, with the fraction determined by the values of the emission and

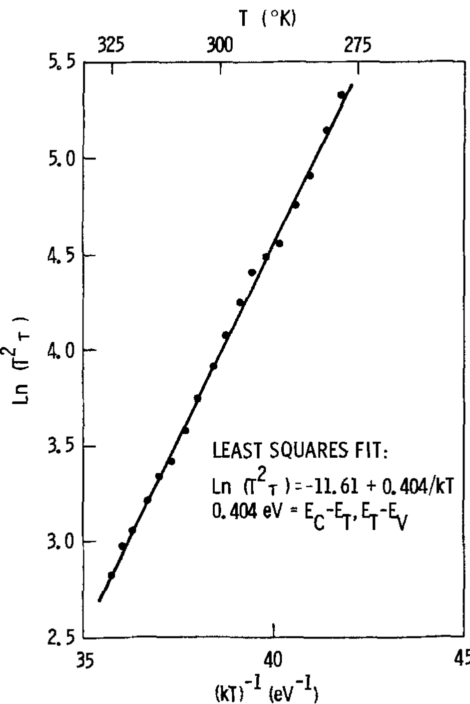

Fig. 5. Experimental data plot yielding bulk state energy level

capture coefficients and the equilibrium doping concentrations.

In our buried N-channel device we have $c_n n_o >> c_p p_o$, and, since the impurity level is near the midgap energy, $c_n n_o >> e_n, e_p$ by comparing Eq. [4] and [5]. Finally, we have assumed that the impurity level emits holes to the valence band so that $e_p >> e_n$. Combining these approximations in Eq. [10], we get $\Delta n_T \simeq (e_n/e_p) N_{TT}$. We have determined $e_p = \tau^{-1}$, but e_n can only be found by another measurement technique. However, we have determined that the concentration of trapped and reemitted carriers, Δn_T, is much less than the impurity concentration or $N_{TT} \simeq (e_p/e_n)\ \Delta n_T >> \Delta n_T$.

Referring to Fig. 4, after the traps have emptied in a full depletion mode so that the first term in Eq. [9] is zero, a full charge packet loses charge represented by a 0.55 drop in output voltage. A second charge packet experiences a 0.13 voltage drop and succeeding full charge packets lose nothing because the traps have reached the equilibrium condition of Eq. [7]. The output circuit has a sensitivity of about 10^{12} V/C, so the 0.55V and 0.13V represent 0.55×10^{-12} C and 0.13×10^{-12} C or a combined total of 4.3×10^6 electrons. These electrons are trapped in a CCD channel that is 250 μm wide $\times$ 1540 μm long $\times$ 1 μm deep for a total volume of 3.8×10^{-7} cm^3. Therefore, the concentration of trapped electrons that can be reemitted is $\Delta n_T = 4.3 \times 10^6 / 3.8 \times 10^{-7} = 1.1 \times 10^{13}$ cm^{-3}. This represents a lower limit on N_{TT}.

Conclusions

By employing the temperature dependent transfer inefficiency of a CCD, we have been able to identify the impurity causing that inefficiency as iron with an energy level 0.40 eV above the silicon valence band. We have also been able to place a lower limit on the iron concentration of 1.1×10^{13} cm^{-3}. A simplified single photograph variation of the double pulse method greatly facilitated determination of the required emission time constants.

This impurity identification immediately threw suspicion on the furnace plumbing for the HCl gas used to getter the threshold shifting sodium ions in isolation oxides. This plumbing contains iron in the stainless steel tubing and the HCl tanks. By eliminating the HCl gas system, an immediate reduction of about two orders of magnitude in thermal leakage current and in charge trapping was observed in finished devices.

High Temperature Oxidation Mechanism of CoO to Co_3O_4

K. Przybylski[1] and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada, L8S 4M1

ABSTRACT

Growth of Co_3O_4 layers on the (100) surface of single crystal CoO was investigated in air at 700° and 800°C. These layers were of duplex structure due to simultaneous inside and outside growth. Measurements on the position of inert gold markers demonstrated that cobalt migration outward in Co_3O_4 was the dominant diffusion mechanism. The oxidation kinetics were parabolic; the parabolic rate constant at 800°C was used to obtain an estimate of $D_{Co} = 3.0 \times 10^{-12}$ cm²/sec for the self-diffusion coefficient of cobalt in Co_3O_4.

The kinetics and mechanism of the growth of Co_3O_4 on CoO have been studied only by a few investigators (1-6). This reaction was found to follow parabolic kinetics at temperatures between 600° and 714°C for exposures extending from 1 to 30 hr in oxygen at 1 atm pressure (1). Growth of Co_3O_4 layers on CoO in air between 700° and 910°C followed cubic or parabolic relationships (2). The initial oxidation rates during 0.05-1 sec between 500° and 1000°C in oxygen at 1-5 atm are much slower than those rates for extensive oxidation and they are strongly influenced by oxygen pressure (3). Oxidation of sintered CoO samples in air at 600°-900°C for periods up to 12 hr have been reported to be determined by Co_3O_4 nucleation processes (4). Attempts using inert gold marker measurements to interpret the reaction mechanism have been inconclusive since inward oxygen (5) and outward cobalt (6) migration have been advanced to account for Co_3O_4 layer growth.

A review of the published literature illustrates that there are many discrepancies among the investigations and that the oxidation kinetics and mechanisms for Co_3O_4 growth on CoO are not understood. It appears that the most important undefined source of errors is associated with the low density of the polycrystalline CoO specimens resulting from cracks and pores. To explain the discrepancies in kinetics and proposed mechanisms, we decided to investigate the growth of Co_3O_4 layers on the (100) surface of CoO single crystals.

Experimental

A crystal of CoO (99.92 weight percent pure) grown by the Verneuil process was homogenized in air at 1200°C for 24 hr. It was oriented by means of Laue x-ray back reflection and a typical diffraction pattern of a (100) face is shown in Fig. 1. Rectangular sheets, $10 \times 5 \times 0.5$ mm, were prepared from this crystal with the large lateral surface at (100) orientation. A suspension hole, 0.5 mm diam, was drilled ultrasonically in each specimen after its surface was abraded by 800 grit SiC. The crystal surfaces then were metallographically polished with kerosene as lubricant to a 1 μm diamond paste finish and they were cleaned ultrasonically using acetone as solvent.

These CoO specimens were subsequently thermally homongenized and subjected to oxidation in air at atmospheric pressure at 700° and 800°C. In the oxidation runs, several specimens were simultaneously exposed from quartz rods using Pt wire in a mullite reaction tube placed horizontally in an electric furnace controlled to ±2°C.

The schedules of the homogenization and oxidation experiments can be explained with reference to the thermodynamics of the CoO-Co_3O_4 system. A wide range of thermodynamic data has been published, which has been discussed by Ingraham (7) who proposes that the equilibrium oxygen pressure for CoO-Co_3O_4 coexistence is given by

$$\log P_{O_2}\ (\text{atm}) = 12.809 - 1.580 \times 10^4/T \quad (1086\text{-}1219\ \text{K})$$

where P_{O_2} is the oxygen pressure and T is the temperature. Part of the diagram for the compositions of cobalt oxides as a function of temperature and oxygen pressure given by Holappa (6) based on results of two investigations (8, 9) is shown in Fig. 2. Accordingly, the CoO crystal homogenized at 1200°C in air ($P_{O_2} = 0.21$ atm) and quenched to room temperature would be expected to exhibit Co_3O_4 precipitates. The degree of this precipitation is illustrated in the micrograph of Fig. 3. The CoO matrix is probably near stoichiometry, because Carter and Richardson (10) have shown that its lattice parameter remains constant independent of thermal pretreatment and quenching method. Specimens of this investigation were subjected to the following thermal pretreatments to minimize Co_3O_4 precipitation. They were heated to 1200°C in a flowing Ar-O_2 atmosphere set at $P_{O_2} = 1.2 \times 10^{-2}$ atm (point A of Fig. 2), slowly cooled to 800°C, and held in this atmosphere (point B of Fig. 2) for 2 weeks before quenching to room temperature. Those specimens to be

oxidized at 700°C were sealed in an evacuated quartz tube containing a $CoO + Co_3O_4$ mixture and equilibrated at this temperature ($P_{O_2} = 3.7 \times 10^{-4}$ atm) for 2 weeks before quenching to room temperature.

It was confirmed by x-ray and reflection electron diffraction that Co_3O_4 was the only product upon oxidizing CoO. Co_3O_4 layer thicknesses and distances within these layers were obtained from scanning electron microscopy (SEM) images of specimen cross sections prepared by metallographic polishing and by fracture. Experiments using inert markers were carried out to determine the predominant diffusion species in Co_3O_4 during its growth. Gold markers, ~0.5-1 μm thick, were deposited by evaporation on several CoO specimens through masks made up of two microscope copper grids (20 × 200 μm) tilted to obtain triangles ~100 μm long and 7-10 μm wide at the base. The lateral size of these markers was reduced to 1-3 μm by careful mechanical removal of gold from the specimen mounted on the stage of an optical microscope. The gold markers and their positions in the Co_3O_4 layer of a metallographically prepared oxidized CoO specimen cross section could be definitively identified by energy dispersive x-ray analysis (EDAX) and the (SEM) images, respectively.

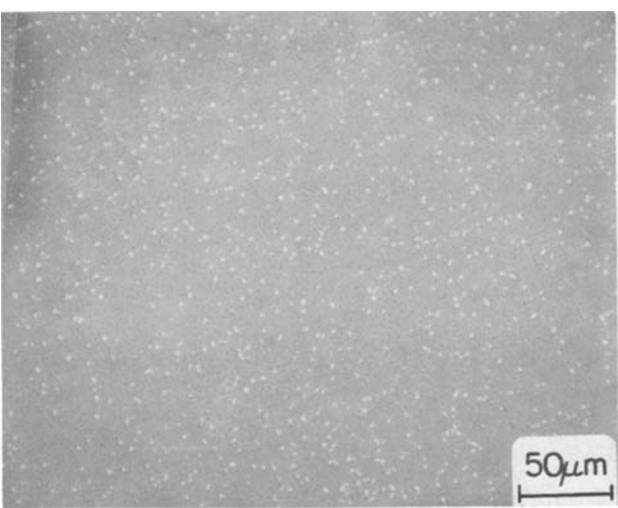

Fig. 3. The (100) CoO surface exhibiting Co_3O_4 precipitates after the specimen was annealed at 1200°C in air for 24 hr and subsequently quenched in air.

Results

The microstructures of the Co_3O_4 layers formed at 800°C during exposures extending from a few minutes to 672 hr are illustrated in the micrographs of Fig. 4.-7. A complete layer developed within 4 min (Fig. 4a) and an examination of its exterior surface showed that the uppermost region of this layer was composed of small grains (Fig. 4b). Although the CoO crystal was at (100) orientation (Fig. 4c), the thin Co_3O_4 layer was polycrystalline (Fig. 4d). This layer during long exposure developed a distinct duplex structure composed of an inner layer of large columnar grains and an outer layer of smaller more equiaxed grains (Fig. 5, 6). Distinct voids occurred at the boundary between the inner and outer layers which lay parallel to the direction of the

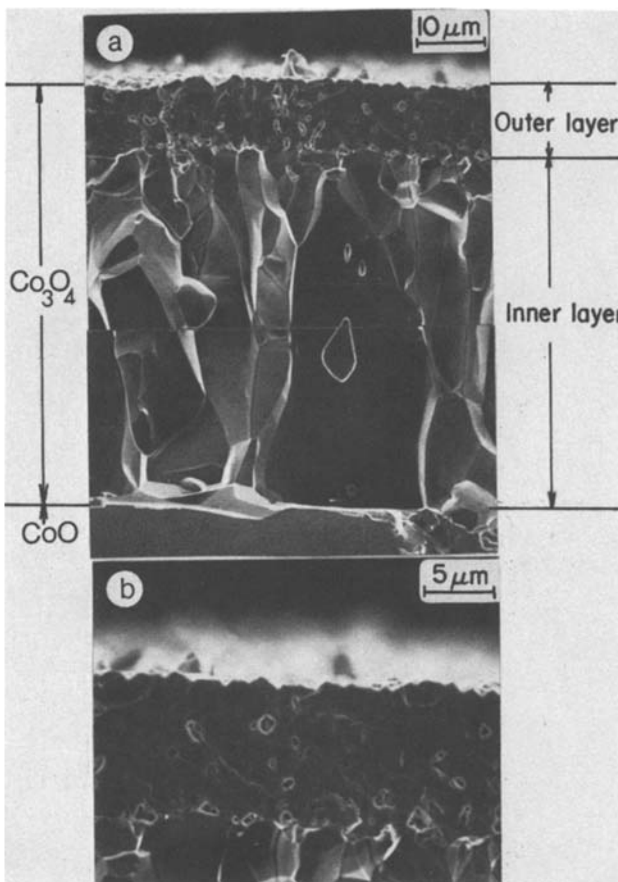

Fig. 6. SEM images of fracture cross sections of Co_3O_4 formed on (100) CoO at 800°C in air after (a) 672 hr and (b) the outer layer of the duplex layer shown in (a).

CoO surface after 24 hr (Fig. 5b). The number and size of these voids increased with time and at exposures extending longer than 200 hr voids of approximately the same size were observable at grain boundaries in the outer layer (Fig. 6, 7). The Co_3O_4 layer retained intimate bonding to the CoO surface; voids were not observed at this essentially planar interface as depicted in the specimen cross sections shown in Fig. 7.

Thicknesses of the total, inner, and outer Co_3O_4 layers were evaluated from metallographic and fracture cross sections of CoO specimens oxdized at 800°C. Eight to ten layer thickness measurements were made on each specimen and these results are recorded in Table I. It was found that growth of these layers follower a parabolic rate equation

$$X^2 = 2k_pt + C \qquad [1]$$

where X represents a layer thickness after time t, k_p is a parabolic rate constant, and C is a constant. The re-

sults from Table I are plotted in Fig. 8 according to this relationship. The values for the parabolic rate constants are

$$k_p \text{ (total } Co_3O_4 \text{ layer)} = (7.65 \pm 0.1) \times 10^{-12} \text{ cm}^2\text{/sec}$$

$$k_p \text{ (inner } Co_3O_4 \text{ layer)} = (4.69 \pm 0.08) \times 10^{-12} \text{ cm}^2\text{/sec}$$

$$k_p \text{ (outer } Co_3O_4 \text{ layer)} = (3.6 \pm 0.2) \times 10^{-13} \text{ cm}^2\text{/sec}$$

An example of results obtained using the inert gold markers to determine the predominant diffusion species during growth of Co_3O_4 at 800°C is presented in Fig. 9. The markers were found at the boundary between the inner and outer layers which corresponds to the initial location of the CoO surface. In this specific example, 23% of the layer thickness is outside the marker. Average values obtained by measuring the positions of four to five markers on each CoO specimen subjected to a different exposure period are recorded in Table I. The ratio of the outer to total Co_3O_4 layer thickness ob-

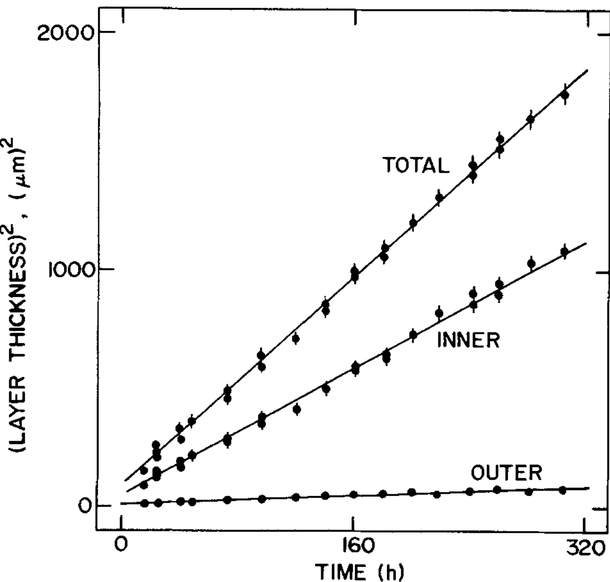

Fig. 8. Co_3O_4 layer growth on (100) CoO at 800°C in air according to a parabolic rate relationship: (layer thickness)^2 vs. time. Plots are given for growth of outer, inner, and total Co_3O_4 layers.

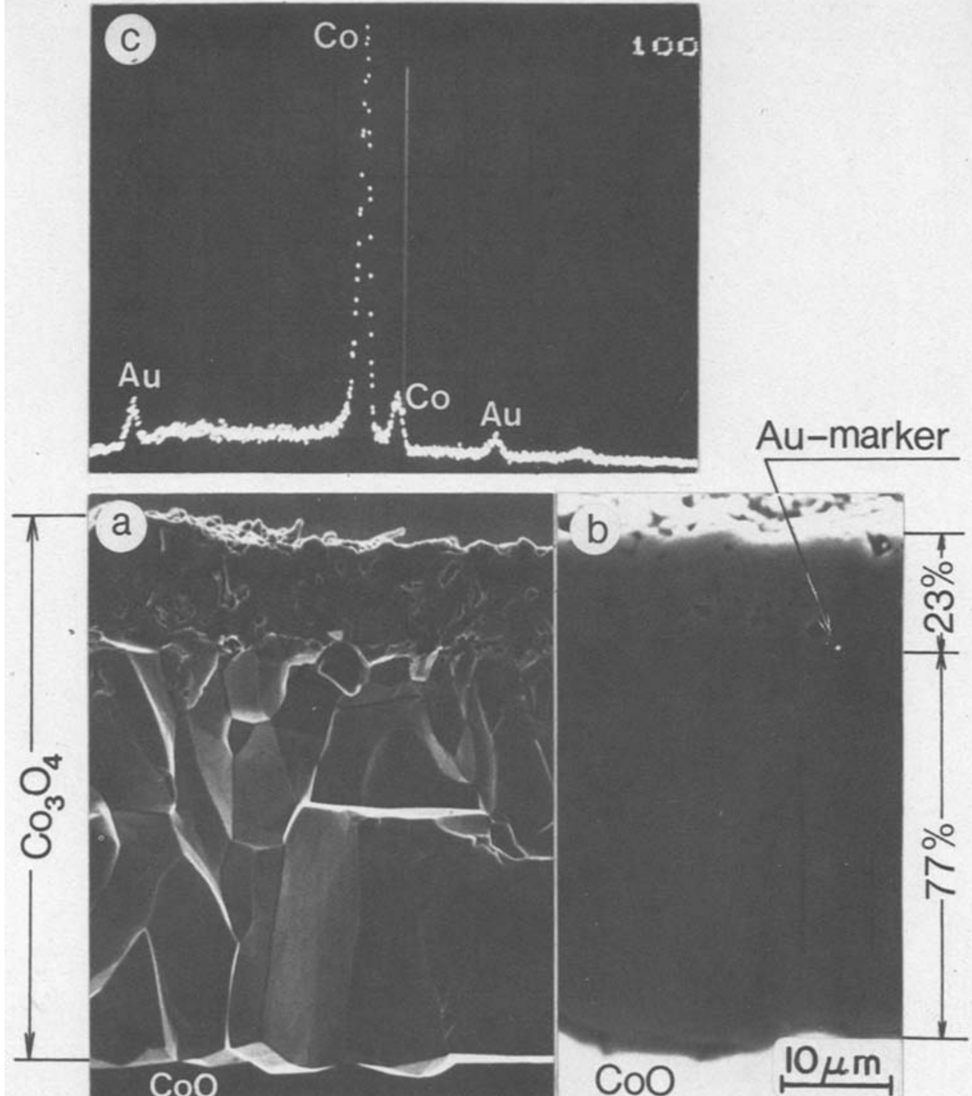

Fig. 9. Co_3O_4 layer formed on (100) CoO at 800°C in air after 384 hr: (a) SEM image of fracture cross section, (b) SEM image of metallographic cross section showing Au marker in Co_3O_4 layer, and (c) EDAX spectra for Au.

tained from direct measurements of layer thicknesses and of marker positions are in agreement.

These general features of Co_3O_4 layer growth at 800°C were also found for the growth of the layers over long time intervals at 700°C. Five exposure tests extending from 24 to 480 hr were completed. Growth of the individual and total Co_3O_4 layers followed parabolic kinetics. The microstructural features were identical and the position of the gold markers was at the boundary between the inner and outer layers as shown in Fig. 10.

Discussion

The parabolic kinetics for growth of the Co_3O_4 layer, the position of the inert metal marker within this layer, and its morphological development to a duplex structure by simultaneous inside and outside growth can be explained by outward cobalt diffusion. A model illustrating growth of the near stoichiometric Co_3O_4 layer is shown in Fig. 11. Outward ambipolar diffusion of Co ions and electrons probably via positive holes (6) across this layer leads to formation of 1 mole of oxide at the Co_3O_4/O_2 interface I by the reaction

$$3(Co^{n+} + 3ne^-) + 2\,O_2 = Co_3O_4$$

upon formation simultaneously of the cobalt reactant by the following displacement reaction at the CoO/Co_3O_4 interface III

$$12CoO = 3Co_3O_4 + 3(Co^{n+} + 3ne^-)$$

In these reactions, $n^+ = 2.67$ is the effective charge for the diffusing Co^{2+} and Co^{3+} ions. The mass balance for these two reactions is

$$12CoO + 2\,O_2 = 4Co_3O_4$$

where 1 and 3 moles of Co_3O_4 are formed at the Co_3O_4/O_2 and CoO/Co_3O_4 interfaces, respectively. An inert metal marker placed initially on the CoO surface, interface II, is therefore positioned at a fractional depth of 25% into the Co_3O_4 layer when distances are measured from its external to interior surface.

Ambipolar diffusion of cobalt through the Co_3O_4 layer leads to parabolic growth kinetics described by the Wagner theory (11). The parabolic rational rate constant k_r can be expressed as

$$k_r\ (\text{equiv./cm sec}) = C_{\text{equiv.}} \int_{a_o'}^{a_o''} \frac{Z_{Co}}{|Z_o|} D_{Co} d \ln a_o \quad [2]$$

where $C_{\text{equiv.}}$ is the cobalt concentration in equivalents/cm^3, the valencies $Z_{Co} = 2.67$ and $|Z_o| = 2$, D_{Co} is the cobalt self-diffusion coefficient and a_o is the oxygen activities having values a_o'' and a_o' at the Co_3O_4/O_2 and CoO/Co_3O_4 interfaces, respectively. Upon expressing this rate constant in terms of k_p from Eq. [1], one obtains

$$k_p\ (\text{cm}^2/\text{sec}) = \frac{4}{3} C_{\text{equiv.}} \tilde{V} \int_{a_o'}^{a_o''} \frac{Z_{Co}}{|Z_o|} D_{Co} d \ln a_o \quad [3]$$

In this latter equation, $\tilde{V}$ is the equivalent volume of Co_3O_4 and the factor equal to 4/3 occurs because only 1/3 mole of Co_3O_4 is formed by 1 mole of cobalt diffusing across the layer to react with oxygen for

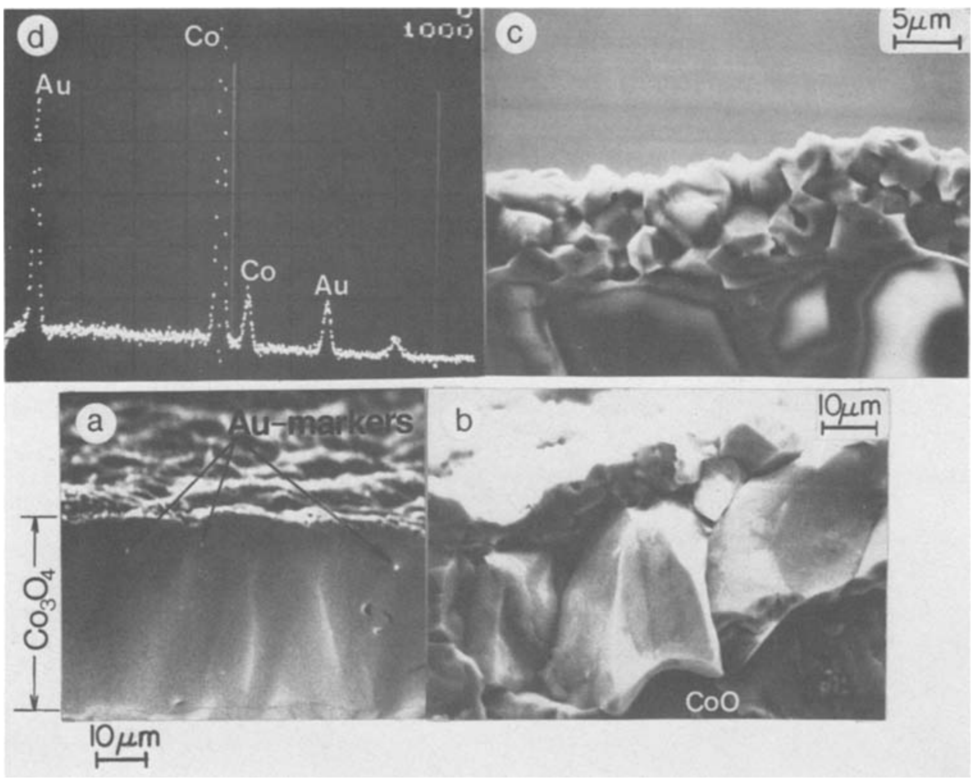

Fig. 10. Co_3O_4 layer formed on (100) CoO at 700°C in air after 480 hr: (a) SEM image of metallographic cross section showing Au markers in this layer, (b) SEM image of fracture cross section, (c) fracture cross section of outer layer region, and (d) EDAX spectra for Au.

each mole of Co_3O_4 simultaneously formed at the CoO/Co_3O_4 interface.

Examination of the results in Table I and Fig. 9 and 10 shows that the position of the gold marker in the Co_3O_4 layers is in close agreement with the prediction from the growth model based on cobalt diffusion and a simultaneous displacement reaction at the CoO/Co_3O_4 interface. This position at a fractional depth beneath the external surface of 22.9% ± 1.5% from the extensive measurements at 800°C and 23% from the measurement at 700°C compares favorably with the predicted value of 25%. Holappa (6) also found that gold markers were ~20% within the Co_3O_4 layer upon oxidizing polycrystalline CoO at 860°C in air for 366 hr. Alcock and Hocking (5) have suggested, however, that Co_3O_4 grows by inward oxygen diffusion since gold markers were positioned at the Co_3O_4/O_2 interface

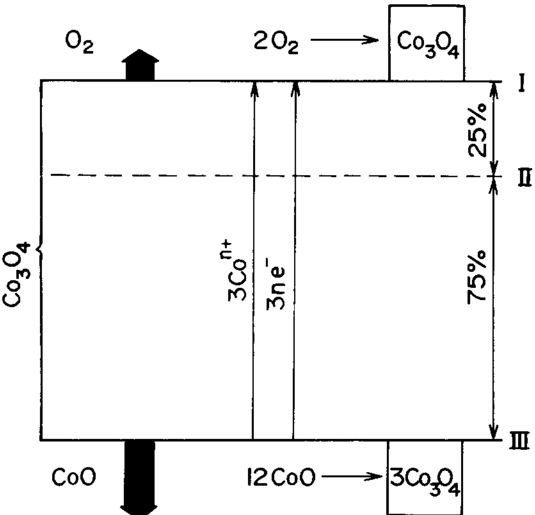

Fig. 11. Schematic model for growth of the Co_3O_4 layer on CoO by oxidation. One mole of Co_3O_4 grows at the Co_3O_4/O_2 interface by outward diffusion of cobalt to react with oxygen and 3 moles of Co_3O_4 are formed at the CoO/Co_3O_4 interface from the reaction of 12 moles of CoO. Designations are I, Co_3O_4/O_2 interface; II, initial position of CoO surface; and III, CoO/Co_3O_4 interface.

upon oxidizing polycrystalline CoO for 168 and 72 hr at 688° and 850°C, respectively. The oxidation experiments of this investigation carried out for exposures up to 384 hr on CoO single crystals utilizing minute gold markers have demonstrated, notwithstanding, that growth of a Co_3O_4 layer proceeds by cobalt diffusion. This type of mechanism for Co_3O_4 layer growth is identical to the mechanism advanced by Davies *et al.* (12) for the growth of Fe_3O_4 layers on FeO by iron diffusion.

Co_3O_4 is a member of the M_3O_4 transition metal oxides of spinel structure which exhibit cation vacancies in octahedral and tetrahedral positions and positive holes as point defects (13, 14). Its defect properties have not been investigated, but it has been shown that the value of the electrical conductivity at 900°C remains unchanged over the oxygen pressure range from 0.21 to 1 atm (15). Moreover, Co_3O_4 transforms at 800°C to CoO at oxygen pressures not far removed from 1 atm as shown in Fig. 2. We have obtained, therefore, an estimate of the self-diffusion coefficient of cobalt for Co_3O_4 at 800°C by integrating the right-hand side of Eq. [3] with the assumption that this diffusivity is not dependent on oxygen pressure over the very small pressure range from 0.21 to 1.2×10^{-2} atm which corresponds to the oxygen pressures at the Co_3O_4/O_2 and CoO/Co_3O_4 interfaces, respectively. A value of $D_{Co} = 3.0 \times 10^{-12}$ cm²/sec is obtained using the experimental value of $k_p = 7.65 \times 10^{-12}$ cm²/sec and $\tilde{V} = 5.0$ cm³/equiv. The assumption that cobalt is the predominant diffusion species is reasonable because the self-diffusion coefficient of oxygen in this polycrystalline oxide is $D_o = 3.3 \times 10^{-14}$ cm²/sec (16) yielding $D_{Co}/D_o \simeq 10^2$.

The gold markers were positioned at the boundary between the columnar and equiaxed layers of a duplex Co_3O_4 layer. Apparently outward growth of Co_3O_4 by cobalt diffusion led to development of a relatively large number of equiaxed grains, while inward penetration of Co_3O_4 into CoO, resulting from the simultaneous displacement reaction, led to development of a relatively smaller number of large, columnar grains. These growth features and the voids observed at this boundary between the different structural layers possibly

arose from imperfections and impurities, since the boundary is situated at the position of the initial metallographically prepared CoO surface. These voids and those observed at grain boundaries within the outer layer would enlarge by acting as sinks for cobalt vacancies migrating across the Co_3O_4 layer during its growth. Thus, any small decrease of the cobalt flux across the outer layer, due to the migration of vacancies to voids and the lateral areal barrier of these voids to cobalt diffusion, can account for the variation to slightly smaller values of the fractional depth of the internal boundary and marker position with increasing exposure time. These fractional depths, as shown in Table I, corresponded to the predicted value of 25% during early periods up to 24 hr, but they decreased slightly to final values of ~ 22% as voids became distinctly observable at and within the outer layer of the duplex Co_3O_4 layers during long exposures.

Conclusions

Oxidation of (100) CoO single crystals produced adherent, uniformly thick Co_3O_4 layers of duplex structure. During oxidation, voids developed at the boundary between the inner and outer layers and within the outer layer. Marker measurements and texture analysis showed that Co_3O_4 grew as a duplex layer due to simultaneous inside and outside growth. It was found that the oxidation kinetics of CoO to Co_3O_4 obeyed a parabolic relationship resulting from the dominating mechanism of cobalt ambipolar diffusion outward through the Co_3O_4 layer. An estimate of $D_{Co} = 3.0 \times 10^{-12}$ cm²/sec was obtained at 800°C for the value of the cobalt self-diffusion coefficient of Co_3O_4.

The Sulfidation Kinetics of Nickel-Aluminum Alloys at 700°C in Hydrogen Sulfide-Hydrogen Atmospheres

V. S. Bhide[1] and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada, L8S 4M1

ABSTRACT

The sulfidation kinetics of Ni-Al alloys containing 3-13 atomic percent Al were investigated at 700°C in H_2S-H_2 atmospheres at sulfur pressures $10^{-8} \leq P_{S_2} \leq 10^{-2}$ atm. The reaction product was comprised of three regions: an external NiS or Ni_3S_2 layer, an Al_2S_3-Ni_3S_2 lamellar layer, and an innermost Al-Ni-S liquid layer. Sigmoidal shaped reaction curves before onset of linear kinetics resulted from the temporally partial protective nature of the oxide films on the metallographically polished specimens. The magnitudes of the linear rate constant for growth of the reaction product layers were predominantly determined by interfacial processes for transfer of reactants at the gas/scale and scale/subscale interfaces.

Aluminum is a commonly used alloying element in Ni-base superalloys for improving their strength and corrosion resistance. These alloys, however, undergo severe degradation by sulfidation. The sulfidation kinetics of pure nickel have been studied by several investigators (1-6). At temperatures in the range 300°-600°C, linear kinetics resulting from a gas/scale phase boundary reaction are observed in sulfur pressures $10^{-4} \leq P_{S_2} \leq 0.1$ atm and parabolic kinetics resulting from reactant diffusion in the nickel sulfide scales are observed at higher sulfur pressures. It has also been

Key words: Ni-Al alloys, sulfidation kinetics.

demonstrated that nickel containing 0.5 atomic percent (a/o) Al sulfidizes at 620°C and 10^{-4} atm sulfur pressure by linear kinetics (2). Since there is a paucity of results for sulfidation of Ni-Al alloys, we have systematically investigated the sulfidation properties of these alloys containing up to 13 a/o Al at 700°C in H_2S-H_2 atmospheres containing sulfur at pressures $10^{-8} \leq P_{S_2} \leq 10^{-2}$ atm.

Experimental

The compositions of the alloys containing 3-13 a/o Al prepared by melting the pure metals in an argon arc furnace are given in Table I. Plates, 1.5 × 0.8 × 0.1 cm, were polished to 600 grit silicon carbide paper using water as lubricant. Following a vacuum anneal at 800°C for 3 days, the specimens were again polished to 600 grit silicon carbide paper and, in several instances, polished to 1 μm size diamond using kerosene as lubricant. The specimens were successively washed with petroleum ether and methyl alcohol, dried, and stored in acetone.

Sulfidation kinetics using H_2S-H_2 atmospheres were determined gravimetrically at 700°C using a McBain balance assembly which has been described elsewhere (7). The sulfur pressures in the atmospheres at 700°C were calculated from the equilibrium constant $K = 5.29 \times 10^{-3}$ for the reaction $H_2S = H_2 + \frac{1}{2} S_2$ (8-10). The oxygen containing impurities in the ultrahigh purity hydrogen were O_2 = 1 ppm and H_2O = 5 ppm, and in the 99.5% chemically pure hydrogen sulfide SO_2 and CO_2 equal to 0.05 and 0.13 mole percent. The scales were examined using optical and scanning electron microscopy. The reaction products were identified by electron microprobe, x-ray diffraction, and differential thermal analyses. Several 125 μm diam Pt markers were spot-welded on a Ni-6 a/o Al alloy specimen before its sulfidation at 10^{-5} atm sulfur pressure.

Results

Sulfidation kinetics.—Results are shown in Fig. 1 and 2 for the alloys containing 6 and 13 a/o Al and with the specimen surfaces subjected to the fine metallographic polish of 1 μm diamond. The curves are regressional fits of the results to a sigmoidal-type rate equation for which the linear rate constants were obtained from observations at long time periods after complete surface coverage of a specimen by a sulfide scale. The irreproducible initial reaction rates were associated with the presence of defective oxide films on these alloy specimens. This characteristic behavior was demonstrated by sulfidizing a Ni-13 a/o Al alloy specimen at $P_{S_2} = 10^{-10}$ atm for 10 hr. The weight gain was less than 0.1 mg/cm² and a thin gray film < 0.5 μm thick was found to have developed. Its composition was not established conclusively; nevertheless, it consisted primarily of oxide rather than Al_2S_3 because it did not react with water. It is thermodynamically feasible to form Al_2O_3 upon taking into account the impurity oxygen concentration in the H_2S-H_2 gas stream. Results are shown in Fig. 2 for this specimen with the above preformed film sulfidized in pure H_2S ($P_{S_2} = 1.9 \times 10^{-2}$ atm). The more protective nature of this thicker film emphasized the initial sigmoidal shape of the reaction curve. The transitory influence of an oxide film was greatly reduced by only coarsely polishing the alloy surface to 15 μm grit silicon carbide paper. This behavior is illustrated by the sulfidation curves at various sulfur pressures for the alloys containing 3 and 10 a/o Al shown in Fig. 3 and 4. Good reproducibility of each sulfidation curve was obtained and the sigmoidal overtones were significantly reduced in the reaction curves.

Morphologies of the reaction products.—An external scale and subscale were formed in all cases. Isolated nickel sulfide growths, Fig. 5, grew over an alloy specimen surface in the very early reaction stages. Differently sized growths appeared in the same topograph suggesting that they did not nucleate simultaneously. These growths merged together to form a compact scale, Fig. 6, with increasing exposure time at intervals significantly longer in the case of the finely polished specimens, which exhibited pronounced sigmoidal-shaped sulfidation curves. The subscale, which was initially confined to regions beneath the isolated nickel sulfide growths, ultimately penetrated uniformly into the alloy when surface coverage with an external scale was complete.

The subscale in all instances was composed of two distinct regions involving a two-phase lamellar solid layer directly beneath the external scale and an innermost liquid layer sandwiched between the solid lamellae and the alloy. These regions are illustrated by the photomicrographs in Fig. 7. With increasing alloy aluminum content, the thickness of the solid lamellar layer increased at the expense of the liquid layer. Thus, the lamellar layer was only detectable on the Ni-3 a/o Al alloy, but became the predominant layer of the subscale in the Ni-13% Al alloy. Marker observations,

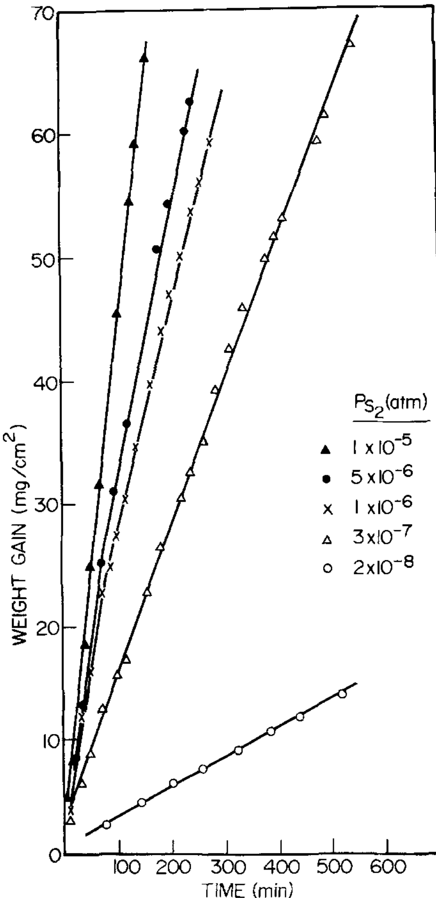

Fig. 3. Sulfidation kinetics at 700°C of the Ni-3 a/o Al alloy subjected to 600 (15 μm) grit silicon carbide metallographic polish.

Fig. 7(a), demonstrated that the Pt marker remained at the external scale/subscale interface consistent with scale growth by outward metal diffusion and subscale growth by inward sulfur diffusion.

(b) Ni-10 a/o Al specimen sulfidized at $P_{S_2} = 10^{-7}$ atm for 49 hr. (c) Ni-13 a/o Al specimen sulfidized at $P_{S_2} = 10^{-18}$ atm for 34 hr. (d) Closeup of liquid/alloy interface in cross section (c).

Identification of phases.—It was necessary to obtain samples of the external scale and the two subscale layers. The scale was easily separated from the specimen by mechanical flaking. Samples of the lamellar layer were obtained by scraping a specimen denuded of the external layer and discarding the initial and final portions of the easily scrapable material. A sample of the solidified liquid layer was obtained by further filing of the specimen. In order to confirm that no underlying alloy was mixed with this sample, it was necessary to cold mount this stripped material and examine its cross section.

The x-ray diffraction patterns of the external scales completely indexed as NiS (millerite) when sulfidation was performed at $P_{S_2} > 10^{-4}$ atm and as β-Ni_3S_2 at lower pressures. The solidified liquid layer was identified as β-Ni_3S_2. The diffraction pattern of the material from the two-phase lamellar layer could be resolved into that of β-Ni_3S_2 and an extraneous pattern. Although the line positions in this extraneous pattern matched that of the standard Al_2S_3 pattern (11), the line intensities did not match. Attempts to compare calculated and observed line intensities under the assumption of several rational fiber textures were also unsuccessful. Al_2S_3 readily undergoes hydrolysis, but attempts to identify the extraneous pattern as hydrated alumina structures failed. Since the diffraction pattern of $NiAl_2S_4$ is not known, the extraneous pattern was compared to standard diffraction patterns of the double sulfides $CrAl_2S_4$, $ZnAl_2S_4$ (cubic-spinel) and $MnAl_2S_4$, $FeAl_2S_4$, $MgAl_2S_4$ (rhombohedral), but without success. Accordingly, x-ray diffraction demonstrated that Ni_3S_2 existed in the lamellar layer, but it did not resolve a reasonable ambiguity whether the second phase was Al_2S_3 or $NiAl_2S_4$.

Figure 8 represents the differential thermal analyses of the different sulfide layers carried out at a heating rate of 20°C/min. Trace 1 was taken from the solidified liquid layer; the peak at 535°C results from the B'-B transformation of Ni_3S_2 and the peak at 637°C corresponds to the melting point of the Ni_3S_2-Ni eutectic. Thus the innermost sulfur containing layer adjacent to the alloy was liquid at the reaction temperature of 700°C. Trace 2 was obtained from a sample of the Ni_3S_2 external scale; peaks at 540° and 805°C correspond to β'-β and solid-liquid transformations, respectively (12, 13). In the preliminary analyses of the lamellar layer samples, it was only possible to obtain the above peaks for transformation and melting of Ni_3S_2. It was therefore suspected that the aluminum-rich phase

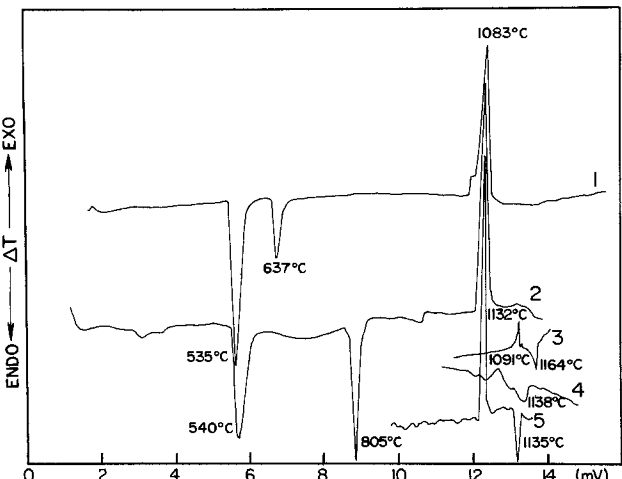

Fig. 8. Differential thermal analyses of the different sulfide layers with the abscissa mV scale corresponding to readings of the Pt-13% Rh thermocouple (the peaks at 1083°C correspond to the melting point of copper standard): curve 1, DTA trace of solidified liquid layer; curve 2, DTA trace of Ni_3S_2 external scale; curves 3, 4, 5, DTA traces of lamellar two-phase solid layer.

was decomposed by hydrolysis during handling of the material or during the course of the test. When freshly prepared samples were analyzed under ultrahigh purity argon, an additional peak at 1135°C was obtained as shown in trace 5. The liquidus temperature of Al_2S_3 varies from 1100° to 1200°C (10). It is reported that an α-γ polymorphic transformation in Al_2S_3 takes place at temperatures higher than 1100°C and that the γ-phase can be retained by fast cooling (11). Upon conducting the analysis using a tin rather than copper standard, the melting point of which interferes with the transformation peak, an exothermic peak was observed prior to the endothermic melting peak as shown in traces 3 and 4. The endothermic peak reappeared as an exothermic peak on cooling, but the exothermic peak did not reappear which can be explained by assuming that the cooling rates of 20°-50°C/min suppressed the above γ-α transformation. Any additional peak which could be attributed to the decomposition of a single phase into lamellar products was not observed below 700°C. Thus, these findings strongly indicate that the aluminum-rich phase is Al_2S_3 and that the two-phase lamellar solid layer was formed during the course of the reaction and not as a result of quenching.

A typical microprobe trace across a sulfidized specimen is shown in Fig. 9. The external scale composition corresponded to NiS at $P_{S_2} > 10^{-4}$ atm and Ni_3S_2 at the lower sulfur pressures investigated. Aluminum was not detected in these scales at the lower detection limit of 0.5 a/o. Close examination of the trace in the lamellar layer reveals that the increases in Al and S counts correspond to a decrease in the Ni counts, and vice versa. This is taken as substantiating evidence that the phases consist of Ni_3S_2 and Al_2S_3. It can be further observed from the traces that the compositions change very sharply across interfaces with a large segregation of aluminum concentration in the lamellar layer. Although the average width of individual dark and bright lamellae was of the order 1-3 μm, a few lamellae were slightly larger than the 5 μm probe diameter. Spot probe analyses proved that the bright lamellae were composed of Ni_3S_2 whereas the dark lamellae contained < 1 a/o Ni. However, insufficiently intense S-kα radiation was obtained to establish that they consisted of Al_2S_3. This latter observation is consistent with the conclusion that the material is hydrated alumina which resulted from hydrolysis of Al_2S_3 lamellae during specimen preparation and analysis. Systematic gradients in the average composition of the

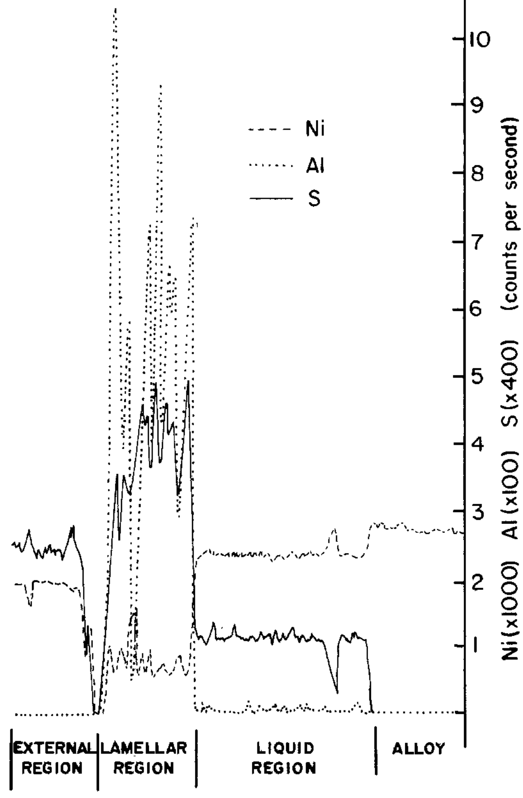

Fig. 9. Microprobe trace for Al, Ni, and S across a sulfidized Ni-6 a/o Al alloy specimen.

innermost solidified liquid layer were not observed but the composition varied to a certain extent from region to region and alloy to alloy. Several compositions are listed in Table II. The variation from an average composition over different analyzed areas on the same specimen arose from solidification of the liquid phase upon cooling into a three-phase structure containing Ni and Al_2S_3 as precipitates in a matrix of Ni_3S_2.

Discussion and Conclusions

Sulfidation of the Ni-Al alloys led to development of NiS or Ni_3S_2 scales and subscales of Al_2S_3-Ni_3S_2 lamellae and liquid Al-Ni-S layers. Scales grew by outward nickel diffusion while subscales penetrated into the alloys by sulfur diffusion. Sigmoidal-shaped reaction curves occurred in several instances as a result of nucleation of nickel sulfide which grew laterally and outward with concurrent growth of subscale from sites of imperfections distributed in the oxide films on the metallographically polished alloy surfaces. The sulfidation kinetics and morphological development of the sulfide scales and subscales can be shown to approximate most closely to a model for reaction control by interfacial processes.

ishing (Fig. 1 and 2) are analyzed by a rate equation in order to determine if the same rate constant governed growth of the isolated nickel sulfide nuclei and the fully developed scales and subscales. An equation of the form

$$\frac{\Delta w}{A} = [1 - \exp - (\beta t)^3][k_i^e t^{1/i} + k_j t^{1/j}] \quad [1]$$

describes this sigmoidal characteristic if the nickel sulfide nuclei are assumed to appear sporadically and the external and internal sulfides grow at linear or parabolic rates. The leading term in Eq. [1], which describes the fractional surface coverage of nickel sulfide, is based upon the derivation given by Evans (14) for nucleation of a phase taking place sporadically in time and position on a substrate and the nuclei subsequently spreading on the surface as expanding circles. Here, $\Delta w/A$, is the weight change per unit area of the reacting specimen, t is the time, β is a parameter having dimension t^{-3} and characteristic of the initial oxide film, and k^e, k^s are the rate constants assigned to vertical growth of the scale and subscale, respectively, where the symbols $i = 1, 2$, $j = 1, 2$ refer to conditions of linear and parabolic sulfidation, respectively.

It can be concluded that growth of the reaction products proceeded linearly since comparison of the variances of the four possible fits of Eq. [1] to results in Fig. 1 and 2 using the x^2 test proved that the variance was least at the 95% confidence level for $i = j = 1$. The overall linear sulfidation rate constant is therefore defined as $k_l = k^e + k^s$. The calculated curves in Fig. 1 and 2 and the kinetic parameters recorded in Table III summarize results of this regression analysis. Note that the irreproducibility of the sulfidation kinetics, which is best evident for two Ni-6 a/o Al specimens sulfidized at $P_{S_2} = 3.5 \times 10^{-7}$ atm, is reflected in the differences for the magnitudes of β whereas the same linear rate constant describes the kinetics. Also the presence of a thicker preformed oxide film, which retarded sulfidation significantly (Fig. 2), did so by affecting β and not by affecting the linear rate constant (Table III).

Occurrence of linear sulfidation kinetics has demonstrated that the sulfide layers were not sufficiently thick to act as rate-controlling diffusion barriers to the reacting species. The reaction rates showed a strong dependence on sulfur pressure but stagnant gas films did not act as effective diffusion barriers since the highest observed reaction rate was lower by an order of magnitude than expected by such calculations (15). Consequently, an attempt was made to determine if a surface reaction involving H_2S dissociative adsorption and sulfur incorporation into nickel sulfide would account for the effect of sulfur pressure on the reaction kinetics. This could be examined because several reaction curves exhibiting linear kinetics were carried out under conditions for growth of Ni_3S_2 scales at $P_{S_2} < 10^{-4}$ atm. Reactant diffusion in the sulfide layers, nevertheless, plays a role in view of the nickel and sulfur activity gradients which exist across the scales. According to the binary equilibrium diagram (12), Ni_3S_2-NiS and liquid sulfide-Ni exist at P_{H_2S}/P_{H_2} ratios of 0.9 and 5×10^{-3}, respectively, at 700°C. It was observed that scales consisted of Ni_3S_2 when the alloys were sulfidized in atmospheres up to ratios $P_{H_2S}/P_{H_2} = 1.5$. Thus, at best, 40% of the total sulfur activity drop across a reaction path occurs at the gas/scale interface.

Table III. Parameters of sigmoidal sulfidation equation (Eq. [1])

Alloy	P_{S_2} (atm)	β (min^{-3})	k_l (mg cm^{-2} min^{-1})
Ni-6 a/o Al	2.8×10^{-5}	$>1.02 \times 10^3$	2.07
	3.5×10^{-7}	1.55×10^{-7}	0.89
	3.5×10^{-7}	4.90×10^{-6}	0.89
Ni-13 a/o Al	1.9×10^{-2}	$>1.02 \times 10^3$	0.45
	1.9×10^{-2}	1.10×10^{-7}	0.45*
	2.8×10^{-5}	$>1.02 \times 10^3$	0.13
	3.4×10^{-6}	4.79×10^{-2}	0.09
	7.8×10^{-8}	$>1.02 \times 10^3$	0.03

* Specimen with preformed film (Fig. 2).

Detailed balancing of two surface reactions is made to obtain the functional dependence of the linear sulfidation rate constant on gas composition

$$H_2S_{(g)} = S_{(ads)} + H_{2(g)} \quad [2]$$

$$S_{(ads)} = S_{(inc)} \quad [3]$$

where $S_{(ads)}$ and $S_{(inc)}$ represent sulfur adsorbed and sulfur incorporated into Ni_3S_2 by nickel outward migration. Forward and backward rate constants in this reaction scheme are represented by k and k'. Accordingly, the linear reaction rate constant is

$$k_l = k_3\theta_S - k_3'\theta_v a_S = k_3\theta_v \left[\frac{\theta_S}{\theta_v} - \frac{k_3'}{k_3} a_S \right] \quad [4]$$

where θ_S and θ_v are the fraction of surface sites covered with sulfur and free of adsorbed species, respectively, and a_S is the sulfur activity in the Ni_3S_2 surface. Under steady-state sulfidation, $d\theta_S/dt = 0$, and

$$\frac{\theta_S}{\theta_v} = \frac{k_2 P_{H_2S} + k_3' a_S}{k_2' P_{H_2} + k_3} \quad [5]$$

At zero rates of reactions [2] and [3] for equilibrium

$$\frac{\theta_S^*}{\theta_v^*} = \frac{k_2 P_{H_2S}^*}{k_2' P_{H_2}^*} = \frac{k_3' a_S}{k_3} \quad [6]$$

where asterisks assigned to parameters of the adsorbed state and gas refer to equilibrium values. The equilibrium gas ratio is defined by

$$\frac{3}{2} Ni + H_2S = \frac{1}{2} Ni_3S_2 + H_2 \quad [7]$$

and its equilibrium constant $K_7 = P_{H_2}^*(a_{Ni_3S_2})^{1/2}/P_{H_2S}^*(a_{Ni})^{3/2}$ where a is an activity. The sulfur activity in the Ni_3S_2 surface can be defined in terms of this equilibrium gas ratio by the reaction

$$H_2S = \frac{1}{2} S_2 + H_2 \quad [8]$$

from which $a_S = K_8 P_{H_2S}^*/P_{H_2}^*$ where K_8 is the equilibrium constant. Substitution of [5] and [6] into [4] using relations from [7] and [8] leads to

$$k_l = \frac{k_2 k_3 \theta_v}{k_2' P_{H_2} + k_3} \left[1 - \frac{a_S}{a_S^{(g)}} \right] P_{H_2S} \quad [9]$$

where a_S has been defined above and $a_S^{(g)}$ is the sulfur activity in the H_2S-H_2 atmosphere during reaction. If $k_3 >> k_2' P_{H_2}$, Eq. [9] can be placed in the following form for analysis of the reaction kinetics

$$\frac{k_l}{P_{H_2}} = k_2\theta_v \left[\frac{P_{H_2S}}{P_{H_2}} - \frac{P_{H_2S}^*}{P_{H_2}^*} \right] = A \frac{P_{H_2S}}{P_{H_2}} - A';$$

$$\frac{A'}{A} = \frac{P_{H_2S}^*}{P_{H_2}^*} \quad [10]$$

Equation [10] describes the sulfur pressure dependence of the linear sulfidation kinetics for the alloys containing 3, 10, and 13 a/o Al as illustrated by the plots in Fig. 10. The intercepts on the abscissa are small and do not differ from zero at the 95% significance level in agreement with the extremely low value for the dissociation pressure of Ni_3S_2. This functional dependence has arisen because dissociative adsorption of hydrogen sulfide partially determined the reaction rate.

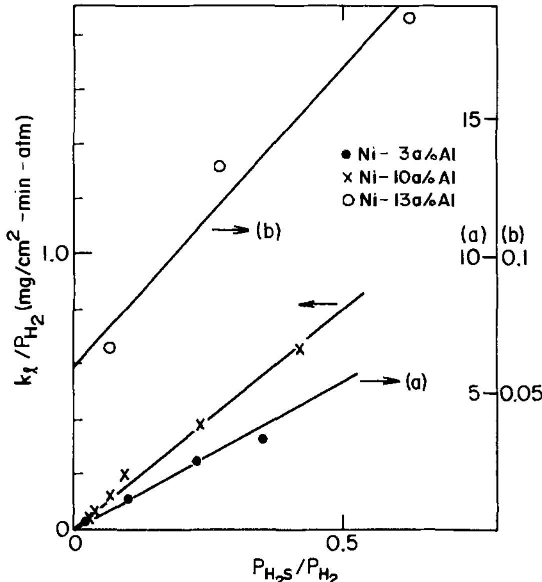

Fig. 10. Graphical representation of the linear sulfidation kinetics of the Ni-Al alloys at 700°C according to Eq. [8].

Equation [1] describing the sigmoidal shape of the reaction curves and Eq. [10] describing the sulfur pressure dependence of the linear reaction rate constant have led only to a cursory description of the sulfidation kinetics. The same linear rate constant did define the growth kinetics of the reaction products as isolated growths or as uniform scales. However, the parameter β in Eq. [1], which determined the nickel sulfide fractional surface coverage exhibited a very large variation of $\sim 10^{10}$ without any correlation to the aluminum alloy contents or to the atmospheric sulfur compositions (Table III). This large variation of β led either to long irreproducible sigmoidal overtones in the reaction curves or to practically immediate onset of linear sulfidation kinetics (Fig. 1 and 2). The model for growth of the sulfide nuclei as expanding circles is only a simple approximation (Fig. 5 and 6). The parameter β, notwithstanding, does qualitatively describe the surface coverage of the alloy by nickel sulfide up to very large sulfur uptakes as illustrated by the reaction curve for the 6 a/o Al alloy at $P_{S_2} = 3.5 \times 10^{-7}$ atm (Fig. 1) where the observed and calculated surface coverage was $\sim$0.5 after 50 min exposure. An attempt could not be made to correlate the magnitudes of the linear rate constants to the aluminum contents of the alloys using Eq. [10] because of the irreproducible influence of the initial oxide films on subsequent sulfidation behavior. For example, the reaction curves (Fig. 1 and 3) demonstrate that the Ni-6 a/o Al alloy (1 μm diamond polish) reacted by linear kinetics at $P_{S_2} = 10^{-5}$ atm five times more rapidly than the Ni-3 a/o Al alloy (15 μm silicon carbide polish). On the other hand, the alloys containing 3, 10, and 13 a/o Al, which were subjected to different metallographic polishes, sulfidized at rates decreasing with increasing alloy aluminum contents. Irreproducible properties of the initial oxide films on the alloy surfaces, accordingly, influenced all stages of the sulfidation kinetics.

The present findings and analysis indicate that reaction control is largely established by transfer of reactants across at least two interfaces, the gas/scale and scale/subscale interfaces. The same linear rate constant defined development of the corrosion products as isolated growths or complete scales, and the sulfur pressure dependence of the linear reaction kinetics was caused by an interfacial gas/scale reaction. The inert metal marker measurements also demonstrated that outward nickel and inward sulfur migration accounted for scale and subscale growth, respectively. An undefined fraction of the scale/subscale interface, nevertheless, remained partially dormant for transfer of reactants. Although nickel sulfide nuclei spread and grew from imperfections in the initial oxide films on the alloys, oxide film remnants due to incomplete dissolution of oxide into the sulfides or alloy acted as partial diffusion barriers to reactant transfer across the scale/subscale interface. This behavior cannot be quantified since the sigmoidal overtones of the reaction curves were irreproducible and the magnitudes of the linear rate constants did not exhibit a consistent dependence on alloy composition.

ABSTRACT

A computer model capable of simulating epitaxial doping profiles resulting from a variety of deposition conditions, including time-varying dopant gas flows during growth, is described. The model takes into account gas-phase dynamics, physicochemical processes at the growing epitaxial surface, and thermal redistribution of impurities during epitaxial growth. The techniques employed to obtain experimentally the values of the parameters in the computer model are described. The numerical implementation of the model in the process simulation program SUPREM is also described. Finally, numerical simulations using the model are compared to epitaxial doping profiles obtained experimentally.

The operation of semiconductor devices is dictated, primarily, by the distribution of impurities in the semiconductor. Therefore, computer programs that simulate the distribution of impurities after a complete integrated circuit fabrication sequence are a necessity. These programs can be used to optimize an IC fabrication sequence by studying the effect of process variations on the final impurity profile.

One such computer program is SUPREM (1). The Stanford University Process Engineering Models program is a computer simulator capable of simulating most typical IC fabrication steps. The input to the program is a set of process specifications for each fabrication step, and the output is a one-dimensional profile of all dopants present in the silicon and silicon dioxide.

SUPREM's capabilities of simulating IC fabrication steps rely on the physical process models that are numerically implemented. As of now, physical models for ion implantation, chemical predeposition, oxidation/drive-in, epitaxy, etching, and oxide deposition have been implemented. Recently, a new model describing the dopant incorporation process in silicon epitaxy has been reported (2, 3). This model considers gas-phase dynamics and the physicochemical processes occurring in the gas phase and at the growing epitaxial surface. By using this model it is possible to calculate the depth-variation of the epitaxial layer dopant concentration that results from any given time-variation of the gas-phase dopant partial pressure during growth (3, 4).

This paper deals primarily with this new epitaxial doping model, and its numerical implementation in the computer program SUPREM. With this new addition, SUPREM's simulation capabilities in the area of silicon epitaxy are considerably enhanced, and epitaxial impurity distributions resulting from either a time-independent or time-varying gas-phase dopant partial pressure can be readily simulated.

It is important to emphasize the relevance of a computer program capable of predicting epitaxial-layer doping profiles. Epitaxial films with uniform impurity distribution are often required in IC fabrication. However, the distribution of impurities near the film-substrate interface is, in general, nonuniform. During the initial stages of growth the dopant incorporation process goes through a transient period, and 2-3 min are required (4) before the steady-state epitaxial doping level is established. As a result, a transition layer corresponding to this initial transient develops, and the epitaxial dopant concentration within this layer is either higher or lower than expected, depending on the initial conditions prior to the deposition cycle (*e.g.*, substrate surface concentration, prebake time, prebake temperature, etc.). A special case of this initial transient problem is the commonly known "autodoping" phenomena, which occurs when lightly doped films are deposited on heavily doped buried-layers/substrates. The extent of this transition layer imposes severe limitations on the fabrication of submicron epitaxial films, which will be required with the development of VLSI technology.

Epitaxial films with intentional, nonuniform, impurity distributions are sometimes also required. These can be used to fabricate specialized devices or to optimize device characteristics. Examples of these are the hyperabrupt epitaxial tuning diodes (5), in which precisely controlled impurity distributions are needed in order to obtain the specific *C-V* characteristics. Nonuniform doping profiles can be fabricated by varying with time the dopant gas flow entering the epitaxial reactor during deposition.

In short, nonuniform epitaxial doping profiles may occur intentionally (*e.g.*, parametric diodes) or unintentionally (*e.g.*, autodoping). The availability of a simulator capable of predicting these nonuniform profiles will allow the integrated-circuit process engineer to assess the importance of any undesired transient phenomena, to optimize the device fabrication sequence, and potentially to open up vistas in the design and fabrication of integrated circuits. Langer and Goldstein (6) have already reported a numerical solution for both front and back autodoping effects as well as for impurity redistribution during epitaxial growth. As mentioned earlier, the autodoping problem is treated in this work as a special case of a more general "initial transient" problem. This approach has the advantage that the same epitaxial doping model is used to describe all transient phenomena occurring during epitaxial deposition, including autodoping.

In this paper, the epitaxial doping model implemented in SUPREM is described in detail. It is based on the model reported earlier (2) with proper modifications to make it suitable for computer implementation and to account for thermal redistribution during epitaxial growth. Following this, the techniques employed to determine experimentally the values of the parameters in the epitaxial doping model are discussed. The numerical implementation of the model in SUPREM is also briefly described. Finally, several

comparisons between SUPREM simulations and experiments are presented.

Equipment

Unless otherwise stated, the epitaxial reactor used in this work was a horizontal, rf-heated Unipak VI (Sola Basic-Tempress) that operates at atmospheric pressure. The quartz reactor tube has an effective cross section of 26 cm^2 above the susceptor. The silicon carbide-coated graphite susceptor has the dimensions 56 cm (length) × 11.4 cm (width) and is tilted at an angle of 1.5°. Hydrogen was used as the carrier gas at a velocity of 67 cm/sec above the susceptor (at room temperature). Silane was used as the source of silicon and arsine diluted in hydrogen was used as the dopant source. The corrected deposition temperature at the wafer surface was approximately 1050°C. The experiments shown in Fig. 7 were carried out in a commercially purchased horizontal reactor (Hugle Model HIER II) described elsewhere (4).

General Statement of the Problem

The problem being addressed in this work is that of determining a computer model capable of simulating the epitaxial doping profile resulting from any given time-varying, gas-phase composition during growth. The model must also account for thermal redistribution of dopant atoms in silicon during epitaxial deposition. Because the redistribution of impurities within the the solid is controlled by diffusion, the starting mathematical framework is to solve Fick's Second Law throughout the solid silicon, from a plane very deep inside the substrate up to the silicon surface. That is (see Fig. 1)

$$\frac{\delta N(z,t)}{\delta t} = D\frac{\delta^2 N(z,t)}{\delta z^2} \qquad \infty > z > z_f \qquad [1]$$

where N is the dopant concentration in the solid, D is the diffusion coefficient of the impurity in solid silicon, and z and t are the spatial and time variables, respectively. As shown in Fig. 1, the z-direction goes perpendicular to the silicon surface, and z_f is defined as the location of the moving gas-solid interface.

The solution to the diffusion equation during epitaxial growth must satisfy the following initial and boundary conditions. The initial condition is given by

$$N(z, 0) = f_1(z) \qquad [2]$$

where $f_1(z)$ represents the distribution of impurities in the substrate just before epitaxial deposition.

The boundary conditions are

$$D\frac{\delta N}{\delta z}\bigg|_{z\to\infty} = 0 \qquad [3]$$

$$D\frac{\delta N}{\delta z}\bigg|_{z=z_f} = f_2(t) \qquad [4]$$

Equation [3] indicates that the impurity diffusive flux at a plane very deep in the silicon substrate is zero. This is a reasonable boundary condition because silicon wafer thicknesses are much larger than diffusion lengths in bulk silicon.

Equation [4] indicates that the impurity diffusive flux in the solid at the gas-solid interface is, during epitaxial growth, a function of time. As will be shown later, an expression for $f_2(t)$ can be derived from a basic understanding of the mechanisms controlling the incorporation of impurities in the epitaxial silicon during growth. The time-dependence of Eq. [4] is related to (*i*) the transients associated with the establishment of a steady-state deposition process, and (*ii*) the time-variation (if any) of the gas-phase composition in the reactor. Notice that the autodoping problem falls in the first category. The right-hand side of Eq. [4] is a function of dopant partial pressure, epitaxial growth rate, deposition temperature, and to a lesser degree: reactor geometry, hydrogen velocity, etc.

In order to solve Fick's Second Law during epitaxial growth an expression for $f_2(t)$ in Eq. [4] must be obtained. This is accomplished by using the epitaxial doping model described in the next section.

Epitaxial Doping Model

In this section, the behavior of dopant species in each important region of an epitaxial reactor is studied in detail, both in terms of gas-flow dynamics and chemical kinetics. Figure 2 shows schematically a section of the horizontal reactor tube along the length of the susceptor. Three main regions are indicated in Fig. 2: 1) main gas stream, 2) boundary layer, and 3) adsorbed layer. The main gas stream consists of hydrogen mixed with silane and arsine flowing by forced convection. The boundary layer is a thin layer, about 5 mm thick, through which reactants diffuse to the silicon surface. The adsorbed layer consists of a population of hydrogen, silicon-, and dopant-containing species that occupy adsorption sites and are capable of moving on the solid surface. The behavior of dopant species in each of these three regions is now discussed, and equations describing this behavior will be derived. These equations will then be used to obtain an expression for $f_2(t)$ in Eq. [4].

Main gas stream.—In most epitaxial reactors, gas-phase depletion of dopant species in the main gas stream is almost negligible. Therefore, the partial pressure of dopant species in the main gas stream region can be assumed to be independent of position, and nearly equal to the partial pressure of dopant species at the reactor input. Moreover, the time constant associated with the transport of dopant species

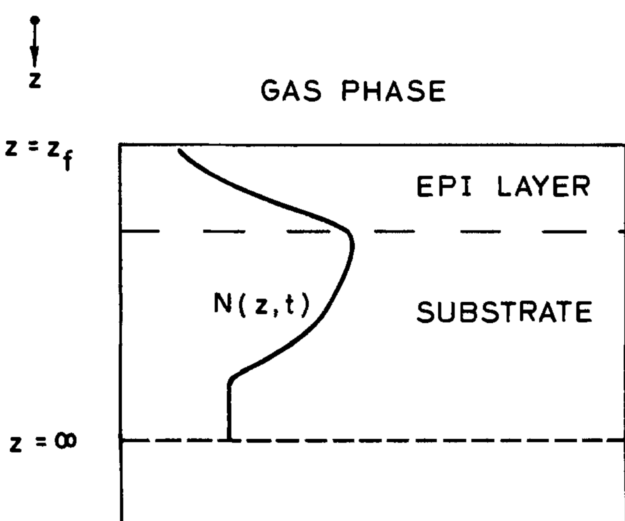

Fig. 1. Schematic cross section of a silicon wafer for the purpose of solving Fick's Second Law.

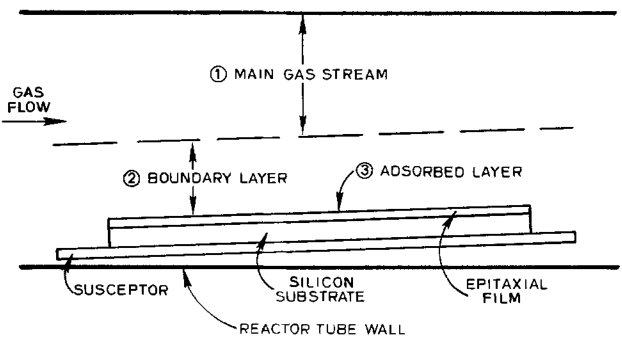

Fig. 2. Schematic section of the horizontal reactor tube along the length of the susceptor.

in the main gas stream by forced convection is of the order of 1 sec (3), while the time constant of the overall doping process in a horizontal reactor is of the order of 40 sec (4). Therefore, it can be assumed that any time-variation of the dopant partial pressure at the reactor input is transmitted "instantaneously" throughout the main gas stream. Consequently, the following expression can be used to describe the behavior of dopant species in the main gas stream region

$$P_D(t) \simeq P_D{}^\circ(t) \qquad [5]$$

in which P_D is the partial pressure of dopant species in the main gas stream region, and $P_D{}^\circ$ is the input dopant partial pressure. A more detailed discussion of the derivation of Eq. [5] is given in Appendix A.

Boundary layer.—The time constant associated with the transport of dopant species through the boundary layer by diffusion is of the order of 0.1 sec (4), which is much shorter than that of the overall doping process. Therefore, it is reasonable to assume that the flux of dopant species leaving the boundary layer by adsorbing on the silicon surface (F_s) follows closely any time-variation of the dopant flux entering the boundary layer from the main gas stream [$F_z(\bar{z})$, see Fig. 12], *i.e.*

$$F_s(t) \simeq F_z(\bar{z}, t) \qquad [6]$$

A more detailed discussion of the derivation of Eq. [6] is presented in Appendix B.

The two fluxes in Eq. [6] can be expressed in terms of deposition parameters. The flux of dopant species leaving the main gas stream toward the wafer surface [$F_z(\bar{z})$] can be approximated by (2)

$$F_z(\bar{z}) = k_m[P_D{}^\circ - P_D{}^*] \qquad [7]$$

in which k_m is the boundary layer mass transport coefficient of dopant species in hydrogen, and $P_D{}^*$ is the dopant partial pressure just above the gas-solid interface. k_m is a function of reactor geometry, hydrogen velocity, gas-phase temperature, etc. An expression for $F_s(t)$ is obtained in the next section.

Adsorbed layer.—In order to determine F_s, the sequence of steps taking part in the doping process and occurring at the silicon surface must be considered in detail. These steps are shown in Fig. 3 (2). When an arsine molecule in the gas phase is close to the silicon surface it undergoes a process of adsorption [step (1)]. The arsine molecule, once adsorbed, decomposes chemically yielding elemental arsenic [step (2)] which then diffuses on the surface until it finds an incorporation site and attaches to it [step (3)]. The arsenic atom, now incorporated in the silicon lattice, is quickly covered by subsequently arriving silicon atoms [step (4)], and diffuses into (or out of) the bulk silicon. For the treatment presented here, it is sufficient to select one of the above steps as the rate-limiting step, leaving all other steps in the sequence near thermodynamic equilibrium (2). If step (1) above is assumed to be the slowest in the sequence, the surface steps can be summarized in the following two reactions

(*i*) Arsine adsorption

$$AsH_3(g) + s \rightleftarrows AsH_3\text{-}s \quad K_1 = \frac{(\theta_D N_s)}{P_D{}^*(\theta N_s)} = \frac{k_F}{k_R} \qquad [8]$$

(*ii*) Chemical decomposition, site incorporation, and covering of arsenic by silicon

$$AsH_3\text{-}s \rightleftarrows As(ss) + s + \frac{3}{2} H_2(g)$$

$$K_2 = \frac{(k_H N)(\theta N_s) P_{H_2}{}^{3/2}}{(\theta_D N_s)} \qquad [9]$$

where s represents a vacant adsorption site on the surface, AsH_3-s represents an arsine molecule occupying an adsorption site, K_1 and K_2 are equilibrium constants, θ_D is the fraction of adsorption sites occupied by arsine, N_s is the surface density of adsorption sites per unit area, k_F and k_R are the forward and reverse reaction rate constants for arsine adsorption, θ is the fraction of adsorption sites which are vacant, k_H is Henry's law constant, and P_{H_2} is the hydrogen pressure ($\sim$ 1 atm). An expression for F_s can now be obtained by using Eq. [8] and [9] (see Appendix C)

$$F_s = k_f[P_D{}^* - N/K_P] \qquad [10]$$

where $k_f \equiv k_F(\theta N_s)$ is a kinetic constant associated with arsine adsorption, and $K_P \equiv K_1K_2/k_H$ is a thermodynamic constant relating dopant species in the gas phase and the solid silicon. Equations [7] and [10] can now be used to obtain the following expression relating F_s and the input dopant partial pressure $P_D{}^\circ$

$$F_s = k_{mf}[P_D{}^\circ - N/K_P] \qquad [11]$$

in which $k_{mf} \equiv [1/k_m + 1/k_f]^{-1}$.

As discussed earlier, the times associated with gas-phase mass transport of dopant species are negligible as compared to the time constants measured for the overall doping process. Therefore, the only mechanisms that could be responsible for these long time constants ought to be associated with the adsorbed layer. This point will become evident in the following discussion of an expression describing the behavior of dopant species in the adsorbed layer.

By considering mass balance of dopant species in the adsorbed layer the following equation is obtained

$$F_s - gN(z_f) + D\left.\frac{\delta N}{\delta z}\right|_{z=z_f} = \frac{d(\theta_D N_s)}{dt} \qquad [12]$$

where g is the epitaxial growth rate. In Eq. [12], F_s represents the rate at which the adsorbed layer increases its population of dopant species. The second term in Eq. [12] represents the rate at which the adsorbed layer decreases its population of dopant species due to the silicon covering step (see Fig. 3), and the third term represents diffusive exchanges between dopant atoms in the adsorbed layer and the bulk silicon. The right-hand side of Eq. [12] represents the rate of change of the density of dopant species per unit area in the adsorbed layer, and becomes zero when the overall doping process reaches steady state. By substituting Eq. [11] into Eq. [12], the following expression is obtained

$$k_{mf}[P_D{}^\circ - N(z_f)/K_P] - gN(z_f) + D\left.\frac{\delta N}{\delta z}\right|_{z=z_f} = K_A\frac{dN(z_f)}{dt} \qquad [13]$$

in which Eq. [9] was used with $K_A \equiv k_H(\theta N_s)P_{H_2}{}^{3/2}/K_2$. Equation [13] relates the epitaxial dopant concentra-

Fig. 3. Steps taking part in the doping process, and occurring at the silicon surface: (1) arsine adsorption, (2) arsine chemical decomposition, (3) arsenic surface diffusion and site incorporation, and (4) covering of incorporated arsenic by subsequently arriving silicon atoms.

tion at the silicon surface $N(z_f)$ and the input dopant partial pressure $P_D°$. It is clear from Eq. [12] and [13] that any abrupt variation of $P_D°$ with time during epitaxial growth is not transmitted "instantaneously" to $N(z_f)$ because some time is required before the population of dopant species in the adsorbed layer $\theta_D N_s$ accommodates to the new steady-state condition. This storage-like behavior of the adsorbed layer is responsible for the relatively long time constants measured experimentally for the overall doping process. Equation [13] can be rearranged to give the boundary condition $f_2(t)$ needed in Eq. [4], *i.e.*

$$D \frac{\delta N}{\delta z}\bigg|_{z=z_f} = f_2(t) = -k_{mf}[P_D° - N(z_f)/K_P] + gN(z_f) + K_A \frac{dN(z_f)}{dt} \quad [14]$$

Fick's Second Law (Eq. [1]) can now be solved subjected to the initial and boundary conditions given by Eq. [2], and [3] and [14], respectively. This will be carried out numerically in a manner analogous to that described by Langer and Goldstein (6). Before this numerical technique is described, however, values for the parameters in the doping model (*i.e.*, k_{mf}, K_P, K_A) need to be determined. In the next section the technique used to determine the values of k_{mf} and K_P is discussed.

Parameter Determination: k_{mf} and K_P

Numerical values for k_{mf}, K_P, and K_A were determined experimentally. In this section, the technique employed to obtain values of k_{mf} and K_P is described. It consists of comparing the predictions of the epitaxial doping model described in the previous section to experimental results. The values of k_{mf} and K_P are extracted by properly fitting theory to experiments.

The epitaxial doping model is contained mathematically in Eq. [13], which relates $N(z_f)$ to $P_D°(t)$. This equation can be simplified, however, when only "steady-state" deposition conditions are considered. The term steady state is used here to describe deposition conditions for which the gas-phase composition in the reactor has remained unchanged for a time longer than several time constants of the epitaxial system. Under these conditions, the epitaxial dopant concentration is uniform and Eq. [13] can be simplified to

$$0 = k_{mf}[P_D° - N/K_P] - gN \quad [15]$$

in which N is the uniform epitaxial doping level, and $P_D°$ and g are time-independent. Equation [15] can be used to determine the uniform epitaxial dopant concentration that results from deposition conditions in which the total deposition time is much longer than the time constant of the system, and the gas flows entering the reactor are kept constant throughout the whole deposition cycle. Equation [15] can be rearranged as

$$P_D°/N = 1/K_P + g/k_{mf} \quad [16]$$

which indicates that a plot of $P_D°/N$ *vs.* g generated experimentally under steady-state deposition conditions should yield a straight line from which values of k_{mf} and K_P can be extracted.

Figure 4 shows a plot of $P_D°/N$ *vs.* g with the circles showing experimental results carried out under steady-state conditions. In these experiments the hydrogen, silane, and arsine flows were unchanged throughout the deposition cycle. The thicknesses of the epitaxial layers were between 7 and 9 μm so as to neglect the influence of the initial transient period. The arsine partial pressure was varied to produce epitaxial doping levels in the 10^{15}-10^{17} cm^{-3} range, and the silane partial pressure was varied to produce growth rates between 0.07 and 0.42 μm/min. Higher growth rates were accompanied by a loss of growth rate and doping level uniformity along the length of the susceptor, with downstream wafers having lower growth rates and higher resistivities than upstream wafers. These nonuniformities were apparently caused by a parasitic homogeneous decomposition of silane in the gas phase. The substrates were (100)-oriented silicon wafers, boron-doped, with resistivities ranging from 1 to 4 Ω-cm. The epitaxial layer thicknesses were measured by a groove and stain technique, and the resistivity of the layers were determined by the four point probe technique. By fitting Eq. [16] to the experimental data in Fig. 4 the following values were obtained: $K_P = 1.05 \times 10^{26}$/cm^3 atm and $k_{mf} = 4.85 \times 10^{19}$/cm^2 sec atm, for the experimental conditions described above.

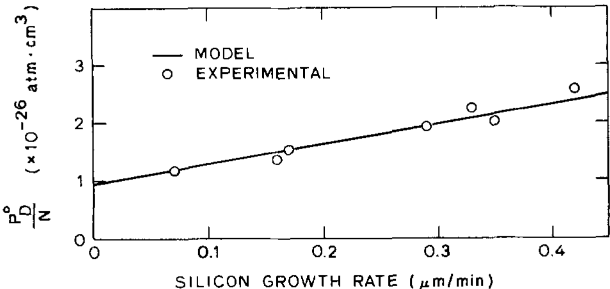

Fig. 4. Plot of $P_D°/N$ vs. silicon growth rate used to determine k_{mf} and K_P.

In this section, the technique used to obtain k_{mf} and K_P for a given set of deposition conditions was described. In order to determine the value of K_A a different technique is required. In this case, Fick's Second Law (Eq. [1]) is solved to determine the epitaxial doping profile that results when $P_D°(t)$ is varied with time during epitaxial growth. At this point, the profile depends on the value of K_A (see Eq. [13]), and a family of profiles can be obtained by varying K_A. Next, the deposition conditions simulated above are carried out experimentally, and the resulting epitaxial doping profile is measured. The value of K_A is now determined by selecting, from the family of calculated profiles, that which gives the best match to the measured profile.

Before this exercise can be carried out, however, it is important to describe the numerical method used to solve Fick's Second Law with the initial and boundary conditions given by Eq. [2], [3], and [14]. This is done in the next section.

Numerical Implementation

The built-in capabilities of the computer program SUPREM were employed in the implementation of the numerical technique used to solve Fick's Second Law with the boundary conditions dictated by the epitaxial deposition process. Because SUPREM is a program essentially capable of solving Fick's Second Law with the initial and boundary condition given by Eq. [2] and [3], respectively, the only remaining problem is to couple the surface boundary condition, *i.e.*, Eq. [14], to the main body of SUPREM. This coupling is described in this section. Figure 5 shows the discretization of the simulation space as implemented in SUPREM (1). In Fig. 5a the solid line separates the gas phase and the solid phase. P_D is the dopant partial pressure in the gas phase which, according to Eq. [5], can be approximated by $P_D°$. The solid silicon is shown partitioned into discrete cells with broken lines delineating the cell boundaries. The dopant concentration within each cell (*i.e.*, N_i, N_{i+1}, N_{i+2}, etc) is considered uniform. The coupling between the surface boundary condition (Eq. [14]) and the main body of SUPREM is carried out in two steps, and is described below.

Step 1.—At time $t = t_o$ (Fig. 5a) the doping profile in the solid silicon is known. This profile is either the initial condition (Eq. [2]) or the result of the simula-

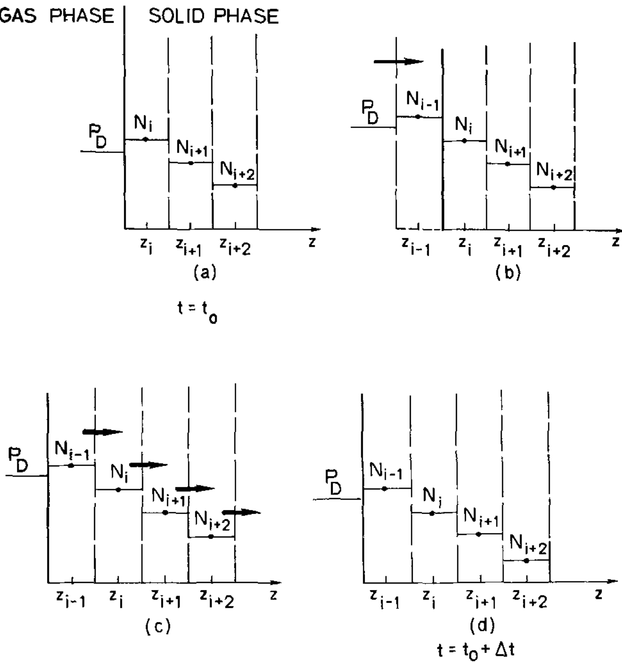

Fig. 5. Implementation of the numerical technique used to solve Fick's Second Law with the surface boundary condition dictated by the epitaxial deposition process. For explanation see text.

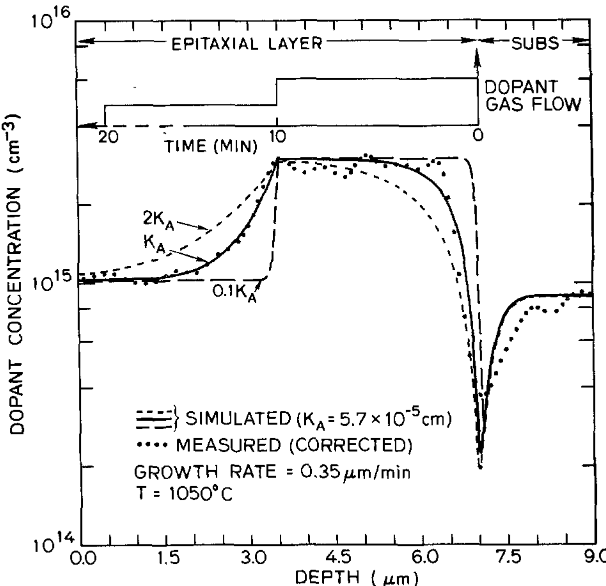

Fig. 6. Measured and simulated doping profiles used to determine K_A.

tion up to the time t_0. The cycle now starts by adding a new cell z_{i-1} (Fig. 5b). In order to calculate the dopant concentration N_{i-1} of this new cell a numerical routine is used to solve Eq. [14] with the left-hand side of the equation set to zero, *i.e.*

$$0 = k_{mf}\left[P_D^\circ - \frac{N_{i-1}}{K_P}\right] - gN_{i-1} - K_A\frac{dN_{i-1}}{dt} \quad [17]$$

This is equivalent to accounting only for dopant introduction into the newly added cell without computing the simultaneous impurity redistribution in the solid silicon. This step is illustrated in Fig. 5b, with the arrow representing the net flux of dopant atoms entering the new cell.

Step 2.—The thermal redistribution of impurities that occurs during the growth of cell z_{i-1} is now computed. This is done by entering the impurity profile shown in Fig. 5b into SUPREM, which then computes the thermal redistribution of impurities during the interval Δt under consideration. This is illustrated in Fig. 5c. The arrows in the figure represent diffusive fluxes crossing cell boundaries. Notice that no flux is shown crossing the gas-solid interface. This is because the net introduction of impurities during this interval Δt was already considered in connection with Fig. 5b and Eq. [17] when N_{i-1} was first determined. After the dopant concentration in each cell is rearranged due to these diffusive fluxes, one time increment Δt has been advanced (Fig. 5d), and the cycle of operations just described is repeated.

Parameter Determination: K_A

In this section, the technique used to determine K_A is described. As mentioned above, it consists of generating a family of doping profiles corresponding to a given $P_D^\circ(t)$ using SUPREM with K_A as a variable, and then comparing these simulated profiles to that obtained experimentally. K_A is obtained from the simulated profile that best fits the measured profile.

Figure 6 shows the results of this experiment. As indicated in the inset, the arsine flow was kept constant for the first 10 min of silicon deposition, at which point it was abruptly decreased and then kept constant at this lower level for the rest of the deposition cycle which lasted 20 min. The corresponding arsine partial pressures were 7.5 and 2.4×10^{-11} atm, respectively. A silane partial pressure of 8.4×10^{-4} atm was used to obtain a growth rate of 0.35 μm/min. In this and the following experiments epitaxial layers were deposited simultaneously on (100) phosphorus and boron-doped substrates. The layers deposited on phosphorus-doped substrates were used to measure the epitaxial doping profile, while the layers deposited on boron-doped substrates were used to measure the epitaxial layer thickness by a groove-and-stain technique. The dotted line in Fig. 6 shows the doping profile that results in the epitaxial film as measured by the spreading resistance technique and corrected using multilayer correction factors (8). (Unless otherwise stated, all measured profiles in this work were determined by the spreading resistance technique and properly corrected.) Capacitance-voltage measurements on planar p-n junctions and deep-depletion MOS structures (9) confirmed the corrected spreading resistance profile shown in Fig. 6. The solid and broken lines in the figure correspond to simulations using SUPREM for three different values of K_A. In order to obtain these simulations the input to SUPREM for the epitaxial step must specify growth rate, deposition time, deposition temperature, doping element, and dopant partial pressure. It is clear from this exercise that the doping profile corresponding to $K_A = 5.7 \times 10^{-5}$ cm shows the best fit to the measured profile.

The dip shown by the measured profile at the epi-substrate interface and predicted by the SUPREM simulations is not an artifact of the measurement technique. It is caused by a combination of phosphorus evaporation from the substrate during the high temperature bake prior to epitaxial growth and the transient in the epitaxial layer associated with the establishment of the steady-state arsenic concentration. Also, notice that the full transition between the two uniform doping levels in the epitaxial film is of approximately 2 μm. This gradual transition is due to the time required to remove the excess arsenic-containing species present in the adsorbed layer as a result of the decreasing step change in the arsine flow. This removal step occurs by dopant incorporation into the growing film and by desorption (see Eq. [12]).

In this section, the technique used to determine K_A was described. It was also shown that the numerical implementation of the epitaxial doping model described here enabled SUPREM to simulate small doping level changes during epitaxial deposition. In the

next section, the capabilities of SUPREM to simulate more complex doping profiles are demonstrated.

Comparison of SUPREM Simulations and Experiments

Figures 7a and 7b show measured and simulated doping profiles corresponding to the time-varying arsine flows indicated in the insets. In both cases the input to the epitaxial system consisted of an increasing step in arsine flow followed by a decreasing step, the combination simulating a pulse. The epitaxial layer in Fig. 7a was deposited at 0.33 μm/min, and the pulse duration was of 8.6 min. The epitaxial layer in Fig. 7b was deposited at 0.59 μm/min, and the pulse duration was only 48 sec. The broken line shows the impurity profile simulated by SUPREM. The solid line shows the corresponding majority-carrier distribution obtained by using the SUPREM output and calculating a one-dimensional solution to the Poisson's equation. The computer program SEDAN was used to obtain the Poisson solution (10). The circles indicate the epitaxial doping profile as determined by capacitance voltage measurements on deep-depletion MOS structures (4, 9). The agreement between the simulated majority-carrier profile and the measured profile is better than that between the SUPREM output and the measured profile. This is because the profile measured by the capacitance-voltage technique is a closer representation of the majority-carrier distribution than it is of the impurity distribution (11). The experiments shown in Fig. 7 were carried out in a horizontal reactor (Hugle Model HIER II) different than the Unipak system described earlier. The equipment details are reported elsewhere (4). The parameters used to simulate the Hugle reactor were obtained from the data in Ref. (4), and are shown in Table I together with those corresponding to the Unipak unit. Table II shows values of decay time τ and decay length L (3, 4) for each reactor at different silicon growth rates, calculated from

$$\tau \equiv \frac{K_A}{g + \dfrac{k_{mf}}{K_P}} \quad [18]$$

$$L \equiv g\tau \quad [19]$$

It is interesting to observe that τ and L of each reactor (for a given growth rate) are remarkably close, which indicates that the extent of any transient phenomena (including autodoping) is independent of the horizontal reactor used. These experiments clearly indicate that SUPREM is capable of simulating epitaxial doping profiles corresponding to different time-varying dopant gas flows. Moreover, these experiments demonstrated that the simulation capability of SUPREM is not restricted to one single reactor.

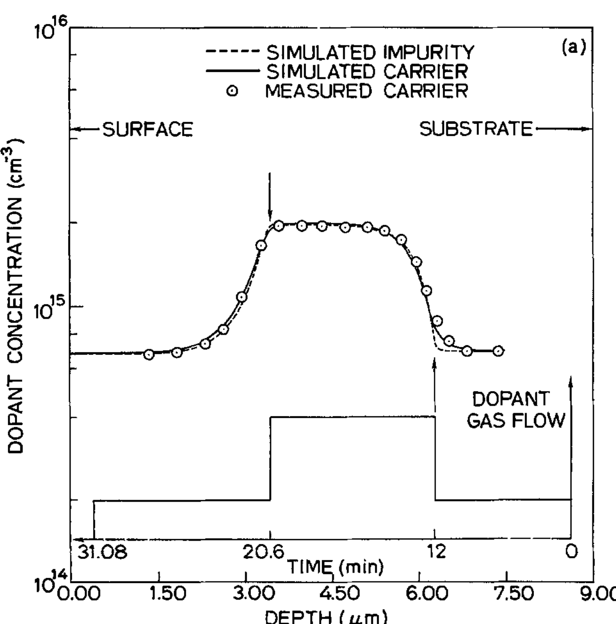
Table I. Reactor parameters corresponding to the Unipak and the Hugle units

	Unipak	Hugle
K_P (cm^{-3} atm^{-1})	1.05×10^{26}	3.8×10^{25}
k_{mf} (cm^{-2} sec^{-1} atm^{-1})	4.85×10^{19}	5.26×10^{18}
K_A (cm)	5.7×10^{-5}	4.1×10^{-5}

Table II. Decay time τ and decay length L calculated for the Unipak and the Hugle reactors at different silicon growth rates

	Unipak		Hugle	
	τ (sec)	L (μm)	τ (sec)	L (μm)
0.3 μm/min	59	0.3	64	0.32
0.45 μm/min	47	0.35	46	0.35
0.6 μm/min	39	0.39	36	0.36

Figure 8 shows measured (dotted line) and simulated (solid line) doping profiles resulting from the decreasing step change in arsine flow indicated in the inset. There are three major differences between this experiment and that described in connection with Fig. 6. These are: (*i*) the doping level change in the epitaxial film of this experiment, as shown in Fig. 8, is one order of magnitude, in contrast with the 3:1 ratio shown in Fig. 6; (*ii*) the growth rate in this experiment was 0.07 μm/min, much slower than 0.35 μm/min; and (*iii*) the total deposition time in this experiment was 90 min instead of 20 min, with the decreasing step change occurring 40 min after the start of the deposition cycle. The agreement between the simulated and measured profiles is excellent. Notice that the full transition between the two uniform doping levels in this experiment is approximately 1 μm, in contrast with 2 μm as shown in Fig. 6. The reason for this more abrupt transition is related to the rate at which silicon is deposited (3). The dip shown in Fig. 6 at the epi-substrate interface is again present in this experiment. On the other hand, the measured profile in Fig. 8 shows a pronounced peak in the epitaxial layer side of the epi-substrate interface. Careful ex-



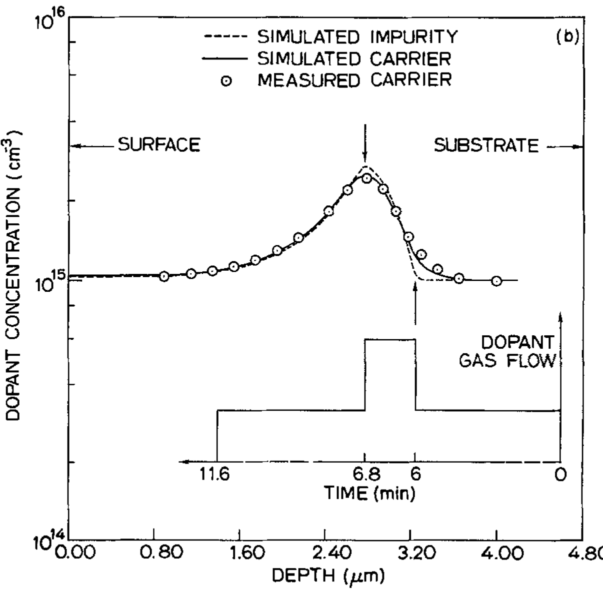


Fig. 7. Measured and simulated epitaxial doping profiles corresponding to the time-varying arsine flows indicated in the insets

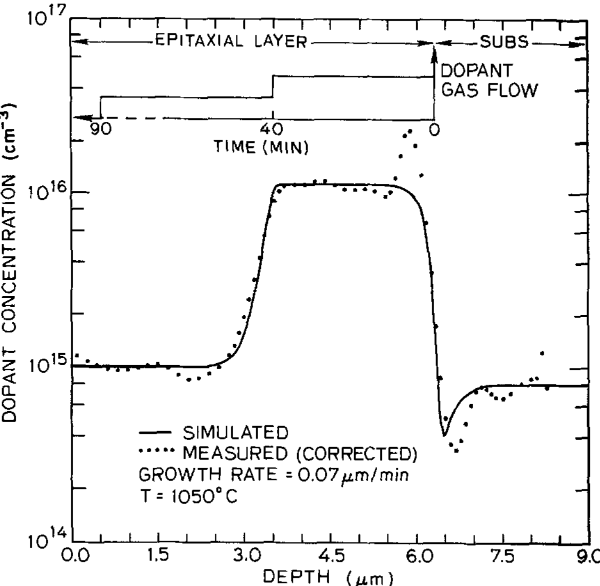

Fig. 8. Measured and simulated doping profiles resulting from the decreasing step change in arsine flow indicated in the inset.

amination of the spreading resistance data indicated that this peak is an artifact created by the computer program used to reduce the spreading resistance profile. The limitation of the program to reduce spreading resistance data for very abrupt transitions creates this artifact. Notice that this peak is also present in Fig. 6, but it is much less evident because the transition is more gradual. The conclusion from this experiment is that SUPREM is also capable of simulating large doping level changes during epitaxial growth.

Figure 9 shows another comparison between the doping profile simulated by SUPREM (solid line) and that measured by the spreading resistance technique (dotted line). In this experiment, two independent and consecutive arsenic-doped epitaxial films were deposited, as indicated in the inset. The arsine flows corresponding to the first and second layers were adjusted to produce epitaxial doping levels of approximately 10^{17} cm^{-3} and 10^{15} cm^{-3}, respectively. The reactor was purged with hydrogen for 8 min at 1050°C between the end of the first deposition cycle and the beginning of the second. The transition between the

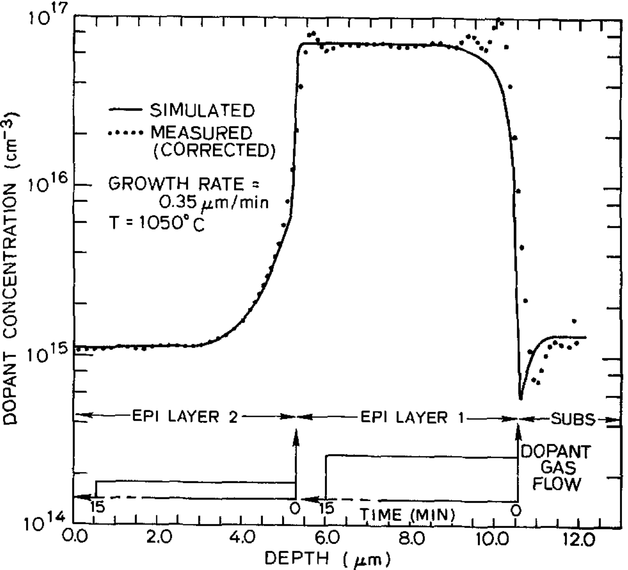

Fig. 9. Measured and simulated doping profiles corresponding to two consecutive epitaxial depositions (see text).

high doping level of layer 1 and the low doping level of layer 2 is typical of that encountered when a lightly doped epitaxial film is deposited on a heavily doped substrate or buried layer. It consisted of a very abrupt transition followed by a more gradual transition until the required impurity concentration is reached. The gradual transition is caused by the "autodoping" phenomena.

The agreement between the simulated and measured profiles in Fig. 9 is excellent. However, in order to simulate this autodoping profile, another parameter must be defined, and its value must also be determined. This new parameter is the concentration of dopant species present in the adsorbed layer prior to the epitaxial deposition step, *i.e.*, $(\theta_D N_S)^\circ$ (see Appendix D). As mentioned earlier, the initial condition of the epitaxial system is given by the distribution of impurities in the solid silicon just before epitaxial deposition. However, in cases like that shown in Fig. 9 in which the substrate doping level is much higher than the required epitaxial doping level, $(\theta_D N_S)^\circ$ is not negligible and must also be taken into account. This is because the dopant species present in the adsorbed layer prior to epitaxial deposition are responsible for the autodoping phenomena (12).

The technique used to determine $(\theta_D N_S)^\circ$ is similar to that used to determine K_A. Several SUPREM simulations, each with a different value of $(\theta_D N_S)^\circ$, were carried out until a good fit was obtained to the measured profile. The simulated doping profile in Fig. 9 was obtained with $(\theta_D N_S)^\circ = 4 \times 10^{11}$ cm^{-2}. Work is under way to determine the dependence of $(\theta_D N_S)^\circ$ on different experimental conditions, such as substrate impurity concentration, prebake time, prebake temperature, deposition temperature, total pressure, etc.

The mechanisms responsible for the autodoping tail in Fig. 9 and for the gradual transition between the two uniform epitaxial doping levels in Fig. 6 are the same. In both cases, the dopant concentration in the epitaxial film reaches the required steady-state doping level slowly, because some time is required to remove the excess dopant species from the adsorbed layer. In Fig. 6, these excess species are produced by the sudden decrease in arsine flow, while in Fig. 9 they come from the evaporation of dopant atoms from the substrate prior to epitaxial growth. Part of the excess dopant species in the adsorbed layer is incorporated in the growing film and produces the gradual transition shown in Fig. 6 and 9, and the rest is released to the gas-phase by desorption.

Finally, Fig. 10 shows the measured (dotted line) and simulated (solid line) profile of a more typical autodoping case. In this experiment arsenic was implanted (3×10^{15} cm^{-2}, 100 keV) into a boron-doped, 10 Ω-cm, (100) silicon wafer, and then redistributed for 2 hr at 1250°C. The substrate was vapor etched with HCl (0.5% by volume, 2 min, 1200°C) and then baked in hydrogen (32 min, 1200°C) before the epitaxial deposition step. The epitaxial layer deposited in this experiment was intended to be intrinsic, *i.e.*, no arsine flow was entered into the reactor. The epitaxial growth rate was of approximately 0.27 μm/min, and the total deposition time was of 6 min. The simulated profile was obtained using $(\theta_D N_S)^\circ = 4 \times 10^{11}$ cm^{-2} and agrees fairly well with the measured profile. In experiments in which different preepitaxial bake times and temperatures were used, the resulting autodoping profile was only slightly affected (13), suggesting that $(\theta_D N_S)^\circ$ is not a strong function of the hydrogen preepitaxial bake cycle. The results shown in Fig. 9 and 10 clearly indicate that SUPREM simulations can be used to estimate the extent of the autodoping phenomena.

Summary and Conclusions

A computer model capable of simulating epitaxial doping profiles resulting from a variety of deposition

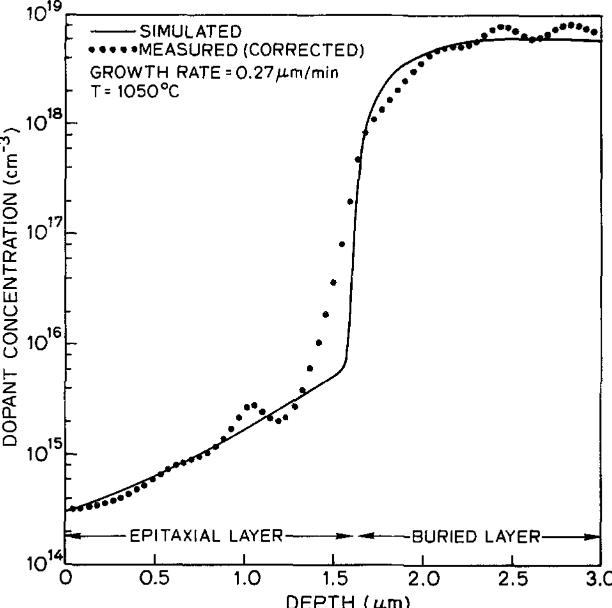

Fig. 10. Measured and simulated doping profiles corresponding to a typical autodoping situation.

conditions was described. The model consists of solving Fick's Second Law throughout the solid silicon with the proper set of initial and boundary conditions. It is necessary to solve Fick's Second Law in order to take into account the thermal redistribution of impurities during epitaxial growth. On the other hand, the boundary condition at the growing silicon surface contains information on the gas-phase dynamics and the physicochemical mechanisms taking part in the doping process. In order to obtain an expression for the surface boundary condition, the epitaxial system was separated into three regions (main gas stream, boundary layer, and adsorbed layer) and equations describing the behavior of dopant species in each of these regions were obtained. These equations were then used to determine the surface boundary condition. According to the model, three parameters are required to completely characterize an epitaxial system: k_{mf}, K_P, and K_A. k_{mf} is a kinetic coefficient associated with the mechanism dominating the dopant incorporation process. K_P and K_A are thermodynamic constants, and relate the epitaxial dopant concentration to the concentration of dopant species in the gas-phase and the adsorbed layer, respectively. A fourth parameter, $(\theta_D N_s)^\circ$, is also required when heavily doped substrates or buried layers are considered. $(\theta_D N_s)^\circ$ is the concentration of dopant species per unit area in the adsorbed layer prior to the epitaxial deposition step, and becomes appreciable for heavily doped substrates, dominating the dopant incorporation process during the first few minutes of growth. The techniques used to determine experimentally the values of these parameters were also described. Finally, the computer model was numerically implemented with the aid of the computer simulator SUPREM, and numerical simulations were carried out and compared to epitaxial doping profiles obtained experimentally. It was concluded that the numerical solution of Fick's Second Law as carried out by SUPREM using the surface boundary condition described here is capable of simulating epitaxial doping profiles corresponding to a variety of deposition conditions, including time-varying gas flows and the autodoping phenomena.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by the Massachusetts Institute of Technology.

APPENDIX A

Figure 11 shows an enlarged view of the main gas stream region. The upper tube wall is at $z = 0$, and the boundary between the main gas stream region and the boundary layer region is at $z = \bar{z}$. In the main gas stream region dopant species travel by forced convection in the x-direction, while in the boundary layer region dopant species travel by diffusion in the z-direction. F_x and F_z will be used to represent the flux of dopant species in the main gas stream and the boundary layer, respectively. F_x is assumed to be only a function of x, while F_z is assumed to be a function of x and z. By considering mass-balance of dopant species within an element of length Δx, height $\bar{z}$, and unit width in the main gas stream (see Fig. 11), the following equation can be obtained

$$[F_x(x_o) - F_x(x_o + \Delta x)]\,\bar{z} - \bar{F}_z(\bar{z})\,\Delta x = \frac{\Delta \bar{C}_x}{\Delta t}\,\Delta x\,\bar{z} \qquad \text{[A-1]}$$

in which $F_x(x_o)$ is the flux of dopant species entering the element at $x = x_o$, $F_x(x_o + \Delta x)$ is the flux of dopant species leaving the element at $x = x_o + \Delta x$, $\bar{F}_z(\bar{z})$ is the average flux of dopant species leaving the element at $z = \bar{z}$, and $\bar{C}_x$ is the average concentration of dopant species per unit volume within the element in the main gas stream. C_x is assumed to be only a function of x. In typical horizontal reactors, the susceptor is tilted to improve the uniformity of silicon deposition (7). Therefore, strictly speaking, the location of $\bar{z}$ is also a function of x. This fact has been neglected here. Equation [A-1] is valid only if (*i*) dopant species do not undergo chemical reactions within the element, and (*ii*) there is no interchange of dopant species between the upper tube wall and the element. By rearranging Eq. [A-1] and letting $\Delta x \to 0$, the following equation is obtained

$$-\frac{\delta F_x}{\delta x} - \frac{\bar{F}_z(\bar{z})}{\bar{z}} = \frac{\delta C_x}{\delta t} \qquad \text{[A-2]}$$

Equation [A-2] describes the behavior of dopant spe-

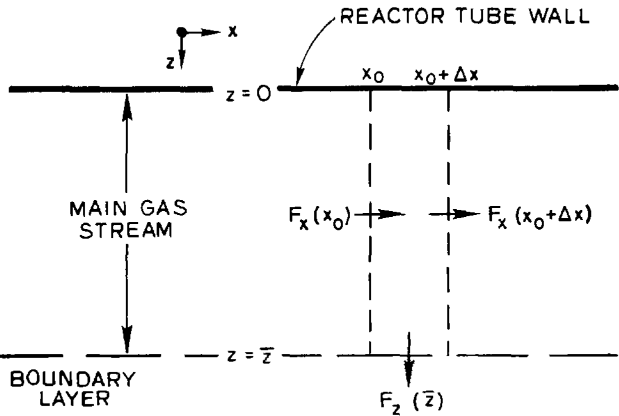

Fig. 11. Enlarged view of the main gas stream region

cies in the main gas stream. As is shown below, this equation can be simplified for most conventional epitaxial reactors.

The time constant associated with Eq. [A-2] is of the order of 1 sec (3). It has been reported, however, that the time constant of the overall doping process in a horizontal reactor is of the order of 40 sec (4). This means that in a transient situation (*e.g.*, an abrupt variation in dopant gas flow during epitaxial growth) the dopant species in the main gas stream reaches steady state long before the new steady-state epitaxial condition is established. By assuming that the main gas stream always reaches steady-state "instantaneously," Eq. [A-2] can be simplified to

$$-\frac{\delta F_x}{\delta x} - \frac{\bar{F}_z(\bar{z})}{\bar{z}} \simeq 0 \quad \text{[A-3]}$$

for the epitaxial doping process. Also, for most epitaxial reactors, the second term in Eq. [A-3] may be neglected because gas-phase depletion of dopant species caused by $\bar{F}_z(\bar{z})$ is very small, and Eq. [A-3] can be further simplified to

$$\frac{\delta F_x}{\delta x} \simeq 0 \quad \text{[A-4]}$$

Equation [A-4] indicates that F_x varies only slightly with position in a conventional epitaxial system. Because dopant species are transported by forced convection in the main gas stream, F_x can be expressed as

$$F_x = v_{H_2}(x)\,\frac{P_D(x)}{kT} \quad \text{[A-5]}$$

in which v_{H_2} is the carrier gas (hydrogen) velocity, k is the Boltzmann constant, and T the absolute temperature. By using Eq. [A-5], Eq. [A-4] can be rewritten as

$$\frac{\delta F_x}{\delta x} = \frac{1}{kT}\,\frac{\delta}{\delta x}\,[v_{H_2}(x)\,P_D(x)] = 0 \quad \text{[A-6]}$$

However, when the tilt of the susceptor is neglected, $v_{H_2}(x)$ in Eq. [A-6] can be replaced by a position-independent effective velocity $\bar{v}_{H_2}$, *i.e.*

$$\frac{\delta F_x}{\delta x} = \frac{\bar{v}_{H_2}}{kT}\,\frac{\delta}{\delta x}\,[P_D(x)] = 0 \quad \text{[A-7]}$$

Equation [A-7] indicates that the partial pressure of dopant species in the main gas stream (P_D) is nearly independent of x. Consequently, because P_D reaches steady state "instantaneously" and is nearly independent of position, then

$$P_D(t) \simeq P_D{}^\circ(t) \quad \text{[A-8]}$$

in which $P_D{}^\circ(t)$ is the input dopant partial pressure. In other words, any time-variation of the dopant partial pressure at the reactor input is transmitted "instantaneously" throughout the main gas stream in the epitaxial reactor. Equation [A-8] is sufficient to describe the behavior of dopant species in the main gas stream of most epitaxial reactors.

APPENDIX B

Figure 12 shows an enlarged view of the boundary layer, with the main gas stream on top, and the solid silicon below. F_s in Fig. 12 is the net flux of dopant species leaving the boundary layer by adsorbing on the silicon surface. An expression describing the behavior of dopant species in the boundary layer can be derived using the same technique employed in Appendix A. By considering mass-balance of dopant species within an element of thickness Δz, unit length, and unit width in the boundary layer (see Fig. 12), the following expression can be obtained

$$-\frac{\delta F_z}{\delta z} = \frac{\delta C_z}{\delta t} \quad \text{[B-1]}$$

where C_z is the concentration of dopant species per unit volume in the boundary layer. Equation [B-1] was obtained assuming that (*i*) dopant species are

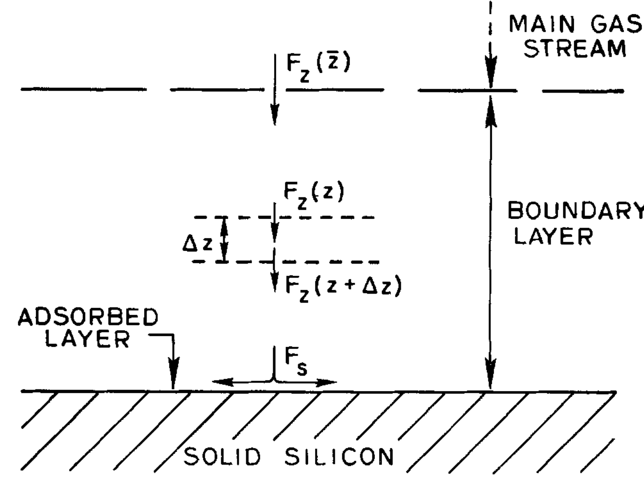

Fig. 12. Enlarged view of the boundary layer region

neither formed nor consumed within the boundary layer, and (*ii*) dopant species in the boundary layer travel only in the z-direction. C_z is assumed to be only a function of z.

Equation [B-1] can be simplified by considerations analogous to those discussed in Appendix A. The time constant associated with Eq. [B-1] is of the order of 0.1 sec (4), which is much shorter than that of the overall doping process. Therefore, the dopant species in the boundary layer are essentially always at steady state, *i.e.*

$$\frac{\delta F_z}{\delta z} \simeq 0 \quad \text{[B-2]}$$

and F_z can be considered position-independent regardless of whether the overall doping process is at steady state or undergoing a transient. This means that the dopant flux leaving the boundary layer due to surface adsorption always follows closely the time-variation of the dopant flux entering the boundary layer, *i.e.*

$$F_s(t) \simeq F_z(\bar{z}, t) \quad \text{[B-3]}$$

and vice versa. Equation [B-3] is sufficient to describe the behavior of dopant species within the boundary layer.

APPENDIX C

From Eq. [8]

$$F_s = k_F(\theta N_s) P_D{}^* - k_R(\theta_D N_s) \quad \text{[C-1]}$$

which can be rearranged as

$$F_s = k_F(\theta N_s)\left[P_D{}^* - \frac{k_R}{k_F}\,\frac{(\theta_D N_s)}{(\theta N_s)}\right] \quad \text{[C-2]}$$

By using Eq. [8] and [9], Eq. [C-2] can be rewritten as

$$F_s = k_F(\theta N_s)\left[P_D{}^* - \frac{1}{K_1}\,\frac{k_H}{K_2}\,P_{H_2}{}^{3/2}N\right] \quad \text{[C-3]}$$

or

$$F_s = k_f[P_D{}^* - N/K_P] \quad \text{[C-4]}$$

in which $k_f \equiv k_F(\theta N_s)$, $K_P \equiv K_1K_2/k_H$, and $P_{H_2} \simeq 1$ atm was omitted for simplicity.

APPENDIX D

As discussed in the section on Numerical Implementation, the dopant concentration of each new cell is first computed by solving Eq. [17], *i.e.*

$$0 = k_{mf}\left[P_D{}^\circ - \frac{N}{K_P}\right] - gN - K_A\frac{dN}{dt} \quad \text{[D-1]}$$

The initial condition of Eq. [D-1] is the dopant concentration of the epitaxial film at $t = 0$, which is given by

$$N(0) = K_A\,(\theta_D N_s)^\circ \quad \text{[D-2]}$$

Technical Notes

Lift-Off Patterning of Sputtered SiO_2 Films

Tadashi Serikawa and Toshiaki Yachi

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratory, Midori-cho, Musashino-shi, Tokyo, 180 Japan

Sputtered SiO_2 film is used as an intermediate insulator in multilevel metallization and as a final passivator in large-scale integrated circuits, because good film characteristics can be obtained at low temperature deposition (1, 2). SiO_2 film is usually patterned by wet chemical etching or plasma etching using photoresist patterns as the etching mask. Wet chemical etching and plasma etching in a barrel reactor, however, have the disadvantage of side-etching due to lateral attack by the etchant. The plasma etching method usually called reactive ion sputter etching does not have this disadvantage. In this method, the pattern sidewall taper is obtained only when many factors, such as photoresist sidewall angle, photoresist thickness, and relative etch rates of substrate and photoresist, are precisely controlled (3). On the other hand, lift-off technique is promising for producing a fine pattern in a large-scale integrated circuit. The lift-off method has been employed in aluminum metallization (4), but no study has been reported on sputtered insulating films. In this study, a lift-off method for sputtered SiO_2 film is proposed. An SiO_2 pattern with positive slope sidewalls was successfully produced without pattern width reduction through successively following the steps shown in Fig. 1: (*i*) photoresist pattern formation, (*ii*) SiO_2 film deposition, (*iii*) slight etching with buffered hydrofluoric acid to remove SiO_2 film deposited on photoresist sidewalls, and (*iv*) removal of the photoresist.

Experimental

Patterns of positive-type photoresist (AZ1370) were formed on a silicon substrate using conventional photolithography. Postbaking was performed at 140°C. These patterns were 1 μm thick and had 60° slope sidewalls. SiO_2 film was deposited on these substrates with a planar rf magnetron sputtering apparatus. The substrates were placed on a rotating substrate holder and were electrically at floating potential during deposition. The smallest spacing between the substrate and the target was 50 mm. The target was a 3 mm thick, 125 mm × 375 mm, 99.99% pure SiO_2 sheet. Film deposition was carried out at 0.3 Pa argon pressure, at a 4 nm/min deposition rate, and at temperatures less than 180°C. SiO_2 film on the photoresist sidewalls was removed by slight etching in buffered hydrofluoric acid [100 ml (50% HF) + 860 ml (40% NH_4F)]. Unwanted SiO_2 film was removed along with photoresist patterns by soaking the substrates in photoresist strip (J-100). After cleaving substrates at various steps, the fractured sections were studied using scanning electron microscopy (SEM).

Key words: intermediate insulator, magnetron sputtering, shadowing effect.

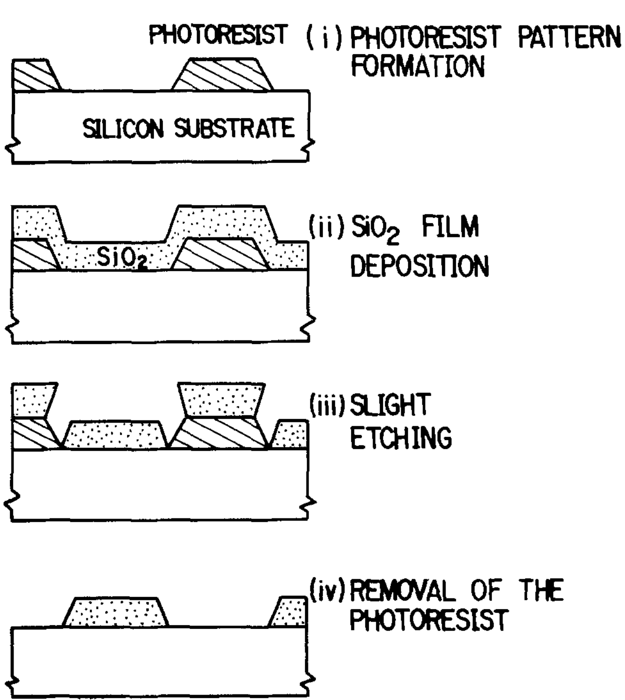

Fig. 1. A diagram of the successive steps for lift-off patterning of sputtered SiO_2 films.

Results

A deposited sample with about 1 μm thick SiO_2 film was lifted off according to the process in Fig. 1. Figure 2 shows SEM photographs at the various steps. The film thickness at photoresist sidewalls is less than the thickness elsewhere, as shown in Fig. 2(a). However, as shown in Fig. 2(b), the film on the photoresist sidewall is completely removed when slightly etched in buffered hydrofluoric acid at 30°C for 30 sec. This is because the film at the sidewall is porous and has about a 2.0 μm/min etching rate, which is much higher than the 0.1 μm/min etching rate elsewhere. Consequently, grooves were formed having tetragonal cross sections on the side of the photoresist pattern sidewall. Soaking the sample in a solution to dissolve photoresist material removed unwanted SiO_2 film along with the photoresist pattern. Thus, an SiO_2 film pattern was formed, as shown in Fig. 2(c). SiO_2 patterns are successfully obtained without pattern width reduction, because a boundary between the porous film and the dense film is formed along a line from the under edge of photoresist pattern to the SiO_2 film edge in the deposited sample. In addition, the SiO_2 lifted-off patterns have sloped sidewalls even when sidewalls of photoresist pattern have positive slopes as shown in Fig. 2.

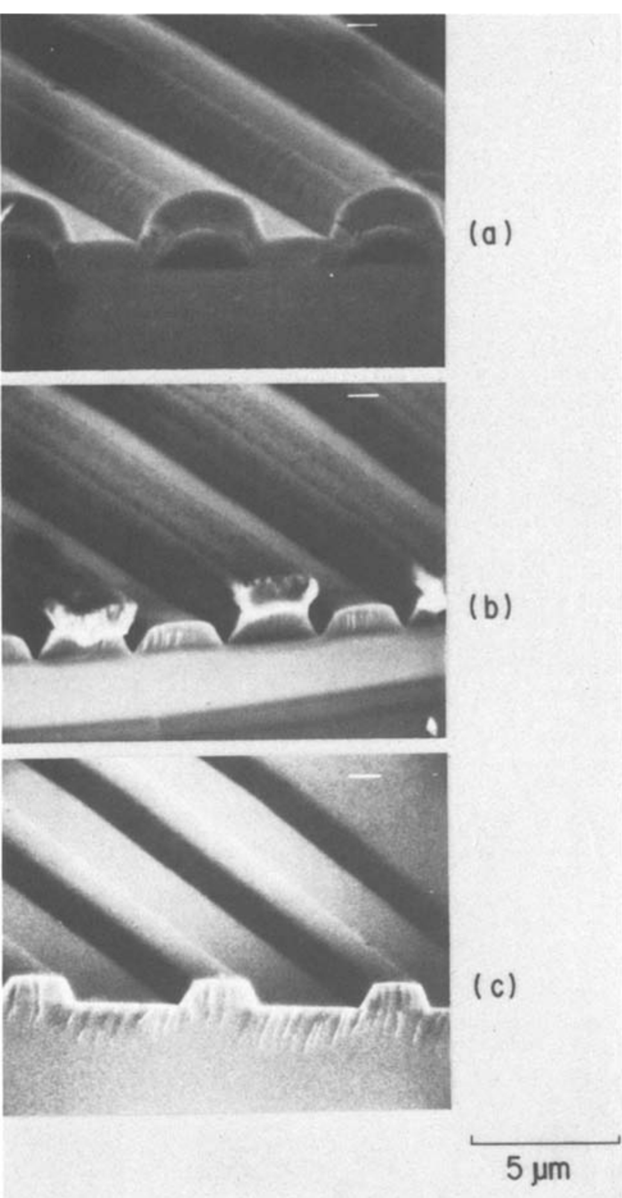

Fig. 2. SEM photographs of lift-off patterning processes. (a) SiO_2 film deposited. (b) After slight etching for 30 sec. (c) After lift-off patterning.

The porous structure near the photoresist pattern sidewall is the result of shadowing of deposited SiO_2 material in the photoresist pattern step (5-7). The substrate near the step sees less of the target area, hence it receives less incoming SiO_2 material than the surrounding surface. Thus, it has a smaller deposition rate. Also, the SiO_2 film deposition rate on the photoresist pattern top is high enough to result in greater shadowing effect, causing the formation of a porous film structure. Consequently, sputtered SiO_2 film patterns are easily lifted off. However, the detailed formation mechanism of a distinct boundary between the porous structure area and the dense film area near the step is not completely understood.

In conclusion, sputtered SiO_2 film patterns with sloped sidewalls were successfully produced using a lift-off technique without pattern width reduction. Therefore, this method is very useful for patterning SiO_2 films in integrated semiconductor device fabrication.

A High Resolution Etching Technique for Determining Epitaxial Layer Thickness

C. W. Pearce*

Western Electric Company, Allentown, Pennsylvania 18103

This paper describes the use of Secco etching to develop the thickness topography of an epitaxial layer. The technique is capable of 0.1 micron resolution and could be used as a test method in research or production. A potential application would be the evaluation of material used for bipolar device fabrication where the epitaxial layer thickness is a key parameter, such as the OXIL (1) (oxide isolated logic) technology. The etching method was more reliable in determining epitaxial thickness variation than infrared measurements in the cases studied.

Background

Preferential etching of silicon to reveal defects (or junctions) has become a well-established investigative tool (2). It is widely used because of its convenient and inexpensive nature in research and production applications. A number of etchants have been reported in the literature (3-5), each with particular characteristics. As a guide to potential applications, there have been a number of etchant comparisons made (6, 7). Schimmel (8) in particular examined the characteristics of the hydrofluoric acid, chromic acid, and water etching system to develop an optimum etch for heavily boron-doped silicon. Futagami (9) added a degree of sophistication by distinguishing decorated from undecorated stacking faults using Sirtl etch.

This report describes the application of silicon etching in determining the radial thickness variation in an epitaxial layer. Customarily, this parameter is measured using an infrared reflectance technique (10), although the geometry of epitaxial stacking faults (11) and junction staining (12) have also been utilized. Evaluating radial variation with such methods is customarily limited to a few measurement points, which may not adequately characterize the surface of a large diameter wafer. Here, the staining which occurs on a heavily boron-doped substrate when using Secco's etch (8), and the etch rate are used to measure epitaxial layer thickness. Although destructive, since the whole wafer is etched, contours of constant thickness can easily be generated by step etching.

Experimental

Developing an accurate topography requires precise control of the etch rate, which entails control of etch temperature and composition. These requirements were accomplished for Secco's etch by using the following procedure. A 5.42g wafer was placed in 150 cm^3 of solution and left to etch until the reaction was complete, resulting in the dissolution of 0.23g of silicon. It was estimated that approximately 25,000 cm^3 of etchant for each gram of silicon to be removed would be of sufficient volume to keep both parameters essentially fixed, yielding a constant etch rate. This estimate was verified by etching 0.22g of silicon in 5300 cm^3 of solution and checking the etch rate at the beginning and the end of etching. The silicon to be removed can be calculated from the nominal layer thickness and wafer surface area. The value should be doubled if the rear surface is unmasked, or adjusted if the substrate has a different etch rate from the layer. In the first example, the substrate etched 3.5$\times$ as fast as the layer (7), hence we decided to mask the rear surface with wax to keep the etch volume reasonable.

The sensitivity of etch rate to temperature was determined to be nominally 0.02 μm/min/°C by measurements at 32° $\pm$ 2°C and at 89° $\pm$ 4°C. This parameter is assumed linear over the range of temperatures studied.

To develop a topograph, a 100 mm diam, P/P+, wafer was etched face up in 5300 cm^3 of solution. The layer thickness was 11 μm and the substrate resistivity 0.008 Ω-cm. The wafer was first measured at five points by the infrared method using a DIGILAB FTG-12.[1] The initial etch rate was 0.45 μm/min after etching for 20 min the substrate first appeared via the stain. At this point, the etch rate was rechecked and found to be the same. The wafer was then step-etched to develop contours representing 0.23 μm, each step representing 30 sec of etching. After each etch, the outline of the stained region was traced onto paper to develop Fig. 1A. There is some subjectivity in the tracing as the stain demarcation is not always abrupt. Temperature was monitored throughout the etching and found not to vary.

A second example consisted of a 76 mm diam wafer etched in 150 cm^3 of etchant. The layer thickness was nominally 2.3 microns and the rear surface was masked with wax. The substrate was patterned and diffused with antimony and boron typical of OXIL processing. The etching time was varied for this wafer based on a visual observation of the developing pattern during the etching. Figure 1B is the resulting topograph.

Discussion

In the case of Fig. 1A, the thickness variation by etching was found to be 1.8 μm, which is three times as great as the variation seen by the five-point infrared measurements. However, the diameter of maximum

[1] Trademark of Digilab Incorporated, Cambridge, Massachusetts.

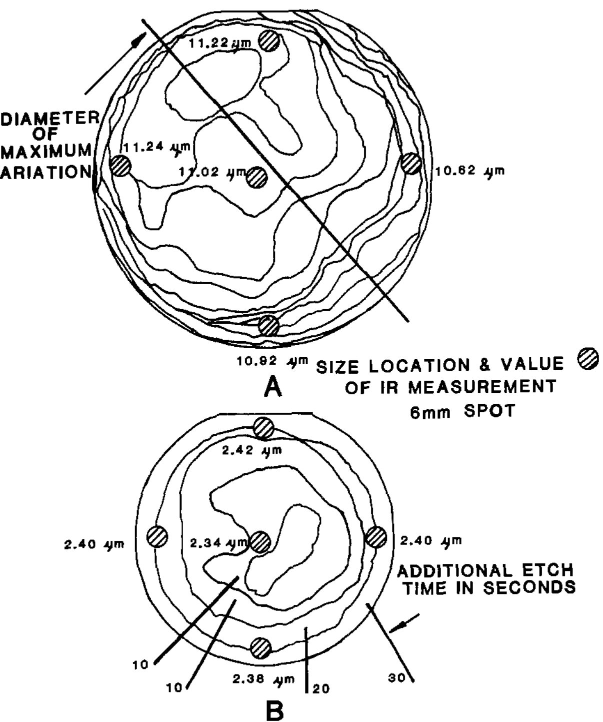

Fig. 1. Two topographs of epitaxial layers by Secco etching

* Electrochemical Society Active Member.
Key words: silicon, etching, defects.

variation did not coincide with any diameter defined by the *IR* measurements. In terms of absolute values, the center thickness was estimated to be 11.60 μm by etching which compares favorably with the *IR* value of 11.02 μm.

The second wafer had a topography (Fig. 1B) nominally concentric about the wafer center, but offset from the center *IR* measurement point. Starting at the first contour the thickness variation was calculated as 0.34 μm. This is substantially greater than the 0.08 μm derived from the *IR* measurements. Furthermore, the *IR* measurements predicted the center to be the thinnest region of the wafer. The *IR* results mainly reflect the measurement scatter of the FTG-12.

The repeatability of the instrument is nominally ±0.1 μm (3 sigma). Thus, on a fairly uniform layer measurement scatter is a dominant effect. The etch method would in general be correct with respect to the direction and shape of thickness variation. Changes in etch rate would lead to uncertainty in the position of a given contour, but the correct sense of thickness variation is maintained between contours. In terms of absolute thickness, the extreme edge cleared first at 3 min of etching, after 3½ min the edge near the *IR* readings was cleared for a thickness of 1.6 μm compared to the 2.4 μm by *IR*. The difference is not unexpected and is ascribed to the faster outdiffusion of the boron buried layer that stains, relative to the slower diffusing antimony buried layer, the latter diffusion determining the position of the *IR* reading. SUPREM (Stanford University Process Engineering Models) calculations show a difference of 1 μm between the peak concentration points of the two diffusions.

By using a sufficient volume of solution it is possible to obtain an etching bath for silicon wafers having a constant etch rate. This can be used to determine the total extent of thickness variation in an epitaxial wafer provided the substrate shows some staining. In the examples presented herein five point *IR* measurements tended to underestimate the thickness variation for two reasons. The customary five-point measurement often misses high and low points on the wafer and generally excludes some edge variation. Given an etch rate of 0.45 μm/min and etch times of 10 sec, the resolution achievable is on the order of 0.1 μm. This would be useful for evaluating wafers where layer thickness is a key parameter such as in the OXIL device fabrication technology. Thus, an epitaxial reactor could be profiled by wafer etching to determine the most meaningful places for *IR* measurements to be made.

Minority Carrier Diffusion Length EBIC Measurements in Cadmium Telluride

P. Gaugash[1] and A. G. Milnes*

Department of Electrical Engineering and Center for the Joining of Materials, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213

Diffusion Lengths in CdTe

CdTe is a direct-gap semiconductor (bandgap 1.45 eV) that is used in nuclear particle detectors and for optical modulation purposes. It is a II-VI compound semiconductor that can be doped both n and p-type and the carriers have acceptable mobilities ($\mu_n \sim$ 500-1200 cm²/Vsec, $\mu_p \sim$ 50 cm²/Vsec) (1).

However, CdTe has potential beyond its present uses. This potential lies in the combination of optical and electrical properties it offers. CdTe is a material of high potential for solar cells with possible efficiencies of npCdTe cells of up to 22-25%, matching that of GaAs. Even heterojunction cells of nCdS/pCdTe are considered to have the potential for 17% efficiency. Ten to 12% efficiency has been achieved in the work of Yamaguchi *et al.* (2) with cells prepared by vapor-phase epitaxy of n+CdS on single crystal pCdTe wafers Among those who have worked with this material there is optimism that heterojunction CdTe/CdS or homojunction pnCdTe thin film cells offer important alternatives to Cu_2S/CdS and GaAs thin film cells (3-6).

One problem that limits the solar cell performance presently obtained with CdTe is the tendency of the single crystal ingot material to have low minority diffusion lengths. For instance, Bell *et al.* (3) report hole diffusion lengths between 0.4 and 0.8 μm for n-type CdTe with Cl, Br, or I doping in the range 2-6 × 10^{17} cm^{-3}. Higher L_p diffusion lengths, such as 1.75-3 μm, may have been observed particularly with "undoped" or In-doped n-CdTe (7). The present work documents such values from EBIC measurements for several ingots and doping levels and reports some unexpected features of the measurements.

Samples and Preparation of Schottky Barrier EBIC Specimens

The specimens available were taken from four n-type ingots and four p-type ingots. All of the ingots, except C, were grown by a modified Bridgman method that used a molten Te zone so that the maximum temperature involved was about 750°C (8). This presum-

ably results in less pick-up of impurities such as silicon, oxygen, and copper, from the system and quartz growth tube, than when a normal Bridgman growth is made at 1100°C.

For the electron-beam-induced current (EBIC) measurements, slices about 0.030 in. thick were cut and polished with Mirrolux and 0.05 μm Al_2O_3 grit and polish-etched in methanol-bromine (0.5%) solution. The ohmic contact on the reverse side of n-type slices was provided by an indium evaporation and the substrate raised to about 200°C for a few minutes to provide some alloying action. Gold for the Schottky barrier ($\phi \sim 0.85$ eV) was then deposited on one side by gold evaporation. The Schottky barrier area was about 10^{-4} cm². For the p-type slices the procedure was to evaporate Au for the ohmic contact with a short 200°-250°C heat-treatment, and then Al was evaporated for the Schottky barrier.

An hour or so before insertion in the scanning electron microscope (JSM-35) the specimens to be measured were cleaved across the Schottky barrier, mounted in a T05 header, and checked for leakage currents of less than 10^{-9}A at a reverse voltage of 1V. The diffusion length measurement procedure was then as described by Sekela *et al.* (10) or others (11-14) with about 0.1V or less reverse voltage applied to the diode. Most of the measurements were made at a beam voltage of 25 keV and a beam current in the low 10^{-10}A. (This current varies by factors of several times between different measurements, depending on the microscope focus and collimation adjustments.) Some measurements were made with larger beam currents, up to 10^{-7}A, and in these the effects of series-resistance drop in the semiconductor caused by larger beam-induced currents required more reverse voltage across the device. A few measurements were also made with the beam voltage varied between 5 and 25 keV, however no well-behaved data were obtained from which the recombination velocity of the cleaved surface could be inferred (11). In general, the surface was found to be rather insensitive: After many weeks of storage on air the specimens gave almost the same diffusion lengths as just after cleaving. Neither did we see any effects of carbon deposition from the vacuum column or of repeated scanning with the electron beam of the surface track measured (14).

Diffusion Length Results

Table I shows the results for some of the specimens measured. The curves obtained for specimens No. 20 and 22 are shown in Fig. 1. The diffusion length for specimen No. 20 is seen to be 2.8 μm. A specimen No. 22 from the same slice given a heat-treatment in Cd vapor at 750°C for 120 hr in a quartz ampul showed only a slightly lower diffusion length, 2.4 μm, even though

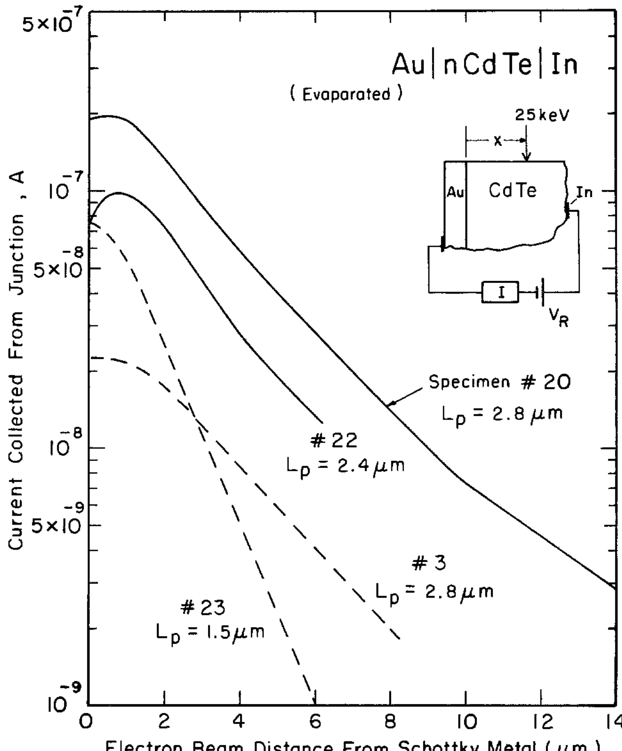

Fig. 1. Diffusion length measurements, L_p, for n CdTe with evaporated Au Schottky barrier.

there was a very large reduction in resistivity. The results for specimens 3, 23, and 49 show a somewhat larger change after Cd vapor treatment.

Specimen No. 27 from a different slice of the ingot A was anomalous since it exhibited an apparent diffusion length of 4.4 μm in the first 5 μm from the barrier surface, followed by 1.3 μm in the next 5 μm. The implication is that lifetime controlling impurities or defects have either entered or been taken from the 5 μm surface region. Annealing of similar material in Cd vapor, at 750°C for 120 hr as before, gave for specimen 30 similarly anomalous results with an initial L_p of 3.3 μm changing into 1.6 μm. If the effect is caused by an impurity entering from the surface during the heat-treatment, it should be noted that a very small surface concentration such as 10^{13} cm^{-2} (about a hundredth of a monolayer) entering to a depth of 5 μm could cause a concentration of 2×10^{16} cm^{-3} if uniformly distributed. This density of defects could have a profound effect on the doping density or on the density of active

* MB means modified Bridgman growth with Te molten zone (8).
B means normal Bridgman growth.

recombination centers. Alternatively a very thin high-concentration surface skin could develop that might have the effect of gettering recombination defects from the bulk. Defect gettering appears to occur in GaAs as a result of sub-monolayer surface contamination from various etches used, even though the chemicals are of semiconductor grade purity for Si processing (13-15). Further experiments to establish whether similar effects occur for CdTe need to be done.

Cd vapor treatment as applied here certainly did not improve the hole diffusion lengths. The large increase in n-type conduction after such a treatment is presumably a consequence of reduction of V_{Cd} or V_{Cd}^{2-} or V_{Cd}-donor complexes [see Table 3.4 of Ref. (1)].

Comparison of the results for specimens 20 and 3 suggest that growth by the modified Bridgman method (8), involving a Te molten zone and a temperature of about 750°C, does not automatically result in a longer hole diffusion length than the normal Bridgman method at 1100°C. However, the sample comparison is limited and one cannot help feeling that the lower temperature process should allow less contamination from the system (8, 16). Ge and Sn are considered to have adverse effects on lifetimes on CdTe but little is reported about the effects of Si. The iodine-doped specimen, No. 13, is seen to have a lower diffusion length than the indium-doped specimens 20 and 22. This is in agreement with the experience of other workers (3, 4).

The results for L_n in p-type CdTe show low diffusion lengths in the range 0.5-0.9 μm, Fig. 2, again in agreement with other reports (3).

In the course of the studies an attempt was made to obtain an Au Schottky barrier, or thin p region, from a solution known as Goldfilm (manufactured by the Emulsitone Company and described as forming a polymer with gold atoms attached through suitable groupings to a carbon-carbon backbone). This material is supplied as a source of Au for use in lifetime control in silicon. The company also states that on Si wafers heated to 250°-300°C, for 5-10 min, film decomposition occurs and a yellow film of 20-100Å of gold is deposited. This Goldfilm was applied to a number of n CdTe specimens prior to the 250°C 10 min heat-treatment for the In ohmic contact. An EBIC curve typical of the results is shown in Fig. 3. It appears that the Au has doped the CdTe p-type to a depth of about 4 μm and both hole and electron diffusion lengths are observed, L_p = 1.6 μm and L_n = 1.5 μm. The flat response region between 4 and 8 μm presumably represents a region of high resistivity where field-aided collection of current occurs. Since the junction depth is deep, the diffusion of gold in CdTe must be rapid at 250°C, but no information on this has been found in the literature (17).

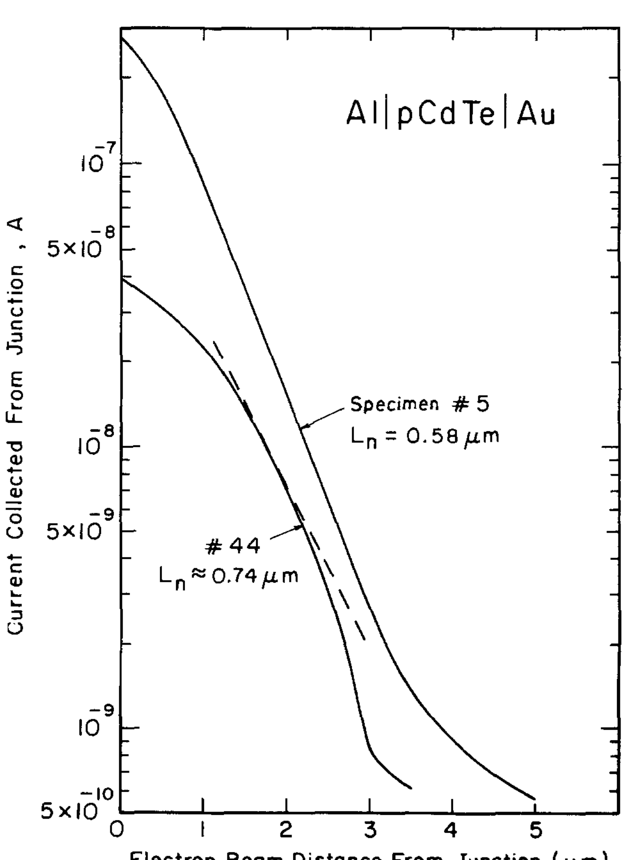

Fig. 2. Diffusion length measurements, L_n, for p CdTe with evaporated Al Schottky barrier.

Conclusions

Hole diffusion lengths of greater than 2.5 μm are obtainable in n-type CdTe ingot material doped in the high 10^{16} cm^3 range. Electron diffusion lengths for p-type ingot material are normally between 0.5 and 0.9 μm.

There is no reason to believe that these represent limiting values that cannot be improved by further attention to purity and crystal perfection and careful handling of the material before heat-treatment.

Etching of Cadmium Telluride

P. Gaugash[1] and A. G. Milnes*

Electrical Engineering Department and Center for the Joining of Materials, Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213

Etching Procedure and Rates

CdTe is a semiconductor of bandgap 1.45 eV that can be doped both n and p-type and also is available in a semi-insulating form (1). It is used in nuclear particle detection and for its electro-optical properties. Interest is also growing in the potential of this material for solar cells.

The slices selected for these etching studies came from ingots grown by a modified Bridgman method with a Te melt zone at 750°C. Details of the material will be found in a companion paper (2). The slices were cut with a diamond saw and lapped with an Al_2O_3 grit and a Mirrolux solution. In general the orientation was (111).

About ten etching solutions were selected from the general literature of etching solutions for semiconductors (4, 8, 9). The experiments were made at room temperature with gently agitated solutions and the etching rate determined by weight loss. The etchant compositions are shown in column (i) of Table I and the etch rates in column (ii). The rates should be taken as a guide only, since repeated experiments were not made to obtain average numbers or to reveal the effects of starting surface conditions or slight differences in solution temperature or agitation rate. Column (iii) comments on the appearances of the surfaces after etching.

Auger Studies

From previous work it is known that there is a tendency for Te rich layers to be formed on CdTe surfaces by some etches. Presumably this is because the etches cause soluble Cd salts to form and do not react with the Te or form insoluble Te salts.

To determine which of the etches studied produced Te rich layers, the surfaces were examined with a Perkin Elmer Physical Electronics Auger spectrometer. The ratio of the Cd signal peak (at 376 eV) to Te signal peak (at 483 eV) is 1.42 with an input electron beam of 3000 eV according to the handbook supplied

Table I. Results of etching and Auger measurements for n CdTe

Composition of etching solution (by volume)* (i)	Approximate etching rate (~300 K) (ii)	Comments on the appearance of surface (iii)	Auger measurements: Ratio Cd_{peak}/Te_{peak} (iv)	Auger measurements: Estimated Te layer thickness (v)
HCl or H_2SO_4	None detected	—	—	—
HNO_3	3.5 μm/min	Dark precipitate, easily removed mechanically	—	—
NaOH	1.6	Produces bright surface	—	—
10% NaOH + Na_2SO_4	1.2	Produces bright surface	1.42	None
2 HF, 1 HNO_3, 1 CH_3COOH	60	Pits form	1.42	None
0.5% Br_2 in CH_3OH (medium red in color)	2.8	Pits form	1.44	None
50 HNO_3 + 10 CH_3COOH + 1 HCl + 18 H_2SO_4	8.0	Polishes	1.40	None
7g $K_2Cr_2O_7$ + 3g H_2SO_4	2.3	Polishes	0.9	50-100A
0.5% Br_2 + 10 mg $AgNO_3$ + CH_3OH (medium red in color)	2.2	Pits form, p-n junction	1.1-1.2	—
2 H_2O_2, 3 HF, 1 H_2O	3.4	Polishes one (111) face (5)	0.2	600-800A
2 HNO_3, 2 HCl, H_2O	12.5	Pits form	0.15	500-800A
10 ml HNO_3, 20 ml H_2O, 4g K_2CrO_7	4.2	Mirror polish	0.08	300-600A

* The concentrations of solutions used in making up these etchants were: HCl 37%; HF 45%; HNO_3 70%; H_2SO_4 97%; H_2O_2 30%; CH_3COOH 100%; NaOH 50%.

with the system (3). This was confirmed for our instrument by separate spectra for pure Cd and pure Te control specimens. Slightly varied ratios, in the range 1.36-1.48, were obtained for fresh CdTe surfaces inserted in the machine shortly after cleaning. The Auger spectrum obtained for such a specimen is shown in Fig. 1. After etching for about 10 min in a solution of 2 H_2O_2 + 3 HF + 1 H_2O (by volume) the spectrum, Fig. 2, shows a ratio of Cd to Te peak of only 0.2 indicating a great enrichment of Te on the surface. The oxygen peak (at 510 eV) has developed in size a little but is still quite minor. The carbon peak at 270 eV is quite small compared with those seen on other semiconductors, such as GaAs, after comparable handling.

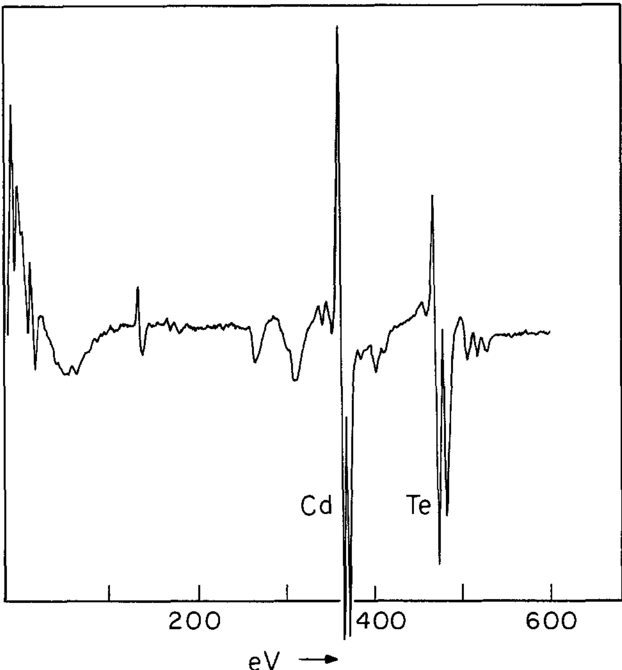

Fig. 1. Auger spectrum for cleaved CdTe to show the normal pattern and Cd/Te peak ratio. (Taken at 3 keV electron input.)

By Ar ion bombardment at a pressure of 5×10^{-6} Torr until the normal Cd/Te peak ratio was obtained, the thickness of the Te rich layer was inferred to be 600-800Å (assuming an ion sputter etching rate of 60-80Å per min).

The results for all the etchants studied may be seen in columns (iv) and (v) of Table I, where the etchants have been listed roughly in order of tendency to form Te rich layers. It is seen that about 4 of the etchants produce no Te enrichment and three produce considerable enrichment. The HNO_3 etchant produces a dark poorly adhering precipitate and the etchant containing $AgNO_3$ tends to form a p-n junction on n CdTe. No significant difference was observed for Cd and Te (111) faces in these etching studies, except for the rate in Table I.

One question of interest to us was whether the composition of electrolytically grown oxides on the surface of CdTe would be markedly affected by the presence of an initial Te layer produced by one of the Te-enhancing etchants. A number of electrolytic solutions were tried, modeled on those used for native oxide layers on GaAs (6, 7), but the one that was most effective was 1-2 parts of KOH in 100 parts of pure H_2O for a *p*H value of 9.0. The CdTe specimen of area about 0.4 cm^2 was the anode and the cathode was platinum foil. The currents applied were 10-40 mA and the voltages were 100-250 V. No attempt was made to regulate the temperature of the solution which became moderately warm. The layers that were grown were estimated to be about 0.5-1.5 μm thick and tended to be brown in color. They were well adhering and high in resistivity ($>10^6$ Ω-cm).

Although it has been suggested that oxides on CdTe might be predominantly TeO_2, this was not our experience (9). As Fig. 3 shows, Auger examination of the top surface of our oxides always showed substantial amounts of Cd. Ar-ion sputtering showed that the proportion of Cd to Te to O did not greatly change through the thickness of the oxide. This seemed to be true whether or not the initial etchant was one that produced a Te rich surface or not. The formation of a tellurate such as $CdTeO_3$ is one possible explanation (9).

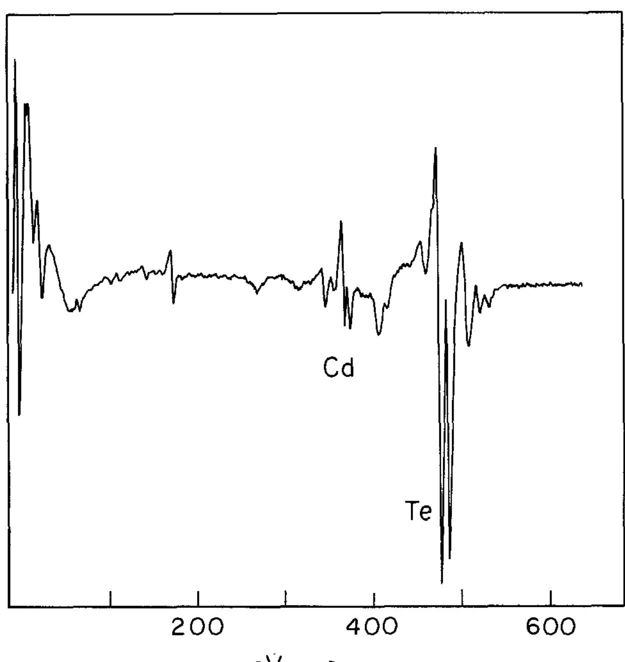

Fig. 2. Auger spectrum of CdTe surface after an etch in $2H_2O_2$ + 3HF + $1H_2O$. This shows the Cd peak greatly reduced relative to the Te peak.

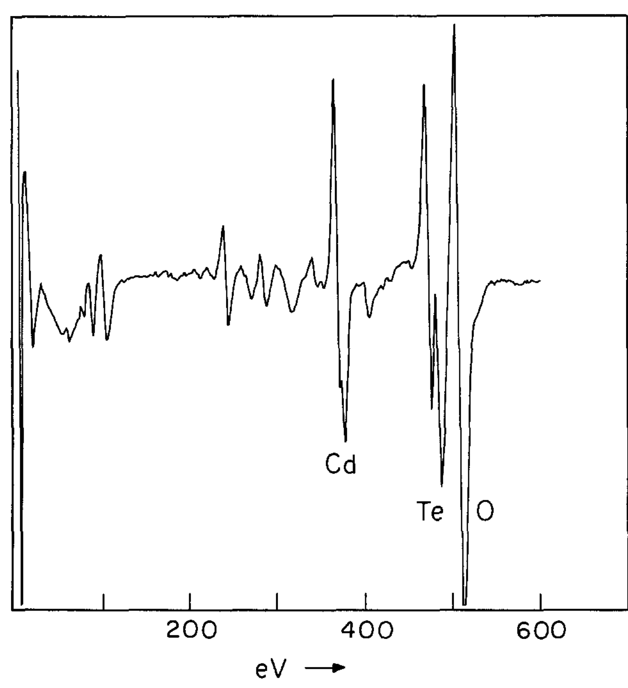

Fig. 3. Auger spectrum for an oxide anodically grown on CdTe. The grown layer is probably a mixture of Cd and Te oxides, possibly in the form of a tellurate such as $CdTeO_3$.

Orientation and Implantation Effects on Stacking Faults during Silicon Buried Layer Processing

McD. Robinson,* G. A. Rozgonyi,* T. E. Seidel,* and M. H. Read

Bell Laboratories, Murray Hill, New Jersey 07974

Bipolar integrated circuit processing requires several oxidation steps, any one of which is a potential source of oxidation-induced stacking faults (OSF). The OSF in turn are well known sources of diode leakage (1-5) and emitted-collector shorts (2, 6-8). Approaches which have been shown to reduce the size, density, and leakage current of OSF include preoxidation back side gettering (POGO) (9-12), preoxidation inert gas anneal (13), high temperature dry oxidation (14-18), processing in low oxygen (4, 5, 19-24) or chlorine-containing (17, 25-27) atmospheres, and deliberate misorientation from low index planes (16, 28, 29).

Bipolar IC processing typically starts with the formation of a masking oxide, followed by implantation or diffusion of a buried collector through an etched pattern of windows in the oxide. An earlier paper (30) showed that surface OSF are prevented or annihilated if wafers with appropriate misorientation receive the initial oxidation in dry oxygen at 1150° or 1200°C. The experiments reported here extend the earlier study to show that properly misoriented wafers remain free of OSF through buried layer processing, and that the correct choice of buried layer drive-in temperature can annihilate preexisting OSF.

Experiments

The starting material was 2 in. diam, 4-9 Ω-cm, n-type Czochralski silicon grown by the Western Electric Corporation. Two boules, nominally grown with (100) and (111) orientations, were cut to the misorientations shown in Table I. All wafers were chemically etched to remove saw damage, followed by chem-mechanical polish on one side.

The above lot received the processing sequence shown in Table II. After an initial clean, half of each wafer was given an implanted dose of 1E14 cm^{-2} boron, in order to introduce a known source of OSF nuclei (4, 31, 32). Boron implantation was followed by 1150°C dry oxidation (3800Å of oxide). Following buried layer pattern definition, the buried layer implant ion and drive-in temperature were split as shown in Tables I and II.

Pieces were cleaved from the wafers and examined after each stage of processing, using Secco etching (33) and optical microscopy with Nomarski interference contrast.

In a separate experiment a wafer oriented 5° from the (100) plane toward the <011> direction was subjected to the first oxidation, then oxide stripped, Secco etched, and compared with the other orientations.

Table I. Wafer orientations; buried layer ion; drive-in time and temperature

Wafer	Orientation*	Ion	Drive-in Temp (°C)	Drive-in Time (hr)
00A-1	0.0° (100)	As	1200	5

Results and Discussion

The first (1150°C, dry) oxidation introduced OSF on the boron-implanted sides of the 0° (100) and 9° (111) orientations. Figure 1A illustrates the boundary between the boron-implanted (left) and nonimplanted (right) regions of a 0° (100) wafer after the first oxidation. This piece was Secco etched for 3 min after stripping the oxide in HF. Figure 1B of a cleaved and Secco etched cross section of the same wafer shows the near-surface origin of the boron implant-induced OSF (4, 30). The 5° (100) and 2.5° (111) wafers were completely free of OSF after oxidation, confirming previous observation (16, 28-30).

Figure 2A shows the wafer which was misoriented 5° from the (100) plane toward the <011> direction. This wafer and a 0° (100) wafer (Fig. 2B) received the initial 1150°C dry oxide. They are shown in the figures following an oxide strip and 30 sec Secco etch. OSF appear along surface scratches. On the 5° (100) <011> wafer the OSF intersect the surface in one <011> direction (Fig. 2A), whereas on the 0° (100) wafer there are OSF in two orthogonal <011> directions. These results are consistent with the observations of Sugita *et al.* (28).

After buried layer implant and drive-in, no OSF were observed on any of the wafers which were driven in at 1270°C. Figure 3 shows the 0° (100) sample which received the arsenic buried layer implant and 1270°C drive-in, followed by oxide strip and a 3 min Secco etch. The pairs of dislocation etch pits in Fig. 3 are believed to be the end points of dislocation loops which remained following annihilation of the OSF by an unfaulting reaction.

Of those samples which received the 1200°C drive-in, the 5° (100) and 2.5° (111) wafers remained free of OSF. The boron-implanted side of the 0° (100) and 9° (111) wafers retained approximately the same density of OSF (2-4E4 cm^{-2}) before and after buried layer implant and drive. These results correlate very well with recent work by Pearce and Rozgonyi (34) who found a large increase in device yield following a change from a 1200°C drive-in.

The buried layer drive-in affected the OSF density, but the buried layer ion implants did not. The OSF density on the 0° (100) and 9° (111) wafers after the 1200°C drive-in was the same inside and outside the buried layer regions, for both arsenic and antimony implants. Secco etching created one artifact, in that

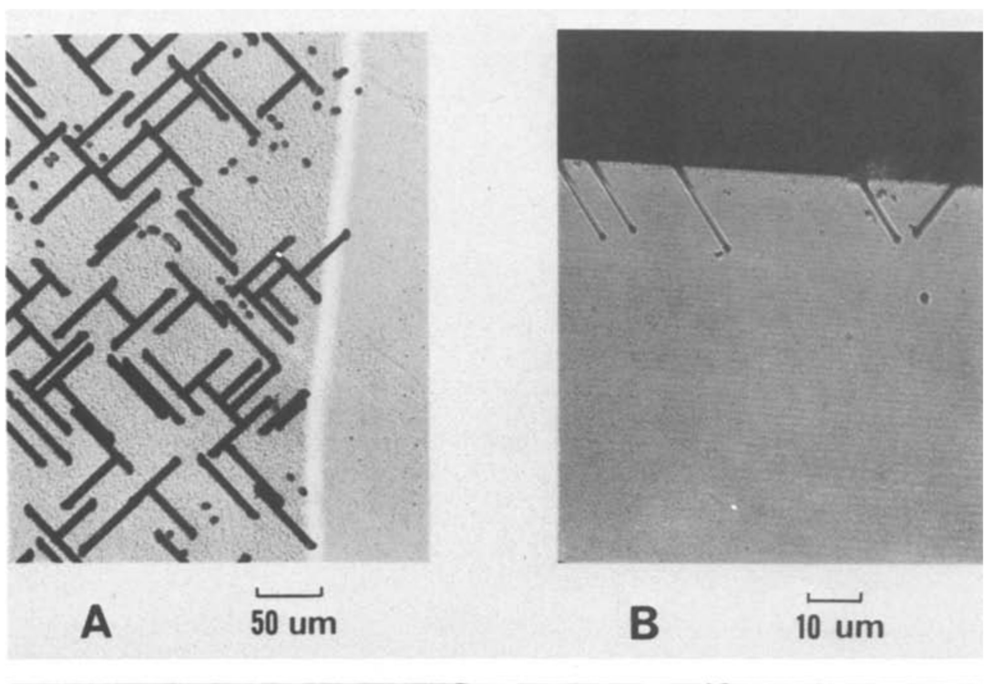

Fig. 1. Wafer 00A1; (100) on-orientation wafer after 1150°C, 6 hr oxidation in 100% O_2. (A) Oxide stripped; Secco etched 3 min. The left half was implanted with 1E14 cm^{-1} boron ions prior to oxidation. (B) Cleaved cross section of the boron-implanted side; Secco etched 15 sec.

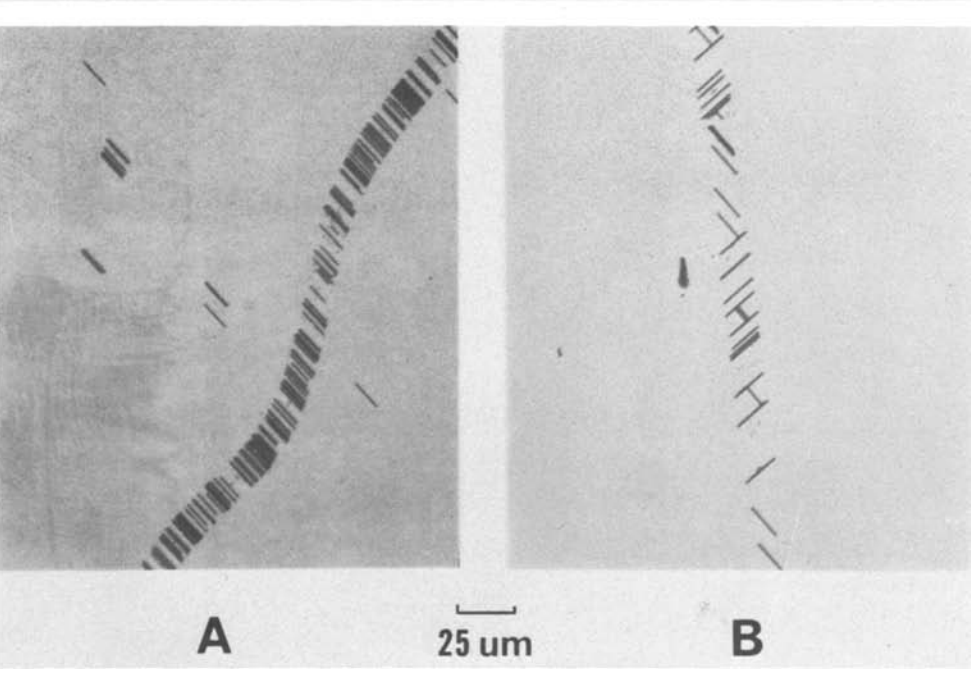

Fig. 2. (100) wafers after first oxidation; oxide stripped; Secco etched 30 sec. (A) Misoriented 5° in the <011> direction. The OSF intersect the surface only in one <011> direction. (B) No misorientation. The OSF intersect the surface in two orthogonal <011> directions.

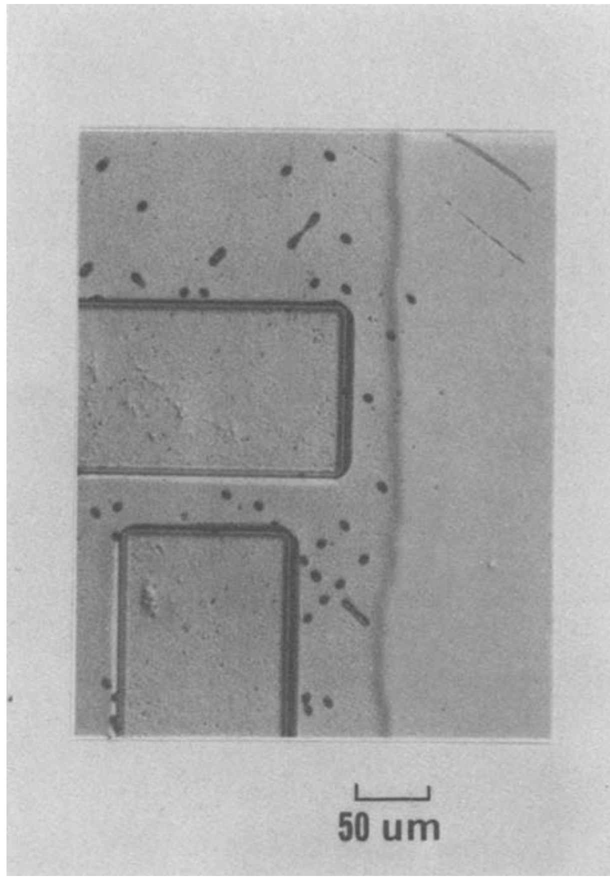

Fig. 3. Wafer 00A2; (100) on-orientation wafer after arsenic buried layer implant and 1270°C drive-in for 1 hr in 100% O_2. Oxide stripped; Secco etched. The dislocation pairs are believed to be remnants of OSF which were annihilated during the 1270°C drive-in. Only the area to the left of the irregular vertical line received the initial boron implant.

etching revealed OSF in all boron implant-nucleated regions except the 0° (100) arsenic-implanted buried layer windows. TEM analysis (Fig. 4) showed, however, that the OSF were present in these windows also.

Conclusions

Several of the results confirm that the proper choice of misorientation and/or oxidation temperature prevents OSF formation during the dry oxidation of silicon:

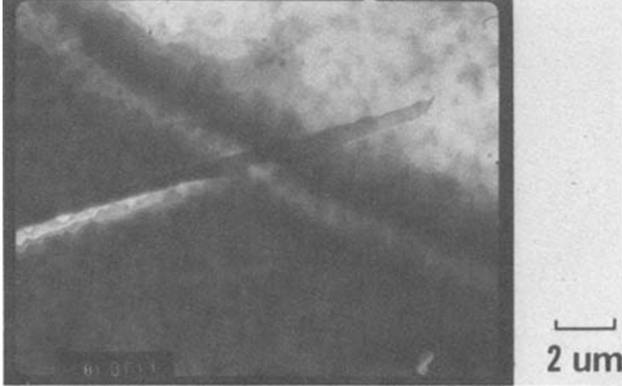

Fig. 4. TEM photograph of a thinned section from wafer 00A1; (100) on-orientation after arsenic implant and 1200°C drive-in. The light region in the upper right half of the photograph is the arsenic-implanted buried layer window. An OSF crosses the boundary into the window.

1. Misorientation of 5° from the (100) toward <001> or 2.5° from the (111) toward <112> prevents OSF formation during a 1150°C, 100% oxygen, 6 hr oxidation, even after 1E14 cm^{-2} boron implant seeding.
2. Wafers oriented on (100) (no deliberate misorientation), and 9° from (111) toward <112>, are subject to OSF formation during the above implant and oxidation.
3. The directional dependance of the misorientation effect is confirmed by the formation of stacking faults of only one orientation on a (100) wafer misoriented 5° toward <011>.

Additional results show that proper choice of buried layer drive-in temperature can annihilate already existing OSF:

1. Drive-in at 1270°C (100% oxygen) eliminates all OSF. The unfaulting reaction leaves behind a dislocation loop.
2. Drive-in at 1200°C (100% oxygen) leaves the OSF density essentially unchanged.

Acknowledgments

The authors are grateful to T. T. Sheng for the TEM work.

Electrical Conductivity of Tetragonal Zirconia below the Transformation Temperature

T. K. Gupta and R. B. Grekila

Westinghouse R&D Center, Pittsburgh, Pennsylvania 15235

and E. C. Subbarao

Indian Institute of Technology, Kanpur 208016, India

Zirconia has three polymorphic modifications: monoclinic up to 1170°C, tetragonal from 1170° to 2350°C, and cubic from 2350°C to the melting point. The tetragonal-monoclinic transformation is martensitic in nature (1), and is accompanied by a large, disruptive volume change. As a result, the properites of the tetragonal phase could not be studied below the transformation temperature. Due to this difficulty of obtaining the tetragonal zirconia at room temperature, the electrical conductivity of tetragonal zirconia has been measured only at high temperatures (2, 3) or at ultrahigh pressure (4) where the tetragonal phase is stable. To conduct measurements below the transformation temperature, the tetragonal phase must first be made stable at room temperature. This has recently been accomplished (5, 6) by taking advantage of fine particle technology and minor doping with Y_2O_3. As a result of this new development, the opportunity is now available to conduct electrical measurements on tetragonal zirconia below the transformation temperature. This note presents the initial data on the conductivity of tetragonal zirconia from 200° to 900°C. The superior mechanical properties of the tetragonal zirconia below the transformation temperature have also been studied and reported elsewhere (7, 8).

Experimental

The detailed procedure for making tetragonal zirconia disks and their identification by x-ray diffraction analysis have been reported (5, 6) previously. Briefly, the fabrication procedure is as follows. Fine powders[1] (100-300Å particle size) of zirconium oxide alloyed with 1.4 mole percent (m/o) Y_2O_3 were isostatically pressed into disks at a pressure of ~200 MPa. The disks were sintered in air at 1300°-1400°C for 5 hr to obtain specimens which were found to contain 97-98% tetragonal phase as determined by x-ray diffraction, and completely crack-free as observed under the microscope. The disk dimensions were ~2 cm diam and ~0.15 cm thick. The density of the specimens was ~5.6 g/cm³, grain size was about 0.25 μm, and mechanical strength was about 600 MPa (7). It should be emphasized here that there is a critical grain size of about 0.3 μm above which the tetragonal phase starts to convert to the monoclinic phase (7) with the appearance of microcracks on the surface of the specimen.

Electrical conductivity was measured using a Wayne Kerr Universal Bridge No. B221 at 20 kHz. Platinum electrodes were applied to the disks by coating the two surfaces with Pt paste and heating to 1000°C in air. The specimens were spring loaded between two platinum blocks to which Pt lead wires were attached. The whole assembly was heated in a platinum-wound tube

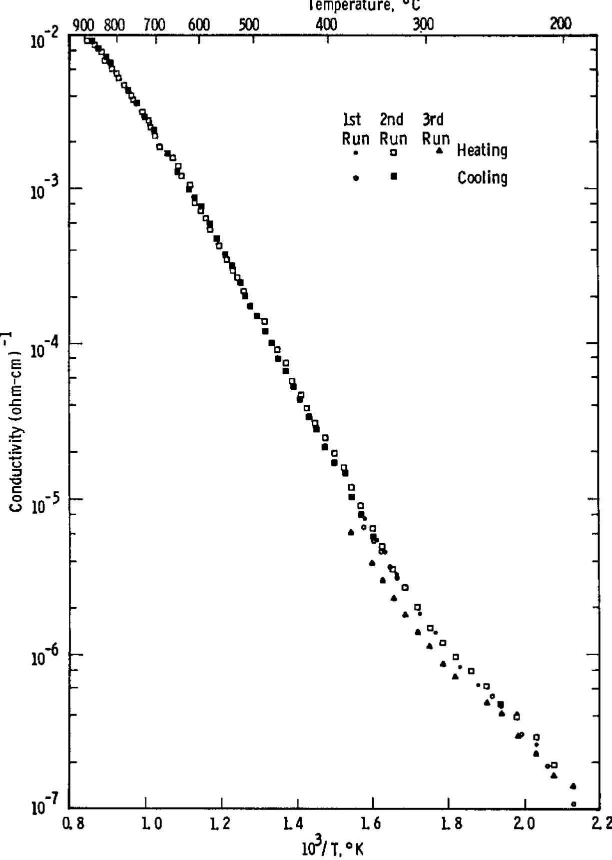

Fig. 1. Temperature dependence of electrical conductivity of 98% tetragonal zirconia.

Key words: tetragonal, zirconia, electrical, conductivity, activation, energy, electrolyte.

[1] Zircar Incorporated, Florida, New York.

furnace at a heating rate of approximately 7°C per minute. The electrical conductivity was measured up to 900°C in air. The data were collected during both heating and cooling, which was accomplished by shutting off the power. Tests were repeated on several specimens to check the reproducibility of the data.

Results and Discussion

The electrical conductivities of tetragonal zirconia (97-98%) as a function of temperature are shown in Fig. 1 and 2 for three different specimens. The results are presented in two figures simply to avoid overlapping of the data. For the data in Fig. 1, the specimen was held at 900°C overnight between each run and the conductivity values are seen to be slightly lower at the third run. Figure 2 shows similar lowering effect (for samples No. 1) at third run during heating (after an overnight hold at 800°C), suggesting perhaps an aging effect at high temperature. During cooling, the values are in close agreement with the other two runs. Above about 400°C, the data in Fig. 1 falls in the middle of that shown in Fig. 2, and below about 400°C, they fall slightly above that shown in Fig. 2. This may be due to slight variation in tetragonal phase between various specimens. The results obtained from other specimens containing 97-98% tetragonal zirconia show agreement with above data, although they are not reported here for redundancy.

The activation energies were calculated by assuming that there is a break in the Arrhenius plots (Fig. 1 and 2) at about 300°C. Actually, there is a region of curvature near this temperature which is, however, ignored for simplicity of calculation. The best fit values for six sets of data gave activation energies between 0.91 and 0.94 eV above 300°C and 0.50 and 0.58 eV below 300°C. The standard deviations are 0.03-0.06 eV in the high temperature region, and 0.04-0.06 eV in the low temperature region. There also appears to be a region of decreased activation energy above 600°C which is again neglected in the present calculation.

In previous studies (2, 3) it was shown that the electrical conductivity of "pure" tetragonal zirconia is predominantly ionic except at very low oxygen partial pressure ($\sim 10^{-13}$ atm) or at very high temperature ($\sim$1400°C). Based on these observations, an ionic conduction mechanism may be suggested for the tetragonal zirconia reported here, although no transference number was measured in the present study. With the above assumption, the high activation energy may be considered as due to transport in the bulk and the low activation energy as that in the grain boundary (grain size ~ 0.25 μm) or as impurity controlled.

Figure 3 compares the conductivity data of "pure" and Y_2O_3 containing zirconia for tetragonal and cubic structures. The estimated activation energies are shown in Table I. It is clear from the figure that the present study has extended the range of measurement to well below the transformation temperature. It is also instructive to note that the conductivity tends to increase with increasing concentrations of Y_2O_3, perhaps due to increasing concentration of oxygen vacancy. The activation energy, however, does not show a similar trend. Furthermore, there is a large discrepancy in conductivity and activation energy for the two reported studies (2, 3) on "pure" zirconia. This discrepancy may be explained partly by the uncertainty of calculation and partly by impurities, grain size, etc. Finally, the conductivity of zirconia containing 1.4 m/o Y_2O_3 is within an order of magnitude of that of zirconia containing 5 and 10 m/o Y_2O_3, although the structure varied from tetragonal to cubic.

Summary

In summary it can be stated that the conductivity of tetragonal zirconia has been measured at temperatures below the transformation temperature within

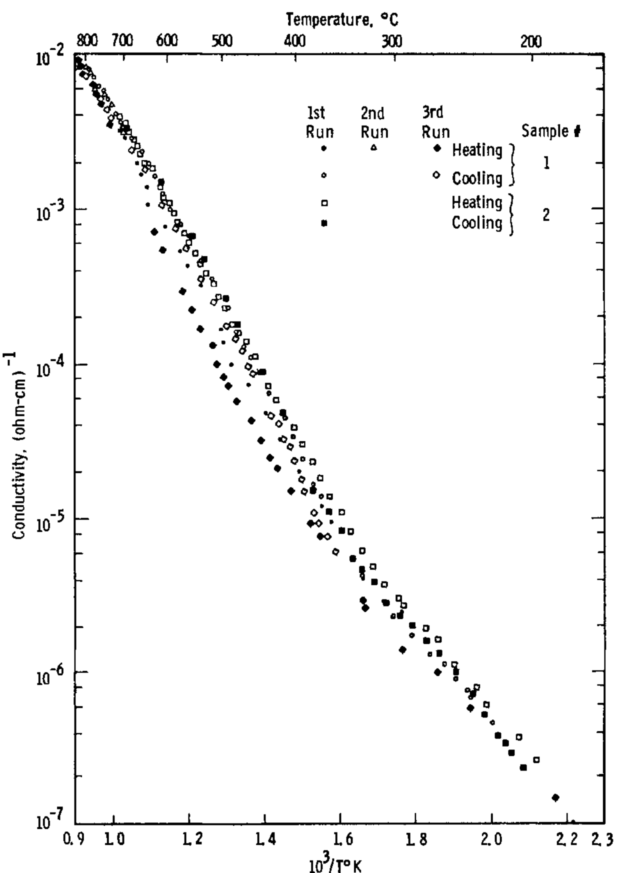

Fig. 2. Temperature dependence of electrical conductivity of 98% tetragonal zirconia.

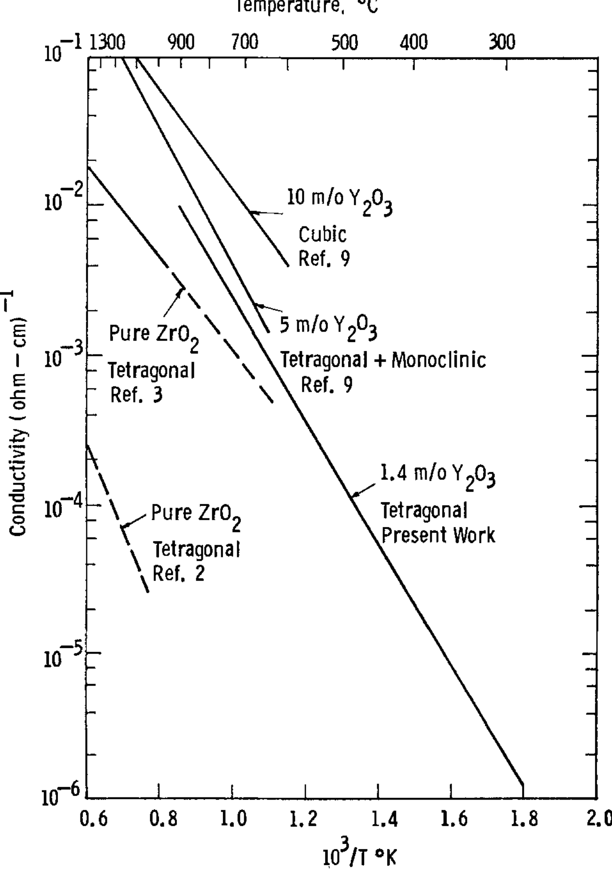

Fig. 3. Temperature dependence of electrical conductivity of tetragonal and cubic zirconia.

Table I. Activation energies of zirconia ceramics

Material	Structure	Temperature range, °C	Activation energy, eV	Ref.
Pure ZrO_2	Tetragonal	1000-1550	~0.86	(3)
Pure ZrO_2	Tetragonal	1227-1330	~1.4	(2)
ZrO_2 + 1.4 m/o Y_2O_3	Tetragonal	300-900	0.91-0.94	Present work
ZrO_2 + 1.4 m/o Y_2O_3	Tetragonal	200-300	0.50-0.58	Present work
ZrO_2 + 5 m/o Y_2O_3	Cubic & monoclinic	600-1300	~1.07	(9)
ZrO_2 + 10 m/o Y_2O_3	Cubic	600-1300	~0.79	(9)

that range. The conductivity has a high temperature region (300°-900°C) with an activation energy of about 0.9 eV and a low temperature region (200°-300°C) with an activation energy of about 0.5 eV. The conductivity values are close to that of Y_2O_3 stabilized cubic zirconia reported in the literature. The high electrical conductivity and the suggestive high ionic transport number combined with high mechanical strength (7) of tetragonal zirconia make it an attractive candidate for solid electrolyte applications.

Lithium Closoboranes II. Stable Nonaqueous Electrolytes for Elevated Temperature Lithium Cells

Jack W. Johnson and A. H. Thompson*

Exxon Research and Engineering, Corporate Research, Linden, New Jersey 07036

Nonaqueous electrolyte secondary lithium cells are of interest for a variety of potential applications, ranging from such low rate applications as in cardiac pacemakers to the high rate systems needed for electric vehicles and off-peak power storage. In particular, Li cells with cathodes of intercalation and insertion compounds have been shown to have highly desirable properties (1,2). A crucial component of Li battery systems is the electrolyte, which must have extraordinary chemical stability in order to allow long cycle life and have sufficient conductivity to allow cell operation at the desired rates. We have previously reported (3) that Li closoborane/dioxolane/DME electrolytes are stable in the presence of both Li metal and TiS_2 at 70°C for extended periods. Herein we report the results of Li-TiS_2 cell tests carried out at elevated temperatures.

The intermediate temperature range (50-180°C) in Li batteries has not yet been thoroughly explored because of the absence of suitable electrolytes, although some plating tests have been reported in $LiAsF_6$/THF in which improved efficiencies are observed over room temperature tests (4). One incentive for testing cells in this regime is the possibility of achieving higher operating rates due to improved mass transport in both the electrolyte and the cathode without requiring the expensive and difficult to fabricate materials for separators and containers needed in high temperature cells (5). In addition, many ambient temperature applications of secondary Li cells such as protection of volatile memory in computers will involve operation at temperatures higher than 25°C. Operation at higher temperatures, near the melting point of the metal, may also improve Li plating. In this communication we report results on the rate performance and cycling stability Li-TiS_2 cells using a Li closoborane/DME/dioxolane electrolyte at temperatures to 110°C.

AC conductivity measurements showed an approximate doubling of the conductivity of $Li_2B_{10}Cl_{10}$ and $Li_2B_{12}Cl_{12}$/DME/dioxolane solutions upon heating from 25 to 100°C (6). In order to test the effect of this conductivity improvement on the rate performance of actual cells, we measured signature curves in Li-TiS_2 cells at various temperatures. The cells contained 2 cm^2 cathodes loaded with 70-90 mg of a 90% TiS_2/10% Teflon mixture hot pressed into a stainless steel grid and wrapped with polypropylene separator. The anodes were excess Li sheet and the electrolyte was 0.61 molal $Li_2B_{10}Cl_{10}\cdot 6DME$/dioxolane. The data were obtained by discharging the cell at a given high rate until the voltage dropped to 1.5 V, then allowing the cell to relax on open circuit to constant potential, and repeating the discharge at a lower rate to the same cut-off voltage. By continuing this process until the cell was totally discharged a plot of cumulative capacity vs. current density was obtained. As can be seen in Figure 1,

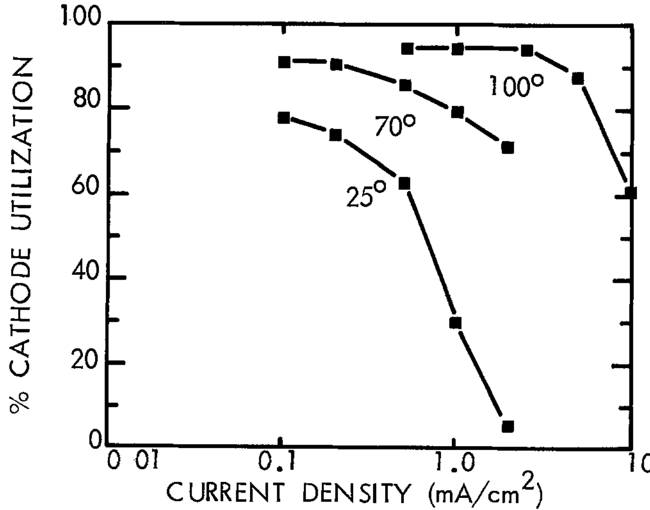

Fig. 1 Signature Curves for Li-TiS_2 Cells

Keywords: closoborane, lithium, electrolyte, battery

*Electrochemical Society Active Member.

a substantial improvement in the rate performance of TiS_2 cells is realized with increasing temperature. At 25°C the rate has to be lowered to 0.5 ma/cm^2 in order to reach 60% discharge, while at 100°C, this level is reached at 10 ma/cm^2 and the cell is fully discharged at 2.5 ma/cm^2.

The stability of the electrolyte system to continued operation at elevated temperatures was demonstrated in the following experiment. A Li-TiS_2 cell constructed like the above cells, but with a cathode made of TiS_2 suspended in a stainless steel mesh bag, was discharged at 0.5 ma and recharged at 0.2 ma at 70°C for 19 cycles with no significant capacity fade (Figure 2). The temperature was then raised to 110°C and the discharge rate to 1.0 ma and cycling continued for 17 more cycles. During this period, the capacity gradually faded by about 5%. Autopsy of the cell showed a decline

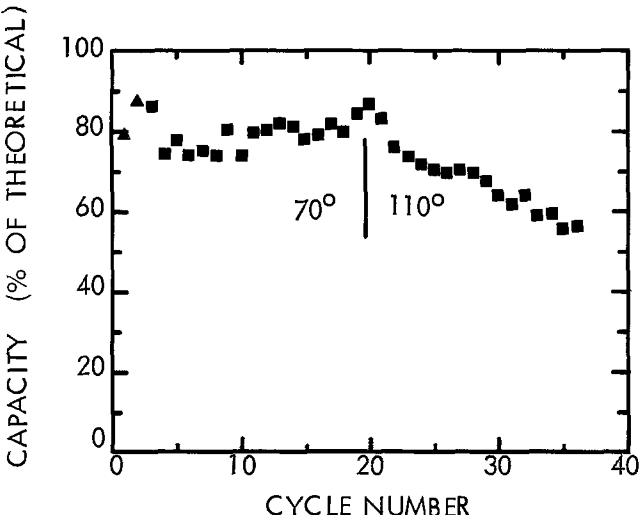

Fig. 2 Elevated Temperature Cell Cycling

in the electrolyte level, so that the entire cathode was no longer immersed. The total duration of the experiment was ten weeks with the cell functioning the entire time at elevated temperatures, thus demonstrating the inherent stability of the Li closoborane electrolyte under these conditions.

In summary, we have shown that Li closoborane electrolytes are stable to the operating conditions of a Li-TiS_2 cell at elevated temperatures, and that there are substantial improvements in the rate performance of such cells operated at increased temperatures. Cells using these electrolytes may be particularly useful where conditions require operating temperatures above 25°C or where increased current densities are required.

Promotion by Carbon of the Reactivity of Lithium with $SOCl_2$ and SO_2—Effect on Lithium Battery Safety

William P. Kilroy* and Stanley D. James*

Naval Surface Weapons Center, Electrochemistry Branch, Silver Spring, Maryland 20910

We wish to draw the attention of the battery community to what may be a pervasive source of dangerously high reactivity in lithium batteries. This is the strong catalytic power of carbon black which is the substrate for the positive electrodes of most lithium primaries. The presence of carbon causes an intense activation of the direct reaction between Li and the battery oxidant (1). This effect may be at the bottom of many of the dangerous incidents involving Li batteries which have occurred over the last few years since there are plausible scenarios by which the lithium and carbon components can become intimately mixed.

Lithium is quite inert to $LiAlCl_4$-$SOCl_2$ and $LiAsF_6$-AN-SO_2 battery electrolytes at room temperature even under conditions of violent mechanical shock. However, prior grinding of the Li with fine carbon black changes this picture dramatically; spontaneous ignition on mixing and explosive energy release on shocking become common, especially with the $SOCl_2$ electrolyte. We examined various parameters that influence this reactivity: nature and freshness of carbon; freshness, purity and conductive salt of the electrolyte; degree of mixing of Li and carbon; presence of Teflon and moisture; undervoltage deposition onto polarized carbon. Both local cell action and Li dispersion contribute to our observed carbon catalysis of the reaction of Li with battery oxidants. The formation of reactive Li binary compounds with C, O or N does not seem to be a factor with the possible exception of a Li-graphite intercalate.

*Electrochemical Society Active Member

REACTIVITY OF PHYSICALLY PREPARED Li-C MIXTURES

Reactivity was relatively low and quite variable if the Li and C were merely lightly pressed together. However, prior grinding of the Li-C mixture significantly raised both the level and reproducibility of the reactivity. Therefore, we routinely studied ground mixtures. Both grinding and addition of electrolyte were done in standard Pyrex Ignition Tubes. Relative reactivity was then assessed with a qualitative scale of numbers from one to ten.

Traces of carbon are insufficient to activate the Li-oxidant reaction. Only when the carbon content of the Li-C mixes rose above 10 and 30% w/w for the $SOCl_2$ and SO_2 electrolytes respectively did reactivity commence. Figure 1 shows this trend and illustrates the far higher reactivity of the $SOCl_2$ electrolyte. For both electrolytes an increase in Li/C mass ratio led to a fall in spontaneous flammability accompanied by a rise in shock-sensitivity.

We studied a variety of carbons (blacks, graphites and charcoal) to correlate Li-C reactivity with the carbon's surface area, graphite crystallinity and purity. For Li-carbon black mixtures reacting with $SOCl_2$-$LiAlCl_4$, reactivity rose smoothly with carbon specific surface. At a value of about 100 m^2/g reactivity had levelled off in the region of 9.5 which means vigorous fires were consistently observed when electrolyte contacted the Li-C mix. Carbon surface area is the biggest factor affecting its ability to promote reactivity with external particle surface being much more active than

internal pore area. The purity and crystallinity of the carbon appear to be of no consequence. Shawinigan acetylene black extensively used as the cathode substrate of Li batteries is one of the most reactive carbons we studied.

REACTIVITY OF CARBON CATHODIZED BETWEEN +1.0 AND +0.1V VERSUS A Li REFERENCE ELECTRODE

Several workers have reported intermediate voltage-time plateaus (above 0, V versus Li) when carbon is cathodized in aprotic solvents free of cathode depolarizer (2-5). These plateaus are thought to involve the undervoltage deposition of Li to form Li-C intercalates. Since these Li-C compounds were shown to be much more reactive than pure Li(2) we prepared carbon that had been cathodized under these conditions and tested its reactivity to battery electrolytes. For various preparations involving different electrolytes and current densities, the undervoltage plateau occurred between +1.2 and +0.2V, versus Li. We found that the most reactive preparations were those formed at the high end of this voltage range. These materials were capable of boiling the $SOCl_2$ electrolyte but appeared to be inert to the SO_2 electrolyte.

RELEVANCE TO LITHIUM BATTERY SAFETY

We observed a very powerful catalysis by carbon of the lithium/battery-oxidant reaction. This effect is important because, in polarized cathodes, Li and C may become intimately mixed (a) by undervoltage deposition to form reactive, Li-C intercalates which react continuously with the electrolyte accumulating heat to possibly dangerous levels (b) by normal overvoltage deposition of passivated Li dendrites. Subsequent shear or shock could then grind dendrites and carbon together causing violent reactivity. Furthermore, severe mechanical distortion of fresh or normally discharged Li batteries could shear Li and C components together with the same dangerous result. With this in mind we are currently testing carbons that have the promise of combining a greatly reduced reactivity in Li-C mixes with unimpaired efficiency as cathodes.

Electron Trap-Free Low Dislocation Melt-Grown GaAs

J. M. Parsey, Jr., Y. Nanishi,* J. Lagowski, and H. C. Gatos*

Department of Materials Science and Engineering,
Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Melt growth of electron trap-free GaAs was achieved for the first time, employing the Bridgman method under conditions permitting high precision control of the As vapor pressure over the melt and by doping the melt with minute amounts of Ga_2O_3. Stringent control of both of these parameters was found to be critical as neither alone leads to electron trap-free material.

. . . . .

The availability of high quality bulk crystals is critical for realizing the full potential of GaAs in electronic applications. At present, high quality material can be produced only in thin layer form by epitaxial techniques. Presently available bulk GaAs exhibits significant concentrations of structural defects and deep states which act as trapping or recombination centers, precluding most of its direct applications as an active device material. GaAs of this quality when used as a substrate in epitaxial technology often has profound adverse effects on the structural and electronic characteristics of epilayers and devices.

In this communication we report on a melt growth process which leads to significant advancement in the electronic and structural characteristics of GaAs and yields reproducibly electron trap-free, very low dislocation material, which thus far is achieved only in thin layer form by epitaxial techniques.

Growth was performed in a horizontal Bridgman apparatus into which two unique features were incorporated: 1) a sodium heat pipe in the low temperature zone for the stabilization and precise control of the arsenic vapor pressure during growth; and 2) a multi-channel thermal monitoring system which makes seeding possible by thermal monitoring rather than by sight. Elimination of the viewing window leads to enhanced thermal symmetry in the high temperature region. Thus, convection in the melt is reduced and thermal stresses in the growing crystal are also reduced. Details of the growth apparatus and its operation will be presented elsewhere (1).

*Electrochemical Society Active Member.

The ampoule is a two-section quartz tube with a breakable seal between the sections as shown in Fig. 1. A very critical step in the growth process is the surface treatment of the high purity quartz (sand blasting with 50 µm Al_2O_3 and cleaning with aqua regia).

The section of ampoule containing $6N^+$ polycrystalline arsenic is sealed (under vacuum) after a bake-out at 250°C for 2 hours at a pressure less than 10^{-6} torr. The high temperature section contains a seal-breaking weight, a diffusion barrier (2), the boat with a seed crystal (<111> B orientation) and 6N polycrystalline GaAs; it is baked under vacuum of about 3×10^{-7} torr at 600°C for 2 hrs and then sealed off. The internal seal is broken magnetically completing the preparation for growth.

The sealed growth ampoule is placed in a quartz tube over which a 4-zone furnace rides. To initiate growth, the preheated furnace is positioned over the quartz tube and stabilized at the desired thermal profile. A 5-hour equilibration takes place prior to growth. Typical macroscopic growth velocities of 5 mm/hr are achieved by controlled furnace motion.

From a series of growth experiments in which the As source temperature was systematically varied it was established that the structural and electronic properties of GaAs depend critically on the arsenic source temperature and that they are optimized when the arsenic source temperature is maintained at 616°C. At this As source temperature (optimum As pressure) crystals with low dislocation densities (below 500 dislocations/cm^2) were reproducibly grown; in these crystals the deep level concentrations and compensation ratios were significantly decreased (3). It was further discovered that under these optimum arsenic pressure conditions light doping of the melt with Ga_2O_3 (in the weight ratio 1 Ga_2O_3: 10^5 GaAs) yields GaAs with undetectable concentrations of deep electron traps.

As seen from typical DLTS spectra shown

in Fig. 2, the crystal doped with Ga_2O_3 grown under optimum As pressure exhibits two deep levels near the seed; as growth proceeds the concentrations of these levels decrease to below detectability limits (approximately 10^{-4} of free carrier concentration, $10^{13}cm^{-3}$ in the present case). It should be noted that only two electron traps are initially present in this material (0.75 eV and 0.40 eV below the conduction band edge) in contrast to three to five deep states typically found in bulk GaAs (4), and also found in the GaAs grown under optimum As pressure without Ga_2O_3 doping. Recently it has been demonstrated that plastic deformation increases the concentration of these states at 0.75 eV suggesting that this level results from native point defects (5).

Photocapacitance measurements confirmed the absence of electron traps. In addition, they revealed a single hole trap at about 0.4 eV above the valence band with a concentration of about $3 \times 10^{15}cm^{-3}$ (i.e., on the order of 1% of carrier concentration). In contrast, high quality LPE GaAs often exhibits two hole traps of similar relative concentrations.

The striking beneficial effect of Ga_2O_3 doping is further evidenced in Table I where typical properties of GaAs crystals grown under optimum As pressure with and without Ga_2O_3 doping are shown. GaAs grown with Ga_2O_3 exhibits a much larger value of minority carrier diffusion length (as determined from photovoltage (6) and SEM-EBIC measurements,(7)) and its minority carrier lifetime value is close to the radiative recombination limit(8). GaAs grown without Ga_2O_3 doping exhibits significant concentrations of deep states and its minority carrier lifetime is nearly 25 times shorter than that of the electron trap-free GaAs.

The remarkable decrease in dislocation density at the optimum As pressure suggests that under this pressure the density of vacancies is significantly reduced (near stoichiometric growth conditions). This conclusion is corroborated by the corresponding reduction of the densities of deep levels which are believed to result from vacancy-vacancy (9) or vacancy-impurity interactions (10) (the total level of impurity contamination was not affected by the As pressure). The role of oxygen (Ga_2O_3 doping of the melt) in eliminating deep levels (or in decreasing their concentrations below the detection limits) is not understood at present. However, it is reasonable to speculate that oxygen-vacancy interactions are responsible for reducing the

Table I. Materials Properties

MATERIAL	DISLOCATION DENSITY (cm^{-2})	CARRIER CONCENTRATION (cm^{-3})	COMPENSATION RATIO (N_A/N_D)
Ga_2O_3 added	<500	1.8×10^{17}	0.58
Ga_2O_3 free	<500	6.2×10^{16}	0.68

MATERIAL	MOBILITY (cm^2/V-s)	MINORITY CARRIER DIFFUSION LENGTH (um)	MINORITY CARRIER LIFETIME (sec)
Ga_2O_3 added	2400	5	3.2×10^{-8}
Ga_2O_3 free	3300	1	1.3×10^{-9}

MATERIAL	ELECTRON TRAP CONCENTRATION (cm^{-3}) 0.75	0.54	0.40	0.34 (eV)
Ga_2O_3 added	N/D	N/D	N/D	N/D
Ga_2O_3 free	2.3×10^{16}	6.8×10^{14}	3.1×10^{15}	6.6×10^{15}

N/D = Not Detected

already low density of free vacancies. It should be pointed out that according to recent studies (11) oxygen is not responsible for the deep level at ~0.8 eV in contrast to earlier prevailing views (9).

In view of the present findings which demonstrate the critical role of the absolute value and control of the As pressure over the melt it is apparent that Czochralski growth, with liquid encapsulation, cannot yield high quality GaAs crystals.

In summary, low dislocation electron trap-free melt-grown GaAs was achieved for the first time. The key contributing factors to the achievement are the addition of minute amounts of Ga_2O_3 in the melt and the precise control of the optimum arsenic vapor pressure attained by the use of a heat pipe (12).

ACKNOWLEDGEMENT

The authors would like to thank Ms. M. Kaminska and Ms. K. Isozumi for assistance in the measurements of our crystals. We are also grateful to the National Aeronautics and Space Administration for financial support of this project.

JOURNAL OF THE ELECTROCHEMICAL SOCIETY

REVIEWS AND NEWS

APRIL
1981

Ernest Yeager

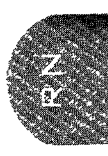
John Yeager*

It is with a feeling of great pleasure that I am speaking to you this afternoon about Ernest Yeager, the recipient of the Edward Goodrich Acheson medal and prize for 1980. I have had good reason to always be proud he is my "big" brother, and thankful to have him as such a close friend.

Ernie was born in 1924 in Orange, New Jersey, and just a few years later my lifelong relationship with him began. Our parents were both Swiss that had immigrated to the United States—our father as a child and our mother in her late teens. They can be best described as dedicated, loving parents committed to raising their sons to the best of their ability. Both had a great respect for the value of education, and from early on instilled that feeling in their sons.

In Ernie's years in the Orange Public Schools, he developed strong interest in the areas that were to be his life's work—the physical sciences and teaching. His choice of career wasn't obvious, however, because he also excelled and had equal interest in mathematics and music. After much hard deliberation, Ernie made his choice, and selected a local college, New Jersey State Teachers College at Montclair, where he did his undergraduate work as a math major with chemistry and physics as minors. The idea of a musical career, however, was very strongly considered. By the time he completed high school, his talent and accomplishment as a classical pianist were considerable, and he was recognized locally as a good dance band musician. The popular music aspect was particularly fortunate because, besides the enjoyment he derived from playing, he was able to help pay for his college education working with local dance bands. With the years, Ernie is a little rusty in his musical skills, but even now when the family is together Ernie's piano playing is a source of real enjoyment for us.

Ernie completed his undergraduate work at Montclair and received the B.A. (summa cum laude) in 1945. Among the faculty there was Dr. Rufus Reed, a chemistry professor that strongly encouraged Ernie to pursue his graduate studies in the Chemistry Department of Western Reserve University. Still interested in math, the choice was difficult, but Ernie elected to carry out his graduate work in physical chemistry and received his M.S. in 1946 and Ph.D. in 1948. At Western Reserve University his thesis professor for both degrees was Dr. Frank Hovorka, an individual, and now a close personal friend, that had a marked effect on development of Ernie's technical career. Ernie was given considerable latitude in selection of his work for his doctoral thesis and, in the course of searching a topic, he came upon an article in the first volume of the Journal of Chemical Physics by Dr. Peter Debye. In it was predicted what became known as the Debye effect of ionic vibrating potentials. The work, Ernie undertook and successfully completed in detection of the effect, developed in him a keen interest in ultrasonics and its application to physical chemistry, particularly its effects on electrolytes. His presently well-recognized interest in electrochemistry developed during this period and blossomed after he remained upon graduation as a faculty member at Western Reserve University. Ernie's work with ultrasonics had led him to consider the effect it might have on electrode processes, and from that entry he became immersed in the study of electrode processes themselves. Ultrasonics and acoustics were not abandoned, however, as evidenced by continuing publications, his being a past vice president and a fellow of the Acoustical Society of America, 14 years as a member of the Committee on Undersea Warfare of the National Research Council, and the two years he served on the Underwater Sound Advisory Committee of the U.S. Navy.



Prior to proceeding further with the technical side of Ernie's career, there are a few personal observations that I want to make to round out your picture of him. I can state he is always busy, but it isn't always in the scientific field. He has a continuing long term involvement with the church from his youth. He has been a Sunday school teacher, and in more recent years, an Elder of the United Presbyterian Church. Ernie is a people person and truly involved with those he contacts. While he has never married, his family is real and big. It includes my wife and I, and our four children who consider him more than just an Uncle; it includes numerous relatives, mostly in Switzerland; and it includes the 54 graduate and 40 post doctoral students that have worked with him and literally been brought into his family over the 30 plus years at Case Western Reserve University. Fortunately, Ernie loves the travel aspect of his technical work, and derives great pleasure on trips visiting with his "family." In fact, for the past twenty or so years he has always managed at least yearly visits to the family in Switzerland. Lastly, to round out the picture of Ernie, he is a very practical guy and quite skilled as a do-it-yourselfer around his home. He does virtually all his own plumbing, painting, gardening, electrical work, and carpentry; and he does it well.

Ernest has been also strongly involved in the necessary operational work at Case Western Reserve University. He has served as Chairman of the Chemistry Department and as Chairman of the University Faculty Senate at the time of the planning and execution of the merger of Case and Western Reserve University. In 1976 he became Director of the newly established Case Laboratories for Electrochemical Studies, a cooperative effort of six departments which, as described by Ernie, is to "push" electrochemistry at Case.

He is a Past President and honorary member of The Electrochemical Society; he has served as chairman of the Theoretical Electrochemistry Division (now Physical Electrochemistry Division) and as chairman of the Cleveland Section of The Electrochemical Society. Further, Ernie is also a past president of the International Society of Electrochemistry.

* Introductory remarks by John Yeager on the occasion of the presentation of the Acheson Medal Award to Ernest Yeager on October 7, 1980 at the Hollywood, Florida, Meeting.

In addition to the prestigious award he is now receiving, he has received Alumni Awards from both Case Western Reserve and New Jersey State College at Montclair, the Biennial Award of the Acoustical Society of America, the Navy Certificate of Commendation the Cleveland Technical Society of America Council Award, and the Heise Award of the Cleveland Section of The Electrochemical Society.

Ernie has served as a member of the IUPAC Commission on electrochemistry, the ARPA Technical Power Panel, and as a representative member of the National Research Council. He is currently serving on the visiting committee for Brookhaven National Laboratories, the Advisory Committee on USSR and Europe of the Commission on International Relations of the National Academy of Sciences, and the Committee on Battery Materials Technology of the National Material Advisory Board of the National Research Council.

Ernie is editor and co-editor of seven books and 154 publications in electrochemistry. These publications as well as his present research emphasis include electrochemical kinetics, electrocatalysis, the electrochemistry of oxides, optical studies of electrochemical interfaces, and the relaxation properties of electrolytes.

President Pell, it is with the greatest of pleasure that I present to you, Ernest Yeager, the recipient of the Edward Goodrich Acheson Medal and Prize for 1980.

Recent Advances in the Science of Electrocatalysis

Ernest Yeager[1]

Case Laboratories for Electrical Studies and the Chemistry Department, Case Western Reserve University, Cleveland, Ohio 44106

Electrochemistry is experiencing a renaissance. The meetings of The Electrochemical Society and its Journal provide ample evidence of this renaissance, which has been stimulated by the energy problem and the importance of electrochemistry conversion, and conservation. Equally important are indications that electrochemistry has reached a critical stage where especially rapid development of the science is likely to occur over the next decade.

Already early in this century, much of the thermodynamics of electrochemistry was reasonably well in place but electrochemical kinetics and electrocatalysis remained more an art than a science. Reproducibility in kinetic studies has been a particular problem but in recent years electrochemists have gained sufficient control over the various experimental factors, including impurity effects, to achieve reproducible results even with surface demanding reactions. Substantial theoretical developments have also occurred over the last two decades in the areas of electron and proton charge transfer at electrochemical interfaces. Further, the impact of various surface chemical physics techniques, both *in situ* and *ex situ* to the electrochemical environment, is starting to be felt in electrocatalysis studies.

Adsorption on the electrode surface plays a key role in electrocatalysis. Little information is available, however, concerning the chemical nature of the interactions of adsorbed species with the electrode and the adsorption sites. This situation has been detrimental to the development of electrocatalysis as a science. There has been a general lack of good molecular level techniques for examining the chemical structure of electrochemical interfaces, analogous to the various spectroscopic techniques which have had such an impact on the physics and chemistry of bulk phases. In most instances electrochemical techniques provide a sensitive tool for the detection of electrosorption but lack the needed molecular level specificity. Even the charge on electrosorbed species cannot be determined electrochemically in most instances because of the difficulty of resolving what fraction of the externally provided charge is transferred to the adsorbed species rather than just on the metal surface and compensating the charge of the electrosorbed species and the remainder of the ionic double layer.

In this lecture I shall first asess some of the more promising *in situ* and *ex situ* techniques of a more or less nontraditional type for obtaining such information and then consider the state of our understanding of some important electrocatalytic systems.

[1] Acheson Medal Address delivered October 7, 1980 at the Hollywood, Florida, Meeting of The Electrochemical Society.

In Situ Techniques for the Study of Electrochemical Interfaces

Table I lists the majority of the presently used *in situ* spectroscopic techniques for the study of electrochemical interfaces. Various windows exists for electromagnetic radiation in solvents such as water; *i.e.,* for x-ray, u.v.-visible and, for very short path lengths, certain parts of the infrared. Consequently optical spectroscopy lends itself to *in situ* studies (1). The majority of the u.v.-visible and infrared studies make use of intensity changes upon reflectance from the electrochemical interface in the external or internal attenuated total reflectance modes, the latter with transparent electrodes. With the external mode, both specular and diffuse reflectance techniques have been used. With transparent electrode, transmission techniques have also been used. The optical changes attending the change of electrode potential and the adsorption of various species at mono- and submonolayer levels are small but still easily measured with modern signal detection-processing techniques. Ellipsometric spectroscopy (2-4), using automatic instrumentation (3), is a particularly powerful technique for obtaining information concerning the collective dielectric properties of the interface and adsorbed layers as a function of wavelength and potential.

The various ultraviolet-visible optical measurements have yielded substantial information concerning sur-

face charge, adsorption isotherms, structural information for adsorbed molecules, the state of water in the compact double layer, structural transitions in underpotential deposited layers, surface roughness, and the electronic properties of anodic films and passivation layers on metals. For the most part, however, these optical techniques have not made as great a fundamental contribution to the understanding of electrochemical interfaces and adsorption at such interfaces as some of us expected at the start of such work in the mid 1960's. In part this is because of limitations on the type of information which can be gained with only ultraviolet-visible spectroscopy. The impact of these measurements, however, has been lessened by the lack of quantitative theoretical treatments of the collective optical properties of the metal-electrolyte interface and adsorbed species to provide a quantitative framework within which to interpret such optical measurements. Only with layers much thicker than monolayer dimensions [*e.g.*, passivation layers on active metals (5)] is a simple three-layer optical model involving two bulk phases with an intermediate thin layer adequate.

Vibrational data for adsorbed species can be very useful. *In situ* infrared studies using internal reflectance have been carried out with semiconductor transparent electrodes. It has been possible to detect the C-H stretched frequency for adsorbed layers of higher molecular weight molecules (6) using D_2O as the solvent to minimize solvent interference. With semiconductor electrodes of sufficient transparency in the infrared, however, most of the potential drop is in the space charge region in the electrode phase and relatively little information is gained concerning the adsorption process. Further, solvent absorption in the infrared imposes very severe restrictions.

Recently Bewick and Pons (7) at the University of Southampton have used external infrared reflectance spectroscopy with very thin electrolyte layers combined with electromodulation techniques to study the water layer adjacent to the interface. This approach is very promising although much care must be exercised to guard against artifacts in the measurements.

Particularly exciting developments have occurred over the past few years in the application of *in situ* Raman spectroscopy to the study of electrochemical interfaces. Since the observation of unusually strong Raman signals for pyridine adsorbed on silver by Fleischmann, Hindra, and McQuillan at Southampton (8, 9) in the early 1970's, great interest has developed in Raman studies of adsorbed species on electrode surfaces. A large number of publications (10, 11) have appeared, mostly concerned with experimental and theoretical studies of possible mechanisms for the extraordinarily large surface enhanced Raman signals observed with most adsorbed molecules on silver and, to a lesser extent, copper.

Several explanations have been offered for the surface enhancement; it is likely that more than one mechanism is involved. Although the Raman signals may only be observable with certain electrode surfaces, this technique is expected to prove of great importance to electrochemistry in providing much needed *in situ* vibrational data. With adsorbed molecules exhibiting strong intrinsic resonance Raman, strong Raman signals can be obtained on other electrodes besides silver and copper (13-15). For example, in our laboratory, we have studied such species as paranitrosodimethyl aniline (14) and the transition metal phthalocyanines (15) adsorbed on platinum as well as silver. Further, Raman spectroscopy has been used in our laboratory to examine the passivation films on iron (16) as well as silver (17).

Aside from the implications of various photoelectrochemical processes for solar energy conversion, they afford interesting information concerning band bending in semiconductor electrodes, surface states, and other electronic features of the interface of importance to electrocatalysis (11). Photoemission from metals into electrolytes also has been studied by electrochemists [see, *e.g.*, Ref. (18, 19)] but so far has not proven very useful for studies of adsorption and electrocatalysis.

Mössbauer spectroscopy has been applied to *in situ* studies of various layers on electrode surfaces containing appropriate elements to serve as either emitters or absorbers, *e.g.*, iron, cobalt. From the Mössbauer spectra, under favorable conditions it is possible to gain insight into spin states and nearest neighbor interactions. Particularly interesting results have been obtained for electrochemical passivation layers on iron (20) and iron transition metal macrocyclic catalyst layers on electrode surfaces such as carbon (21, 22).

When the potential across an electrochemical interface is a-c modulated, both shear and compressional acoustical waves are generated. The shear waves result from the modulation of the a-c interfacial tension and are detected in the solid electrode phase with a shear sensitive transducer attached to the back side of the electrode (23, 24). The compressional waves are readily detected in the electrolyte phase with a hydrophone (25, 26). With solid metal electrodes, these compressional waves are produced principally by the a-c modulation of the volume of the ionic double layer—particularly the compact double layer. With semiconductor electrodes, intrinsic and field-induced piezoelectric properties may result in large compressional components in the electrolyte phase and both shear and compressional components in the solid electrode phase. Both the shear and compressional acousto-electrochemical effects are quite sensitive to adsorbed species at the electrode surface and can be used to follow the adsorption-desorption of such. Quantitative measurements of the compressional effect on metal electrodes should yield dV/dE (where V is the volume, E is the applied potential) and hence be of special interest in testing double layer models.

Electron spin resonance has been used to detect various free radicals in the electrolyte phase (27-29) and in principal can be used to examine radicals adsorbed on electrode surfaces by proper location and configuration of the electrode in the microwave cavity of the spectrometer.

Two techniques that appear promising for *in situ* studies of electrochemical interfaces and particularly catalyst and passivation layers are extended x-ray absorption fine structure (EXAFS) and nuclear magnetic resonance. In both instances it will probably be necessary to use high area electrodes such as dispersed ultrasmall metal particles on a high area carbon support or metal blacks. With the *in situ* EXAFS, it is worthwhile to consider fluorescence yield as well as the more conventional absorption measurements. With the recent developments in NMR solids, using magic angle spinning and various spin decoupling techniques, it may be possible to obtain the fine line NMR spectra of adsorbed species even at the monolayer level using very high surface area dispersed electrocatalysts.

Ex Situ Techniques

The electron and ion spectroscopies listed in Table II can be used to characterize electrode surfaces including single crystal systems before and after electrochemical measurements. The critical question is whether the electrode surface can be transferred from the ultrahigh vacuum environment to the electrochemical environment and vice versa without substantial restructuring of the surface as well as chemical changes and contamination. Several research groups (30-35) have carried out electrochemical measurements such as hydrogen electrosorption and lead underpotential electrodeposition on noble metal single crystal surfaces which have been prepared and characterized with LEED or RHEAD in ultrahigh vacuum.

Table II. *Ex situ* electron and ion techniques for the study of electrochemical interfaces

Ex situ

Electron physics
- X-ray photoelectron spectroscopy (XPS)
- Ultraviolet photoelectron spectroscopy (UPS)
- Auger spectroscopy
- Electron energy loss spectroscopy
- Low energy electron diffraction (LEED)
- Reflection high energy electron diffraction (RHEED)
- Inelastic electron tunneling
- Transmission electron microscopy—diffraction

Ion
- Ion scattering spectroscopy
- Secondary ion mass spectroscopy

Special precautions have been used to minimize the possibility of restructuring during the transfer into the electrolyte. The approach used in our laboratory for accomplishing such is as follows (30, 31, 36). Clean single crystal platinum or gold surface of known orientation are prepared by repeated sputtering with argon and high temperature annealing in an ultrahigh vacuum chamber on the right in Fig. 1. The surfaces are examined with LEED and Auger spectroscopy in ultrahigh vacuum (10^{-10}-10^{-11} Torr) and then transferred into a second vacuum chamber on the left in Fig. 1, also at $\sim 10^{-10}$-10^{-11} Torr without removal from the vacuum environment by means of a magnetically operated transfer wand. Ultrapure argon is then admitted to this vacuum container. A second parallel electrode surface with a drop of electrolyte on it is next brought close to the single crystal surface to form a thin layer electrochemical cell with a gap of $\sim 10^{-3}$ cm. This second electrode is chosen so as to serve as a combined counter and reference electrode. The use of the thin layer cell technique results in a high area-to-volume of electrolyte ratio and hence much less sensitivity of the single crystal surface to impurities in the electrolyte (*e.g.*, 10^{-6}m of a typical ionic impurity corresponds to 10^{-3} of a monolayer even if all adsorbed on the electrode surface). Following the electrochemical measurements, the electrodes are separated. With an electrolyte such as aqueous dilute HF, the electrolyte can be completely vaporized at room temperature as the argon is pumped out. The single crystal electrode is then retransferred into the LEED-Auger chamber and the surface is re-examined.

This system has been used at Case with some success for studies of underpotential electrodeposition, hydrogen electrosorption, and anodic film formation on platinum and gold single crystal surfaces. The electrochemical behavior is highly dependent on the particular surface crystal plane. Such information is of critical importance to the understanding of electrocatalysis on a microscopic level.

Complementary *Ex Situ* Experiments

The electrochemical interface cannot be simulated even approximately with solid-vacuum interfaces. Nonetheless, studies of the adsorption of water, hydrogen, oxygen, carbon monoxide, various organic molecules, and other species at metal and semiconductor interfaces can provide information of help in understanding electrochemical interfaces. The interaction of water with such metals as gold and platinum is relatively weak at electrochemical interfaces, and hence, some similarities are expected between the behavior of various adsorbed neutral species such as hydrogen atoms and CO on these metals in the electrochemical and vacuum environments. Such comparisons are more likely to be valid when the electrochemical interface is near the potential of zero charge and the potential gradient at the interface is small.

Particular types of experimental and theoretical information which can prove useful to the electrochemist include the energetics of the adsorption process, types of adsorption sites, configuration, electronic and vibrational properties of the adsorbed species, and chemical modifications of the adsorbate attending the adsorption process. Most electrochemists concerned with various electrocatalysis processes already pay considerable attention to solid-gas catalytic literature and this trend is likely to increase.

Specific Electrocatalytic Processes

Some typical electrocatalytic processes are listed in Table III. By far the most research effort has been applied to the hydrogen and oxygen electrode reactions. The most exciting development in applied electrocatalysis in recent years, however, has been the development of the dimensionally stable anode as a replacement for the carbon electrode for the generation of chlorine in the chlor-alkali industry. The catalyst for this reaction is ruthenium oxide, perhaps with additives, on a titanium substrate. In contrast to carbon anodes, the RuO_x/Ti electrode is not attacked at an appreciable rate and is dimensionally stable over years. Almost all of the Cl_2 produced electrochemically in the United States is generated with this electrode with large savings in energy because of the very low overpotential.

3. Chlorine generation
   $2Cl^- \rightleftharpoons Cl_2 + 2e^-$
4. Organic oxidations
   $CH_3OH + H_2O \rightleftharpoons CO_2 + 6H^+ + 6e^-$
   $C_3H_8 + 6H_2O \rightleftharpoons 3CO_2 + 20H^+ + 20e^-$
5. Organic synthetic reactions
   Kolbe reaction: $R\text{-}CO_2^- \rightarrow 2CO_2 + RR + 2e^-$

Our laboratory at Case has directed much attention to the hydrogen and oxygen electrode reactions and I shall emphasize these two areas of electrocatalysis in the remainder of this lecture.

The hydrogen electrode reaction.—Hydrogen generation on various electrode surfaces is generally considered to involve the following steps

I. Discharge: $H^+ + e^- \rightleftharpoons H_{ads}$ [1]

II. Recombination: $2\ H_{ads} \rightleftharpoons H_2$ [2]

III. Ion-plus-atom: $H_{ads} + H^+ \rightleftharpoons (H—H)_{ads}{}^+$ [3]

e^- ⇅ e^- H_2 [3a]

In recent years some general insight has been achieved into the relationship of hydrogen electrode kinetics to hydrogen adsorption energies. For a given step the exchange current density is related to the standard free energy of adsorption of the particular type of adsorbed hydrogen involved in this step ($\Delta G°$). This dependence is represented by the familiar volcano-shaped curves (37-39) shown in Fig. 2 according to Parsons (37) for the three reaction steps just listed. The flat portion of the curves corresponds to the Temkin region of the adsorption isotherm. In constructing the volcano curves, the cathodic and anodic transfer coefficients have been taken to be 1/2. This may be open to question for reactions II and III. Arguments have been put forth (40), based on Bond's model of nonactivated adsorption of hydrogen (type C) (41), that the free energy of activation for reaction II approaches the free energy change for this step on some metals. Further, it is likely that the activated state $(H—H)^+$ for reaction III involves the direct interaction of both hydrogens with the surface rather than an end-on interaction of an H—H intermediate. Consequently, the transfer coefficient α for reaction III may also approach unity rather than 1/2. Under such circumstances, the volcano curves take on the form (40) indicated in Fig. 3, using a combination of Breiter's

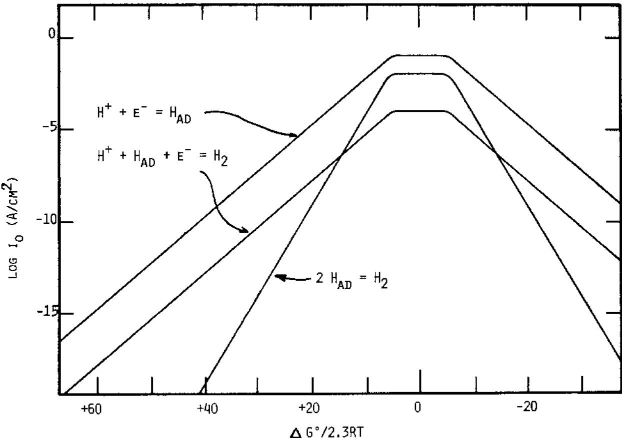

Fig. 2. Volcano curves for the exchange current densities of the hydrogen electrode component steps vs. the standard free energy of adsorption of hydrogen (39). Transfer coefficient for each process: $\alpha = 1/2$.

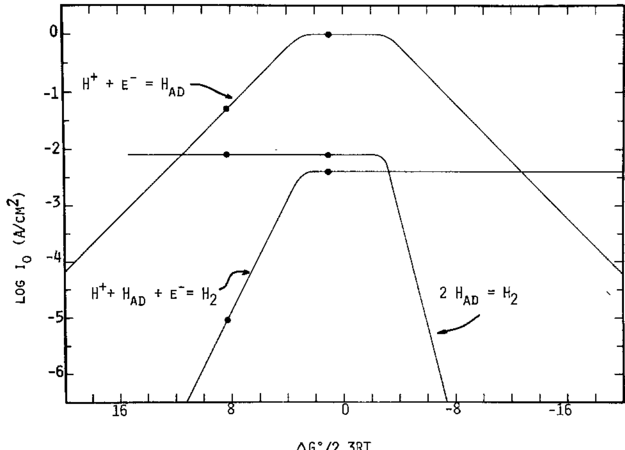

Fig. 3. Volcano curves (40) in 3m HCl with $\alpha_I = 1/2$ for the discharge reaction; $\alpha_{II} = 1$ for the recombination reaction; and $\alpha_{III} = 1$ for the ion-plus-atom reactions.

data (42) and Ludwig's data (40) as a few calibration points.

The experimentally observed behavior of hydrogen overpotential on various metals correlates reasonably well with Fig. 3. Metals such as Hg, Tl, Zn, Cd, and Pb, which adsorb hydrogen only weakly (large positive values of $\Delta G°$), have low values for the apparent exchange current density, Tafel slopes ($dE/d \log i$) of $-2.30\ (2\ RT/F)$, and reaction I rate controlling. Metals such as Pt and the Pt family with $\Delta G°$ values close to 0 have high apparent exchange current densities and kinetics which indicate that reaction II follows reaction I and is rate controlling. Metals such as Mo, Ta, and W, which strongly adsorb hydrogen and have very negative values of $\Delta G°$, again have low exchange current densities and kinetics which indicate region III follows reaction I.

An important implication of the volcano curves is that it is unlikely a catalyst will be found with an overall exchange current density higher than that for Pt since this metal has $\Delta G°$ close to 0. The main thrust of applied research on hydrogen electrocatalysts should be the finding of catalysts with higher exchange currents per unit cost and resistance to poisoning and to loss of area when used in high area forms.

Various authors have examined the discharge step I theoretically [for a review, see Ref. (44)]. Bockris, Matthews, and Srinivasan (45, 46) have proposed the model in Fig. 4 in which the proton is transferred over a barrier representing the intersection of two Morse curves. The vertical transition ΔE_0 corresponds to the transfer of an electron from the Fermi level of the metal to the H_3O^+ ion with no change in the reaction coordinate. Radiationless electron transfer by tunneling occurs at the intersection of the two Morse curves, from the metal to the vibrationally excited H_3O^+. The various electron energy levels in the metal correspond to translation vertically of the Morse curve for the initial state. The principal levels contributing to the discharge current are those within kT of the Fermi level. This model yields reasonable predictions for the kinetics of the discharge step.

Various electrochemists have considered proton tunneling through the potential energy barrier rather than transmission over the barrier. These include Bockris and his co-workers (45, 46); Christov (47-49); Conway and Salomon (50, 51); Dogonadze, Kuznetsov, and Levich (52-54); Kharkats and Ulstrup (55). All of the treatments involve questionable assumptions. The extent to which proton tunneling is involved in the discharge process is very sensitive to the barrier thickness as well as height. Isotopic studies of hydrogen discharge on mercury, however, do provide evidence that proton tunneling is involved (21, 22).

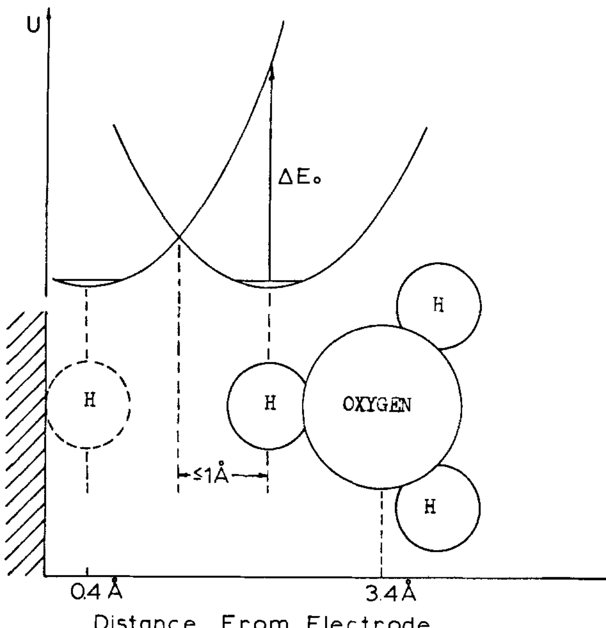

Fig. 4. Potential energy surfaces in the Bockris-Matthews model for proton discharge (110).

Hydrogen electrode kinetics are of special interest on Pt because of its high catalytic activity. Various workers have found a Tafel slope for the cathodic branch of $-2.30(RT/2\mathbf{F})$ or -30 mV/decade and high exchange current densities (*e.g.*, $\geqq 10^{-2}$ A/cm²). Two explanations have been advanced for this behavior. Schuldiner (56) and Bockris *et al.* (57) have used a mechanism involving reactions I and II (discharge followed by atomic recombination) with reaction II rate controlling. Breiter has proposed pure diffusion control involving dissolved H_2 (58). On the basis of ultrasonic and rotating disk-ring measurements, Yeager *et al.* (43, 59, 61) have proposed that the cathodic process is controlled by combined H_2 diffusion and recombination kinetics. Parsons (37) and Krishtalik (60) have offered theoretical arguments for desorption by reaction II as rate controlling.

The anodic oxidation of H_2 exhibits first-order dependence on H_2 concentration, and most workers consider the dissociative-adsorption of H_2 (the reverse of the recombination of reaction II) as rate controlling. Here again, however, the high exchange current density makes it difficult to examine the kinetics without transport of dissolved H_2 to the electrode surface being the predominant control, even with the rotating disk electrode technique, particularly with Pt electrodes which have relatively high area, and hence high activity, as a result of repeated cycling to anodic potentials prior to the H_2 oxidation measurements. The current-potential data from rotating disk data are very well fitted with equations involving combined kinetic and molecular H_2 diffusion control with the atomic recombination step rate controlling. With Langmuir behavior, the current potential data for the anodic and cathodic branches is

$$\ln X = -\frac{2\mathbf{F}\eta}{RT} + \ln X_o \qquad [4]$$

$$X = i \bigg/ \left(1 - \exp\frac{2\mathbf{F}\eta}{RT}\right) \qquad [4a]$$

$$\frac{1}{X_o} = \frac{1}{i_o} + \frac{1}{i_d} = \frac{1}{i_o} + \frac{1}{B\sqrt{\omega}} \qquad [5]$$

where η is the overpotential, i_d is the anodic limiting current density for H_2 transport, i_o is the exchange current density, ω is the rotation rate, B is a constant dependence on the H_2 diffusion coefficient and concentration, and the other symbols have their usual meaning. Equation [5] has been tested for Pt by Ludwig *et al.* (43) using the rotating disk data and fits the data quite well (see Fig. 5). The slope is essentially $-2.30(RT/2\mathbf{F})$ over seven decades. The rotation rate dependence of the function X_o indicates that i_o is of the same order as i_d under most circumstances.

A problem associated with H_2 formation with the kinetics controlled by reaction II is that the Tafel linearity with a slope of $-2.30(RT/2\mathbf{F})$ is to be expected only with low H(ads) coverage. On the other hand, various electrochemical measurements, including impedance (66), linear sweep voltammetry (63, 64), and charging curves (66, 67) indicate that the total H(ads) coverage is already close to unity at the reversible potential. This problem can be resolved by assuming that two types of H(ads) are involved in the overall electrode process and that the adsorbed hydrogen involved in reaction II is at low coverage, as suggested by Schuldiner (62).

The question remains open as to what type of adsorbed hydrogen is involved in the desorption reaction II on platinum. It is unlikely that the lower coverage H involved in this step corresponds to any of the hydrogen peaks observed by linear sweep voltammetry and other chemical techniques on Pt. Nonetheless, it will be helpful to understand the various factors contributing to up to several hydrogen peaks observed in the voltammetry curves (63). Figure 6 indicates some of the peaks found for Pt in 0.1m HF and the effects of adding H_2SO_4 (64). Various explanations have been proposed for the several peaks including different adsorption sites on a given single crystal surface, a distribution of crystallographic surfaces, induced heterogeneity associated with hydrogen adsorption itself and anion adsorption which induces heterogeneity by blocking sites to varying degrees and perturbing adjacent sites. The pronounced dependence of the hydrogen electrosorption on the type and concentration of anion (Fig. 6) indicates that hydrogen ad-

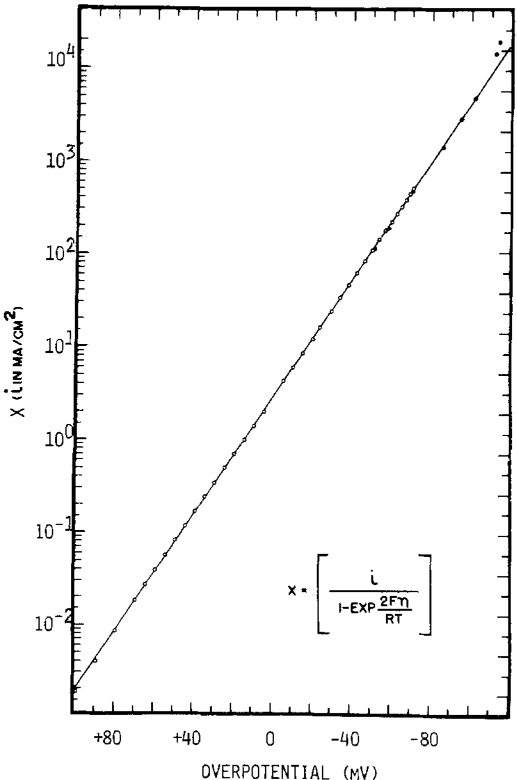

Fig. 5. Hydrogen electrode kinetics on Pt (43). Rotating disk electrode. Rotation rate: 187 Hz; $T = 26°C$; 6.1m HCl (H_2 saturated).

sorption-desorption are coupled to anion desorption-adsorption.

In an attempt to resolve this problem, various electrochemists have examined hydrogen electrosorption on single crystal Pt. Will (65) examined the low index planes (100), (110), and (111) and found the same two major peaks on these three orientations although the relative heights depended on the crystal orientation. The single crystal Pt electrodes studied by Will probably did not expose a single crystallographic surface. The distribution of crystallographic surface planes depends on the overall orientation and the extent to which the surface has been cycled to anodic potentials. Will arrived at the conclusion that the strongly adsorbed hydrogen peak corresponding to IV, IV′ in Fig. 6 is on the (100) plane and the weakly adsorbed peaks I, I′ are on the (110) plane. Rather analogous results have been reported by Bronel *et al.* (68) for the (100) and (111) Pt surfaces. These workers used electron microscopy to establish that the surfaces were facet-free. Kinoshita and Stonehart (69) have examined hydrogen adsorption on dispersed Pt as a function of crystallite size and found a dependence which they interpret as further evidence that the multiple peaks result from different surface crystallographic structures.

In contrast, Bagotzky *et al.* (70) and Conway *et al.* (63) have concluded from their single crystal Pt studies that there is little difference in the hydrogen adsorption on the (100), (110), and (111) planes. Conway *et al.* (63) attributed the multiple peaks principally to induced heterogeneity arising from collective long range electronic interactions.

The probability is high in all of the single crystal studies just cited that the surface prevailing during the electrochemical measurements does not correspond to a single crystal plane. Even if the Pt crystal has only one plane predominant before the electrosorption measurements, these workers generally cycled their electrodes to anodic potentials in the anodic film region to oxidize or desorb interfering surface contaminants and this procedure is likely to cause restructuring.

Recently several groups have attempted to devise techniques which permit the introduction of a single crystal surface of predominantly one plane and free of impurities into an electrochemical environment with a minimum possibility of restructuring and contamination. In the USA these include A. Hubbard (71, 72) at the University of California at Santa Barbara, J. A. Joebstl (73, 74) at Fort Belvoir, P. Ross (75, 76) at the Lawrence Berkeley Laboratories, and our group (30, 31, 77) at Case Western Reserve University. Each group has turned its attention to the (100), (110), and (111) planes of Pt and first established that the surface is predominantly one plane using low energy electron diffraction (LEED) and free of surface impurities down to a few percent of a monolayer using Auger electron spectroscopy.

The key features of the techniques used in our laboratory by O'Grady *et al.* (30, 31, 77) with the equipment in Fig. 1 are vacuum transfer; thin layer electrochemical cell techniques to avoid contamination; and introduction of the Pt single crystal surfaces into the electrolyte at controlled potentials in the hydrogen adsorption region. In the cyclic voltammetry studies of hydrogen electrosorption, the potential range is restricted to +0.05-0.50V *vs.* RHE to reduce any possible restructuring. The voltammetry curves on the single crystal Pt surfaces retract with repeated cycling, starting with the very first sweep. If the voltage sweep is extended into the anodic film formation region to ≧ 1.4V *vs.* RHE, the hydrogen adsorption region changes significantly with new peaks appearing or very minor peaks becoming major peaks, depending on the original surface. This is probably the result of restructuring although the possibility exists that oxygen has been irreversibly adsorbed into sites within the surface layer.

On the (100) Pt surface, Hubbard *et al.* (72), Ross (75, 76), and our group (30, 31) find one predominant peak (Fig. 7) corresponding to the strongly adsorbed hydrogen peak on polycrystalline Pt in acid solutions. The LEED pattern for the Pt (100) indicates a 5 × 20 overlayer. This surface probably reverts to (1 × 1) in contract with the electrolyte. On the (111) surface, our group finds only a minor peak corresponding to weakly adsorbed hydrogen while Ross and Hubbard *et al.* report a major peak. The source of this discrepancy is not fully clear but may be caused by the cycling of the electrode to anodic potentials in the case of Ross's work and possibly also that of Hubbard *et al.* Alternatively our Pt (111) surface may have some of the sites blocked by an impurity such as carbon.

With the sulfuric acid electrolyte, it was not possible to volatilize the residual electrolyte off of the single crystal surface without encountering an oxidizing range of sulfuric acid concentrations. More recently, Arthur Homa, a graduate student in my group, has repeated these studies with 0.1m HF as the electrolyte. This acid is completely volatilizable and does not specifically adsorb. Thus it has been possible to examine the LEED patterns and Auger spectrum following the electrochemical measurements. The postelectrochemical LEED patterns are usually of reasonably good quality with the same symmetry as for the original surfaces. Small amounts of carbon, up to 10%, are usually found with the Auger examination. This carbon is believed to originate from CO released from ion pumps during the pumping out of the ultrapure argon support gas following the electrochemical measure-

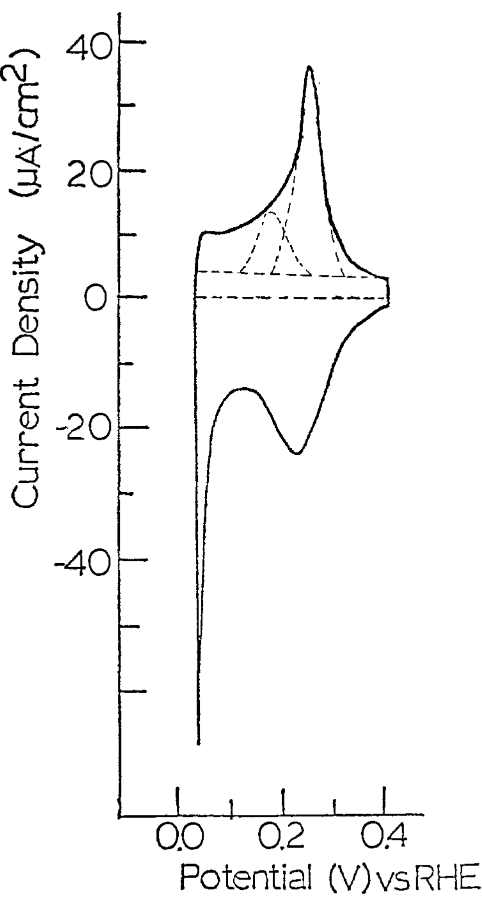

Fig. 7. Voltammogram for Pt (100) — (5 × 20) in 0.05m H_2SO_4. Sweep rate: 50 mV/sec. T = 25°C (30).

ments and not to have been present during these measurements.

The voltammetry results in the 0.1m HF are very similar to those in the 0.05m H_2SO_4 on the (111) and (110) (1 × 2) surfaces with only one H adsorption peak on each surface and the H coverage much lower than a monolayer. The (100) (5 × 20) surface also shows only one principal peak but a sharp cathodic spike appears in the anodic sweep (Fig. 8). This spike remains to be explained but may be caused by surface restructuring. Repeated cycling of the three low index surfaces to potentials well in the anodic film region produces large increments in the peaks on these low index surfaces, disappearance of the cathodic spike on (100) surface, and voltammetry curves resembling those of Ross and the Hubbard group. We do not believe that these large changes are the result of the stripping of a minor carbon impurity but rather are related to some special role of oxygen in the hydrogen adsorption process. Rather similar results with cycling for polycrystalline platinum treated in high vacuum have been reported by the Soviet Academy Institute of Electrochemistry in Moscow (78).

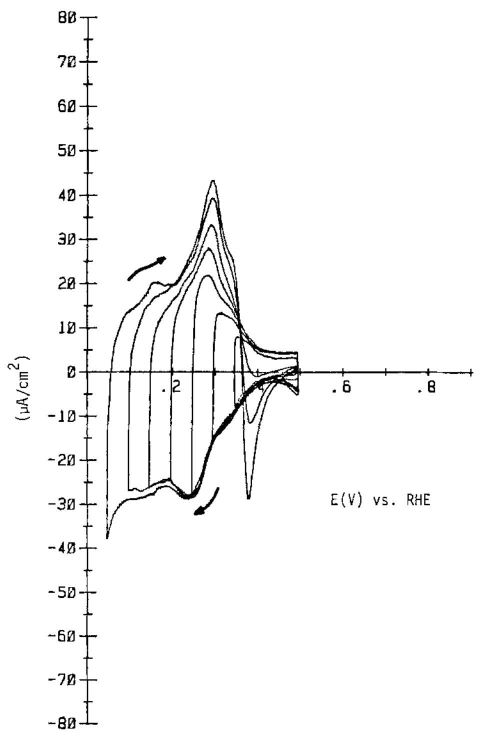

Fig. 8. Voltammogram for Pt (100) — (5 × 20) in 0.1m HF. Sweep rate: 50 mV/sec. T = 25°C.

Note is taken of the very unusual results for hydrogen voltammetry curves on Pt (111) found by J. Clavilier *et al.* (79, 80) and described by Roger Parsons in his Palladium Award address before this Society. This strange behavior is difficult to explain either as the true situation or as an artifact.

In perspective, it appears that the question of hydrogen adsorption on single crystal Pt surfaces is still not a settled issue experimentally. Similar anomalous results for hydrogen adsorption on Pt single crystal surfaces are also to be found in the solid-gas phase literature.

The oxygen electrode.—The oxygen electrode reactions are even less well understood than for the hydrogen electrode. The pronounced irreversibility of the oxygen electrode reactions at moderate temperatures has complicated mechanistic studies. The exchange current densities for the oxygen electrode are very low —typically 10^{-10} to 10^{-11} A/cm^2 on an effective catalytic surface such as platinum at room temperature. Consequently, the current densities near the reversible potential are generally too low to permit measurements under conditions where the kinetics are sensitive to the reverse as well as forward reactions. Further, the experimentally accessible portions of the cathodic and anodic branches of the polarization curves are sufficiently separated in potential that the surface conditions differ very substantially. Therefore, the cathodic and anodic processes under these conditions are probably not the reverse of each other. To complicate the situation further, the oxygen electrode reactions may proceed through a large number of pathways. This explains why the mechanisms of O_2 generation and reduction are still not fully understood even on platinum, the most extensively used and most studied O_2 electroreduction catalyst. I shall address only the question of the catalysis of the O_2 reduction reactions.

Oxygen reduction is usually considered to proceed by two pathways:

1. *The peroxide pathway (the series process):*

$$HOH + O_2 \xrightarrow{2e^-} HO_2^-(ads) + OH^- \quad \searrow^{2e^-} HO_2^- + OH^- \quad (HO_2^-(ads) \rightleftarrows HO_2^-) \qquad [6]$$

The peroxide is then either electroreduced further to OH^- or catalytically decomposed; *i.e.*

a. *peroxide reduction*

$$HOH + HO_2^- \xrightarrow{2e^-} 3\,OH^-; \quad HOH + HO_2^- \rightleftarrows HOH + HO_2^-(ads) \xrightarrow{2e^-} 3\,OH^- \qquad [7]$$

b. *peroxide catalytic decomposition*

$$2HO_2^- \rightleftarrows 2HO_2^-(ads) \rightarrow 2\,OH^- + O_2; \quad 2HO_2^- \rightarrow 2\,OH^- + O_2 \qquad [8]$$

The overall reaction is the 4-electron reduction reaction

$$O_2 + 2H_2O + 4e^- \rightarrow 4\,OH^- \quad [9]$$

regardless of whether the peroxide elimination occurs via reaction [7] or [8] since the O_2 resulting from reaction [8] is recycled through reaction [6].

2. *The direct 4-electron pathway:*

This pathway involves a series of steps in which O_2 is reduced to OH^- or water without hydrogen peroxide being produced in the solution phase. This does not mean that the reduction process does not involve an adsorbed peroxide intermediate but rather that the reduction does not involve any adsorbed intermediate which leads to appreciable peroxide in the solution phase. When both pathways are operating on a given electrode surface, the reduction is referred to as involving parallel mechanisms.

The distinction between these two pathways mechanistically can be quite diffuse since the question of whether a peroxide adsorbed intermediate desorbs or not can depend on various impurities in the electrolyte as well as electrode potential and temperature. An adsorbed peroxide state is very likely involved in the direct 4-electron pathway as well as the peroxide pathway. The classification of the pathway as "direct 4-electron" then may depend on whether the peroxide desorption proceeds to a significant extent. This may depend on the type of site. Two sets of sites may each support the reaction through essentially the same surface reaction pathway but differ in the extent to which the peroxide desorbs from each. If the desorption is very slow or thermodynamically unfavorable from one set of sites but not another, the O_2 reduction will proceed by the so-called "parallel" pathways.

Illustrations of catalysts on which the peroxide pathway is clearly predominant include carbon, graphite, and gold in alkaline electrolytes while the direct 4-electron pathway is predominant on clean platinum surfaces and also certain transition metal macrocyclics. In the presence of impurities peroxide pathway *a* can become predominant even on platinum.

Under some circumstances it is possible that the superoxide species $O_2^{\overline{\cdot}}$ may be formed in the outer Helmholtz plane by outer sphere electron transfer. This ion is formed as a reasonably stable entity during O_2 reduction in aprotic solvents [see, *e.g.*, Ref. (81-84)] and probably in carbonate melts (85). The superoxide ion also has been proposed to be formed in aqueous solutions of Hg (85, 86), and amalgamated gold (87) and carbon paste (88) cathodes in the presence of surface active agents. In the absence of adsorbed organic species, however, it does not appear in alkaline solutions that an $O_2^{\overline{\cdot}}$ species in the solution phase contributes significantly to the observed current (89).

The specific adsorption of O_2 molecules.—The search for effective 4-electron catalysts is guided by the models in Fig. 9 for the interaction of O_2 and related oxygen species with adsorption sites. O_2 reduction in aqueous solutions requires a strong interaction with the electrode surface for the reaction to proceed at a reasonable rate. Three types of interactions have been proposed. Partial charge transfer is probably involved with each of these models. The Griffiths model (112) involves a lateral interaction of the π-orbitals of the O_2 interacting with empty d_z2 orbitals of a transition element, ion, or metal atom with back bonding from at least partially filled d_{xz} orbitals of the transition element to the π^* orbitals of the O_2. A strong metal-to-oxygen interaction results in a weakening of the O-O bond and an increment in the length of this bond. Sufficiently strong interaction of this type may lead to the dissociative adsorption of O_2 with probably simultaneous proton addition and valency change of the transition element in the manner represented by pathway I in Fig. 9 followed by reduction of the $M(OH)_2$ to regenerate the catalyst site. Sandstede *et al.* (91, 92) have attempted to explain oxygen reduction with square pyramidal Co(II), Fe(II), and Fe(III) complexes as well as on the thiospinels on the basis of such π bonding.

With most transition metal catalysts, the most probable structure for O_2 adsorption is the Pauling model (93) in which the π^* orbitals of O_2 interact with d_z2 orbitals of the transition metal. The square pyramidal complexes of Fe(II) and Co(II), which have good activity for O_2 reduction in acid solutions, appear to involve such an end-on interaction on the basis of ESR and other evidence (94). This adsorption of O_2 is expected to be accompanied by at least a partial charge

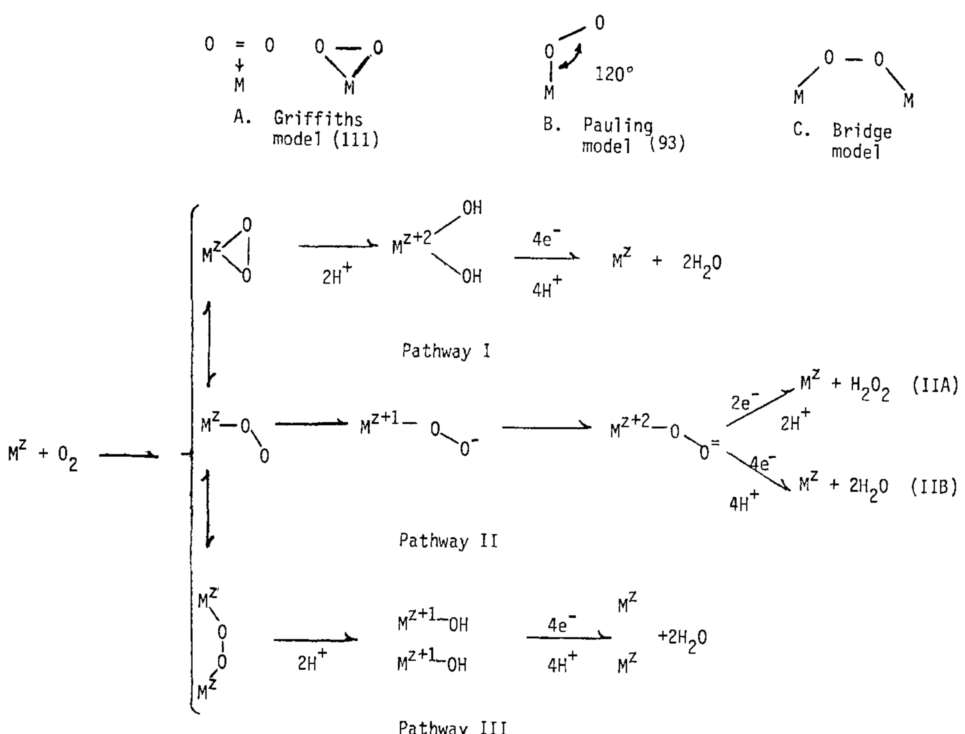

Fig. 9. Reaction pathways for O_2 electroreduction in acid electrolytes [Yeager(111)].

transfer to yield a superoxide and then peroxide state, as represented by pathway II in Fig. 9. The adsorption of the O_2 on the square pyramidal complexes of Fe(II) and Co(II) may lead directly to the superoxide state. With somewhat similar oxyhemoglobin complexes of iron, various workers have proposed that O_2 binding to the iron involves O_2^- or $O_2^=$ states with Fe in the III valent state (95-97). The change in valency state of the transition metal coupled with the change in O_2 oxidation state during formation of the O_2 adduct corresponds in principle to the redox electrocatalyst concept proposed by Beck *et al.* (98, 99).

The further reduction of the O_2 beyond the peroxide state requires rupture of the O-O bond. Such can occur in pathway IIB through the formation of $O^{\overline{\cdot}}$ or HO· free radicals in solution or the simultaneous reduction bond cleavage (electrochemical desorption) to yield H_2O or OH^-. Neither of these processes are likely to be sufficiently fast at practical operating potentials for O_2 cathodes. The free energies of formation of the $O^{\overline{\cdot}}$ and HO· free radicals in solution are just too high.

Pathway III in Fig. 9 provides an alternate means for bringing about rupture of the O-O bond through the formation of an O-O bridge. Such a mechanism may come into play with the proper surface spacing of transition metal atoms or ions in a metal, oxide, or thiospinel or in a bimetal complex such as a macrocycle. The formation of the bridge species also requires that the two metal species have partially filled d orbitals to participate in bonding with the π^* orbitals of the O_2. Bimetal macrocyclic complexes with the proper M-M distance have been synthesized [*e.g.*, see Ref. (100-103)] and appear to occur naturally in hemeythrin.

For any of the pathways in Fig. 9, considerable questions exist as to the reversibility of the O_2 adsorption step at the rather high rates involved with practical O_2 cathodes. For O_2 to bond to M^z will generally require the replacement of a water molecule or anion of the electrolyte—a situation which would normally be expected to be unfavorable to O_2 unless the O_2 adduct has a pronounced dipolar character ($M^{z+1}O\text{-}O^-$) (104, 105).

Of the various possibilities for catalysts which promote the 4-electron reduction, the transition metal macrocyclics appear particularly promising. In the work in our laboratory these are adsorptively attached to high area conducting substrates, as monolayers. The water soluble iron tetrasulfonated phthalocyanine (Fe-TSPc) (Fig. 10) strongly adsorbs on graphite and at monolayer levels has high activity for the overall 4-electron reduction of O_2 in neutral and dilute alkaline electrolytes. The catalytic activity per unit surface area is higher than for platinum. Rotating disk-ring electrode measurements indicate no detectable peroxide over a substantial potential range (106). The principal problem is the stability of the iron macrocyclic in concentrated caustic and acid solutions. In contrast to the Fe-TSPc, the adsorbed Co-TSPc catalyzes the reduction of O_2 to the peroxide (106, 107).

The interaction of the adsorbed Co-TSPc and Fe-TSPc with the substrate electrode surface (graphite, Pt, and Au) has been studied using visible reflectance spectroscopy (108) (see Fig. 11). The reflectance spectra of the adsorbed Fe-TSPc and Co-TSPc monolayers undergo substantial changes at constant potential with the introduction of O_2 into the electrolyte. We

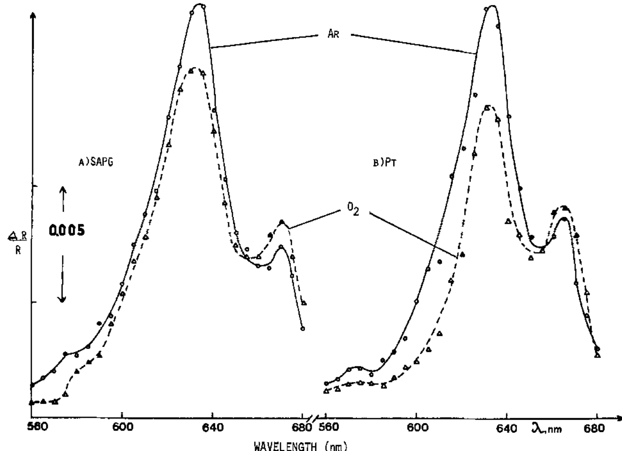

Fig. 11. Reflectance spectra of Fe(III)-TSPc in 0.1m NaOH adsorbed on (a) the basal plane of stress annealed pyrolytic graphite electrode (SAPG) at 0.90V vs. RHE and (b) a Pt electrode at 0.70V with Ar(——) and O_2 (- - -) saturated solutions. Perpendicular polarization (108).

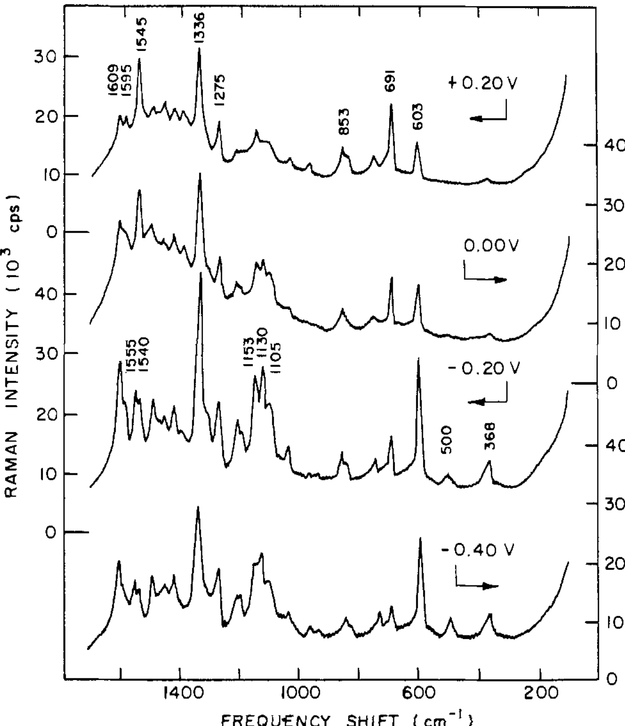

Fig. 12. Raman spectra of CoTSPc adsorbed on an Ag electrode for different electrode potentials in 0.05m H_2SO_4 + 10^{-5}m CoTSPc; 514.5 nm; power at the sample 50 mW (15).

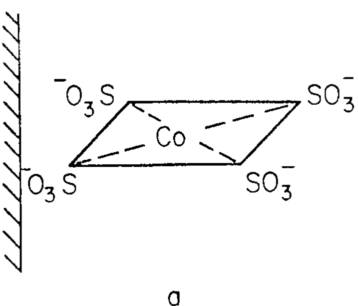

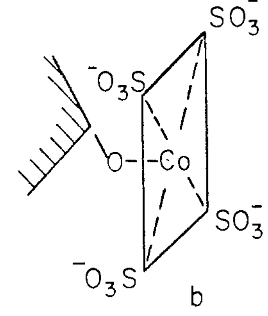

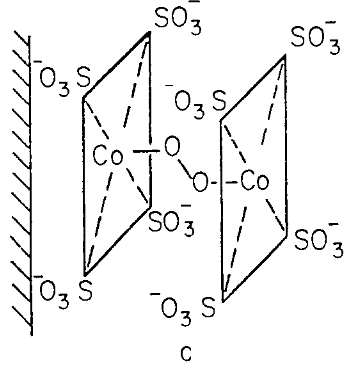

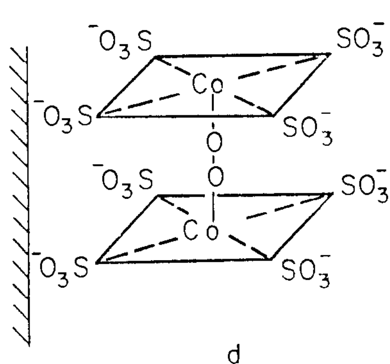

Fig. 13. Possible configurations for CoTSPc adsorbed on an electrode surface (15).

believe this is caused by the formation of an O_2 adduct with the adsorbed species. The Raman spectrum of the Co-TSPc (Fig. 12) has also been obtained with this complex adsorbed on silver, which provides a large surface enhancement of the Raman signal (15). Further work is needed to interpret the Raman spectra and their potential dependence. On the basis of the strong adsorption and the Raman data, we believe that the Co-TSPc is adsorbed on the silver as shown by model C in Fig. 13 with one of the Co-TSPc units in the O_2 bridge dimer interacting directly with the metal substrate. We do not yet have Raman data for the Fe-TSPc but suspect that the adsorption may be in a similar configuration. Dimeric -O-O- complexes have been proposed in aqueous solutions for both the Fe-TSPc and Co-TSPc, principally on the basis of the u.v.-visible absorption spectra. The -O-O- bridged complex would be a likely candidate in the case of the adsorbed Fe-TSPc to explain the 4-electron reduction. The Co-TSPc apparently also forms such a bridge but because of its redox properties or some other factors, does not undergo reduction via a 4-electron pathway (107).

Collman, Anson, and their co-workers (109) have recently synthesized covalently linked face-to-face dicobalt prophyrin dimers with the proper spacing to form a Co-O-O-Co bridge. With relatively thick layers of this complex graphite, rotating disk-ring electrode measurements also indicate a 4-electron reduction in acid electrolytes, verifying that the bridged complex can promote the overall 4-electron reduction. The complexes of Collman *et al.*, however, are expensive to synthesize with many steps while the approach involving adsorbed solubilized complexes is not.

While these are encouraging fundamental developments in O_2 electrocatalysis. it is difficult to translate them into practical electrodes, principally because of catalyst stability problems. Research is in progress at Case to establish whether other macrocyclic catalysts affording M-O-O-M bridging may have greater stability.

Acknowledgment

The research sited in this address in the awardee's laboratory in the field of electrocatalysis has been carried out by a number of former and present graduate and postdoctoral students, whose names in most instances are in the cited publications. Most of the credit for this work belongs to them.

The Office of Naval Research has supported the awardee's research in the field of electrocatalysis continuously since 1952 and is gratefully acknowledged. The awardee also is pleased to acknowledge support for the research on O_2 electrocatalysis in more recent years from the U.S. Department of Energy, the Electric Power Research Institute, NASA, and several other companies including Diamond Shamrock, General Motors, Union Carbide, and the International Nickel Company.

Electrochemical Behavior of Copper in Thionyl Chloride Solutions

Wishvender K. Behl*

U.S. Army Electronics Technology and Devices Laboratory (ERADCOM), Power Sources Division, Fort Monmouth, New Jersey 07703

ABSTRACT

The electrochemical and chemical behavior of copper and copper chlorides was studied in 1.5M $LiAlCl_4$-$SOCl_2$ solutions using cyclic voltammetric, controlled potential electrolysis, and x-ray techniques. It was shown that copper metal reacts with thionyl chloride even at ambient temperatures resulting in the formation of cuprous chloride and cupric sulfide. In $LiAlCl_4$-$SOCl_2$ solutions, cuprous chloride is further oxidized, chemically as well as electrochemically, to cupric chloride. Cupric chloride was found to be electroactive in these solutions and undergoes reduction in the solid state to cuprous chloride and copper, respectively. It was also found that due to the presence of copper chloride films at the copper metal electrode in these solutions, the electrochemical reduction of thionyl chloride at copper electrodes occurs at more negative potentials than observed at carbon electrodes.

Copper metal has been recently used as a cathode additive (1) to enhance the performance of lithium-thionyl chloride batteries. Thionyl chloride is known (2, 3) to react rapidly with a number of metals at high temperatures and more slowly at ambient temperatures but the chemical literature is devoid of any information on the reaction of copper metal with thionyl chloride. Further, to date, no studies have been reported on the electrochemical behavior of copper metal in thionyl chloride solutions. We have, therefore, investigated the chemical as well as electrochemical behavior of copper metal in 1.5M $LiAlCl_4$-$SOCl_2$ solutions using cyclic voltammetric technique and x-ray analysis. This paper summarizes our results.

Experimental

The preparation and purification (4) of thionyl chloride ($SOCl_2$) and lithium tetrachloroaluminate ($LiAlCl_4$) and other experimental details (5-7) have been described previously. A three electrode system was used for all measurements. The lithium reference electrode was separated from the lithium counter-electrode and copper working electrode by use of a Pyrex tube (10 mm diam) with a coarse porosity fritted glass bottom. The copper electrode was fabricated by machining a piece of pure copper rod (m5*N* + purity; Alfa Division, Ventron Corporation) to 4.064 mm diam and threading it to another copper rod of unknown purity. The electrode was then heat sealed in a shrinkable Teflon tubing and the end ground flush with the seal so as to expose the cross section of the pure copper rod.

The copper electrodes were mechanically polished on crocus cloth and soft paper before recording each voltammogram. The cross-section area of the copper electrode was 0.13 cm^2. For controlled potential electrolysis experiments, a strip of pure copper metal foil (m5*N* purity; Alfa Division, Ventron Corporation, 1 × 5 cm; 0.127 mm thick) was used as the working electrode.

All experiments were performed inside a dry-train, dry-lab (Vacuum Atmosphere Corporation) in a pure dried argon atmosphere.

Results and Discussion

Thionyl chloride was found to react with copper metal (foil or wire) even at room temperature resulting first in the formation of a black film on the copper metal surface followed by its complete disintegration in a few days. The reaction was also accompanied by gassing, presumably due to the formation of sulfur dioxide (see Eq. [1] below). X-ray analysis of the solid product indicated it to be mainly cuprous chloride (CuCl). However, the product was only partially soluble in hydrochloric acid and left behind a small residue after a number of washings with hydrochloric acid. The hydrochloric acid solution was analyzed and gave positive tests (8, 9) for cuprous chloride. The black residue was identified by x-ray analysis to be cupric sulfide (CuS). The reaction of copper with thionyl chloride at ambient temperatures may, therefore, be represented by the equation

$$5Cu + 2SOCl_2 \rightarrow 4CuCl + CuS + SO_2 \qquad [1]$$

Cupric sulfide is known (2, 10) to react with thionyl chloride at 150°C according to the equation

$$CuS + 2SOCl_2 \rightarrow CuCl_2 + S_2Cl_2 + SO_2 \qquad [2]$$

However, it appears that this reaction (Eq. [2]) does not occur at ambient temperatures.

In $LiAlCl_4$-$SOCl_2$ solutions, a black film is formed on the copper metal first but it rapidly transforms into a yellow film. After a few hours, the copper metal foil covered with the yellow film was removed, washed

* Electrochemical Society Active Member.

Key words. cathode, electrolyte, voltammetry.

with thionyl chloride, and vacuum dried. The yellow film was identified by x-ray analysis to be cupric chloride ($CuCl_2$). It, therefore, appears that in $LiAlCl_4$-$SOCl_2$ solutions, both cuprous chloride and cupric sulfide are at least partially converted to cupric chloride. The reactions may be represented by equations

$$4CuCl + 2SOCl_2 \rightarrow 4CuCl_2 + S + SO_2 \quad [3]$$

$$CuS + LiAlCl_4 \rightarrow LiAlSCl_2 + CuCl_2 \quad [4]$$

A reaction similar to Eq. [4] has been shown to occur (11) between lithium sulfide and lithium tetrachloroaluminate in thionyl chloride solutions. Lithium thiochloroaluminate ($LiAlSCl_2$) is soluble in thionyl chloride and has been proposed (11) as a new electrolyte for lithium thionyl chloride batteries.

The reactions of cuprous chloride and cupric sulfide in $LiAlCl_4$-$SOCl_2$ solutions were independently confirmed by treating reagent grade samples with 1.5M solutions. While the cuprous chloride sample was completely converted to brown cupric chloride in a few hours, the reaction of cupric sulfide was much slower and only a part of the black cupric sulfide sample was converted to brown cupric chloride. The specific role of lithium tetrachloroaluminate in these reactions, however, needs to be further investigated.

Copper metal also reacted with $AlCl_3$-$SOCl_2$ solutions to form an outer layer of cupric chloride film. Since aluminum chloride is known (12) to catalyze the reaction of metals with thionyl chloride, cuprous chloride formed by the reaction of copper metal with thionyl chloride is further oxidized to cupric chloride in $AlCl_3$-$SOCl_2$ solutions. However, in contrast to $LiAlCl_4$-$SOCl_2$ solutions, cupric sulfide does not react with $AlCl_3$-$SOCl_2$ solutions to form cupric chloride.

If the yellow cupric chloride film formed on copper electrodes in $LiAlCl_4$-$SOCl_2$ or $AlCl_3$-$SOCl_2$ solutions is carefully scraped, a thin layer of original mainly cuprous chloride film is found intact next to the copper metal surface and underneath the outer cupric chloride film. This is not surprising since copper metal would be thermodynamically unstable in contact with cupric chloride.

Copper metal electrode momentarily exhibits an open-circuit potential[1] of ~2.85V when first introduced in 1.5M $LiAlCl_4$-$SOCl_2$ solution, but the potential quickly increases to ~3.36V. This increase in open-circuit potential can be explained by the chemical transformation of the original mainly cuprous chloride film to cupric chloride film as discussed above. Thus the copper electrode assumes the Cu(I)-Cu(O) couple potential when first introduced in $LiAlCl_4$-$SOCl_2$ solution but as some of the cuprous chloride film is chemically converted to cupric chloride, the electrode assumes a mixed potential involving the two processes.

A typical cyclic voltammogram obtained at the copper electrode by scanning it in the anodic direction from 3.3 to 5.8V at a scan rate of 0.09 V/sec is shown in Fig. 1. The cyclic voltammogram shows an increasing anodic current as the potential becomes more positive and exhibits an anodic peak at ~3.63V. After the anodic peak, the electrode is passivated due to the formation of a yellow film on the electrode surface. Thus, due to the passivation of the electrode, the cyclic voltammogram does not show the anodic peaks for the oxidation of $LiAlCl_4$-$SOCl_2$ solutions which are observed (6, 11) at glassy carbon electrodes at potentials above 4.0V. The electrode remains passivated during the reverse scan till the onset of a reduction process at ~3.55V.

Cyclic voltammograms similar to those presented in Fig. 1 were obtained at scan rates of 0.01-1.0 V/sec and the anodic peak height increased with increasing scan rate.

[1] All potentials are reported with respect to the lithium reference electrode.

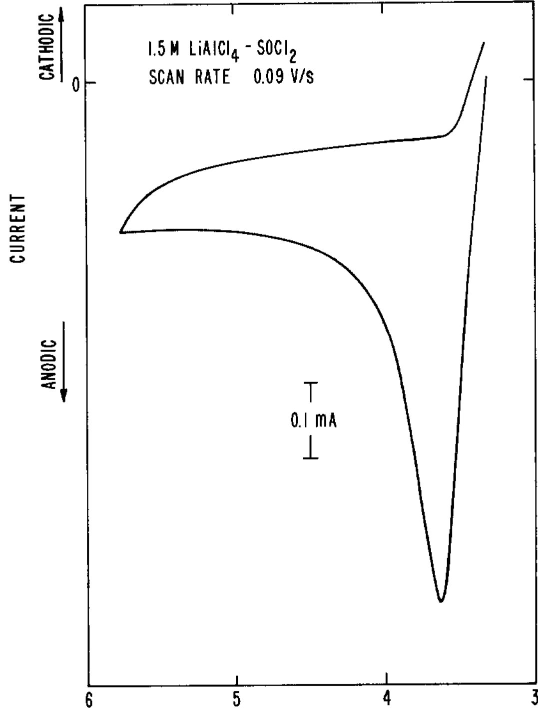

Fig. 1. Typical cyclic voltammogram obtained by scanning the copper electrode between 3.3 and 5.8V.

Controlled potential electrolysis of a strip of copper foil at 4.0V for 16 hr resulted in the formation of a thick yellow film. After the electrolysis, the copper foil covered with the yellow film was removed, repeatedly washed with thionyl chloride, and vacuum dried. The yellow film was then identified by x-ray analysis to be cupric chloride ($CuCl_2$). Again a thin layer of mainly cuprous chloride film was found intact next to the copper metal surface and underneath the outer cupric chloride film.

Thus, the anodic peak at ~3.63V in the cyclic voltammogram presented in Fig. 1 may be assigned to the oxidation of cuprous chloride to cupric chloride

$$CuCl + SOCl_2 + AlCl_4^- \rightarrow CuCl_2 + SOCl^+AlCl_4^- + e \quad [5]$$

The anodic peak height in these voltammograms was found to depend to a large extent on the time for which the electrode was held at open circuit before recording the cyclic voltammograms. Thus as the time interval was increased, a larger part of the cuprous chloride-cupric sulfide film converted chemically to cupric chloride (Eq. [3] and [4]) so that only a small anodic peak, due to the electrochemical oxidation of cuprous chloride to cupric chloride, was observed.

In the next series of experiments, the copper metal electrode was held at 4.0V for a few minutes before recording the cyclic voltammograms in the cathodic direction. A large anodic current is initially observed at 4.0V due to the formation of cupric chloride but it quickly decreases to a small steady-state anodic current. A typical cyclic voltammogram obtained by scanning the copper electrode from 4.0 to 2.0V at a scan rate of 0.05 V/sec is shown in Fig. 2. The cyclic voltammogram shows two reduction peaks at ~2.7 and ~2.1V and corresponding anodic peaks are observed at ~3.7 and ~2.9V, respectively, during the reverse scan. If the copper electrode is scanned to 2.5V, only the reduction peak at ~2.7V and the corresponding oxidation peak at ~3.7V are observed in the cyclic voltammograms. Similar cyclic voltammograms were obtained at scan rates of 0.01 to 0.1 V/sec. At higher scan rates, the reduction peak at

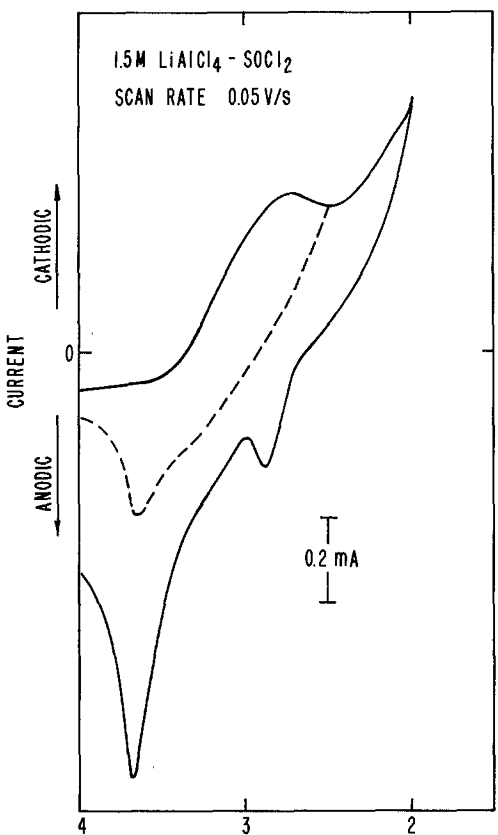

Fig. 2. Typical cyclic voltammogram obtained by scanning the copper electrode between 4.0 and 2.0V (solid curve); broken curve is obtained if the scan is reversed at 2.5V.

~2.1V was indiscernible and only one large anodic peak was observed during the reverse scan.

Controlled potential electrolysis of a strip of pure metal foil at 2.75V for ~16 hr resulted in a light blue film on the electrode surface. The copper metal foil was removed, washed with thionyl chloride, and vacuum dried. The light blue film was identified as cuprous chloride (CuCl) by x-ray analysis. Thus, the reduction peak in the cyclic voltammograms at ~2.7V (Fig. 2) may be ascribed due to the reduction of cupric chloride to cuprous chloride according to the equation

$$CuCl_2 + Li^+ + e \rightarrow CuCl + LiCl \quad [6]$$

and the corresponding anodic at ~3.7V to the oxidation of cuprous chloride to cupric chloride according to Eq. [5] as discussed above.

The cell potential for the hypothetical solid-state cell, Li/LiCl/CuCl$_2$,CuCl/C was calculated to be 3.557V from the free energies of formation of lithium chloride (13a), cupric chloride (13b), and cuprous chloride (13b). It is seen that the electrochemical reduction of cupric chloride to cuprous chloride in $LiAlCl_4$-$SOCl_2$ solutions occurs at potentials (~3.5V) close to the theoretically predicted value.

During the course of these experiments, it was noticed that a thin layer of metallic copper deposited on the lithium counterelectrode. Since cupric chloride was found to have negligible solubility in $LiAlCl_4$-$SOCl_2$ solutions, it appears likely that during the reduction of cupric chloride to cuprous chloride, part of cupric chloride complexes with chloride ions and goes into solution as $CuCl_4^{--}$ ions. A similar explanation was offered by Rao (14) to account for the increased solubility of cuprous chloride during discharge in $LiAlCl_4$-propylene carbonate solutions. Copper metal is then plated on the lithium counterelectrode by the reaction of lithium metal with $CuCl_4^{--}$ ions in solution.

The reduction peak at ~2.1V in the cyclic voltammograms (Fig. 2) may be ascribed to the reduction of cuprous chloride to copper metal

$$CuCl + Li^+ + e \rightarrow Cu + LiCl \quad [7]$$

and the corresponding anodic peak at ~2.9V to the oxidation of copper metal to cuprous chloride according to the equation

$$Cu + SOCl_2 + AlCl_4^- \rightarrow CuCl + SOCl^+AlCl_4^- + e \quad [8]$$

As soon as some cuprous chloride is reduced to copper metal, the cathodic current rapidly increases at ~2.0V due to the simultaneous reduction of thionyl chloride at the bare copper metal surface. Thus, the cuprous chloride reduction peak at ~2.1V appears only as a small step to the larger reduction peak at ~1.6V in the cyclic voltammograms (Fig. 3) at scan rates below ~0.1 V/sec and merges with the larger reduction peak at higher scan rates.

Controlled potential electrolysis of a strip of copper metal foil at 1.5V resulted only in a lithium chloride film on the bare copper metal surface. Thus, at potentials negative to ~2.0V, the copper chloride films as well as any unreacted cupric sulfide on the electrode surface are all reduced to metallic copper. It is also seen that the presence of various films on copper electrodes at potentials positive to ~2.0V block the reduction of thionyl chloride. As soon as these films are reduced, the copper metal surface becomes available for the reduction of thionyl chloride. Thus, the electrochemical reduction of thionyl chloride at copper electrodes occurs at more negative potentials than observed at carbon electrodes (6, 7, 11, 15, 16) and may be represented by the generally accepted equation (6, 7, 11, 17-20)

$$2SOCl_2 + 4Li^+ + 4e \rightarrow 4LiCl + S + SO_2 \quad [9]$$

Due to high background currents at copper electrodes in the potential region of 1-2V, other minor reduction peaks (6, 7, 11, 15) observed at carbon electrodes in this potential region are not discernible in the cyclic voltammograms. At more negative potentials (~ −0.25V), a large increase in the cathodic current is observed due to the deposition of lithium metal. On the reverse scan, an anodic peak for the dissolution of deposited lithium metal is observed at ~0.15V and at more positive potentials, a minor oxi-

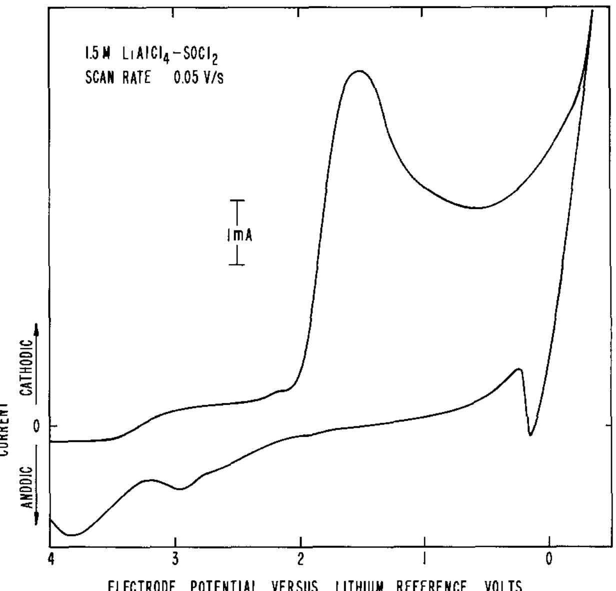

Fig. 3. Typical cyclic voltammogram obtained by scanning the copper electrode between 4.0 and −0.35V.

dation peak is observed at ~1.9V followed by the anodic peaks for the oxidation of copper to cuprous chloride at ~2.95V and cuprous chloride to cupric chloride at ~3.7V, respectively.

From the results presented above, it is seen that the electrochemical reduction of cupric chloride to cuprous chloride in $LiAlCl_4$-$SOCl_2$ solutions occurs at about similar potentials as the electrochemical reduction of thionyl chloride at Shawinigan black carbon electrodes (4). It is also seen that the cupric chloride/cuprous chloride redox couple is catalytic in $LiAlCl_4$-$SOCl_2$ solutions and results in the regeneration of cupric chloride by the reaction of cuprous chloride with thionyl chloride. Cupric chloride, therefore, appears to be a useful cathode additive for lithium-thionyl chloride batteries. Preliminary results (21) with Shawinigan black carbon cathodes containing about 21.7 weight percent of cupric chloride indicate that these electrodes show less polarization, particularly at high current densities, than the Shawinigan black carbon cathodes without the cupric chloride additive.

Effect of Sulfur Impurities on Li/TiS_2 Cells

B. M. L. Rao and J. A. Shropshire

Exxon Research and Engineering Company, Advanced Energy Systems Laboratory, Linden, New Jersey 07036

ABSTRACT

Conditions leading to the generation of sulfur and hydrogen sulfide from TiS_2 can occur with uncontrolled handling of the active material during the fabrication of Li/TiS_2 cells. These impurities affect the storage behavior of the ambient temperatures rechargeable organic electrolyte cells. An increase in the lithium anode polarization and self-discharge of the cells is witnessed in the presence of these impurities. A mechanism of Li_2S_n film formation and S_n^{-2}/S_{n-x}^{-2} redox shuttle is discussed to account for the observed results.

In previous work, operation of high energy density Li/TiS_2 cells in organic electrolytes (1-3), molten salts (4-6), and solid electrolyte (7), has drawn attention to several important chemical reactions which influence the TiS_2 half-cell performance in organic electrolyte cells. These include: (*i*) the effect of nonstoichiometry in the titanium and sulfur ratio in the active material, and (*ii*) the intercalation of solvents. The former, leading to the generation of $Ti_{1+x}S_2$, results in diminished rate capability of the cells, due to a reduction of lithium diffusion rate in the host lattice (8). The latter, a phenomenon of solvent co-intercalation along with lithium, results in a large expansion of c-axis distance. This event occurs in the presence of trace amounts of water, which is a common impurity in organic electrolytes. For example, co-intercalation of electrolyte solvents, such as propylene carbonate, dimethyl sulfoxide, and diglyme, result (6) in c-lattice expansion of 14-19Å compared to 6.2Å for the intercalation of lithium into TiS_2. Such large lattice expansion causes an excessive volume change during the cell operation. In this study, we have observed that sulfur-based impurities also affect the rate capability and storage life of Li/TiS_2 cells.

Key words: electrolyte cell, discharge, chelation.

Background Information

Origin of sulfur-based impurities, *i.e.*, free elemental sulfur, or hydrogen sulfide in TiS_2, may be traced to either of the following sources: (*i*) nonequilibrium conditions of production of TiS_2 (from the elements, or by the reaction of H_2S and $TiCl_4$), and (*ii*) uncontrolled treatments and handling of the active material.

Solvent extraction procedures (9) are effective in the removal of impurities from the TiS_2 samples. The purified TiS_2 is stable in a dry, inert environment, as the estimated equilibrium sulfur vapor pressure is $\sim 10^{-6}$ atm at room temperature. However, regeneration of these impurities occurs on contact with moisture and air. Moist air (~40% RH) reacts with battery grade, high surface area (~5 m^2/g) TiS_2 powder and releases hydrogen sulfide. This reaction appears to be gradually retarded by the formation of a TiO_2 surface film. Although TiS_2 may be handled, to a limited extent, in the dry room (<1.5% RH), H_2S monitoring systems need to be employed to take precautions against an accumulation or release of toxic levels of the gas. Interaction of TiS_2 with dry air results in the release of free elemental sulfur (7), with the formation of nonstoichiometric TiS_2, *i.e.*, $Ti_{1+x}S_2$ and TiO_{2y} ($y \sim 1$). This reaction is naturally accelerated by an increase in temperature. Combustion of TiS_2 ensues at >232°C, initiated by the auto-ignition of liberated sulfur. This reaction is of importance in controlling conditions of fabrication (9) of thermal bonded TiS_2 electrodes with plastic binders.

Based on the aforementioned reactions, regeneration of sulfur-based impurities may reoccur in purified TiS_2 during handling of the material for the manufacture of electrodes, cell assembly, and storage conditions. This paper discusses the effect of these impurities on the storage behavior of Li/TiS_2 cells in an organic electrolyte.

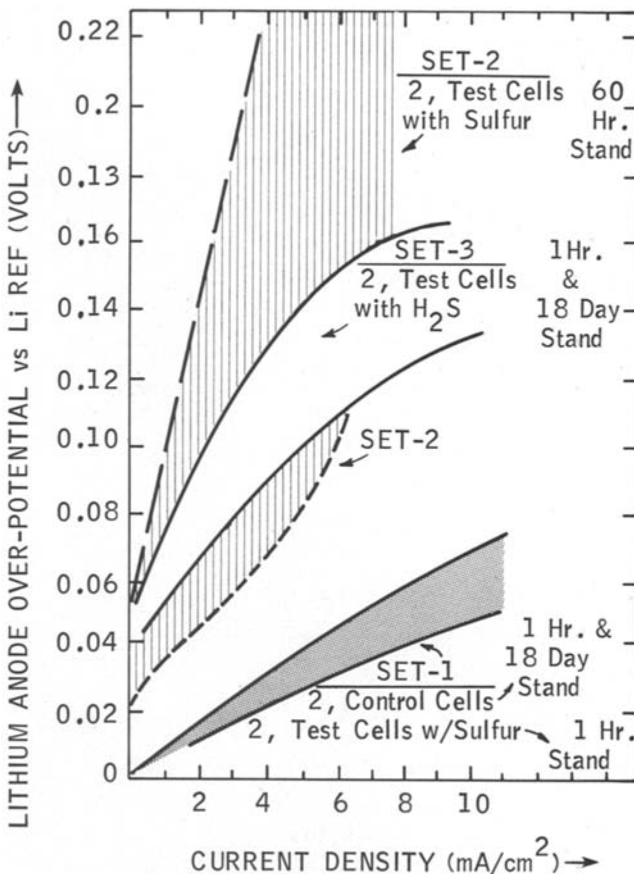

Fig. 1. Anode polarization data on open-circuit stand in the presence of "S" and "H_2S" in Li/TiS_2 cells.

Experimental

Cells.—The Li/TiS_2 test cells were of one anode, one cathode, parallel plate, prismatic configuration. The negative electrode was 0.025 cm thick, 6.45 cm^2 lithium foil pressed on copper grid. The positive electrode was a sintered porous cake (~45% porosity) of ~0.99g TiS_2 and 0.1g polytetrafluoroethylene, which was prepared using solvent-treated TiS_2 and hot-pressed onto a (6.45 cm^2) tantalum grid in a helium dry box. The electrodes were individually enclosed in microporous polyethylene bags and were sandwiched across a 0.04 cm porous fiberglass mat separator. A polyethylene bag served as the cell container. Stack pressure was realized by clamping the cell between metal plates. The cells were assembled with lithium reference electrodes in a dry room (<1.5% RH) and placed in suitable jars with leads to exclude atmospheric contamination. The cells were tested after addition of 2.5-3.5 ml of 2.5M LiSCN·1,3-dioxolane, an electrolyte previously developed for rechargeable Li/TiS_2 cells (10).

Tests.—Cells assembled, as described above, served as controls for comparison of storage behavior in the presence of sulfur and hydrogen sulfide impurities. Current-potential profiles and the open-circuit voltage behavior were investigated as a function of room temperature storage duration in these experiments. The former was obtained in a galvanostatic polarization for a period of 1 min, measuring the lithium half-cell behavior during the test. The spread in the data indicated in various sets of data in Fig. 1 cover the voltage excursions noted from the start to the end of the polarization experiments.

The effect of elemental sulfur was studied by assembling Li/TiS_2 cells, as above, with deliberate contamination of the TiS_2 electrode with the impurity as different from the use of excess sulfur as cathode active material with transition metal chalcogenide by Broadhead (11). For this purpose, TiS_2 electrodes, similar to the ones used in control cells, were smeared with 0.06g of sulfur powder on the 6.45 cm^2 area. Test cells were assembled with the sulfur-containing side facing the lithium electrode. The effect of hydrogen sulfide was examined by using TiS_2 cathodes exposed to laboratory humidity (~40% RH). The formation of >200 ppm H_2S under this condition was noted in ~20 min of exposure (5), by the tarnishing of lead acetate paper positioned 1 in. away from the electrode.

In supplementary experiments, the solubility of sulfur in 1:3-dioxolane was measured to be 0.02g/100 ml solvent. Chemical analysis of electrode products of self-discharged cells indicated sulfur species in the anode film by x-ray fluorescence and Li_xTiS_2 was detected in the TiS_2 cathode by x-ray diffraction.

Results

Figure 1, set 1, provides the current-potential behavior of the lithium half-cell of the Li/TiS_2 cell observed during discharge of two control cells, at 1 hr and 18 days storage, after the addition of electrolyte. This set also represents the lithium anode polarization data at 1 hr soak, for two cells containing sulfur impurity. After 60 hr of stand, the lithium anode exhibited the behavior represented in Fig. 1, set 2, in the presence of sulfur in the cell. Figure 1, set 3, illustrates lithium anode polarization for two cells, with cathodes containing H_2S, after 1 hr and 18 days of open-circuit stand, at room temperature.

Figure 2 provides a comparison of open-circuit voltage of Li/TiS_2 control cells, with similar data over a 2 month period at ~23°C, on cells containing sulfur and hydrogen sulfide impurities at levels of earlier description.

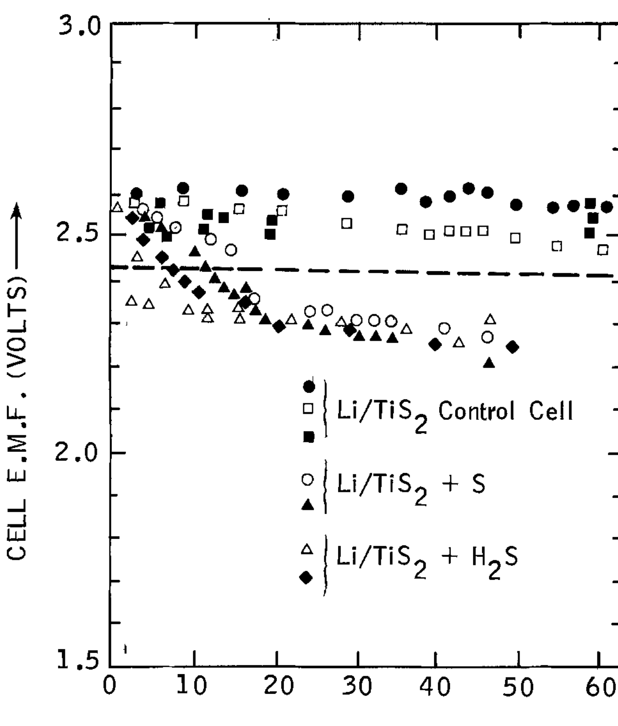

Fig. 2. Open-circuit voltage of Li/TiS_2 cells

Discussion

Data in Fig. 1 and 2 indicate an increase in lithium anode polarization and a self-discharge of Li/TiS_2 cells in the presence of sulfur and hydrogen sulfide. As these impurities originate at the TiS_2 electrode, they are presumably transported to the anode, as dissolved species, and interactions in Eq. [1]-[3] occur

$$2Li + \frac{n}{8} S_8 \rightarrow Li_2S_n \quad [1]$$

$$2Li + H_2S \rightarrow Li_2S + H_2 \quad [2]$$

$$2Li + 2H_2S \rightarrow 2LiHS + H_2 \quad [3]$$

The formation of Li_2S_n, Li_2S, or LiHS films on the anode account for the increase in polarization voltage of the lithium half-cells in Fig. 1. This is plausible, as sulfur and H_2S are observed to be soluble in the electrolyte and sulfur has been detected on the anode by x-ray fluorescence analysis. The differences in the magnitude of the polarization voltage and the time effect variations between sulfur and H_2S containing cells in Fig. 1, sets 1-3, are not only caused by the differences in the quantity of impurities, their solubility, diffusion transport, etc., but also by the film composition, compactness, and other parameters.

Although the reactions in [1]-[3] may account for the increased polarization voltage of the lithium electrode on storage of Li/TiS_2 cells, these reactions alone cannot explain the self-discharge noted in Fig. 2.

It is noted, in Fig. 2, that control cells exhibit formal potentials of Li/TiS_2 cells above 2.42V measured for fully charged cycled cells. This initial behavior is due to the fact that the TiS_2 half-cell potential is not in equilibrium in the absence of small amounts of Li_xTiS_2. The formal potential is influenced by small quantities of other impurities, such as dissolved oxygen peroxides, or $(CNS)_x$ in the LiSCN-1:3·dioxolane electrolyte. However, emf of the control cells stored in the dry room over a 60 day period do not drift below the expected 2.42V for the Li/TiS_2 system.

In comparison to the data of the control cells, the open-circuit voltage of Li/TiS_2 shows a self-discharge behavior, in that the cell voltage drifts below 2.42V in the presence of sulfur and H_2S impurities. It appears that these impurities partially solubilize the films formed in reactions [1]-[3] to generate polysulfides of composition S_n^{-2}. If the emf of the TiS_2 and Li_xTiS_2 half-cell is favorable for the oxidation of the polysulfide species, then a soluble redox couple may result. Shuttling of these species between the lithium and TiS_2 electrodes could cause the observed self-discharge. Equations [4]-[6] describe this phenomenon

$$Li_2S_n \rightarrow 2Li^+ + S_n^{-2} \quad [4]$$

At Li° (−ve) electrode

$$S_n^{-2} + xLi^\circ \rightarrow xLi^+ + S_{n-x}^{-2} + xe \quad [5]$$

At TiS_2 (+ve) electrode

$$S_{n-x}^{-2} + xLi^+ + TiS_2 + xe \rightarrow S_n^{-2} + Li_xTiS_2 \quad [6]$$

Conditions for the reoxidation of S_n^{-2}/S_{n-x}^{-2} couple is indicated by Rauh *et al.* (12) to be 2.1V in electrolytes with tetrahydrofuran, a cyclic ether solvent similar to 1:3-dioxolane. This, indeed, is noted in Fig. 2, as the emf of the Li/TiS_2 cells is >2.1V. The formation of Li_xTiS_2, as evidenced by x-ray diffraction analysis of the cathode, represents the self-discharge reaction and the drop in cell voltage noted in the presence of the impurities in question. The initial fast drop in the open-circuit voltage noted in Fig. 2 may correspond to a redox shuttle of S_8/S_8^{-2} to ~2.3V (12,13), and the remaining slower reactions to S_n^{-2}/S_{n-x}^{-2} ($n = 8$, $x = 2$-4), as observed, to 2.1V in the previous work (12) on the study of the lithium/dissolved sulfur battery. Sulfur and H_2S are likely to generate similar redox shuttles, in reactions [5] and [6] and, hence, the similarity in self-discharge in the presence of these impurities (Fig. 2). Lack of polysulfide formation indicated by Broadhead (11) in $Li/NbSe_2$ and S cells, appears to be an effect of propylene carbonate medium.

Based on the results of this study, it is indicated that exclusion of sulfur-based impurities is required to minimize the self-discharge of Li/TiS_2 cells operating in cyclic ether solvents.

Acknowledgment

The authors wish to acknowledge helpful discussions with Dr. D. J. Eustace and the laboratory assistance of Mr. R. J. Solarczyk.

Manuscript submitted April 17, 1980; revised manuscript received Dec. 15, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by Exxon Research and Engineering Company.

Semiconductor Electrodes

XXXVI. Characteristics of n-$MoSe_2$, n- and p-WSe_2 Electrodes in Aqueous Solution

Fu-Ren F. Fan* and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

Capacitance and voltammetric measurements were employed to investigate the electrochemical and photoelectrochemical (PEC) behavior of n-WSe_2, p-WSe_2, and n-$MoSe_2$ single crystal electrodes in aqueous solutions containing various redox couples (Br^-/Br_2, I^-/I_3^-, $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$, Fe^{2+}/Fe^{3+}, $HV^{\overset{+}{\cdot}}/HV^{2+}$, and $MV^{\overset{+}{\cdot}}/MV^{2+}$, where HV is heptyl viologen and MV is methyl viologen). In supporting electrolyte (0.5M Na_2SO_4), the conduction bandedges of $MoSe_2$ and WSe_2, determined from the capacitance measurement, are at -0.14 and -0.44V *vs.* SCE, respectively, and the valence bandedge of WSe_2 is at 0.93V *vs.* SCE. A bandgap of 1.4 eV for WSe_2 was determined either from the photocurrent action spectrum or from the capacitance measurement. The specific effects of iodide on the capacitance and voltammetric behavior of layer-type compounds are compared. The characteristics of several PEC cells are also described.

The application of semiconductor electrode photoelectrochemical (PEC) cells (1) for the utilization of solar energy for the production of electricity or chemical species depends on the discovery of inexpensive and abundant materials with an energy gap which matches the solar spectrum and which are capable of stable operation. Thus there has been an active search for new semiconductor materials for PEC cells which meet these requirements.

Tributsch (2) introduced the concept of using layer-type electrodes (*e.g.*, MoS_2, $MoSe_2$, WSe_2) for such applications and a number of recent papers (3-8)[1] have described PEC cells based on these materials. These cells show quite good efficiencies and good stability in aqueous and acetonitrile solutions containing redox couples with reasonably positive redox potentials (*e.g.*, I^-/I_3^-). Wrighton and co-workers demonstrated that $MoSe_2$ and MoS_2 can even photo-oxidize chloride in highly concentrated aqueous LiCl solutions (3).

The behavior and efficiencies of these cells depend strongly on the nature of the electrode surface (4-8). A wide range of scatter in the electrochemical parameters (*e.g.*, flatband potential, V_{FB}) and the PEC behavior is reported from different laboratories. These different results are apparently due to the significant sample-to-sample variations in the morphology of crystals. For example, the presence of exposed edges in the van der Waals surface ($\perp$ C-axis) has been shown to lead to significant dark anodic currents at n-type electrodes and lower photocurrent efficiencies (4c, 8b).

In this report, we describe the voltammetric and impedance measurements of some carefully selected and well-behaved n-$MoSe_2$, n- and p-WSe_2 single crystals. Some physical properties, *e.g.*, V_{FB} and the bandgap, E_g, of WSe_2, obtained by different techniques are compared. The specific effect of iodide on the onset photopotentials of layer-type compounds is compared with V_{FB} obtained by capacitance measurements. We also discuss the performance of several solar cells composed of n-$MoSe_2$ and (halogen/halide) redox couples.

Experimental

The semiconductors used, n-$MoSe_2$, n- and p-WSe_2, were single crystals generously donated by Dr. Barry Miller and Dr. Frank DiSalvo, Bell Laboratories. The detailed procedures for selecting, mounting, cleaning, and etching the single crystals and preparing the ohmic contacts are similar to those previously reported (4). The electrodes studied here showed mirror-like surfaces with no obvious edges and pits on the surfaces when examined at a magnification of 100×. They produced negligibly small dark oxidation currents ($< 1\ \mu A\ cm^{-2}$) in 0.5M Na_2SO_4 between -0.5 and 1V *vs.* SCE. Typically, the electrode areas of the semiconductors were 0.03-0.2 cm^2. If not otherwise mentioned, the exposed surface is the van der Waals surface ($\perp$ C-axis).

A conventional three-electrode, single-compartment cell was used for all experiments. The electrochemical cell (volume ~ 25 ml) contained Pt disk and semiconductor working electrodes and was fitted with a flat Pyrex window for illumination of the semiconductor electrode. A platinum foil (~ 40 cm^2) was used as the counterelectrode in the voltammetric and impedance measurements. An aqueous saturated calomel electrode (SCE) was used as the reference electrode.

The voltammetric experiments and the solar cell measurements were performed with the same apparatus and procedures as reported previously (4). The light source used in the study of the PEC effect was an Oriel Corporation (Stamford, Connecticut) 450W Xe lamp. Experiments designed for specific wavelengths employed an Oriel 7240 grating monochromator with a 20 nm bandpass. A red filter (590 nm cut-on) was used with the Xe lamp. The radiant intensity was measured with an EG & G (Salem, Massachusetts) Model

* Electrochemical Society Active Member.

Key words: capacitance, voltammetry, impedance, photoelectrochemical behavior, solar cells.

[1] A solar power conversion efficiency of 10.2% has been reported for a cell based on n-WSe_2 and I^-/I_3^- systems (5).

550 Radiometer/Photometer. Neutral density filters were used to vary the intensity of the light.

All impedance measurements were carried out with an aqueous 0.5M Na_2SO_4 solution, if not otherwise mentioned. The electrical circuit allowed the application of a variable potential at the semiconductor electrode with respect to the reference electrode. The impedance was measured between this working electrode and a large ($\sim$ 40 cm^2) counterelectrode. The applied potential was controlled potentiostatically, and the capacitance was measured as the 90° quadrature signal from a lock-in amplifier (Princeton Applied Research, Model HR-8) with excitation by an external a-c generator via the potentiostat. The amplitude of the sinusoidal wave superimposed on the d-c bias potential was $\sim$ 5 mV. The measured capacitances were calibrated by replacing the electrochemical cell by a set of standard capacitors. The quantity measured was the equivalent series capacitance, C, since the dissipation factor ωRC, where ω is the angular frequency and R is equivalent series resistance, was much smaller than unity for all systems studied here, as shown in the results below. The measured impedance values were not changed when the counterelectrode was partially lifted out of the solution; thus the counterelectrode did not contribute significantly to the reported capacitances. All impedance measurements were performed in the dark.

Reagent grade chemicals were used without further purification. All solutions were prepared from triply distilled water and were deoxygenated for at least 30 min with purified nitrogen before each experiment. All experiments were carried out with the solution under a nitrogen atmosphere.

Results

Impedance measurements.—The capacitance of an electrode as a function of frequency and potential was a useful indicator of the electrode quality. The n-$MoSe_2$ and n-WSe_2 electrodes were subjected to impedance measurements in supporting electrolyte solutions, if not otherwise mentioned, at d-c bias potentials where the residual currents were negligibly small (< 1 μA cm^{-2}). Thus the measured value of C is the equivalent differential capacitance of the interface, with no faradaic contribution. If the presence of the oxidized form of a redox couple was required, its concentration was kept as low as possible to prevent substantial reduction current, which might distort the Mott-Schottky plots.

The value of the flatband potential, V_{FB}, was determined from the intercept of the plot of $1/C^2$ *vs.* potential according to the Mott-Schottky equation (9)

$$\left(\frac{1}{C}\right)^2 = \frac{2}{\epsilon\epsilon_0 e_0 n}\left(|V - V_{fb}| - \frac{kT}{e_0}\right) \quad [1]$$

In this equation ϵ is the dielectric constant of the semiconductor, ϵ_0 is the permittivity of free space, n is the donor density, n_D, for n-type and the acceptor density, n_A, for p-type semiconductors, e_0 is the absolute value of the charge of the electron, T is the absolute temperature, and k is the Boltzmann constant.

n-$MoSe_2$.—As shown in Fig. 1a, at frequencies between 1 and 10 kHz, a linear C^{-2} *vs.* V relationship was observed over a considerable potential range. Since the capacitance at these potentials is frequency independent, the intercept of the Mott-Schottky plot gives the flatband potential after correction for the thermal term in Eq. [1] and the potential drop across the Helmholtz double layer (*i.e.*, for the contribution of capacitance of the Helmholtz layer). The flatband potential of this n-$MoSe_2$ electrode was $\sim$0.0V *vs.* SCE at pH 4.5.

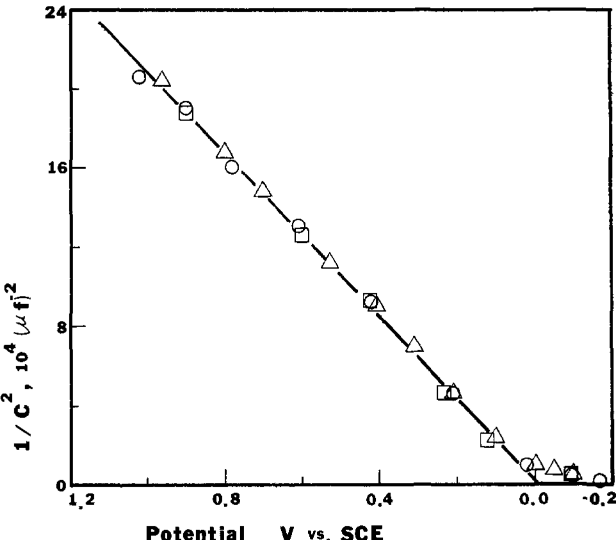

Fig. 1a. C^{-2} *vs.* V at different frequencies for n-$MoSe_2$ electrode in aqueous solution of 0.5M Na_2SO_4 at pH 4.5: (□) 1 kHz, (○) 3 kHz, (△) 10 kHz. Electrode area, 0.030 cm^2.

If we take the dielectric constant perpendicular to the C-axis, $\epsilon_{\perp}$, as 6.8 (10),[2] the slope of the Mott-Schottky plot yields $n_D \sim 1.2 \times 10^{17}$ cm^{-3}. With this value of the donor density of the $MoSe_2$ single crystal, the location of conduction bandedge, E_c, was calculated from Eq. [2] (9), assuming that the donor impurities are completely ionized. Since $N_c >> n_D$ (see below)

$$n_D = N_c \exp\left[-(E_c - E_F)/kT\right] \quad [2]$$

in which E_F is the Fermi energy and N_c is the density of the effective states in the conduction band, which is given by

$$N_c = 2\left(\frac{2\pi M_e^* kT}{h^2}\right)^{3/2} \quad [3]$$

where h is the Planck constant and M_e^* is the effective mass of electrons in the conduction band. With the assumption $M_e^* \approx M_o$ (11),[3] in which M_o is the mass of a free electron, N_c was estimated to be $\sim 2.5 \times 10^{19}$ cm^{-3}. Thus, E_c was $\sim$ 0.14 eV above the V_{FB} Fermi level energy, *i.e.*, the conduction bandedge is located at a potential $\sim -$ 0.14V *vs.* SCE.

The frequency independence of the capacitance implies that no oxide layer was on the surface of $MoSe_2$. The presence of an oxide layer often leads to frequency dispersion in the measured capacitance values because of dielectric relaxation in this layer.

As shown in Fig. 1b, the flatband potential of the n-$MoSe_2$ electrode was independent of pH, at least in the range studied (0-8). This finding further confirms the absence of an oxide layer on the electrode surface.

The flatband potential of the n-$MoSe_2$ electrode shifted to a more negative potential when iodide was present in the solution (Fig. 2a). Moreover, addition of a small amount of triiodide (0.25 mmole) shifted V_{FB} to an even more negative potential. However, bromide had no effect on V_{FB} (Fig. 2b). These results parallel those obtained by the voltammetric measurements which are described later. We can also estimate the resistivity, ρ, of this n-$MoSe_2$ electrode from the mobility, μ_e, of electrons and the free electron density, n_e, based on Eq. [4]

$$\rho \cong 1/(e_0 n_e \mu_e) \quad [4]$$

Here we neglect the contribution from the minority

[2] The $\epsilon_{\perp}$ value of $MoSe_2$ was assumed close to that of MoS_2. The $\epsilon_{\perp}$ of MoS_2 has been reported by Evans *et al.* (10).

[3] Here we assume that electrons in $MoSe_2$ have similar effective mass to that in WSe_2 (11).

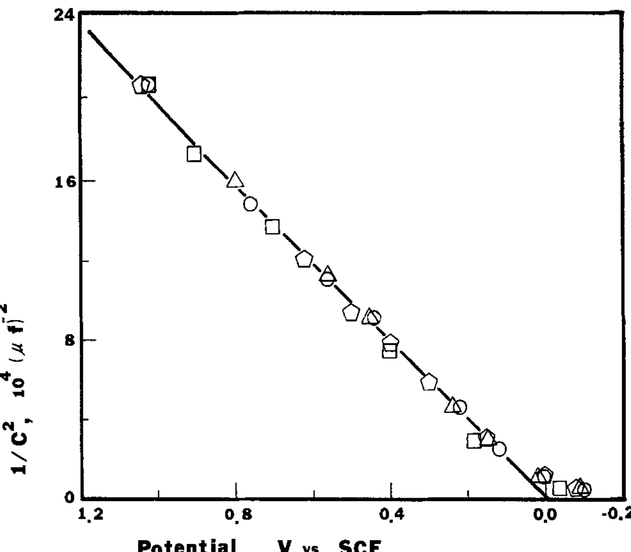

Fig. 1b. C^{-2} vs. V at different pH for n-$MoSe_2$ electrode in aqueous solution of 0.5M Na_2SO_4 at 2 kHz; (□) pH 0.5, (○) pH 2.5, (△) pH 4.5, (⬠) pH 8.0.

charge carriers. With $\mu_e = 10 \sim 50$ cm² V⁻¹ sec⁻¹ (12) and the assumption that the donors are completely ionized, ρ can be estimated to be $1 \sim 5$ Ω-cm.

n-WSe_2.—The general behavior for n-WSe_2 electrodes was similar to that of the n-$MoSe_2$ electrode described above. At frequencies between 0.2 and 2 kHz, a linear C^{-2} *vs.* V relationship was obtained over a considerable potential range and the capacitance was essentially frequency independent (see Fig. 3). Thus, V_{fb} of this n-WSe_2 electrode was ~ -0.32V *vs.* SCE. Assuming that $\epsilon_{\perp} \approx 10$ for WSe_2 (13),[4] we estimate a donor density of this electrode of $\sim 2.0 \times 10^{17}$ cm⁻³. According to Hicks (11), $M_e^* \approx M_h^* \approx M_o$; hence N_c was $\sim 2.5 \times 10^{19}$ cm⁻³ and E_c was ~ 0.12 eV beyond the V_{FB} Fermi level energy. With $\mu e = 100 \sim 150$ cm² V⁻¹ sec⁻¹ for the n-WSe_2 single crystals (12), the resistivity of this n-WSe_2 is $0.1 \sim 0.2$ Ω-cm.

p-WSe_2.—As shown in Fig. 4a, p-WSe_2 electrodes show quite different capacitance-potential curves from their n-counterparts. With potentials positive of 0.05V *vs.* SCE, a linear C^{-2} *vs.* V relationship was observed at frequencies of 1-10 kHz (Fig. 5a). For potentials more negative than 0.05V *vs.* SCE, frequency dispersion of capacitance occurs. The capacitance at − 0.2V *vs.* SCE for p-WSe_2 follows a (frequency)$^{-2}$ dependence at frequencies > 2 kHz. The origin of this frequency dispersion is still not clear, but might involve the presence of interface states or the onset inversion coupled with a faradaic process. Further investigations are required to explain this behavior.

[4] An approximate value was taken here since the exact dielectric constant at the frequency range studied is unknown (13).

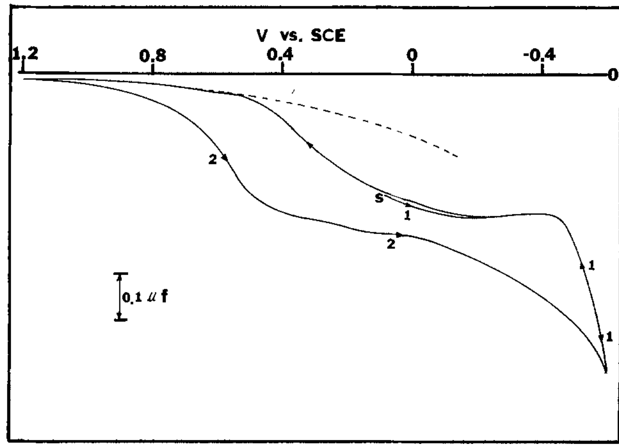

Fig. 4b. Capacitance vs. potential plot for n-WSe_2 electrode, type E. The potential was scanned beginning at point "s" at 5 mV/sec in the direction indicated by the arrows. $f = 200$ Hz. The dotted line indicates the expected capacitance for an electrode following the Mott-Schottky relation.

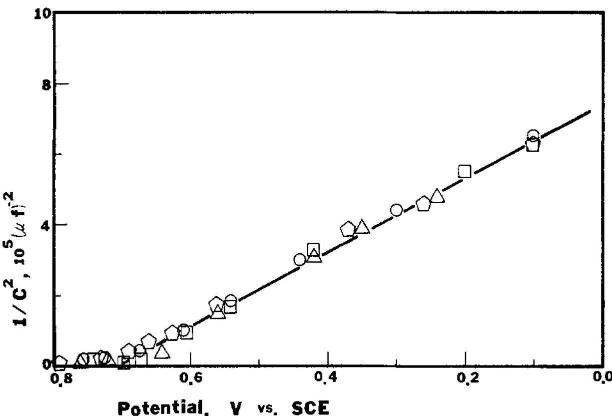

Fig. 5a. C^{-2} vs. V at different frequencies for p-WSe_2 electrode in aqueous solution of 0.5M Na_2SO_4 at pH 4.5: (△) 1 kHz, (⬠) 2 kHz, (□) 5 kHz, (○) 10 kHz. Electrode area, 0.050 cm².

Since frequency dispersion is found only at potentials negative of 0.0V *vs.* SCE which is well negative of V_{FB}, it has essentially no effect on the Mott-Schottky plots as shown in Fig. 5a. V_{FB} of this p-WSe_2 electrode was thus ~ 0.72V *vs.* SCE. If $\epsilon \approx 10$ for WSe_2 (13), the acceptor density of this electrode can be estimated as ~ 5×10^{15} cm^{-3}. The density of effective states in the valence band of WSe_2, N_v, the energy of the valence bandedge, E_v, and the resistivity of this p-WSe_2 are shown in Table I. As found with n-$MoSe_2$, V_{FB} of p-WSe_2 is pH independent (Fig. 5b) in the pH range studied.

The capacitance-potential plots which correspond well to that expected of the semiconductor space charge capacitance (*e.g.*, well-behaved Mott-Schottky plots

and frequency independence) found with edge-free electrode material (*e.g.*, Fig. 4a for n-WSe_2) can be contrasted with that found with material which contains some edges and discontinuities on the surfaces [designated "type E" in previous studies (4c)]. For type E n-WSe_2 electrodes, discontinuities are seen in the capacitance plots (Fig. 4b) as well as hysteresis effects and frequency dispersion. Thus capacitance plots are useful in distinguishing electrode material which produces low dark currents and efficient PEC cells from less efficient (type E) material.

Voltammetric behavior.—Electrochemical and PEC behavior of n- and p-WSe_2 electrodes have been reported previously (4). The following results mainly involve n-$MoSe_2$ electrodes. The voltammetric behavior of iodide at n-$MoSe_2$ and Pt is shown in Fig. 6. With or without I^- in the solution, in the dark a negligibly small background current was observed (curves a and b). Under illumination with slowly chopped red light (wavelength ≧ 590 nm), an anodic photocurrent commencing at 0.5V *vs.* SCE (curve c) was observed in the supporting electrolyte containing 0.50M H_2SO_4. No cathodic photocurrent was found, as expected for an n-type material. In the presence of 1.0M NaI, the onset photopotential, V_{on}, shifted to a much more negative potential, − 0.26V *vs.* SCE (curve d). The addition of iodine (0.10M) to the solution shifted V_{on} to slightly more negative potentials (~ −0.30V *vs.* SCE) (curve e). Note that the specific effects of iodide and triiodide on V_{on} parallel their effects on the V_{FB} determined from impedance measurements. The current-potential curves on Pt (curve f) and n-$MoSe_2$ in an I^-/I_3^- solution yield an "underpotential" for I^- photo-oxidation at n-$MoSe_2$ $V_{on} - V_{redox}$, of − 0.59V. This value agrees fairly well with the experimental open-circuit voltage, V_{oc}, of an n-$MoSe_2$/I_2, I^-/Pt PEC cell described below.

The voltammetric data and photopotentials of other redox couples on n-$MoSe_2$ electrodes are summarized in Table II. For redox couples with standard potentials, V^o, much more negative than V_{FB}, no photoeffect was observed. The V_{on} for the redox couples with $V_{FB} \lesssim V^o \lesssim 0.29$V *vs.* SCE (except for I^-/I_3^-) are nearly independent of the redox couples and are close to V_{FB} (~ 0.0V *vs.* SCE). For redox couples with 0.50V < V^o < 1.0V *vs.* SCE, V_{on} depended on the particular species and varied from ~ 0.25V for Br^- to ~ 0.50V for background oxidation. The photo-oxidation of compounds with V^o more positive than for water oxidation is uncertain because of the background photoreaction. It is interesting to compare the reduction of various oxidants on n-$MoSe_2$ electrodes in the dark. As shown in Fig. 7, reduction of bromine (curve a) and Fe^{3+} (curve b) occurs at potentials negative of 0.5V *vs.* SCE

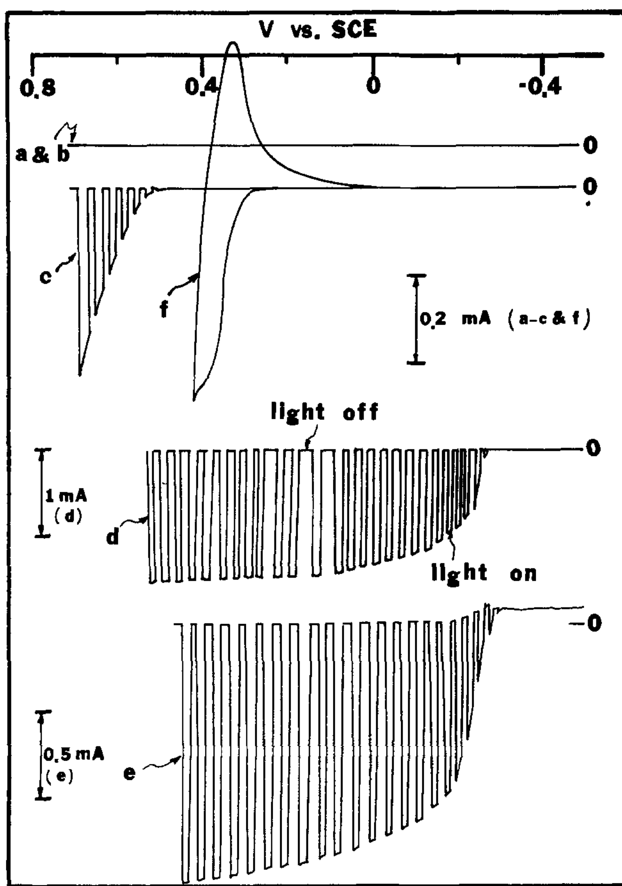

Fig. 6. Voltammetric curves of n-$MoSe_2$ and Pt in 0.5M Na_2SO_4 and 0.5M H_2SO_4. Scan rate, 10 mV/sec. Light source, 450W Xe lamp with a 590 nm cut-on filter. (a) Dark cyclic voltammogram on n-$MoSe_2$. (b) Dark cyclic voltammogram on n-$MoSe_2$. Solution contained 1.0M NaI. (c) Voltammetric curve under illumination by chopped red light on n-$MoSe_2$. No iodide or iodine in solution. (d) Current-potential curve under illumination by chopped red light on n-$MoSe_2$. Solution contained 1.0M NaI. (e) Same conditions as in (d) but solution contained 1.0M NaI and 0.10M iodine. (f) Cyclic voltammogram on Pt. Solution contained 0.10M NaI. Initial potential at −0.10V *vs.* SCE.

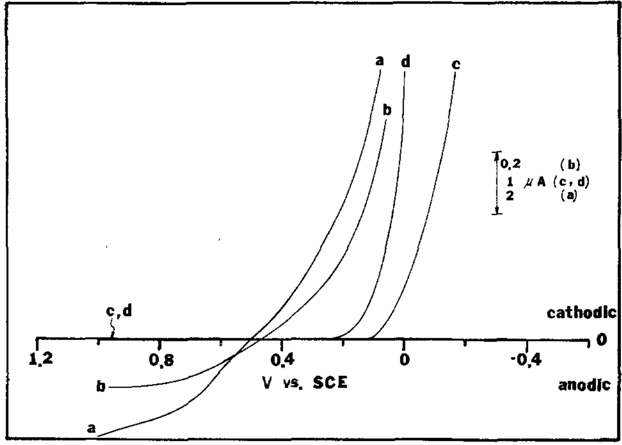

Fig. 7. Voltammetric curves in the dark on n-$MoSe_2$ electrode in 0.50M Na_2SO_4. Scan rate, 10 mV/sec. (a) Solution contained 1.0M NaBr and 0.02M bromine. (b) Solution contained 0.10M Fe^{2+}, 0.02M Fe^{3+}, and 0.50M H_2SO_4. (c) Solution contained 1.0M NaI and 0.10M iodine. (d) Solution contained 0.1M $Fe(CN)_6^{4-}$ and 0.1M $Fe(CN)_6^{3-}$.

(well positive of V_{FB}). However, iodine reduction occurs only at potentials well negative of 0.1V *vs.* SCE (curve c). The reduction of ferricyanide (curve d) occurs at a potential ~ 0.25V *vs.* SCE. Under irradiation these significant cathodic currents would constitute a back-reaction of a photogenerated oxidant which can affect the performance of the solar cells, as described below.

Photovoltaic cell measurements.—Regenerative semiconductor/liquid junction solar cells were fabricated by immersing the semiconductor electrode and a suitable counterelectrode in an aqueous solution containing the appropriate redox couple.

The n-$MoSe_2$/iodide, triiodide/Pt system.—Photovoltaic cells were set up with an n-$MoSe_2$ photoanode and a platinum foil cathode immersed in a solution containing 1.0M I^-, 0.025M I_3^-, and 1.0M H^+. The action spectrum of the short-circuit photocurrent, i_{ss}, is shown in Fig. 8. The bandgap of WSe_2 and $MoSe_2$ can be determined from the $(\eta h\nu)^2$ *vs.* $h\nu$ plot (for a direct transition) or the $(\eta h\nu)^{1/2}$ *vs.* $h\nu$ plot (for an indirect transition) near the bandedge region (14). η here is the quantum efficiency (proportional to i_{ss}) and $h\nu$ is the photon energy. As shown in Fig. 9, both $(\eta h\nu)^2$ *vs.* $h\nu$ and $(\eta h\nu)^{1/2}$ *vs.* $h\nu$ plots give fairly good straight lines. The nature of the fundamental optical transition is thus ambiguous as simply determined from the action spectrum. However, the determination of E_g from the capacitance measurements, as discussed later, is helpful in deciding on the value of E_g.

The *i-V* characteristics of this cell under irradiation, shown in Fig. 10, yields a fill factor of 0.53. The light intensity dependence of the open-circuit photovoltage and the short-circuit photocurrent of the cell is shown in Fig. 11. Irradiation of the n-$MoSe_2$ crystal with the full visible (longer than 590 nm and infrared filtered) output (150 mW/cm^2) from a 450W Xe lamp focused onto the photoelectrode surface yielded a constant i_{ss} ~ 50 mA/cm^2 and an open-circuit photovoltage ~0.59V. The photocurrent and photovoltage were essentially the same and the electrode surface showed no apparent change during the experimental period (~8 hr).

Table II. Voltammetric data, onset photopotential* and underpotential at n-$MoSe_2$

Redox couple	V^o (V *vs.* SCE)**	V_{on} (V *vs.* SCE)	Experimental underpotential, $\Delta V = V_{on} - V^o$ (V)	Theoretical underpotential,*** $\Delta V' = V_{FB} - V^o$ (V)

* The onset photopotential V_{on} here is defined as the potential at which 1% of the limiting or maximal photocurrent is observed.
** V^o = standard potential.
*** V_{FB} is based on that obtained from the impedance measurement. It is −0.3V *vs.* SCE for I^-/I_3^- and 0V for other redox couples.
† HV = heptyl viologen (1,1'-diheptyl-4,4'-bipyridyl).
‡ MV = methyl viologen (1,1'-dimethyl-4,4'-bipyridyl).

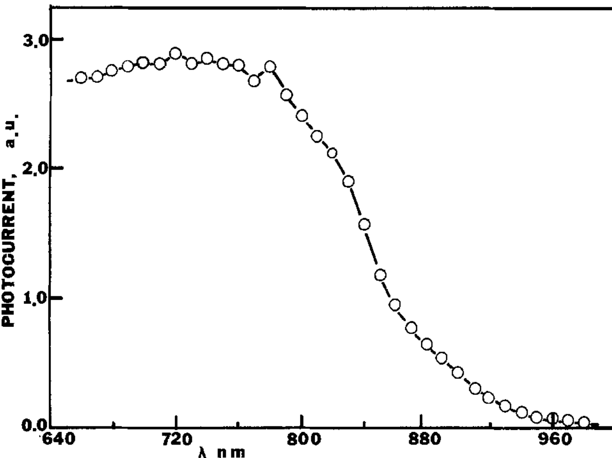

Fig. 8. Action spectrum of the short-circuit photocurrent for an n-$MoSe_2$/1.0M NaI, 0.05M I/Pt solar cell. The spectrum has been corrected for the solution absorbance.

The n-$MoSe_2$/bromide, bromine/Pt system.—When a solution containing 1.0M Br^-, 0.02M Br_2, and 1.0M H^+ was used as the electrolyte, a lower open-circuit photovoltage (0.52V), and a lower fill factor (0.25) were found (Fig. 10) (15).[5] However, the short-circuit photocurrent was higher (~60 mA/cm²) under the same intensity irradiation. This difference is probably attributable to the lower light absorbance by the Br^-, Br_2 solution. The light intensity dependence of the short-circuit photocurrent and the open-circuit photovoltage is shown in Fig. 12.

[5] Solar cells with higher fill factors but lower open-circuit voltages have been reported by Ang *et al.* (15).

Discussion

The (n-$MoSe_2$/solution) interface.—A model for the behavior of the n-WSe_2/solution interface in aqueous electrolyte has been discussed previously (4). A similar model, *i.e.*, the recombinative model, is applicable to explain the voltammetric behavior of n-$MoSe_2$ in various redox electrolytes. V_{FB} of the n-$MoSe_2$ electrode determined from the impedance measurement is ~0.0V *vs.* SCE. When no specific adsorption occurs, the expected most negative V_{on} value was obtained for redox couples with $0 \leq V^o \leq 0.5V$ *vs.* SCE. (The I^-/I_3^- couple involves adsorption effects and is discussed later.) For redox couples with V^o more positive than 0.5V, however, V_{on} occurs at more positive potentials. This can be ascribed to the effects of dark reduction of the oxidized form of redox couples. Recall that considerable dark reduction of the $Fe(CN)_6^{3-}$ takes place at a potential ~0.3V positive of V_{FB} (Fig. 7). The reduction of I_3^- occurred at more negative potentials probably because the bandedges shift with specific adsorption as suggested by the impedance measurements and the voltammetric experiments. For the couples with V^o more positive than 0.5V *vs.* SCE, *e.g.*, Fe^{2+}/Fe^{3+} and Br^-/Br_2, the reduction occurred at a potential ~0.5V *vs.* SCE. This positive shift of the zero current or onset potential might involve induced positive surface charges. The positive shift of V_{on} is attributed to the dark reduction of photogenerated species. There are several different mechanisms by which such dark reduction can occur at an n-type material at potentials significantly positive of that for V_{FB} (*i.e.*, of the energy of the conduction bandedge) in the supporting electro-

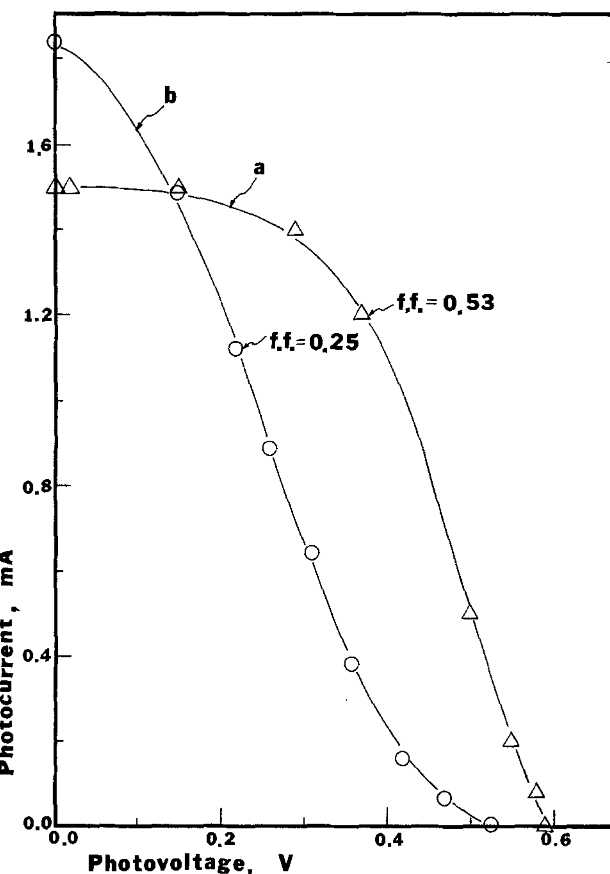

Fig. 10. Performance characteristics of n-$MoSe_2$ based PEC cells. 450W Xe lamp fitted with a 590 nm cut-on filter was used as the light source. (a) n-$MoSe_2$/0.50M Na_2SO_4, 0.50M H_2SO_4, 1.0M NaI, 0.05M I/Pt. (b) n-$MoSe_2$/0.50M Na_2SO_4, 0.50M H_2SO_4, 1.0M NaBr, 0.02M Br/Pt.

lyte solution. One involves a recombination model and the existence of filled surface states or intermediate levels at energies within the bandgap which can be emptied by electron donation to solution oxidants (or by photogenerated holes in the valence band) (16). The lack of detection of such states in the capacitance plots and the lack of significant dark anodic current implies that such states are very "slow" with respect to emptying via the conduction band. An alternative mechanism involves positive charge injection into the surface states (via solution species or photogenerated holes) causing a shift in the conduction bandedge toward more positive potentials and allowing electron transfer directly from the conduction band. This latter mechanism should result in a shift in V_{FB} in the presence of the redox couple; determination of such a shift by capacitance measurements are made difficult by the interference of faradaic reactions in determination of the actual space charge capacitance. Inversion could also cause such a shift in the bandedge (8); however, the location of the Fe^{3+}/Fe^{2+} couple is such that inversion would not occur at these potentials. A schematic representation of the energetic situation at the n-$MoSe_2$/solution interface, neglecting any band bending and specific surface interactions, is shown in Fig. 13. A direct-transition bandgap of 1.4 eV[6] is taken here based on the agreement of E_g determined from the action spectrum and the capacitance measurements for WSe_2 electrodes, discussed later.

Photovoltaic cells based on n-$MoSe_2$ electrodes.—The n-$MoSe_2$/I^-, I_3^-/Pt system shows a V_{oc} of 0.59V which is identical to the value predicted either from the experimental, ΔV, or the theoretical, $\Delta V'$, underpotential 0.59V, as shown in Table II. For the n-$MoSe_2$/Br^-, Br_2/Pt system, the V_{oc} of 0.52V was close to ΔV, 0.57V; however, it was much smaller than $\Delta V'$, 0.82V. This

[6] An indirect transition bandgap of 1.1 eV has been reported (8c). An E_g of 1.4 eV has also been reported (7).

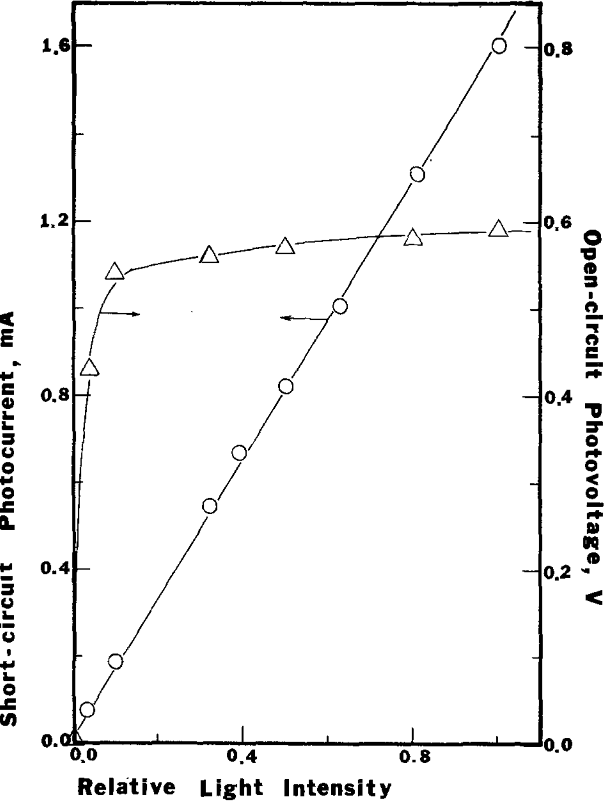

Fig. 11. Open-circuit photovoltage and short-circuit photocurrent as functions of light intensity. Same light source as in Fig. 10. Same solar cell as used in Fig. 10(a).

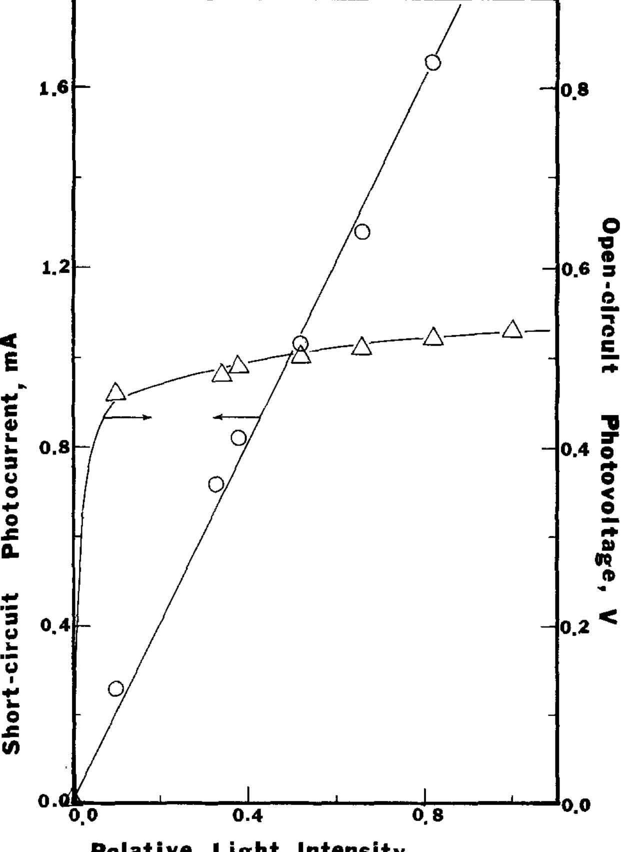

Fig. 12. Open-circuit photovoltage and short-circuit photocurrent as functions of light intensity. Same light source and solar cell as used in Fig. 10(b).

discrepancy can be attributed to the dark reduction processes or to a shift in the bandedges toward positive potentials because of induced positive surface charges. Besides this striking difference in V_{oc} between I^-/I_3^- and Br^-/Br_2 system, the fill factors for these two systems were also quite different, probably again because of the effects discussed above.

E_g of WSe_2.—As shown in Table I, E_v and E_c of WSe_2 in aqueous solution correspond to 0.93V and −0.44V *vs.* SCE, respectively. The uncertainty of E_v and E_c due to the uncertainties in the dielectric constant taken here is less than 20 meV. Thus E_g of WSe_2 is ~ (1.4 ± 0.05) eV. This agrees fairly well with the direct transition bandgap determined from the action spectrum of the photocurrent.

The Detection of Corrosion Phenomena with *pH*-Sensitive Fluorescent Dyes on Aluminum- and Gold-Metallized IC Devices

ABSTRACT

Corrosion sites on IC devices are often difficult to detect before a significant amount of metallization deterioration occurs. The identification of corrosion sites in their early stages would be a powerful tool in studies of metallized IC device reliability and of corrosion processes themselves. Recently, this laboratory has been investigating metallization corrosion phenomena on IC devices. During these studies we explored the use of pH-sensitive fluorescent dyes to decorate the IC device surface. After application of pH-sensitive fluorescent dye molecules to the surface of the IC test device, an external d-c bias was applied to the device which activated or deactivated localized fluorescence on the device. We believe this observed behavior relates to corrosion phenomena occurring on the metallization of the IC. Here we report the results of these exploratory experiments conducted on aluminum- and gold-metallized IC test devices.

Experimental Procedures

Test devices used for these studies consisted of interdigitated combs of metal. The dielectric below the metal was 6 kÅ of SiO_2. Four comb pairs were on each test chip. The passivation over each comb pair varied; pair A had continuous passivation over the entire comb, pair B had 7 μm diam openings over every metal line, with the openings spaced 50 μm; pair C had 7 μm diam openings over one comb and 7 μm wide slots over the other; pair D had the passivation completely removed from the metal combs. The passivating layer was 4.9% phosphorus by weight phosphosilicate glass. Electrical bias was applied to each comb pair through bond pads, causing each comb to act essentially like an electrode. The positive bias was applied to one comb, while the other comb of the pair received the negative bias. Figure 1 displays the layout of the two photomasks required to fabricate this test vehicle. The first-level mask is used to define the metallization. The second is used to etch intentional pinholes and vias into the passivating glass overcoat. Metallization consisted of E-beam deposited 99.999% pure aluminum. The linewidth of each tooth of the comb was nominally 12 μm. The gold-metallized test devices consisted only of adjacent positively and negatively bias lines with and without a passivation glass.

Three pH-sensitive fluorescent dyes were used for our experiments: β-methylumbelliferone, β-naphthol, and fluorescein. These dyes were applied directly to the test device surface in a 1 to 2 × 10^{-4}M solution consisting mainly of ethanol. The ethanol evaporates rapidly, leaving the fluorescent dye molecules behind. We have achieved improved results (*i.e.*, more intense fluorescence) when a small amount of a nonvolatile solvent is added to the ethanol-dye solution. Typically, a 1% glycerol solution by volume was used, with a surfactant added to insure that the solution flowed evenly over the entire device surface. Apparently, the residual glycerol promotes the proton transfer processes necessary to activate or deactivate the pH-sensitive dye molecules on the IC surface.

If the same test device was to be treated with successive dye coatings, an acetone rinse treatment proved adequate to remove the previous coating. The acetone treatment can dry the surface of the IC, and often moisture has to be restored to the IC surface before the corrosion process can again be studied. We recommend that the test device be exposed to a humid ambient (RH greater than 50%) before applying an initial or successive dye coating.

Aluminum Metallization Test Results

Several test devices with aluminum metallization were coated in humid ambients with the pH-sensitive fluorescent dyes. The application solvent was allowed to evaporate and the device was inspected with and without an external d-c bias in the presence of a long-wavelength u.v. actinic radiation source. A faint fluorescence was detected on and above the aluminum metallization of the β-methylumbelliferone treated de-

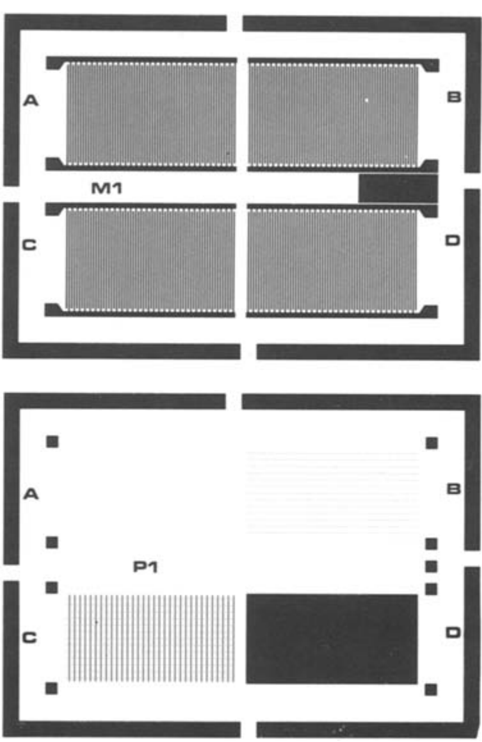

Fig. 1. Layout of photomasks for test vehicle fabrication: Top: metallization level mask; bottom: passivation level mask.

Key words: corrosion, aluminum metallization, gold metallization, fluorescence, integrated circuit.

vice without any d-c bias applied. When a d-c bias was applied to the comb pairs, an intense localized fluorescence was immediately activated at several localized sites and tended to spread out from a central point as the bias was kept on. The site of the fluorescence was not confined to metallized regions on the device, but frequently extended into dielectric regions between the metal lines. After the localized fluorescent site reached a relatively stable size, the perimeter of the localized fluorescent sites continued to fluctuate as the d-c bias remained on. When the d-c bias was turned off, the fluorescent intensity reverted very slowly to its original intensity. In addition, gas bubbles were observed to emanate from the sites exhibiting the localized fluorescence, while the bias was on and shortly after removal of the bias. Evidently, the surface tension of the liquid film on the moist substrate surface tended to trap the bubbles. A similar experiment conducted with the β-naphthol dye yielded the same results, with the localized fluorescent sites occurring in the same regions on each test device. As low as a 0.5V bias was sufficient to activate some localized fluorescence. Figures 2 and 3 display photos of β-methylumbelliferone and β-napthol decorated devices, respectively.

Fluorescein, although exhibiting a bright green fluorescence when applied to the aluminized IC test device (*i.e.*, before the ethanol solvent evaporates) did not perform well. Its fluorescent intensity is quite sensitive to the amount of solvent present and diminishes drastically with solvent evaporation. However, for a short period of time as the application solvent is evaporating, localized fluorescence can be activated by an external bias. β-methylumbelliferone and β-naphthol apparently exhibit better proton transfer properties in relatively dry environments. Their localized fluorescence can be observed in a humid ambient for long periods of time after application and evaporation of the solvent.

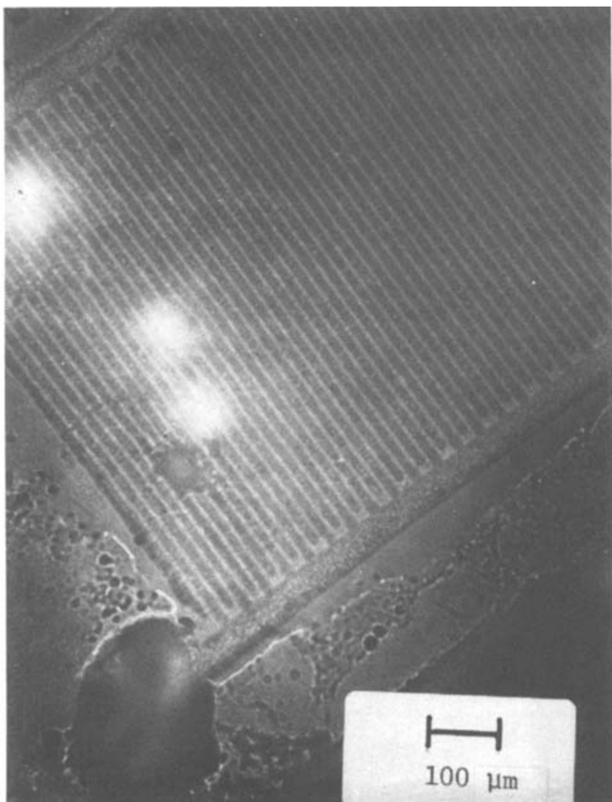

Fig. 2. β-methylumbelliferone decoration of IC: Long-wave u.v. source, 20V bias, humid ambient, room temperature. The width of metal lines in the comb is nominally 12 μm. Spacing between lines is also 12 μm.

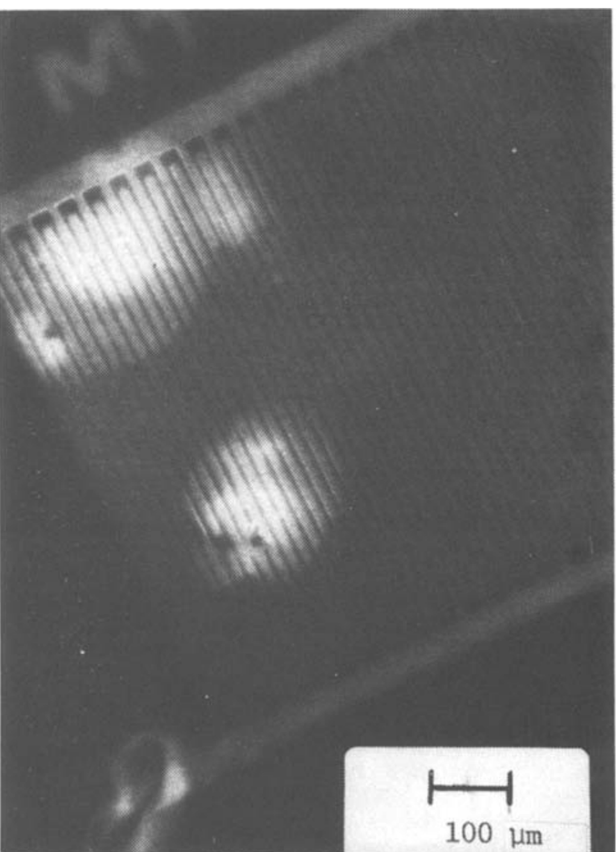

Fig. 3. β-napthol decoration of IC: Long-wave u.v. source, 20V bias, humid ambient, room temperature. The width of metal lines in the comb is nominally 12 μm. Spacing between lines is also 12 μm.

The reason for formation of the localized fluorescent sites was difficult to characterize from these preliminary studies. Not all visually obvious defects in the passivation layer over the metallization fluoresced, and localized fluorescence was observed where no apparent defect was present. Fluorescence was observed in localized regions on the comb pairs with and without the protective glass passivating layer. We did attempt to correlate the localized fluorescent sites with intentional defects in the passivating overcoat, but localized fluorescence was observed only occasionally at intentional pinholes in the passivation glass. The localized fluorescence was not strictly confined to positively or negatively biased lines. Some test devices had numerous fluorescent sites and others very few.

The production of gas bubbles at fluorescent sites strongly suggests that the pH-sensitive fluorescent dye is detecting corrosion sites of a cathodic nature. The gas bubbles are presumably hydrogen. Other investigators (1-3) have observed H_2 gas bubbles from corrosion on aluminum metal. Theoretical calculations of the corrosion reactions within pits show that the cathodic reaction site can spread outside a pit or defect under certain conditions (4, 5). The reduction of hydronium ion to hydrogen, $2H_3O^+ + 2e^- \rightarrow H_2\uparrow + 2H_2O$ or $H_2O + 2e^- \rightarrow H_2\uparrow + 2OH^-$ is the most likely cathodic reaction accompanying Al corrosion (6-8) and is also the cathodic reaction for the electrolysis of water. The production of hydrogen gas depletes the hydronium ion concentration in regions near the cathodic reaction site. Our pH-sensitive fluorescent dyes have the property of releasing a proton (H^+) with relative ease, ($HM \rightarrow H^+ + M^-$). The deprotonated species (M^-) exhibits fluorescence while the protonated species (HM) does not. The dye molecules can be expected to supply protons for the cathodic reaction, and thus become active fluorescent species in the vicinity of the cathodic reaction site. Different degrees of sol-

vation (hydration) are required to facilitate the release of the protons from certain dye molecules. Hence, some dyes will fluoresce in drier ambients than others.

Although the *p*H-sensitive fluorescent dye molecules are activated in specific *p*H ranges in an aqueous solution [*i.e.*, *p*H ~ 7.6 for β-methylumbelliferone, *p*H ~ 8.4 for β-napthol, and *p*H ~ 4.5 for fluorescein (9)], their behavior on surfaces and in presence of external d-c bias may be somewhat different. Both the dye molecules and water molecules bound to a surface can have significantly different properties than unbound molecules. The d-c bias introduces the possibility of an electrochemical potential bias into the environment which can affect the molecular equilibria. However, the localized fluorescence at a specific site does suggest that the site has a lower hydronium ion concentration than that of its surroundings.

We believe that the cathodic electrolysis sites decorated by the *p*H-sensitive dye identifies aluminum corrosion sites for two related reasons. The region where the cathodic electrolysis reaction occurs shows an increased *p*H, according to our *p*H-sensitive fluorescent dyes. Aluminum-water corrosion reactions are known to be thermodynamically favorable at high *p*H (10, 11). The electrolysis site identifies or may produce a high *p*H region where the aluminum corrosion can occur. Also, the reduction of hydronium ion is thought to be a complementary reaction to the oxidation of Al metal. The humid ambient (*i.e.*, water bound to the IC surface) and the electrical bias may accelerate and propagate small corrosion sites already present.

Gold Metallization Test Results

Decorating gold-metallized devices with *p*H-sensitive dyes produced substantially different results. For these experiments, the *p*H-sensitive fluorescent dye was deactivated rather than activated. This was observed by coating the device with a fluorescein-ethanol solution and then turning on the u.v. actinic radiation before the solvent had completely dried. Under these conditions, the entire surface of the device fluoresced under u.v. actinic radiation, with no applied bias. When the bias was turned on, fluorescence was quenched locally on exposed metal lines for only the positively biased lines. Reversing the polarity of the bias changed the lines that exhibited a quenched fluorescence at exposed metal, accordingly. A 12V d-c bias was sufficient to quench the fluorescent dye coating on exposed metal at the anodic lines.

The observations are consistent with our corrosion testing of gold-metallized IC's (12). Corrosion was observed only at the anodically biased lines. Recently, Frankenthal and Becker (13) have reported gold corrosion products on anodic portions of IC devices. Previous corrosion studies of gold metal have reported similar results (14). The quenching of fluorescence is the expected result after analyzing the anodic corrosion reaction. Gold hydroxides are formed on the anodically biased metal and these hydroxides generally remain bound to the metal surface. The hydronium ion, (H_3O^+) produced during this reaction is left unneutralized in the water film; generally, $Au + 3H_2O \rightarrow Au(OH)_3\downarrow + 3H^+ + 3e^-$. A substantial *p*H drop is expected, provided that the gold hydroxide corrosion products remain relatively insoluble. The *p*H drop induces a quenching of the *p*H-sensitive fluorescent dye molecules at the anodic corrosion site on the gold metallization.

No localized fluorescence was activated during these experiments, contrary to what was observed for the Al-metallized test device. Although electrolysis of water is certainly possible at these voltages, none was observed on the Au metallization with the *p*H-sensitive indicators. This observation suggests that the cathodic reaction (*i.e.*, the reduction of hydronium ion) detected on Al metallization is more related to an Al-induced corrosion reaction rather than the electrolysis of water, per se. Electrochemical bias studies (12) of test electrodes in aqueous solution showed that aluminum metallization produced mainly cathodic reactions and gold metallization only anodic reactions.

Conclusions

We have demonstrated that decorating procedures employing *p*H-sensitive fluorescent dyes can provide valuable information relating to IC device reliability and corrosion phenomenon in general. The *p*H-sensitive fluorescent dye decoration behaves differently depending on the metallization of the IC. Our results on aluminum metallization suggest that the technique can be used to identify corrosion sites on IC devices before much metal deterioration has occurred. The technique may facilitate identification of specific defects that produce corrosion sites. The propagation of corrosion reactions may be monitored during or after stress-bias reliability testing. The technique may also offer a procedure for evaluating device design, materials, and processing variables that contribute to corrosion/reliability problems. For example, our test device showed that adjacent negatively and positively biased lines spaced nominally 12 μm apart on an SiO_2 dielectric may frequently produce a cathodic electrolysis site in a humid ambient.

The decoration of gold metallization with *p*H-sensitive dyes appears to have different reliability testing applications. Under a sufficiently large bias voltage, all exposed portions of the gold under anodic bias deactivated the *p*H-sensitive fluorescent dye. This observation suggests that the technique may offer an inspection procedure for detecting pinholes through a passivation glass over a gold-metallized surface.

These studies have supplied information about the corrosion phenomenon themselves, most notably *p*H differences in the vicinity of a corrosion site. On aluminum metallization, the *p*H-sensitive fluorescent dyes show an increased effective *p*H in the vicinity of cathodic electrolysis sites, while on gold metallization the effective *p*H in the water film above anodic corrosion sites was significantly decreased. In both cases, the *p*H-sensitive fluorescent dye detects *p*H differences caused by H_3O^+ or OH^- being effectively removed from the moist surface by a corrosion reaction. Also, the *p*H-sensitive fluorescent dye continues to be activated or deactivated after the external bias is turned off. The slow return of the fluorescent dye to its pre-bias condition reflects proton transfer processes occurring on the surface of the IC. These processes are related to diffusion rates of H_3O^+ and OH^- on the moist IC surface and the inertia of the corrosion reaction after the bias is turned off. Characterization of these processes may be possible with the fluorescent dye decoration technique.

These experiments were largely of an exploratory nature to demonstrate the potential application of this technique. More detailed studies using this technique could provide additional information relating to IC device corrosion processes and reliability.

Hysteresis in Formation and Reduction of Submonolayer Quantities of Surface Oxide at Pt in an Almost Anhydrous Solvent

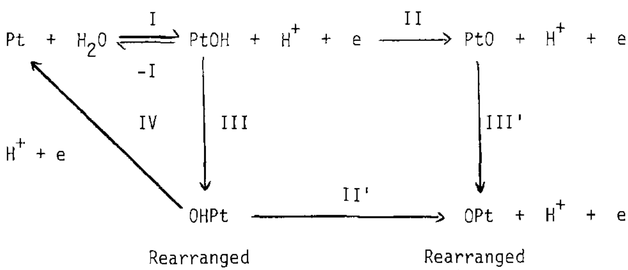
B. E. Conway* and D. M. Novak*,[1]

Chemistry Department, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT

Surface oxidation of Pt at small coverages by O-species has been investigated in trifluoroacetic acid as solvent containing traces of water from which Pt surface oxide species are generated. It is shown that even at quite low, submonolayer coverages, there is a large extent of hysteresis between the potential range for surface oxide formation and that for reduction, comparable with that found in water as solvent only when strong anodic oxidation has taken place. Also the relations between reduction peak potentials in a cyclic-voltammetry experiment and the surface oxide reduction charges are similar to those for extensively formed films in water, rather than to those for submonolayers. The behavior observed is attributed mainly to strong anion (CF_3COO^-) adsorption in the TFA solvent but the possibility of the surface oxide existing in 2-d phase-oxide islands, stabilized by lateral attractive interactions, is also considered.

In previous potentiodynamic work (1-4), we have investigated the origin of hysteresis effects in the surface oxidation of noble metals (5) and interpreted them in terms of a place-exchange process (6, 7) which takes place as an irreversible postelectrochemical step with respect to an initial anodic electrodeposition reaction, according to a reaction and reconstruction sequence of the following schematic kind



Step I, in the anodic direction, is a fast process (3) and its reverse, —I, is also rapid but can only be observed at high sweep rates and low temperatures (3) owing to the alternative rearrangement step III. Under such conditions, a cathodic current component in cyclic voltammetry due to reaction (—I) can be resolved (3) from the cathodic pathway III, IV involving a rearranged state of OH on Pt, written as "OHPt," especially at low coverages by chemisorbed OH deposited in I. Steps II, II', and III' represent pathways for formation of a more highly oxidized state of the Pt surface, to "PtO" or "OPt."

In the present communication, we describe some interesting observations on the surface oxidation of Pt itself in anhydrous and almost anhydrous trifluoroacetic acid (TFA) where the degree of surface oxidation normally attained at a given potential (for a given sweep rate) is limited and can be controlled by the water content of the TFA solvent as well as by potential. The point of special interest in this paper is the observation of a quite large degree of hysteresis between the processes of formation and reduction of Pt surface oxide but at extents of coverage far less than a monolayer where, in ordinary aqueous solutions, the behavior would be almost reversible or exhibit only small hysteresis (3).

In other work (8, 9), we have investigated the behavior of Pt in electrooxidation reactions of formic acid (8) and H_2 (9) also in almost anhydrous media with the idea of diminishing the inhibition of these reactions which sets in at potentials where surface

oxidation of the metal commences on account of the presence of water as solvent.

Experimental

General experimental procedure.—Potentiodynamic experiments were carried out using the programmable system previously described (2, 3) in which linear potential sweeps could be applied to the electrode at various sweep-rates, s, and after various times of holding the potential constant at certain desired values (2). Electrodes and cells used were as described previously (2, 3). An $(\alpha + \beta)$ PdH electrode was used as a reference electrode in all the work and behaved satisfactorily in the anhydrous TFA solutions. It was checked periodically against a platinized Pt hydrogen electrode in the same solution but in an external compartment. All potentials are referred to the H_2/H^+ potential and denoted by E_H.

Choice of solvent.—Trifluoroacetic acid (TFA) was used as solvent in this work because (*i*) it can be made initially almost anhydrous and may be well purified by normal solvent purification and drying procedures; also it can be made very anhydrous (9, 10) by "gettering" any remaining traces of water by addition of a trace of trifluoroacetic anhydride through the reaction $CF_3CO{\cdot}O{\cdot}COCF_3 + H_2O(\text{traces} \rightarrow 2\ CF_2COOH)$; (*ii*) it can be made "electrochemically" pure, *i.e.*, no spurious oxidation or reduction currents arise from reaction of any impurities over a wide potential range at Pt; and (*iii*) it is a good ionizing solvent for a number of salts including potassium trifluoroacetate (KTFA). Also (*iv*) it is itself, with KTFA as electrolyte, not oxidizable until about +2.2V E_H when it undergoes the Kolbe reaction (10). Thus, there exists a large anodic[2] potential range over which the solvent is electrochemically inactive. Also, since TFA does not have actively available the "elements of oxygen," there is no possibility of oxidation of the Pt electrode surface by species discharged from the solvent itself over a wide potential range until the carboxylate function is discharged (10). Hence, effects of controlled trace additions of water which lead to limited surface oxidation of the Pt and to underpotential deposition of H (see below) can conveniently be examined.

Chemicals and purification procedures.—All chemicals used were analytical reagent grade. Further purification procedures were performed as described below:

(a) TFA (Eastman Kodak Company) was first gently refluxed over $KMnO_4$ (Fisher Company, Limited) for at least 24 hr. The mixture was then slowly distilled, three successive distillations being performed. Prior to the third distillation, 0.05% of trifluoroacetic anhydride was added to eliminate any residual traces of water in the acid to be used immediately after the distillation in the initial experimental runs in completely anhydrous TFA (Fig. 1).

(b) Trifluoroacetic anhydride (Eastman Kodak Company) was used to diminish water content in the TFA, as mentioned above. It was purified first by distillation from $KMnO_4$ followed by another slow distillation at 312.5 K prior to use in a run.

(c) KTFA, the K^+ salt of TFA, used as electrolyte, was prepared by neutralization of previously purified TFA with 5M potassium carbonate (Fisher ACS analytical grade). The mixture was heated gently until saturation was achieved. The solution was then left to crystallize slowly. The crystals were washed with the mother liquor followed by some of the purified TFA and dried under vacuum at 373 K.

(d) Water used for controlled additions of water in the runs was obtained by the pyrocatalytic distillation procedure previously described (12).

[2] There is evidence (11) that, in aq. media, cathodic reduction of TFA can occur. However, in the present work, the effects studied were mostly at potentials well positive to those where reduction of the molecule could occur.

(e) H_2 and N_2 gases used for bubbling in the cell were purified and dried as described previously (1-3).

Solutions and solution purity.—The solutions used consisted of 0.5M KTFA dissolved in the pure 100% TFA liquid. The dryness or wetness of each solution was controlled with additions of trifluoroacetic anhydride or of the pyrodistilled water, respectively, as required.

Aqueous solutions of $HClO_4$ and H_2SO_4 were made up from pyrodistilled water, prepared as previously described (12), using the Aristar (B.D.H.) high purity acids. The $HClO_4$ contained no detectable Cl^- ions.

The criteria for solution purity, formulated previously (12), were applied to the experiments in the aqueous media. For the TFA solutions, purity was judged acceptable when a potentiodynamic *i-V* profile such as that in Fig. 1a, showing virtually no diffusion-controlled residual oxidation or reduction currents, was observed. The cathodic and anodic current profiles at the least positive potentials in the sweep are associated with underpotential deposition of H in a reversible reaction $CF_3COOH + Pt + e \rightleftharpoons CF_3COO^- + PtH_{ads}$, as in aqueous solutions, as indicated by (a) linear dependence of peak currents on s and (b) independence of peak currents on stirring.

Water additions.—After establishing an *i vs. V* profile for the completely anhydrous TFA solution, such as shown in Fig. 1a, the effects of addition of controlled traces of pyrodistilled water were investigated.

Integration of potentiodynamic i-V profiles.—Charges for surface oxide reduction or formation, and for H deposition and ionization, were evaluated by weighing the cut-out *i-V* profiles recorded on good quality graph paper of uniform thickness and previously calibrated weight per unit area. Charges thus evaluated were accurate to *ca.* 1%, *i.e.*, much better than can be achieved using a planimeter for measuring small areas. The double-layer charge contributions were subtracted using the base lines of *i-V* profiles such as those in Fig. 1a.

Results

Aims of the experiments.—The aims of the experiments were to evaluate the surface oxidation behavior of Pt which arises when small coverages of surface oxide [the general term is used here since a variety of 2-dimensional lattice states can be formed, leading to "PtOH," "PtO," and corresponding place-exchanged species "OHPt," "OPt" (4)—(see Scheme I)] are generated from traces of water in an excess of the initially anhydrous solvent. The *i vs. V* profiles for Pt in TFA + KTFA solutions, with and without traces of water present, will be described first.

The current vs. potential profiles for Pt in anhydrous TFA and with added traces of water.—Behavior in ultradry and slightly aqueous solutions.—We show first the potentiodynamic *i vs. V* profiles at Pt for the most anhydrous TFA solutions (Fig. 1a) and then comparatively (Fig. 1b, 1c) those for the same solutions with controlled additions of water. Effects of holding the potential at the positive limit V_a of the anodic sweep for various times are also shown.

If the initial preparation of distilled TFA contains, as it usually does, a residual trace of water, this is indicated by small but significant oxide film formation currents at potentials more positive than *ca.* 1.05V E_H and a small oxide reduction current peak in the cathodic sweep. An ultradry solution can then be obtained by adding controlled traces of trifluoroacetic anhydride until the *i vs. V* profile takes the form of Fig. 1a with zero surface oxidation current and no oxide reduction peak in the cathodic sweep. Confirmation of ultradryness of the initial solutions is given by holding the potential at the positive end of the sweep for 1-5 min and demonstrating (Fig. 1a, curves 2, 3) no development ($<1\%$ coverage) of any signifi-

cant Pt surface oxide reduction peak in a following cathodic sweep.

Surface oxidation behavior.—Three families of potentiodynamic i vs. V profiles for a Pt electrode over the potential range 0.0V to +1.86V E_H electrode in the same solution, are recorded in Fig. 1. Figure 1a shows the behavior in the most anhydrous TFA solution, gettered by addition of a trace of trifluoroacetic anhydride. No surface oxidation currents are detectable but underpotential deposition of H in two distinguishable states is observed (region A). Addition of traces of water (Fig. 1b, 1c) causes development of surface oxide in the anodic sweeps, commencing detectably at 1.05V E_H, and a current profile for its reduction is observed around 0.7-0.6V in the following cathodic sweep.

In order to follow the transition towards aqueous solution behavior and to provide comparisons with surface oxide formation and reduction behavior in largely aqueous solutions, experiments were performed in TFA containing 0.2, 0.5, 0.98, 2.6, and 4.1 mole percent (m/o) H_2O, in water 0.1 and 1.0M in TFA and in water 0.1, 1.0, and 6.0M in $HClO_4$.

In the absence of significant quantities of water, it is seen from the profiles of Fig. 1a that it is possible to reach quite high positive potentials and thus relatively high interphasial fields without establishing currents either for surface oxidation (as would occur in regular aqueous solutions) or for dissolution of Pt. When traces of water are present, holding the potential for various times (curves 1, 2, 3, 4 in Fig. 1b, 1c) causes an increase in the extent of surface oxidation as occurs (1, 2) under aqueous solution conditions but to much larger extents.

It is found, somewhat surprisingly, that the extent of surface oxidation attained on holding or during a sweep is almost independent of solution stirring (Fig. 1c). This is presumably because the oxide growth process is sufficiently slow and the quantity of H_2O molecules required to produce the submonolayer oxide film is sufficiently small, *ca.* 4×10^{-10} mole cm^{-2}, in a fairly dry solution, that the process of oxide film growth is not diffusion-controlled with respect to H_2O.

The points of interest to be discussed later are (*i*) the relation between the charge Q for reduction of the surface oxide formed up to various potentials, V_a, at the positive end of a previous anodic sweep as shown in Fig. 2; (*ii*) the relation between the peak potential, V_p, of the cathodic i *vs.* V profile for surface oxide reduction, and the oxide reduction charge, Q, as shown in Fig. 3; (*iii*) the hysteresis that arises typically in Fig. 1b, 1c for quite small degrees of surface oxidation, down to a relative surface coverage $\theta_{OH} = 0.023$ (*i.e.*, $Q \simeq 5$ μC cm^{-2}); and (*iv*) the difference of behavior of surface oxide reduction at Pt in aq. and TFA solutions shown in Fig. 2 and 3.

It is to be noted that the potential scales in Fig. 2 and 3 for the results obtained in aqueous and in the TFA solutions are, of course, different on account of the different solvents. However, the potential span between the reversible H_2-potential in TFA and the onset of surface oxidation of Pt from small concentrations of water in TFA is only a little longer than that from water itself containing small quantities of $HClO_4$ or H_2SO_4. Also, for a given solution, it is the relation between Q and V_p or V_a that is of interest.

H adsorption in anhydrous and almost anhydrous TFA.—Before proceeding to the discussion of the surface oxidation behavior, it is interesting to note that even in the driest solution, current peaks for adsorbed H atom deposition and ionization are observed (Fig. 1a) indicating that underpotential deposition of chemisorbed H in at least two states [there are 4 or 5 observable in water (13)] on the Pt surface is possible in a solvent other than water. Comparative experiments in 0.1M aq. $HClO_4$ on the same electrodes (see below) showed that the H-accommodation at Pt in anhydrous TFA up to the H_2-reversible potential is about 40% of that in water. This is probably due to displacement of the H deposition region to more negative potentials due to anion adsorption. Similar effects are seen in aq. KTFA + TFA solutions where CF_3COO^- modifies H adsorption.

Absence of impurity effects in TFA was demonstrated by showing that the H charge attains a well-defined value (Fig. 1c) of 109 ± 10 μC cm^{-2}, independent of the extents of surface oxide generated from traces of water (Fig. 1b, 1c) by the "holding" experiments, at 2.090V *vs.* PdH. In 0.1M aq. $HClO_4$, the same electrode gave 270 μC cm^{-2} for the H charge. This charge was used as a standard of reference for comparative evaluation of extents of surface oxidation of the same Pt electrode in the TFA solutions.

Discussion

The extent of surface oxidation as a function of potential.—Several overlapping states of surface oxidation of Pt can be resolved (3, 17) in an anodic sweep up to *ca.* 1.1V E_H; however, the total charge, Q, for surface oxidation is an approximately linear function of V_a, as found, *e.g.*, in aqueous 0.1M $HClO_4$ or H_2SO_4, except at quite low coverages, $Q < 30$ μC cm^{-2}.

In TFA solutions containing traces of water, the Q *vs.* V_a relations have much lower slopes (Fig. 2) than for the aqueous acid solutions, indicating that surface oxidation is more difficult in such almost nonaqueous solutions than in water. The slopes give the average electrochemical capacitance, dQ/dV_a, of the film over various potential ranges for its formation. dQ/dV_a values for aqueous 0.1M $HClO_4$ and H_2SO_4 are almost the same (426 ± 10 μF cm^{-2}). However, for the TFA solutions containing traces of water, $dQ/dV_a = 91$ μF cm^{-2}, *i.e.*, some 4.7 times smaller. This latter result is not due to restriction of the quantity of oxide that can be grown by diffusion of water, as was shown by the stirring experiments referred to earlier.

The low slope, dQ/dV_a, for surface oxide formation in the TFA solutions may be due (*i*) to difficulty in displacing strongly adsorbed TFA solvent molecules and CF_3COO^- ions and/or (*ii*) absence of stabilization of the OH/O layer which can arise in the water solvent through H-bond bridging through H_2O molecules at the oxide film/solution interface.

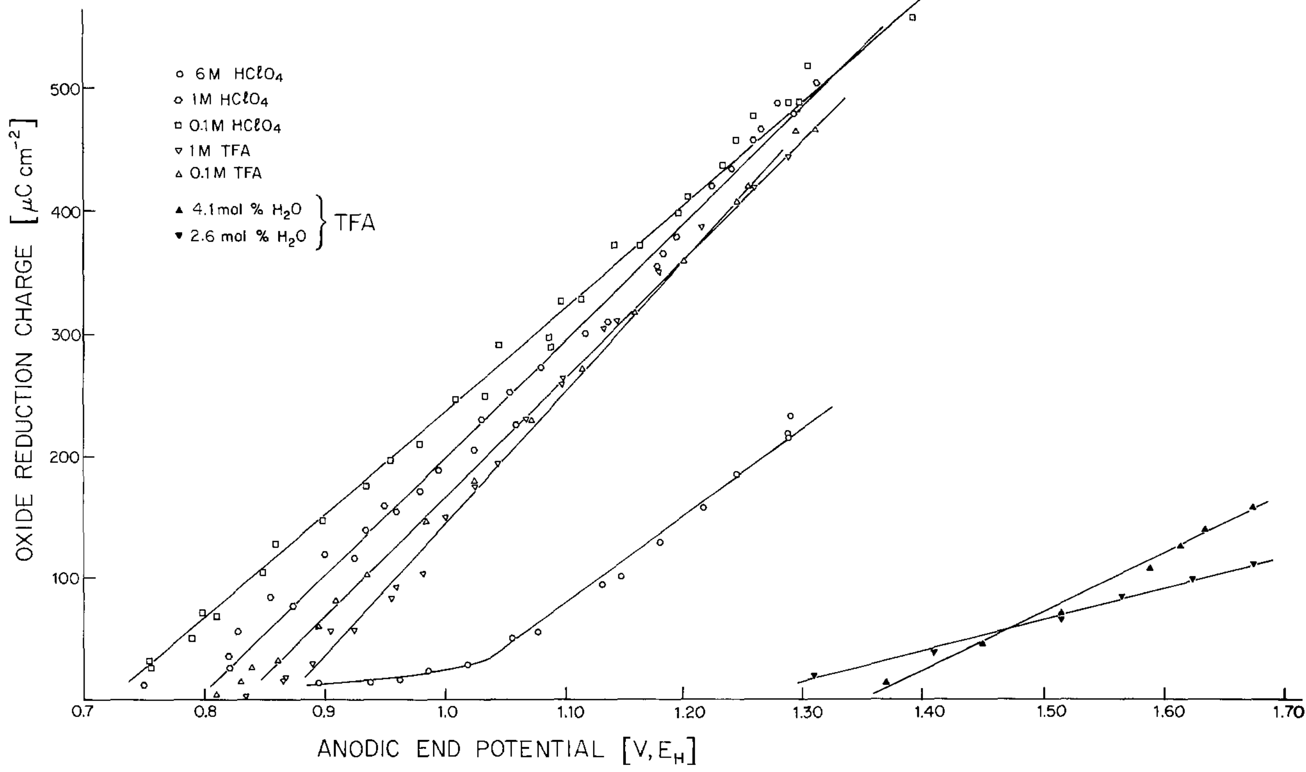

Fig. 2. Comparison of oxide reduction charges, Q, as a function of anodic end potential, V_a, in repetitive sweeps at 8.2×10^{-2} V sec^{-1} for small quantities of water in TFA, for aq. TFA and for aq. $HClO_4$ solutions.

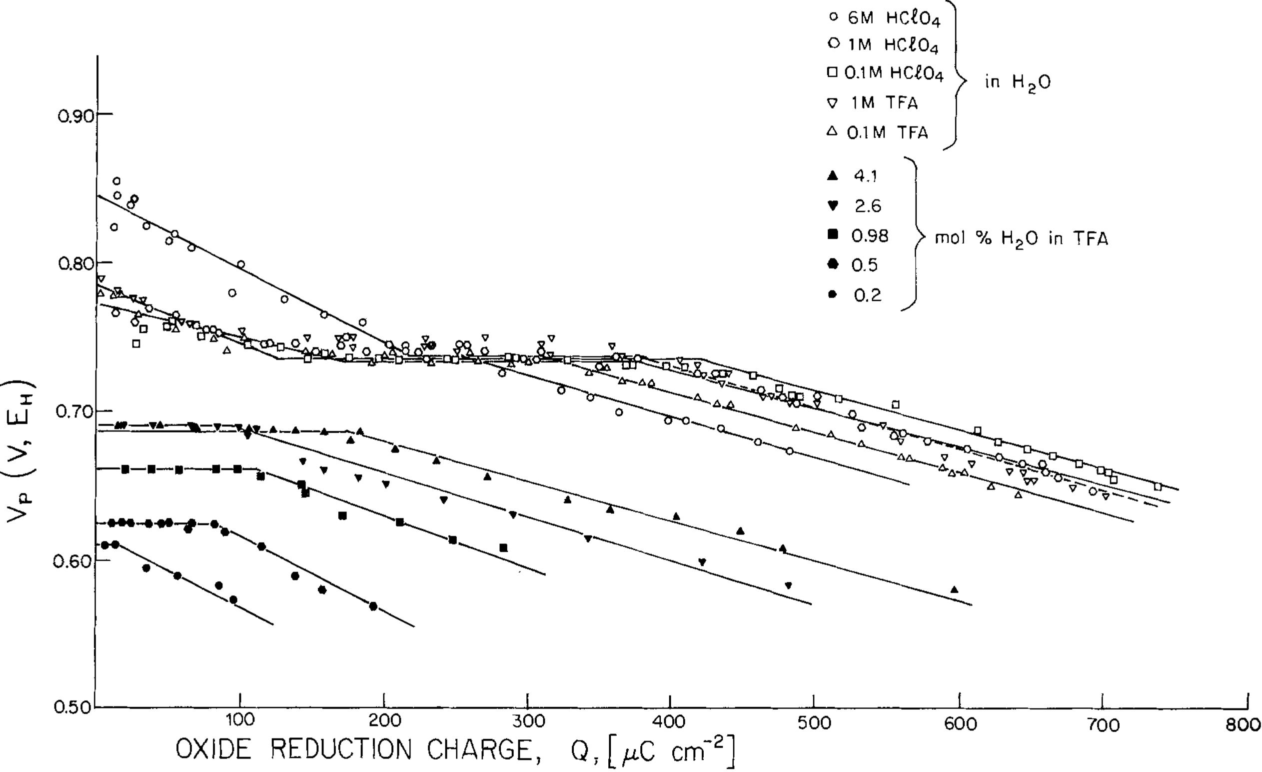

Fig. 3. Oxide film reduction peak potential, V_p, as a function of oxide reduction charge Q for various concentrations of water in TFA, for aq. TFA and for aq. $HClO_4$. [The increasing Q values are achieved by holding the potential at various V_a values for controlled periods of time [cf. Ref. (2, 3)]. V_p values are referred, in each solution, to the potential of the H_2/H^+ electrode in that solution.

Hysteresis and irreversibility in surface oxide formation and reduction.—As we have shown previously (2, 3), the state of the oxide film formed up to a given V_a [and for a controlled time (1,2)] is conveniently characterized electrochemically by the peak potential, V_p, of the *i vs. V* reduction profile in a cathodic potentiodynamic sweep following an anodic sweep to some potential V_a. Usually, with increasing extent of surface oxidation (V_a and/or time increasing), V_p becomes less positive and the peak narrower (2, 3). Thus, in dilute aqueous acid solutions, it is well known (2, 3, 14) that V_p becomes less positive with increasing extent of surface oxidation, measured by *Q*, but there is an inflection in this relation with a section in which V_p is independent of *Q* (3). This corresponds approximately to a situation where the full OH monolayer at Pt (completed at *ca.* 1.1V) is converted to O species by reaction II (or II′ from "OHPt") without change of geometrical coverage. Plots of V_p *vs.* Q are shown in Fig. 3 for water in TFA and for several aqueous solutions of $HClO_4$ (lines with points marked □, ○, △, and ▽). In sufficiently strong (6M) aqueous $HClO_4$, the region where V_p is independent of *Q* is much smaller than in dilute aq. acid solution (3) and an almost continuous linear relation (points marked ○) is seen between V_p and *Q*.

In the plot of V_p for the reduction profile *vs. Q* (Fig. 3), these submonolayer quantities of oxide give only continuously decreasing (less positive) values of V_p with increasing *Q* or, at higher water contents (0.5-4.1 m/o H_2O), an initially flat region (V_p independent of Q) followed by a region where V_p decreases linearly with *Q*. These regions look like the right-hand side parts of the V_p *vs. Q* relations for the dilute aqueous solutions [*cf.* Ref. (3)], also shown in Fig. 3 (results for aq. TFA and $HClO_4$), where much larger *Q* values are involved.

Since V_p becomes, in general, less positive with increasing V_a and *Q*, it is evident that the processes of formation and reduction of the surface oxide become progressively more irreversible with respect to one another, giving rise to the observed hysteresis (1, 2) between these processes. It is convenient to define this hysteresis arbitrarily as the difference, ΔV, in volts between the potential for detectable onset of surface oxidation in the anodic sweep and the potential, V_p, at the maximum current in the reduction curve.

The striking feature of the *i vs. V* profiles for small extents of surface oxidation of Pt attained in TFA with traces of water present, is that the hysteresis, ΔV, is much larger than is found for corresponding small *Q* values in ordinary aqueous media. This is illustrated in Fig. 4 where ΔV is plotted against *Q* in the series of points for ~0-4.1 m/o H_2O in initially anhydrous TFA.

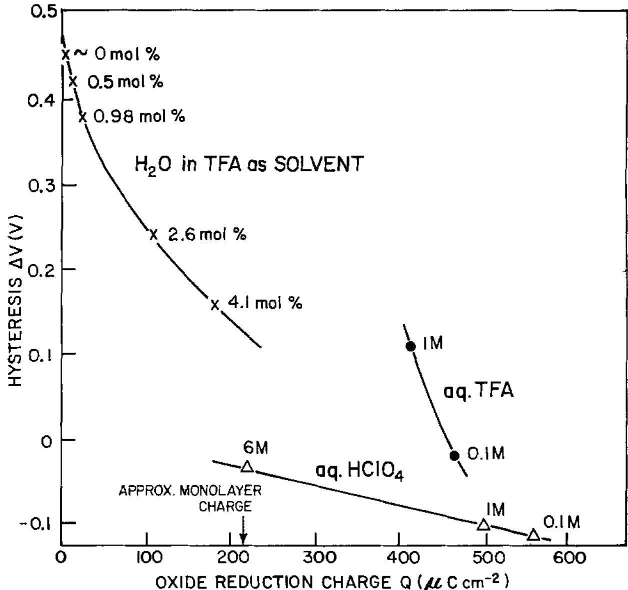

Fig. 4. Hysteresis (ΔV volts) between potential for onset of surface oxidation of Pt and reduction peak potential as a function of oxide reduction charge, Q, for various solutions. End potentials, V_a, in anodic sweeps: for TFA soutions, 1.66V; for aq. solutions of TFA and $HClO_4$, +1.35V.

This figure also shows how ΔV depends on Q for aqueous TFA (0.1 and 1.0M) and for aqueous $HClO_4$ (0.1-6M). Comparison between the ΔV values for the oxide films formed in the various solutions indicated in Fig. 4 shows that there is a large difference between the behavior of the oxide films formed from traces of water in excess TFA and that for films formed in excess water in dilute acid solutions. The small submonolayer quantities of oxide, produced under the former conditions, behave [*cf.* Ref. (1, 2)] like full oxide films, with $Q > 400\ \mu C\ cm^{-2}$, formed at high V_a values in aqueous solutions.

The fact that the submonolayer films produced in TFA with traces of water are reduced at less and less positive potentials as more surface oxide is generated (Fig. 3, lines for H_2O in TFA), indicates that there is the usual [*cf.* Ref. (1-3)] progressive stabilization of the oxide film (probably in a rearranged "OPt" state) with increasing coverage, even at low apparent geometrical coverages of the electrode surface. Such films, at low coverages, seem already to be in the so-called "phase-oxide" state (6, 15).

This is quite unlike the situation for irreversible reduction of a randomly deposited film where the reduction peak potential, we have shown (16), should be independent of the quantity of material (below a monolayer) initially existing if interaction effects are absent. However, if attractive interactions are significant, then the reduction peak potential does become less positive with increasing initial coverage, depending on the magnitude of the g factor (4) characterizing these interactions.

The results of the present work show that experiments in TFA containing traces of water allow low coverages of surface oxide to be formed (Fig. 1 and 2) up to substantially higher V_a values than are normally possible in aqueous solutions where the water activity is invariant, *i.e.*, where a given coverage is determined only by V_a and time spent at V_a in that case [*cf.* Ref. (2)]. Two electrostatic factors can then tend to enhance the extent and velocity of place-exchange: (*i*) the metal/solution field will be greater for the conditions (high V_a) of surface oxide formation in TFA than for those for surface oxidation in water; such conditions will promote more rapid and extensive field-dependent place-exchange; (*ii*) the local dielectric constant in the inner region of the double-layer would be smaller in TFA than in water, giving higher surface fields for a given surface charge density on the electrode.

The use of a range of solvents with widely different ϵ would be required to test the role of factor (*ii*). However, practically, this is difficult as there are few, if any, other nonaqueous solvents that can survive strong anodic polarization at Pt without suffering oxidation; also, the varying solvating power of such solvents for anions of the electrolyte would cause a simultaneous variation of the strength of competitive anion adsorption (see "Anion adsorption effects" below).

Both the factors (*i*) and (*ii*) above tend to induce a relatively more facile place-exchange since the place-exchange process is field assisted (the PtOH or PtO surface dipole is presumably of opposite direction to that of place-exchanged OHPt or OPt, so that anodic fields assist the process).

Commentary on the state of the oxide films.—The behavior described above must be examined in the light of previous ideas (2-6) on surface oxidation of Pt involving place-exchange and the role of anion adsorption (17, 18). The results presented above indicate that the characteristics of the submonolayer quantities of surface oxide formed from traces of water in excess TFA [as determined by the V_p *vs.* Q behavior (Fig. 3) and the ΔV values] are surprisingly similar to those of oxide films formed to much greater coverages, at high V_a values, in excess water.

The unusual behavior of the submonolayer oxide films formed in TFA from traces of water can be considered in terms of two possible effects: (*i*) the adsorption of the CF_3COO^- anion (*cf.* Fig. 5) may promote irreversibility in the formation of the oxide film in TFA solutions by assisting (18) the place-exchange and leading to deposition of the film in a rearranged state without observable prior development of the reversibility electrosorbed OH layer at significant coverage [*ca.* 15% in dilute aqueous $HClO_4$ (3) or 30% in dilute KOH (17)]; and (*ii*) the submonolayer oxide films are deposited as islands within which a large degree of place-exchange and conversion of electrodeposited OH species to O species has taken place, giving rise to the observed irreversibility and hysteresis shown in Fig. 4. This would be facilitated by the relatively large anodic potentials V_a which can be reached in the anhydrous TFA (Fig. 1).

Anion adsorption effects.—In connection with (*i*), it is to be noted that similar behavior is observed when the Pt surface oxide film is grown in dilute aqueous H_2SO_4 or $HClO_4$ to which Cl^- ions (that are strongly adsorbed) are added[3] (18): For Cl^- concentrations > *ca.* 10^{-4} M, Pt surface oxidation occurs in a completely irreversible manner with the three partially reversible states (3, 17) normally distinguishable between 0.8 and 1.1V E_H, being eliminated on account of competitive adsorption of Cl^- ions. Figure 5 shows that the surface oxidation of Pt in aqueous solutions of TFA at 0.1 and 1.0M concentrations is much inhibited in comparison with the behavior in aq. $HClO_4$. Also the H region is changed in a way characteristic of strong anion adsorption, *e.g.*, as observed with Cl^-. The behavior observed confirms that CF_3COO^- (and/or CF_3COOH) can have a strong effect, like Cl^- ion (18), on the formation and reduction behavior of the monolayer oxide film at Pt. In TFA, the adsorption of CF_3COO^- is likely to be stronger than in water due to its weaker solvation than in the latter medium. However, there are difficulties in seeing how an anion effect alone could cause the hysteresis effects observed if the submonolayer films formed in TFA were dilute random arrays of OH/O species. Hence rearrangement into 2-dimensional condensed island regions has also to be considered.

Island formation.—Here we examine to what extent a 2-dimensional formation of islands of place-exchanged OH or O species could account for the hysteresis behavior as an additional effect to that caused by anion adsorption, indicated above. Two dimensional islands could arise if the place-exchanged OH or O species are sufficiently stabilized by attractive lateral interactions, *i.e.*, with a g-factor [see Ref. (16)] in the ad-

[3] In the present work, there is no question of there being traces of Cl- ion present that might lead to the effects observed: The TFA used was triply distilled and solutions gave no positive test for Cl- by the sensitive nephelometric method.

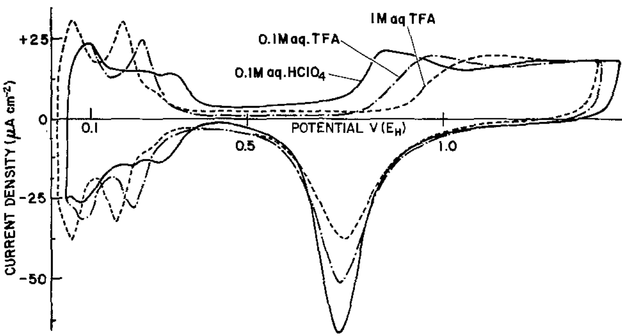

Fig. 5. Cyclic-voltammetry *i* vs. *V* profiles for Pt in 0.1M aq. 0.025 V sec^{-1} at 298 K and in 0.1M aq. $HClO_4$ with addition of CF_3COOH at concentrations of 0.1 and 1.0M causing blocking of surface oxide formation.

sorption isotherm < -4. This would follow if a random array such as

```
OH  OH      OH      OH
Pt  Pt  Pt  Pt  Pt  Pt  Pt  Pt
```

became restructured into a 2-d phase such as

```
    OH  Pt  OH  Pt
Pt  Pt  OH  Pt  OH  Pt  Pt
```

where PtOH and OHPt dipoles are oriented in attractive configurations, leading to stabilization.[4] These representations are, of course, highly schematic.

The suggestion that the benavior observed with the submonolayer oxide films formed from water in TFA is associated with formation of islands of the place-exchanged species is not inconsistent with the picture we have given previously (3, 4) for the progressive development of a monolayer of surface oxide on Pt and other noble metals. Place-exchanged species, "OHPt" or "OPt," will tend to be most stable when adjacent to 'unexchanged" adsorbed OH or O species on the Pt surface, as shown schematically above (in fact, this is probably part of the driving force for place-exchange), so that the tendency for formation of islands of the place-exchanged species has to be included in mechanisms of surface oxidation. Initially, formation of lattices of electrodeposited OH species up to a monolayer (at 1.1V E_H in water) seems to account (3) for the anodic i *vs.* V profile in water. Hence, the ultimate formation of the surface oxide film in a state which is reducible only at less positive potentials than those required for its formation [the hysteresis effect; Ref. (1-4)] would seem to require surface diffusion of the initially deposited species coupled with their place-exchange. At any reasonably significant coverage, say 25%, surface diffusion, if involved, would need to be over $2 \sim 3$ lattice sites only and would thus be difficult to distinguish from the lattice reconstruction processes. These effects are presumably those which give rise to the time-dependence of oxide film formation (1-3) and the aging effects reported by Arvia (19).

Although the viewpoint examined here on the role of development of submonolayer islands of surface oxide in the process of surface oxidation of Pt from traces of water in TFA is related to the recent treatment of Gilroy (20) in which a nucleation and growth mechanism is advanced for explaining the logarithmic law of growth (1, 15) for increasing degree of oxidation at Pt at constant potential, it must be mentioned that the following type of transient experiment does not indicate a nucleation and growth mechanism that could lead to island formation: If a rapid potential sweep is made to a particular potential V_a in the potential range where surface oxide formation occurs, and the resulting current-time transient is recorded at (this constant) V_a, then only a continuously diminishing $i(t)$ transient is observed, not one in which i at first increases and then decreases with t, which would be characteristic of nucleation and growth of the oxide film. A similar experiment, made in the reduction direction after a monolayer or submonolayer of oxide has been formed anodically, similarly does not indicate "hole" nucleation and growth as the film reduction mechanism.

[4] Island stability will be influenced by edge-to-area ratio. In square arrays of n^2 particles, for example, the number of particles in the edges relative to the number inside the edges is given by $[n^2 - (n - 2)]^2/(n - 2)^2$, *i.e.*, $4(n - 1)/(n - 2)^2$. As $n >> 1$, this ratio approaches $4/n$. Thus, *e.g.*, 40×40 particle squares still contain 10% of particles in their perimeters.

ABSTRACT

The structural characteristics of CdS films cathodically electrodeposited from a dimethylsulfoxide solution containing cadmium chloride and elemental sulfur have been studied. The thickness, continuity, smoothness, and the degree of substrate coverage of the CdS films have been examined using stylus-type surface profiling techniques, x-ray diffractometer patterns, and scanning electron microscopy. The composition of the films was examined using Rutherford backscattering spectrometry. It is concluded that high quality films of CdS with a high degree of crystal structure can be electrodeposited in this manner and that minority components may be easily incorporated in the films.

Recently, there has been a great deal of interest in the applications of n-CdS in the conversion of solar energy to electrical energy (1-3). The use of semiconductors in photovoltaic cells is well known; more recently, they have also been employed in photoelectrochemical cells in which they are stabilized by hole consumption reactions involving redox couples in the electrolyte (4, 5). Although the majority of CdS used in these devices is produced by vapor deposition techniques, recent work has described the electrochemical deposition of thin layers of CdS and other semiconductors (6-10). CdS and Bi_2S_3 films may be grown on Cd and Bi metal, respectively, by anodic oxidation of the parent metal in an electrolyte solution containing sulfide ion (6-8). CdSe (9) and CdTe (10) have been deposited cathodically from acidified aqueous solutions containing $CdSO_4$ and either SeO_2 or TeO_2. The electrode process in which the chalcogen dioxide is reduced to its corresponding dianion is obviously complex since it involves six electrons. However, in the case of CdTe where the structure of the resulting film has been studied (10), the quality of the deposit is quite good. A third method of electrodepositing II-VI compounds involves a cathodic process in a solution containing the desired metal ion and soluble chalcogen (11, 12), the overall reaction being

$$M^{++} + X + 2e \rightarrow MX \quad [1]$$

where M^{++} is a divalent cation and X, the chalcogen. Since the chalcogens are not soluble in water under normal conditions, these reactions were carried out in a variety of nonaqueous solvents.

In the present paper, the structural characteristics and composition of CdS films electrodeposited from dimethylsulfoxide (DMSO) solutions containing cadmium chloride and elemental sulfur are described for a variety of electrodeposition conditions. The electrical properties of the films and the mechanism of film formation will be discussed in future papers.

Experimental

The CdS films were deposited on high purity platinum foil (99.9999%) of thickness 0.05 mm and total exposed area of 2.00 cm². Electrical contact to the platinum squares was made with platinum wire arc-welded to the foil and mounted in a glass tube. A platinum counterelectrode of similar geometry was used and oriented to provide uniform charge distribution (see Fig. 1). All voltages were measured against a Cd/$CdCl_2$ reference electrode in DMSO held at the temperature of the electrolyte solution. The electrolyte solution consisted of 0.055M $CdCl_2$ and 0.19M S in reagent grade DMSO; it was held at constant temperature by immersing the cell in an oil bath whose temperature was maintained by a temperature controller/circulator.

The Pt cathode was etched in concentrated HCl, then rinsed first with triply distilled water, followed by acetone. Electrolysis was carried out at constant current density using a PAR Model 170 programmable potentiostat/galvanostat, the voltage across the cell being monitored on a strip chart recorder. The solution was stirred with a magnetic stirrer during deposition.

Key words: electrodeposition of semiconductors, CdS films, semiconductor films.

The squares of Pt coated with CdS were immediately removed from the electrolyte, rinsed first with hot DMSO, then with acetone. For observation under the scanning electron microscope (SEM), the samples were mounted with silver coagulant on machined aluminum stubs (suitable for insertion into the SEM). The CdS films were examined within 24 hr of electrodeposition with an Etec Autoscan SEM using the backscattered electron technique. All micrographs were taken on Kodak FXP120 film with a Graphex lens and aperture. The procedure was repeated for a series of films varying the time of deposition, the current density, the temperature of the electrolyte solution, the concentration of additives in the electrolyte solution, such as thiourea, potassium iodide, and thallium chloride, and finally the nature of the substrate conductor. In the case that the substrate was not Pt, the required metal (Au or Cd) was first electrodeposited from aqueous electrolytes using standard techniques.

The structure of the CdS films was investigated using a General Electric Model 11GN1 x-ray diffractometer with a cobalt target. The films were also analyzed in a rotating crystal geometry. The stoichiometry and uniformity of selected films were measured using backscattering spectrometry (13) utilizing a 3 MV Van der Graff accelerator.

In order that thickness measurements of the CdS films could be performed, the semiconductor layers were deposited on smooth substrates of Pt sputtered on glass. The thickness of the film was measured with a Sloan Dektak, stylus-type device. The sputtering of the Pt was carried out with an Edwards S150A sputter coater, the resulting metal films being heated for 3 min at 575°C after formation. After electrodeposition of the CdS film by the methods described above, the film was scratched away from the substrate and the thickness was measured at a minimum of 5 positions on the surface.

Results and Discussion

Film smoothness, continuity, grain size, adhesion to substrate, and the percentage of substrate coverage were all considered to be criteria for determining film quality.

Typical plots of voltage during deposition against time for varying current densities are shown in Fig. 2. The initial sharp rise in voltage is attributed to the charging of the double layer and the initialization of the deposition process. This is followed by a 100-200 sec film nucleation step, after which the semiconductor is deposited at a constant rate. Film "breakdown," inferred from the erratic fluctuation at high voltages, occurred independent of current density at $\simeq$5V.

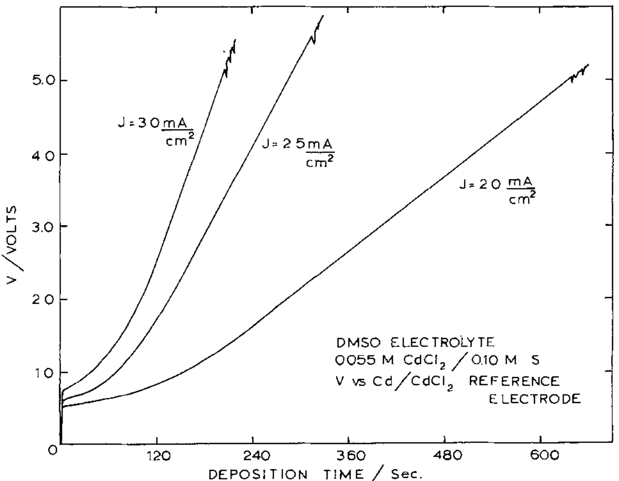

Fig. 2. Plots of voltage against deposition time during the deposition of CdS films at several current densities as indicated.

Electron micrographs of CdS films grown for 50, 150, 500, and 1500 sec at 110°C and a current density of 2.5 mA/cm^2 are shown in Fig. 3. It is apparent that the films grown for longer than 250 sec at 2.5 mA/cm^2, that is, for a cell voltage greater than 5V, had significant cracking and defects. The defects, namely undulations and outgrowths, are probably due to charge concentration at the substrate surface caused by macroscopic defects in the substrate. The ridges visible in Fig. 3a and 3b are due to scratches in the underlying Pt. The dependence of the cracking on deposition time, and hence voltage, consistent with the growth curves in Fig. 2, suggests that cracking occurs during deposition.

The x-ray diffractometer pattern shown in Fig. 4 is for a CdS film grown for 500 sec at 110°C and a current density of 2.5 mA/cm^2. The intense peak at $2\theta = 31.5°$ corresponds to an interplanar distance of 3.34Å and compares well with the theoretical value of 3.36Å for the <111> planes of β-CdS. The minor peaks in the pattern correspond to the Pt substrate and reflect its limited degree of orientation. It is significant that only one peak associated with CdS was observed. This result indicates a high degree of symmetry along the axis perpendicular to the substrate surface. Rotating-crystal x-ray patterns were typical of single crystal CdS in the β-CdS form. A typical Rutherford spectrum for α-particles backscattered from a CdS film deposited on Pt is illustrated in Fig. 5. The spectrum is shown for the energy ranges where backscattering is due to $S^{=}$ and Cd^{++} ions; the central peak between 0.95 and 11.8 MeV which is due to the Pt substrate has been left out for the sake of clarity. The rise in backscattered intensity at the high energy side of the region corresponding to Cd^{++} at 139 MeV is qualitative confirmation of the presence of this atom and the yield at this energy permits precise determination of the relative amount of Cd in the film. The corresponding high energy intensity for the S peak is obscured by the Pt peak. However, approximate analysis yields an S to Cd ratio of 0.9 $\pm$ 0.1 to one. The shape of the Cd and S peaks provides evidence that the film composition is uniform as a function of depth (13). There is some evidence of a peak due to Cl^- ions at channel numbers corresponding to lower energies but the intensity was too low with respect to background noise for this element to be positively identified from the Rutherford analysis. However, it is probable that Cl^- ions are incorporated into the film to a minor extent during deposition.

The cracking of the thicker film (see Fig. 3c and 3d) has been observed previously in CdS films grown by anodic polarization of Cd in an Na_2S solution (7) and was attributed to water loss. Due to the strong solvation of the Cd^{2+} ion in DMSO, there is probably a small amount of solvent incorporated into the CdS films; however, the above results suggest a secondary, more complex cracking mechanism. Cracking may result during deposition due to tensile stress in the CdS crystal resulting from a strong, secondary piezoelectric effect (14) which is permitted because the <111> axis has no center of symmetry. Thus, the electric field applied during deposition in this direction may result in the displacement of deposited ions and hence the incorporation of stress during growth. The nonequilibrium positions of the ions in the film would result in stress causing the observed "breakdown" (cracking) when the force was of sufficient magnitude. This conclusion is consistent with the experimental observation of a constant voltage at which "breakdown" occurred, independent of applied current density. It is also reasonable that some cracking may occur after deposition caused by migration of the ions to equilibrium lattice positions.

Figure 6 shows a micrograph of a CdS film grown by decreasing the current density from 2.5 mA/cm^2 (at $t = 0$ sec) to 0 (at $t = 900$ sec) in equal incre-

ments every 180 sec. Although there are significant surface undulations and irregularities in the CdS film, characteristic of thicker films, there is a complete absence of cracks, 100% substrate coverage being achieved. Limiting the applied field by decreasing the current density during deposition may allow a gradual relaxation and migration process to occur. One also notes that in Fig. 6, there is evidence of overlapping plates, probably originating from the presence of different nucleating sites on the substrate surface.

A plot of the average film thickness, $<d>$ against deposition time is shown in Fig. 7. The dotted line corresponds to the theoretical relationship between thickness and time assuming that the only electrode

process is

$$Cd^{2+} + S + 2e^{-} \rightarrow CdS \quad [2]$$

Accordingly

$$d = \frac{jM}{n\mathbf{F}\rho} t \quad [3]$$

where j is the current density, M the molecular weight of CdS (144.46g), n the number of electrons transferred, $\mathbf{F}$ the Faraday, and ρ the density of the electrodeposited material. ρ was assumed to be that for β-CdS, namely, 4.82 g/cm^3 and n was assumed to be 2.

The most notable feature of the experimental data is the linear dependence of film thickness on time. Comparison of the slope observed (Fig. 7) with that predicted for reaction [2] according to Eq. [3] yields an efficiency of 81% for the deposition process. The discrepancy between the experimental and theoretical slopes may be attributed to several factors. Firstly, it may result from the presence in solution of sulfur compounds with sulfur in a higher oxidation state. If sulfur in these forms is involved in the deposition process to a significant extent, the effective number of electrons transferred during the process would be greater than that proposed by the simpler process involving elemental sulfur. Such sulfur compounds are most surely present in DMSO at 110°C due to the oxidation of elemental sulfur by atmospheric oxygen. The presence of sulfur containing impurities is strongly suggested by the distinctive odor of reagent grade DMSO, the pure solvent being odorless. Alternatively, the presence of oxygen and water in the solvent may result in other side reactions.

A plot of average CdS film thickness <d> against current density j for a fixed deposition time is shown in Fig. 8. Again, the relationship predicted by Eq. [3] on the basis of Faraday's laws is plotted as a dotted line. Below 3.0 mA/cm^2, the plot of experimental data is reasonably linear, whereas at higher current densities there is significant deviation from linearity. It is possible that the discrepancies between the experimental data and the theoretical relationships are due to varying composition of the film with current density. At high current density, the interface between the Pt and the CdS was observed to be darker in color than the surface of the CdS layer (the Pt layer was translucent). The darkening may indicate an excess of cadmium in the initial layers of the semiconductor film. The variation of the film composition with cur-

rent density suggests that the stoichiometry of the electrodeposited CdS, and hence its electrical properties, may be altered.

Modifying the substrate surface, prior to depositing the CdS, by adding water or thiourea to the electrolyte solution or by predepositing gold or cadmium had a significant effect on the quality of the deposit. Figure 9a illustrates a characteristic CdS film grown on a gold substrate and Fig. 9b shows a film grown from an electrolyte solution containing thiourea. The films grown on a cadmium substrate and from an electrolyte solution containing water had similar characteristics. These films were much smoother with fewer undulations than films grown from electrolyte solution with no additives; however as can be seen in Fig. 9, such films exhibited poor adhesion to the substrate. The thiourea or water in the DMSO solution is believed to be adsorbed at the electrode surface at sites of high energy (outgrowths). This adsorption may retard film growth at these points and allow growth in "valleys," thus producing a smoother, more uniform deposit. The above results probably illustrate a reduction in the number of points of charge concentration by a smoothing of the substrate surface.

Voltage against deposition time curves for CdS films deposited with TlCl in the electrolyte solution are shown in Fig. 10. It is noted that the slope of voltage against time curves (after the nucleation step) decreased with increasing concentration of TlCl in the solution, reflecting a decreased resistivity of the deposited CdS layer due to possible incorporation of Tl^+ in the film. Selected CdS films deposited from the electrolyte solution containing TlCl were analyzed using the Rutherford backscattering technique. Figure 11 shows a typical spectrum of 2 MeV alpha particles scattered from a CdS film grown for 500 sec from a solution containing 10^{-3}M TlCl. The relative heights H_1 and H_2 due to scattering from Cd and Tl nuclei, respectively, are directly indicative of a 2% abundance of Tl^+ in CdS. The shape of the spectrum suggests an even distribution of Tl^+ as a function of depth within the film.

In conclusion, CdS films electrodeposited as described above from DMSO solution are of high quality based on their continuity, adhesion to the substrate, substrate coverage, and degree of crystallinity. The deposition process is technically simple, fast, and has numerous advantages over vapor deposition processes. The observed cracking due to piezoelectric and substrate surface effects is not a serious problem and can be overcome in a straightforward manner. The possibility that minor impurities may be incorporated into the CdS film by electrodeposition is of great significance. This result suggests that CdS films of the desirable electrical properties may be achieved merely by dissolving different doping ions in the deposition solution in suitable concentrations. Preliminary studies have indicated that carrier concentrations on the order of

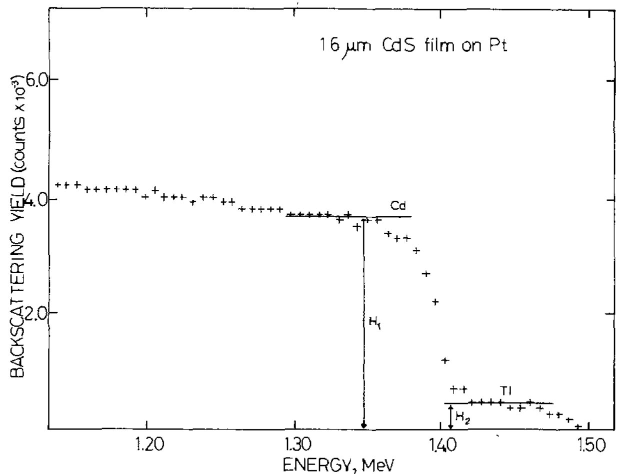

Fig. 11. Rutherford backscattered spectrum of a CdS film deposited from electrolyte solution containing 10^{-3}M TlCl.

10^{14} cm^{-3} and carrier mobilities of approximately 50 cm^2 V^{-1} sec^{-1} can be achieved in this manner.

An Admittance Study of the Copper Electrode

S. H. Glarum* and J. H. Marshall

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The admittance of a rotating-disk copper electrode in $CuSO_4/H_2SO_4$ has been measured as a function of frequency, potential, and concentration. A theoretical analysis of the Mattson-Bockris model incorporating finite exchange currents for the redox and crystallization reactions and diffusion of both cuprous and cupric ions leads to a simple equivalent circuit representation. Although this basic electrode model provides an adequate explanation for results at the equilibrium potential, substantial deviations occur at anodic potentials due to disproportionation. 10^{-5}M chloride concentrations lead to formation of a surface monolayer which alters relaxation at both anodic and cathodic potentials. No evidence was found for the conventional adatom relaxation process.

The deposition and dissolution of copper in an electrochemical environment is a complex and challenging problem for electrochemistry. Our present understanding of copper electrode kinetics has been recently reviewed by Bertocci and Turner (1, 2), and bears little resemblance to the complexities of practical copper plating. What seems clearly established is the importance of cuprous ions as intermediates in the electrochemical reactions

$$Cu^{++} \underset{I_1}{\rightleftharpoons} Cu^{+} \quad [1]$$

and

$$Cu^{+} \underset{I_2}{\rightleftharpoons} Cu \quad [2]$$

which we shall refer to as the redox and crystallization reactions. As was first demonstrated by Mattson and Bockris (3), and confirmed by others (4, 5), the asymmetry in current-voltage plots is explained by the above reactions with the redox step being rate determining. Given a Butler-Volmer relationship between current and overpotential, equating the steady-state currents of both reactions, and assuming the exchange current, I_{10} of [1] is much less than that of [2], one obtains the Mattson-Bockris results

$$I = 2I_{10} \left[\exp(2 - \alpha_1)e\eta/kT - \exp(-\alpha e\eta/kT)\right] \quad [3]$$

$$[Cu^+] = [Cu^+]_{eq} \exp(e\eta/kT) \quad [4]$$

One puzzling aspect of this model, as noted by Bertocci and Turner (1), is that current-voltage response depends only upon the parameters of a redox reaction, making it difficult to rationalize the range of values reported for these parameters and their sensitivity to surface preparation.

Many studies have attempted to probe more deeply into electrode kinetics using either pulse (3, 4, 6, 7) or alternating current modulations (8-14). The former experiments have generally involved large potential excursions (>10 mV), and the interpretation of nonlinear, time-dependent phenomena requires the assumption of a specific model uncomplicated by instrumental or chemical side effects. A-C measurements, although more time consuming, are more readily analyzed by reduction to an equivalent circuit description without recourse to a specific model. Complex-plane analysis provides a powerful tool for unraveling multi-element circuits, and often the shape alone of a complex-plane plot can be a powerful mechanistic discriminator. One might note that, based largely upon the interpretation of pulse experiments, adatom diffusion had been credited with playing an important role in copper electrocrystallization near equilibrium (3, 6, 8, 10). Subsequent a-c work revealed that this dispersion could also be explained by diffusion of cuprous ions from the electrode (11-14).

* Electrochemical Society Active Member.

Key words: circuits, relaxation, potential.

Clearly any analysis of copper electrode kinetics must consider diffusion of both cupric and cuprous ions

$$Cu^{++}(\infty) \overset{D}{\rightleftharpoons} Cu^{++}(O) \qquad [5]$$

$$Cu^{+}(\infty) \overset{D}{\rightleftharpoons} Cu^{+}(O) \qquad [6]$$

Although these steps constitute a straightforward addition to reactions [1] and [2] if a Nernst diffusion model is adopted, a full treatment has not been previously given. One aspect of this work is the derivation of kinetic results for the steady state and the a-c admittance behavior for the coupled reactions [1], [2], [5], and [6]. This will be referred to as the basic electrode model (BEM).

The majority of a-c measurements on copper electrodes have been confined to equilibrium studies, although Burrows, Harrison, and Thompson have recently published, without interpretation, complex-plane plots at several anodic and cathodic potentials (14). A second objective of our study is the determination of the a-c admittance for copper electrodes over a range of frequencies and potentials. Two basic experiments are involved, frequency-sweep measurements of admittance at fixed potentials, $Y_\eta^*(\omega)$, and potential-sweep measurements of admittance at fixed frequencies, $Y_\omega^*(\eta)$. The former experiments are more useful for characterizing the response function, while the latter better reveal parameter changes with potential. The need for both experiments is predicated by the difficulty in maintaining a reproducible electrode surface over long periods of time. Using newly developed experimental techniques in conjunction with computer-controlled data acquisition and processing, essentially continuous measurements of $Y_\eta^*(\omega)$ and $Y_\omega^*(\eta)$ can be made, and complex-plane analyses can be expeditiously carried out with this large data base.

Finally, we are especially interested in detecting and understanding deviations from the simplistic BEM, for these "discrepancies" may reveal the complexities of copper electrode kinetics. As we shall find, careful data analysis shows a variety of differences from BEM predictions. Although definitive interpretations seem premature, accurate and detailed admittance studies can tell us considerably more about electrode processes than has been observed in the past.

Experimental

Cupric sulfate was recrystallized from the anhydrous, analytical-grade compound. Solutions were prepared with Baker Ultratex sulfuric acid and water from a Millipore Super-Q system. A copper wire inserted through rigid glass capillary tubing served as a reference electrode. It was positioned so that the exposed tip lay in the plane of the electrode about 1.5 cm from its center. All experimental potentials reported are with respect to this reference.[1] The cell was thermostated at 25°C and degassed with argon.

The potentiostat and admittance measuring apparatus have been previously described (15). Low frequency sweep measurements were expedited by the addition of four sample-and-hold circuits to the phase-detector outputs. The in-phase voltage was sampled at 90° and 270°, and the two signals added. The out-of-phase voltage was similarly sampled at 0° and 180°. Provided the response or filtering functions for both channels are identical, it may be shown that the complex ratio of unknown and reference input voltages to the phase detector is given by the ratio of the sample-and-hold outputs. Tests on *R-C* admittances confirmed the reliability of this procedure. In this fashion the output signal could be updated four times per cycle, and 1 Hz measurements were possible with a time constant of 10 msec.

Platinum disk electrodes with diameters of 1/4 and 1/16 in. were potted in thin epoxy sheaths and surrounded by Teflon mantles. The surface was mechanically polished with alumina powders. The electrodes were plated with copper from the solution under investigation, either in a potential cycling mode or by stepping to a set cathodic potential. Deposit thicknesses were estimated from coulometric measurements. Following a measurement, the deposit was stripped and then reformed. Even 2000Å deposits showed responses dependent upon platinum pretreatment. The d-c equilibrium admittance of copper plated on freshly polished platinum decreased threefold over several hours of continuous plating and stripping. If the electrode was first cycled for several minutes to anodic potentials so that a surface oxide was formed and reduced, this drift was eliminated and the lower admittance values could be maintained for several hours.

After cycling solutions of low chloride concentration for 30 min, a narrow, copper-colored band was often observed adhering to the epoxy insulation near the periphery of the electrode. This band could be seen to grow when the electrode was cathodic, but it was not completely removed at anodic potentials, presumably because of a break in electrical contact. We could not recreate this behavior with a copper electrode, and surmise that chloride removes platinum from the electrode during anodic stripping, and this platinum in some manner sensitizes the epoxy surface to the lateral growth of a copper layer. The working time of an electrode in 10^{-4}M chloride was about 20 min before results became erratic.

Prior to each type of measurement it was necessary to find conditions which optimized reproducibility. For studies of $Y_{eq}^*(\omega)$ approximately 600Å were deposited at −150 mV. Eight triangular frequency-sweep measurements were then summed by signal averaging, requiring about 160 sec. A storage oscilloscope monitor ensured that there was no drift of the input data during the measuring period. The deposit was then stripped, reformed, and the reference voltage similarly determined. The nonequilibrium functions, $Y_\eta^*(\omega)$, had to be measured in less time because of rapid surface changes, and they were restricted to frequencies above 200 Hz. For these studies the electrode was cycled between −300 and +200 mV. The cycle was halted at a preset potential, a single sweep-frequency measurement requiring 1 sec was taken, and cycling then resumed until eight such sweeps had been accumulated. For $Y_\omega^*(\eta)$ measurements the electrode was continuously cycled between −250 and +170 mV at about 18 mV/sec, data storage being triggered at the start of each anodic trace.

For all experiments it was most important to determine as accurately as possible the high frequency cell resistance. Extrapolations of high frequency data on copper surfaces proved unreliable. Best results were given by a sweep-frequency measurement of an oxidized platinum surface, for its double-layer capacitance is comparatively large and shows only a small frequency dispersion (15).

Current-voltage curves were also taken to check reproducibility and to permit subsequent potential corrections for electrolyte *IR* drop. Tafel plot data were obtained from current-voltage cycling curves with internal *IR* compensation by the potentiostat.

Results

The majority of experiments were made with 0.25M $CuSO_4$/1.75M H_2SO_4 solutions. This composition is presently used in commercial plating baths designed for high throwing power, and its high conductivity is especially suitable for high frequency studies. Although

[1] If the bulk Cu^+ concentration is not in equilibrium with copper metal, the reference adopts a mixed potential. This difference may be estimated from the BEM equations to be $(RTD_{Cu^+}\Delta[Cu^+]/4I_{10}\,\delta)$ where δ is the effective Nernst layer thickness. For the rotating disk electrode $\delta \simeq 10^{-3}$ cm and the error is less than 1 mV. At the reference δ is not well defined, but it is certainly larger so that the offset is negligible for our purposes.

we do not intend to explore here additive effects in copper plating, the ubiquitous role of chloride in copper baths prompted several experiments which revealed marked effects for concentrations in the 10^{-6}M to 10^{-3}M range. At these low concentrations precipitation of CuCl or formation of soluble cuprous chloride complexes is unimportant. Because the changes induced by trace amounts of chloride are helpful in understanding the properties of chloride-free solutions, we include these results in this report.

The procedures for a complex-plane analysis are formally straightforward, but we think it beneficial to illustrate one such case in detail, in order to expose the difficulties inherent in the interpretation of any linear experiment, be it a.c. or transient in nature. The data we shall discuss were obtained with an 0.25M $CuSO_4$/1.75M H_2SO_4 solution at the equilibrium potential. 640Å of copper were plated at −150 mV on a 1/4 in. platinum electrode rotating 200 rad/sec.

The initial stage in our analysis is a correction for series lead resistance (0.05Ω) and inductance (0.28 μH). The latter is not a negligible value for high frequencies in a 1Ω circuit. Next, correction is made for nonuniform current distributions as discussed in a previous paper (15), and complex admittance plots examined. Figure 1a shows such plots for an oxidized platinum surface and a plated copper surface. Because the platinum data more closely approximate a semicircle or series R-C circuit, Y_∞ was obtained with ±0.5% accuracy from a numerical analysis of $1/Y^*$. Actually

this parameter is needed for the preceding current distribution corrections, but the iteration is rapidly convergent.

Subsequent analysis was made in terms of the circuit depicted in Fig. 2. Formally the surface admittance, Y_e^*, may be resolved into three components

$$G_O = \lim_{\omega \to 0} Y_e^* \qquad [7]$$

$$C_\infty = \lim_{\omega \to \infty} (Y_e^*/i\omega)$$

and Y_x^* includes whatever remains. Given Y_∞, a com-

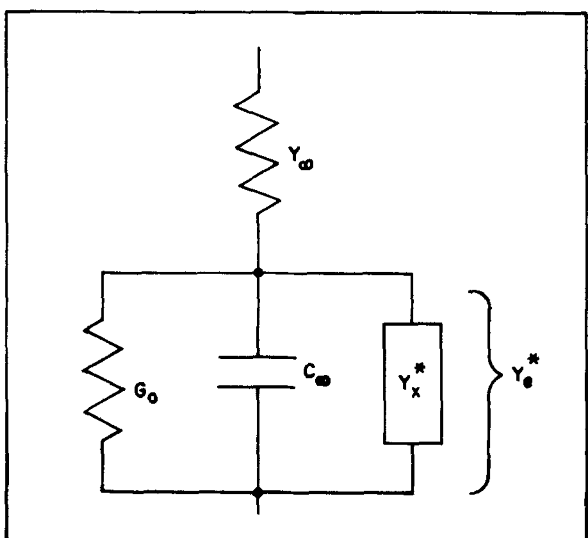

Fig. 2. Equivalent circuit defining deconvolution parameters

plex-plane plot is next made of $Y_e^*/i\omega$, and C_∞ evaluated by extrapolation to infinite frequency (Fig. 1b). Assuming the plot retains its general form above our experimental frequency range, $C_\infty = 20.9 \pm 0.4\ \mu F/cm^2$. The greater scatter in high frequency points reflects the fact that these data are largely determined by Y_∞.

We then examine plots of $Y_e^* - i\omega C_\infty$ (Fig. 1c), which will show the presence of time-dependent surface processes. Data are only plotted for frequencies below 35 kHz, for, although the curve continues its apparent course at higher frequencies, the measurement is dominated by Y_∞ and C_∞, and scatter is much greater. Subtraction of C_∞ is necessary to avoid a high frequency divergence in these plots. It is often desirable to also plot $C_e^* = (Y_e^* - G_O)/i\omega$ (Fig. 1d), and G_O, obtained from a low frequency extrapolation of admittance plots, avoids an analogous low frequency divergence. Although the plots in Fig. 1c and 1d contain similar information, they are complementary in that admittance plots emphasize high frequency behavior while capacitance plots exaggerate low frequency data.

At low frequencies both Y_e^* and C_e^* plots appear linear, indicating an admittance proportional to a power of the frequency, *i.e.*, $(i\omega)^\alpha$, and from the slopes $\alpha = 0.50_5$. A separate 1-1400 Hz sweep measurement is shown in Fig. 1e. A new surface had been formed for this run, and, although comparison with the preceding data at overlapping frequencies shows 5% differences, linear behavior persists down to 1 Hz. From the slope, $\alpha = 0.49_0$. Evidently the low frequency response of a copper electrode is accurately given by an empirical expression

$$Y_e^* = G_O + \sqrt{i\omega}W \qquad [8]$$

Above 5 kHz (Fig. 1c), admittance plots show a slight negative curvature. Mention should also be made that, although not apparent in the data shown, Y_e^* plots sometimes showed a tailing off at low frequencies so that no unambiguous extrapolation to $\omega = 0$ was feasible. Values for G_O, C, and W are summarized in Table I.

Solutions of $CuSO_4$ with concentrations ranging 0.001-1.0M in 1M H_2SO_4 were then examined. Deposi-

Table I. Equilibrium relaxation parameters for 600Å deposits from 0.25M $CuSO_4$/1.75M H_2SO_4 solutions

	0M Cl-	10^{-4}M Cl-	10^{-3}M Cl-
C_∞ ($\mu F/cm^2$)	20.9	22.6	23.7
G_O (mho/cm^2)	0.17	0.10	0.15
W ($mho\text{-}sec^{1/2}/cm^2$)	5.0×10^{-3}	4.7×10^{-3}	6.8×10^{-3}

tions conditions were 600Å at −150 mV. Complex-plane plots were similar to those already discussed, although at the highest and lowest concentrations the low frequency asymptotic behavior was not always as close to 45°. Results for G_O and W are plotted in Fig. 3. The error bars show the range of values calculated from data between 1 kHz and 50 Hz assuming Eq. [8] applies. The capacitances C_∞, ranged 21-25 $\mu F/cm^2$, with no evident concentration dependence. Although deposition conditions were chosen to minimize the effects of thickness and deposition potential upon response, the scatter in Fig. 3 indicates the importance of other uncontrolled parameters.

Measurements of $Y_\eta^*(\omega)$ were made with a 1/16 in. platinum disk electrode in 0.25M $CuSO_4$/1.75M H_2SO_4. The electrode was cycled between −300 and +200 mV, with data taken at 25 mV intervals between −275 and +100 mV. Subsequently, potentials were recalculated to take into account electrolyte *IR* drop. The maximum deposit thickness was of order 1000Å at $\eta = 0$. High frequency capacitances varied between 26 and 30 $\mu F/cm^2$, with higher values found at higher overpotentials. Figure 4 shows several admittance plots obtained after elimination of Y_∞ and C_∞. Low frequency intercepts, estimated by linear extrapolation, are comparable with the slope of the current-voltage curve at the corresponding potential.

The dispersion increases with potential, and, above +50 mV, plots approach the real axis perpendicularly

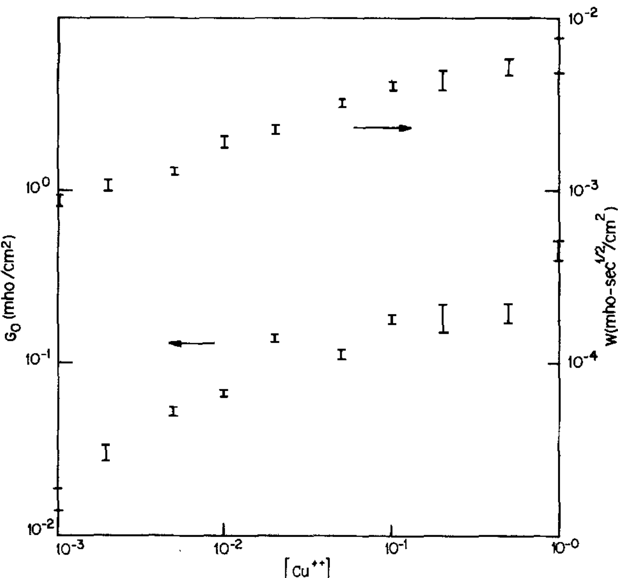

Fig. 3. Concentration dependence of G_O and W for $CuSO_4$ in 1M H_2SO_4.

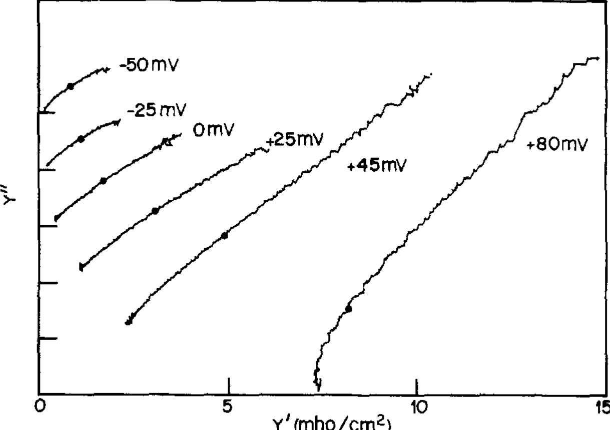

Fig. 4. Complex surface admittance plots at various potentials. 10 kHz points are shown.

at low frequencies. Below −50 mV only a small dispersion remains, and admittance plots also near the real axis at an angle significantly steeper than 45°. C_e^* plots shown in Fig. 5 offer a capacitive interpretation for the residual relaxation of magnitude 50-100 $\mu F/cm^2$, with the amplitude and relaxation time decreasing with potential. The dispersion is not that of a simple relaxation process, but appears to be better described by a circular-arc function.

When $10^{-4}M$ chloride was added, $\sqrt{i\omega}$ low frequency response was found at all potentials. The curvature in anodic plots (Fig. 4) was suppressed, and the cathodic capacitative dispersion was reduced to less than 5 $\mu F/cm^2$ between −100 and −200 mV. The high frequency capacitance exhibited a greater variation with potential, changing from 20 $\mu F/cm^2$ at −250 mV to 27 $\mu F/cm^2$ at equilibrium, and rising to over 60 $\mu F/cm^2$ above +50 mV. These measurements were complicated by an increase in electrode area due to the spreading of copper from the electrode as mentioned previously. The resulting uncertainties in Y_∞ were reflected in deviant high frequency behavior.

Studies of $Y_\omega^*(\eta)$ were made with the ¼ in. electrode and 0.25M $CuSO_4$/1.75M H_2SO_4 solutions. Because dispersion analysis had shown a tendency towards a $\sqrt{i\omega}$ variation of Y_e^* (Eq. [8]), we show plots of $Y_\omega''(\eta)/\sqrt{\pi f}$ in Fig. 6. These results were calculated from experimental data by subtraction of Y_∞ and a fixed value for C_∞. One notes a prominent peak at +50 mV and a lesser peak at −100 mV. Near 100 Hz Y_e'' dropped reproducibly to negative values at high anodic overpotentials. There is also a definite dispersion at potentials more than ±25 mV from equilibrium, indicating the limitations of Eq. [8].

Upon addition of $10^{-4}M$ chloride these plots were dramatically altered (Fig. 7). The maxima disappeared and for frequencies 0.02-30 kHz no deviations from Eq. [8] are evident between +75 and −100 mV. At more cathodic potentials a new low frequency dispersion appears. Figure 8 compares low frequency plots of $Y_\omega'(\eta)$ for both solutions. Chloride addition has shifted the minimum 25 mV anodically and raised substantially the curve in the cathodic region. As expected, these plots are comparable to those found by differentiating current-voltage curves.

Discussion

The Mattson-Bockris results (Eq. [3] and [4]) follow from several specific assumptions and it is desirable to test their validity by a more thorough analysis of the BEM. Bertocci has considered this question in some detail (2), but explicit calculations of current-voltage or Tafel plots have not been offered. The Butler-Volmer equations corresponding to reactions [1] and [2] are

where

$$x_1 = [Cu^+(O)]/[Cu^+]_{eq};$$

$$x_2 = [Cu^{++}(O)]/[Cu^{++}]_{eq} \quad [10]$$

In the steady state, reactions [5] and [6] yield

$$O = (FD_2/\delta_2)\,[Cu^{++}]_{eq}(1 - x_2) + I_1$$

$$O = (FD_1/\delta_1)\,[Cu^+]_{eq}(x_0 - x_1) - I_1 + I_2$$

$$x_0 = [Cu^+]_{bulk}/[Cu^+]_{eq} \quad [11]$$

In these equations $[Cu^+(O)]$ and $[Cu^{++}(O)]$ are concentrations at the electrode surface while $[Cu^+]_{bulk}$ and $[Cu^{++}]_{eq}$ are actual concentrations in the bulk of the electrolyte. $[Cu^+]_{eq}$ is the concentration which would exist in the bulk if the solution were in thermodynamic equilibrium with copper metal.

The four relevant linear equations may now be solved for the four unknowns I_1, I_2, x_1, and x_2. As we are primarily interested in ascertaining what deviations from simple Tafel behavior occur when both exchange currents are finite and concentration polarization is present, it is expedient to neglect the difference in diffusion coefficients, assume $\alpha_1 = \alpha_2 = 0.5$, and introduce the four reduced parameters

$$\gamma_1 = FD\,[Cu^{++}]_{eq}/\delta I_{10} = I_1^{lim}/I_{10}$$

$$\gamma_2 = [Cu^{++}]_{eq}/[Cu^+]_{eq} = ([Cu^{++}]_{eq}/K_{eq})^{1/2}$$

$$\gamma_3 = I_{20}/I_{10}$$

$$\gamma_4 = [Cu^+]_{bulk}/[Cu^+]_{eq} \quad [12]$$

The calculations can be readily handled by a pocket calculator and current-voltage behavior examined for various choices of the γ parameters. K_{eq} fixes γ_2, and, according to Tindall and Bruckenstein, equals 5.6×10^{-7}M (16). Nonequilibrium cuprous bulk concentrations, $\gamma_4 \neq 1$, have their principle effect when $\eta \simeq 0$, slightly shifting the open-circuit potential (4). Changing γ_1, corresponding to varying the rotational speed of a disk electrode, shows up most prominently in the limiting current regime at large cathodic overpotentials. We are particularly interested in the kinetics of the second electrochemical step which are reflected in γ_3. Typical plots in Fig. 9 show that the major changes occur at anodic potentials. When the anodic current exceeds I_{20} by an order of magnitude, Tafel slopes are reduced from 40 to 120 mV/decade. As a practical matter, if data taken below +100 mV show a 40-50 mV/decade slope, a lower limit to γ_3 of about 30 can be set.

This more realistic calculation also indicates that good agreement is expected for exchange currents found from Tafel intercepts and the equation

$$I_0 = (kT/2e)\,(\partial I/\partial \eta)_{\eta=0} \quad [13]$$

For the parameters used for Fig. 9, the slope of the current-voltage curve near $\eta = 0$ is independent of γ_4, although the open-circuit potential shifts to -1 mV when $\gamma_4 = 0$. The separate currents I_1 and I_2 agree to within 10%. Because of the slight curvature of the cathodic plot in Fig. 9 for $\gamma_3 = 10^4$, the apparent slope is 135 mV/decade, leading to $\alpha_1 = 0.44$, although 0.5 was assumed in the calculations. Generally we observe no serious pitfalls in using Eq. [3] instead of a more precise calculation unless unrealistically high values are chosen for γ_1. Major differences between experiment and the BEM must be due to inadequacies of the model, not to the simplifying assumptions made in the derivation of Eq. [3].

Our Tafel results for 0.25M $CuSO_4$/1.75M H_2SO_4 solutions show a 40 mV/decade slope on the anodic

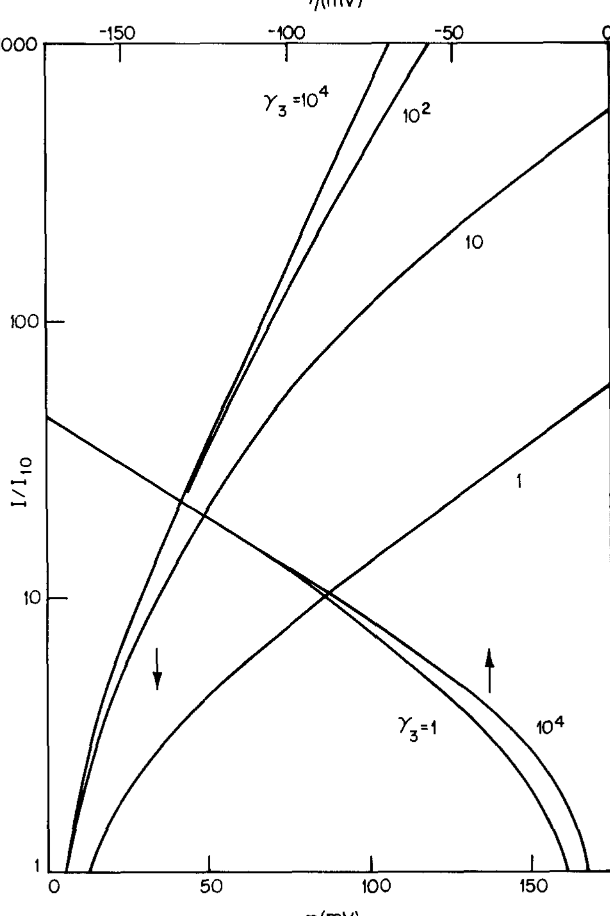

Fig. 9. Theoretical BEM Tafel plots for $\gamma_1 = 100$, $\gamma_2 = 663$, and $\gamma_4 = 1$. Values for γ_3 are shown.

side at 30-40 mV, but the curve bends gradually with increasing potential, showing no truly linear region (Fig. 10). A formal comparison with calculated plots for $\alpha = 0.5$ can give a good fit if $\gamma_3 \simeq 25$ and $I_0 = 3.5$ mA/cm^2. For the cathodic plot a well-defined linear region is fit by $\alpha = 0.33$ and $I_0 = 5.0$ mA/cm^2, while, from the slope at $\eta = 0$, $I_0 = 2.2$ mA/cm^2. The magnitude of these currents and their variation with the manner of calculation are similar to those reported by Mattson and Bockris for electrodes prepared by electrodeposition (3). These variations are not explained by model calculations which consider diffusion and finite rates for both electrochemical steps.

Tafel plots were significantly altered upon addition of 10^{-4}M chloride (Fig. 11). The anodic curve remains linear to beyond +100 mV, with a 48 mV/decade slope and an intercept giving $I_0 = 1.5$ mA/cm^2. The cathodic plots are no longer so nicely linear, but show a slope at −100 mV giving $\alpha = 0.56$ and $I_0 = 2.2$ mA/cm^2.

These Tafel results are consistent with earlier work (3, 4), and verify the equivalence of our deposits with those of prior studies. We believe it is important to recognize that traces of chloride can seriously influence such measurements. Bearing in mind that we observed major changes with a 10^{-4}M concentration on surfaces freshly formed during continuous potential cycling, much lower levels can affect measurements on "aged" surfaces. The scavenging of chloride ions by a copper surface tends to shift Tafel slopes towards values yielding $\alpha = 0.50$.

Several authors have derived expressions for the a-c response of an electrode reaction equivalent to that represented by Eq. [1], [2], [5], and [6], assuming an infinite diffusion layer (17, 18). In the advent of a finite layer of thickness δ, a Nernst calculation for the gradient of the concentration modulation yields

$$(\partial A^*/\partial x)_{x=0} = -\sqrt{i\omega/D}\coth\sqrt{i\omega\delta^2/D}\,A^*(\mathrm{O}) \quad [14]$$

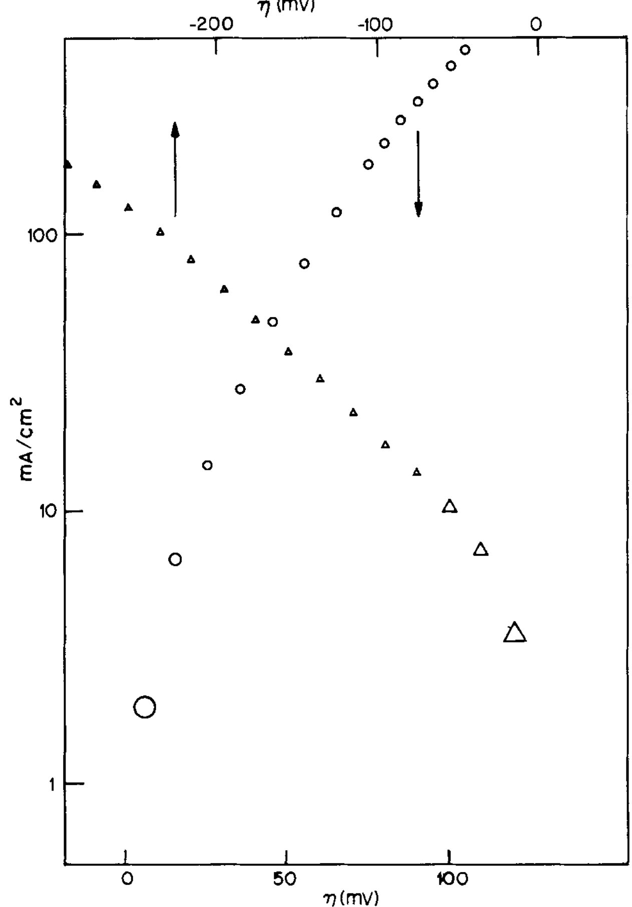

Fig. 10. Experimental Tafel plots for chloride-free solutions

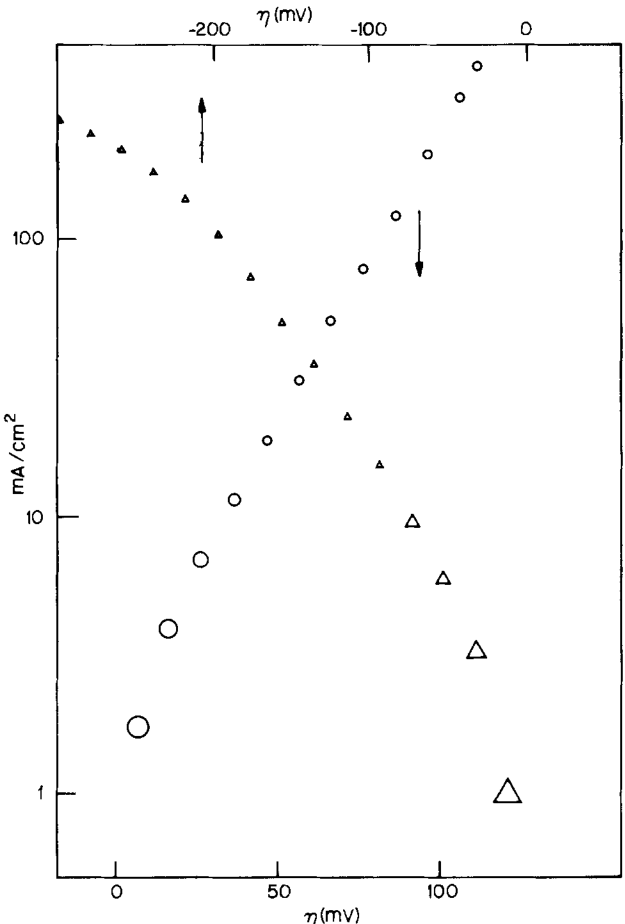

Fig. 11. Experimental Tafel plots for 10^{-4}M chloride solutions

For a disk rotating 200 rad/sec, $\delta^2/D \simeq 0.2$ sec, and the high frequency approximation suffices above 1 Hz.

When the results of Armstrong and Firman are applied to the copper problem (18), one obtains

$$Y^* = \frac{\dfrac{\partial(I_1+I_2)}{\partial\eta} - \dfrac{1}{\sqrt{i\omega}}\left(2\dfrac{\partial I_1}{\partial\eta}\dfrac{\partial I_2}{\partial\lambda_1} - 2\dfrac{\partial I_1}{\partial\lambda_1}\dfrac{\partial I_2}{\partial\eta} + \dfrac{\partial I_1}{\partial\lambda_2}\dfrac{\partial I_2}{\partial\eta}\right)}{1 - \dfrac{1}{\sqrt{i\omega}}\left(\dfrac{\partial I_1}{\partial\lambda_2} - \dfrac{\partial I_1}{\partial\lambda_1} + \dfrac{\partial I_2}{\partial\lambda_1}\right) + \dfrac{1}{i\omega}\dfrac{\partial I_1}{\partial\lambda_2}\dfrac{\partial I_2}{\partial\lambda_1}} \quad [15]$$

where

$$\lambda_1 = \mathbf{F}\sqrt{D_1}\,[\mathrm{Cu^+(O)}]$$

$$\lambda_2 = \mathbf{F}\sqrt{D_2}\,[\mathrm{Cu^{++}(O)}] \quad [16]$$

This rather formidable expression has a simple complex-plane representation, for it can be factored into

$$Y^* = Y_1/[1 + (i\omega\tau_1)^{-1/2}] + (Y_2 - Y_1)/[1 + (i\omega\tau_2)^{-1/2}] \quad [17]$$

A complex-plane plot of Eq. [17] will therefore consist of the superposition of two 45° circular arcs (32). How well resolved they will appear depends upon the ratio τ_1/τ_2. The corresponding equivalent circuit is the parallel combination of two partial circuits, each composed of a resistance in series with a Warburg admittance.

For copper kinetics $I_{20} >> I_{10}$ and $[\mathrm{Cu^{++}}]_{eq} >> [\mathrm{Cu^+}]_{eq}$, so that

$$\partial I_2/\partial\lambda_1 >> \partial I_1/\partial\lambda_2 \quad [18]$$

Under this condition the dispersions are well resolved and

$$1/\sqrt{\tau_1} = -\partial I_1/\partial \lambda_2$$
$$1/\sqrt{\tau_2} = \partial (I_1 - I_2)/\partial \lambda_1$$
$$Y_1 = 2\left(\frac{\partial I_1}{\partial \lambda_1}\frac{\partial I_2}{\partial \eta} - \frac{\partial I_1}{\partial \eta}\frac{\partial I_2}{\partial \lambda_1}\right) \Big/ \left(\frac{\partial I_1}{\partial \lambda_1} - \frac{\partial I_2}{\partial \lambda_1}\right) \quad [19]$$
$$Y_2 = \partial (I_1 + I_2)/\partial \eta$$

Assuming the functional relations of Eq. [9], with $I_{20} >> I_{10}$ and $x_1 = \exp(e\eta/kT)$

$$1/\sqrt{\tau_1} = (I_{10}/\mathbf{F}\sqrt{D_2}[\mathrm{Cu}^{++}]_{eq})e^{-\alpha_1 e\eta/kT}$$
$$1/\sqrt{\tau_2} = (I_{20}/\mathbf{F}\sqrt{D_1}[\mathrm{Cu}^{+}]_{eq})e^{-\alpha_2 e\eta/kT}$$
$$Y_2 = (e\,I_{20}/kT)e^{(1-\alpha_2)e\eta/kT} \quad [20]$$
$$Y_1 = (2e\,I_{10}/kT)[(2-\alpha_1)e^{(2-\alpha_1)e\eta/kT} + \alpha_1 e^{-\alpha_1 e\eta/kT}]$$

It should be evident that Y_1 is the derivative of Eq. [3].

Heuristic estimates for a 1M solution at equilibrium with $I_{10} = 2$ mA/cm² and $I_{20}/I_{10} > 30$ yield $\tau_1 = 2 \times 10^4$ sec and $\tau_2 < 10^{-5}$ sec. The low frequency dispersion will be quenched by a finite diffusion layer thickness. At sufficiently cathodic potentials, *i.e.*, in the limiting current region, τ_1 will decrease sufficiently for this dispersion to appear. It should be possible to characterize the high frequency dispersion at $\eta = 0$ for the lowest estimate of I_{20}, but increasing I_{20} by an order of magnitude shortens τ_2 by a factor of 100, shifting the high frequency dispersion beyond the accessible experimental range. Best chances for detecting τ_2 would be in concentrated solutions at large anodic potentials. Thus, at +200 mV for $\tau_2 > 10^{-6}$ sec, $I_{20} < 10$ A/cm². When $1/\tau_1 << \omega << 1/\tau_2$, Eq. [17] reduces to

$$Y^* = Y_1 + \sqrt{i\omega}\frac{e\mathbf{F}}{kT}\sqrt{D_1}[\mathrm{Cu}^+(\mathrm{O})] \quad [21]$$

This expression is equivalent to Eq. [8] which was found to provide a good description of low frequency data.

Turning now to our experimental results, analyses of numerous runs gave high frequency capacitance values of 20-25 μF/cm² for deposits grown at a fixed overpotential. While slightly higher values appeared for surfaces formed during potential cycling, no major reproducible dependence of C_∞ upon deposition conditions, deposit thickness, potential, or chloride concentration was apparent. This limiting capacitance may be attributed to the double layer, and our values are comparable with recent data of Slaiman and Lorenz (8). Variations can be rationalized by minor surface roughness changes, although the narrow range observed indicates that roughness is probably determined by the platinum substrate.

Using Eq. [21] and the results of Tindall and Bruckenstein for D_1 and K_{eq} (16), the BEM predicts $W = 5.2 \times 10^{-3}$ mho-sec$^{1/2}$/cm² at equilibrium, in excellent agreement with our measurements (Table I). The values for Y_1 are also commensurate with Tafel results for I_0, indicating the absence of major additional low frequency dispersions.

Equation [17] suggests that the curvature seen in Fig. 1c may be due to a finite Y_2. A plot of $1/(Y_e^* - Y_1)$ should then give a 45° line with a high frequency intercept $1/Y_2$. In making this plot (Fig. 12), it is apparent that slight errors in C_∞ lead to large errors in Y_2. Given the uncertainty in finding C_∞ by extrapolation (Fig. 1b), $Y_2 = 10\text{-}25$ mho/cm², or $I_{20} = 0.25\text{-}0.65$ A/cm². Corresponding values for τ_2 are $4\text{-}30 \times 10^{-8}$ sec and show that even 100 kHz is too low a frequency to furnish a reliable estimate for I_{20}.

No obvious explanation for the effects of chloride ions were evident from these equilibrium studies. The double-layer capacitance showed no shift indicating large roughness changes. The BEM predicts that W depends upon equilibrium rather than kinetic parameters, and changes in W were indeed small. The decrease in Y_1 for 10^{-4}M chloride and subsequent rise at 10^{-3}M were reproducible, and a BEM interpretation would suggest an influence upon the exchange current of the redox reaction. Complex capacitance plots were erratic at high frequencies in these solutions and estimates of Y_2 were not feasible. There was no indication in admittance plots, however, of a reduction in Y_2 beyond the uncertainties in its evaluation.

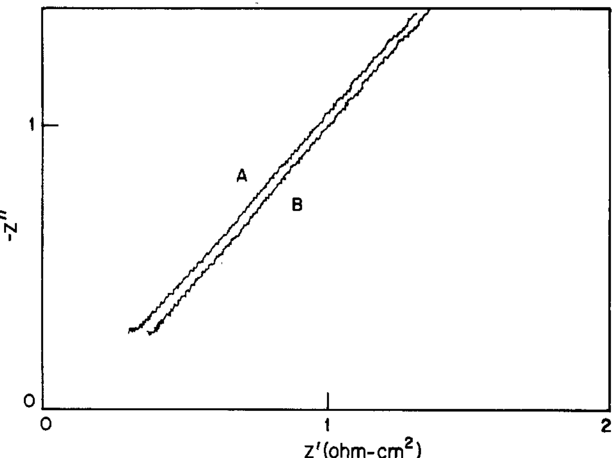

Fig. 12. Complex impedance plot for the estimation of Y_2 (see text). Values for C_∞ are (A) 20.4 F/cm² and (B) 21.4 F/cm².

One might conclude from an equilibrium analysis that the BEM provides an excellent explanation for the electrode response function, with no need for the invocation of crystallization or other processes. Such a conclusion was reached by Burrows, Harrison, and Thompson (14). Unfortunately, the problem is not so clear-cut. The equilibrium cuprous ion concentration should vary as $[\mathrm{Cu}^{++}]^{1/2}$, yet the variation of W is significantly less (Fig. 3). That data for an 0.25M $CuSO_4$ solution agree so well with the Tindall-Bruckenstein diffusion coefficient and equilibrium constant values appears somewhat fortuitous. Despite numerous attempts involving variously formed and aged copper surfaces, we have not been able to obtain a W value greater than 6×10^{-3} in a 1M solution, although, by comparison with 0.25M results, 1×10^{-2} is expected. The intercept Y_1 also varies more as the 0.4 power of concentration than the 0.75 power predicted by the Mattson-Bockris model for $\alpha = 0.50$. This discrepancy has been found in other concentration studies (4, 19). It has been attributed to surface differences for deposits formed under different conditions (4), but what these differences are remains unanswered. They are not apparent in the double-layer capacitance.

For 0.005-1.0M solutions complex admittance plots were linear between 50 and 1500 Hz, making angles of 45° ± 2° with the real axis. Often, but not reproducibly, a deviation with a positive curvature was seen below 50 Hz. This additional dispersion was most evident with surfaces which had remained for some time near $\eta = 0$. It was further noted that current-voltage cycling curves between +5 and −20 mV concurrently developed a slight hysteresis loop with inflection points near 0 mV on anodic traces and −10 mV on cathodic traces. The loop was independent of sweep rate for 1-20 mV/sec rates. The details of the low frequency response changes could not be determined from measurements above 1 Hz, but rough estimates suggest an admittance magnitude of 0.05 mho/cm² and a relaxation time > 0.1 sec. Formally a capacitance of 5×10^{-3} F/cm² may be inferred, and, for unit charges, a surface density of 10^{15} cm^{-2} ($C = Ne^2/kT$). Values for W and Y_1 obtained from data above 50 Hz indicated no significant changes as this added dispersion developed.

It is tempting to suppose that this irregular behavior reflects morphological or crystallization processes, for it is difficult to rationalize the surface density estimate and the narrow potential range cited in terms of impurity effects. The equivalent low frequency circuit predicted by the BEM (Eq. [21]) is the parallel combination of resistive and Warburg admittances. The additional low frequency dispersion requires the insertion of a complex admittance in the resistive path, which is tantamount to a modification of the redox reaction. One would have anticipated a crystallization impedance to appear in series with the Warburg path. We can not recreate the shape of the low frequency dispersion by adding plausible elements in this path. The conventional adatom model may be represented by a parallel *R-C* circuit (20, 21), and leads to deviations in the wrong direction. Previous studies of silver electrocrystallization have found that an admittance proportional to $\sqrt{i\omega}$ also characterizes equilibrium response and is not due to bulk diffusion (22, 23). If such an element were inserted in the deposition portion of the circuit, $\sqrt{i\omega}$ dependence would be retained, but *W* would be less than predicted for cuprous ion diffusion. This could explain why, at high concentrations, *W* levels off instead of increasing as expected.

Examination of electrode response as a function of potential offers a more critical test of the BEM. Within ± 25 mV of equilibrium the response function behaved as predicted, approaching the real axis at 45° at low frequencies (Fig. 4). Analysis of the curvature in these plots at high frequencies (*c.f.* Fig. 12) gave $Y_2 = 18$ mho/cm² at equilibrium, while the variation of Y_2 with potential indicated $\alpha_2 \sim 0.4$ (Eq. [20]). Use of the smaller electrode lessened the importance of electrolyte resistance and increased the accuracy of high frequency results. These are still quite sensitive to errors in C_∞, but they do support the hypothesis that the curvature in Y^* plots is due to a finite Y_2.

The predictions of the BEM are not fulfilled at potentials farther from equilibrium. The low frequency curvature appearing at the higher anodic potentials can be simulated by insertion of a capacitance, ~ 200 μF/cm², in series with the Warburg admittance for cuprous ion diffusion. Below -75 mV a dispersion remains which is not consistent with the BEM. A capacitive interpretation suggests a possible double-layer process, and the dispersion is not unlike that observed in the double-layer region of the Pt/H_2SO_4 interface (15). Both anodic and cathodic deviations from BEM behavior were suppressed upon addition of 10^{-4}M chloride.

Changes in relaxation parameters with potential are seen more clearly in $Y_\omega^*(\eta)$ experiments. When cupric ion concentration polarization is negligible, the BEM predicts that Y^* varies as $\sqrt{i\omega}$ at low frequencies (Eq. [21]) and linearly with the surface cuprous ion concentration. Hence plots of $Y''/\sqrt{\eta f} = W$ should be independent of frequency and increase exponentially with potential. Within ± 25 mV of equilibrium Fig. 6 shows this to be the case. The anodic maximum is clearly inconsistent with the BEM, while the maximum seen at -100 mV is also not explained. Comparison of a log plot of *W* with BEM theory based on the Tindall-Bruckenstein parameters (Fig. 13) shows agreement only in magnitude near $\eta = 0$.

The variation of Y_e' at 15 Hz is plotted in Tafel fashion in Fig. 14. Anodic and cathodic slopes are 48 and 160 mV/decade, values similar to those found directly from current-voltage measurements. According to Eq. [20], from the minimum at -40 mV, $\alpha = 0.35$, while from the ratio Y_{min}'/Y_{eq}' one finds $\alpha = 0.45$. These values are consistent with the cathodic Tafel slope, although the agreement is not overly impressive, and Eq. [20] provides only a rough description of this curve.

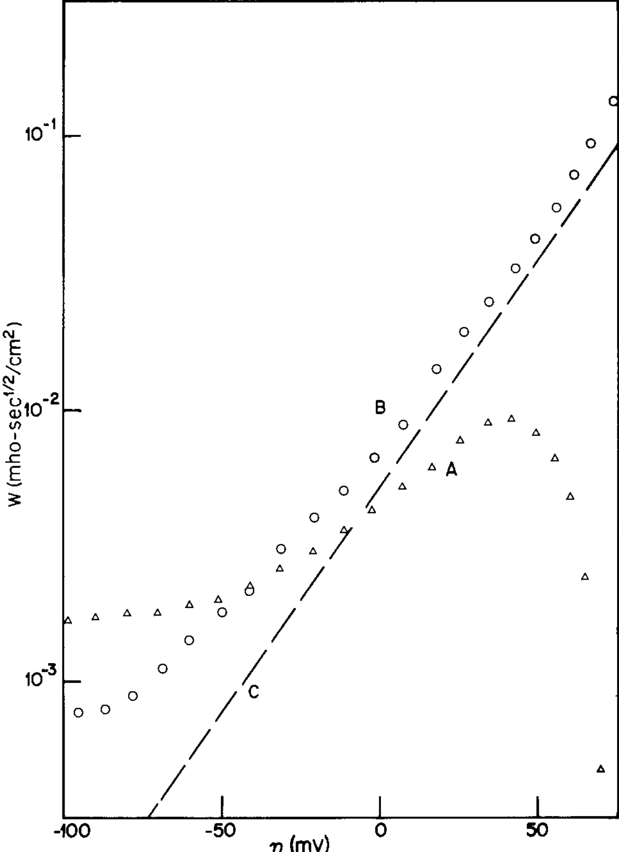

Fig. 13. Log plot of *W* vs. potential for (A) chloride-free solutions, (B) 10^{-4}M chloride solutions, and (C) a theoretical plot based on Tindall-Bruckenstein parameters.

Addition of 10^{-4}M chloride produces striking changes. A Tafel plot of Y_e' (Fig. 14) agrees with current-voltage measurements having cathodic and anodic slopes of 110 and 45 mV/decade. From either the potential for which Y_e' is a minimum or the ratio

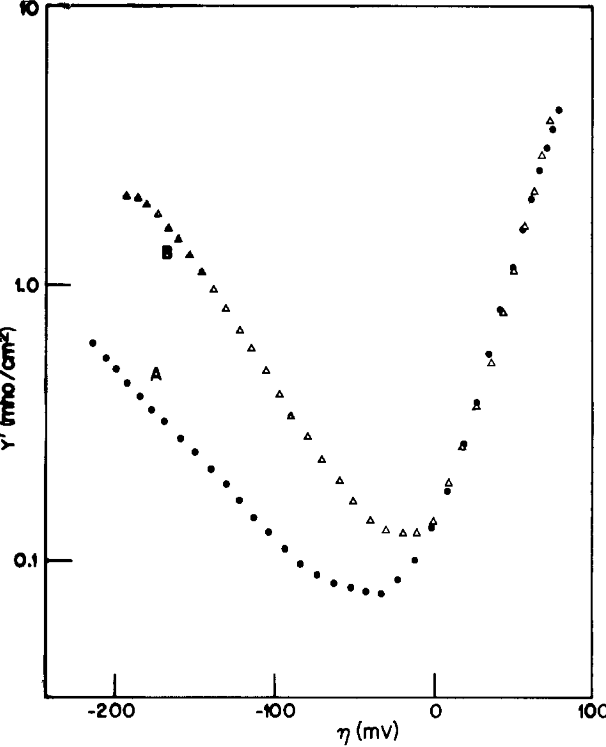

Fig. 14. Log plot of $Y_\omega'(\eta)$ for (A) chloride-free and (B) 10^{-4}M chloride solutions for 15 Hz data.

Y_{min}'/Y_{eq}' one finds $\alpha = 0.53$, in accord with the cathodic slope and Eq. [20].

Plots of $Y_e''/\sqrt{\pi f}$ also agree quite well with the BEM (Fig. 7). From 17 Hz to 10 kHz they are independent of frequency above -100 mV. A log plot *vs.* potential is linear with a 61 mV/decade slope (Fig. 13) precisely as expected if the dispersion is due to cuprous ion diffusion. Below -100 mV the plots again rise. For frequencies below 200 Hz the rise varies as $1/\omega$, and may be quantitatively explained by cupric ion diffusion. The d-c currents are significantly larger at these cathodic potentials in chloride solutions because of the increase in α, and the relaxation time, τ_1, has decreased sufficiently for the low frequency dispersion due to Cu^{++} to appear. Above 200 Hz, however, the cathodic rise requires an alternative explanation.

The ability of dilute chloride solutions to "clean up" the relaxation characteristics of copper electrodes is most evident in measurements of this form. Varying chloride concentrations showed that 10^{-5}M was a critical concentration for an electrode rotational speed of 200 rad/sec. Between 3×10^{-5} and 10^{-3}M, changes were comparatively minor, while above this range an additional hump appeared in $Y_\omega''(\eta)$ plots which was attributed to precipitation of CuCl. Slight changes could be seen upon addition of 10^{-6}M chloride, but this level could be comparable to residual chloride in solution (35 ppb).

A physical picture of the electrode processes is helpful for discussing changes in relaxation behavior. At the surface, possibly at preferential sites, a rapid exchange occurs between the metal and cuprous ions. On our shortest time scale, 10^{-6} sec, these ions will diffuse about 250Å, and a uniform surface concentration should then be established. Within the solution a diffuse cloud of cuprous ions extends outward through the Nernst layer, which is about 10^{-3} cm thick for our experiments. Following a small anodic change in electrode potential, a new surface concentration is quickly established. The added ions diffuse from the surface and are replaced by further metal dissolution. It is this time-dependent flux which is responsible for the experimental relaxation. A steady-state profile is established after about 0.3 sec, and the relaxation ceases. In this state the cloud continues to be drained by diffusive escape through the Nernst layer and the surface redox reaction. The latter does not contribute to a relaxation if cupric ion concentration polarization is negligible, for it depends only upon the surface density of cuprous ions which very rapidly adjusts to this sink.

The changes seen in chloride-free solutions at high anodic overpotentials occur below 1-3 kHz, or after about 10^{-4} sec. This would indicate a change in those cuprous ions which have been able to diffuse ~3000Å into solution. This distance is comparable with surface roughness, and one might anticipate a change in behavior as the concentration contours shift from the microscopic to the geometric surface. There is no evident reason, however, why $\sqrt{i\omega}$ response should not resume at lower frequencies, with W values decreased by a surface roughness factor.

If one postulates a reactive decay path in solution such that

$$\frac{d}{dt}[Cu^+(x)] = D\frac{\partial^2}{\partial x^2}[Cu^+(x)] - k[Cu^+(x)] \quad [22]$$

then Eq. [21] becomes

$$Y_e^* = Y_1 + \sqrt{i\omega + k}\,\frac{e\mathbf{F}}{kT}\sqrt{D_1}[Cu^+(O)] \quad [23]$$

At low frequencies this expression is equivalent to a parallel R-C circuit. The shape of this function in the complex plane is similar to that observed at large anodic overpotentials, and the capacitances measured are in accord with our estimates for k and $[Cu^+(O)]$.

Disproportionation

$$2Cu^+ \rightarrow Cu^{++} + Cu \quad [24]$$

is a possible explanation for the disappearance of cuprous ions under anodic conditions where their concentration exceeds its equilibrium value. This reaction, however, does not occur homogeneously, but only at metallic copper surfaces (24). Practical experience has shown that copper particles are formed at copper anodes (24, 25), and we may postulate that at large anodic overpotentials clusters of copper atoms break away from the surface and diffuse into the Nernst layer, providing nuclei for the disproportionation reaction. The nuclei will grow in size until the local cuprous concentration is reduced to its equilibrium value, and then they may either escape into the bulk electrolyte or, with a greater probability, diffuse back to the anode and dissolve electrolytically. Should they break away before the latter process is completed, a renewable source of nuclei would be established.

An upper limit can be set for the rate constant if disproportionation is limited by diffusive meetings of cuprous ions and spherical clusters

$$k = 4\pi D R_m N_m \quad [25]$$

where R_m is the cluster radius and N_m their number density (26). Setting the particle volume equal to their accrete atomic volume

$$(4\pi/3) R_m^3 N_m = N_{Cu} + v_{Cu} \quad [26]$$

For $k \simeq 10^4$ sec^{-1}, we obtain $R_m = 34$Å and $N_m = 2 \times 10^{14}$ cm^{-3}. These appear to be feasible values for the 3000Å solution layer near the surface. The diffusion coefficient for a particle of this size is ~10^{-6} cm^2/sec, and re-encounters with the electrode should occur in 10^{-3} sec. There is some indication in the experimental data (Fig. 6) that the negative or inductive low frequency response peaks between 100-200 Hz, and this is consistent with surface fluctuations due to particle re-encounters. We trust it apparent that these heuristics are not a rigorous calculation. A proper treatment considering the spatial and temporal changes in cuprous ion concentration and particle size and diffusion is beyond the scope of this discussion.

The large change in low frequency anodic response following chloride ion addition provides a means to investigate their role in copper electrode kinetics. The most sensitive experiment is a measurement of $Y_\omega''(\eta)$ near 100 Hz. When the bulk chloride concentration is 10^{-5}M and cycling takes place between -300 and $+200$ mV at 20 mV/sec, only a small effect is noted when the electrode's rotation is less than 10 rad/sec, while at 400 rad/sec the changes approximately equal those in 10^{-4}M to 10^{-3}M solutions. The latter response is seen if plating occurs at 400 rad/sec, the potential scan is halted for 15 sec at $\eta = 0$ with rotation off, and the anodic scan then resumed with no rotation. It also occurs if plating takes place at 0 rad/sec, the scan is halted at $\eta = 0$ for 15 sec and rotation stepped to 400 rad/sec before resuming the sweep. When plating and stripping both occur at 0 rad/sec, but during a hold at $\eta = 0$ rotation is increased, the anodic response depends upon both the holding time and the rotational speed. At 400 rad/sec optimum changes follow a 10-20 sec pause, while at 100 rad/sec a 20-40 sec halt is needed for an equivalent response. These results show that the chloride effect is determined by diffusion and that 10^{15} ions/cm^2 are involved. Because the effect appears in the absence of a hold with plating at 400 rad/sec, it appears that the accumulation of surface chloride is unimpeded by deposition. The large numbers suggest formation of a full surface layer of chloride, not just preferential adsorption at specific sites, and the layer must be sufficiently tenacious to ride out vigorous surface changes at large anodic and cathodic current densities. The electrostatic energy for such a

high ionic coverage would prevent its formation unless compensating cations are also present, and we suggest that the surface is covered by a monolayer of CuCl. Based on the solubility product of CuCl, 10^{-6}, formation of a bulk surface deposit is only expected for chloride concentrations greater than 10^{-3}M, and a true surface species must be involved.

The presence of a surface chloride layer could affect disproportionation by either impeding the flux of metallic nuclei into solution or retarding the reaction at cluster surfaces. The former explanation is more likely, for there are insufficient ions in solution to mask a growing surface, and the high exchange current of the $Cu^+ \rightarrow Cu$ reaction is not greatly reduced by chloride. Whether chloride additions are beneficial in controlling anodic reactions in plating baths is debatable, for while the rate of formation of fines may be reduced, there will be an attendant accumulation of Cu^+ in solution which may disproportionate at undesirable sites.

Near equilibrium and at cathodic potentials, as is evident in Fig. 13, the variation of W with potential in chloride-free solutions is less than predicted by the BEM. Either the apparent surface concentration of Cu^+ is "buffered" by kinetics or W is dependent on other factors. One possible deposition path would be the surface reduction of Cu^{++} to Cu^+, followed by the diffusion of Cu^+ to lattice incorporation sites. This might create a bottleneck leading to an excess surface accumulation of Cu^+ at cathodic potentials.

We can estimate this effect in the following manner (27). Assume that crystal growth occurs only at linear steps of length L, and that a hemicylindrical diffusion zone exists along the step, with rapid equilibration at a distance a of atomic dimensions. Then, within this zone the cuprous concentration will vary as

$$c(r) - c(a) = (c_\lambda - c_a)\frac{\ln r/a}{\ln \lambda/a} \qquad [27]$$

where the distance λ is a measure of the size of the zone, which we assume equals half the step spacing. In the steady state let us equate the inward flux at a with the redox flux which we assume to be generated uniformly on the plane between steps. Making the crude approximation that the surface concentration on this plane is equivalent to c_λ

$$-\frac{\pi DFL(c_\lambda - c_a)}{\ln \lambda/a} = 2\lambda L I_{10}[(c_\lambda - c_a) \exp(1-\alpha_1)e\eta/kT - \exp(-\alpha_1 e\eta/kT)] \qquad [28]$$

Upon solving for c_λ and I, with $c_a = c_e \exp(e\eta/kT)$

$$c_\lambda/c_e = \frac{\exp(e\eta/kT) + (I_{10}/I_c)\exp(-\alpha_1 e\eta/kT)}{1 + (I_{10}/I_c)\exp[(1-\alpha_1)e\eta/kT]} \qquad [29]$$

$$I = 2I_{10}\frac{\exp(2-\alpha_1)e\eta/kT - \exp(-\alpha_1 e\eta/kT)}{1 + (I_{10}/I_c)\exp[(1-\alpha_1)e\eta/kT]}$$

where

$$I_c = \frac{\pi DFc_e}{2\lambda \ln \lambda/a} \qquad [30]$$

If for estimates we take $\lambda = 10^{-6}$ cm and $a = 2 \times 10^{-8}$ cm, $I_c = 200$ mA/cm^2.

Anodic Tafel plots will show a negative curvature, shifting to a 60 mV/decade slope above 240 mV if $\alpha_1 = 0.5$, while the surface cuprous concentration should rise at potentials below -90 mV. Provided the value chosen for λ remains feasible under high current density conditions, this bottleneck could explain Tafel curvatures and the frequency-independent rise of W at cathodic potentials in chloride solutions. It does not explain deviations near equilibrium, for the ratio I_{10}/I_c is far too small.

If a hemispherical diffusion zone were postulated, corresponding to diffusion to kinks instead of steps, a similar level of analysis yields

$$I_c = \pi DFa\, c_e/2\lambda^2 \qquad [31]$$

or $I_c \sim 16$ mA/cm^2. Even in this more restrictive model one cannot explain the behavior near $\eta = 0$, although much larger changes are predicted at anodic and cathodic potentials than are actually observed.

An alternative possibility is that an additional mechanism is inserting an admittance also varying as $\sqrt{i\omega}$ in series with the Cu^+ diffusional admittance. The required value is of order 10^{-2} mho-sec$^{1/2}$/cm^2. Studies of silver deposition revealed such an admittance with $W = 0.03$, and no apparent concentration dependence (23). If such an admittance were present in our copper studies it would explain both the constancy of W values at high cupric concentrations and the reduced potential dependence of W. An analogy between silver and Cu^+/Cu deposition seems reasonable, but unfortunately we lack a satisfying interpretation for the process responsible for the $\sqrt{i\omega}$ relaxation behavior. It is not compatible with the adatom diffusion models which have been analyzed in considerable detail.

The frequency dispersion of W at potentials below -25 mV (Fig. 6) remains unexplained. $W_\omega(\eta)$ plots might be interpreted as showing an adsorption maxima at -100 mV. From C^* plots the equivalent dispersion amplitude is about 50 μF/cm^2, equivalent to 10^{13} atoms/cm^2, and the response time is 10^{-4} sec. A double-layer relaxation involving specific adsorption is the simplest explanation. The potential of zero charge for copper is -240 mV with respect to the equilibrium potential (28), and is not correlated with the -100 mV peak. Chloride adsorption appears to quench this dispersion, but our experimental results are insufficient to justify an interpretation. Morphological investigations have revealed considerable changes in the growth habit of copper deposits between 0 and -200 mV (29-31). It is tempting to suppose that these variations are in some manner reflected in our admittance results, but no connection is obvious. The high frequency double-layer capacitance is independent of potential in this region and offers no evidence for changes in the microscopic surface.

Conclusions

Near equilibrium, the two-step model proposed by Mattson and Bockris for copper electrodes generally agrees with admittance measurements if allowance is made for the diffusion of cupric and cuprous ions and a finite exchange current for the crystallization reaction. Analysis of this model leads to an equivalent circuit description with parallel contributions from the redox and crystallization reactions. The complex-plane reduction of experimental data can reveal which branch is affected when deviations from this model are encountered. At anodic potentials the exponential increase in cuprous ion concentration is quenched, and this has been attributed to disproportionation and the growth of metallic clusters in solution. In the cathodic region only a comparatively small surface dispersion was found, and this could be due to a double-layer relaxation. The addition of low concentrations of chloride leads to the rapid formation of a surface monolayer which increases the cathodic Tafel slope, eliminates anodic disproportionation at the electrode, and reduces the cathodic dispersion.

No clear-cut evidence for crystallization-controlled kinetics was found for freshly formed surfaces. Aged surfaces did exhibit irregularities which might be construed as due to cooperative processes. Other "inconsistencies" begging further explanation are the concentration dependences of the relaxation parameters Y_1 and W, and the potential dependence of W.

Experimental Study of the Gas Bubble Effects on the IR Drop at Inclined Electrodes

G. Kreysa* and H.-J. Külps

Dechema-Institute, 6000 Frankfurt/M. 97, Germany

ABSTRACT

The existence of a gas evolving electrode in industrial electrolysis cells may greatly increase the cell voltage due to the additional *IR* drop caused by the gas bubbles. The main area of expanded metal electrodes as they are used in the industry consists of inclined planes. It was therefore considered of interest to study the influence of the inclination angle on the *IR* drop caused by the gas layer at an inclined hydrogen evolving electrode. Evaluation of *IR* drop measurements at various current densities shows that slightly up-facing oriented electrodes ($\alpha = -15°$) have a gas layer of an optimum state in terms of a minimum *IR* drop. A simple model of the motion of gas bubbles near the electrode surface allows the dependence of the *IR* drop on the inclination angle to be calculated. Calculations based on this model show good agreement with experimental results.

In practical electrolysis processes involving gas evolving electrode reactions the effect of the gas bubbles on the electrolyte resistivity is an important factor. Depending on the magnitude of the current density this bubble effect causes an additional *IR* drop increasing the cell voltage by about 100-200 mV and thus the specific energy consumption of the chemicals produced. A number of authors have already investigated the effects of gas bubbles on the electrolyte resistivity, cell voltage, and the current density distribution both by experimental studies and theoretical

* Electrochemical Society Active Member.

Key words: gas evolution, theoretical model, optimization, electrolysis.

models. Most of these papers deal with gas bubble *IR* effects in narrow flow channels with planar electrodes (1-6) or the mass transfer enhancement due to the gas bubbles (6-14). However, in industrial electrolysis cells planar electrodes are relatively rare and mainly machined block electrodes, mesh electrodes, and expanded metal electrodes are being used. Investigations of bubble effects on industrial electrodes have been carried out by Müller (15), Kuhn (16), and Jorne (17).

Expanded metal electrodes, as recently studied by Jorne (17), are mainly consisting of inclined electrode planes, the inclination angle being dependent on the degree of expansion. In industrial cells these electrodes are mounted with an up-facing inclination of the metal bands. This configuration allows the evolving gases to divert mainly on the back side of the electrode resulting in a lower *IR* drop.

Many papers have dealt with mass and heat transfer as well as natural convection at inclined gas evolving electrodes (18, 19). Some authors (20-22) have studied also the influence of the inclination angle more extensively. However, there is a lack of knowledge concerning the dependence of the *IR* drop caused by the gas bubbles on the inclination angle. The present work studies the *IR* drop due to the gas bubbles in the electrolyte and its dependence on the inclination angle of the electrode. An attempt was also undertaken to discuss the results in terms of a simple theoretical model.

In the following the sign of the electrode inclination angle is defined as shown in Fig. 1. Positive and negative signs refer to down-facing and up-facing inclinations of the electrode, respectively. Close to the electrode a gas layer with a finite thickness exists as was already assumed in a model proposed by Hine (3). If one considers the vectorial splitting of the rising velocity (u_{ss}) of the bubble swarm into two components, parallel (u_p) and normal (u_n) to the electrode, respectively, it results in an expansion of the gas layer at negative inclination angles and in a compression at positive ones. On one hand, the *IR* drop increases with increasing thickness of the gas layer; on the other hand, the decrease of the gas void fraction due to the gas layer expansion results in a decrease of the resistivity. Therefore, an optimum inclination angle corresponding to a minimum *IR* drop of the gas layer should exist.

The experiments described in this paper are aimed to verify the existence of an optimum inclination angle. The experimental conditions were chosen to allow a certain analogy to commercial expanded metal electrodes and, furthermore, to minimize the effect of the current distribution on the experimental results. Of course, the hydrodynamic conditions in a narrow gap are not the same as the undisturbed free convection which we have investigated.

Experimental

As a model system of a gas evolving electrode the hydrogen evolution on a planar platinum electrode was chosen. A 4m KOH solution with 0.5 g/liter isooctanol (6) was used as an electrolyte. The addition of this surfactant was important for obtaining reproducible results (6). The conductivity of the gas-free electrolyte was determined to 0.350 mho/cm and the kinematic viscosity was $2.23 \cdot 10^{-2}$ cm²/sec. The 1 × 1 cm platinum foil electrodes were fixed to a Perspex support. The small electrode size was chosen for two reasons. First, the dimensions of the metal bands of expanded metal electrodes should not be essentially exceeded. Second, the nonuniform current density distribution due to the bubble accumulation as studied by Tobias (1) should be almost avoided.

An inclination of the cathode alone would alter the potential and current density distributions due to the varying interelectrode gap. In order to avoid this complication the cathode and the anode were mounted on a pivoted disk in a fixed parallel position as shown in Fig. 2. Thus, the angle of the cathode could be varied by turning the disk without changing the relative position to the anode. The Luggin probe containing a saturated calomel electrode was mounted in a fixed position at a distance of 5 mm from the electrode. The distance from the electrode to the capillary was always larger than the thickness of the bubble layer. The electrolytic cell was controlled potentiostatically (Potentiostat LB 75M, Bank Elektronik, Göttingen), and between the potentiostat and the working electrode an electronic interrupter unit (Model PU1, Forschungsinstitut Meinsberg) was applied to measure the *IR* drop between electrode and Luggin probe (23). During each measurement the electrode polarization was varied with a scan rate of 1 mV/sec from 0 to −1V and from −1 to 0V using a voltage scan generator (Model VSG 72, Bank Elektronik, Göttingen). During the scanning the *IR* drop between electrode and Luggin probe was plotted on a X-Y-Recorder (Servogor XY, Type RE 551, Metrawatt, Nürnberg) as a function of the current density. Since the shape of these curves was independent of the the polarization direction, the equilibrium of dissolution of hydrogen was established. A schematic diagram of the experimental equipment is shown in Fig. 3. For a gas-free electrolyte the *IR vs. i* plot should result in a straight line. Due to the in-

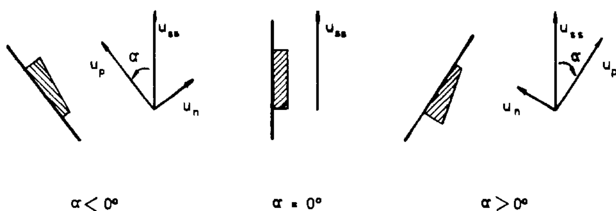

Fig. 1. Angle definitions for inclined electrodes and deformation of the gas bubble layer (shaded area).

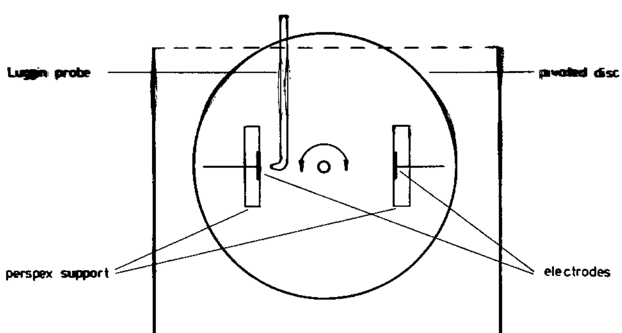

Fig. 2. Schematic view of the electrolysis cell

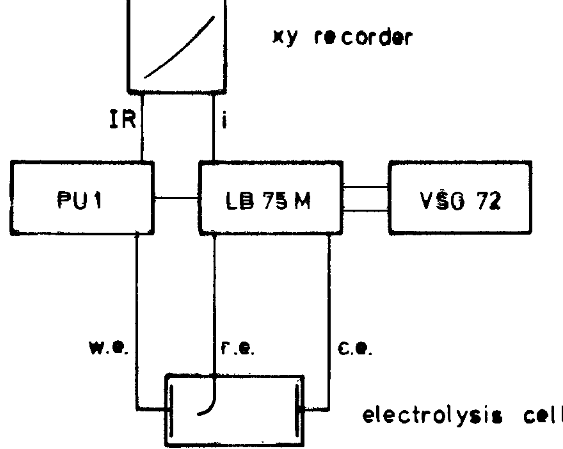

Fig. 3. Schematic diagram of instrumentation (w.e., working electrode; r.e., reference electrode; c.e., counterelectrode).

creasing gas evolution with increasing current density the experimentally obtained *IR* drop deviates from a linear dependence toward large *IR* values, *e.g.*, as shown in Fig. 4. A second-order regression polynomial can be fitted to the experimentally obtained *IR-i* plots.

The described experimental technique for measuring the *IR* effects of the gas bubbles offers the following advantages:

1. The actual electrode potential and the *IR* drop in the gas-containing electrolyte can be measured separately.
2. A single potentiokinetic scanning yields *IR* drop data for the whole current density range applied (up to 1 A/cm²).
3. *IR* drop oscillations due to the statistics of gas evolution can easily be equalized by a regression polynom.
4. The tangent of the *IR vs. i* curve at $i = 0$ corresponds to the *IR* drop for the gas-free solution. At any *i* value the difference between the overall *IR* drop and this straight line thus represents the additional *IR* drop caused by the gas bubbles.

It should be noted that the results given in the following do not cover all possibilities offered by this technique. Further investigations into this problem are being carried out.

Results and Discussion

In Fig. 5 the additional *IR* drop caused by the gas bubbles has been plotted as a function of the current density. The *IR* drop is obviously strongly dependent on the current density and reaches about 200 mV at 10 kA/m². Measurements similar to those shown in Fig. 4 were carried out at inclination angles ranging from −60 to +60°. Figure 6 shows a photograph of the gas-evolving electrode at an inclination angle of −30°. In this figure the expansion of the bubble layer as previously shown schematically in Fig. 1 is quite apparent. Measurements of the angular dependence of the *IR* drop were performed at current densities of 1, 3, and 5 kA/m² thus covering the range usually applied in industrial cells. Comparable results could be obtained for different current densities by applying the normalization

$$\Delta U = IR(\alpha) - IR(0) \quad [1]$$

The ΔU value in [1] represents the part of the *IR* drop which is dependent on the inclination angle. In Fig. 7 the angular dependence of ΔU values is shown for various current densities. From this figure it is obvious that the *IR* drop has a minimum at an electrode inclination of about −15° independent of the current density. It is interesting to note that due to the expansion degree the inclination of industrial expanded metal electrodes is usually close to this value. Furthermore, Fig. 7 shows that the angular dependence of the *IR* drop is clearly asymmetric. A compression of the

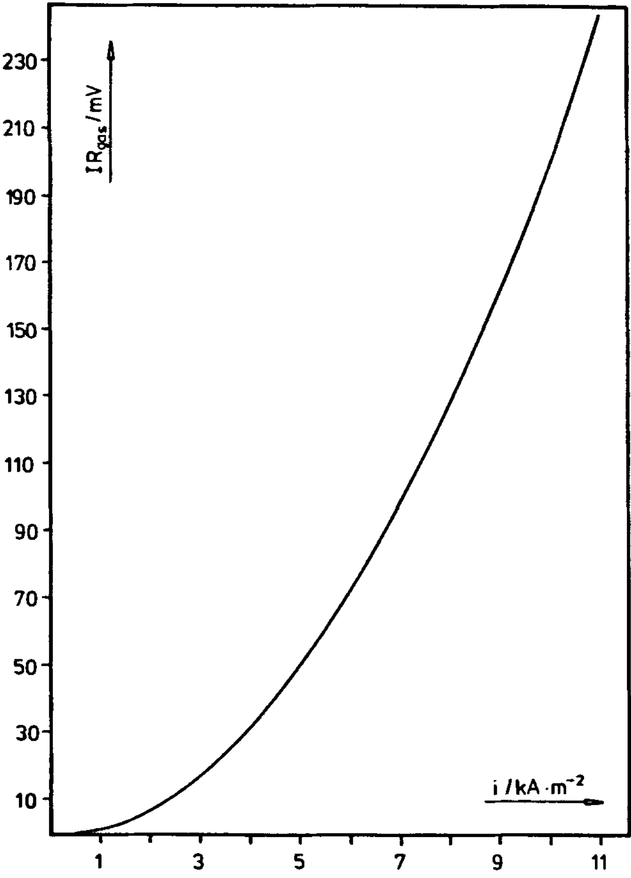

Fig. 5. *IR* drop due to the gas bubbles as a function of the current density ($\alpha = 0°$).

gas layer thus results in a markedly higher *IR* drop than an expansion.

In the following a theoretical model based on well-known principles of the gas bubble motion is suggested. This model reflects the experimentally obtained angular dependence of the *IR* drop if realistic parameter values are assumed. The following assumptions are made:

1. The gas bubbles have a uniform size, *i.e.*, their actual size distribution is disregarded.
2. Instead of the real gas layer expansion and the gas accumulation with height the gas layer is considered to have a defined mean thickness and a mean uniform gas void fraction as a first-order approximation.
3. Shape changes of the bubbles at various angles are ignored as a reasonable simplification of the real physical situation.

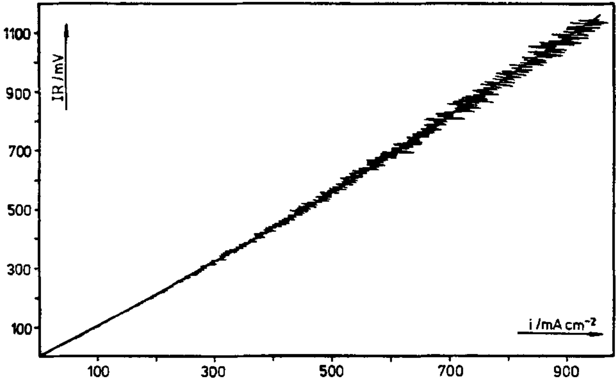

Fig. 4. Experimental plot of the *IR* drop *vs.* current density with the regression curve ($\alpha = 0°$).

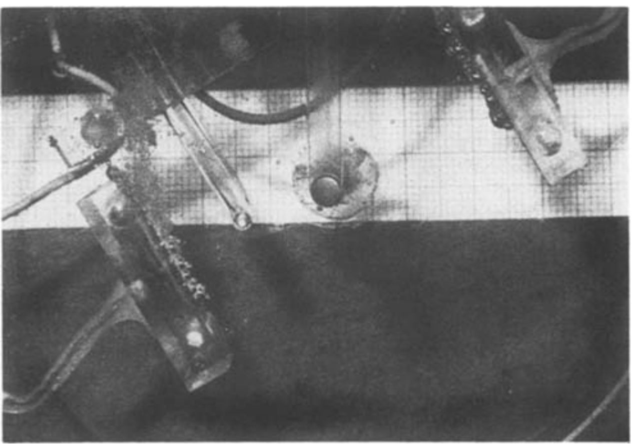

Fig. 6. Photographic picture of the gas evolving electrode at −30°.

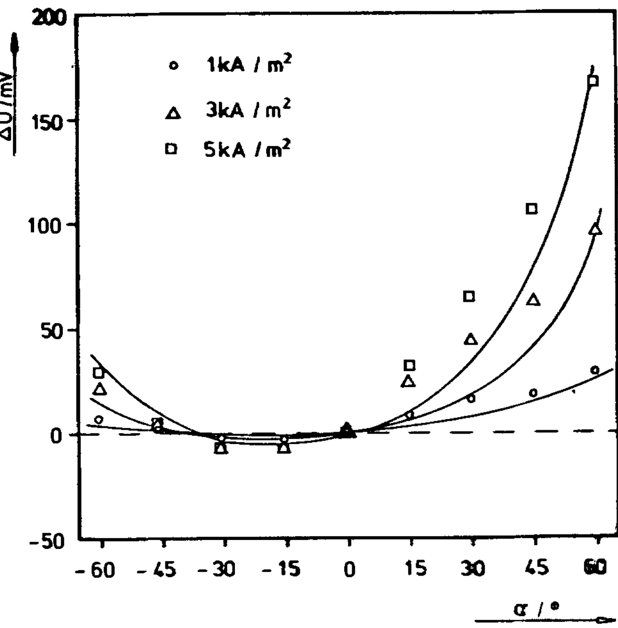

Fig. 7. Relative ΔU values (related to $\alpha = 0°$) vs. the angle of inclination and calculated curves.

4. On vertically positioned electrodes the bubble layer thickness increases with increasing current density, but the gas void fraction remains constant.
5. The gas flow velocity within the bubble layer is constant and equal to the sum of the electrolyte flow velocity due to natural convection and the rising velocity of the swarm of bubbles.
6. The electrolyte flow velocity due to convection depends on the inclination angle of the electrode.
7. The expansion and the compression of the bubble layer results from the vectorial splitting of the vertical rising velocity of the swarm of bubbles.
8. The current density distribution at the electrode is assumed to be uniform.

As the observed bubble diameter is smaller than 0.2 mm the rising velocity of a single bubble can be calculated using the Levich equation (24)

$$u_b = \frac{d_b^2 g}{12\nu} \quad [2]$$

The rising velocity of the swarm of bubbles is then given by Marucci's equation (25)

$$u_{ss}(0) = u_b \frac{(1 - \epsilon(0))^2}{1 - \epsilon(0)^{5/3}} \quad [3]$$

Sigrist (6) has experimentally demonstrated that at gas void fractions up to 0.6 the conductivity of the gas-containing electrolyte can be calculated by the Maxwell equation. For a vertical electrode this equation yields

$$\chi(0) = \chi_o \frac{1 - \epsilon(0)}{1 + \epsilon(0)/2} \quad [4]$$

From the gas flow velocity, u_g

$$u_g = u_l + u_{ss} \quad [5]$$

and Faraday's law the thickness of the bubble layer can be calculated for a vertical electrode provided that a constant gas void fraction is assumed

$$d(0) = \frac{V_M I}{z\mathbf{F} b \epsilon(0) u_g(0)} \quad [6]$$

The electrolyte flow velocity, u_l, results from natural convection due to the difference in hydrostatic pressure. If h_o means the height of the vertical electrode then

$$\Delta p_h \sim \epsilon(\alpha) h_o \cos \alpha \quad [7]$$

If the bubble layer is assumed as a flow channel, the pressure drop must fulfill the relation

$$\Delta p \sim u_l^2 \quad [8]$$

In the steady state the difference in hydrostatic pressure is equal to the pressure drop. Combination of Eq. [7] and [8] leads to the relation between the electrolyte flow velocity parallel to the electrode surface and the inclination angle

$$u_l(\alpha) = C(\epsilon(\alpha) \cos \alpha)^{1/2} \quad [9]$$

For a vertical electrode [9] can be written

$$u_l(0) = C\epsilon(0)^{1/2} \quad [10]$$

Assuming realistic values for $\epsilon(0)$ and $u_l(0)$ Eq. [10] can be applied to calculate the constant C. Due to the compression and expansion of the bubble layer, respectively, an inclination of the electrode results in a change of the gas void fraction and the thickness of the bubble layer. Similar to Eq. [3] the rising velocity of the bubble swarm at a gas void fraction $\epsilon(\alpha)$ can be written as

$$u_{ss}(\alpha) = u_b \frac{(1 - \epsilon(\alpha))^2}{1 - \epsilon(\alpha)^{5/3}} \quad [11]$$

The vectorial splitting of the bubble swarm velocity (see Fig. 1) into two components, one parallel ($u_{ss} \cos \alpha$) and one normal ($u_{ss} \sin \alpha$) to the electrode plane and using Eq. [5] and [9] leads to the equation

$$u_g(\alpha) = C(\epsilon(\alpha) \cos \alpha)^{1/2} + u_{ss}(\alpha) \cos \alpha \quad [12]$$

Using the normal component of the bubble swarm velocity gives the mean thickness of the compressed or expanded gas bubble layer

$$d(\alpha) = d(0) - \frac{h_o}{2u_g(\alpha)} u_{ss}(\alpha) \sin \alpha \quad [13]$$

According to Eq. [6] the gas void fraction of the bubble layer is given by

$$\epsilon(\alpha) = \frac{V_M I}{z\mathbf{F} u_g(\alpha) b d(\alpha)} \quad [14]$$

Equations [11] and [14] define $\epsilon(\alpha)$ and $d(\alpha)$ for each α and thus $\epsilon(\alpha)$ can be calculated by common numerical methods (*e.g.*, a uniform search method). The value introduced in Eq. [11] must be fitted in such a way that the value resulting from Eq. [14] yields the same result within the accuracy limits given. The Maxwell equation is again applied to obtain the conductivity of the bubble layer

$$\chi(\alpha) = \chi_o \frac{1 - \epsilon(\alpha)}{1 + \epsilon(\alpha)/2} \quad [15]$$

If a is the distance between electrode and the Luggin probe it follows from Ohm's law

$$IR(0) = \left[\frac{d(0)}{\chi(0)} + \frac{a - d(0)}{\chi_o} \right] i \quad [16]$$

and

$$IR(\alpha) = \left[\frac{d(\alpha)}{\chi(\alpha)} + \frac{a - d(\alpha)}{\chi_o} \right] i \quad [17]$$

By introducing Eq. [16] and [17] in Eq. [1] and simple algebraic steps one obtains the angle dependence equation of the normalized part of the IR drop of the gas bubbles

$$\Delta U = i \left[\frac{d(\alpha)}{\chi(\alpha)} - \frac{d(0)}{\chi(0)} + \frac{1}{\chi_o} (d(0) - d(\alpha)) \right] \quad [18]$$

In the list of symbols the parameter values defined by the experimental conditions used for the calculation of the ΔU functions are given. The theoretical model

contains three further parameters which must be estimated by assuming realistic values

$$d_b = 0.012 \text{ cm}$$

$$\epsilon(0) = 0.45$$

$$u_l(0) = 2.0 \text{ cm/sec}$$

The assumed bubble diameter is in close agreement with data of other authors (2). Unfortunately, the real bubble diameter cannot be taken from Fig. 6 because large adhering bubbles on the edge of the electrode hide the small bubbles in front of the electrode. However, these small bubbles are detectable in the rising swarm far from the electrode. The electrolyte flow velocity represents the main part (about 90%) of the gas flow velocity and can be estimated by visual observations. Introducing an estimated value of the bubble layer thickness into Eq. [6] yields the gas void fraction given above for a vertical electrode. Theoretical ΔU functions calculated with this model using the above-mentioned data are shown also in Fig. 7. In agreement with the experimental data the theoretical curves also show the minimum at $-15°$ and the asymmetric shape. Considering that the theoretical model was based on several simplifying assumptions the agreement between experiments and theoretical calculations may be regarded as satisfactory. Regarding the *IR* drop minimum at $-15°$ it should be mentioned here that for a natural convection flow around a plate at nearly the same angle Lloyd (20) has found a transition from wave-type flow disturbances to longitudinal vortices. In a mass transfer study at inclined gas evolving electrodes Wragg (22) also obtained a local minimum of the Sherwood number in the same range of inclination angles. A possible relation between these interesting observations cannot be clarified in the present state.

Conclusions

The present investigation has shown that a change of the state of the gas bubble layer in front of an inclined electrode is accompanied by a marked change of the *IR* drop which may amount up to 200 mV. This demonstrates that in industrial electrolysis cells the inclination of the metal bands of the electrode is an important factor, especially if expanded metal electrodes are used. Independent of the current density, the gas bubble layer has an optimum structure in terms of a minimum *IR* drop at an inclination angle of $-15°$. However, the *IR* drop minimum shows a flat range between $15° \geqq \alpha \geqq -45°$. This means that an angle can be chosen within this range relatively freely that is optimum to meet other goals as, *e.g.*, the diversion of the gas bubbles which is also influenced by the hydrodynamic conditions in the electrode membrane gap. There is a need of further detailed investigations. The inclined surfaces of commercial expanded metal electrodes usually have an inclination within the optimum range. Thus, it seems reasonable that the ohmic drop saving of these electrodes is not only caused by enabling the diversion of the gas to the rear of the electrode, but also due to an optimum state of the bubble layer at this inclination angle.

The Polarography of Vitamin B_{12a} in Acidic Media

Ronald L. Birke* and S. Venkatesan*

The City University of New York, Department of Chemistry, The City College, New York, New York 10031

ABSTRACT

The nature of the polarographic reduction wave of vitamin B_{12a} in acidic media (*p*H 1-5) has been investigated. The wave exhibits a region of negative differential resistance which is due to the blockage of the electrode reaction by adsorption of a reduced species and by a double layer repulsion effect. A protonation step follows the electroreduction of vitamin B_{12a} to vitamin B_{12r} and the protonated vitamin B_{12r} is adsorbed on the dropping mercury electrode. The pK_a for this follow-up protonation step has been measured, and the mechanism of the electrode process is discussed.

Since the oxidation-reduction chemistry of vitamin B_{12} compounds plays a definite role in many important biochemical processes, there has been much interest in the electrochemistry of these bioinorganic compounds (1). There are many forms of the vitamin which have the so-called Cob(III)alamin structure with a cobalt ion in the 3+ oxidation state as the central atom and various substituted axial ligands in the β position (2). We have studied the electrode processes of the aquo-substituted Cob(III)alamin complex, vitamin B_{12a}, because reduction of any other axial substituted form of Cob(III)alamin and subsequent reoxidation usually gives aquocobalamin, *i.e.* vitamin B_{12a}. Various features of the polarography and cyclic voltammetry of vitamin B_{12a} have already been studied by several investigators using mercury and other electrodes in acidic to neutral aqueous media (3-11). The reduction process is well established as two separate one-electron transfers yielding two well-separated polarographic waves. The second step representing the reduction of vitamin B_{12r} (Co(II)) to vitamin B_{12s} (Co(I)) is coupled to the opening of the nucleotide side chain in neutral *p*H and becomes a simple reversible electron transfer reaction if the supporting electrolyte is a strong acid. A good deal of attention had been focused on this process (5, 6). Less attention has been given to the reduction of vitamin B_{12a}, Co(III), to B_{12r}, Co(II), because of its irreversible nature. A recent investigation deals with the B_{12a}/B_{12r} system electrode process on vitreous carbon and gold electrodes (12) over a wide *p*H range. The nature of the adsorption of vitamin B_{12a} and B_{12r} on mercury has been studied by cyclic voltammetry, chronopotentiometry, and differential double layer measurements (11). Spectroelectrochemical studies (13, 14) have also been made which involve determining the electrode potential of the vitamin B_{12a}/B_{12r} couple, but no attempt has been made to explain the electrode process in the polarographic wave for this couple in the concentration range above 1×10^{-5}M. This electrode process has a rather unusual polarographic behavior which warrants further investigation. In neutral *p*H the first polarographic wave of vitamin B_{12a} has a depression on the rising portion of the first wave as it slowly rises to a plateau while in more acidic media such as acetate buffer (*p*H 4.5 in 0.5M $NaNO_3$) a maximum develops at *ca.* -0.1V *vs.* SCE followed by a minimum at *ca.* -0.18V *vs.* SCE and then the wave slowly rises to a plateau at -0.4V *vs.* SCE (7). Imhoff (7) attributed the depression to adsorption on the dropping mercury electrode (DME). He also found from differential double layer capacity studies that vitamin B_{12r} was strongly adsorbed on the mercury surface in the region of the depression. These results have been confirmed recently (11).

Preliminary investigations in this laboratory indicated that both *p*H and ionic strength greatly affect the behavior of this polarographic wave. The present investigation is a more detailed study of the polarographic electroreduction mechanism of vitamin B_{12a} in acidic media.

Experimental

Aquocobalamin samples were obtained from Sigma Chemical Company in the form of hydroxycobalamin hydrochloride and their percentage purity was determined spectrophotometrically by calculating the concentration after conversion to dicyanocobalamin (5). For the differential pulse polarographic experiments aquocobalamin samples free of chloride were prepared by the electrolysis of cyanocobalamin in $NaNO_3$ solution. At sufficiently cathodic potentials it is well known that the cyanide group in the cyanocobalamin gets cleaved (7). The HCN formed was driven away by the current of nitrogen and was absorbed into NaOH solution. After about 10 min the current of nitrogen was replaced by a current of air which was maintained for 10 min. The solution changes to the characteristic red color of vitamin B_{12a}. The B_{12a} in the catholyte solution was extracted using the solvent extraction technique described by Dolphin (15). The purity of the product was tested by paper chromatography in various aqueous-butanol solvent systems. Only one spot showed up with some streaming. The polarograms obtained from this procedure were identical to those of aquocobalamin obtained from Sigma Chemical Company in contrast to those made by the electrochemical procedure of Kenyhercz and Mark (16) which gave aquocobalamin polarograms of an unusual nature unless Triton X-100 was added.

All the other chemicals were Fischer A.C.S. certified grade chemicals. The Triton X-100 and Triton QS-30 were obtained from Sigma Chemical Company. The decyl, octyl, hexyl, and butyl sodium sulfate were obtained from Eastman Organic Chemicals.

A Princeton Applied Research (PARC) Model 173 potentiostat/galvanostat in combination with a PARC Model 175 Universal Programmer was used for polarographic measurements. A commercial fiber plug type saturated calomel electrode (SCE) was used in all

cases. Thus potentials quoted in this paper are always with respect to an SCE. An MFE Model 815 Plotomatic X-Y recorder served for recording the polarograms. Pulse polarograms were obtained with a Tacussel Model PGR-5 pulse polarograph. Cells were of the commercial, Metrohm type with water jacket (EA-76) (Brinkmann Instruments, Incorporated). The temperature of the test solution was varied by circulating hot water from a Haake Model FK thermostat. The accuracy of temperature maintenance was ± 0.5°C. The dropping mercury electrode had a column height of 86 cm and a mass flow rate of 2.05 mg sec^{-1}.

Cyclic voltammetry experiments were also performed using the PARC potentiostat/galvanostat universal programmer combination. At low scan rates a recorder was used for recording voltammograms. At high scan rates the voltammograms, were recorded with Tektronix 5403 oscilloscope and photographed with Tektronix C12 camera attachment.

*p*H was measured with a Beckman Zeromatic SS-3 *p*H meter or an Orion Research digital *p*H meter Model 801A. In both cases a combination electrode system was used. The *p*H of the various electrolytes used was adjusted by additions of NaOH solution.

A Metrohm microburette hanging mercury drop apparatus (E410) was used to form drops which were collected in a small glass holder and attached to an amalgamated Pt recessed tip electrode which was then used as the hanging Hg drop electrode. The area of the hanging Hg drop was 0.0403 cm^2.

The polarographic potential variations were followed with a Keithley Model 160B digital voltmeter.

All solutions were deaerated in a stream of high purity nitrogen gas.

Results and Discussion

Nature of current-potential curves.—Figure 1 shows a typical d-c polarogram of 4.8×10^{-4}M vitamin B_{12a} in 0.1M H_2SO_4 at *p*H 1.2. This figure has a distinctive peak around 0.06V and a pronounced dip between 0.0 and −0.4V similar to that observed by Imhoff in acetate buffer (7). The bottom of the dip shows a narrow range of potentials around −0.2V where the current *vs.* time oscillations are reminiscent of an inhibited electrode reaction. Following the dip the current slowly rises to a first plateau at about −0.4V. Another wave with an $E_{1/2}$ value of *ca.* −0.75V follows the first one. As mentioned above the diffusion current on the first plateau represents the Co(III) to Co(II) reduction and on the second plateau the diffusion current represents the reduction of the diffusing Co(III) species to Co(II) and then to a Co(I) species.

Figure 2 shows a representative cyclic voltammogram (CV) of vitamin B_{12a} in 0.1M $NaClO_4$ at *p*H 3.8

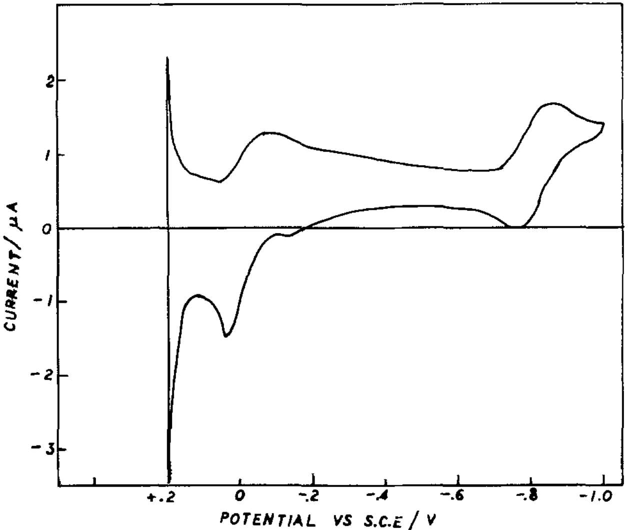

Fig. 2. Cyclic voltammogram of 1.6×10^{-4} vitamin B_{12a} in 0.1M $NaClO_4$, *p*H 3.8. 50 mV sec^{-1} scan rate. Temperature 29°C.

on a hanging drop mercury electrode (HDME). The sharp decaying cathodic and anodic currents at +0.2V are due to adsorption processes difficult to ascertain since they may involve a mercurous chloride species. The cathodic peak at −0.08V is mainly diffusion controlled at low scan rates since a plot of cathodic current *vs.* the square root of scan rate is linear up to 100 mV sec^{-1} and then the slope of the plot increases at higher scan rates. On the other hand, the sharp anodic current peak at +0.04V is definitely due to the oxidation of adsorbed vitamin B_{12r} since a plot of anodic peak current *vs.* the first power of scan rate is linear over the entire range measured up to 200 mV sec^{-1}. In addition the nearly reversible nature of the vitamin B_{12r} and B_{12s} couple can also be seen in the −0.8V region of this figure.

Figure 3 shows differential pulse (DP) polarograms of chloride-free vitamin B_{12a} for a series of concentrations in 0.1M H_2SO_4, *p*H 1.07. The peak at *ca.* +0.2V grows linearly as a function of concentration until about 5×10^{-5}M where it levels off and then begins to decrease as the concentration is increased further. The peak at *ca.* +0.02V is an impurity in background current and appears in the DP polarogram of 0.1M H_2SO_4. It is noteworthy that the reduction is taking place at a potential quite positive to that of the reversible B_{12a}/B_{12r} couple (13) (−0.040V) and this reduction appears to involve the adsorption of the product of the electrode reaction (11). Furthermore, although in neutral media the DP detection limits of

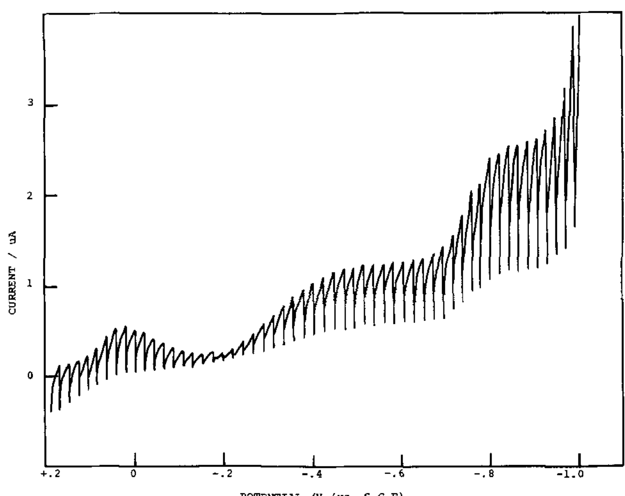

Fig. 1. Polarogram of 4.8×10^{-4}M vitamin B_{12a} in 0.1M H_2SO_4, *p*H 1.2.

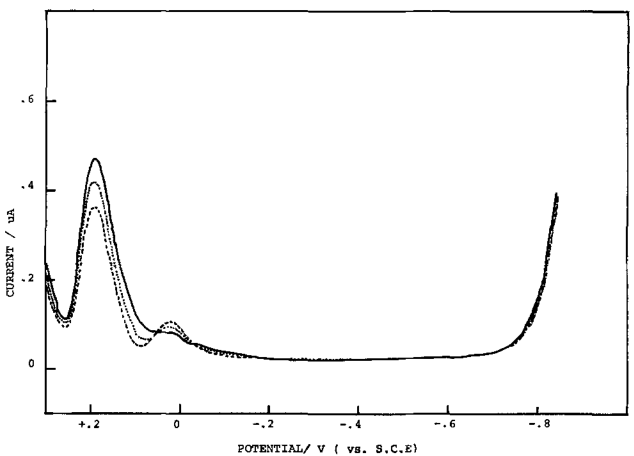

Fig. 3. Differential pulse polarograms of 2.2, 2.6, and 3.0 $\times 10^{-5}$M vitamin B_{12a} in 0.1M H_2SO_4, *p*H 1.1. Potential pulse is 50 mV, drop time is 1.0 sec, and pulse duration 40 msec.

the vitamin B_{12a} to B_{12r} peak negative to zero volts *vs.* SCE is about 1.0×10^{-4}M (17), the detection limit in acidic media for this peak as can be seen from Fig. 3 is around 1.0×10^{-6}M. Indeed only at much higher concentration of around 10^{-4}M does the diffusion-controlled vitamin $B_{12r}H^+$ to B_{12s} peak at -0.73V appear in DP polarogram in 0.1M H_2SO_4. The DP polarographic peaks for reduction of diffusing vitamin B_{12a} appear in the potential range of -0.1 to -0.3V and are complicated due to the dip phenomenon in the d-c polarogram.

Effect of ionic strength and the pH.—Figure 4 shows the effect of changing the pH on the vitamin B_{12a} system in an H_3PO_4 medium. Decreasing the pH tends to increase the magnitude of the dip and below pH 4.3 decreasing the pH causes a positive potential shift in the peak potential and the rising part of the wave. It can also be seen from Fig. 4 that the second wave becomes more reversible with a decrease in pH (6). Although only the envelopes of the polarograms are shown in Fig. 4 an examination of the current-time behavior of individual drops in the region of the valley of the dip shows a current which first decreases with time and then increases toward the end of the drop-life indicating highly inhibited currents with possibly a rearrangement of the adsorbed species (7, 11). Identical behavior was found with an H_2SO_4 medium.

Plots of E_{DME} *vs.* log $((i_D - i)/i)$ were made in H_2SO_4 buffer media and found to be straight lines for the initial rising part of the curves (0.2 to *ca.* 0.0V). The slopes of these plots had close to a Nernst value at lower vitamin B_{12a} (4×10^{-4}M) concentrations and short drop times, but were not Nernstian at higher B_{12a} (10^{-3}M); however, the current-potential curves are complicated by the adsorption process which accounts for the change in slope. The $E_{1/2}$ values obtained from the logarithmic analysis were plotted against pH for a solution containing 1M Na_2SO_4. The $\Delta E_{1/2}/\Delta$pH value was -56.7 mV/pH. The crossing point of the straight line portions in curve A of Fig. 5 is at 2.7 which corresponds to the pK_a for the protonation of the 5,6-dimethylbenzimidazole (DMB) nucleotide base-on form of vitamin B_{12r}. The $E_{1/2}$ value of the vitamin B_{12a}/B_{12r} couple found at values above pH 3 on the flat part of the curve is $-0.034V \pm 0.004V$ which is close to the reversible value measured spectroelectrochemically (13). The value of pK_a found lies between the value found by ESR measurements (18) (pK_a = 2.5) and the value found by pH titration (6) and cyclic voltammetry (19) (pK_a = 2.9). Since the slope of the plot agrees with theory (59 mV) and the $E°$ found is within 6 mV of that measured spectroelectrochemically (13), under the conditions of high ionic strength the polarographic system appears reversible.

If the total ionic strength is reduced by starting with 0.1M H_2SO_4 medium the $E_{1/2}$ *vs.* pH plot using a 3.0 sec drop time shows a slope of 59.7 mV/pH with a cross-over point of 2.8 for the pK_a and an $E° = -0.017$V. However, when the drop time is lowered to 0.5 sec for this media, the slope becomes 34.4 mV/pH with a cross-over point of 3.7 and an $E° = -0.003$V (curve B, Fig. 5). The slopes of the E_{DME} *vs.* log $((i_D - i)/i)$ varied somewhat with pH, but were around twice the value of the slope of the $E_{1/2}$ *vs.* pH plots. This fact is consistent with an electrode process involving a follow-up protonation step. Indeed, on the rising part of the polarographic wave at potentials between 0.04 and 0.10V in the pH range between 1 and 3, the current was found to be directly proportional to $[H^+]^{0.4}$ which is close to $[H^+]^{0.5}$ which would be expected for a postkinetic current.

The ionic strength of the supporting electrolyte was found to have a dramatic effect on the shape of the polarograms of vitamin B_{12a}. When the ionic strength is increased at nearly constant pH, the dip in the polarogram begins to decrease and almost completely disappears at an ionic strength of around 1M in pH 3 to 4 media.

Effect of concentration, temperature, and mercury column parameters.—The relationship between current and vitamin B_{12a} concentration was also investigated at various potentials. Figure 6 shows these results for

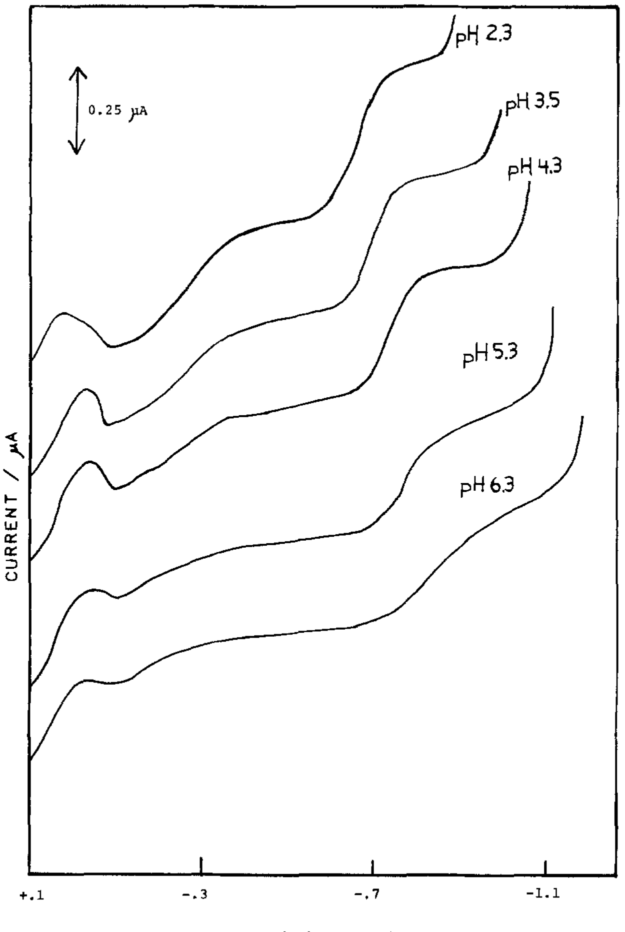

Fig. 4. Effect of pH on the polarographic wave of 1.6×10^{-4}M vitamin B_{12a} in 0.1M H_3PO_4. The pH was adjusted by adding NaOH.

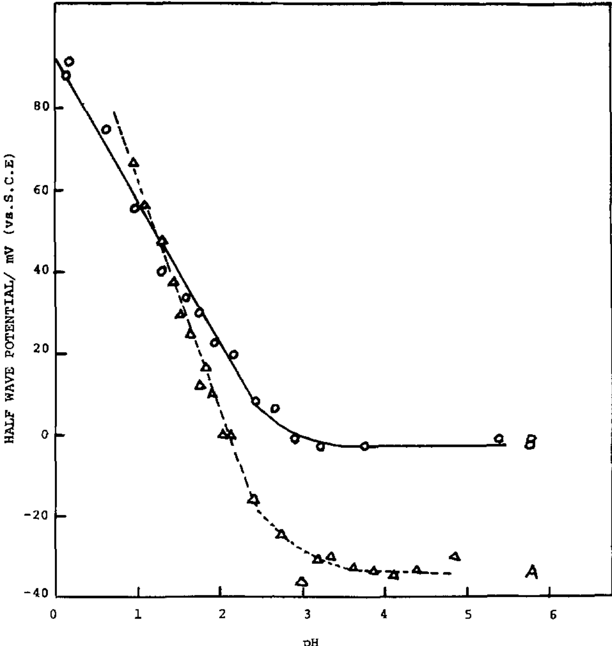

Fig. 5. Plot of $E_{1/2}$ vs. pH for 2.0×10^{-4} vitamin B_{12a} (A) 1M Na_2SO_4, drop time of 3.0 sec. (B) 0.1M H_2SO_4, drop time of 0.5 sec.

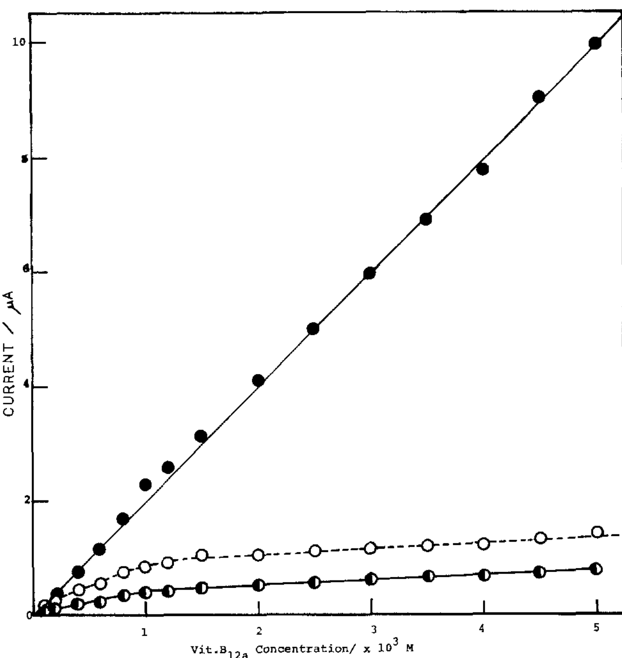

Fig. 6. Current vs. concentration of vitamin B_{12a} at various values of potential: ●—● diffusion limited potential, ○—○ peak potential 0.0V, ◐—◐ valley potential −0.15V. The electrolyte is 0.1M H_2SO_4, pH 1.2.

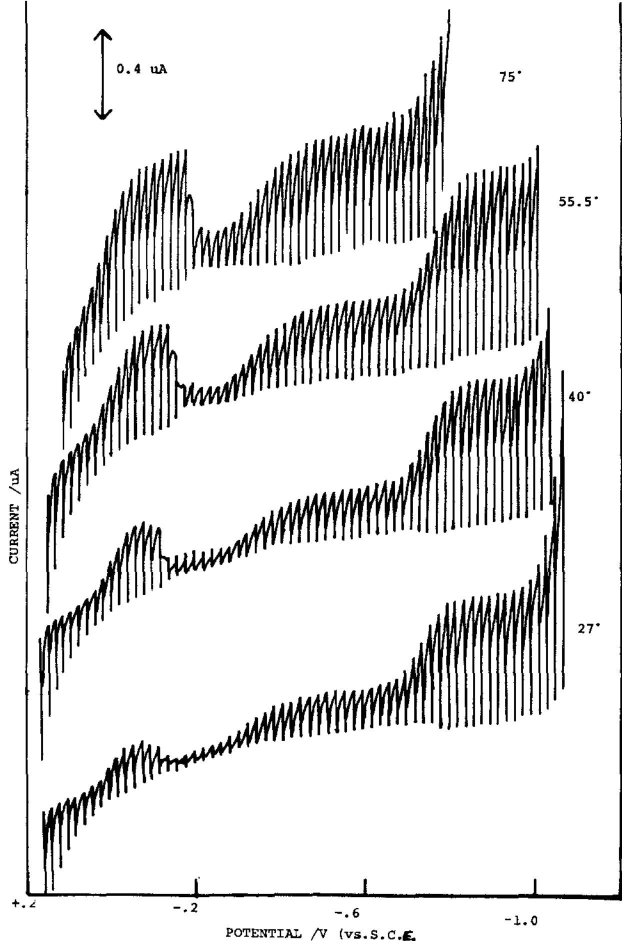

Fig. 7. Polarograms of 1.6 × 10^{-4}M vitamin B_{12a} in 0.01M Na_2SO_4 (pH 3.0) at various values of temperature.

the potential of the peak current, valley current, and diffusion plateau current. The peak current has a linear increase with concentration up to about 1.5 × 10^{-3}M and then reaches a steady state. The valley current (*i.e.*, at the bottom of the dip) shows very similar behavior. At −0.5V which is on the diffusion plateau the current increases linearly with concentration throughout the entire concentration range used. These results indicate that the potential range from peak potential through the valley potential and up the ascending branch of the curve is a region of blockage of the electrode reaction by the product of the electrode reaction, vitamin B_{12r}, and its protonated form.

The effect of temperature can be seen in Fig. 7 which shows a series of polarograms recorded from 27° to 75°C. The inhibited nature of the current in the valley is clearly seen at 27° and 40°C, whereas at 56° and 75°C the valley current-time profiles lose their inhibited nature. As the temperature increases the peak becomes more of a plateau region and the dip or valley becomes more pronounced. The most likely cause of the current-time profiles at low temperature is an electrode process blocked by adsorption as concluded by Imhoff (7). The computed temperature coefficients of the current both at the peak and valley potentials are positive (1.0%) so that these currents are not adsorption controlled which would be indicated by a negative coefficient (20).

Further information on the nature of the electrode process was obtained from a study of current as a function of the height of the mercury column, *h*. This study was made for different potentials on the d-c polarogram of 4 × 10^{-3}M vitamin B_{12a} in 0.1M H_2SO_4 solution, *p*H 1.2. The slope of the log *i* *vs.* log *h* plot was found in the following regions of the polarograms: on the rising part of the initial peak (+0.2 to 0.06V), near the peak potential (+0.00V), on the descending branch of the current-potential curve, in the valley (−0.14V), on the ascending branch of the curve (−0.18 to −0.3V), and finally on the diffusion plateau (−0.5V). The slope at the most positive potential was close to zero showing the independence of the current on the column height and indicating kinetic control by the follow-up chemical reaction. On the peak, descending branch, and the ascending curve, the exponent was between 0.37 and 0.16 so that there is a mixed control most likely by slow electron transfer and diffusion until diffusion control takes over on the plateau where the exponent was 0.43. Figure 6 shows that the *i* *vs.* c curve reaches a maximum at the peak and valley indicating a blocked electrode reaction, however, the log *i* *vs.* log *h* plot shows that these are not adsorption currents. Thus reduction can take place even on a blocked surface (7).

In addition to the independence of *h* on the polarographic current another criterion for a following chemical reaction (postkinetic current) is the shift in $E_{1/2}$ with drop time. The $E_{1/2}$ value should shift by *ca.* 30 mV per decade of drop time for a postkinetic current. An irreversible electrode reaction also shows a shift of $E_{1/2}$ with drop time, however, in this case only if the charge transfer coefficient, α, is unity would the shift be 30 mV and for $\alpha = 0.5$ the $E_{1/2}$ shift is 60 mV. Values of $E_{1/2}$ were determined for six drop times in 0.5-4.5 sec range and the plot of $E_{1/2}$ *vs.* log *t* had a slope of 23 mV per log unit. Again this value is additional evidence for a postkinetic current.

Another mercury column parameter which was studied was the drop time as a function of potential. These measurements were performed at various *p*H values and ionic strengths with the view that the curves would qualitatively resemble surface tension *vs.* potential curves. Figures 8 and 9 show these drop times *vs.* potential curves. As can be seen in the presence of vitamin B_{12a} the total curve is lower than the pure supporting electrolyte curve indicating that adsorption is present at all *p*H values and ionic strengths over a wide potential region. Almost identical drop time *vs.* potential curves were obtained in 0.1M Na_2SO_4 at various *p*H values from 2.0 to 8.0.

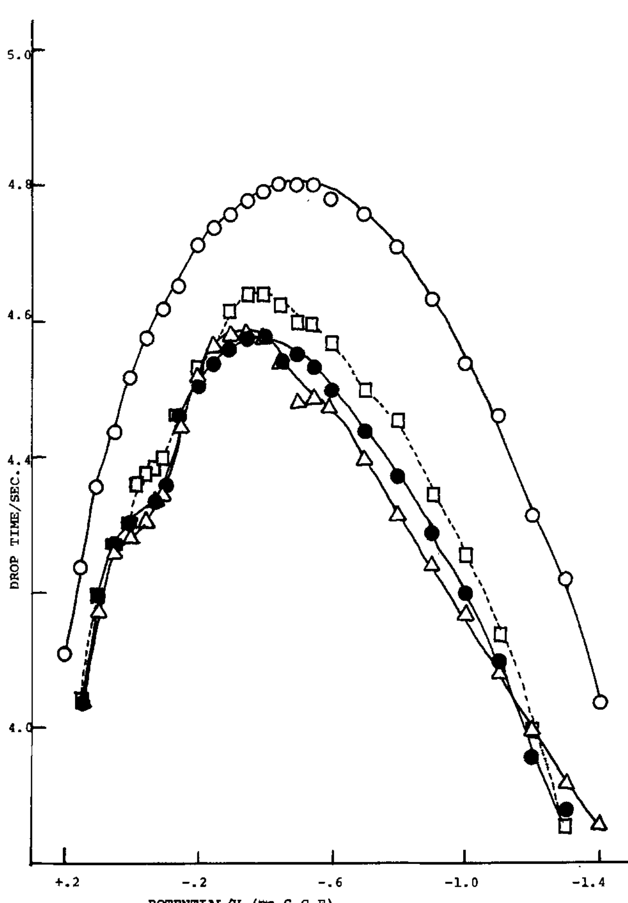

Fig. 8. Drop time *vs.* potential curves at various values of *p*H: ○—○ pure electrolyte 0.1M $HC_2H_3O_2$; □—□ vitamin B_{12a} in acetic acid buffer, *p*H 5.0; ●—● vitamin B_{12a} in acetic acid buffer, *p*H 4.2; △—△ vitamin B_{12a} in acetic acid buffer, *p*H 3.5. All vitamin B_{12a} concentrations are 1.6×10^{-4}M.

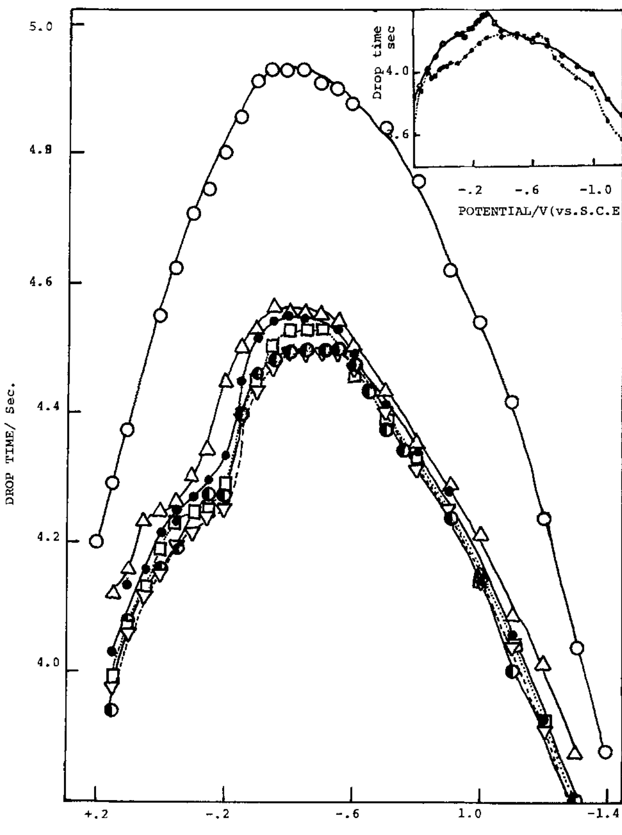

Fig. 9. Drop time *vs.* potential curves at various values of ionic strength of $NaNO_3$: △—△ vitamin B_{12a} in 0.1M $NaNO_3$, ●—● vitamin B_{12a} in 0.3M $NaNO_3$, □—□ vitamin B_{12a} in 0.5M $NaNO_3$, ◐—◐ vitamin B_{12a} in 0.7M $NaNO_3$, ▽—▽ vitamin B_{12a} in 0.9M $NaNO_3$. Room temperature. Insert: ○—○ 0.1M $NaNO_3$ at 76°C, ●—● vitamin B_{12a} in 0.1M $NaNO_3$ at 76°C. All vitamin B_{12a} concentrations are 1.6×10^{-4}M.

Both figures show a peculiar inflection from 0.0 to −0.1V which is in the same potential region as the peak and dip in the polarographic curves. Also this inflection is found to decrease with an increase in *p*H (Fig. 8) suggesting that at low *p*H the protonated vitamin B_{12r} which is the species present at the electrode surface in the potential region of the inflection is the cause of the inflection. This inflection is interpreted as caused by a rearrangement of the adsorbed molecule on the electrode surface. Similar results and interpretation have been recently obtained using differential double layer capacity measurements (11). Furthermore as the *p*H decreases, the drop time *vs.* potential maximum shifts in a positive direction indicating cationic adsorption, *i.e.*, of the protonated vitamin B_{12r}. It is seen in Fig. 9 that increasing the ionic strength shifts the maximum to more negative potentials in an $NaNO_3$ medium at *p*H 2.1. In addition, the total profile of the curves drops with increasing ionic strength. Both these observations indicate that these changes are due to anionic adsorption which is increasing with increasing electrolyte $NaNO_3$ or Na_2SO_4 concentration. Although the polarographic dip nearly disappears at high ionic strength in *p*H 3-4 media the nature of the drop time-potential curve indicates that the vitamin B_{12r} and $B_{12}H^+$ are not desorbed at high ionic strengths and that specific anionic adsorption is taking place under these conditions. The insert in Fig. 9 shows the effect of temperature on the drop time *vs.* potential curve. It is seen that even at an elevated temperature of 76°C the separation of the pure electrolyte curve from that with B_{12a} added is still present indicating that although adsorption decreases at higher temperatures, especially at the potential extremities, it is still present. The curve in the potential region of the inflection still indicates that this effect is present although it is much less pronounced at the higher temperature.

In an effort to decrease adsorption of vitamin B_{12} compounds, various surfactants were added. This technique proved to be effective in the study of the B_{12r} to B_{12s} system (6). We have tested Triton X-100, a nonionic surfactant, Triton QS30, an anionic surfactant, and several other anionic surfactants (decyl, octyl, hexyl, or butyl) sodium sulfates. The Triton surfactants had no effect on the maximum which was originally taken as evidence that the maximum was not a normal polarographic maximum. The effect of sulfate surfactant on the polarographic wave of 2×10^{-4}M B_{12a} in 0.1M Na_2SO_4 (*p*H 4.0) did show some interesting effects. At concentrations of the surfactants up to 5×10^{-3}M the peak current was completely suppressed and an irreversible wave developed starting at around 0.0V. On increasing the surfactant concentration the usually observed peak and valley reappeared, but at more positive potentials and with higher concentration the second diffusion current plateau disappeared. Thus, the surfactant which competes for adsorption sites with the protonated vitamin B_{12r} appears to either make the electrode simply irreversible at low surfactant concentrations or produces a similar effect to the protonated vitamin B_{12r} at higher surfactant concentrations with the additional effect of suppressing the second wave completely.

Interpretation of the electrode process.—The cyclic voltammetry and drop time *vs.* potential curves indicate that B_{12r} and its protonated form are adsorbed on the electrode surface depending on the potential. Weak vitamin B_{12a} adsorption is also indicated since the cathodic peak current rises above a square root dependence on scan rate at scan rates above 100 mV per

sec^{-1}. The nature of the DPP wave at *ca.* 0.2V, furthermore, shows strong adsorption of the electrode product and this wave is probably related to the Brdicka adsorption waves (21) of d-c polarography.

The inflection on the drop time-potential curve, which mirrors the dip on the polarographic curve, is still present at elevated temperatures, but disappears at *p*H values above 5.0. We, therefore, conclude that the protonated vitamin B_{12r} is the most effective blocking species. While vitamin B_{12a} and B_{12r} may only differ in structure in a minor way (22), the protonation of the nucleotide base leads to the unfolding of this chain portion of the molecule. A model of the compound shows a doubling of the linear dimensions of the molecule and indicates that the adsorbed state of the protonated molecule would cover much more surface area than the nonprotonated molecule.

The dependence of the current on the square root of the hydrogen ion concentration, the positive shift of $E_{1/2}$ with *p*H, and the independence of the current on the column height at the beginning of the polarographic curve all indicate that a homogeneous postkinetic chemical protonation reaction is kinetically coupled to the electrode process. Also, there is no evidence that a prior chemical step involving the protonation of vitamin B_{12a} is taking place at the DME in the *p*H range investigated (*p*H 1-3), the pK_a of this reaction is −2.4 (23).

A current-potential expression for the electrode process in the potential region +0.2-0.0V can be obtained using the steady-state approach as illustrated by Guidelli (24). The electron transfer process is given by the expression

$$\frac{i}{n\mathbf{F}A} = C_A\overrightarrow{k}_2 - \theta_R\overleftarrow{k}_2 \quad [1]$$

where C_A is the volume concentration of vitamin B_{12a} in the reaction layer and θ_R is the fraction of the surface occupied by vitamin B_{12r} in the adsorbed state, the other variables have their usual significance. The volume concentration of vitamin B_{12a} has been used in Eq. [1] since the cyclic voltammetry experiment indicates that the current is due to a diffusing species at slow sweep rates. The anodic current is clearly due to adsorbed species and thus θ_R has been introduced in Eq. [1]. The follow-up chemical reaction is considered to be in a steady state with the electrode reaction. This current is represented by

$$\frac{i}{n\mathbf{F}A} = \mu k_1[H^+]C_R \quad [2]$$

where the backward step in Eq. [2] has been neglected, k_1 is a first-order rate constant, and μ is the Brdicka-Wiesner reaction layer thickness (24). The follow-up protonation is definitely a homogeneous chemical step as shown by the dependence of the current on the square root of the $[H^+]$. For short drop times (0.5 sec), a linear adsorption isotherm $\theta = \beta C$ is assumed to hold with $\beta = \beta_M e^{-a(E-E_M)}$, where β_M is the maximum adsorption constant, a is the adsorption coefficient, and E_M is the potential of maximum adsorption. The linear form of the potential dependence is taken because of the very strong adsorption (25) and because this form fits the data as opposed to a quadratic form. Use of Eq. [1], [2], the adsorption isotherm, and $\mu = \sqrt{D_R/k_1[H^+]}$ yields

$$\frac{i}{n\mathbf{F}A} = \frac{\overrightarrow{k}_1 C_A}{1 + [(\overleftarrow{k}_2\beta_M e^{-a(E-E_M)})/\sqrt{D_R k_1[H^+]}]} \quad [3]$$

For the condition $\overleftarrow{k}_2\beta > \sqrt{D_R k_1[H^+]}$, one obtains a current which is proportional to $\sqrt{[H^+]}$, and by approximating C_A by the Ilkovic equation, the final result is

$$\frac{i}{i_D - i} = \sqrt{\left(\frac{3\pi}{7}\right)\frac{D_R k_1[H^+]t}{D_A\beta}} \exp\left[-\frac{n\mathbf{F}}{RT}(E - E^\circ) + a(E - E_M)\right] \quad [4]$$

The factor $\sqrt{3\pi/7}$ will be slightly in error as shown by more rigorous derivations in the absence of adsorption (26, 27). Equation [4] when plotted as E_{DME} *vs.* log $(i/(i_D - i))$ will have a slope larger than the Nernst factor. Also in agreement with the experimental data, the slope from the $E_{1/2}$ *vs.* *p*H plot should be one-half the slope from the E_{DME} *vs.* log $(i/(i_D - i))$ plot.

The condition $\overleftarrow{k}_2\beta > \sqrt{D_R k_1[H^+]}$ indicates that the electron transfer rate constant for vitamin B_{12a} to B_{12r} should be large, but the condition also depends on β which may also be large. A logarithmic plot of E_{DME} *vs.* log $(i/i_D - i))$ as given by Eq. [4] will be a straight line with a slope of $-1 \Big/ \left(\frac{n\mathbf{F}}{RT} - a\right)2.3$ which will be larger than the Nernst factor, 59.2 mV, as was found experimentally. The plot of $E_{1/2}$ *vs.* *p*H should have a positive slope one-half that of the latter value and this fact was also verified experimentally (Table I). Calculation of k_1 however, depends on knowing β which must be measured independently. The data appear to be consistent with the current-potential relationship derived.

The electrode mechanism giving rise to Eq. [3] involves protonation of a solution vitamin B_{12r} species. Thus the adsorption-desorption equilibrium must be reversible.

In order for the protonation to be the rate-determining follow-up step it must be faster than a protonation mechanism involving side chain opening and subsequent protonation of free dimethylbenzimidozole. The latter step would be diffusion controlled [the k for imidazole protonation (28) is 1.5×10^{10} M^{-1} sec^{-1}]. Since the experimental results show that at low *p*H the reaction is dependent on $[H^+]$ we concluded that the pathway has an initial attack of the proton on the base-on species. If the rate constant for this protonation is also very large a subsequent step of side chain opening of the protonated species would be rate determining.

As the potential is moved into the region of the dip in the polarographic curve, the assumptions of low coverage and rapid adsorption equilibrium for the various cobalamin moieties break down completely. From Fig. 8 the maximum of the drop time *vs.* potential curve comes at −0.30V for *p*H 3.5 indicating that the maximum coverage moves to more positive potentials as the *p*H is decreased. We also conclude that there is high electrode coverage over a broad range of potentials as illustrated by the inflection and the rounded top of Fig. 8 (7, 11). The fact that the plot of current as a function of vitamin B_{12a} concentration in acidic media reaches a plateau for both the peak and valley potentials is in agreement with the concept of electrode blockage at sites covered by the product of the electrode process, protonated base-off vitamin B_{12r}. Since the polarographic dip only occurs at a low *p*H, this phenomenon must be attributed specifically to adsorption of protonated vitamin B_{12r}.

Table I. Comparison of the slopes of logarithm current *vs.* potential data and $E_{1/2}$ *vs.* *p*H data

Conditions	$\Delta E/\Delta\log(i/(i_D - i))$ (mV)	$\Delta E_{1/2}/\Delta pH$ (mV)	pK_a
1.0M Na_2SO_4 (drop time equals 3.05 sec)	122	−56.7	2.7
0.1M Na_2SO_4 (drop time equals 3.05 sec)	117	−59.7	2.8

In the region of the peak and valley of the polarographic curve, the electrode potential is at least 0.1V positive to the point of zero charge (*ca.* −0.3V) and the electrode should be positively charged. Specifically adsorbed protonated B_{12r} will increase the positive surface charge although specifically adsorbed anions should decrease it. The drop time *vs.* potentials curves, indeed, show that both protonated vitamin B_{12r} and NO_3^- can be simultaneously adsorbed. However, a net positive surface charge would account for retardation of the charge transfer rate in the region of the dip due to charge repulsion of the positively charged vitamin B_{12a}. An increase in ionic strength causes the dip to almost completely disappear. This result can be explained by three phenomena: (*i*) a decrease in the effective thickness of the diffuse double layer, (*ii*) a decrease in the net positive surface charge due to increased specific anion adsorption, and (*iii*) desorption caused by increased ionic strength.

In the region of the dip a linear isotherm can no longer be used since the electrode coverage is high. Once the potential reaches a value where vitamin $B_{12r}H^+$ is adsorbed we can envisage both an electrostatic repulsive effect and a blockage effect due to the adsorbed molecules so that the rate constant for electron transfer on the covered electrode surface would be much lower than that for the uncovered surface. Here the reaction becomes totally irreversible. The inflection on the drop-time *vs.* potential curves (Fig. 8-9) ends around −0.2V which is in the valley of the current *vs.* potential curve. This inflection indicates a rearrangement of the adsorbed molecules and the new configuration could allow electron transfer as the potential is moved negative even though the surface is still covered. As the current rises to the first plateau, between *ca.* −0.2 to −0.4V the surface coverage has increased to a maximum and then electron transfer must take place on the covered surface. However, now the value of forward heterogeneous rate constant increases because the potential is negative enough to overcome the activation energy barrier. The electrode process in this region is then controlled by slow-electron transfer and diffusion.

Conclusion

The investigation of the electroreduction of vitamin B_{12a} on a dropping mercury electrode in acidic medium (*p*H 1-5) has led to the conclusion that the structure of the interface dramatically influences the intrinsic rate of the reduction reaction. At potentials positive to the polarographic dip the electrode reaction is either reversible or quasireversible; whereas, at potentials negative to the dip the reaction is completely irreversible. Recently it was reported, by Tacconi, Lexa, and Saveant (12) from the results of a cyclic voltammetry study that the rate of this electron-transfer reaction on a vitreous carbon electrode is always quite irreversible ($k_s \sim 10^{-5}$ cm sec^{-1}). It would appear that the structure of the interfaces of the mercury and vitreous carbon electrodes are quite different which would explain the discrepancy. The latter authors did not investigate the shift in cathodic peak potential with *p*H. In our experiments the anodic shift in $E_{1/2}$ with decreasing *p*H definitely shows that electrode process must depend on the reduced species B_{12r} which is the only species that can be protonated in this *p*H range.

The theory of electron transfer processes (29) shows that the intrinsic rate constant of charge transfer, *i.e.*, the electron transfer probability, depends on the distance of the molecule from the electrode surface. With a large molecule like vitamin B_{12a} it is quite reasonable that the electrode interface structure will effect the orientation of the molecule and the distance of closest approach. Thus it is possible that the interfacial structure could effect the electron-transfer probability which depends on the molecule having a distance of closest approach.

The homogeneous exchange rate for the vitamin B_{12a}/B_{12r} couple has been measured by an NMR line broadening technique (30) and was found to be around 2.0×10^3 M^{-1} sec^{-1} and to be nearly independent of *p*H. Also this couple has the fastest exchange rate yet reported for a Co(III)-Co(II) couple. The electron transfer theory of Marcus (31) can be used to find a heterogeneous charge transfer rate constant, k_{het}, from the homogeneous exchange rate constant, k_{ex}. The values of k_{het} for B_{12a}/B_{12r} couple turns out to be around 1 cm/sec. On the basis of this calculation one would expect that under certain conditions the electrode reduction of vitamin B_{12a} to B_{12r} could be fast. The conditions under which Eq. [4] reduces to Eq. [3] is only consistent with a fast electron transfer reaction of vitamin B_{12a} to B_{12r}. Thus it can be concluded that when the Hg electrode is not blocked by adsorption the electron transfer rate for the B_{12a}/B_{12r} couple should be fast. The significance of these results for biochemical situations is that the electron transfer rate is very sensitive to the environment of the molecules.

ABSTRACT

A molten carbonate electrolytic cell of the Broers and Ketalaar type was used to study the reaction

$$CO_2 + \frac{1}{2} O_2 + 2e^- \rightleftharpoons CO_3^{=}$$

in an Li/K carbonate eutectic melt with porous NiO electrodes. A noble gas Au wire reference electrode was used to measure anodic and cathodic polarization during electrolysis. Steady-state polarization curves were obtained at 800-1000 K with a matrix of fifteen CO_2/O_2 mixtures: 0.5, 1, 10, 20, 50% CO_2/1, 19, 50% O_2. Kinetic analysis in the linear overpotential region indicated ($\partial \log i_o/\partial \log P$) is near zero for CO_2 and 0.5 for O_2. The kinetic Tafel slope was measured from current-potential curves for current densities well below the diffusion limiting current and was found to be *ca.* $RT/2F$ for cathodic polarization and *ca.* $3RT/2F$ for anodic polarization. The reaction orders are $+ \frac{1}{4}$ in CO_2 and $+ \frac{5}{8}$ in O_2 in the cathodic direction, and $- \frac{3}{4}$ in CO_2 and $+ \frac{1}{8}$ in O_2 in the anodic direction.

The molten carbonate fuel cell is undergoing extensive research and development (1-3) as a potential option for converting synthesis gas to electric power. In these cells a fuel gas containing principally hydrogen and carbon monoxide is electrochemically oxidized in the fuel cell anode

$$H_2 + CO_3^{2-} \rightarrow H_2O + CO_2 + 2e^- \quad [1]$$

$$CO + CO_3^{2-} \rightarrow 2CO_2 + 2e^-$$

The carbon dioxide produced is recycled to the air intake for the cathode to form the gas mixture that is electrochemically reduced

$$CO_2 + \frac{1}{2} O_2 + 2e^- \rightarrow CO_3^{2-} \quad [2]$$

This process is somewhat similar to that which occurs in the aqueous alkaline electrolysis cell used by NASA as a CO_2 concentrator (4-6). Ambient levels of CO_2 are removed at the cathode to be rejected at high concentration at the anode. A molten carbonate electrolyte cell also has the promise of use as a CO_2 concentrator, either with a reducing gas at the anode or in an electrolysis mode. In the latter case, application of an external potential produces a concentration gradient across the cell, the cathodic reaction being the evolution of CO_2 from the carbonate melt

$$CO_3^{2-} \rightarrow CO_2 + \frac{1}{2} O_2 + 2e^-$$

Recent work on molten carbonate cells has focused on either the kinetics in free electrolyte on noble electrodes (7) or performance characteristics of subscale commercial cells with paste electrolyte and porous nickel electrodes (2, 3). Development of these cells as gas concentrators requires knowledge of the behavior under both anodic and cathodic polarization with very low CO_2 partial pressures. Fundamentally, observation of the kinetic reaction orders is an essential step in the evaluation of mechanistic sequences proposed for the O_2/CO_2 reaction.

The basic experimental approach we have used in this work is similar to that used in the classic experiments of Broers and Ketelaar (8). Here we employed paste electrolytes and *in situ* oxidized sintered nickel electrodes. For the purposes of measuring reaction kinetics, free-electrolyte cells with either rotating disk electrodes or smooth (nonporous) foil electrodes are preferred, since the transport characteristics of reactants (and products) can be carefully controlled. However, rotating disk electrodes for molten carbonate electrolytes have not yet been perfected even for gold electrodes. Nickel foils oxidized *in situ* are porous and thus present an uncontrolled (nonanalytic) electrode structure to the electrolyte. For kinetic studies of nickel oxide formed by *in situ* oxidation, which is the

* Electrochemical Society Active Member.

* Key words: cell, molten carbonate, polarization.

electrode material of interest for practical devices, the Broers and Ketelaar type cell appears to be the best available. With optimal experimental design, the gas diffusion properties of cells of this type are such that the transport limiting currents are very high, and a region of polarization exists where a kinetically controlled current-potential relation may be observed if the exchange currents are below ca. 1 mA/cm^2 (9).

In order to minimize the possible effects of diffusion, we have used a two-step approach to the determination of reaction orders. First, exchange currents at various P_{CO_2} and P_{O_2} were measured using the low polarization method. We assume a steady-state current-voltage relationship of the form

$$I = I_0 [\exp(\alpha_+ \mathbf{F}\eta/RT) - \exp(-\alpha_- \mathbf{F}\eta/RT)] \quad [3]$$

where $\eta = E - E_0$, α_+ is the anodic transfer coefficient, α_- the cathodic transfer coefficient ($\alpha_+ + \alpha_- = 2$). For $\eta << \alpha RT/\mathbf{F}$, Eq. [3] simplifies to

$$I \doteq (2\mathbf{F}I_0/RT)\,\eta$$

so that $I_0 = (RT/2\mathbf{F})\ (\partial I/\partial\eta)_{T,P}$. The reaction orders can be obtained from the partial pressure dependence of I_0 and the values of the transfer coefficient α_+ and α_-. Let

$$\left(\frac{\partial \log I_0}{\partial \log P_{CO_2}}\right)_T = m \quad [4]$$

$$\left(\frac{\partial \log I_0}{\partial \log P_{O_2}}\right)_T = n \quad [5]$$

Then the reaction orders for the anodic (I_+) and cathodic (I_-) partial currents, after accounting for the Nernst effect (10), are

$$\left(\frac{\partial \log I_\pm}{\partial \log p_{CO_2}}\right)_{E,T} = \begin{cases} m - 1 + (\alpha_-/2) & \text{anodic} \\ m + (\alpha_-/2) & \text{cathodic} \end{cases} \quad [6]$$

$$\left(\frac{\partial \log I_\pm}{\partial \log P_{O_2}}\right)_{E,T} = \begin{cases} n - 1/2 + (\alpha_-/4) & \text{anodic} \\ n + (\alpha_-/4) & \text{cathodic} \end{cases} \quad [7]$$

Second, the transfer coefficients were obtained from the slope of the Allen-Hickling plot

$$\ln [I/\{\exp (2\mathbf{F}\eta/RT) - 1\}] = \ln I_0 - (\alpha_- \mathbf{F}\eta/RT) \quad [8]$$

for current densities low enough so that concentration polarization within the electrode can be neglected.

Apparatus and Procedure

We assembled a molten carbonate test cell using paste electrolyte tiles and porous nickel electrodes typical of those used in current subscale molten carbonate cells. The cell was comprised of two housings of 316 stainless steel which hold the electrolyte tile between them. The electrodes, made of porous nickel, were 0.07 cm in thickness and 1.9 cm in diameter. They fitted snugly in the center of the cavity, in firm contact with the gas distributors (see Fig. 1). The faces of the housings were aluminized to provide a wet-seal against the tile upon melting of the carbonate. The upper housing had a 0.5 cm hole drilled through for the reference electrode, which was a gold flag suspended in the eutectic melt, as in Fig. 2. The noble gas mixture (67% CO_2, 33% O_2) was bubbled slowly through the inner alumina tube past the electrode and then out through the center tube. A small hole in the bottom of the outer tube allowed communication between the free electrolyte in the tube and that in the tile. The upper housing had a well in which was placed an iron-constantan thermocouple, sheathed in a stainless steel tube and mounted with a standard fitting. When assembled, the cell was mounted on a ceramic block, held in place with steel guides, and placed inside a furnace made of two clam-shell heaters. The gas inlet line, of stainless tubing, passed around the outside of the heater allowing the gas to be preheated before entry into the cell. The outlet line, also of stainless, led straight out of the furnace. The furnace was insulated with transite panels and fibrous zirconia felt. The entire apparatus was mounted in a steel frame and a pneumatic cylinder applied pressure to the top of the upper housing to assure firm contact between cell components.

The gases were calibrated mixtures purchased from Matheson. Fifteen binary combinations were used from the matrix 0.5, 1, 10, 20, 50% CO_2; 1, 19, 50% O_2, the balance N_2 in every case. The noble gas mixture 67% CO_2/33% O_2 was used as the reference gas.

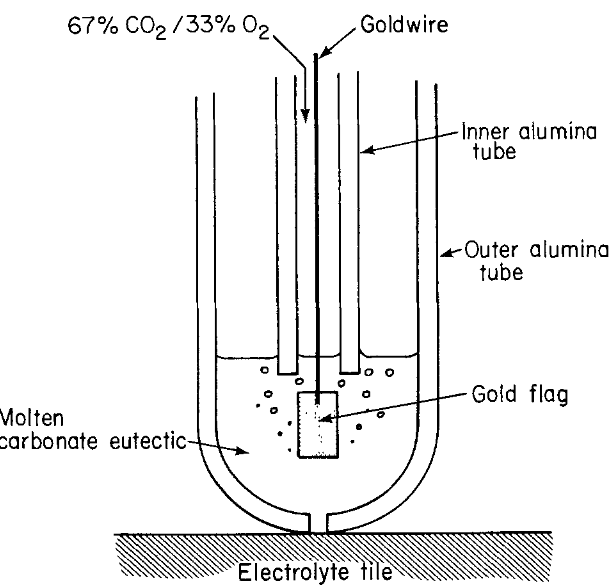

Fig. 1. Schematic diagram of the electrolysis cell assembly

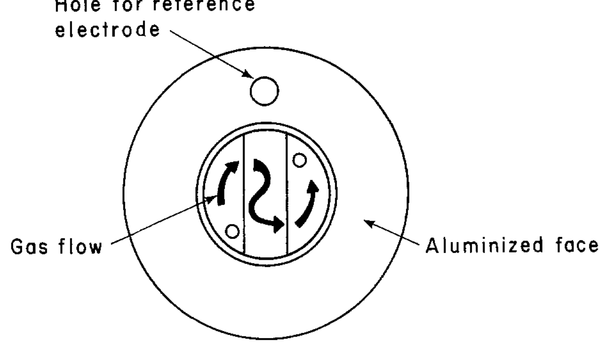

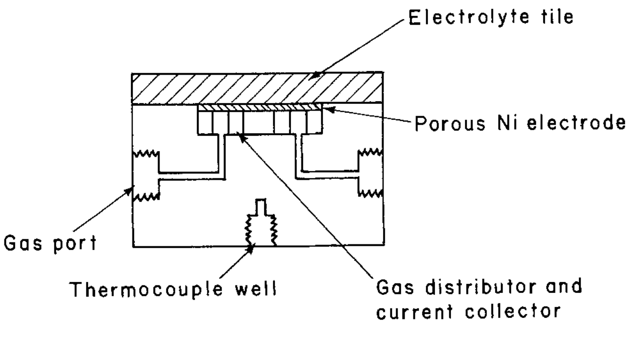

Fig. 2. Schematic diagram of the reference electrode

The experiments were begun by assembling the cell with an electrolyte tile supplied by Argonne National Laboratory. The composition by weight of this tile was 25.6% Li_2CO_3, 29.4% K_2CO_3, and 45.0% $LiAlO_2$. The porous electrodes were fabricated by Gould for use in molten carbonate fuel cells and were pure nickel when the cell was assembled. The physical characteristics of these electrodes are given in Table I. At start-up, the cell was heated slowly while oxidant gases continually flowed over both electrodes. About 5 hr were necessary to bring the cell to 600°C. The cell was left in this open-circuit condition for 30-50 hr before experiments were begun to assure complete conversion of the electrodes to NiO.

Measurements were made only of the steady-state polarization of the top electrode using a Princeton Applied Research Potentiostat/Galvanostat (Model 371) in the galvanostatic mode. The gas flow to the top electrode was increased until no change in polarization was seen. The voltage reading was taken when apparent steady state was reached although some fluctuation was still seen. A current-interruption technique was occasionally employed to measure the *IR* drop between reference and top electrode. This loss averaged about 3 mV at 100 mA, as measured on an oscilloscope (Tektronix 5111) and was linear over the range studied. This yields a specific conductivity of 2.1 $(\Omega \text{ cm})^{-1}$ for the 0.18 cm thick tile. The current was increased step-wise until the potential was about −0.5V (all potentials are relative to the 67% CO_2/33% O_2 reference electrode). Larger polarizations were avoided because, in a sacrificial experiment, cyclic voltammetry disclosed that the reduction of NiO to Ni occurred at about −0.6V and cycling through this potential region irreversibly changed the electrolyte/porous electrode structure.

Results

The use of very low polarizations and the linear form of Eq. [3] to measure exchange current requires the absence of interfering reactions near the rest potential of the system, *i.e.*, the observed rest potential is not a mixed potential. The rest potentials we observed were within ±10 mV of the theoretical open-circuit calculated from the Nernst equation

$$E = E_o + \frac{RT}{2\mathbf{F}} \ln P_{CO_2} P_{O_2}{}^{1/2} \qquad [9]$$

After anodic or cathodic polarization, the cell returned quickly to the starting rest potential. These observations indicated the only faradaic process occurring at a measureable rate near the rest potential is the O_2/CO_2 reaction. Typical current-voltage curves in the very low polarization region are shown in Fig. 3. These curves were reasonably linear and showed clearly that the CO_2 partial pressure dependence of the exchange current, which is proportional to the slope of these lines, is very nearly zero. More than 100 sets of curves were obtained with varying gas composition and temperature. The correlation that resulted from analysis of the current-potential curves at very low polarization was

$$I_o = (1.5 \times 10^2)\, P_{CO_2}{}^0\, P_{O_2}{}^{0.5} \exp\,[-6 \times 10^3/(T + 273)] \qquad [10]$$

where I_o is in A/cm² for $T = 550°\text{-}750°C$ and partial pressures of 0.1-0.5 atm. We can report only the exchange current density per external area of electrode, since the internal area of the electrode contacted by electrolyte is not known. If all of the internal area were contacted, then about 100 cm² of NiO is available per cm² external area. At 700°C, this would mean an i_o of about 1.4 mA/cm² for 20% CO_2/20% O_2, about the same as that found by Appleby and Nicholson for smooth Au in Li/K eutectic melt (11).

Table I. Physical characteristics of Ni sinter electrodes

Mean pore size, μm	9
Pore size distribution (80%), μm	3 to 16
Porosity	77%
BET surface area	0.15 m²/g
BET area after oxidation	0.20 m²/g

The second step necessary for determining reaction orders according to Eq. [6] and [7] is the measurement of the cathodic transfer coefficient, α_-. The current-voltage behavior of these electrodes at polarization *ca.* $RT/\mathbf{F}$ was typically like those in Fig. 4; no reaction limiting current was observed either anodically or cathodically, nor was a cathodic diffusion limiting current observed above −0.6V, where the NiO undergoes reduction to Ni. At current densities an order of magnitude below the diffusion limiting current, the currents are predominantly kinetically controlled. Typical Allen-Hickling plots for cathodic polarizations to 2 $RT/\mathbf{F}$ are shown in Fig. 5. According to Eq. [8], the intercept is just ln I_o, which Fig. 5 shows corresponds to $I_o \doteq 150$ mA (53.5 mA/cm² external), in good agreement with the Fig. 3 values. The average values found from analysis of *ca.* 100 polarization curves were 0.5 ± 0.1 for α_-, 1.6 ± 0.1 for α_+. Figure 5 also shows the characteristic effect of CO_2 partial pressure on both I_o and α_- and, as in Fig. 3, the exchange current is essentially zero order in CO_2 pressure. From Eq. [6] and [7], the reaction orders are, therefore

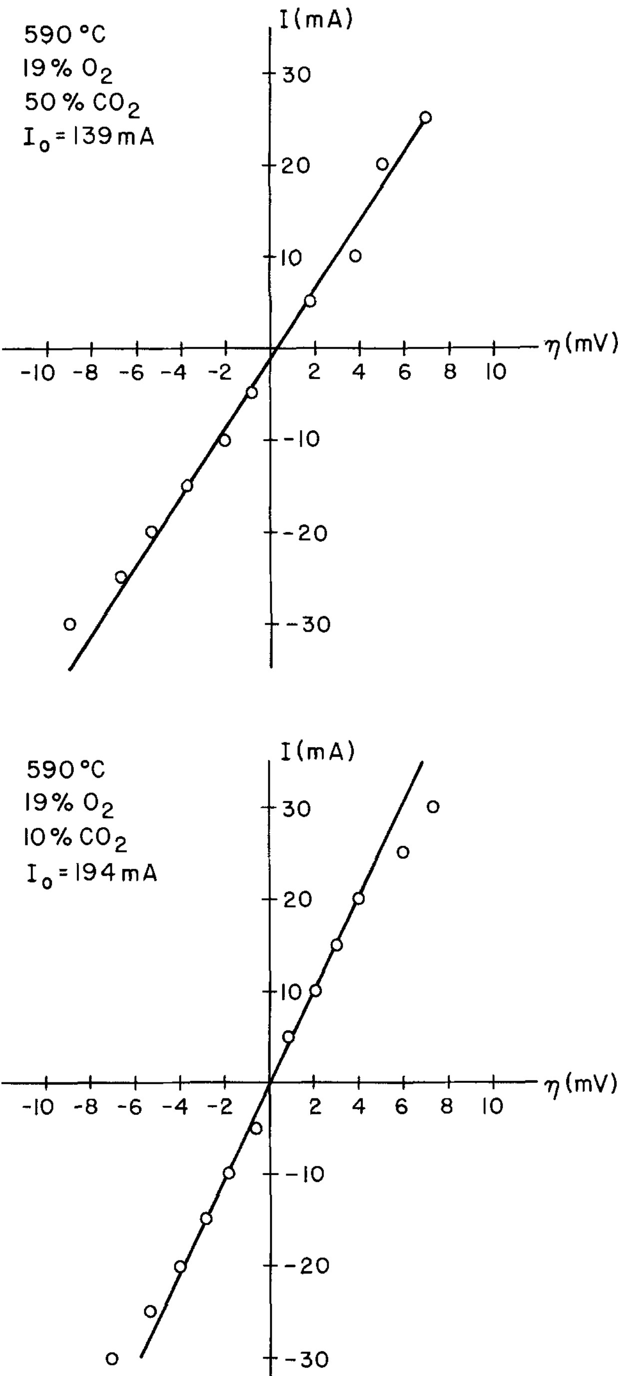
$$\left(\frac{\partial \log I_\pm}{\partial \log P_{CO_2}}\right)_{E,T} = \begin{cases} -3/4 & \text{anodic} \\ +1/4 & \text{cathodic} \end{cases} \qquad [11]$$

$$\left(\frac{\partial \log I_\pm}{\partial \log P_{O_2}}\right)_{E,T} = \begin{cases} +1/8 & \text{anodic} \\ +5/8 & \text{cathodic} \end{cases} \qquad [12]$$

Discussion

It should be emphasized that the reaction orders given by Eq. [11] and [12] represent only apparent reaction orders, and not necessarily the true kinetic reaction orders. The distinction arises because the values of the transfer coefficient (α_-) were determined using porous electrodes, and the possible effects of diffusion on the polarization behavior of these electrodes must either be accounted for or eliminated experimentally. Modeling studies (9) on Ni sinter electrodes like those used here have indicated that diffusion polarization is not significant for total polarizations *ca.* $RT/\mathbf{F}$ if the carbonate melt wets the electrode in an optimal fashion. The very high limiting currents observed with these electrodes (as in Fig. 4) indicate that the ideal thin-meniscus structure was approached with this cell configuration, and that polarization behavior observed here was essentially kinetically controlled. Independent studies (12) utilizing nonporous electrodes and applying transient techniques have indicated the transfer coefficient α_- is 0.6 ± 0.05, close to that found here. However, while there is some support for a claim that the reaction orders found in this work are the kinetic orders, the determination is certainly not definitive. More properly, one should regard these reaction orders as representative of the polarization behavior of the paste electrolyte-Ni sinter electrode technology represented by our apparatus. As such, they are useful for systems analysis and for the design of large scale hardware based on this representative technology.

The cathodic reaction, of primary interest for fuel cell application, has a low but finite order in CO_2 pressure and the power density of the cell at constant voltage will increase with increasing CO_2 pressure. However, increasing CO_2 partial pressure decreases O_2 pressure, and since the reaction order for O_2 is higher than that for CO_2, this will result in a power density function that has an optimum CO_2/O_2 ratio, *i.e.*, an



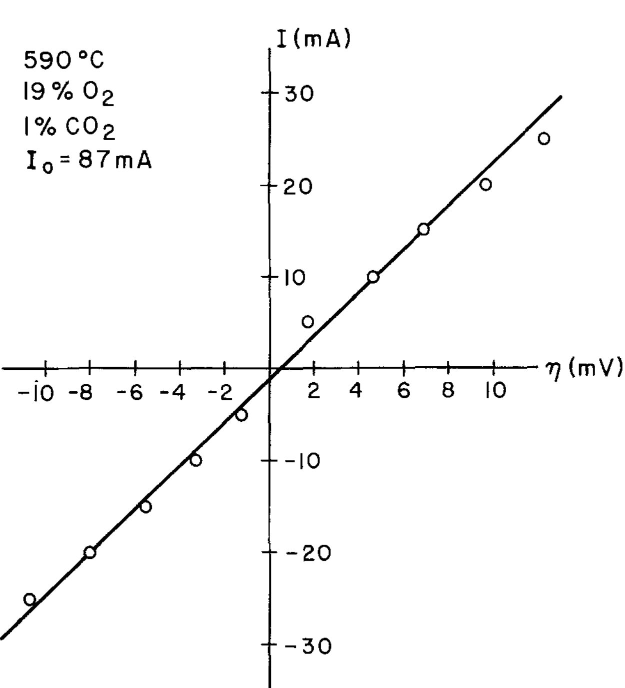


Fig. 3. Polarization curves near the rest potential as a function of CO_2 pressure.

optimum CO_2 recycle ratio subject to the constraint of no net rate of removal of carbonate from the cell.

The reaction orders in CO_2 are ideally suited to the operation of this cell as a gas concentrator. In this application, CO_2 is removed from a CO_2/O_2 mixture with very low (*e.g.*, 0.005 atm) CO_2 partial pressure by cathodic reduction to CO_3^{2-}, and transported by anodic evolution to a carrier gas stream where the CO_2 pressure is relatively high. The cathodic reaction has a low order in CO_2, so that the kinetics for CO_2 reduction are high even at very low CO_2 partial pressure.

It is interesting to note that none of the reaction mechanisms yet proposed (7, 11) for the CO_2/O_2 reaction in alkali carbonate melts are consistent with the reaction orders we report here. They are also very different from the values reported by Appleby and Nicholson (7, 11) for Au, which may be indicative of differences in kinetics between Au and NiO electrodes. Since the possible influence of diffusion on the reaction orders has not been eliminated in this work, conclusive statements about reaction mechanisms cannot be made. It is also possible that the NiO electrode surface chemistry changes as a function of the CO_2/O_2 ratio by virtue of the Lux-Flood acid-base properties of the carbonate electrolyte, *i.e.*, the equilibrium concentration of oxide ion in the melt. Future mechanistic studies of the CO_2/O_2 reaction should consider the use of (specific) oxide ion electrodes to monitor possible changes in melt basicity with gas composition.

Electrocatalytic Activity of Cubic Sodium Tungsten Bronze

I. Effects of Platinum Doping, Anodization, and Platinum Pre-Electrolysis of the Electrolyte

Michael Francis Weber,*[,1] A. J. Bevolo, H. R. Shanks, and G. C. Danielson

Ames Laboratory-USDOE and Department of Physics, Iowa State University, Ames, Iowa 50011

ABSTRACT

The electrocatalytic activity of cubic sodium tungsten bronzes, including high purity and platinum-doped crystals, has been measured for oxygen reduction before and after anodization in both fresh and platinum pre-electrolyzed acid solutions. The effects of platinum doping, anodization, and platinum pre-electrolysis have been separately studied for current densities between 10^{-8} and 10^{-3} A/cm^2. A previously unreported break in the Tafel curve at 4×10^{-5} A/cm^2 was observed for all clean undoped bronze samples. Below this break the Tafel slope was −110 mV/decade while above it the Tafel slope was −200 mV/decade. Anodization of a pure bronze electrode failed to produce any change in the Tafel curve. Platinum pre-electrolysis of an anodized, undoped bronze produced a general increase in activity for all current densities. The break in the Tafel curve increased to 1×10^{-4} A/cm^2 while the Tafel slopes above and below this current density were unchanged. Platinum doping to 130 ppm increased the electrode activity at current densities below 1×10^{-6} A/cm^2, even when measured in platinum-free solutions before anodization of the electrode. The increased activity of an unanodized electrode in fresh solutions could be accounted for by the surface platinum concentration expected from the bulk platinum doping. Anodization of a doped bronze electrode increased the limiting current from 1×10^{-6} to 5×10^{-6} A/cm^2 even in fresh solutions while subsequent platinum pre-electrolysis increased the limiting current to 5×10^{-5} A/cm^2. Auger analysis of the anodized, platinum-doped electrode exposed to the platinum pre-electrolyzed solution revealed platinum on the surface of the bronze electrode at a coverage sufficient to account for the increased electrode activity below 5×10^{-5} A/cm^2. A small but reproducible increase in activity was found at high current densities near 10^{-3} A/cm^2 after either a pure or platinum-doped bronze electrode was exposed to a platinum pre-electrolyzed solution that lead to the research reported in the following paper (II).

After Sepa *et al.* (1) reported the sodium tungsten bronzes to be excellent electrocatalysts for oxygen reduction, several workers tried to confirm their results. Experiments by Broyde (2) did not reproduce the spectacular results. He reported only limited catalytic activity for oxygen reduction on powdered bronzes, including sodium, cerium, and nickel tungsten bronzes. A subsequent paper by Fishman, Henry, and Tessore (3) observed that traces of platinum on the sodium tungsten bronze surface were needed to produce the high catalytic activity. In their experiments, they found that platinum could be deposited on the bronze by dissolving minute traces of platinum from a large platinum electrode in the test cell. Bockris and McHardy (4) then claimed that only 400 ppm platinum doping of the bronze produced platinum-like behavior for oxygen reduction. They assumed that the surface concentration of platinum was the same as the bulk concentration, which led them to suggest that a synergistic effect for oxygen reduction existed in the platinum-bronze system. However, the findings of Bockris and McHardy (4) on platinum-doped single crystals were disputed by Randin (5) and by Weber and Shanks (6). On the other hand, the results of Bockris and McHardy were reproduced by Appleby and Van Drunen (7). Platinum pre-electrolysis (PPE) was used to clean the solutions used in their experiments, as it was in Bockris and McHardy's experiments, but possibilities of platinum contamination were not considered by either group. Fredlein (8) has recently reported on the effects of PPE on the activity of platinum-doped as well as undoped Na_xWO_3. He observed only a change in Tafel slope from −240 to −120 mV/decade after his PPE treatment of undoped bronzes. Upon doping he observed increased activity at low current densities of the type reported in Ref. (4 and 7). He concluded that his PPE treatment, which was identical to that of Ref. (4), primarily resulted in the deposition of platinum onto the bronze surface. However the type of increased activity associated with platinum doping was different from that observed after his PPE treatment. The possibility that the change in Tafel slope after his PPE treatment was primarily due to removal of organic impurities from the bronze surface was not eliminated. A number of other papers have dealt with oxygen reduction on pure bronzes (9-11) and on platinum-coated bronze powders (12), but not for platinum-doped single crystals.

Bockris and McHardy (4) platinum pre-electrolyzed their solutions to reduce the organic contamination so that measurements could be made as low as 10^{-9} A/cm^2. Their interpretation of the enhanced activity as a synergistic effect failed to take into account the possibility of additional platinum contamination of their electrodes. On the other hand, Randin (5), who chose to avoid the possible contaminating effects of PPE, was forced to take measurements above 10^{-5} A/cm^2 because of the presence of other impurities in the electrolytes. Since nearly all of the results reported by Bockris and McHardy (4) were taken below 10^{-5} A/cm^2, a comparison of their results with those of Randin (5) necessarily involved extrapolation from one current density to another. As we shall see this proved to be impossible since the Tafel plots are anything but straight lines from 10^{-7} to 10^{-3} A/cm^2.

Clearly, then, what was required was the ability to take Tafel data below 10^{-5} A/cm^2 without PPE. By careful attention to the possible sources of contamina-

Key words: surfaces, fuel cell, current density, Tafel slape.

tion from the gases, the electrolyte, the cell itself, and the bronze crystals we have been able to make Tafel measurements to current densities below 10^{-7} A/cm^2 without platinum pre-electrolysis. This system allowed reproducible data to be taken so that the effects of bronze surface treatments, anodization, bulk platinum doping, and PPE could be separately studied from 10^{-7} to 10^{-3} A/cm^2. In addition to the electrochemical studies, Auger electron spectroscopy was used to examine the surface of the treated bronze samples with special regard to the incorporation of Pt after various treatments. This surface analytical tool is especially suited for studies of suspected irreversible contamination of an electrode surface and it proved invaluable in unraveling the complex electrochemistry of the sodium tungsten bronzes.

The results of this investigation are reported in two parts. The first part, presented in this paper (I), concerns the effects of bulk Pt doping, anodization, and platinum pre-electrolysis. The second part, given in the following paper (II), concerns the activation of a pure bronze electrode by intentionally incorporating Pt onto its surface by a variety of electrochemical techniques.

Experimental

Crystal growth.—All measurements in this study were done on single crystals of sodium tungsten bronze, which were prepared by the electrolysis of a fused salt of sodium tungstate and tungsten trioxide as described by Shanks (13). By this method single crystals, approximately 2 cm or more on an edge, were obtained with a composition of $Na_{0.7}WO_3$. Platinum doping was achieved by the use of a platinum anode in the melt. The doped crystal contained 800 ppm atomic platinum referred to tungsten as determined by mass spectrographic analysis. Referred to Na_xWO_3 this concentration of platinum becomes 130 ppm by weight which is the form used in Ref. (4 and 8).

Sample preparation.—For the electrochemical studies the bronze crystals were either cleaved or cut on a high speed diamond saw into smaller pieces, a typical sample size being 4 $\times$ 4 $\times$ 6 mm. The cleaved crystals were cleaned in boiling conductivity water, but the crystals cut on the diamond saw required a more elaborate cleaning procedure. Contaminants were removed first by boiling in ethyl acetate, followed by hot concentrated NaOH, and finally by boiling in conductivity water. The samples cut on the diamond saw were then either polished, or one end was cleaved away to ensure a fresh, pure bronze surface. Polishing was performed after the crystal was mounted in Teflon using the method described by Nagy and McHardy (14).

The samples were mechanically polished on microcloth with alumina powder down to 0.05 μm particle size. Immediately before insertion into the cell, all samples were washed with acetone, then with isopropyl alcohol. The final cleaning was done with an isopropyl alcohol vapor phase degreaser. The area of each sample was determined from a photograph of the mounted crystal, with no corrections being made for surface roughness. After insertion into the cell, the potential on each electrode was cycled between -0.1 and 1.6V NHE for approximately 20 min to further clean the surface. Only small changes in the cyclic voltammetry curves were observed during this time.

Test cell and distillation unit.—Research in many areas of electrochemistry requires ultrahigh purity experimental conditions before reliable information can be obtained (15). The most notable problem area in this regard is the electrochemistry of oxygen. The correct rest potential of 1.23V HE for oxygen reduction in acid solutions can be obtained only under extremely stringent conditions of purity on carefully prepared electrodes (16-18). Fortunately, a good Tafel plot, with the correct slope and exchange current, can be obtained under somewhat less stringent conditions, although the problems are still serious.

A common practice is that of "pre-electrolyzing" the solution, usually with large platinum electrodes (19). However, it was suspected that trace amounts of platinum were dissolved from these electrodes (20) which could then plate out onto the test electrodes (6). If the electrode being studied is also platinum, then no problem should result, but such a situation limits the use of pre-electrolysis to a minority of experiments. Therefore, a cell of sufficiently high purity had to be constructed which permitted studies of oxygen reduction to be performed without the use of pre-electrolysis. This cell was connected to a high purity water distillation unit that permitted the *in situ* distillation of water and solution preparation. Complete details of this electrochemical test apparatus are given in a separate report (21). A brief description is given here.

The electrochemical cell had three compartments each constructed entirely of quartz and Teflon. The counterelectrode was a gold foil with H_2 gas bubbled over it. A palladium hydride electrode (22) was used as a reference electrode. The Pd-H electrode was constantly checked against a saturated calomel reference electrode since its potential tended to drift for long times after recharging with hydrogen. Thus all potentials given here are referenced to the normal hydrogen electrode using the relation

$$V_{\mathrm{NHE}} = V_{\mathrm{SCE}} + 0.242\mathrm{V}$$

Since the effects of traces of platinum were being investigated, no platinum electrodes touched the solutions used for studies on the bronzes, except for those solutions that were Pt pre-electrolyzed.

Extensive efforts were made to purify the gases bubbled into the cell. "Zero oxygen" with 0.2 ppm total hydrocarbons (THC) was passed through a quartz tube of platinized asbestos at 450°C, then over moist KOH, and finally through two traps containing Linde 13X molecular sieve. When an inert atmosphere was needed "zero helium" ($<$0.5 ppm THC) was passed over hot copper turnings and through two liquid N_2 cooled cold traps also containing Linde 13X molecular sieve. Zero hydrogen (0.5 ppm THC) was passed through two traps of Linde 13X molecular sieve when a hydrogen atmosphere was required. The gas handling system was constructed entirely of acid-etched stainless steel and Pyrex tubing, with Fischer and Porter glass-Teflon valves and stainless steel Swagelock tubing connectors.

Platinum pre-electrolysis was done with a 20 cm^2 shiny platinum foil anode and a gold cathode carrying current of 20 mA for 24 hr prior to the exposure of the bronze electrode to the PPE solution.

The degree of cleanliness of the system is indicated in Fig. 1 by a cyclic voltage scan on a high purity platinum electrode. The platinum electrode was mounted in Teflon and polished in the same manner as described above for the bronze samples. No PPE of the solution had been performed. Well-defined hydrogen adsorption and desorption peaks and platinum oxide formation and reduction peaks are observed. No impurity oxidation peaks were observed at lower sweep rates or when the solution was stirred. Rest potentials on the platinum test electrode in fresh solutions were normally near 0.98V NHE. The only solution used in the cell for this study was 0.1*N* H_2SO_4 (*p*H 1.2) mixed *in situ* from Apache Chemical 99.9999% pure (distilled in Vycor) sulfuric acid. This *p*H value permitted comparison to the work of other investigators, particularly, Bockris and McHardy (4), and reduced corrosion currents to a minimum.

The catalytic activity of a sample for the oxygen or hydrogen reaction was determined from the Tafel plots of the current-potential data. The general electrochemical properties of the bronzes were studied by linear sweep cyclic voltammetry and these results were reported in a previous publication (23). Chemical compositional analysis of the electrode surfaces was performed by Auger electron spectroscopy. In addition,

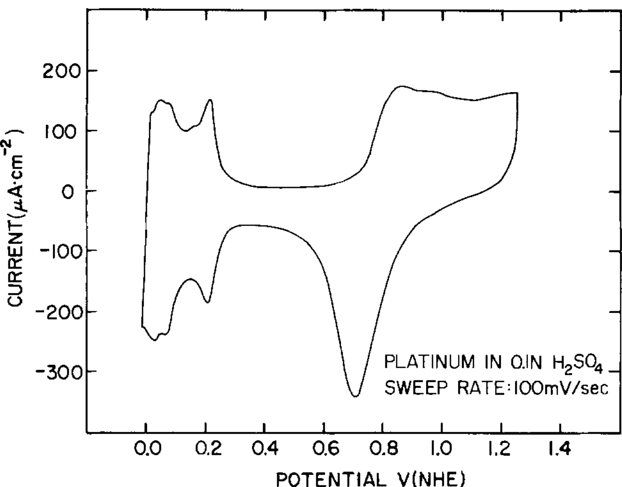

Fig. 1. Cyclic voltammetric curve for Pt taken in high purity test cell without Pt pre-electrolysis of the acid solution. The well-defined H_2 absorption and desorption peaks near 0.0V and PtO oxidation and reduction peaks near 0.7V indicate very clean experimental conditions in the cell.

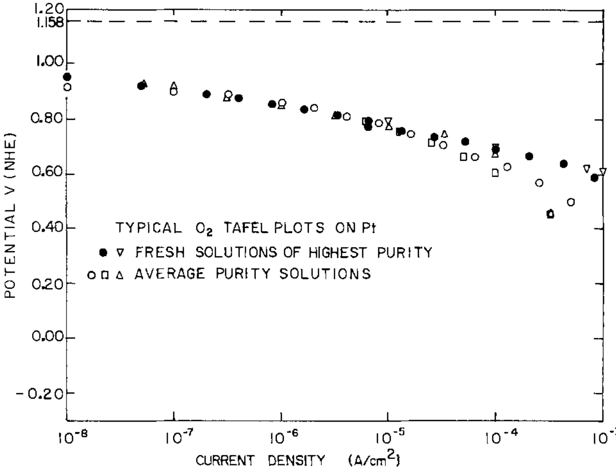

Fig. 2. Oxygen Tafel plots taken on a Pt electrode under the same experimental conditions as used for testing the bronze crystals. This data was taken without Pt pre-electrolysis of the solution.

scanning electron micrographs helped reveal the surface morphology of the samples.

Data for the Tafel plots on all samples were obtained galvanostatically, in the current density range 10^{-3}-10^{-8} A/cm². Currents were generated with a very stable, constant current power supply (24). A Keithley Model 640 electrometer was used to measure the potentials, while its output was read on a Dymec Model 2401A five digit integrating DVM. All measurements were made at 25° ± 2°C. All samples required from 2 to 5 hr at each data point to reach a steady-state potential, which was defined to be a potential drift of less than 1 mV/10 min. True steady-state conditions were checked by allowing 9 hr for the steady-state condition to occur on approximately 1/6 of all data points. Also, the first point was allowed at least 8 hr to reach steady state. This procedure insured reproducible curves. Data were taken by starting at high currents and decreasing the current by halving it for each succeeding point. No difference in the steady-state data was observed if the data were taken by starting at low current densities. However, the time to reach steady state was longer if the data were taken at low current densities first. A similar effect was reported in Ref. (4 and 8). For a valid comparison to pure platinum, the Tafel plot on the platinum sample was obtained in exactly the same manner. For this reason, the Tafel plot shown for platinum is somewhat different than the data usually seen in the literature. In most figures shown here, a Tafel plot for O_2 reduction in platinum is given for comparison with the bronzes.

A variety of Tafel plots for the platinum can be found in the literature because of different measurement procedures or different solution purities. Most steady-state data on platinum involves a 2-5 min wait between data points. Prolonged cathodic polarization for O_2 reduction may result in the buildup of hydrogen peroxide in the solution, which results in a lowering of the observed potentials (25). Each Tafel plot for the bronzes required 2 or 3 days because of a 3-4 hr wait for steady state to occur at each point. Comparison with the bronze electrodes becomes difficult because platinum is more sensitive than the bronzes to the buildup of impurities in the cell during a 2 day Tafel measurement. Since the cell was rather well sealed, and ultrapure solutions could normally be stored for several weeks in the storage flask, the impurity was either hydrogen peroxide, which was produced during oxygen reduction, or residual impurities from the gas and solution that showed a preferential adsorption on the platinum electrode. In any case, the high rest potentials of 1.00V NHE could not be reproduced after 1 day of measurements, and after 2 days of measurements, large deviations in potential occurred at the higher current densities on platinum. Our Tafel data on platinum are shown in Fig. 2. The solutions were not pre-electrolyzed, so the slope was less than the normal 100 mV/decade due to traces of impurities remaining in the solution. In 0.1N H_2SO_4, the theoretical rest potential of the oxygen reaction is 1.158V NHE and is −0.072V NHE for the hydrogen reaction.

Auger analysis.—The Auger analysis of the bronze surfaces was performed using a Physical Electronics Model 10-155 cylindrical mirror analyzer with a 5 kV-50 μA integral electron gun. Typically a 4 kV-5 μA electron beam, focused to 50 microns, was incident to the sample normal at an angle of 60°. Figure 3 shows a typical Auger spectrum of a pure Na_xWO_3 crystal before any electrochemical treatment. The most important transitions for each element were labeled by their electron energies. The carbon peak at 272 eV was always present and is due to approximately one monolayer coverage of hydrocarbons picked up by the sample as it was transferred from the electrochemical test station to the surface analysis chamber. Preferential desorption of oxygen by the focused 5 μA electron beam was observed and this resulted in an equilibrium oxygen to tungsten ratio closer to two than the bulk value of three. However, the electron beam current

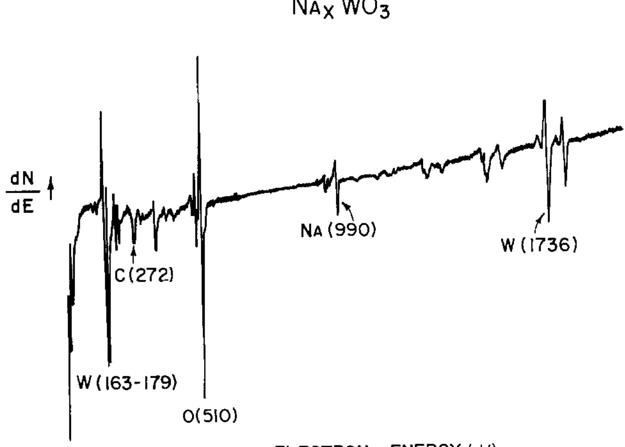

Fig. 3. Auger spectrum of an air cleaved single crystal of $Na_{0.7}WO_3$ prior to any electrochemical treatment showing the prominent Auger peaks of the tungsten bronze and the carbon peak due to the thin hydrocarbon overlayer. The peaks are labeled by their respective electron energies.

density could not be reduced any further without hampering the detection of small amounts of platinum on the bronze surface.

Results

Undoped Na_xWO_3 electrodes.—Figure 4 shows data for undoped Na_xWO_3 crystals before and after our PPE treatment as well as results for pure platinum and an undoped bronze in a helium-saturated solution. Also shown in Fig. 4 are the data from Ref. (5, 6, 8) for undoped bronze electrodes. In the complete absence of platinum, from either bulk doping or possible contamination by our PPE treatment, a pure Na_xWO_3 electrode does exhibit some activity for oxygen reduction when the results are compared to those taken in a helium-saturated solution. However, the exchange current density is estimated to be 10^{-14} A/cm² and the rest potential is near 0.5V (NHE), both of which are very low values. Not shown in Fig. 4 are the data on samples before anodization since the results are essentially unchanged after anodization. Also not shown in Fig. 4 are the data for polished or cleaved samples since there is little difference from that of the polished and NaOH etched sample used to take the data given in Fig. 4.

Two features of the Tafel curve shown in Fig. 4 taken prior to our PPE treatment have not been previously reported. First, we find a break in the Tafel curve at 4×10^{-5} A/cm² which moves to 1×10^{-4} A/cm² after our PPE treatment. This break was observed on all samples that had been thoroughly cleaned and measured in our test cell, but it was not observed in our first report on the bronze electrodes (6) where less stringent cell and sample cleanliness procedures were used. The second new feature is that below 1×10^{-4} A/cm² the Tafel slope is −110 mV/decade, close to $-2\ RT/F$. All previous measurements in this current density range prior to any PPE treatment produced Tafel slopes near $-4\ RT/F$, even our prior measurements (6) performed in a less clean environment.

After our PPE treatment of undoped bronzes slightly higher potentials at all current densities were observed with no change in Tafel slope at low current densities from the $-2\ RT/F$ value observed before PPE. The straight line Tafel behavior below 4×10^{-5} A/cm² down to current densities near 1×10^{-7} A/cm² indicates very low corrosion rates for the bronze electrodes.

Platinum doped Na_xWO_3 electrodes.—Figure 5 shows data on bronze electrodes doped with platinum as a function of anodization and our PPE treatment. Prior to either anodization or PPE there is an increased activity below 1×10^{-6} A/cm², but no change in the Tafel plot above this current density when compared to an undoped bronze (Fig. 4). The increased activity below 1×10^{-6} A/cm² can only come from the presence of platinum atoms on the bronze surface due to the bulk doping.

Prolonged anodization of this sample at 1 mA/cm² to a potential of 9V prior to our PPE treatment significantly improved its activity for current densities between 1 and 5×10^{-6} A/cm². The rest potential of the anodized, doped bronze electrode reached 0.72V (NHE). No change in the Tafel curve was detected above 5×10^{-6} A/cm².

Our PPE treatment of the anodized, doped bronze electrode shown in Fig. 5. resulted in further increases in potential at all current densities. The rest potential rose to 0.8V (NHE) while increased activity occurred from 5×10^{-6} to 4×10^{-5} A/cm². Also there was an increase in potential above 4×10^{-5} A/cm² similar to that observed for an undoped bronze. It is significant that our PPE treatment of a platinum-doped bronze electrode (Fig. 5) produced a qualitatively different increase in activity from 5×10^{-6} to 4×10^{-5} A/cm² when compared to its effect on an undoped electrode (Fig. 4). This anodized, doped bronze electrode after PPE produced the highest electrocatalytic activity for oxygen reduction of any sample reported in this study. Its overpotential was only 0.1V larger than that of bulk platinum at all current densities below 1×10^{-5} A/cm². It was noted that if the doped samples were anodized for longer periods of time in the PPE solutions their activities would increase.

Auger analysis.—Figure 6 shows the Auger spectrum of a $Na_{0.7}WO_3$ sample doped with 130 ppm Pt after cleaving in air. Even at the highest possible gain no platinum signals were observed at 1967 and 2044 eV. It is estimated that the minimum detectable Pt/W ratio, averaged over the 25Å escape depth (26) expected for these high energy Auger transitions, is about 0.003 which is higher than the bulk Pt/W ratio of 0.0008. Figure 7 shows the Auger spectra of an anodized sample after it had been measured in a Pt

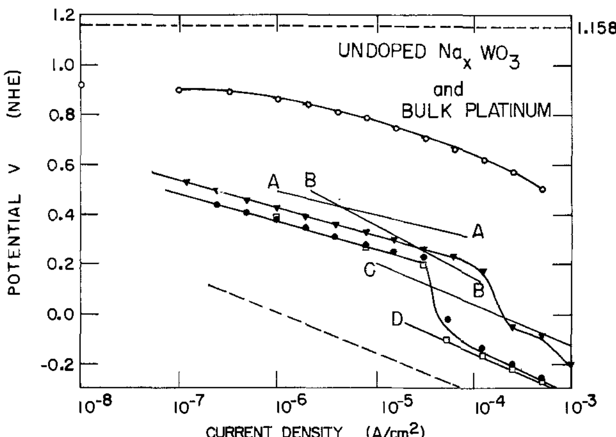

Fig. 4. Oxygen Tafel plots of an undoped bronze sample taken in fresh (●, □) and platinum pre-electrolyzed (▼) solutions. The dashed line represents the Tafel line for an undoped bronze in a helium-saturated solution. Also shown are Tafel plots of undoped bronzes taken from Ref. (8) before (B) and after (A) platinum pre-electrolysis and from Ref. (6) (C) and Ref. (5) (D) before platinum pre-electrolysis. Only this work (●, □) shows a slope of nearly $-2\ RT/F$ and a break in the Tafel plot at 5×10^{-5} A/cm² prior to platinum pre-electrolysis. All previous results show no break and a Tafel slope of approximately $-4\ RT/F$. Tafel plot for pure platinum (○) is also shown (○).

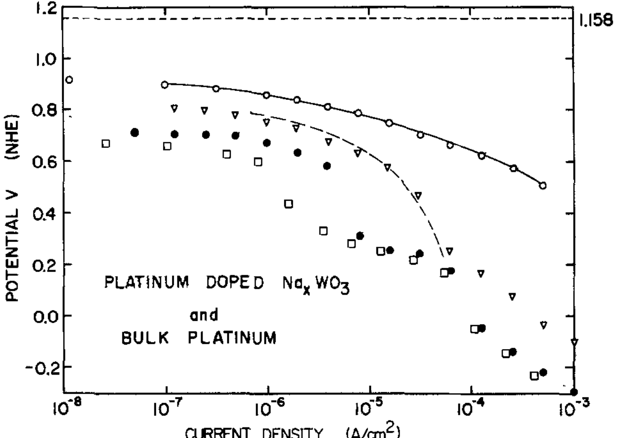

Fig. 5. Oxygen Tafel plots of a platinum-doped Na_xWO_3 electrode before anodization or platinum pre-electrolysis (□), after anodization but before platinum pre-electrolysis (●), and after both anodization and platinum pre-electrolysis (▽). Both anodization and platinum pre-electrolysis increase the electrode activity at lower current densities, while only platinum pre-electrolysis has any significant affect at high current densities. The increased activity below 10^{-4} A/cm² is believed to be due to increased surface platinum produced by anodization and pre-electrolysis. A Tafel plot for pure platinum (○) and that taken from Ref. (8) (- - -) for a doped Na_xWO_3 electrode before platinum pre-electrolysis but after anodization are also shown.

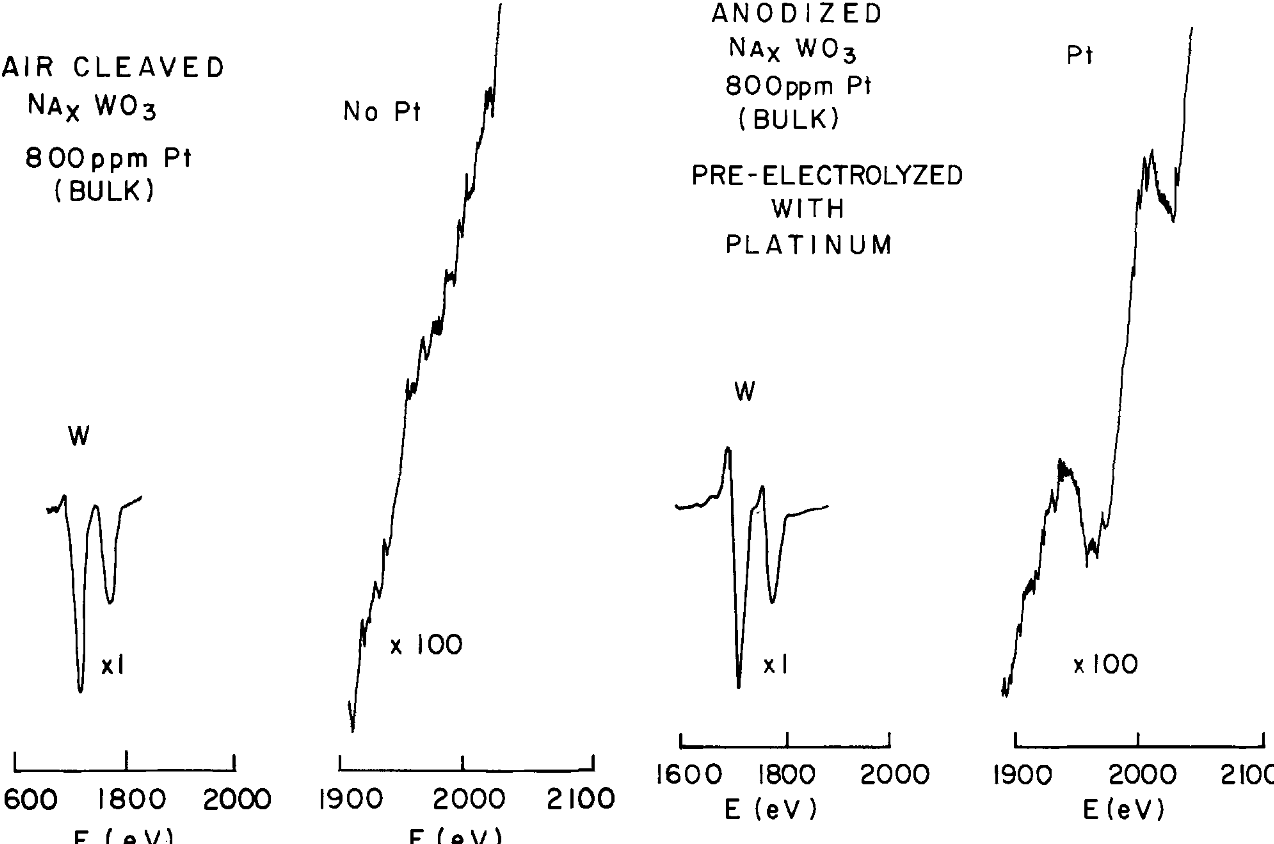

Fig. 6. Auger high energy spectra of a platinum-doped (Pt/W atomic ratio of 800 ppm) bronze crystal cleaved in air. No Pt (1967) Auger signal is evident.

Fig. 7. Auger high energy spectra of platinum-doped (Pt/W atomic ratio of 800 ppm) bronze crystal after anodization and platinum pre-electrolysis treatment resulting in the Tafel plot denoted by ▽ in Fig. 4. The platinum doublet is clearly evident.

pre-electrolyzed solution which resulted in the enhanced activity previously shown in Fig. 5. The presence of platinum Auger signals at their correct energies and relative intensities confirms that combined anodization and Pt pre-electrolysis results in an increase surface platinum coverage of the bronze electrode over and above the presence due to bulk Pt doping. From the relative sensitivity factors for these tungsten and platinum Auger transitions, measured from bulk metal samples taken under the same experimental conditions, we estimate the Pt/W ratio to be 1%. Assuming a WO_3 surface composition for the bronze sample the Pt concentration is 0.25% referenced to sodium, the most likely site to be occupied by the platinum atoms.

In the Auger spectrum of clean, bulk Pt there is a very intense transition at 64 eV. Because of a very small escape depth of about 4Å (26), this transition proved to be very sensitive to small changes in the surface carbon layer and could not be used to measure reliably the platinum surface coverage. Although considerably weaker than this 64 eV transition, the high energy peaks shown in Fig. 6 and 7 have escape depths of about 25Å so that they were much less sensitive to variations in the thickness of the hydrocarbon layer. In addition, these high energy transitions have nearly the same escape depth so that their intensity ratio is expected to be independent of the thickness of the carbon overlayer. The 0.25% Pt concentration quoted above assumed that the platinum is uniformly distributed over the 25Å escape depth of the Pt and W transitions. If the platinum is confined to the top monolayer (~2.5Å) of the bronze surface then the Pt coverage would be approximately ten times larger or about 3% for the Auger spectra shown in Fig. 7.

Discussion

Undoped Na_xWO_3 electrodes.—Referring to Fig. 4, all three previous investigations (5, 6, 8) in the absence of PPE have nearly identical slopes of $-4\ RT/\mathbf{F}$ while our data in the absence of PPE show a slope of $-2\ RT/\mathbf{F}$ for current densities below 4×10^{-5} A/cm^2. Only above the break in our Tafel plot does the slope change to $-4\ RT/\mathbf{F}$. A slope of $-2\ RT/\mathbf{F}$ was obtained even before any PPE treatment so that it cannot be associated with absorbed platinum on the bronze electrode as Fredlein (8) has proposed. It is our contention that the $-4\ RT/\mathbf{F}$ slope is due to surface organic contamination of the bronze electrode whose source is either the electrode itself or the solution. Only by using stringent cell design and sample cleaning methods were we able to produce the $-2\ RT/\mathbf{F}$ in the absence of any PPE. Support for this assumption comes from our prior observations (6) under less stringent conditions that produce a $-4\ RT/\mathbf{F}$ slope and no break in the Tafel plot at 4×10^{-5} A/cm^2. Also cyclic voltammograms of undoped bronzes in platinum-free solutions showed little change after the first sweep indicating a very clean surface. Fredlein (8) after PPE treatment observed a $-2\ RT/\mathbf{F}$ slope which suggests to us that the cause of this change in slope is the removal of organic contaminants by PPE of the electrolyte. Fredlein (8) ascribed this change in slope to adsorbed platinum released during PPE treatment. We reject this interpretation on two grounds. First as just discussed we observed a $-2\ RT/\mathbf{F}$ slope prior to any surface platinum contamination of the electrode by either PPE or bulk doping. Second, the type of changes in Tafel behavior observed after PPE by us, as well as Fredlein (8), is distinctly different than that observed on doped samples measured prior to PPE (see Fig. 4 and 5). We conclude that our samples were nearly free of organic contamination in fresh electrolytes and that the Tafel behavior shown in Fig. 4 with the break at 4×10^{-5} A/cm^2 is a test, along with the $-2\ RT/\mathbf{F}$ slope, of the cleanliness of the bronze surface. This conclusion is supported by the fact that after our PPE treatment no change in the $-2\ RT/\mathbf{F}$ slope is evident

below 4×10^{-5} A/cm^2 while the break at 4×10^{-5} A/cm^2 increased after our PPE, both of which are readily explained as a further cleaning of the electrodes by the PPE treatment, if we interpret this break as a limiting current for oxygen reduction on a platinum-free bronze surface i_L(B).

It is of some interest to compare our results on undoped bronze electrodes with those of Bockris and McHardy (4) and Randin (5). The data of Ref. (4) (not shown for clarity in Fig. 4) taken after PPE is identical to our data taken after PPE over the complete range in current density from 1×10^{-7} to 1×10^{-4} A/cm^2 that is available from Ref. (4). The data of Ref. (4) did not extend to current densities above 1×10^{-4} A/cm^2 where we observed a break in the Tafel slope. However below 1×10^{-4} A/cm^2 the slopes are identical at $-2\ RT/\mathbf{F}$ which we interpret to mean that the samples used by Bockris and McHardy (4) are nearly free of organic contamination as a result of PPE treatment. Our data above 4×10^{-5} A/cm^2 taken prior to any PPE also agree very well with those of Randin (5) who did not use any PPE treatment. Our data showing a break in Tafel slope before and after PPE eliminates PPE as a source of the difference between the results of Bockris and McHardy (4) and those of Randin (5). Rather this difference is due to an intrinsic property of a clean bronze electrode, namely, the break in Tafel slope we have observed.

Platinum doped Na_xWO_3 electrodes.—Results on a platinum-doped electrode prior to either anodization or any PPE are shown in Fig. 5. The break at 1×10^{-6} A/cm^2 presumably represents a limiting current for oxygen reduction due to surface platinum on the bronze surface, i_L(BP), which is about 10^{-3} times smaller than the limiting current for pure platinum i_L(P) as measured in the same cell. The expected surface concentration of platinum on the doped bronze electrodes is 0.0008 which is also about 10^{-3} times smaller than the surface platinum coverage of a pure platinum electrode. Thus our value of i_L(BP) is readily accounted for by the expected surface platinum concentration of the doped Na_xWO_3 electrode if the activity of a platinum atom is the same for both types of electrodes. This latter point is discussed below.

All previous investigations have reported enhanced activity of platinum-doped Na_xWO_3 electrodes after anodization. We have shown the effects of prolonged anodization to 9V in Fig. 5, prior to any PPE, where the increased activity is confined to current densities below 10^{-5} A/cm^2. In particular no change in i_L(B) at 10^{-4} A/cm^2 or any significant increase in potential above i_L(BP) was observed after anodization. This indicates that the enhanced activity in the 10^{-5} A/cm^2 current density region is not due to surface roughening. The form of the increased activity after anodization suggests additional surface platinum on the bronze electrode that causes i_L(BP) to increase from 1×10^{-6} A/cm^2 to about 5×10^{-6} A/cm^2 and the rest potential to rise from 0.65 to 0.72V (NHE). It has been known for some time that anodization removes sodium from the surface of Na_xWO_3. The heavy anodization used to produce the results shown in Fig. 5 is shown in Part II to produce a sodium depletion layer approximately 1000Å thick. Having eliminated surface roughing and platinum absorption from the solution (*i.e.*, data taken prior to any PPE) and accepting that the form of the increased activity suggests increased platinum surface coverage, a possible source of the additional surface platinum is the electromigration of platinum atoms from the bulk of the crystal. The empty sodium sites provide diffusion paths for the Pt^{++} ions to migrate to the surface under the influence of the anodic potential applied during anodization. In addition, the ionic radius of Pt^{++} is nearly identical to that of Na^+ at 0.96Å so that size effects would not inhibit electromigration. Unfortunately the required fivefold increase in surface platinum coverage is just below the detection limit of our Auger spectrometer, so our hypothesis of platinum electromigration could not be directly verified.

Our data for anodized, doped platinum bronzes as well as those of Fredlein (8) both taken after PPE are shown in Fig. 5. Our data show increased activity for nearly all current densities after PPE treatment. The increases above 1×10^{-4} A/cm^2 are similar to those observed for undoped Na_xWO_3 shown in Fig. 4 after PPE. This increase at high current densities following PPE had not been previously reported and formed the basis for the studies reported in the next paper. The increased activity below 1×10^{-4} A/cm^2 is of the type associated with bulk platinum doping, *i.e.*, increased platinum on the surface of the bronze electrode. Indeed the surface platinum coverage required to explain the observed value of i_L(BP) is very close to that found by Auger analysis. It is proposed that the increased surface platinum on the bronze electrode after the PPE treatment is due to platinum dissolved in the electrolyte during the PPE treatment becoming attached to the bronze surface. Before this assumption can be fully accepted two results have to be explained. First, we did not observe any significant activity for an undoped bronze electrode after PPE. Second, no effect due to PPE was observed by Fredlein (8) on an anodized, doped bronze electrode and yet the activity of his electrode is very similar to ours after PPE treatment.

As shown in Fig. 4 for an undoped bronze electrode our PPE did not produce any significant increase in electrode activity of the type observed for a platinum-doped electrode which we have identified as surface platinum. A clue to the different response of undoped and doped Na_xWO_3 to our PPE is provided by the fact that attempts to intentionally contaminate the bronze surface (as described in II) were more successful at low platinum coverages when the bronze electrode was doped with platinum. This suggests that the platinum present on the bronze surface by virtue of bulk doping provides nucleation sites for those platinum atoms present in the electrolyte after PPE. In the absence of these nucleation sites the activation energy for absorption of platinum on a clean bronze surface is high enough to inhibit the incorporation of platinum onto the undoped bronze surface. Because of the low coverages involved we were unable to verify by Auger analysis whether platinum was present on an undoped bronze electrode after PPE treatment. As a result it is possible that platinum was present, but in an inactive form. Of the two hypotheses presented above it is our judgment that the nucleation hypothesis seems more feasible than the inactive platinum model.

If the nucleation model is accepted it remains to account for the absence of enhanced activity of an anodized, doped bronze electrode observed by Fredlein (8) after PPE treatment. Before addressing this point let us consider the relative i_L(BP) values before PPE of our electrode compared to Fredlein (8). Our value of i_L(BP) is about ten times less than that of Fredlein. Certainly one source of this discrepancy is the threefold increase in bulk platinum used by Fredlein (400 ppm) compared to our 130 ppm platinum concentration. In addition differences in surface roughness or types of anodizations used could be important in explaining the relative difference in the reported activities of the electrodes before any PPE. However, none of these factors are relevant to the fact that Fredlein (8) did not observe any increase after PPE while we certainly did. The explanation lies in the different types of PPE used by the two studies. Fredlein (8) passed a 2 mA current through a cell volume of 100 cm^3 with a platinum gauze electrode with a geometric area of 50 cm^2 for 12 hr. Our PPE treatment passed a 20 mA current through a nearly equal cell volume with a platinum foil of 20 cm^2 for 24 hr. In addition, our PPE treatment was continued using a 5 mA current during the several days it took to acquire the Tafel data. Assuming equal surface roughness for the platinum electrodes, it would appear that our PPE treatment dis-

solved some twenty times the amount of platinum than the PPE treatment used by Fredlein. This large, additional source of platinum in our solutions is believed to be responsible for the increased activity of a doped, anodized bronze electrode after our PPE treatment.

Since Bockris and McHardy (4) used the same PPE treatment as Fredlein (8) it is evident that the effects they observed on anodized, platinum-doped bronzes were not dominated by adsorbed platinum from their PPE solutions. Rather it appears from our results that the increase in activity was due to anodization which produced an i_L(BP) only two orders of magnitude below i_L(P). It was the approximately three orders of magnitude lower platinum surface coverage, assumed by Ref. (4) to be present due to bulk platinum doping, that required a spillover model to increase the i_L(BP) by a factor of ten. As explained above, before anodization our i_L(BP) was 10^{-3} lower than i_L(P) so that the extra factor of ten must come from the effects of anodization. We have proposed that the primary mechanism is an increased surface coverage of platinum due to electromigration of bulk platinum atoms to the bronze surface during anodization. Certainly no spillover model was required to explain the combined effects of anodization and our PPE treatment since the Auger results show a surface platinum coverage sufficient to explain the observed value of i_L(BP).

Our results and those of Randin (5) for current densities above 5×10^{-5} A/cm² are in full agreement in that no effects due to platinum doping are evident (Fig. 4 and 5). However, in this current density range our PPE treatment did increase the potentials.

Some comments on the role of anodization are in order. Only in the presence of platinum did anodization enhance the bronze electrode activity. The removal of sodium from the surface after anodization provides vacant sites that permit the incorporation of additional platinum onto the bronze surface if there is a supply of platinum available from either the platinum pre-electrolyzed electrolytes or from bulk platinum doping. At very low coverages it seems that bulk platinum doping is required to induce platinum absorption from electrolytes containing platinum.

Simple bulk doping of the bronze crystal to a value of 800 ppm atomic referred to tungsten should result in atomically dispersed platinum atoms at a surface coverage of about 10^{-3}. Our data showing a value of i_L(BP) about 10^{-3} lower than i_L(P), prior to anodization or any PPE treatment, becomes understandable only if the presumably isolated platinum atoms on the bronze surface are just as active as they are when they are on the surface of a piece of platinum metal. It has been long suspected that a major source of platinum's electrocatalytic activity is its electronic structure with its high density of states near the Fermi energy. Recently a calculation of the density of states of Pt_xWO_3 with $x = 1$ has been made (27) which also gives a very high density of states at is Fermi energy. In a manner analogous to Na^+ ions in Na_xWO_3, the Pt^{++} ion in Pt_xWO_3 donates its outer electrons to the conduction band formed by tungsten d orbitals. Thus although the platinum atoms at sodium sites on the surface of Na_xWO_3 are isolated from each other in a chemical bonding sense, they find themselves in an electronic environment very similar to that of platinum metal. To the extent that electronic properties are important for electrocatalytic activity it seems plausible that a surface coverage of 10^{-3} on a doped bronze electrode would produce an i_L(BP) some 10^{-3} less than that of platinum metal. Thus the role of the bronze electrode, besides providing a corrosion-free substrate, seems to extend to provide a very favorable electronic environment for isolated platinum atoms.

Summary and Conclusions

In agreement with previous studies we find that pure cubic Na_xWO_3 free of any surface platinum is a poor electrocatalyst for oxygen reduction in acid solutions. Careful attention to cleanliness of the electrolyte and the bronze surface produced two new, reproducible features in the Tafel plot of an undoped bronze electrode measured in platinum-free solutions. A limiting current density, i_L(B), of 4×10^{-5} A/cm² for oxygen reduction on an undoped bronze electrode was observed. Also for the first time, a Tafel slope very near $-2\ RT/\mathbf{F}$ was measured for current densities below 4×10^{-5} A/cm² prior to any PPE treatment. All previous measurements (5, 6, 8), including our own (6) done under less stringent conditions of purity, produced a Tafel slope near $-4\ RT/\mathbf{F}$ for a platinum-free bronze electrode. Our ability to observe a $-2\ RT/\mathbf{F}$ Tafel slope prior to any PPE treatment rules out Fredlein's (8) contention that this slope is due to incorporation of platinum from platinum-contaminated solutions. The presence of the break in the Tafel plot at 4×10^{-5} A/cm² and the $-2\ RT/\mathbf{F}$ Tafel slope below this current density we believe is a test of the organic cleanliness of a bronze surface and therefore establishes the need for any PPE treatment of the electrolyte to remove this form of contamination.

Anodization of an undoped bronze electrode in platinum-free solutions produced little or no change in the Tafel plot of the electrode.

Our platinum pre-electrolysis treatment of an undoped, anodized bronze electrode did not change the $-2\ RT/\mathbf{F}$ Tafel slope at current densities below 4×10^{-5} A/cm², but it did increase i_L(B) from 4×10^{-5} to 1×10^{-4} A/cm². These effects along with the overall increase in potential at all current densities are believed to be due primarily to the further cleaning of the bronze electrode with respect to organic impurities rather than any absorption of platinum from the PPE treated electrolyte. These changes are not of the same type observed by bulk platinum doping of the bronze electrode.

Prior to either anodization or any PPE of the electrolyte, a bronze electrode doped with 800 ppm atomic platinum referenced to tungsten produced a significant increase in rest potential and enhanced electrocatalytic activity. However, this enhanced activity was totally confined to current densities below 1×10^{-6} A/cm², which was taken to be a limiting current density for oxygen reduction due to platinum on the surface of the bronze electrode, i_L(BP). This magnitude of i_L(BP) could be accounted for if the surface platinum atoms on the doped electrode had an activity equal to that of platinum atoms on a bulk platinum electrode.

Anodization of a doped bronze electrode even in platinum-free solutions produced increased electrocatalytic activity of the type found by bulk doping. The value of i_L(BP) increased from 1×10^{-6} to 5×10^{-6} A/cm² after anodization of the platinum-doped bronze, but no change in Tafel behavior above 5×10^{-6} A/cm² was observed. The latter observation eliminated surface roughening as a source of the increase in i_L(BP). Since this result was found in platinum-free solutions the only source of additional surface platinum to account for the increase in i_L(BP) was platinum from the bulk of the electrode. We proposed that electromigration of bulk Pt^{++} ions occurs to the surface of the bronze electrode during anodization. The presence of empty sodium sites after anodization, the polarity of the electrode during anodization, and the nearly equal ionic radii of Pt^{++} and Na^+ formed the basis for proposing electromigration as a mechanism to explain the increase in i_L(BP). This mechanism also accounts for the fact that anodization of an undoped bronze electrode does not produce increased activity of the type observed for doped bronze electrodes. The expected increase in surface platinum concentration was below the detection limit of our Auger spectrometer so that direct verification of platinum electromigration in a doped bronze electrode after anodization could not be obtained.

A further increase in electrocatalytic activity of the type associated with surface platinum was observed

when a doped bronze electrode was anodized in a heavily platinum pre-electrolyzed solution. The value of i_L(BP) increased to 4×10^{-5} A/cm^2. The source of this additional surface platinum was clearly the platinum that had been dissolved into the electrolyte following our PPE treatment. The magnitude of the surface concentration of platinum acquired to explain the observed value of i_L(BP) was confirmed by Auger measurements. Previous measurements of Fredlein (8) who found no effect due to PPE of a doped, anodized bronze electrode was consistent with the much less contaminating PPE treatment he used when compared to ours.

Since the PPE treatment used by Fredlein (8) was identical to that of Bockris and McHardy (4) our interpretation of the effects of platinum doping, anodization, and the various PPE treatments has an important bearing on the understanding of their results. Bockris and McHardy (4), as well as Fredlein (8) and us, obtained i_L(BP) about two orders of magnitude less than the limiting current of pure platinum i_L(P) on anodized bronze electrodes doped with platinum when measured in solutions that had been PPE. An i_L(BP) of three orders of magnitude less than i_L(P) could only be expected from bulk platinum doping of the bronze. Since Bockris and McHardy (4) did not consider that other sources of surface platinum might be responsible for the additional tenfold increase in i_L(BP) they observed, they were forced to consider a spillover model that required a synergism between the surface platinum and the Na_xWO_3 lattice. We have shown that anodization of a doped bronze electrode prior to any PPE treatment can produce nearly an order of magnitude increase in i_L(BP), which we have interpreted as being due to electromigration of bulk platinum through the sodium depletion layer to the bronze surface. Also the absence of any effect due to the same PPE treatment used by both Fredlein (8) and Bockris and McHardy (4) on a doped, anodized bronze eliminates PPE as a source of the increased i_L(BP) required by the measurements of Bockris and McHardy (4). Thus we conclude that the additional tenfold increase in i_L(BP), over and above that expected from bulk platinum doping, is accounted for primarily by anodization rather than platinum pre-electrolysis of the electrolyte or a spillover mechanism.

Finally, at current densities above 10^{-5} A/cm^2 our results are in agreement with those of Randin (4) and Weber and Shanks (6) in that no effect due to bulk platinum doping could be formed. However, our PPE treatment did affect the bronze activity even at current densities approaching 10^{-3} A/cm^2. Although this previously unreported effect was small and independent of bulk platinum doping no sign of a limiting current seemed evident. This result led to a study of various electrochemical schemes to intentionally increase the amount of platinum that could be incorporated onto the bronze surface .This study is reported in the following paper where it is shown that certain platinized Na_xWO_3 electrodes gave overpotentials comparable to those for bulk platinum at current densities as high as 10^{-3} A/cm^2.

Electrocatalytic Activity of Cubic Sodium Tungsten Bronze

II. Effects of Intentional Platinization

Ames Laboratory-USDOE and Department of Physics, Iowa State University, Ames, Iowa 50011

ABSTRACT

This paper is an extension of the work reported in the preceding paper (I) and concerns the effects of intentional platinization of sodium tungsten bronze electrodes on their electrocatalytic activity for oxygen reduction in an acid electrolyte. Some of these electrodes had activities and stabilities at 10^{-3} A/cm^2 better than those for bulk platinum electrodes measured in the same solutions. The samples were prepared by three separate techniques and were characterized by SEM, cyclic voltammetry, x-ray dispersive analysis, Auger surface measurements, depth profiles, and microprobe analysis. Two types of platinum morphology were produced. The first type consisted of 1000-3000Å platinum particles attached to a platinum-free bronze surface. For platinum coverages θ_p less than a few percent the activity of the electrodes was proportional to θ_p. The apparent activity per platinum atom was higher than that of bulk platinum although surface roughening effects made it difficult to quantify the specific activity of these electrodes. For θ_p approaching 10% there was a large unexplained increase in activity. The second type of platinum morphology is best viewed as layer of $PtWO_3$ on top of the bronze surface. These electrodes failed to exhibit any PtO reduction peak even though the Auger results indicated platinum atoms were present. In some cases, it was found that the activity per atom was as good as that of bulk platinum and that these electrodes had better long-term stability than bulk platinum. In all cases the bronze provided: (*i*) a corrosion resistance support, (*ii*) a good lattice matrix for either the growth of platinum particles or the incorporation of $PtWO_3$ layers, and (*iii*) an electronic environment comparable to bulk platinum with its large density of states near the Fermi level. Techniques used in this study could provide the basis for construction of an economical fuel cell cathode.

This paper is an extension of the research presented in the preceding article (referred to here as I) concerning the electrocatalytic activity of single crystal cubic sodium tungsten bronzes for oxygen reduction in acid electrolytes. As reported in I, a small but reproducible enhancement of the electrode activity near 10^{-3} A/cm^2 was produced by platinum pre-electrolysis of the electrolyte. Based on this previously unreported result, a series of platinized Na_xWO_3 electrodes were prepared by a variety of methods. The purpose of this experiment was to compare the electrode activity with the surface platinum coverage as determined by SEM and Auger analysis. A significant result of this study was the enormously enhanced activity of the platinized Na_xWO_3 for oxygen reduction, as well as hydrogen reduction and oxidation, when activated by comparatively small amounts of platinum. In some cases activities as high as bulk platinum and electrode stability better than bulk platinum were obtained at current densities approaching 10^{-3} A/cm^2.

Experiment

Three methods for incorporating platinum onto the Na_xWO_3 surface were attempted. In all cases it was found that platinum would not adhere to a fresh, thoroughly cleaned bronze surface unless it was first anodized to at least 2V (NHE). The first method, denoted as method A, involved platinum plating from a 0.3M HCl solution containing 7.5×10^{-5}M H_2PtCl_6. Cleaved samples were not used because SEM micrographs revealed that micron-sized platinum platelets had formed on the crystal surface. All of the A samples were first polished (see I) and then anodized to 9V (NHE). The bronze electrode was rotated at 900 rpm to insure uniform deposition. The effects of plating time and potential were investigated. For the second method, method B, a large 20 cm^2 shiny platinum electrode was used as a counterelectrode for cycling a preanodized bronze crystal from -0.2 to 1.8V (NHE) for approximately 12 hr using a sweep rate of 100 mV/sec. After this treatment the electrolyte was analyzed by an inductively coupled plasma technique (1) and it was found to contain platinum. The third method, method C, was a variation of method B. The 20 cm^2 platinum electrode itself was cycled between 0.0 and 1.50V (NHE) for 3.5 hr using a gold counterelectrode. Oxygen was then passed into the cell and a bronze electrode was lowered into the electrolyte. An anodic current of 400 μA/cm^2 was passed for 1.5 hr followed by an equal cathodic current. Initially the cathodic potentials were low, but after several minutes they increased. For both method B and C the platinizing electrolyte was a helium-saturated 0.1*N* H_2SO_4 solution. All three methods resulted in platinum deposition on the bronze electrode surfaces as verified by Auger analysis.

Three analytical tools were used to characterize the surfaces of the platinized bronze crystals. First, scanning electron microscopy (SEM) with a 200Å lateral resolution was used to examine the morphology of the platinum deposits. An x-ray energy dispersive analyzer on the SEM was used to probe the composition of the surface features with a depth resolution of approximately one micron. Second, some samples were examined using cyclic voltammograms, especially near the PtO reduction peak at 0.7V (NHE). Third, Auger spectroscopy was used to determine surface composition and depth profiles were taken with a depth resolution of several monolayers. In addition to the Auger spectrometer and measurement conditions as described in I, a Physical Electronics, Incorporated, Model 595 scanning Auger microprobe was also used. This instrument has a lateral resolution of only 500Å compared

to the 40 microns obtained from the other Auger spectrometer described in I, which was used to obtain surface Pt/W ratios and compositional depth profiles.

The electrochemical apparatus and preparation of the bronze electrodes were the same as described in I unless otherwise noted. None of the bronze electrodes had been doped with platinum during their growth. Tafel plots were obtained as described in I.

Results

Electrochemical.—Intentional platinum incorporation into the electrolyte could be used to activate the Na_xWO_3 crystals to a wide variety of electrocatalytic activities. The first such experiment demonstrated the vastly improved activity of an undoped bronze electrode after treatment by method C. Oxygen reduction Tafel plots for sample 4C before and after platinum depositions are shown in Fig. 1, along with the Tafel plots of pure platinum and an 800 ppm platinum-doped Na_xWO_3 taken earlier in a platinum-free electrolyte. The overpotential of sample 4C near 10^{-3} A/cm^2 is only 0.1V below that of bulk platinum, indicating considerably enhanced activity over any of the bronze electrodes investigated in I.

After this encouraging result, experiments were performed to determine if the increased activity could be quantitatively related to the platinum surface coverage. The three methods of platinizing the bronze samples, described in the experimental section, were used to prepare a series of samples with a wide range of platinum coverages. A true steady-state condition, requiring several hours, was allowed to occur for all the data points presented here since considerably higher potentials, especially at high current densities, were obtained if fast (5 min) measurements were attempted.

The data for six samples platinized by plating at 0.120V (NHE) in chloroplatinic acid (method A) are shown in Fig. 2 along with the Tafel plots for bulk platinum and a pure Na_xWO_3 sample. It is clear that for all current densities the activity of the plated bronze electrodes increases with plating time. Subsequent Auger measurements show an increasing platinum coverage with increasing plating time, except for the slowest plating time which had a platinum coverage below the Auger detection limit. Figure 3 shows the effect of changing the plating potential on the Tafel plots using sample 3A plated at 0.120V (NHE) and sample 8A plated at 0.040V (NHE). Although the activities of these two samples are clearly different the calculated platinum coverage was nearly identical at 4%.

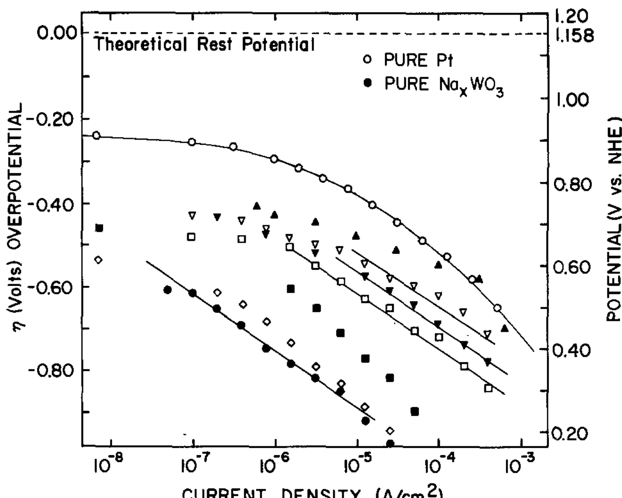

Fig. 2. Oxygen Tafel plots for Na_xWO_3 crystals plated at 0.120V (NHE) in chloroplatinic acid (method A) compared to those for pure platinum (○) and a pure uncontaminated Na_xWO_3 (●). The plated samples are: 1A plated for 8 min (◇), 2A plated for 20 min (■), 4A plated for 60 min (□), 5A plated for 100 min (▼), 7A plated for 160 min (▽), and 9A plated for 240 min (▲). The activity for oxygen reduction increases with platinum plating time.

Figure 4 shows the results for methods B and C for two samples each. As was the case for method A, increasing the surface coverage of platinum increased the electrocatalytic activity for oxygen reduction for all current densities, even those near 10^{-3} A/cm^2. Of the three methods used, method B produced the highest activity. In fact, these samples showed activities greater than that for bulk platinum at the highest current densities.

Encouraged by the effects of platinizing the bronze electrodes on the oxygen reduction reaction, we investigated other electrochemical reactions using these electrodes. A Tafel plot for hydrogen evolution from an anodized, platinum-free Na_xWO_3 is shown in Fig. 5. The exchange current density of this sample was about 10^{-7} A/cm^2, which is very low. Figure 6 shows the Tafel plots for hydrogen oxidation and reduction for samples 3A and 8A compared to bulk platinum. One should note the difference in overpotential scale between Fig. 5 and Fig. 6. Figure 6 is a linear plot of overpotential *vs.* current and the exchange currents are calculated from the slopes. It is interesting that the hydrogen reaction exchange current densities for oxidation and reduction of sample 3A were nearly

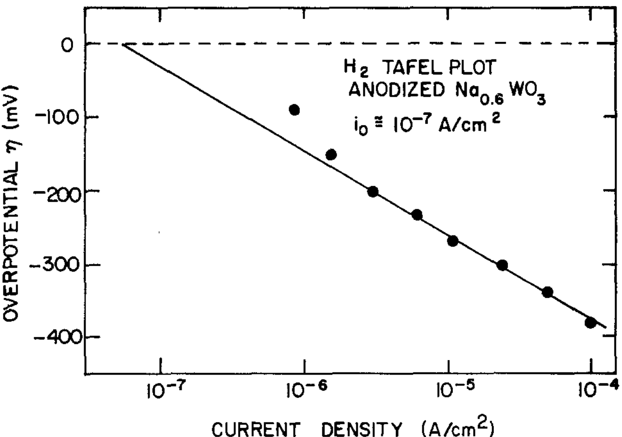

Fig. 5. Typical H_2 Tafel plot for an anodized Na_xWO_3 crystal. The slope is 120 mV/decade and the exchange current is approximately 10^{-7} A/cm^2. Such a low exchange current is very poor for a hydrogen electrode. The sample had not been platinized.

twice as large as those of 8A, while the current density for oxygen reduction at 0.5V (NHE) was twenty times lower for 3A when compared to 8A.

Platinum morphology.—Vital information on the form of the platinum deposits was provided by SEM, AES, and PtO reduction peaks. Platinum particles were observed by SEM on all samples prepared by method A. This is illustrated using sample 8A in Fig. 7 where the light areas on the surface were found to be platinum by using the x-ray detection capability of the SEM. The average particle in Fig. 7 is 1500Å, uniformly distributed over the bronze surface. The platinum particles on sample 8A covered approximately 10% of the bronze surface. In contrast to method A, samples prepared by methods B and C did not have platinum particles visible within the 200Å lateral resolution of the SEM.

The presence of the platinum particles on the A samples was always detectable *in situ* by monitoring the PtO reduction peak at 0.7V (NHE) in the cyclic voltammograms. As a result the PtO reduction peak was a good indicator of the metallic, bulklike nature of the platinum particles on the bronze surface. No PtO reduction peak was observed on any of the C samples despite the fact that the Auger results indicated that sufficient platinum was present on the surface of these samples to have produced a PtO peak. No cyclic voltammograms were taken of either of the two B samples. However, the B samples were prepared in a

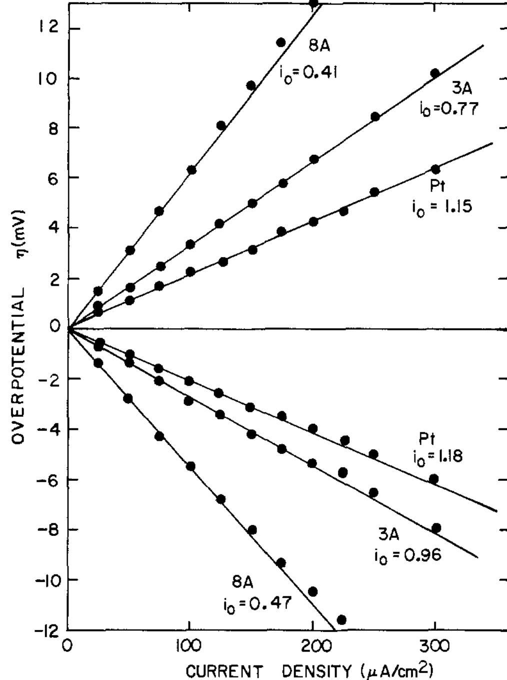

Fig. 6. Current-potential data for the hydrogen reduction and oxidation on two platinized Na_xWO_3 electrodes, 3A and 8A. The exchange current i_0 are in mA/cm^2 and show the large improvement obtained after platinization (see Fig. 5) with respect to bulk platinum.

manner identical to that used by Fishman *et al.* (2) to activate Na_xWO_3 electrodes with platinum. They found no PtO reduction peaks on their samples which they attributed to either the absence of any platinum on the bronze surface or to its presence in a chemical state different from that found on the surface of a bulk platinum electrode.

Auger experiments.—Two types of Auger data were available. The first was an Auger spectrum of the sample surface, while the second consisted of compositional depth profiles obtained during ion bombardment. Nearly all of the Auger spectra of the first type were taken using the 40 micron electron beam of the Physical Electronics Model 10-155 Auger spectrometer. The lateral dimension of the electron beam of this spectrometer was sufficient to provide an average composition of the bronze surface. The 500Å lateral resol-

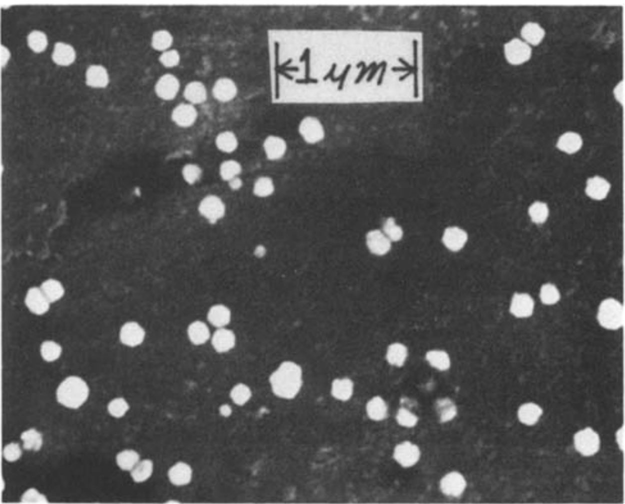

Fig. 7. SEM micrograph of sample 8A which was platinum plated at 0.040V (NHE) in 7.5 × 10^{-5}M chloroplatinic acid. The platinum particles visible in the photograph are about 1500Å in diameter.

ution of the Physical Electronic Model 595 was used to probe the surface composition of the A samples between the large (>1000Å) platinum particles. All of the depth profiles were taken with the Model 10-155 Auger system.

As explained in I, the Pt(1967) and W(1796) Auger transitions provided the best measure of the platinum concentration on the surface of a bronze sample before any ion bombardment. The 25Å escape depths of these two transitions (3) minimized the attenuating effects of the approximately one monolayer overlayer of carbon always present on the samples. The effects of the carbon overlayer are nearly completely eliminated when the ratio R of the intensity of the Pt(1967) transition to that of the W(1796) transition are used as a measure of the platinum coverage θ_p, since the attenuation of each transition is nearly equal. This effect is a direct consequence of the near identity of the escape depths of these two transitions. The measured values of R for all of the bronze samples, as determined using the Model 10-155 Auger system, are given in Table I. The disadvantage of using these two high energy Auger transitions is that subsurface platinum atoms could contribute significantly to the intensity of the Pt(1967) transition without effecting θ_p which depends entirely on platinum atoms present on the top monolayer of the electrode. Auger microprobe, SEM, and Pt(64) Auger depth profiles all provided vital information on the subsurface platinum distribution.

Auger depth profiles were obtained in the usual manner by monitoring the peak-to-peak Auger signals from a continuously sputtered surface. In this case we used the Pt(64) Auger transition, which has an escape depth of approximately two monolayers (3), to provide high surface sensitivity. To obtain the exact thickness of the platinum layer required accurate knowledge of the sputter removal rate. No data on the sputter yield of Na_xWO_3 or pure platinum could be found that would permit the exact conversion of sputter time to depth. The ion beam consisted of 2.5 keV Ar^+ ions at normal incidence with a current of 30 nA focused to a diameter of 250 microns. The ion beam was rastered over a 2 × 2 mm square area to avoid crater edge effects. We have assumed that the sputter yield for $Na_{0.7}WO_3$ is 2 atoms per incident ion so that the sputter removal rate for $Na_{0.7}WO_3$ becomes 1 Å/min. For bulk platinum, Wehner (4) reported a value of 1.4 atoms/ion for 0.5 keV Ar^+ ions, while Almén and Bruce (5) find 12 atoms/ion for 45 keV Kr^+ ions. Based on these values and knowledge of the general dependence of sputter yields with ion energy and mass (6), we estimate that for 2.5 keV Ar^+ ions, platinum would have a sputter yield of approximately 5 atoms/ion. For our ion beam flux we calculate a sputter removal rate for pure platinum to be 3.5 Å/min. As we shall discover, for platinum layers in the monolayer range the presence of the carbon overlayer makes it very difficult to obtain exact values for the platinum depth distribution even if the sputter yields were accurately known. However, the Auger depth profiles were very useful in a comparative analysis of the platinum layer thickness and for measuring the extent of the sodium depletion layer after anodization.

Table I. The measured ratio R of the intensities of the Pt(1967) and W(1796) Auger transitions, the calculated platinum coverages θ_p, and measured current density ($\mu A/cm^2$) at 0.5V (NHE) for oxygen reduction I of a series of cubic sodium tungsten bronze electrodes platinized by three (A, B, and C) different electrochemical techniques

[a] Values determined by plating time.

Figure 8 shows a depth profile of pure Na_xWO_3 crystal after mechanical polishing but before any electrochemical treatment. There are three regions of interest in this figure. For sputter depths below 15Å the profile is dominated by the removal of the ever present carbon overlayer. As the carbon is removed, the Auger signals coming from the bronze crystal increase in intensity because of their finite escape depths. The second region occurs from 15 to 150Å and shows decreasing oxygen and sodium signals and an increasing tungsten signal. There are two possible explanations for this behavior. First, the concentrations of these elements may actually vary in the manner shown in Fig. 8, that is, oxygen and sodium concentrations are higher in the first 150Å of the bronze surface. Alternatively, the effect may be due to preferential sputtering of oxygen and sodium from the crystal until equilibrium is reached at 150Å. In this case the concentration variations are ion induced. Preferential sputtering of light elements from a compound or alloy is not uncommon. Considering the current state of our knowledge of the sputtering process for compound targets it is difficult to judge the importance of preferential sputtering in Fig. 8. In any case, this profile represents the standard against which the depth profiles of electrochemically treated bronzes will be compared.

Figure 9 shows the Auger depth profile of sample 7A, which had been heavily anodized to 9V (NHE) at 1 mA/cm^2 prior to platinization by method A. This sample had 1500Å platinum particles present at a coverage of about 6% as confirmed by PtO reduction and SEM

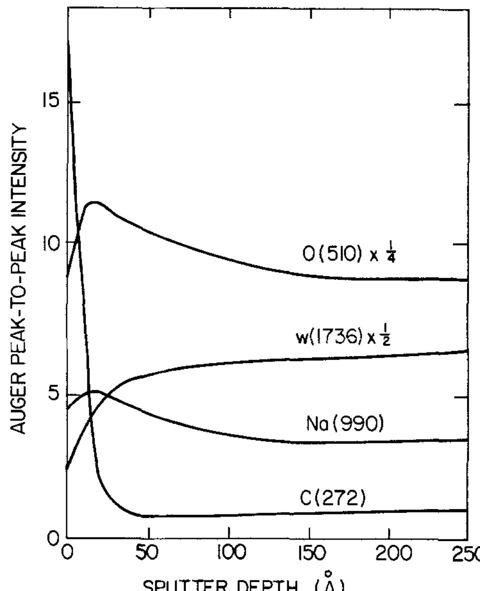

Fig. 8. Auger depth profile of a pure sodium tungsten bronze before any electrochemical treatment, but after mechanical polishing through 0.05 μm alumina. Assuming a sputter yield of 2 atoms/ion the sputter removal rate is 1Å/min. The enhanced oxygen and sodium signals for sputter depths less than 150Å may represent preferential sputtering of the light elements from the nearly carbon-free Na_xWO_3 surface.

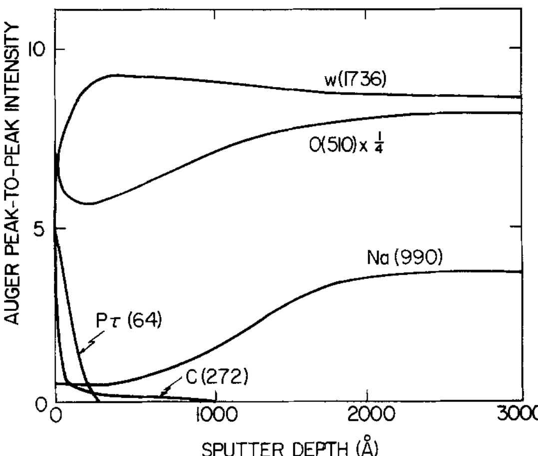

Fig. 9. Auger depth profile of a platinum-plated Na_xWO_3 crystal (sample 7A) that had been heavily anodized prior to platinization. The sodium depletion layer extends nearly 2000Å into the bronze surface. The Pt(64) signal represents the removal of the platinum particles known to be on the sample surface. As in Fig. 8 the assumed bronze sputter rate is 1Å/min.

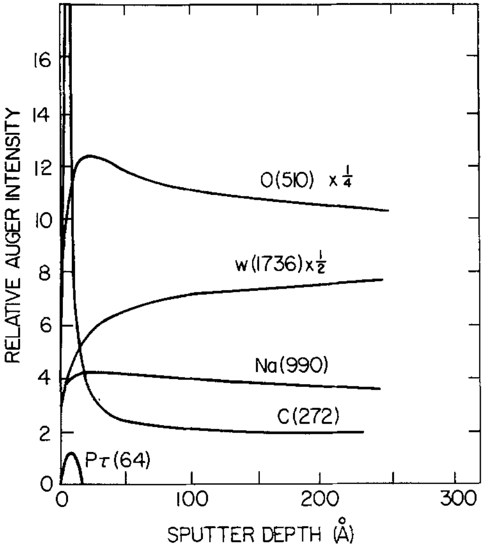

Fig. 10. Auger depth profile of sample 4C which was only lightly anodized to 2V (NHE) prior to platinization. No sodium depletion layer is found. The rapid disappearance of the Pt(64) signal even before the C(272) signal has reached its equilibrium value suggests a platinum coverage of approximately one monolayer.

micrographs. As a result the interpretation of this depth profile requires some care. The Auger peaks for sodium, oxygen, and tungsten are the same as for a platinum-free surface because it is shown later that no platinum was present between the platinum particles. The presence of the sodium depletion layer is evident from the behavior of the Na(990) signal and extends about 1500Å into the sample. With regard to the Pt(64) signal it represents the sputter ion removal of the essentially pure platinum particles. The 300 min required to remove the platinum particles, combined with our estimated 3.5 Å/min sputter rate for pure platinum, gives about 1000Å as the thickness of the platinum particles. This is reasonable considering their lateral dimension of 1500Å.

Before leaving Fig. 9 it is interesting to note that the O(510) signal parallels that of the Na(990) suggesting that heavily anodized Na_xWO_3 also loses some oxygen in the sodium depletion layer. Although the oxygen depletion depth is the same as for sodium, the amount of oxygen lost is much less than that of sodium. It should be noted that the decreased O(510) intensity for depths less than 2000Å is opposite to the behavior of the O(510) transition found in Fig. 8 for an unanodized bronze. This implies that the reduced oxygen Auger signal does represent a reduced oxygen concentration in the sodium depletion layer.

Figure 10 shows a depth profile of sample 4C which had been initially anodized to only 2V (NHE) before platinum deposition. The depth distribution for O(510), W(1736), Na(990), and C(272) are nearly identical to those found for a mechanically polished bronze surface shown in Fig. 8. In particular, anodization to 2V (NHE) did not produce any evidence of a sodium depletion layer. The depth distribution of the Pt(64) transition is important in the determination of the platinum morphology. The initial rise occurs because of the removal of the carbon overlayer. During the next 10Å the Pt(64) goes to zero. It is evident that the platinum signal completely disappears even before the carbon coverage has reached its equilibrium value. This behavior of the Pt(64) signal for sample 4C is in marked contrast to that shown in Fig. 9 for sample 7A which was known from SEM studies to contain 1500Å platinum particles over 6% of its surface. No platinum particles were evident in SEM micrographs of sample 4C. The presence of a significant carbon signal during the evolution of the Pt(64) signal complicates the extraction of the exact depth of the platinum composition. Our best estimate is that the platinum is confined to the first few monolayers of the bronze surface. Auger depth profiles of the other C samples were similar to that shown in Fig. 10 for sample 4C.

Auger depth profiles were also performed using the B samples, which like the C samples did not have any large platinum particles evident in their SEM micrographs. A depth profile of sample 1B produced a Pt(64) depth distribution more like that of sample 7A (Fig. 9) than that of sample 4C (Fig. 10) in that the Pt(64) signal was still strong well after the carbon signal had reached its low equilibrium value. In addition, the oxygen and tungsten Auger peaks were evident even before sputtering began. These results suggest that the platinum-containing layer was hundreds of angstroms thick, but that it did not consist of a pure platinum overlayer, since any pure platinum layer that thick would have completely suppressed the oxygen and tungsten signals from the covered bronze surface. In fact in none of the Auger depth profiles was there any evidence that a bronze surface was uniformly covered by a pure platinum layer thick enough to suppress the oxygen and tungsten signals from the bronze crystal.

It was important to know whether any platinum was deposited between the platinum particles produced by method A. Although the electron microscope had x-ray dispersive analysis capable of chemical identification and sufficient lateral resolution, its depth resolution of about one micron was insufficient to detect a monolayer coverage of platinum between the platinum particles. Using the Model 595 scanning Auger microprobe, an Auger spectrum was taken on and off a platinum particle on the surface of sample 3A. No Pt(64) peak was evident from the bronze matrix. No sputtering was used, so that even a small fraction of a monolayer of platinum was not removed from the surface. As a result, Auger spectra from the platinum particle and the bronze matrix did have some carbon evident. However for the platinum particle, the Pt(64) line was clearly evident, while the W(38), W(48), and W(150-180) lines with their correspondingly small escape depths were observed from the bronze matrix. Correcting for the carbon overlayer and the relative Auger sensitivities (7) we estimate that no more than 1% of the top monolayer of the bronze matrix was occupied by platinum. This result implies that for this sample, and presumably all samples prepared by method A, all of the platinum on the surface of these

bronze electrodes resides in the large platinum particles.

Dependence of electrochemical activity on platinum morphology.—Although platinum particles were observed on all of the samples prepared by method A, the electrocatalytic activity for oxygen reduction was not always proportional to the number of platinum particles observed in the SEM micrographs. This was strikingly demonstrated in the following manner using sample 6A. The platinum particles could be removed from the bronze surface by reanodizing the crystal to 10V (NHE). The disappearance of the platinum particles was confirmed by SEM measurement and the absence of the PtO reduction peak. The oxygen reduction Tafel plots of this sample before (sample 6A) and after (sample 6A*) the particles were removed is shown in Fig. 11. Surprisingly very little change in the relatively high activity of the electrode was observed. A depth profile of sample 6A* (not shown) was performed and a very thin platinum layer was found indicating that the platinum was confined to the top few monolayers of the bronze electrode. The observation that the electrocatalytic activity of samples 6A and 6A* was essentially unchanged even though the platinum morphology was drastically altered, represents one of the most interesting observations made during this study.

Discussion

Platinum coverage.—The ultimate aim of this study is to compare the electrocatalytic activity of platinized Na_xWO_3 electrodes to that of bulk platinum and to the platinum coverage θ_p on the bronze surface. Only by determining the platinum coverage on a bronze surface can the electrocatalytic activity of a platinum atom on the bronze surface be compared to that of a platinum atom on a bulk platinum surface. Once this is known, the role of the bronze in catalyzing the oxygen reduction reaction in the presence of the surface platinum can be clearly elucidated. In I it was shown that a pure bronze surface is a very poor electrocatalyst for oxygen reduction. Even when activated by surface platinum produced by anodization or platinum pre-electrolysis of the electrolyte no clear evidence of synergism was found in I. However the possibility of a synergistic relation between the platinum and the bronze surface may exist for the more heavily platinized bronze electrodes prepared for this study by techniques different from those used in I.

We start from the assumption that only the top monolayer of any electrode actively participates in the oxygen reduction process. This assumption is based on the fact that the absorption of reactants and products occurs only on the top monolayer of the electrode even though electron exchange can occur over several monolayers by electron tunneling. For bulk platinum foils the number of active sites is equal to the surface density of platinum atoms. Platinum has a face-centered cubic structure (fcc) shown in Fig. 12A with a lattice constant $a_{Pt} = 3.916Å$. Let us assume that the polycrystalline foils used in our experiment had predominantly (100) faces exposed to the electrolyte. Assuming no lattice rearrangements at the surface, the surface density of platinum atoms, σ_{Pt}, is given by

$$\sigma_{Pt} = 2/a_{Pt}^2 = 1.304 \times 10^{15}/cm^2 \quad [1]$$

where the factor of two is the number of platinum atoms per unit cell on a (100) face of the fcc structure.

Before the platinum coverage θ_p for a bronze electrode can be calculated, the morphology of the platinum layer must be known. The results we have observed on the presence of a PtO reduction peak on bulk platinum and the A samples as well as the absence of such a peak on the B, C, and 6A* samples are significant. The Auger analysis shows that the absence of a PtO peak on the B, C, and 6A* samples does not occur because of the absence of any platinum. The alternative is that, for those samples which did not produce a PtO reduction peak, the platinum is on the bronze surface in a chemical state different from the platinum on the surface of bulk platinum or the A samples. An appealing hypothesis is that the platinum atoms on the surface of the B, C, and 6A* samples are located at the empty sodium sites of the anodized bronze electrodes, forming a $PtWO_3$ phase. If the platinum atoms were to reside at the empty sodium sites, then one would expect that they would give up their two 6s electrons to the conduction band formed by the tungsten-oxygen bands forming Pt^{2+}, just as sodium gives up its one 3s electron forming Na^+. The ionic radius of Na^+ is 0.95Å and that of Pt^{2+} ions is 0.96Å, which is a very good match. In addition, the bronze lattice provides a very good lattice match to that of bulk platinum. A unit cell of the cubic perovskite structure of $NaWO_3$ is shown in Fig. 12B. The

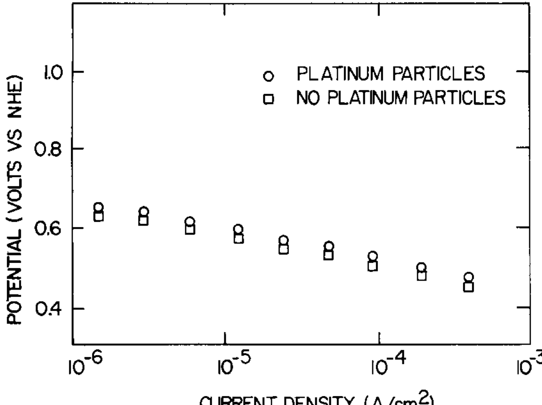

Fig. 11. Oxygen Tafel plots of sample 6A before (○) and after (□) removal of platinum particles by anodization to 10V (NHE). Little difference in the high electrocatalytic activity of the sample was found after removal of the platinum particles.

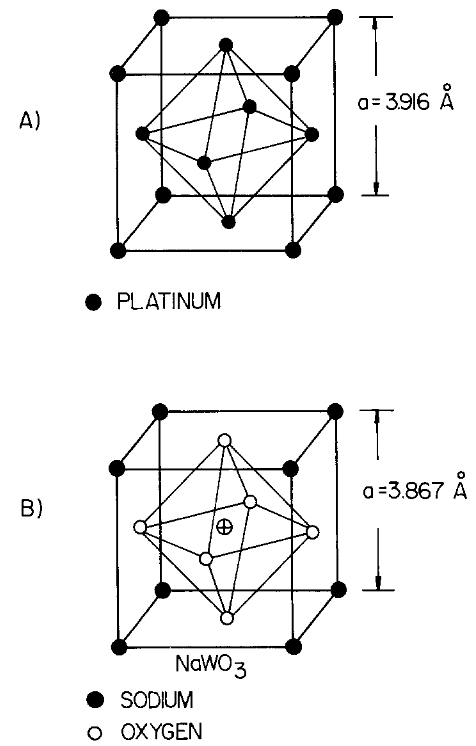

Fig. 12. A. Unit cell of face-centered cubic platinum. B. Unit cell of cubic perovskite structure.

lattice constant for $x = 1$ for $NaWO_3$ is $a_B = 3.876Å$ (8), which is within 1.5% of that for bulk platinum. The sublattice of the empty sodium sites provides a very good matrix for the growth of platinum on the surface of the bronze crystal. Depending on the experimental conditions, there are two possible fates for the arriving platinum atoms after the top monolayer sodium sites of the bronze surface have been filled; either the platinum atoms grow on top of the bronze forming platinum islands as was found for the A samples, or the platinum atoms could diffuse into the sodium depletion region by hopping among the empty sodium sites forming $PtWO_3$. We propose that the latter mechanism has probably occurred for the B, C, and 6A* samples. The formation of a $PtWO_3$ layer would explain the absence of a PtO reduction peak associated with the Pt—Pt bonds of bulk platinum.

Given these two proposed models for the platinum morphology, θ_p can be defined for the various platinized bronze electrodes. For the A samples, which have large, discrete platinum particles, θ_p is simply the percentage of the bronze surface area covered by these platinum particles. The Auger microprobe results ruled out any contribution to θ_p from the bronze surface not covered by the platinum particles. For the other bronze electrodes we assume islands of $PtWO_3$ covering α% of the bronze surface. Neglecting the small difference in lattice spacings (see Fig. 12A and 12B), the surface density of potential platinum sites on the bronze surface (*i.e.*, sodium vacancies of the anodized bronze) is one-half that of the platinum sites on bulk platinum so that

$$\theta_p = \tfrac{1}{2}\alpha \quad [2]$$

We can now calculate $\theta_p(R)$ for the various types of bronze electrodes using the well-known dependence of Auger intensities on the concentration *vs.* depth and surface coverage (9).

Consider first the A samples. Based on SEM, Auger microprobe, and Auger depth profiles we assume that all of the platinum is confined to islands many times thicker than the 25Å escape depth of the Pt(1967) or W(1796) Auger transitions. As a result the only source of W(1796) Auger electrons are those from the bronze surface not covered by the platinum islands, while the only source of Pt(1967) Auger electrons is the platinum islands themselves which cover θ_p% of the electrode surface. The intensity of the Pt(1967) transition on the bronze surface $I_{Pt}(B)$ can be written in terms of the intensity of the same transition from a platinum foil $I_{Pt}(Pt)$ as

$$I_{Pt}(B) = \theta_p I_{Pt}(Pt) \quad [3]$$

The intensity of the W(1796) transition from the $1 - \theta_p$% of the bronze surface free of any platinum islands $I_W(B)$ can be given in terms of the intensity of the same transition from a tungsten foil $I_W(W)$ as follows

$$I_W(B) = (1 - \theta_p) I_W(W) K_1 \quad [4]$$

where K_1 is the ratio of the volume density of tungsten atoms in the anodized bronze surface ($\sim WO_3$) to that in a tungsten foil. Tungsten has a bcc structure with two atoms per unit cell and a lattice spacing of $a_W = 3.159Å$ so that

$$K_1 = \left[\frac{1}{a_B^3}\right] \Big/ \left[\frac{2}{a_W^3}\right] = 0.27 \quad [5]$$

since $a_B = 3.876Å$. From the definition of R we write

$$R \equiv \frac{I_{Pt}(B)}{I_W(B)} = \frac{\theta_p I_{Pt}(Pt)}{K_1(1 - \theta_p) I_W(W)} \quad [6]$$

When measured under the same conditions used to obtain the bronze Auger spectrum we find

$$I_{Pt}(Pt) = I_W(W) \quad [7]$$

Solving Eq. [6] for θ_p using Eq. [5] and [7] we find

$$\theta_p(R) = R/(3.7 + R) \quad [8]$$

for the A samples. It is noted that a measured value of R provides a unique value for θ_p independent of the thickness of the platinum islands assuming that these platinum islands are much thicker than the 25Å escape depth of the W(1796) and Pt(1967) Auger transitions used to calculate $\theta_p(R)$.

Consider now the B samples. The absence of a PtO reduction peak implies no metallic, bulklike platinum is present even below the lateral detection limit (200Å) of the SEM. The Auger depth profiles gave evidence of a platinum distribution many times thicker than the 25Å escape depth. These results lead us to assume a model where α% of the bronze surface has been converted to a $PtWO_3$ phase extending many hundreds of angstroms beneath the bronze surface. The appropriate connection between α and θ_p is given by Eq. [2]. The intensity of the Pt(1967) transition from the $PtWO_3$ phase $I_{Pt}(B)$ can be written in terms of $I_{Pt}(Pt)$ as

$$I_{Pt}(B) = \alpha I_{Pt}(Pt) K_2 \quad [9]$$

where K_2 is defined as the ratio of the volume concentration of platinum in $PtWO_3$ to that of metallic platinum or

$$K_2 = \left[\frac{1}{a_B^3}\right] \Big/ \left[\frac{2}{a_{Pt}^3}\right] = 0.26 \quad [10]$$

The intensity of the W(1796) transition from the $PtWO_3$ and WO_3 phases $I_W(B)$ is given by

$$I_W(B) = \alpha I_W(W) K_1 + (1 - \alpha) I_W(W) K_1 \quad [11]$$

respectively. In Eq. [11] we have assumed no change in the tungsten concentration on going from the WO_3 to the $PtWO_3$ phase so that Eq. [11] reduces to

$$I_W(B) = K_1 I_W(W) \quad [12]$$

We find for the B samples that

$$R \equiv \frac{I_{Pt}(B)}{I_W(B)} = \frac{2\theta_p K_2}{K_1} \quad [13]$$

using Eq. [2], [7], [9], and [12]. Solving Eq. [13] for θ_p we get

$$\theta_p = 0.54R \quad [14]$$

using Eq. [5] and [10]. Again as for the A samples, a given measured value of R produces a unique value of θ_p independent of the exact platinum depth distribution as long as it is assumed to be uniform for depths larger than a few escape depths as indicated by the Auger depth profiles.

Consider next the C samples. Like the B samples the absence of a PtO reduction peak allows us to assume no metallic platinum islands are present. However, in contrast to the B samples, the Auger depth profiles indicate a platinum distribution very localized near the top monolayer of the bronze surface (see Fig. 10). For simplicity it will be assumed that all of the platinum atoms of the $PtWO_3$ phase on the C samples are confined to the top monolayer of the bronze surface covering α% of the bronze surface. We can then write

$$I_{Pt}(B) = \alpha I_{Pt}(Pt) K_3 (1/l) \quad \text{for} \quad l >> 1 \quad [15]$$

where l is the escape depth of the Pt(1967) transition in monolayers and K_3 is the ratio of the surface concentration of platinum sites for $PtWO_3$ to that of platinum metal. Thus

$$K_3 = \left[\frac{1}{a_B^2}\right] \Big/ \left[\frac{2}{a_{Pt}^2}\right] = 0.51 \quad [16]$$

referring to Fig. 12A and 12B. Since one monolayer of

$PtWO_3$ is very nearly equal to ½ a_B we obtain

$$l = 25Å/1.94Å \simeq 13 \text{ monolayers} \quad [17]$$

For the tungsten Auger intensity from the bronze surface we can use Eq. [12]. From the definition of R we find

$$R \equiv \frac{I_{Pt}(B)}{I_W(B)} = \frac{\alpha K_3 I_{Pt}(Pt)}{l K_1 I_W(W)} \quad [18]$$

which reduces to

$$R = \frac{2\theta_p K_3}{K_1} \quad [19]$$

using Eq. [2] and [7]. Solving Eq. [19] for $\theta_p(R)$ we find for the C samples that

$$\theta_p = 3.4R \quad [20]$$

using Eq. [5], [16], and [17]. Again given a measured value of R a unique θ_p is determined if we assume all of the platinum atoms of the C samples are confined to the top monolayer of the bronze surface.

Sample 6A* is unique since it was prepared by removing the platinum particles from sample 6A. From the measured value of $R = 0.30$ we find $\theta_p = 0.076$ for sample 6A using Eq. [8]. If we assume that the platinum remaining on sample 6A* is in the $PtWO_3$ phase as evidenced by the lack of a PtO reduction peak, then we envision the 6A* surface to be covered by a $PtWO_3$ layer covering 7.6% of the bronze surface. This gives $\theta_p = 3.8\%$ for 6A* since there are half as many available platinum sites (*i.e.*, sodium vacancies) for $PtWO_3$ as for bulk platinum. Using $\theta = 0.038$ we find that the thickness of the $PtWO_3$ layer on 6A* must be about four monolayers to produce the measured R value of 0.02 for 6A*.

It should be noted that for those samples that did not show any PtO reduction peaks (B, C, and 6A* samples), it has been assumed that not even one monolayer of bulk platinum exists on the surface of the bronze crystal. It is not clear how thin a layer of platinum metal would continue to produce a PtO reduction peak at 0.7V (NHE). Let us assume the worst case so that a single monolayer of platinum metal would not produce a PtO reduction peak at 0.7V (NHE). The effect of such a monolayer on our calculated θ_p depends on the sample type considered. For the A samples, the Auger microprobe results rule out any monolayer coverage by platinum in any form. The B samples have sufficient total platinum concentration as evidenced by the Auger depth profiles and R values that a platinum monolayer could be present. If such a layer existed then $\theta_p = 1$ for these samples instead of 0.27 for 1B and 0.47 for 2B. For the C samples we previously had placed all of the platinum on the top monolayer of the bronze surface and still calculated $\theta_p < 1$. Simply rearranging the platinum atoms into submonolayer platinum islands would not change θ_p at all. However, if some of the platinum atoms were stacked into islands more than monolayer thick then θ_p would be reduced. Thus the θ_p calculated for the C samples represents their maximum values. For sample 6A* we calculated a model where the platinum atoms are distributed into $PtWO_3$ islands about four monolayers thick, so that roughly one-fourth of the platinum atoms contribute to θ_p. If all of the platinum atoms were now placed on the top monolayer of the bronze θ_p would be increased by a factor of four. For this to happen, however, would require that during the 10V anodization, used to remove the platinum particles from 6A, some of the platinum atoms had migrated from those platinum particles onto the bronze matrix. We consider that process to be unlikely. Summarizing, the θ_p values, calculated assuming no metallic platinum whenever no PtO reduction peak was observed, appear to be good approximations and they will be used to compare the electrocatalytic activity of the bronzes with bulk platinum and each other.

Comparison of platinum coverage to electrocatalytic activity.—The electrocatalytic activity of the platinized bronze electrodes and bulk platinum were obtained from steady-state oxygen reduction Tafel plots as presented in the Results section. Exchange current densities could not be used to compare the relative activities of these electrodes because their low Tafel slopes made extrapolation to zero overvoltage very unreliable. Instead the current density at 0.5V (NHE) was used as a measure of electrode activity because most of the Tafel lines passed through this potential. For those Tafel lines which did not cross 0.5V (NHE) only short extrapolation was required. The values of θ_p and oxygen reduction current density ($\mu A/cm^2$) at 0.5V (NHE) are both plotted logarithmically in Fig. 13 for all of the bronze electrodes as well as bulk platinum. For bulk platinum θ_p is of course equal to one. A straight line of slope one passing through the point for bulk platinum is shown in Fig. 13. This line, which we call the platinum line, divides the area in Fig. 13 into two regions, one above the line and one below the line. For a sample to be placed above the line implies that the electrode activity is due to more than just the platinum present on the electrode surface, *i.e.*, the bronze matrix is directly participating in the oxygen reduction reaction. For a sample placed below the line the electrode activity per platinum atom is less than that of bulk platinum and it is very unlikely that the bronze matrix directly contributes to the reaction rate for oxygen reduction. The errors in placing a sample in the $i - \theta_p$ plane are of several types. We have discussed the effects of our assumptions concerning the platinum morphology on the cal-

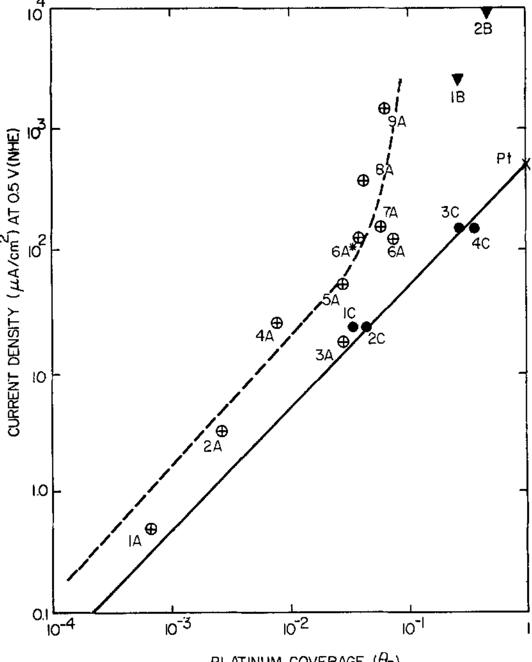

Fig. 13. Log-log plot of platinum coverage θ_p and electrocatalytic activity as measured by the current density at 0.5V (NHE) for all the platinized tungsten bronzes and for a bulk platinum electrode polished and measured in the same manner as the bronze electrodes. The solid line is a straight line of slope one passing through the bulk platinum point. The dashed line passes through those samples prepared by method A and it shows the sharp increase in activity as the platinum coverage approaches 10%. Sample 1B and 2B show anomalously high activity because of the considerably roughened surface they acquired during platinization. Samples 1-4C fall along a solid line of slope one.

culated values of θ_p for the various types of bronze electrodes. For the A and C samples no changes are necessary and for the B samples the θ_p values in Table I are minimum ones while for 6A* θ_p could be four times that plotted in Fig. 13. One other fact, not yet discussed, is surface roughness which could affect current density through the effective surface area of the electrode. For the A samples the SEM micrographs of the platinum particles suggest a microroughness that could increase the atomically smooth surface assumed calculating θ_p. This would have the effect of moving the data points for the A samples lower on the current density scale closer to the platinum line. A definite surface roughening of the B samples, where the bronze electrode was swept in potential, is evident in their SEM micrographs. An order of magnitude increase in surface area is not unreasonable. This would move the points for the 1B and 2B samples much closer to the platinum line. No evidence of surface roughening was present on the C samples which had the platinum counterelectrode swept in potential. In fact the surface roughness of the C sample was comparable to that of the bulk platinum electrodes. As a result no effects due to surface roughness are expected for the four C samples. Sample 6A* showed evidence of surface roughening after the second anodization was used to remove the platinum particles. With these qualifications in mind we can now discuss the significance of the data presented in Fig. 13.

The data for the A samples all fall above the platinum line. The activity is roughly proportional to platinum coverage except near $\theta_p = 0.10$ where the activity rises dramatically with little change in θ_p. The somewhat higher activity for $\theta_p < 0.05$ with respect to the platinum line probably results from the microroughness of the platinum particles rather than any active participation by the bronze matrix. The rapid rise near $\theta_p = 0.10$ is not understood.

The two B samples have the highest activity of any of the bronze samples and they have a specific activity nearly an order of magnitude better than bulk platinum. However the combined effects of surface roughness, which moves the data points toward lower activity, and the possibility of a full monolayer coverage of platinum, which moves the data points toward higher θ_p, leave some doubt as to whether the specific activity of these electrodes is any better than that of bulk platinum. Certainly no definite evidence for direct involvement of the bronze electrode can be deduced from our data on the two B samples.

The four C samples lie directly along the platinum line. As discussed above no significant corrections for surface roughness or platinum coverage are expected for these samples. The results for the C samples suggest that the platinum atoms on the surface of these bronze electrodes are as active per atom as those platinum atoms on the surface of bulk platinum. This conclusion is independent of the location or arrangement of the platinum atoms because the $PtWO_3$ model used to calculate θ_p had all of the available platinum atoms on the top monolayer of the bronze. If any of the platinum atoms are below that top monolayer, the θ_p for these samples is decreased, moving them above the platinum line. This would lead to the conclusion that either the bronze is an active partner to the platinum or that the top surface platinum atoms are more active than those of a bulk platinum electrode. Samples 1C and 2C have $\theta_p \approx 0.004$ so that only one-tenth of the vacant sodium sites are occupied. The nearest neighbor platinum distance for these samples is therefore about 10Å. In spite of this, each of the platinum atoms on the surface of 1C and 2C is just as active as a platinum atom on the surface of bulk platinum where the nearest neighbor spacing is only 2Å. Our conclusion is that isolated platinum atoms, without any Pt—Pt bonds, still are very active as oxygen reduction catalysts when present on a properly prepared bronze surface. A similar conclusion was reached in I for a platinum-doped bronze after anodization and treatment in a platinum pre-electrolyzed solution where $\theta_p \approx 3\%$.

One of the important properties of pure platinum as a catalyst is the high density of electron states near the Fermi energy. The band structure of $PtWO_3$ has been calculated (10) and a larger peak in the density of states occurs at the Fermi level. This peak is due to the highly localized platinum 5d electrons, which are known to be important for the catalytic properties of platinum. The role of the bronze matrix of the C samples seems to extend beyond providing a good lattice match to platinum and a noncorrosive substrate to providing a favorable electronic environment for individual platinum atoms. The bronze matrix may also be involved in providing for the superior stability of these electrodes at high current densities when compared to bulk platinum. It is well known (11) that H_2O_2 builds up in an electrolyte after prolonged oxygen reduction and that its presence contributes to the decreasing activity of a platinum electrode. Randin (12) has shown that a pure bronze electrode is a good electrocatalyst for the reduction of H_2O_2. Thus a potential mechanism for the enhanced stability of the C sample is that the bronze surface is removing the H_2O_2 and thereby preventing the poisoning of the submonolayer platinum layer. In summary, the samples prepared by method C could provide a basis for an economic fuel cell cathode for oxygen reduction in an acid electrolyte with the activity of pure platinum and superior long-term stability.

Sample 6A* lies above the platinum line in Fig. 13. The surface roughening found after the 10V anodization could result in a lower current density. In addition, if all of the platinum atoms are placed on the surface of the bronze electrode, then θ_p would be increased from 3.9% to about 14%. The combined effect of these two assumptions would move the 6A* much closer to the platinum line. Even so, the $PtWO_3$ model is probably valid and the same conclusion reached for the C samples are valid except for the enhanced stability. Clearly the method used to produce 6A* also is worthy of further investigation as the basis for an economical oxygen reduction cathode.

As described above one of the most interesting and puzzling observations of this study was that found for sample 6A. After platinizing by method A SEM revealed platinum particles present on the surface, a PtO reduction peak was found, and the Auger measurements gave $R = 0.30$. The activity of the electrode was comparatively high (see Fig. 11). After anodization to 10V no platinum particles were evident by SEM, the PtO reduction peak had disappeared while the Auger still gave evidence of platinum with $R = 0.02$. Despite this order of magnitude decrease in Pt/W ratio after anodization to 10V the activity of the electrode, now denoted at 6A*, was essentially unchanged (see Fig. 11).

Several possibilities presented themselves to explain these results. If there was a monolayer of platinum on sample 6A that was responsible for its activity, then the removal of the platinum particles covering only about 7% of the electrode would have little effect on its activity. However the scanning Auger results convincingly showed that all of the platinum on 6A resided in the platinum particles: A second possibility was that the anodization had left some platinum on the electrode despite the removal of the platinum particles and the absence of the PtO peak. This was confirmed by the Auger Pt/W ratio measurement of 6A*. Although the intensity of the Pt(1467) transition was small it was consistent with the idea that after anodization there remained a thin layer of platinum of equal surface area to that of the platinum particles at the former interface between the platinum particles at the bronze surface. The fact that anodization failed

to remove this platinum suggested a different chemical environment as did the absence of a PtO peak. Realizing that the surface platinum is the only platinum that contributes to the electrocatalytic activity it became clear that, despite the order of magnitude decrease in R, the surface coverage of platinum could be nearly the same for 6A and 6A*. If the activity of the isolated platinum atoms on the surface of 6A* could be shown to be nearly the same as for the platinum atoms of bulk platinum, then the near equivalence of the electrode activity of 6A and 6A* could be accounted for. Our analysis of the lattice match of platinum of Na_xWO_3, the ionic sizes of Pt^{++} and Na^+, the role of anodization, and the expected electronic structure of $PtWO_3$ all gave support to the concept of isolated platinum atoms at the empty sodium sites of an anodized bronze electrode having a specific activity similar to that of bulk platinum. It is fair to state that the observation of 6A and 6A* provided a crucial test for our understanding of the role of platinum on the surface of a bronze electrode.

Conclusions

A large number of undoped Na_xWO_3 crystals were plated with platinum by a variety of techniques and tested as cathodes for oxygen reduction. Electrocatalytic activities equal to and higher than bulk platinum electrodes were obtained as well as improved stability for some bronze electrodes over that of bulk platinum. Two types of platinum morphology were postulated. First, there were distinct platinum islands whose minimum sizes were larger than 200Å as determined by SEM micrographs. The activity of these electrodes at low platinum coverages was directly proportional to the platinum coverage and no synergistic effects of the bronze electrode was indicated. Near 10% coverage there was a dramatic increase in electrode activity that has not been explained. The second type of platinum distribution consisted of about a monolayer or less coverage over the bronze surface. Because of the absence of a PtO peak and the lattice match between the crystal structure of Na_xWO_3 and platinum, we have proposed a $PtWO_3$ layer formed by the diffusion of platinum atoms from the electrolyte into the empty sodium sites of an anodized bronze surface. Depending on the preparation method, the $PtWO_3$ layer was either approximately one monolayer thick or several hundred angstroms thick. The activity per platinum atom, taking into account surface roughness and different possible platinum morphologies, is about the same as that of bulk platinum. It is the second form of platinum incorporation that provides a basis for the further development of an economically competitive oxygen reduction fuel cell cathode.

Photoelectrochemical Reduction of 2-*t*-Butyl-9,10-Anthraquinone at Illuminated P-Type Si: An Approach to the Photochemical Synthesis of Hydrogen Peroxide

Gary S. Calabrese* and Mark S. Wrighton**

Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

The electrochemical behavior of 2-*t*-butyl-9,10-anthraquinone, BAQ, has been investigated at illuminated (632.8 nm, ~50 mW/cm^2) p-type semiconducting Si in CH_3CN/0.1*M* [*n*-Bu_4N]ClO_4 with and without added CH_3COOH. In the absence of CH_3COOH the BAQ is photoreducible at the photocathode to form $BAQ^{\bar{\cdot}}$. Relative to $E°(BAQ/BAQ^{\bar{\cdot}}) = -0.95V$ *vs.* SCE the photovoltage E_V, at open circuit is ~0.5V. An efficiency for a regenerative photoelectrochemical cell based on the $BAQ/BAQ^{\bar{\cdot}}$ is ~4% for the conversion of 632.8 nm light. In the presence of 0.5*M* CH_3COOH the BAQ is photoreducible to 2-*t*-butyl-9,10-dihydroxyanthracene, H_2BAQ, with a measured current efficiency of >90% when the p-type Si photocathode is held at −0.3V *vs.* SCE in a two-compartment cell. Preparative, controlled-potential photoelectrochemical reduction of BAQ to H_2BAQ in CH_3CN/0.5*M* CH_3COOH/0.1*M* [*n*-Bu_4N]ClO_4 has been demonstrated for >90% conversion of 0.2*M* BAQ to H_2BAQ. Reaction of the photoelectrochemically generated H_2BAQ (>0.18*M*) with O_2 from air yields solutions containing >0.18*M* H_2O_2. The BAQ → H_2BAQ has only ~2% photoelectrochemical energy conversion efficiency. The low efficiency is apparently a consequence of sluggish electrode kinetics or adsorption problems that lead to a low E_V with respect to the $E°(BAQ/H_2BAQ) \approx -0.35V$ *vs.* SCE in the presence of 0.5*M* CH_3COOH.

Much effort has recently been directed toward the use of semiconductor-based photoelectrochemical cells for splitting H_2O to H_2 and O_2 (1-3). While the photoelectrolysis of H_2O is an important objective, there are other worthwhile redox reactions that could, in principle, be photochemically driven by illumination of semiconductors immersed in liquid electrolytes (4). For solar driven processes, it would seem that generation of a reduced or oxidized reagent at the photoelectrode followed by its use in concentrated form at a remote reactor would have practical advantages. For example, rather than direct H_2 production from H_2O in large area devices, it might be best to effect the direct generation of a reducing agent capable of effecting H_2O reduction via a catalyzed process at a reaction remote from the solar device (5-7).

With the long range objective of demonstrating photochemical routes to H_2O_2, we have undertaken a study of the photoelectrochemical reduction of 2-*t*-butyl-9,10-anthraquinone, BAQ, according to Eq. [1]. The relationship to H_2O_2 synthesis is established by

$$BAQ \xrightarrow[\text{Nonaqueous Solvent}]{2H^+, 2e^-} H_2BAQ \qquad [1]$$

the known process represented by Eq. [2] (8). Indeed, catalytic

$$\text{(R-substituted 9,10-dihydroxyanthracene)} + O_2 \xrightarrow[\text{Nonaqueous Solvent}]{25°C} H_2O_2 + \text{(R-substituted anthraquinone)} \qquad [2]$$

hydrogenation of BAQ-like molecules followed by reaction of O_2 with the H_2BAQ-like reduction product is an industrial process for the production of H_2O_2. Our objective here is to demonstrate that reaction according to Eq. [1] can be sustained in a thermodynamically uphill sense by illumination of a p-type semiconducting photocathode. Photogeneration of H_2BAQ in an uphill sense is an example of the production of a useful redox reagent that can be used in concentrated form at a remote reactor. The BAQ/H_2BAQ redox couple is transparent to the bulk of the visible spectrum and particularly at 632.8 nm, the wavelength employed in these studies. Chemical durability of the BAQ/H_2BAQ couple is sufficiently good that >0.18*M* H_2O_2 can be generated photoelectrochemically (*vide infra*).

Compared to the direct reduction of O_2 to H_2O_2 in aqueous acid solution, Eq. [3], the cyclic process represented by Eq. [1] and [2]

$$O_2 \xrightarrow{2H^+, 2e^-} H_2O_2 \qquad [3]$$

involving photogeneration of H_2BAQ has a lower theoretical efficiency for energy utilization because $E°(O_2/H_2O_2) \approx +0.45V$ *vs.* SCE in acid solution (9), whereas $E°(BAQ/H_2BAQ) \approx -0.35V$ *vs.* SCE.[1] While the quantitative considerations are clouded by the differences in the media associated with these potentials, it is very clear that H_2BAQ is a far more powerful reductant than required thermodynamically. Thus, a low efficiency for energy utilization in the indirect process is to be expected. However, the indirect process may be desirable in practice on the basis of overall current efficiency, since H_2O_2 is reducible to H_2O at the same

[1] We find that the potential for the BAQ/H_2BAQ is acid strength dependent as would be expected. The −0.35V *vs.* SCE that we give here is the value we determine from cyclic voltammetry of BAQ in CH_3CN/0.5*M* CH_3COOH/0.1*M* [*n*-Bu_4N]ClO_4 at an Hg-drop working electrode. 9,10-Anthraquinone itself has been studied as a function of CH_3COOH concentration in dimethylformamide/0.05*M* [Et_4N]I. The $E_{1/2}$ value varies in a manner similar to that which we find, *cf.* L. Y. Kheifets. V. D. Bezuglyi, and L. I. Dmitrievskaya, *Zh. Obshch. Khim.*, **41**, 68 (1971), and D. H. Evans, in "Encyclopedia of Electrochemistry of the Elements," Vol. XII, Chap. 1, A. J. Bard, Editor, Marcel Dekker, New York (1973).

Key words: solar energy, oxygen reduction, photoreduction.

potential as O_2 is reducible to H_2O_2; $E^\circ(H_2O_2/H_2O) \approx +1.54V$ *vs.* SCE (9). Further, the reduction of O_2 to H_2O, Eq. [4], may compete with H_2O_2 production

$$O_2 \xrightarrow{4e^-,\ 4H^+} 2H_2O \qquad [4]$$

since $E^\circ(O_2/H_2O) \approx +1.00V$ *vs.* SCE (9). Finally, the presence of H_2O_2 in high concentration in the photoelectrochemical device might prove to be incompatible with the cell components, especially the photocathode.

Experimental

Materials—Single crystal p -type Si wafers (0.35 mm thick, 111 face) doped with B and with a resistivity of 3-7 Ωcm were obtained from Monsanto Company, Electronics Division (Palo Alto, California). Ohmic contact to the back side of the Si was made by vapor deposition of Al followed by sintering at 723 K under N_2 for 5 min. The Al-plated surface was then lightly scratched and secured to a coiled Cu wire with conducting silver epoxy. The Cu wire lead was passed through a 4 mm glass tubing. All surfaces were then sealed with ordinary epoxy so as to leave only the front surface (111 face) of the p-type Si single crystal exposed.

Just prior to use, all electrodes were pretreated by etching at 25°C in concentrated HF for 60 sec, rinsed with distilled water followed by acetone, and air dried.

Chemicals.—Reagent grade CH_3CN was distilled from P_2O_5; $[n\text{-}Bu_4N]ClO_4$ (Southwestern Analytical Chemicals) was vacuum dried at 70°C for 24 hr; reagent grade glacial acetic acid (Mallinckrodt), NaCl, and 2-*t*-butyl-9,10-anthraquinone (Aldrich) were all used without further purification.

Equipment and procedures.—All experiments employed solutions of $CH_3CN/0.1M$ $[n\text{-}Bu_4N]ClO_4$ that were degassed with Ar or N_2. The Ar or N_2 was first passed through an oxygen scrubber (acidic aqueous solution of ~0.4*M* Cr^{2+}) and then over P_2O_5 and $CaSO_4$ to remove H_2O.

Cyclic voltammograms and steady-state current-voltage curves were obtained using a PAR Model 173 potentiostat equipped with a Model 175 programmer. Data were recorded on a Houston Instruments XY recorder, or, for current *vs.* time plots, on a Hewlett-Packard strip chart recorder. For cyclic voltammograms a single-compartment cell was used employing a standard three-electrode configuration with a p-type Si, Hg, or Pt cathode, a Pt counterelectrode, and reference electrodes being either a saturated calomel electrode (SCE) or a silver wire (Ag/Ag^+) immersed in 0.1*M* $AgNO_3$/0.1*M* $[n\text{-}Bu_4N]ClO_4$ in CH_3CN (+0.35V *vs.* SCE). Current *vs.* time experiments were carried out using the same type of cell except that an Hg pool counterelectrode was used in place of a Pt wire. Current efficiency and exhaustive electrolysis experiments were carried out in two-compartment cells in which the Pt anode was isolated by an ultrafine glass frit.

Electrodes were illuminated using a beam-expanded 632.8 nm He-Ne laser (Coherent Radiation) providing ~50 mW/cm². Laser intensity was varied using Corning colored glass filters and monitored using a beam splitter and a Tektronix J16 radiometer equipped with a J6502 probe. The laser beam was masked to match the size of the Si surface.

Optical density measurements were made using 1.00 cm path optical cells with a Cary 17 spectrophotometer that operates in the ultraviolet, visible, and near infrared regions.

Current efficiency determination.—The current efficiency for the reduction of BAQ to H_2BAQ at a p-Si photocathode was determined in CH_3CN containing 0.5*M* CH_3COOH, 0.01*M* BAQ, and 0.1*M* $[n\text{-}Bu_4N]ClO_4$. First, a similar solution containing a precisely known concentration of BAQ was exhaustively electrolyzed in a two-compartment cell at a Pt electrode such that no further changes in the optical density of the solution at 380 nm (corresponding to H_2BAQ) were observed. Thus, a molar extinction coefficient of 9600 ± 200 $lmole^{-1}\ cm^{-1}$ at 380 nm was calculated for H_2BAQ in CH_3CN.[2] The relative current efficiency at irradiated p-Si was then determined by measuring changes in optical density at 380 nm of the cathode compartment of a two-compartment cell containing 20.0 cm³ of the solution described above. The electrode potential of the p-Si was fixed at −0.3V *vs.* SCE.

Analysis of H_2O_2.—Small volumes of CH_3CN containing H_2O_2 were diluted with H_2O containing an excess of Ti(IV) ions. The optical density at 405 nm corresponding to the Ti(IV)-H_2O_2 complex was used to determine H_2O_2 concentrations (10). Control analyses using authentic samples of H_2O_2 were run to insure the reliability of the technique. Standard solutions of H_2O_2 for preparation of calibration curves for the Ti(IV) analyses were prepared using reagent grade H_2O_2 and their H_2O_2 concentration was determined by titration with standard solutions of $KMnO_4$.

Results

Cyclic voltammetry of BAQ in nonaqueous solution at illuminated p-type Si.—P-type Si has been well characterized (5) in $CH_3CN/0.1M$ $[n\text{-}Bu_4N]ClO_4$ and the ($BAQ/BAQ^{\overline{\cdot}}$) system appears to be well behaved. Figure 1a shows the cyclic voltammetry corresponding to the reversible $BAQ \rightleftarrows BAQ^{\overline{\cdot}}$ system at Hg, Pt, and Si. The E° ($BAQ/BAQ^{\overline{\cdot}}$) falls in a potential regime where the output photovoltage of p-type Si is expected to be ~0.5V (5). Consistent with this expectation we find that the photocathodic current peak is ~0.45V more positive than at Hg or Pt. The difference in the cathodic current peak positions is one measure of the output photovoltage (5) for the photocathode with respect to the E° of the solution couple.

Figure 1b shows the effect from adding 10 mM CH_3COOH as a source of H^+. The cathodic current peak in each case is more positive and is ~twice that found in the absence of H^+. These facts indicate that the reduction current corresponds to the two-electron reduction process to form H_2BAQ. The reoxidation $H_2BAQ \xrightarrow{-2e^-,\ -2H^+} BAQ$ appears to be sluggish, and even the reduction peak positions differ at Pt and Hg suggesting kinetic difficulties there as well. Addition of CH_3COOH to 0.5*M* gives somewhat sharper cyclic waves and the cathodic current peaks are somewhat more positive, Fig. 1c. Use of Pt in 0.5*M* CH_3COOH is not useful, since H_2 evolution current obscures the BAQ electroactivity. The presence of small amounts of H_2O does not affect our results. The use of H_2O as a solvent is precluded because the BAQ/H_2BAQ couple is not soluble.

The $E^\circ(BAQ/H_2BAQ)$ in $CH_3CN/0.5M$ $CH_3COOH/0.1M$ $[n\text{-}Bu_4N]ClO_4$ would appear to be about −0.35V *vs.* SCE. This potential is again in the regime where fast, one-electron redox systems can be reduced with ~0.5V output photovoltage at p-type Si (5). Note, however, that the peak at p-type Si is only 0.2V more positive than that at Hg. This indicates that the extent to which the $BAQ \rightarrow H_2BAQ$ reduction can be driven uphill at illuminated p-type Si will be limited to ~0.2V.

The low output photovoltage for the $BAQ \rightarrow H_2BAQ$ process is disappointing. Previous experiments (5) showing ~0.5V output for couples in the same potential regime were done using $CH_3CN/0.1M$ $[n\text{-}Bu_4N]ClO_4$ as the solvent/electrolyte system. We thus wondered whether the 0.5*M* CH_3COOH could deleteriously affect the interface energetics. We find this not to be the

[2] A similar molar absorptivity has been found for 9,10-dihydroxyanthracene, *cf.* R. M. Wightman, J. R. Cockrell, R. W. Murray, J. N. Burnett, and S. B. Jones, *J. Am. Chem. Soc.*, 98, 2562 (1976).

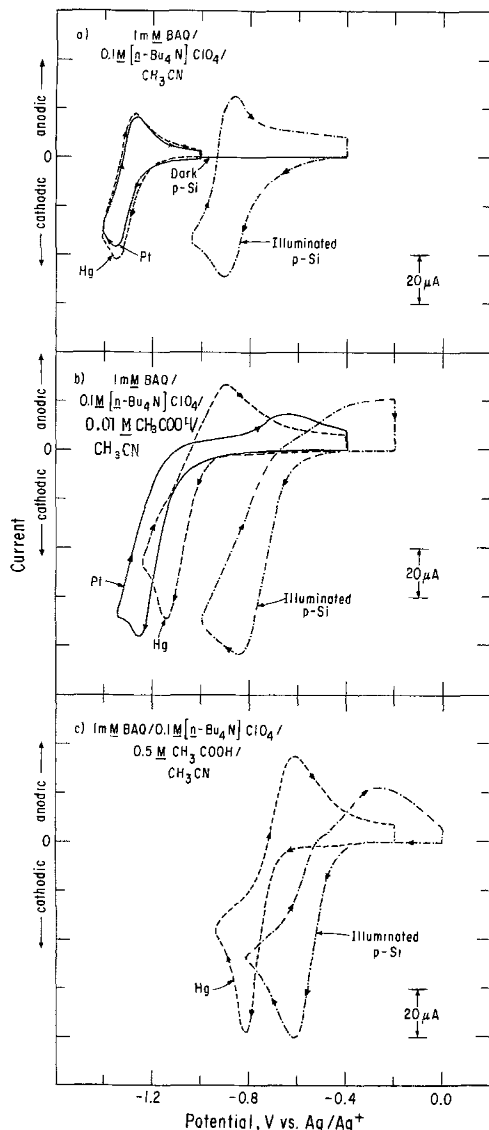

Fig. 1. Cyclic voltammetry at 200 mV/sec for Pt, Hg, and p-Si under the conditions shown. Illumination of the p-Si was at 632.8 nm, 50 mW/cm^2. The initial potential was the positive limit in all cases.

case, since the output photovoltage (~0.5V) for the reduction of N,N'-dimethyl-4,4'-bipyridinium (5, 11) is independent of whether the CH_3COOH is present. We thus conclude that the low photovoltage that can be achieved reflects relatively sluggish kinetics for the BAQ → H_2BAQ process. The data in Fig. 1b show that Hg and Pt differ in their behavior with respect to reduction and it is possible that Si has poor kinetics. Kinetics for reduction of quinones is known to be dependent on the electrode material (12). We thus conclude that the poor photovoltage may be improved by altering the photocathode surface to improve the kinetics.

Current efficiency for BAQ → H_2BAQ photoreduction.—The current efficiency for the photoreduction of BAQ at illuminated p-type Si has been found to be quite high. The reduction product H_2BAQ has unique visible near ultraviolet absorption spectral properties that allow its concentration to be monitored in a two-compartment cell. Figure 2 shows the results of a determination of moles of H_2BAQ formed as a function of charge passed. Within experimental error the current efficiency is 100%, two moles of electrons passed per mole of H_2BAQ formed.

Steady-state photocurrent-voltage curves and durability of the photocathode.—Figure 3 shows steady-state

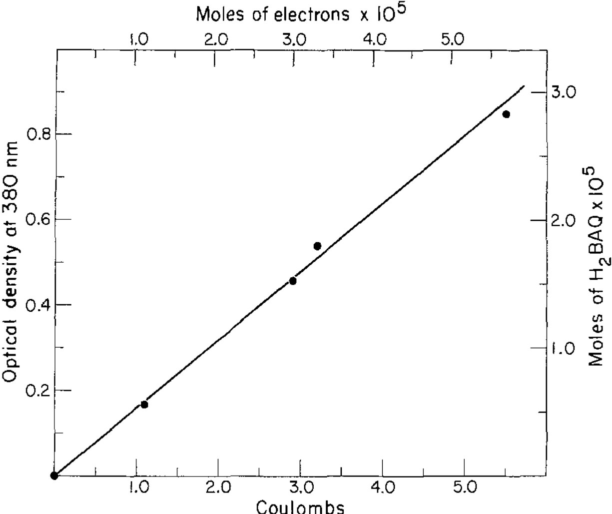

Fig. 2. Plot of increase of optical density at 380 nm associated with H_2BAQ generation from BAQ at a p-Si electrode illuminated with 632.8 nm light in a two-compartment cell. The current efficiency for this electrode is thus 100 ± 5%. The photocurrent density was ~5 mA/cm^2.

photocurrent voltage curves for the reduction of BAQ to H_2BAQ as a function of light intensity. As expected from the cyclic voltammetry results, Fig. 1, the output photovoltage with respect to the E_{redox} (BAQ/H_2BAQ) is rather modest. Table I summarizes the efficiency for the photoelectrochemical reduction of BAQ from the curves given in Fig. 2. The maximum energy conver-

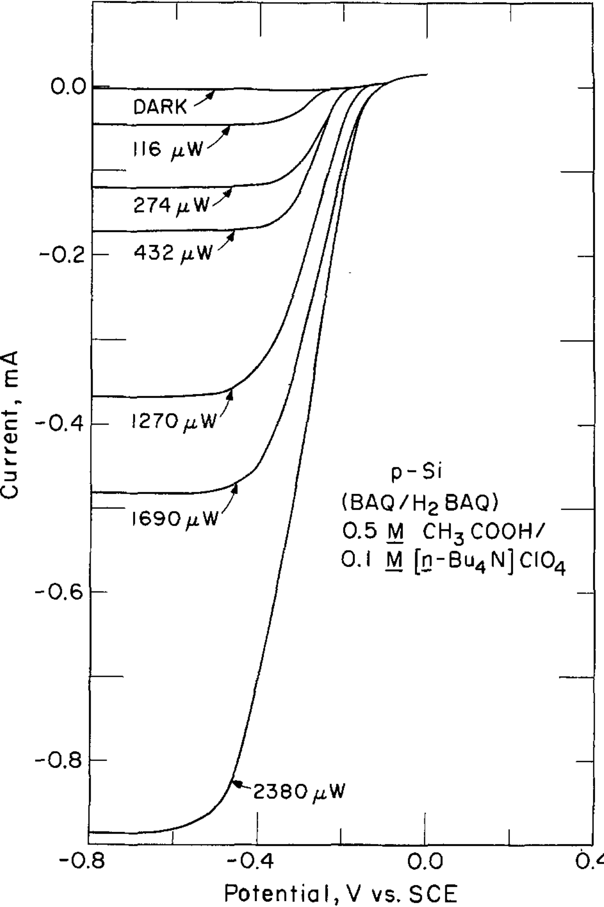

Fig. 3. Representative steady-state current-voltage curves at 10 mV/sec for a 0.03 cm^2 p-Si electrode in CH_3CN containing 0.2M BAQ, ~1 mM H_2BAQ, 0.5M CH_3COOH, and 0.1M [n-Bu_4N]ClO_4. Incident 632.8 nm optical power is given in μW. The solution redox potential was measured at an Hg pool to be ~−0.4V vs. SCE.

[d] Efficiency for conversion of 632.8 nm light to electricity.

sion efficiency, η, is given by Eq. [5], where E_V is the output voltage in volts at

$$\eta = \frac{(E_V \times i)_{max} \times 100\%}{\text{Input optical power}} \quad [5]$$

the maximum power point; i is the photocurrent in amperes at the maximum power point and the input optical power is the power in watts from a 632.8 nm He-Ne laser source. Thus, we can realize an energy conversion efficiency of ~2% for the uphill reduction of BAQ. As Table I shows, the major loss would appear to be associated with the low open-circuit photovoltage. The quantum yield for electron flow is ≥0.50 and much of the inefficiency is reflection loss from the polished Si. In the absence of CH_3COOH we find ~4% efficiency for a photoelectrochemical cell based on $BAQ/BAQ^{\bar{\cdot}}$ converting 632.8 nm light to electricity. This doubled efficiency is about what is expected (5) for a fast, outer-sphere, one-electron redox couple.

The behavior of the p-type Si photocathode is constant in time. Figure 4 shows the photocurrent against time for a BAQ/CH_3CN/0.5*M* CH_3COOH/0.1*M* [*n*-Bu_4N]ClO_4 solution. As shown, the efficiency for a cell where the photocathode process is according to Eq. [1] and where the anode process is its reverse can be sustained for a 20 hr period. There is no evidence that the photoelectrode undergoes any deterioration. Similar data have been published for the photoreduction of other species in nonaqueous media (5).

Preparative, controlled-potential photoreduction of BAQ.—We have demonstrated that synthetically significant quantities of H_2BAQ can be prepared by photoelectrochemical reduction of BAQ in CH_3CN/CH_3COOH. Irradiation (632.8 nm) of a p-type Si photocathode held at −0.3V *vs.* SCE in a two compartment cell containing 0.2*M* BAQ/0.5*M* CH_3COOH in the CH_3CN/0.1*M* [*n*-Bu_4N]ClO_4 solution results in the generation of H_2BAQ. Spectrophotometric analysis reveals >0.18*M* H_2BAQ generated. The photocurrent in the stirred cathode compartment was constant to ~90% depletion of the BAQ. Exposure of the resulting H_2BAQ solution to air resulted in the generation of a >0.18*M* H_2O_2 solution as determined by a spectrophotometric analysis by complexation with Ti(IV) (10).

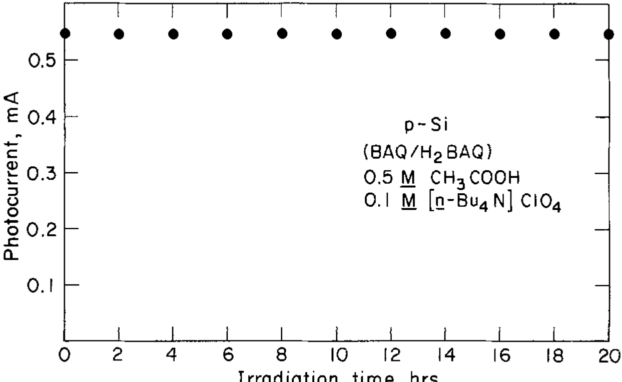

Fig. 4. Plot of photocurrent against time for a 0.1 cm^2 p-Si electrode irradiated with 632.8 nm (~50 mW/cm^2) light. The run was performed in 5.0 cm^3 of rigorously deoxygenated CH_3CN containing 0.2M BAQ, ~1 mM H_2BAQ, 0.5M CH_3COOH, and 0.1M [*n*-Bu_4N] ClO_4. The electrode was maintained at −0.3V *vs.* SCE.

Discussion

Our data establish that p-type Si photocathodes can be used to sustain the uphill generation of H_2BAQ. Synthetically significant concentrations of H_2BAQ and subsequently H_2O_2 can be generated. However, there is a disappointingly low overall efficiency for the process with respect to the utilization of the light energy in the BAQ → H_2BAQ step. Figure 3, for example, represents the photocurrent-voltage curves in what has been termed a regenerative photoelectrochemical cell for the conversion of light to electricity. "Regenerative" refers to the fact that the photoelectrode process is reversed at the counterelectrode. In the present case, the photocathode process is BAQ → H_2BAQ and the anode process is the reverse. The 632.8 nm light is converted to electricity with an efficiency of ~2%, Table I. This efficiency also represents the efficiency for effecting the uphill reduction of BAQ to H_2BAQ. Such an efficiency is probably far too low to be useful inasmuch as the cost of electricity from conventional sources is significantly less than would be the cost of electricity generated photoelectrochemically when the solar efficiency is <2%. It is widely believed that solar efficiencies for photovoltaic and photoelectrochemical processes must exceed ~10% in order to be practical, even if the cell is free (13). When a chemical such as H_2O_2 is the final product a lower efficiency might be allowable, except that conventional electricity can be generated at low cost. Thus, the photoelectrochemical approach to H_2O_2, though demonstrated to work, must be improved significantly with respect to efficiency.

The problem of low efficiency for p-type Si-based cells for the BAQ → H_2BAQ is apparently associated with a low value of E_V. The low fill factors for the photocurrent-voltage curves in Fig. 3 are misleading because the E_V at open circuit is so low. The low E_V for BAQ → H_2BAQ, compared to fast, outer-sphere, one-electron reagents like N.N′-dimethyl-4,4′-bipyridinium, appears to be a consequence of sluggish kinetics at the photoelectrode for the BAQ → H_2BAQ process. The electrochemical behavior of quinones has been the object of many studies showing that the mechanism is complicated and the interfacial kinetics sluggish (12). Adsorption may contribute to the difficulties associated with the BAQ → H_2BAQ reduction.[3] We conclude that favorable manipulation of the kinetics of the BAQ reduction in acid medium is an important objective and our present research is directed toward this goal.

It is gratifying that the p-type Si/BAQ/H_2BAQ system is durable. The direct reduction of O_2 in the presence of H^+ to form H_2O_2 in the photocathode compartment would very likely lead to fast, chemical deterioration of the p-type semiconductor, since H_2O_2 is a powerful oxidant. Further, most of p-type semiconductors that would be considered viable from the standpoint of solar efficiency are known to be unstable at very positive potentials or in the presence of strong oxidants (14).

[3] We note that an earlier study of 9,10-anthraquinone itself at illuminated p-type Si showed little or no photovoltage, *cf.* D. Laser and A. J. Bard, *J. Phys. Chem.*, 80, 5 (1976).

A final problem area concerns the overall cell chemistry. In our two-compartment cell the photocathode compartment gives the BAQ → H_2BAQ. The BAQ can be regenerated in the H_2O_2 forming step, but $2H^+$ is consumed in the compartment per H_2O_2 molecule formed. The anode compartment in our cell has not been dealt with. Ideally, we would like to effect the overall chemistry represented by Eq. [6] where the only consumables are

$$H_2O_{(l)} + \tfrac{1}{2} O_{2(g)} \xrightarrow{h\nu} H_2O_{2(l)} \quad [6]$$

truly abundant and inexpensive. Further, the free energy change associated with Eq. [6] is ~25 kcal/mole of H_2O_2 (9) and would in these terms represent an excellent match to the solar spectrum. But in order to do the chemistry represented by Eq. [6] the anode must effect the oxidation of H_2O to either H_2O_2 or to O_2. If the anode generates H_2O_2 then O_2 from air could be photoreduced at the cathode. If H_2O is oxidized to O_2 then there is no need for an external O_2 feed. There are photoanode materials, *e.g.*, $SrTiO_3$, TiO_2, Fe_2O_3, etc., that are known to be able to effect the photooxidation of H_2O (1-3, 15). These anodes give poor solar efficiency for production of either O_2 or H_2O_2, from H_2O. More generally, H_2O_2 formation by the chemistry represented by Eq. [7] should be explored. For example

$$2HX + O_2 \rightarrow H_2O_2 + X_2 \quad [7]$$
$$X^- = I^-, Br^-, \text{etc.}$$

n-type CdS is known to be able to effect photo-oxidation of I^- in nonaqueous media to complete the cycle for the anode compartment (16). Further studies of such systems are underway in this laboratory.

The Variation of Supporting Electrolyte Concentration in Impedance Studies at a Rotating Disk Electrode

Daniel A. Scherson and John Newman*

Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

An analytic expression for the flux of the electrolyte cation at the surface of a rotating disk electrode subject to a sinusoidally varying electrical perturbation is presented. The boundary conditions to which this treatment is relevant as well as some advantages of the impedance technique are discussed briefly.

The study of electrode kinetics in the presence of an excess of supporting electrolyte is a common practice in experimental electrochemistry. Solution conductivities can in this way be appreciably increased, thus diminishing the magnitude of the electric field. This represents in certain cases a real advantage in the sense that migration of the reactive species can effectively be ignored. However, the interaction between these and the ions of the inert electrolyte cannot be neglected, if double layer effects are to be considered. Mass transfer equations accounting for this coupling can be derived by separating the flux into diffusion and migration contributions. In particular, if the ratio of reactant to electrolyte concentration is small, a linearization procedure can be applied, thereby reducing the complexity of the governing laws. Based

* Electrochemical Society Active Member.

Key words: convection, diffusion, mass transport.

on the latter, Newman (1) has obtained analytic expressions for steady-state concentration profiles of a system containing three species, for a rotating disk with neglect of radial variations. This communication will examine within the same framework of approximations the system reponse to sinusoidally varying boundary conditions [see also Ref. (2)]. Following an analysis previously reported by Scherson and Newman (3), a series expansion for the frequency dependence of the flux of the electrolyte ions at the surface will be presented. Krylov and Babak (4) have earlier stated that these series converge in the whole domain; however, a numerical evaluation of the expansion coefficients (5) has given a strong indication that this is not the case. It is important to note that a complete numerical treatment of the impedance of a rotating disk electrode including radial convection and without an *a priori* separation of the current has been recently described by Appel (6) [see also Ref. 7]. Although this is a significant advancement in attempting to account adequately for double layer effects, the time required for computer calculations makes its general use rather impractical.

Mathematical Formulation

The linearized form of the equation of convective diffusion to a rotating disk for the electrolyte cation is given, according to Newman (1) by

$$\frac{\partial c_+}{\partial t_+^*} - 3\zeta_+^2 \frac{\partial c_+}{\partial \zeta_+} = \frac{\partial^2 c_+}{\partial \zeta_+^2} + \frac{1}{D_e}\left\{\delta_R\left(\frac{D_e}{D_R}\right)^{2/3}\frac{\partial^2 c_R}{\partial \zeta_R^2} + \delta_P\left(\frac{D_e}{D_P}\right)^{2/3}\frac{\partial^2 c_P}{\partial \zeta_P^2}\right\} \quad [1]$$

where c_i is the concentration of species i. The dimensionless variables t_i^* and ζ_i are related to the time, t, and axial distance, y, by

$$t_i^* = \Omega\left(\frac{D_i}{\nu}\right)^{1/3}\left(\frac{a}{3}\right)^{2/3} t,$$

$$\zeta_i = y\left(\frac{a\nu}{3D_i}\right)^{1/3}\sqrt{\frac{\Omega}{\nu}} \qquad i = +, R, P \quad [2]$$

and the parameters D_e and δ_j are defined as follows

$$D_e = \frac{z_+u_+D_- - z_-u_-D_+}{z_+u_+ - z_-u_-},$$

$$\delta_j = \frac{u_+z_j(D_- - D_j)}{u_+z_+ - u_-z_-} \qquad j = R, P \quad [3]$$

The subscripts $-$, $+$, R, and P refer to the anion, cation, reactant, and product, respectively, and other constants are specified in the List of Symbols.

As it becomes clear from Eq. [1], a previous knowledge of the functional dependence of c_R and c_P is necessary in order to solve the differential equation. According to this formalism, the effect of migration on the reactive species is ignored, therefore these functions can be obtained by solving independently the convective diffusion equation for reactant and product subject to appropriate boundary conditions.

If a sinusoidal perturbation is applied to the surface of the electrode, a state will be reached in which all variables involved will oscillate with the same frequency prescribed by the external signal. However, due to the approximations introduced in this analysis, only perturbations of very small amplitude will be considered.

A solution for the transient concentration profiles can be formally expressed as

$$c_i = c_i^{ss} + \tilde{c}_i \qquad i = +, R, P \quad [4]$$

where c_i^{ss} and $\tilde{c}_i$ are the steady-state and time dependent solutions, respectively. A procedure to determine c_i^{ss} has been described by Newman (1) and will not be reproduced here. Furthermore, because of the unique character of the perturbing signal, an explicit functional dependence for $\tilde{c}_i$ can be established, namely

$$\tilde{c}_i = \theta_i \exp(jK_it_i^*) \qquad i = +, R, P \quad [5]$$

where θ_i (i = +, R, P) are coordinate dependent functions, and K_i are dimensionless frequencies defined by

$$K_i = \omega\nu\left(\frac{3D_i}{a\nu}\right)^{2/3} \Big/ \Omega D_i \qquad i = R, P,$$

$$K_+ = \omega\nu\left(\frac{3D_e}{a\nu}\right)^{2/3} \Big/ \Omega D_e \quad [6]$$

Upon substitution of Eq. [5] into Eq. [1], the following differential equation is obtained

$$jK_+\theta_+ - 3\zeta_+^2\frac{\partial\theta_+}{\partial\zeta_+} = \frac{\partial^2\theta_+}{\partial\zeta_+^2} + \frac{1}{D_e}\left\{\delta_R\left(\frac{D_e}{D_R}\right)^{2/3}\frac{\partial^2\theta_R}{\partial\zeta_R^2} + \delta_P\left(\frac{D_e}{D_P}\right)^{2/3}\frac{\partial^2\theta_P}{\partial\zeta_P^2}\right\} \quad [7]$$

subject to

$$\theta_+ = 1 \text{ at } \zeta_+ = 0, \quad \theta_+ \to 0 \text{ as } \zeta_+ \to \infty \quad [8]$$

As discussed in a previous communication (3), the functions θ_R and θ_P can be determined by a Laplace transformation of the solution for the problem of transient convective diffusion under unit concentration step conditions at the surface of the electrode. Krylov and Babak (4) have analyzed this last problem and arrived at a series expansion in terms of parabolic cylinder functions, denoted hereafter by D_k. Based on this particular solution, the inverse Laplace transform of Eq. [7] and Eq. [8], regarding $jK_+ = p$ as a complex parameter, yields a differential equation in the real space

$$\frac{\partial\tilde{\theta}}{\partial\tau} = \frac{\partial^2\tilde{\theta}}{\partial\zeta^2} + 3\zeta^2\frac{\partial\tilde{\theta}}{\partial\zeta} + \sum_{i=R,P}\sum_{n=0}^{\infty}\alpha_i^{-n/2}2^{3n-1}\tau^{(3n-2)/2}\Theta_i(\eta) \quad [9]$$

where

$$\tilde{\theta}(\zeta,\tau) = \mathcal{L}_p^{-1}\{\theta_+(\zeta_+, p)\} \quad [10]$$

and

$$\Theta_i(\eta) = \frac{\delta_i\alpha_i}{D_e}\exp\left(-\frac{\alpha_i}{2}\eta^2\right)\sum_{k=-3n-1}^{3n-1}{}^{**} b_k^{(n)}D_{k+2}(\alpha_i^{1/2}\eta\sqrt{2}) \quad [11]$$

The similarity variables η and α_i are defined by

$$\eta = \frac{\zeta}{2\sqrt{\tau}}, \quad \alpha_i = \frac{D_e}{D_i} \quad i = R, P \quad [12]$$

and the double asterisk in Eq. [11] indicates that k assumes odd values for even n, or even values for odd n. The expansion coefficients $b_k^{(n)}$ are given in Appendix A.

Finally, from Eq. [8]

$$\tilde{\theta} = 1, \text{ at } \zeta = 0, \quad \tilde{\theta} \to 0 \text{ as } \zeta \to \infty \quad [13]$$

Introduction of a new variable $z = 2\tau^{1/2}$ into Eq. [9] yields

$$2z\frac{\partial\tilde{\theta}}{\partial z} - \eta\frac{\partial\tilde{\theta}}{\partial\eta}\{2 + 3z^3\eta\} = \frac{\partial^2\tilde{\theta}}{\partial\eta^2} + 2\sum_{i=R,P}\sum_{n=0}^{\infty}\alpha_i^{-n/2}z^{3n}\Theta_i(\eta) \quad [14]$$

and a solution can therefore be sought in the form

$$\tilde{\theta}(\eta, z) = \sum_{n=0}^{\infty}\theta_n(\eta)z^{3n} \quad [15]$$

Substitution of Eq. [15] into Eq. [14], followed by a comparison of terms of identical order in z, generates a recursion relationship for the resulting set of differential equations

$$\theta_n'' + 2\eta\theta_n' - 6n\theta_n = -3\eta^2\theta_{n-1}' - 2\sum_{i=R,P}\alpha_i^{-n/2}\Theta_i(\eta) \quad [16]$$

Furthermore, it can be shown that a generalized expression that satisfies Eq. [16] is given by

$$\theta_n(\eta) = e^{-\eta^2/2}\sum_{k=-3n-1}^{3n-1}{}^{**}A_k^{(n)}D_k(\eta\sqrt{2}) + e^{-\alpha_R\eta^2/2}\sum_{k=-3n-1}^{3n-1}{}^{**}B_k^{(n)}D_k(\alpha_R^{1/2}\eta\sqrt{2}) + e^{-\alpha_P\eta^2/2}\sum_{k=-3n-1}^{3n-1}{}^{**}C_k^{(n)}D_k(\alpha_P^{1/2}\eta\sqrt{2}) \quad [17]$$

In particular, for $n = 0$[1]

$$\theta_0(\eta) = \sqrt{\frac{\pi}{2}}\{A_{-1}^{(o)}\,\text{erfc}\,(\eta) + B_{-1}^{(o)}\,\text{erfc}\,(\alpha_R^{1/2}\eta) + C_{-1}^{(o)}\,\text{erfc}\,(\alpha_P^{1/2}\eta)\} \quad [18]$$

Based on the assumption that $\theta_0(\eta)$ satisfies the boundary conditions specified in Eq. [10], an explicit form for the zeroth order coefficient is established by substitution of Eq. [18] into Eq. [16]

$$A_{-1}^{(o)} = \sqrt{\frac{2}{\pi}}\{1 - \Delta_R^{(o)} - \Delta_P^{(o)}\}$$

$$B_{-1}^{(o)} = \sqrt{\frac{2}{\pi}}\Delta_R^{(o)} \text{ and } C_{-1}^{(o)} = \sqrt{\frac{2}{\pi}}\Delta_P^{(o)} \quad [19]$$

where

$$\Delta_i^{(n)} = \frac{\delta_i\alpha_i^{(1-n/2}}{D_e(1-\alpha_i)} \quad i = R,P \quad [20]$$

Therefore, for n greater than zero

$$\theta_n(\eta) = 0 \text{ at } \eta = 0, \text{ and } \theta_n(\eta) \to 0 \text{ as } \eta \to \infty \quad [21]$$

The first relationship in Eq. [21] determines $A_{-3n-1}^{(n)}$

$$A_{-3n-1}^{(n)} = -\frac{3}{2}n\Gamma\left(\frac{3}{2}n\right)\sum_{k=-3n+1}^{2n-1}{}^{**}\frac{\{A_k^{(n)} + B_k^{(n)} + C_k^{(n)}\}}{\Gamma\left(\frac{1-k}{2}\right)}2^{(3n+k+1)/2} \quad [22]$$

and further substitution of Eq. [17] into Eq. [16] yields after extensive algebraic manipulations recursion formulas for all remaining coefficients. These are given in Appendix B.

Based on Eq. [17], the derivative of $\tilde{\theta}(\zeta)$ evaluated at $\zeta = 0$ is given by

$$-\frac{\partial\tilde{\theta}}{\partial\zeta}\bigg|_{\zeta=0} = \sum_{n=0}^{\infty}\tau^{1/2(3n-1)}\sum_{k=-3n-1}^{3n-1}{}^{**}\{A_k^{(n)} + \alpha_R^{1/2}B_k^{(n)} + \alpha_P^{1/2}C_k^{(n)}\}\frac{2^{3n+k/2}\pi^{1/2}}{\Gamma\left(-\frac{k}{2}\right)} \quad [23]$$

which after a Laplace transformation yields the derivative of the concentration of the electrolyte cation at the surface of the electrode, that is

$$\mathcal{L}_\tau\left\{-\frac{\partial\tilde{\theta}}{\partial\zeta}\bigg|_{\zeta=0}\right\} = -\frac{\partial\theta_+}{\partial\zeta_+}\bigg|_{\zeta_+=0} = \sum_{n=0}^{\infty}\Gamma\left(\frac{3n+1}{2}\right)(jK_+)^{-1/2(3n-1)}\sum_{k=-3n-1}^{3n-1}{}^{**}\frac{2^{3n+k/2}\pi^{1/2}}{\Gamma\left(-\frac{k}{2}\right)}\times\{A_k^{(n)} + \alpha_R^{1/2}B_k^{(n)} + \alpha_P^{1/2}C_k^{(n)}\} \quad [24]$$

The effect of the supporting electrolyte on the overall impedance can be obtained by introducing this last expression into the boundary conditions which in turn are to be equated to the specific linearized kinetics that prescribe the system.

Discussion and Conclusions

The individual fluxes corresponding to the electrolyte cation and anion can be reduced to a single equation by elimination of the electric field contributions and further use of the electroneutrality condition

$$\left\{\frac{z_+ - z_-}{z_-}\right\}\frac{\partial\theta_+}{\partial\zeta}\bigg|_{\zeta=0} + \frac{z_R}{z_-}\frac{\partial\theta_R}{\partial\zeta}\bigg|_{\zeta=0} + \frac{z_R}{z_-}\frac{\partial\theta_P}{\partial\zeta}\bigg|_{\zeta=0} = f(\Gamma_+,\Gamma_-) \quad [25]$$

where $f(\Gamma_+,\Gamma_-)$ corresponds to a linearized form for the kinetics of the particular system under analysis. Moreover Γ_i ($i = +,-$) are functions of a properly defined overpotential and surface concentrations of all ions involved. In addition, similar boundary conditions can be established for reactant and product as outlined elsewhere (6).

The treatment presented above allows individual fluxes of all ions to be expressed in terms of analytic functions, which represents an advantage over strictly numerical techniques. The theoretical interpretation of results obtained through the use of the impedance method will be strongly influenced by the particular model chosen especially in connection with the non *a priori* separation of the current in terms of double layer charging and faradaic reaction. A detailed description of these processes invariably leads to the introduction of certain quantities which may not be easily measured independently. It is precisely in this

[1] The function $\theta_0(\eta)$ is obtained from Eq. [16] for $n = 0$ under the assumption $\theta_{-1}'(\eta) = 0$.

respect that this transient technique could prove extremely useful because a large set of experimental data is obtained, therefore allowing a strict test of a general mathematical model.

APPENDIX A

Based on the particular set of dimensionless variables chosen in this work the $b_k^{(n)}$ coefficients are slightly different from those reported by Krylov and Babak (3), namely

$$b_{-1}^{(0)} = \sqrt{\frac{2}{\pi}} \quad \text{[A-1]}$$

$$b_2^{(1)} = -\frac{1}{4\sqrt{\pi}}, \quad b_0^{(1)} = -\frac{3}{8\sqrt{\pi}},$$
$$b_{-2}^{(1)} = 0, \quad b_{-4}^{(0)} = \frac{3}{8\sqrt{\pi}} \quad \text{[A-2]}$$

The values of $b_k^{(1)}$ given in Eq. [A-2] serve as a basis to generate any higher order coefficients ($n > 1$), through the recursion formulas specified below

$$b_{3n-1}^{(n)} = -\frac{\sqrt{2}}{8n} b_{3n-4}^{(n-1)} \quad \text{[A-3]}$$

$$b_{3n-3}^{(n)} = -\frac{3\sqrt{2}}{8(3n-1)} \{b_{3n-6}^{(n-1)} + (6n-5) b_{3n-4}^{(n-1)}\} \quad \text{[A-4]}$$

$$b_{-3n+1}^{(n)} = -\frac{9\sqrt{2}}{8} (3n-2)(n-1) b_{-3n+2}^{(n)} \quad \text{[A-5]}$$

$$b_{-3n+3}^{(n)} = \frac{3\sqrt{2}}{16} \{(6n-7) b_{-3n+2}^{(n-1)} - (3n-5)(3n-4) b_{-3n+4}^{(n-1)}\} \quad \text{[A-6]}$$

$$b_k^{(n)} = \frac{-3\sqrt{2}}{4(3n+k+1)} \{b_{k-3}^{(n-1)} + (2k+1) b_{k-1}^{n-1} + (k+1)(k+2) b_{k+1}^{(n-1)}\} \quad \text{[A-7]}$$

for $-3n + 5 \leq k \leq 3n - 5$

and

$$b_{-3n-1}^{(n)} = -\frac{3}{2} n \,\Gamma\left(\frac{3}{2} n\right) \sum_{k=-3n+1}^{3n-1}{}^{**} \; b_k^{(n)} \frac{2^{\frac{1}{2}(3n+k+1)}}{\Gamma\left(\frac{1-k}{2}\right)} \quad \text{[A-8]}$$

APPENDIX B

The first term in the RHS of Eq. [17] can be regarded as the solution for the electrolyte cation behaving as if it were a minor species. Therefore, it is not surprising that the recursion formulas for $A_k^{(n)}$ ($n > 1$) are precisely those specified in Appendix A, Eq. [A-3] through Eq. [A-7]. Moreover, $A_k^{(1)} = b_k^{(1)}$ for $k = 2, 0, -2$, and $A_{-4}^{(1)}$ is determined from Eq. [22], that is

$$A_{-4}^{(1)} = -\frac{3}{2} \Gamma\left(\frac{3}{2} n\right) \sum_{-2}^{2}{}^{**} \frac{\{A_k^{(1)} + B_k^{(1)} + C_k^{(1)}\}}{\Gamma\left(\frac{1-k}{2}\right)} 2^{\frac{1}{2}(3+k+1)} \quad \text{[B-1]}$$

where $B_k^{(n)}$ and $C_k^{(n)}$ are listed below.

Defining

$${}^i\chi_k^{(n)} = B_k^{(n)} \text{ for } i = R \ (= C_k^{(n)} \text{ for } i = P) \quad \text{[B-2]}$$

the governing relationships for these coefficients are given as follows

$${}^i\chi_2^{(1)} = -\frac{1}{4\sqrt{\pi}} \Delta_i^{(1)} \quad {}^i\chi_0^{(1)} = -\frac{(7-3\alpha_i)}{8\sqrt{\pi}(1-\alpha_i)} \Delta_i^{(1)} \quad \text{[B-3]}$$

$${}^i\chi_{-2}^{(1)} = \frac{2}{\sqrt{\pi}(1-\alpha_i)^2} \Delta_i^{(1)}$$

$${}^i\chi_{-4}^{(1)} = -\frac{\{16(1-\alpha_i)^3 - 3\}}{8\sqrt{\pi}(1-\alpha_i)^3} \Delta_i^{(1)} \quad \text{[B-4]}$$

and for $n > 1$

$${}^i\chi_{3n-1}^{(n)} = \Delta_i^{(n)} b_{3n-1}^{(n)} \quad \text{[B-5]}$$

$${}^i\chi_{3n-3}^{(n)} = \Delta_i^{(n)} b_{3n-3}^{(n)} - \Phi_i {}^i\chi_{3n-4}^{(n-1)} - \frac{6n}{(1-\alpha_i)} {}^i\chi_{3n-1}^{(n)} \quad \text{[B-6]}$$

$${}^i\chi_{3n-5}^{(n)} = -\Phi_i {}^i\chi_{3n-6}^{(n-1)} - \frac{(6n-2)}{(1-\alpha_i)} {}^i\chi_{3n-3}^{(n)} - \Phi_i (6n-5) {}^i\chi_{3n-4}^{(n-1)} + \Delta_i^{(n)} b_{3n-5}^{(n)} \quad \text{[B-7]}$$

$${}^i\chi_{k-2}^{(n)} = -\Phi_i \{{}^i\chi_{k-3}^{(n-1)} + (2k+1) {}^i\chi_{k-1}^{(n-1)} + (k+1)(k+2) {}^i\chi_{k+1}^{(n-1)}\} + \Delta_i^{(n)} b_{k-2}^{(n)} - \frac{(3n+k+1)}{(1-\alpha_i)} {}^i\chi_k^{(n)} \quad \text{for} \quad -3n+5 \leq k \leq 3n-5 \quad \text{[B-8]}$$

$${}^i\chi_{-3n+1}^{(n)} = -\frac{4}{(1-\alpha_i)} {}^i\chi_{-3n+3}^{(n)} + \Phi_i (6n-7) {}^i\chi_{-3n+2}^{(n-1)} - \Phi_i (3n-5)(3n-4) {}^i\chi_{-3n+4}^{(n-1)} + \Delta_i^{(n)} b_{-3n+1}^{(n)} \quad \text{[B-9]}$$

$${}^i\chi_{-3n-1}^{(n)} = -\frac{2}{(1-\alpha_i)} {}^i\chi_{-3n+1}^{(n)} - \Phi_i (3n-3)(3n-2) {}^i\chi_{-3n+2}^{(n-1)} + \Delta_i^{(n)} b_{-3n-1}^{(n)} \quad \text{[B-10]}$$

where

$$\Phi_i = \frac{3\sqrt{2}}{4(1-\alpha_i)} \alpha_i^{-\frac{1}{3}} \quad \text{[B-11]}$$

Method for Kinetic Analysis of a Recombination-Controlled Reaction over a Wide Range of Current-Densities from the Reversible Region up to the Limiting Current

B. E. Conway* and D. M. Novak*,[1]

Chemistry Department, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT

Hitherto, the criterion for recombination-control in an electrochemical reaction sequence has been simply the observation of a Tafel slope of $RT/2\mathbf{F}$ but applicable only to potential ranges where the coverage of the intermediate concerned is low ($<$ *ca.* 15%). A new general method is proposed which enables recombination kinetics to be tested over a full range of coverages and corresponding current-densities, up to the saturation limiting value, by means of linear plots of a function in $i^{1/2}$ and exp $\eta\mathbf{F}/RT$. If linear plots are found, both the recombination rate-constant and the quasi-equilibrium constant for the prior ion discharge/chemisorption step can be calculated. The method is illustrated by application to data for Cl_2-evolution kinetics. The steepness of approach of overpotential *vs.* log [current] curves to the saturation limiting current is shown to be dependent on interaction effects in the ad-layer, as seems to be indicated experimentally.

In a number of electrochemical gas evolution reactions (*e.g.*, O_2, H_2, Cl_2, C_2F_6, C_2H_6), the step of recombination of radicals derived from a prior initial discharge of ions has been suggested as the rate-controlling step in the overall reaction. Only at one or two metals, however, has such a step been indicated experimentally, *e.g.*, for H_2 on Pt (1), but then the evidence has been questioned (2). With the anodic Cl_2 evolution reaction, on the other hand, a number of authors (3-9) have proposed the recombination mechanism with various kinds of supporting evidence, *e.g.*, Tafel slope and reaction order information.

At Pt anodes in aq. Cl^- solutions, the general curved shape of the log [current-density i] *vs.* potential curves (3) is suggestive of a recombination-controlled mechanism with coverage $\theta_{Cl\cdot}$ by the intermediate, Cl· discharged from Cl^-, reaching values near saturation corresponding (1) to the approach of currents to limiting recombination-controlled values as $\theta_{Cl\cdot} \rightarrow 1$. At catalytically active electrodes, the curved approach of the Tafel relation towards the reversible potential, at low overpotentials, becomes experimentally accessible and makes an added complication in the interpretation of curved Tafel relations, so that corrections for the back-reaction current component are then desirable.

In terms of analyses of consecutive reactions of heterogeneous multistep electrochemical processes (1, 10), it is well known that a rate-limiting recombination step following an ionic discharge process, producing a chemisorbed reactive intermediate, can lead to a Tafel slope of the potential *vs.* log [current-density] relation equal to $RT/2\mathbf{F}$ for "nonactivated" (11) adsorption or $RT/\mathbf{F}$ for "activated" adsorption (11).

* Electrochemical Society Active Member.
[1] Present address, Eldorado Nuclear Ltd., Research Laboratories, Ottawa, Ontario, Canada.

Observation of the lower value of $RT/2\mathbf{F}$ would usually be a clear indication of a recombination-controlled, 2-stage electrode process. However, such a Tafel slope is only predicted if the coverage θ of the electro-active intermediate has a low value, *viz.* $\theta < 0.1$. The more general case, where $\theta > 0.1$, corresponds to a curved log i *vs.* overpotential, η, relation with i eventually approaching a limiting value, i_{lim}, as is observed in the anodic Cl_2 evolution reaction at certain electrodes, *e.g.*, Pt, C (3, 8). This implies that θ is already $>$ *ca.* 0.1 at potentials somewhat positive to the reversible potential, so that diagnostic information from a Tafel slope cannot be obtained.

We present here a more general way of examining the kinetics of a reaction, where recombination control may apply, which is not limited by any restrictive assumptions about coverage by the intermediate. For convenience, the anodic Cl_2 evolution reaction is considered as it seems that this is one of the few cases where recombination-controlled kinetics might arise, so that our analysis may be applicable.

A mechanism previously considered [*cf.* Ref. (3-9)] for Cl_2 evolution is

$$Cl^- + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} S\,Cl\cdot + e \qquad \text{I}$$

$$2\,S\,Cl\cdot \xrightarrow{k_2} Cl_2 \qquad \text{II}$$

where k_1 and k_{-1} are the electrochemical rate constants of the forward and backward directions of step I, and k_2 in the heterogeneous chemical rate constant of step II. S represents surface sites on the electrode on which a Cl· radical is discharged into a presumably chemisorbed state; θ will represent the fractional cov-

erage of such species on the electrode surface and $1 - \theta$ the free area site fraction. S can be an oxide-free metal surface site or, more usually in aqueous medium, S is a site on an oxidized or partially oxidized Pt electrode surface. The degree of oxidation of the surface at the reversible potential for Cl_2 evolution in H_2O corresponds to about $2e$ per surface Pt atom in the absence of adsorbed Cl^-, *i.e.*, "PtO," but due to competitive Cl^- ion adsorption (12), Cl_2 evolution must usually occur on an only partially oxide-covered surface. This aspect of the Cl_2 electrode reaction will be considered elsewhere (13). Here we shall concentrate on the kinetics of step II, when rate determining, in relation to the kinetics of step I and its reverse, especially as the current-density i_2 (controlled by II) increases toward its limiting value $i_{2,\lim}$ corresponding to supposed saturation coverage by the intermediate.

Experimental Data

The experimental data to which the treatment given in this paper is applied, were obtained in point-by-point (30 sec at each potential) potentiostatic measurements at 298 K in aq. KCl + 0.05M HCl solutions made up from 3 × recrystallized KCl and pyrodistilled water and in 0.5M RbCl in anhydrous trifluoroacetic acid. In this solvent, Cl_2 evolution can be established at an oxide-free surface over a wide potential range, up to 2.1V, E_H. More complete details of the experimental work, where Cl_2 evolution kinetics are related to Cl^- ion adsorption and surface oxide coverage at Pt, are given elsewhere (13, 15).

General Kinetic Analysis for the Recombination Mechanism I, II

The following method enables the kinetic behavior associated with pathways I, II to be represented over the whole range of $\theta_{Cl\cdot}$ and corresponding currents up to $i_{2,\lim}$, by means of a linear test plot. The procedure applies without any restriction to special conditions (*cf.*, 10, 11) that may lead limitingly to a Tafel slope of $RT/2\mathbf{F}$, $RT/\mathbf{F}$, or ∞ (limiting current).

The current-density for II is written as

$$i_2 = 2\,\mathbf{F}k_2\theta_{Cl}{}^2 \quad [1]$$

in the absence of interaction or heterogeneity effects [see Ref. (11), (14), and below]. If II is rate controlling, $\theta_{Cl\cdot}$ may be represented as $f(\eta)$ in the usual way (employing the quasi-equilibrium hypothesis) approximately by the electrochemical (Langmuir) adsorption isotherm as a first approach to the discussion of the current-potential behavior

$$\theta_{Cl\cdot} = \frac{\overline{K}_1\,C_{Cl^-}\,\exp[\eta\mathbf{F}/RT]}{1 + \overline{K}_1\,C_{Cl^-}\,\exp[\eta\mathbf{F}/RT]} \quad [2]$$

where $\overline{K}_1$ $(= k_1/k_{-1})$ is the electrochemical quasi-equilibrium constant[2] for step I and C_{Cl^-} is the chloride ion concentration. Then the i_2 *vs.* η relation over any range of anodic overpotentials is

$$i_2 = 2\mathbf{F}k_2\left[\frac{\overline{K}_1\,C_{Cl^-}\,\exp[\eta\mathbf{F}/RT]}{1 + \overline{K}_1\,C_{Cl^-}\,\exp[\eta\mathbf{F}/RT]}\right]^2 \quad [3]$$

It is convenient to rearrange Eq. [3] to the form

$$\frac{\exp[\eta\mathbf{F}/RT]}{i_2{}^{1/2}} = \frac{1}{(2\,\mathbf{F}k_2)^{1/2}\,\overline{K}_1\,C_{Cl^-}} + \frac{\exp[\eta\mathbf{F}/RT]}{(2\,\mathbf{F}k_2)^{1/2}} \quad [4]$$

Hence, a plot of $\exp[\eta\mathbf{F}/RT]/i_2{}^{1/2}$ *vs.* $\exp[\eta\mathbf{F}/RT]$ should give a straight line of slope $(2\mathbf{F}k_2)^{-1/2}$ and an intercept $[(2\mathbf{F}k_2)^{-1/2}/\overline{K}_1\,C_{Cl^-}]$, and will be applicable to any range of values of $\theta_{Cl\cdot}$. Thus, both the quasi-equilibrium constant $\overline{K}_1$ and k_2 the rate constant of the rate-controlling recombination step II can be quantitatively evaluated.

An alternative way of examining experimental results, which provides a more sensitive basis for analyzing the kinetic behavior at high $\theta_{Cl\cdot}$, follows by rearranging Eq. [3] to

$$i_2{}^{-1/2} = (2\mathbf{F}k_2)^{-1/2} + (2\mathbf{F}k_2)^{-1/4}\,(K_1C_{Cl^-})^{-1}\exp[-\eta\mathbf{F}/RT] \quad [5]$$

which enables again both k_2 and $\overline{K}_1$ to be evaluated, this time from the slope and intercept of a plot of $i_2{}^{-1/2}$ *vs.* $\exp[-\eta\mathbf{F}/RT]$.

Application to Some Experimental Results

In the course of examination (13) of the role of surface oxidation of Pt and specific adsorption of Cl^- ions on the kinetics of anodic Cl_2 evolution at that metal, some results for Cl_2-evolution currents at closely spaced intervals of potential were obtained (15). The currents tended to approach a limiting value at high η suggesting recombination control with $\theta_{Cl\cdot} \rightarrow 1$. Experimentally, by working at a rotating Pt disk electrode, it was shown that the limiting currents were not diffusion controlled, as may also be calculated from the known concentrations and diffusion constant. It is therefore of interest to apply the above analysis to these data.

Application of Eq. [4] to the experimental results expressed as steady-state current-densities for Cl_2 evolution at various η values (Fig.1) gives the plots shown in Fig. 2. Good linearity evidently obtains over almost the whole range of η (except, because of the back-reaction, as $\eta \rightarrow 0$; see below), indicating applicability of the recombination-controlled mechanism. It is of interest that the results of Yokoyama and Enyo (3), obtained from an enlarged photo of their published η *vs.* log i curves which show an approach to limiting currents at Pt, also plot out in a similar way (based on Eq. [4]) and thus appear to indicate re-

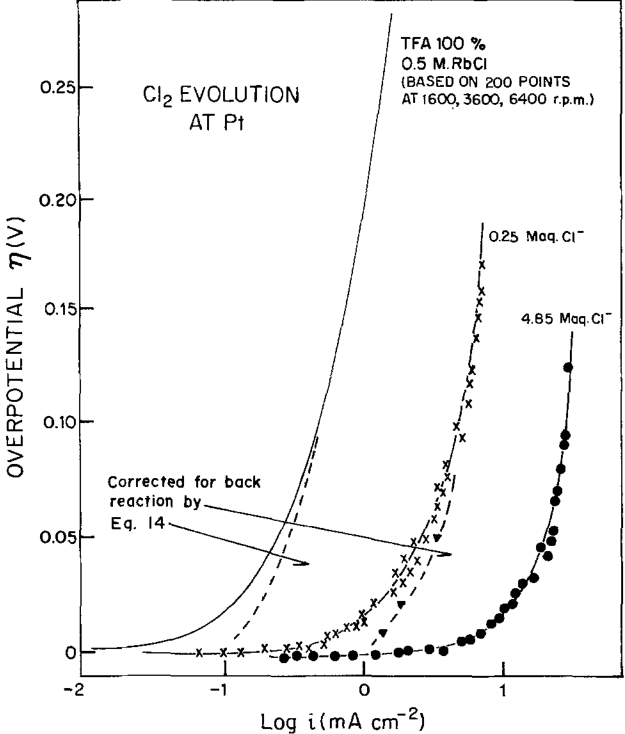

Fig. 1. Overpotential-log[current-density] relations for anodic Cl_2 evolution at rotating Pt disk electrode from 0.5M RbCl in anhydrous trifluoroacetic acid, 0.25M and 4.85M KCl in water at 298 K, showing approaches to kinetically controlled limiting currents. Plots shown are based on *iR* corrected data and are independent of electrode rotation rate. Back reaction corrections are also shown.

[2] $\overline{K}_1$ being an electrochemical equilibrium constant for step I contains the exp factor in $V_{rev}\mathbf{F}/RT$ where V_{rev} refers to the reversible potential for the overall reaction on which the scale of η is based.

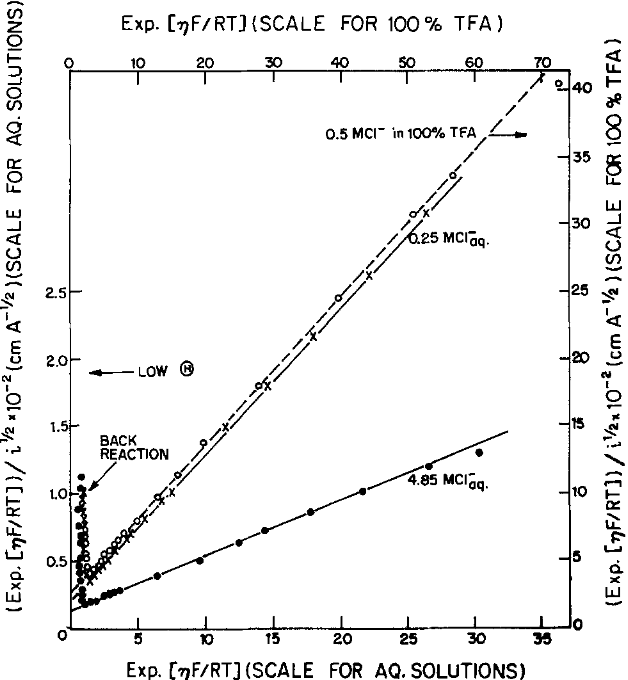

Fig. 2. Plots of the data in Fig. 1 according to Eq. [4]

combination-controlled kinetics. However, only a small number of experimental points are available from that work in order to make the test plot. In the present work, many more were obtained in order to provide a good basis for test of linearity of the plots. Faita and Fiori's work (9) also led to the conclusion that the recombination reaction was rate controlling, but on the basis of observation of an $RT/2F$ Tafel slope.

Plots according to Eq. [5] may also be made, as shown in Fig. 3. In this method of treating the results, there is some small but significant curvature in the resulting lines for the data at higher current-densities as $i \rightarrow i_{2,\lim}$ or $\theta_{Cl\cdot} \rightarrow 1$. The effect due to neglect of the back-reaction gives the curvature at the other ends of the lines in Fig. 3. For high $\theta_{Cl\cdot}$, lateral interactions between adsorbed Cl· should be taken into account [*cf.* (11)] and will give rise to deviations from the behavior expected according to Eq. [5]. Such effects may be treated as follows.

When lateral interactions are signficant, both the rate equation for recombination and the electrochemical isotherms for Cl· adsorption must be modified (11, 14) to include interaction terms. Thus Eq. [1] becomes

$$i_2 = 2\mathbf{F}k_2\theta_{Cl\cdot}^2 \exp[2g\theta_{Cl\cdot}] \quad [6]$$

for "nonactivated" adsorption (11) and the isotherm corresponding to Eq. [2] would be of the form

$$\frac{\theta_{Cl\cdot}}{1-\theta_{Cl\cdot}} = \overline{K}_1 \exp[-g\theta_{Cl\cdot}]\cdot C_{Cl^-} \exp[\eta\mathbf{F}/RT] \quad [7]$$

In these equations, g is a lateral interaction parameter (14) which measures in units of "RT" the assumed linear (17) change of free energy of adsorption of Cl· with coverage at the electrode surface according to a Frumkin type isotherm.

Following a procedure similar to that for deriving Eq. [4] or [5] by substituting for $\theta_{Cl\cdot}$ from Eq. [7] into [6], we obtain

$$i_2^{-1/2} = (2\mathbf{F}k_2)^{1/2} \exp[-g\theta_{Cl\cdot}] + (2\mathbf{F}k_2)^{-1/2} (\overline{K}_1 C_{Cl^-})^{-1} \exp[-\eta\mathbf{F}/RT] \quad [8]$$

This equation shows that when $g \neq 0$, $i^{-1/2}$ is no longer proportional to $\exp[-\eta\mathbf{F}/RT]$ as is indicated by Eq. [5] since there is an additional term involving $g\theta_{Cl\cdot}$ in the function for potential dependence of $\theta_{Cl\cdot}$, now given by Eq. [7] rather than Eq. [2]. Equation [8] cannot be explicitly evaluated but numerical treatment for selected reasonable values of g (= 0, 2, 4, and −2 units of RT) enables the form of Eq. [8] for the variation of $i_2^{1/2}$ with $\theta_{Cl\cdot}$, and hence η, to be obtained as shown in Fig. 4. The resulting behavior towards $\theta_{Cl\cdot} = 1$ may be compared with that based on the experimental results shown in Fig. 3. The evaluation of Eq. [8] is made by choosing a range of $\theta_{Cl\cdot}$ values up to $\theta_{Cl\cdot} \rightarrow 1$ and taking arbitrary values of $k_2 = 1$, $K = 1$, and $C_{Cl^-} = 1$ so that the scales of the plots are relative ones but the four curves are self-consistent ones. The potentials in $\exp[-\eta\mathbf{F}/RT]$ are taken on an overpotential scale relative to a reversible potential, V_r, taken as zero, corresponding to $\overline{K}_1 = 1 \exp[-V_r\mathbf{F}/RT] = 1$, where V_r is defined in footnote 2.

It will be noted that g-dependent deviations from the (linear) Langmuir plot which arises when g is taken as zero in Eq. [7] appear in a characteristic way, dependent on the sign and magnitude of g (= 0, 2, 4, and −2 units of RT). All four curves in Fig. 4 become asymptotic to the $g = 0$ line for sufficiently low η, as expected.

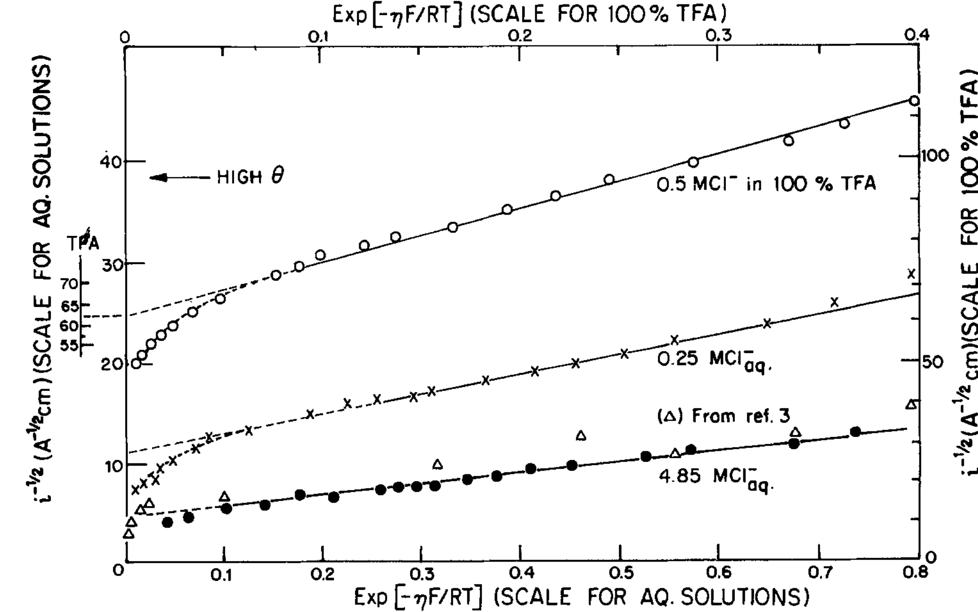

Fig. 3. Plots of the data of Fig. 1 according to Eq. [5].

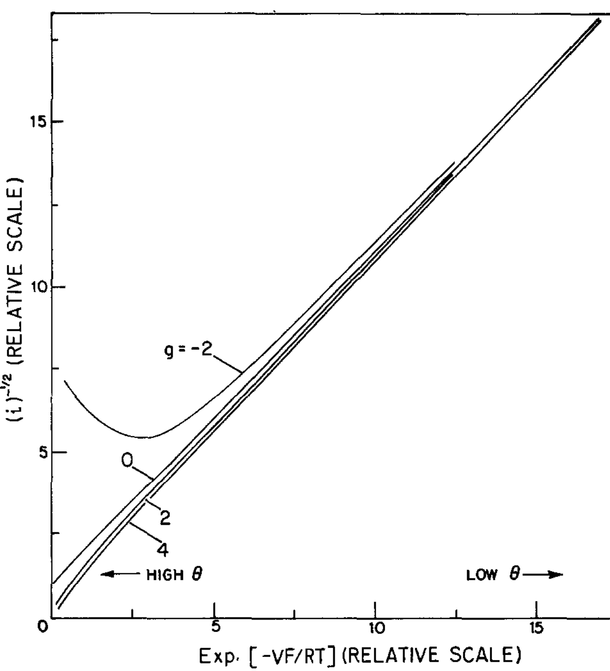

Fig. 4. Simulation of the behavior of a recombinotion-controlled process according to Eq. [8] with various values of the g factor (g = 4, 2, 0, and −2). Langmuir case (g = 0) gives a straight line.

The plots of (Fig. 4) of $i^{-1/2}$ *vs.* exp $[-\eta R/RT]$ derived by this numerical evaluation of Eq. [8] for values of $g > 0$ have similar directions of curvature to those of Fig. 3, based on the experimental data, as $\theta_{Cl\cdot} \rightarrow 1$, *i.e.*, as $i^{-1/2} \rightarrow 0$. The Langmuir case ($g = 0$) is indicated as a reference and gives, of course, a linear plot, as for Eq. [5]. A more realistic interaction term for this case of metal-to-Cl surface dipoles would be written with an $\exp[-g\theta_{Cl\cdot}^{3/2}]$ term or a more complex one if dipole imaging were included (18). Such a term arises from surface dipole repulsion in the nearest-neighbor approximation and gives a somewhat steeper curvature of the plots near $\theta_{Cl\cdot} \rightarrow 1$. A value of $g \simeq 2$ is required to fit the observed experimental behavior in aqueous solutions.

The intercepts and slopes of the almost linear relations of Fig. 2 or 3 give values of the rate constant k_2 and the quasi-equilibrium constant $\overline{K}_1$ (Table I).

It should be mentioned[3] that any exponential relation of the form $i_\eta = i_o \exp[\beta\eta\mathbf{F}/RT]$ for a discharge-controlled process, or a more general one including the back-reaction component, $i_\eta/i_o = 2 \sinh[\eta\mathbf{F}/2RT]$, where $\beta = 0.5$ is the transfer symmetry factor, can give a plot of $(i_\eta)^{-1/2}$ which is an exp function of η; for example, in the above case for a simple single-stage process, $i^{-1/2}$ would be linear in $\exp[-\beta\eta\mathbf{F}/2RT]$ or $\sinh^{-1/2}[\eta\mathbf{F}/2RT]$. However, for the present type of case involving recombination control, the linear test plot has to be made in terms of $i_\eta^{-1/2}$ *vs.* $\exp[-\eta\mathbf{F}/RT]$ and not *vs.* $\exp[-\beta\eta\mathbf{F}/2RT]$. A more important point is that a simple exp Tafel relation for a discharge-controlled step cannot give an intercept as in Eq. [5] at higher η for the recombination-controlled process. Such an intercept arises, of course, from the form of the adsorption Eq. [2] and hence [3], when $\overline{K}_1 C_{Cl^-} \exp(\eta\mathbf{F}/RT)$ is neither small nor large compared with 1. The results shown above demonstrate that tests of experimental data according to Eq. [4] or [5], corresponding to the mechanism I, II, do, in fact, give (*i*) good linear relations over most (see above) of the potential range and (*ii*) significant nonzero intercepts. These are critical aspects of the fit of the experimental kinetic data to the recombination type of mechanism according to Eq. [4] or [5], based on a large number of experimental i, η points in the original measurements.

[3] We are grateful to Professor M. Enyo for remarks in correspondence on this point. [See Ref. (19).]

Table I. Values of $\overline{K}_1$ and k_2 for the Cl_2 evolution process, I, II, in various solutions

Solution	$\overline{K}_1$ × 10^{-3} cm³ mol⁻¹	k_2 × 10^9 mol sec⁻¹ cm⁻²
0.5M RbCl in trifluoracetic acid	0.764	1.96
0.25M KCl in water	2.63	49.5
4.85 KCl in water	0.12	290

Role of the Back-Reaction

When the experimental data are treated in terms of Eq. [4], *e.g.*, as shown in Fig. 2, the plots always show a sharp bend-up at low values of η. The Cl_2 evolution reaction is a relatively reversible one at Pt and the measured current-overpotential relations (in the presence of Cl_2 at 1 atm pressure) are always asymptotic to the log i axis at low η, *i.e.*, participation of the back-reaction sets in at easily accessible current densities (Fig. 1). The bend-up of the lines of Fig. 2 at low η can be accounted for simply by the increasing participation of the back-reaction as the condition $\eta \rightarrow 0$ is approached, corresponding to the observed asymptotic approach of the log i *vs.* η curve to the current-density axis as $\eta \rightarrow 0$.

The above method for analysis of recombination-controlled kinetics necessarily applies only to the anodic component, i_a, of the net current density, i. Near the reversible potential, i_a differs from the measured net current i according to $i_a = i + |i_c|$, where $|i_c|$ is the numerical value of the back-reaction component of i. We can write for a general case, with recombination control

$$i = i_a - |i_c| = 2\mathbf{F}k_2\theta^2 - 2\mathbf{F}k_{-2}(1-\theta)^2 \quad [9]$$

At $\eta = 0$, $i = 0$ and $|i_c| = i_a = i_o$ and $\theta = \theta_r$, the value of θ at the reversible potential. Then i can be written in terms of θ_r, with i_a and $|i_c|$ as

$$i = i_o\,\theta^2/\theta_r^2 - i_o(1-\theta)^2/(1-\theta_r)^2 \quad [10]$$

where i_o is defined by comparing the last equation with Eq. [9]. i_a is obtained from Eq. [10], after elementary rearrangements, as

$$i_a = i \Big/ \left[1 - \frac{(1-\theta)^2}{\theta^2}\cdot\frac{\theta_r^2}{(1-\theta_r^2)}\right] \quad [11]$$

Quasi-equilibrium in step I enables θ and θ_r to be related to the reversible potential V_r and η as follows

$$\frac{\theta_r}{1-\theta_r} = K_1C_{Cl^-}\exp\left[\frac{V_r\mathbf{F}}{RT}\right];\quad \frac{\theta}{1-\theta} = K_1C_{Cl^-}\exp\left[\frac{V_r+\eta}{RT}\right] \quad [12]$$

so that

$$\frac{\theta}{1-\theta} = \frac{\theta_r}{1-\theta_r}\exp\left[\frac{\eta\mathbf{F}}{RT}\right] \quad [13]$$

Hence

$$i_a = i \Big/ \left[1 - \exp\left(-\frac{2\eta\mathbf{F}}{RT}\right)\right] \quad [14]$$

Thus, near the reversible potential, the measured net current-densities have to be corrected by the factor $[1-\exp(-2\eta\mathbf{F}/RT)]^{-1}$ in order to obtain the relevant anodic current-densities controlled by the kinetics of the recombination step. Then Eq. [4] for testing the recombination kinetics is written

$$\frac{\exp[\eta\mathbf{F}/RT]\cdot(1-\exp[-2\eta\mathbf{F}/RT])^{1/2}}{i_2^{1/2}} = \frac{1}{(2\mathbf{F}k_2)^{1/2}\overline{K}_1 C_{Cl^-}} + \frac{\exp[\eta\mathbf{F}/RT]}{(2\mathbf{F}k_2)^{1/2}} \quad [15]$$

which eliminates the hook at low η values in the plots of Fig. 2. It should also be noted in relation to the recombination-controlled kinetics, indicated by the test plots according to Eq. [4] (or [15]), or [5], that a direct plot of log $i_2/(1 - \exp[-2\eta\mathbf{F}/RT)]$ *vs.* η for the Pt data does not (*cf.* Fig. 1) give a linear corrected Tafel plot as do corresponding plots for Cl_2 evolution currents on Ir which then exhibit a Tafel slope of 1 $RT/R\mathbf{F}$ for a variety of conditions. In the latter case, for a process with potential-dependent exp factors in the component currents of $\alpha\eta\mathbf{F}/RT$ and $-(1 - \alpha)\eta\mathbf{F}/RT$, the correction factor for back-reaction current is $1/(1 - \exp[\eta\mathbf{F}/RT])$.

Application of this correction causes the points in the hook of the lines of Fig. 2 at their lower ends to be reduced in magnitude so that they all fall more or less on the line after correction. The hook is therefore due to participation of the back-reaction at low η values. The correspondence of the corrected points at low η values with the line connecting points derived for higher η shows, incidentally, that the mechanism which applies at high η, giving a limiting current, persists down to the reversible potential without change.

Form of η vs ln i Curves: Steepness of Approach to the Limiting Current

The rate of approach of the current to its limiting value is an easily observable and interesting aspect of the experimental behavior. In the Langmuir case for the adsorption of the intermediate according to Eq. [2], this is determined by the range of potentials over which $\theta_{Cl\cdot}$ increases from *ca.* 0.15 (below which a linear Tafel relation is observed) to *ca.* 0.95, *viz.* 105 mV. When significant repulsive interaction effects arise in the ad-layer of the intermediate, the adsorption isotherm Eq. [7] applies and the range of potentials over which $\theta_{Cl\cdot}$ increases from 0.15, for example, to 0.95 increases approximately in proportion to g. Then the range of potentials over which the current increases towards its limiting value (Eq. [6]) correspondingly increases but the value of the limiting current itself also increases with g when $g > 0$ according to the factor exp $2g$ (Eq. [6]). Thus g has only to be 1.15 for the limiting current to be increased by a factor of 10 and when $g > 0$ in the general case, the approach of the current to its limiting value is less steep than in the Langmuir case. This is the kind of behavior observed experimentally [Fig. 1 and Ref. (3)].

Thus, by means of the general rate Eq. [6] and the corresponding electrosorption isotherm (Eq. [7]), the reciprocal slope of the η *vs.* ln i relation at any point may be calculated from

$$d \ln i/d\eta = (d \ln i/d\theta)(d\theta/d\eta) \quad [15]$$

where θ here is written for any intermediate in a mechanism of the type I, II. Thus

$$d \ln i/d\theta = 2/\theta + 2g \quad [16]$$

and

$$d\eta/d\theta = \frac{RT}{\mathbf{F}}\left[\frac{1 + g\theta(1 - \theta)}{\theta(1 - \theta)}\right] \quad [17]$$

Then

$$d\eta/d \ln i = \frac{RT}{2\mathbf{F}}\left[\frac{1 + g\theta(1 - \theta)}{(1 - \theta)(1 + g\theta)}\right] \quad [18]$$

which gives the required limiting values of the Tafel slope as $RT/2\mathbf{F}$ as $\theta \rightarrow 0$ and ∞ as $\theta \rightarrow 1$, and the slope of the g-dependent η *vs.* ln i curve for any intermediate θ values. The corresponding changes of the limiting current itself when $g > 0$ can be expressed (*cf.* Eq. [6]) as

$$i_{\lim\cdot g}/i_{\lim\cdot g=0} = \exp 2g \quad [19]$$

Thus, when $g > 0$, a quasi-catalytic effect arises in recombination control due to lateral interaction effects.

Illustrative values of the gradients, $d\eta/d$ ln i, of the overpotential *vs.* ln [current-density] curves near the limiting current condition ($i \rightarrow i_{\lim}$ as $\theta \rightarrow 1$) are given in Table II as multiples of $RT/2\mathbf{F}$ for $g = 0$, 1, and 2, and show the trend toward less steep approaches of i to $i_{\lim}$ as g is larger than zero; the corresponding $i/i_{\lim}$ ratios are given. The slope is given as a multiple of the limiting value $RT/2\mathbf{F}$ attained for all g values at sufficiently low θ (Eq. [18]). The experimental behavior in this work and that of Ref. (3) is fitted by a value of $g = 1.5 \sim 2.0$.

Table II. Some values of $d\eta/d$ ln i near the limiting current-density for various g values

Coverage	g value/RT	Slope $\frac{RT}{2F}$ at θ	$i/i_{\lim}$ at θ
$[\theta = 0]$	$\sim$	$\rightarrow 1$	<<1
$\theta = 0.95$	0	20	0.903
	1	10.4	0.817
	2	7.55	0.739
$\theta = 0.99$	0	100	0.980
	1	50.7	0.961
	2	32.9	0.942
$\theta = 1$	Any value	∞	1

Conclusion

A new method for treating electrode-kinetic data for reactions where a recombination-controlled process may be occurring is proposed. It gives linear test plots over the whole range of coverage of the intermediate involved, corresponding to a wide range of current-densities from low values up to the limiting value determined by saturation coverage by the intermediate. If linear behavior is found in such test plots, quantitative evaluation of the rate constant of the recombination step and the quasi-equilibrium constant of the prior discharge/deposition step can be made. Interaction effects cause deviations from linearity.

It is shown how the approach of the current to the recombination-controlled limiting value, *i.e.*, the steepness of the curved η *vs.* ln i relation, depends on interactions between the ad-species in the recombination step. Experimental behavior in anodic Cl_2 evolution at Pt corresponds to significant repulsive interactions between Pt-Cl· surface dipoles, dependent on coverage.

Diffusion and Solid-Film Formation during Electropolishing of Metals

R. Kirchheim, K. Maier, and G. Tölg

Max-Planck-Institut für Metallforschung, Institut für Werkstoffwissenschaften, 7000 Stuttgart 1, Germany

ABSTRACT

Various metals and electrolytes were used for potentiostatic electropolishing. When measuring the current-time behavior over several orders of magnitude and for the different temperatures, three stages were observed: (*i*) a short stage I, during which the current density was approximately constant; (*ii*) during the following stage II saturation of the dissolved metal ions (reaction products) was obtained in the vicinity of the anode surface, and the current density decreased with the reciprocal square root of time; and (*iii*) after sufficiently long times, during stage III a steady-state current density was approached by an exponential time law. The known theoretical models, based on the work of Elmore, are able to explain the relations between current density, time, and temperature for stage I and II. For stage III a new model is presented which takes convection within the electrolyte into account. The possible formation of a solid film at the transition from stage I to stage II is thought to be responsible for characteristic deviations from the expected current-time behavior. A mathematical treatment of this formation yields film thicknesses of 3-30 nm.

Electropolishing is a well-known method for anodic dissolution of metals and for simultaneous smoothing of the metal surface. Since the first fundamental work of Jaquet (1), many experimental and theoretical contributions have been made in order to explain the process of electropolishing.

In a very important investigation, Elmore (2) could show that the diffusion of a species of the cell reaction determines the rate of dissolution. Kojima and Tobias (3) concluded from diffusion data that the diffusing species for copper/phosphoric acid is some copper phosphate. This contradicts the concept of Edwards (4), who assumed water or phosphoric acid diffusion to be rate controlling.

In this study the current-time behavior is thoroughly examined for different metals and electrolytes with constant cell voltage. The theoretical treatment is extended to describe the influence of natural and forced convection and of the formation of a solid film on the current-time function.

The occurrence of a solid film during electropolishing, its thickness and composition, and its role in brightening are not fully understood (5-9). Direct experimental evidence of the film is difficult to obtain, because the film is dissolved in the electrolyte after switching off the cell voltage (9).

According to theory (2), the product of initial current density and square root of transition time should be proportional to the product of solubility and square root of diffusivity. This was checked for copper in phosphoric acid by measuring the temperature dependence of all quantities.

Experimental Procedure

The cell and the electric circuit used in this study are shown schematically in Fig. 1. This arrangement has also been used in another study to determine concentration-depth profiles on microsectioning specimens (10).

The apparent area of the portion of the anode exposed to the electrolyte was 1.00 cm². The anodes were prepared from high purity polycrystalline material, both mechanically and electrolytically polished before they were mounted in the cell. The cathode was made of a platinum disk spot welded on a steel cylinder. Analytical grade acids were diluted with bidistilled water to the desired concentration.

Usually the experiments were run with constant cell voltage. A voltage slightly less than necessary for oxygen evolution, just at the end of the so-called polishing plateau (11), was applied. In some cases, a saturated calomel reference electrode was used to achieve potentiostatic conditions (12). For measuring temperature effects, the cell was placed into a thermostated bath.

Theory

The equations derived below should describe the time dependence of the cell current during potentiostatic electropolishing, where diffusion into the elec-

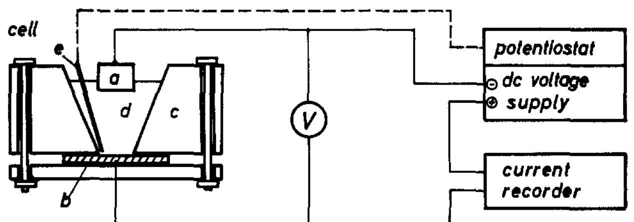

Fig. 1. Schematic view of the experimental cell and the electric circuit. a, Cathode; b, sample (anode); c, Teflon cell body; d, electrolyte; e, reference electrode.

Key words: electrolyte, electrode, current density.

trolyte is the rate-controlling step of the overall cell reaction. Three stages of the current-time function, schematically shown in Fig. 2, are distinguished due to changing boundary conditions.

During stage I from $t = 0$ to $t = t_s$ the concentration of dissolved metal ions at the anode/electrolyte interface increases until the solubility limit is reached. Supersaturation can occur and may cause a solid film to be formed on the anode during stage IIa. Assuming local equilibrium between the solid film and the adjacent electrolyte, the concentration of metal ions is kept constant at that interface for the duration of stage II. If electropolishing times are long or if the electrolyte is stirred, natural or forced convection must be taken into account, thus giving rise to stage III. The diffusion of metal ions in the presence of excess supporting electrolyte obeys Fick's second law

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial x^2} \qquad [1]$$

with a constant diffusion coefficient D. Because the boundary conditions are different for each stage, it is convenient to discuss the stages separately. The following mathematical treatment is also applicable for the depletion of a so-called acceptor (4) where $c(0, t_s) = 0$ instead of $c(0, t_s) = c_s$ has to be inserted.

Diffusion during stage I.—At the onset of electropolishing, the concentration c_b of metal ions in the electrolyte, which is zero in this study, should be uniform. The current density i is related to the ion flux if only one electrochemical reaction is taken into account. The initial and boundary conditions on Eq. [1] are, therefore, (2)

$$c_I(\infty, t) = c_b$$

$$c_I(x, 0) = c_b$$

$$\frac{\partial c_I}{\partial x}(0, t) = -\frac{i_I(t)}{n\mathbf{F}D}$$

giving the well-known solution (13) for stage I

$$c_I(x, t) = c_b + \frac{1}{n\mathbf{F}\sqrt{\pi D}} \int_{t'=0}^{t'} \frac{i(t')}{\sqrt{t - t'}} \exp\left(-\frac{x^2}{4D(t - t')}\right) dt' \qquad [2]$$

For constant current density i_o, the integration yields

$$c_I(x, t) = c_b + \frac{2i_o}{n\mathbf{F}} \sqrt{\frac{t}{\pi D}} \exp\left(-\frac{x^2}{4Dt}\right) - \frac{i_o x}{n\mathbf{F}D} \operatorname{erfc}\left(\frac{x}{2\sqrt{Dt}}\right) \qquad [3]$$

From the last equation a relation between diffusivity D and solubility limit c_s and the measurable quantities i_o and t_s is easily obtained

$$i_o\sqrt{t_s} = \frac{n\mathbf{F}}{2}(c_s - c_b)\sqrt{\pi D} \qquad [4]$$

where t_s is the time necessary to reach the saturation concentration c_s at the electrode ($x = 0$).

Diffusion during stage II.—For $t \geq t_s$ the concentration at the anode/electrolyte interface is c_s, and Eq. [1] has to be solved with the new boundary condition

$$c_{II}(0, t) = c_s$$

The new initial condition is the concentration profile built up in the electrolyte during stage I (Eq. [2])

$$c_{II}(x, 0) = c_I(x, t_s)$$

For convenience a new zero point at $t = t_s$ is used on the time scale during stage II. Then the concentration distribution is (14)

$$c_{II}(x, t) = c_b + \frac{x c_s}{2\sqrt{\pi D}} \int_{t'=0}^{t} (t - t')^{-3/2} \exp\left(-\frac{x^2}{4D(t - t')}\right) dt' + \frac{1}{2\sqrt{\pi D t}} \int_{x'=0}^{\infty} \left[c_b + \frac{1}{n\mathbf{F}\sqrt{\pi D}} \int_{t'=0}^{t_s} \frac{i_I(t')}{\sqrt{t_s - t'}} \exp\left(-\frac{x'^2}{4D(t_s - t')}\right) dt'\right] \cdot \left[\exp\left(-\frac{(x - x')^2}{4Dt}\right) - \exp\left(-\frac{(x + x')^2}{4Dt}\right)\right] dx' \qquad [5]$$

No attempt is made to find an analytical solution for $c_{II}(x, t)$. However, the current density

$$i_{II}(t) = -n\mathbf{F}D \left.\frac{\partial c_{II}}{\partial x}\right|_{x=0}$$

is readily calculated, especially after changing the sequence of integration in the third term of Eq. [5].

Substituting $t_s - t'$ by r^2 one obtains

$$i_{II}(t) = \frac{(c_s - c_b) n\mathbf{F}\sqrt{D}}{\sqrt{\pi t}} - \frac{2}{\pi\sqrt{t}} \int_{r=\sqrt{t_s}}^{0} \frac{r^2 i_I(r)}{t + r^2} dr \qquad [6]$$

where in the first term $c_s - c_b$ and $\sqrt{D}$ can be substituted by i_o and t_s according to Eq. [4]. For a constant current $i_I = i_o$ during stage I, the analytical solution is

$$\frac{i_{II}(t)}{i_o} = \frac{2}{\pi} \arctan \sqrt{\frac{t_s}{t}} = \frac{2}{\pi} \operatorname{arccot} \sqrt{\frac{t}{t_s}} \qquad [7]$$

As an asymptotic approximation for $t >> t_s$ the following form can be used

$$\frac{i_{II}(t)}{i_o} = \frac{2}{\pi} \sqrt{\frac{t_s}{t}} \qquad [8]$$

which is independent of the history of stage I, because it is the solution for the initial condition $c(x, 0) = c_b$ as well. Using Heaviside-Carson operators, Elmore (2) obtained the same results as Eq. [7]. Nevertheless the mathematical treatment of stage I and II was repeated, because the more general Eq. [2] and [6] are better descriptions of electropolishing with constant cell voltage, where the current density i_I usually decreases more or less during stage I. With slight changes the mathematical treatment presented in this section is applied in the following section to demonstrate possible changes of the current density i_{II} caused by the formation of a solid film on the anode.

Formation of a solid film during stage IIa.—The existence of a solid film on the anode is usually assumed

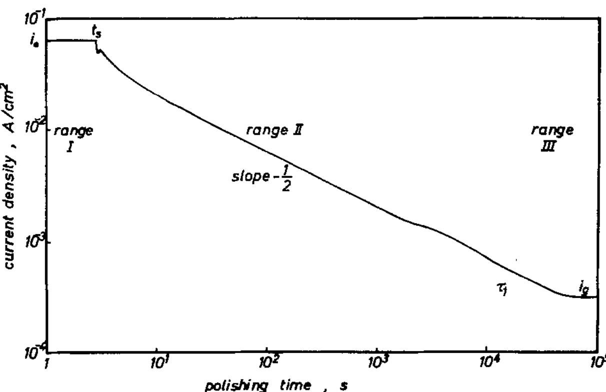

Fig. 2. Double logarithmic plot of current vs. time

for electropolishing, and there are some experimental studies (6-9) which agree on the thickness of the film, but disagree on the chemical composition.

The necessary material for the film might be supplied by backward diffusion from the supersaturated electrolyte. This process is described by a model which also has been recently used by Alkire *et al.* (15) for the occurrence of salt films during repassivation. In this model the concentration at the anode is raised during stage I from $t = 0$ to $t = t_{ss}$ to a supersaturated value c_{ss}. At $t = t_{ss}$ the solid film appears on the metal surface, and the concentration there instantaneously drops from c_{ss} to the equilibrium value c_s. The concentration distribution following the onset of precipitation is given by Eq. [3] with $t = t_{ss}$, except at the surface where $c = c_s$. Then the solution of Eq. [1] is given again by Eq. [5] where t_s has to be replaced by t_{ss}. Neglecting any charge consumption for the film formation, the electrical current density i is given again by the concentration gradient in the electrolyte, and its evaluation follows the lines shown in the section before. Inserting t_{ss} in Eq. [6], the general solution is obtained. For constant density i_o during stage I, the following solution is found by using Eq. [4] with c_{ss} and t_{ss} instead of c_s and t_s

$$\frac{i_{IIa}}{i_o} = \frac{(c_s - c_{ss})nF\sqrt{D}}{\sqrt{\pi t}} + \frac{2}{\pi}\operatorname{arccot}\sqrt{\frac{t}{t_{ss}}} \quad [9]$$

where the first term with $c_s - c_{ss}$ describes the amount of supersaturation. This analytical solution is also applicable to the work of Alkire *et al.*, who used numerical solutions of Eq. [5].

For $t >> t_{ss}$ the perturbation caused by the film formation is negligible, and the asymptotic solution of Eq. [8] can be applied again. For very small times, however, i_{IIa} deviates remarkably from i_{II} as shown in Fig. 3 schematically, where solutions of Eq. [7] and [9] are presented. According to the anticipated backward diffusion i_{IIa} becomes negative during the time interval $0 \leq t \leq t_1$, where t_1 is the only solution of Eq. [9] with $i_{IIa} = 0$. A negative current does not flow through the cell in reality, but it corresponds to an equivalent amount of matter, which diffuses back to the anode to form a solid film. Thus the thickness d of the film can be calculated from the charge flowing back to the metal surface between $t = 0$ and $t = t_1$

$$d = -\frac{V}{nF}\int_{t=0}^{t_1} i_{IIa}\, dt \quad [10]$$

where V is the mole volume of the solid film. Usually the relation $t_1 << t_{ss}$ is valid, and the following approximation can be used

$$d = -V(c_s - c_{ss})^2 nFD \frac{\pi}{i_o}$$

Diffusion and convection during stage III.—For stage I and II diffusion in a semi-infinite electrolyte corresponding to the boundary condition $c(\infty, t) = c_b$ is

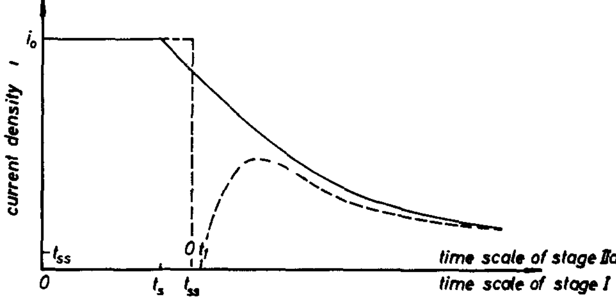

Fig. 3. Schematic current-time plot during stage I and II with and without solid film formation according to Eq. [7] and [9]. Solid lines without, dashed lines with film formation.

considered, and from Eq. [8] it can be concluded that i goes to zero if t goes to infinity. Experimental results (Fig. 2), however, show that a steady-state value i_g is attained, which is attributed in electrochemistry (16) to the influence of convection. In order to take convection into account the following model is frequently used (17).

In front of the electrode an undisturbed layer of thickness δ is assumed in which only diffusion occurs. Adjacent to the layer convection is the rate-controlling phenomenon, rapidly transporting away the ions supplied by diffusion. Thus the concentration is kept at the initial value c_b. The boundary conditions for this model are

$$c(0, t) = c_s$$
$$c(\delta, t) = c_b$$
$$c(x, 0) = c_b$$

Here, the simple initial condition $c(x, 0) = c_b$ is used instead of the complex concentration profile caused by stage I and described by Eq. [3]. This is only correct if convection appears a long time after the end of stage I, otherwise the concentration changes caused by stage I have to be considered. The analytical solution of Eq. [1] with the boundary and initial conditions above is

$$c_{III}(x, t) = c_b + \frac{2}{\delta}\sum_{m=1}^{\infty}\frac{(c_s - c_b)}{m\pi}\left[1 - \exp\left(-\frac{t}{\tau_m}\right)\right]\sin\frac{m\pi x}{\delta}$$

where the time constants τ_m are defined as

$$\tau_m = \frac{\delta^2}{m^2\pi^2 D} \quad [11]$$

From $c_{III}(x, t)$ the current density i_{III} can be calculated, and for $t > \tau_1$ all exponential terms except the first one can be neglected. Thus

$$i_{III}(t) = i_g\left[1 + 2\exp\left(-\frac{t}{\tau_1}\right)\right] \quad [12]$$

with the steady-state current density

$$i_g = \frac{nF(c_s - c_b)\sqrt{D}}{\pi\sqrt{\tau_1}} = \frac{2}{\pi\sqrt{\pi\tau_1}}\, i_o\sqrt{t_s} \quad [13]$$

This steady-state current density is approached by the exponential time law in Eq. [12] and corresponds to a linear decrease of concentration from c_s at $x = 0$ to c_b at $x = \delta$.

Experimental Results and Discussion

Pure diffusion (stages I and II).—During stage I the current density i_I depends on the cell voltage and the resistivity of the cell and, therefore, it depends on arbitrary quantities like geometry, polarization of the cathode, etc. The assumption $i_I = i_o =$ const. frequently made in the theoretical treatment before is not fulfilled for an applied constant cell voltage. With the experimental setup of this study i_I decreased by about 10-20% of its initial value from $t = 0$ to $t = t_s$. It will be shown in the Appendix that the Eq. [4], [7], and [8] can be applied to this case if the mean value of i_I is inserted for i_o. Elmore (2) avoided this complication by using galvanostatic conditions during stage I and switching to potentiostatic conditions at the beginning of stage II. In this work constant cell voltage was applied from the beginning of the whole electropolishing process because this is more important for practical applications.

Another basic assumption necessary for the validity of the derived equations is that diffusion controls the rate of the overall cell reaction, especially during stages I and II. This is fulfilled if the anode potential is

high enough to be within the polishing region (12). The potential drop at the anode was measured with a calomel reference electrode. For appropriate constant cell voltages it increased, and the necessary anode potential was reached at stage II. In some cases the anode potential drop was held constant by a potentiostatic device during the experiment. But even then the desired potential was not achieved during stage I, because the current limit of the potentiostat (4A) was reached as short-time measurements with an oscilloscope revealed. With the onset of stage II, however, the anode potential approached the valve set on the potentiostat, which is probably due to the formation of a solid film after stage I and its additional ohmic resistance.

Table I shows results for i_o, t_s and $i_o\sqrt{t_s}$ of stage I for different metals, electrolytes, and temperatures, where t_s is easily determined from the recorder plot. It is evident as a large change of the slope of the current-time curve.

The current density i_o was then defined by the equation

$$i_o t_s = \int_{t=0}^{t_s} i dt$$

corresponding to the arithmetic average during stage I (cf. Appendix). From those values for i_o and t_s the product $i_o\sqrt{t_s}$ was calculated. The current density during stage II was plotted *vs.* $t^{-1/2}$ and straight lines cut the origin in excellent agreement with Eq. [8]. A typical example is shown in Fig. 4. From the slopes of the straight lines which are $2/\pi\, i_o\sqrt{t_s}$, other values of $i_o\sqrt{t_s}$ were obtained and compiled in Table I. They were always in good agreement with the less precise values evaluated from stage I. From the validity of Eq. [8] it can be concluded that during stage II the current density only depends on time and on the product $i_o\sqrt{t_s}$, which is according to Eq. 4 a material constant of the electrolyte. Thus starting with different i_o values during stage I, due to different cell geometry for instance, the same current densities are obtained during stage II. Deviations from the straight lines in Fig. 4 for long times are caused by convection and are described below.

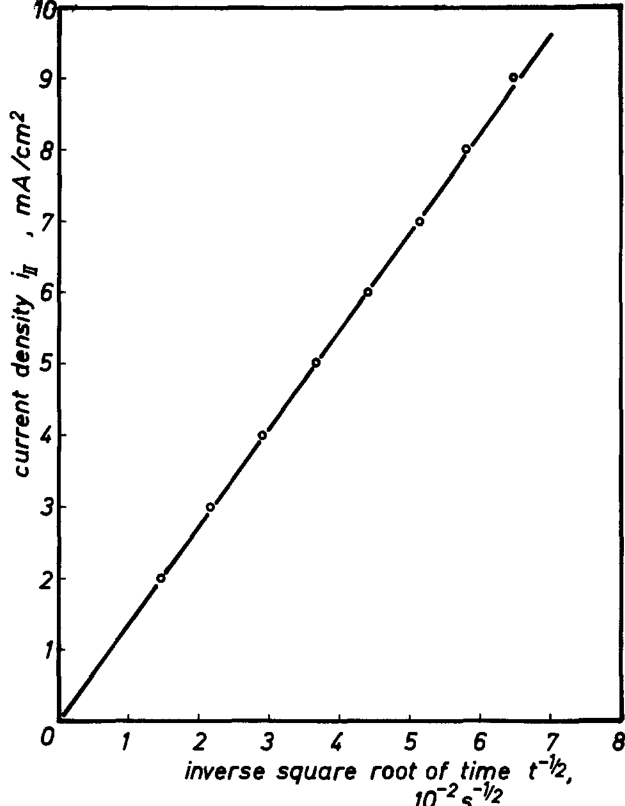

Fig. 4. Current density *vs.* $t^{-1/2}$

The characteristic product $i_o\sqrt{t_s}$ of the electrolyte depends on the temperature and the composition of the electrolyte. For copper/phosphoric acid, the concentration dependence at 20°C is described in the literature (3), where measurements were made only for stage I. A comparison with the results of this study is shown in Fig. 5. The dependence on temperature is discussed in a separate section.

Deviations from the square root time law for stage II also occur at short times, because then Eq. [7] is

the appropriate description of the current-time behavior. Neglecting perturbations by a solid film formation after $t = t_s$, the arccot-function of Eq. [7] was always in good agreement with experimental data, as has been already proved by Elmore (2) for the special system Cu/H_3PO_4. If the cell voltage was chosen to be within the polishing region, no influence of the voltage on the measured product $i_0\sqrt{t_s}$ could be observed. At lower voltages some oscillations of the cell current were seen, which may be due to the formation and solution of solid films (18).

Solid film formation (stage IIa).—Figure 6 shows a typical recorder plot of the current density during stage I and II, which is similar to the schematic plot in Fig. 3. The end of stage I is obvious by a sharp drop of the current. The mathematical solutions ($i = i_0$ for $t < t_s$) and Eq. [7] are presented as dashed lines. Deviations from the anticipated behavior during stage I are shown in the Appendix to be negligible for the solution of stage II. Therefore, solid film formation is assumed to be responsible for the difference between the solid and the dashed line. This difference can be written as

$$i_{II} - i_0 \frac{2}{\pi} \operatorname{arccot} \sqrt{\frac{t}{t_s}}$$

If supersaturation of the electrolyte and subsequent precipitation of a solid film is assumed, Eq. [9] should be valid according to the model used for that process above. In order to check Eq. [9] the difference between the two lines in Fig. 6 was plotted in Fig. 7 *vs.* $t^{-1/2}$. A straight line is obtained, but it does not go through the origin as predicted by Eq. [9]. From that we may conclude that the model is probably too simple to account for all the experimental effects. Nevertheless Eq. [10], derived within this model, was used to calculate the thickness of the solid layer. If both the amount of supersaturation from Eq. [9] and the slope of the straight line in Fig. 7 are evaluated, all parameters of Eq. [9] are known, and Eq. [10] can be solved. Such calculations were carried out for various electropolishing experiments of copper in different phosphoric acids, and they gave always the same order of magnitude for the thickness d. A mean value of d was 3-30 nm corresponding to mole volumes of $V = 10$ cm^3 for CuO and $V = 100$ cm^3 estimated for some copper phosphate. Thicknesses reported in the literature for copper (6-9) are of the same order of magnitude.

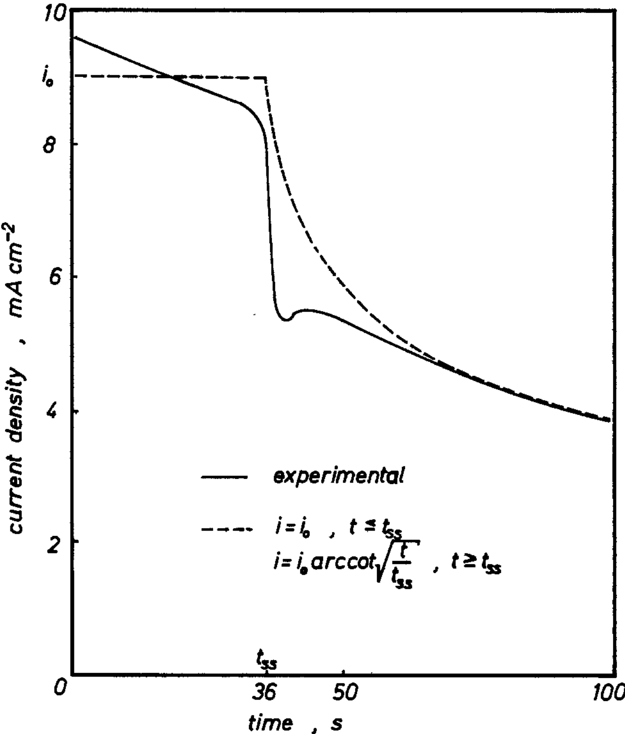

Fig. 6. Recorder plot of the current density for electropolishing of copper in H_3PO_4 (85%)-glycerol (1 + 2). Dashed line calculated from Eq. [7].

In some cases (high temperatures and/or low concentrated phosphoric acids) a salt precipitated onto the electrode forming layers of about 1 mm thickness. The precipitation took place far away from the end of stage I, and it shows that a supersaturated electrolyte is still present in front of the anode. If only a few crystallization nuclei are present on the polishing area and if the crystals grow very slowly, polishing goes on at the uncovered surface regions and is stopped at the covered regions. Therefore, hills are formed at

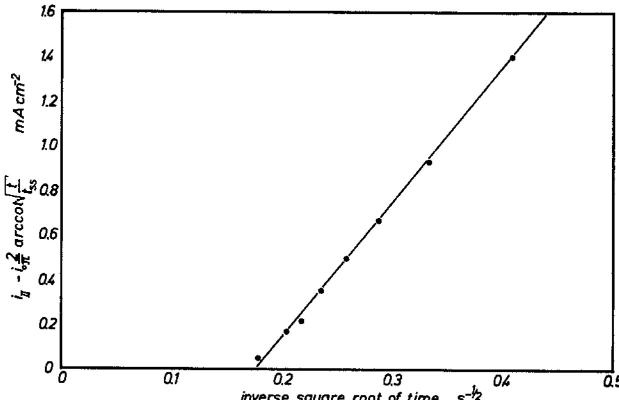

Fig. 7. Results of Fig. 6 plotted as $i_{II} - i_0\, 2/\pi \operatorname{arccot} \sqrt{t/t_{ss}}$ vs. $t^{-1/2}$.

places where the crystallization starts and valleys are left at places where growing crystals from different nuclei meet each other. Thus the history of crystal growth is sometimes beautifully impressed on the sample surface, as can be seen in Fig. 8, where dendritic growth of the precipitated film must have occurred.

Diffusion and convection (stage III).—For the evaluation of stage III the samples were polished until a constant current density i_g was obtained. The logarithm of the current i_{III} minus the steady-state value i_g was then plotted *vs.* time. Always straight lines were obtained which cut the current axis more or less exactly at $2i_g$ as predicted by Eq. [12]. A typical result for iron and acetic-perchloric acid is shown in Fig. 9.

From the slope of the straight lines τ_1 was calculated. Values of i_g and τ_1 determined in this way are compiled in Table I. Usually the reproducibility of such measurements was poor because natural convection is strongly influenced by small temperature fluctuations or small vibrations. However, it could be stated that τ_1 increases with increasing viscosity η of the electrolyte for natural convection.

This corresponds, as predicted by some models (16), to an increase of δ (cf. Eq. [11]) and a decrease of diffusivity D according to the Stokes-Einstein equation

$$D = kT/6\pi\eta r$$

(with k = Boltzmann constant, r = molecule radius).

Fig. 8. Copper surface showing the history of salt precipitation

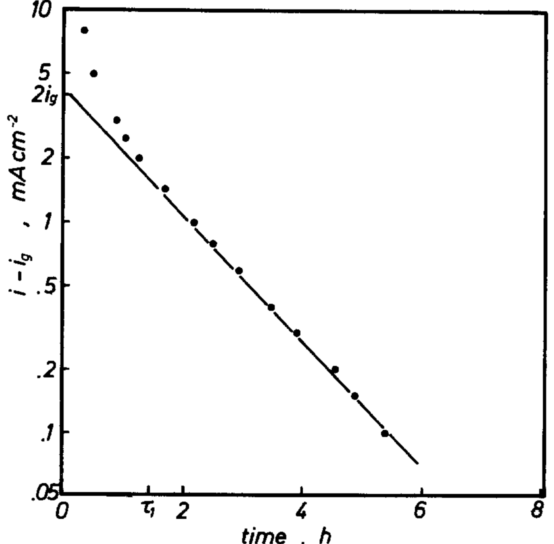

Fig. 9. log(i — i_g) vs. time for stage III (cf. Eq. [12]) [Fe, 30V, 100 volume parts acetic acid (99%) and 5 volume parts perchloric acid (70%)].

If the electrolyte was stirred, τ_1 could be reduced by about four orders of magnitude. In these cases stage I was immediately followed by stage III. Increasing stirring velocity will reduce δ and τ_1 even more, and for $\tau_1 < t_s$ i_g becomes i_o before the saturation concentration c_s is reached.

These are reasons why electropolishing becomes ineffective with increasing stirring velocities (19), since one sufficient condition for polishing is that roughness should be smaller than the thickness of the "viscous layer" (20), which may be defined as the layer of thickness δ. With the results of this study δ can be calculated from τ_1 and D. For copper/phosphoric acid values for D at 20°C are available (21, 22) which give a thickness δ of about 1 mm under natural convection.

From the validity of an exponential time law only it cannot be concluded that the model proposed for stage III is useful because diffusion through a solid film yields the same time dependence. The assumption of diffusion through a liquid layer is justified by the good agreement of experimental and calculated (Eq. [13]) values of i_g over four orders of magnitude as shown in Fig. 10.

Temperature dependence.—The temperature dependence of the product $i_o\sqrt{t_s}$ can be predicted by Eq. [4] from that of the solubility c_s and that of the diffusivity D. For a comparison of the copper/phosphoric acid results it is assumed that according to the Stokes-Einstein equation the inverse square root of viscosity shows the same temperature dependence as the square root of diffusivity. Measured values (23) are shown in Fig. 11 in the form of an Arrhenius plot, and straight lines are best fits to the experimental values according to the equations

$$i_o\sqrt{t_s} = 696 \exp\left(-\frac{2550}{T}\right) A \cdot s^{1/2}$$

$$c_s = 7.6 \exp\left(-\frac{840}{T}\right) \text{mole/liter}$$

$$\eta^{-1/2} = 28 \exp\left(-\frac{1580}{T}\right) \text{cp}^{-1/2}$$

From these relationships an activation energy of 21 kJ/mole for $i_o\sqrt{t_s}$ was evaluated in good agreement with the value of 20 kJ/mole for $c_s\sqrt{D} \propto c_s\sqrt{\eta}$ ($c_b = 0$).

The time constant τ_1, obtained during stage III for copper and 14.8M H_3PO_4 (cf. Table I), decreases

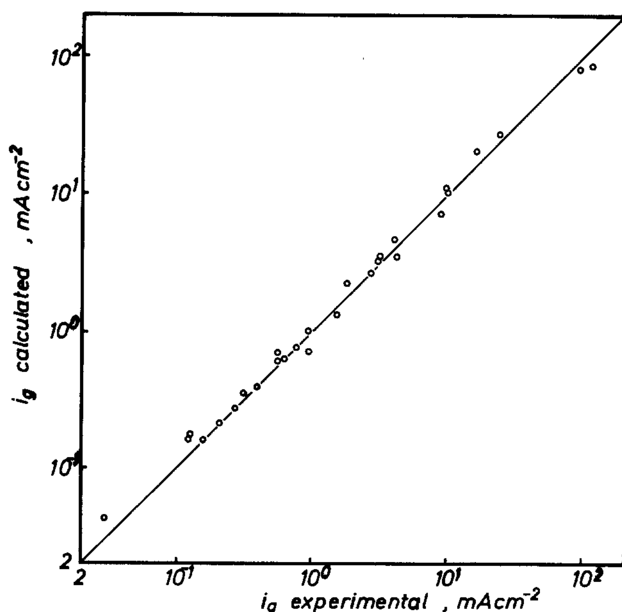

Fig. 10. Comparison of experimental (Table I) and calculated (Eq. [13]) values of the steady-state current density i_g.

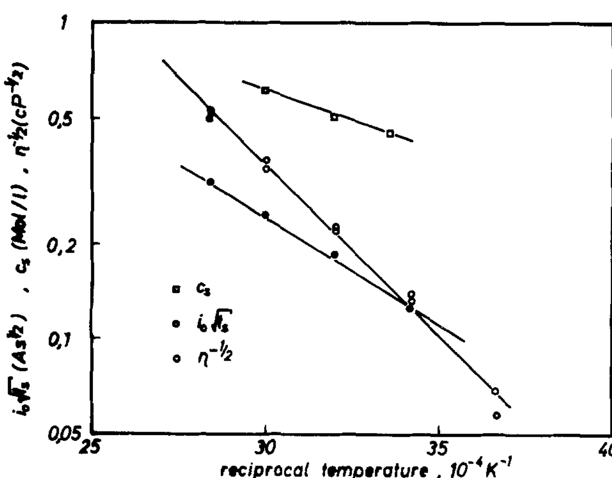

Fig. 11. Arrhenius plot of $i_0\sqrt{t_s}$, solubility c_s, and inverse square root of viscosity for Cu/14.8M H_3PO_4.

strongly with increasing temperature corresponding to an activation energy of about 50 kJ/mole. For a constant thickness δ of the diffusion layer, Eq. [11] predicts 26 kJ/mole since τ_1 is proportional to D^{-1} and, therefore, to η. The disagreement of the activation energies indicates that δ is temperature dependent, decreasing with increasing temperature.

Concluding Remarks

The results of this study show that the current-time behavior of potentiostatic electropolishing can be completely described with solutions of Fick's second law, assuming that diffusion in the electrolyte is the rate-determining step and different boundary conditions cause the occurrence of three stages. Even the formation of a solid film on the anode and its influence on the current can be described by backward diffusion from a supersaturated electrolyte consistent with experimental findings.

In all three stages of electropolishing the same transport mechanism within the diffusion layer is valid, since it depends in any case on the characteristic parameter $i_0\sqrt{t_s}$. The duration of the particular stages cannot be calculated for a certain material system from first principles, because it is influenced for stage I by the geometry and the cathodic process and for stage II and III by natural and forced convection within the electrolyte.

Therefore, the transport of a species through the solid film cannot be rate determining, in contradiction to the concept of Hoar *et al.* (6). Only at the transition from stage I to II, can deviations from the simple diffusional concept be attributed to solid-film formation.

From the relationships derived it is possible to calculate the thickness of the viscous layer. This layer must be thick enough to reach the saturation concentration and to smooth surface roughness.

APPENDIX

Variable Current Density during Stage I

The variable current density is represented by a linear decrease of i from a maximum value i_1 at $t = 0$ to i_2 at $t = t_s$

$$i(t) = i_0 + \frac{\Delta i}{2t_s}(t_s - 2t) \qquad \text{[A-1]}$$

where $i_0 = \frac{1}{2}(i_1 + i_2)$ and $\Delta i = i_2 - i_1$. This is the simplest case for the solution of Eq. [2] and [6], and it is a good description of the experimental behavior of the cell used in this study.

Then the increase of concentration at the anode ($x = 0$) is given by Eq. [2]

$$c_I(0, t) = c_b + \frac{1}{nF\sqrt{\pi D}} \int_{t'=0}^{t} \frac{i(t')}{\sqrt{t - t'}} dt' \qquad \text{[A-2]}$$

The saturation c_s is reached for $t = t_s$, and with Eq. [A-1] the relation between i_0, t_s, and c_s, D corresponding to Eq. [4] is obtained by integrating Eq. [A-2]

$$\left[1 - \frac{\Delta i}{6i_0}\right] i_0\sqrt{t_s} = \frac{nF}{2}(c_s - c_b)\sqrt{\pi D} \qquad \text{[A-3]}$$

The brackets on the left side of Eq. [A-3] contain a correction coefficient in comparison with Eq. [4], which equals approximately one in this study because the condition $\Delta i/i_0 = 0.1$ was fulfilled throughout the experiments.

In order to describe the influence of a variable current density during stage I on stage II, Eq. [6] has to be solved. This has been done by using Eq. [A-1] and [A-3]. The result can be written in the following form

$$i_{II} = \frac{2i_0}{\pi}\left[1 - \frac{\Delta i}{2i_0}\right] \text{arccot}\sqrt{\frac{t}{t_s}} + \frac{2i_0\Delta i}{\pi}\left[\frac{t}{t_s}\,\text{arccot}\sqrt{\frac{t}{t_s}} - \sqrt{\frac{t}{t_s}}\right]$$

For $t >> t_s$ the simple form

$$\frac{i_{II}}{i_0\left[1 - \frac{\Delta i}{2i_0}\right]} = \frac{i_{II}}{i_2} = \frac{2}{\pi}\sqrt{\frac{t_s}{t}}$$

is obtained as an analogy of Eq. [8].

LIST OF SYMBOLS

c	concentration (mole/liter)
c_b	initial and bulk concentration
c_s	saturation concentration
c_{ss}	supersaturation concentration
c_I, c_{II}, c_{III}	concentrations during stages I, II, and III
D	diffusion coefficient (cm^2/sec)
d	thickness of the solid film (nm)
F	Faraday constant
i	current density (A/cm^2)
i_0	constant current density during stage I
i_1, i_2	current densities at the beginning and the end of stage I
i_I, i_{II}, i_{IIa}, i_{III}	current densities during stages I, II, IIa, and III
i_g	steady-state current density during stage III
Δi	current density drop during stage I
k	Boltzmann constant
m	number of order
n	electrochemical valence number
r	molecule radius
T	temperature (K)
t	polishing time (sec)
t_1	time to form the solid film
t_s	time to reach c_s
t_{ss}	time to reach c_{ss}
V	mole volume (cm^3/mole)
x	distance from the anode
δ	thickness of the diffusion layer (mm)
η	viscosity (cp)
τ_m	time constant during stage III, mth order
τ_1	time constant during stage III, first order (sec)

The Soret Effect in Molten Ag-Te Solutions

R. K. Williams

and W. O. Philbrook

Carnegie-Mellon University, Pittsburgh, Pennsylvania 15213

ABSTRACT

The Soret effect was studied in liquid Te solutions containing 17.5 to 69 a/o Ag. The measurements extended from close to the liquidus temperatures to 1100-1200 K. The factors affecting the experimental uncertainty were examined and used to estimate the accuracy of the data. Thermodynamic data for the liquid solutions and solid Ag_2Te were compiled and used to calculate experimental heat of transport, Q^*, values. These Q^* values were found to have strong negative temperature coefficients; this observation can be explained on the basis of a correlation between the Soret segregation and the thermoelectric properties of the melts.

The results presented in this paper were obtained some years ago, during the course of a study of the thermal conductivity of a series of semiconducing Ag-Te melts (1). The Soret effect is important for these measurements because it can enhance natural convection (2) and must be considered in analyzing experimental data. At the time it was apparent that the Soret results showed some unusual features, but we could not proceed with an analysis of the data because the required theoretical background had not been developed and thermodynamic data needed for computation of the heats of transport were not available. Since that time both of these deficiencies have been at least partially eliminated by other workers, and publication of our results now offer some improved experimental evidence of the connection between mass flow and the electronic transport properties.

The principal components of this paper are: (*i*) a brief review of the information available on other properties of the melts; (*ii*) description of the apparatus and an attempt to define the experimental errors; (*iii*) the experimental results; and (*iv*) a discussion which also includes a review of the thermodynamic data for the system.

Dancy (3) published the first systematic study of the electronic transport properties of Ag-Te solutions. The electrical conductivity, σ_e, and Seebeck coefficient, S, data showed semiconducting behavior over a wide range of compositions with high S and low σ_e values associated with compositions near Ag_2Te. The data were interpreted in terms of degenerate semiconduction and the possibility that a bandgap could exist at some composition near Ag_2Te. The thermal conductivity study (1), showed that the conductivities are low and that the relatively weak electronic contribution is roughly consistent with degenerate behavior. Glazov *et al.* (4) showed that the viscosity exhibits a sharp maximum at Ag_2Te and suggested that the compound persists as a stable entity into the liquid phase. Their work also included σ_e values, which differ from those of Dancy for Ag-rich compositions. The Russian data, if correct, would indicate that the thermal conductivity data for Ag rich melts (1) can be explained by the degenerate semiconductor model. Wobst (5) showed that the curve of surface energy *vs.* composition exhibits an inflection near the stoichiometric ratio whereas the density does not show any unusual behavior. Other related, though not directly relevant, studies include the study of electromigration in Cu_2Te by Glazov and Burkhanov (6) and a study of the Soret effect in Te-Se solutions (7).

Key words: liquid, thermoelectricity, mass transport, activity coefficient, Soret effect.

Experimental Method

To study the Soret effect, a vertical column of liquid was held in a known, linear temperature gradient until the steady-state composition distribution had been attained. The liquid was then rapidly frozen, and the Ag content of samples taken along the lengths of the ingots was determined. The experimental observations pro-

vide the basic relationship between the increments of temperature, ΔT, and composition, ΔX. With the small (15-30 deg/cm) temperature gradients used, the composition, X, *vs.* distance, Z, plots could adequately be described by straight lines, so the T-Z and X-Z data were combined to yield the two increments, and experimental Soret coefficients, σ, were calculated from the defining equation (8)

$$\sigma \equiv \frac{\Delta X_{Ag}}{X_{Ag} X_{Te} \Delta T} \quad [1]$$

X_i = atom fraction of component i

The samples were prepared by melting 99.999 purity Ag shot with 99.99 purity Te crystals under argon in a high purity graphite crucible. The resulting ingots were crushed and cast in fused-silica tubes, producing the thermal diffusion samples which were 6 mm diam cylinders and about 38 mm long. Fused-silica tubing was also used for the thermotransport runs because it is inert to the melts. The sample capsules were sealed off under vacuum and attached to a long silica tube for positioning in the furnace. The compositions studied are described in Table I.

The approximately (±5%) linear temperature gradients were produced in a vertical furnace which had two sets of windings. Power to the outer, uniform windings was automatically controlled, and a smaller amount of power was also supplied to an inner, nonuniform winding from a manually adjusted Variac. All of the samples were positioned so that the top of the liquid column would be hotter, thus minimizing convective remixing.

The temperature differences were obtained from two uncalibrated, 0.13 mm diam Chromel-P *vs.* Alumel thermocouples which were attached to the outside of the sample capsules. The corrosive nature of the melts precluded placing the thermoelements in direct contact with the liquid, but one test with thermocouples inside and outside a capsule showed that this procedure did not introduce a serious error. This was the expected result because the thermal conductivities of the melts are not much different from fused silica (1).

The experiments were begun by positioning the sample capsules in the uniform-temperature zone of the furnace to homogenize the melts. During this 1 hr period the samples were 50-200 K hotter than the average temperature during the run and were also agitated to promote mixing and remove bubbles. Table II shows data for three samples which were water-quenched either after the homogenization treatment or after a short time in the temperature gradient. These results indicate that the homogenization treatment was effective.

Homogenized samples were then lowered into the desired position in the temperature gradient and held there until the steady-state concentration gradients had been established. Some tests with the 32 atomic percent (a/o) Ag melt at 740 K showed that the σ values did not change after 70-80 hr, and 120-hr runs were used at lower temperatures. The experiments

were terminated by carefully lifting the samples from the furnace and quenching them into an ice-water bath. Water and ice-brine quenches were also used, but the results did not show any sensitivity to quenching rate.

After quenching, the thermocouple positions were rechecked, and the samples were removed from the fused silica capsules, identified, and measured. Each sample was then sawed into five equal segments, and the sections were analyzed for Ag by a standard gravimetric technique. Values of the quantity $\Delta X_{Ag}/\Delta Z$ were then computed from a linear least square analysis and combined with the measured temperature gradient to calculate σ. Two extreme examples of the experimental concentration profiles are shown in Fig. 1.

Experimental Data

For three of the melts (Table I) only one or two samples were run, and these data are shown in Table III. Data for the other four compositions are shown in Fig. 2. The data were not corrected for the effects of differential thermal expansion and the volumetric change on fusion. Presumably (5) this correction would lower all of the σ values by about 5%. For reasons explained in the following section, the overall trend lines for the data shown in Fig. 2 are drawn to favor the higher data points. The general form of the composition dependence is a gradual increase in slope with increasing Ag content, but the results for the 60 a/o Ag melt cannot be distinguished from those for the 48 a/o

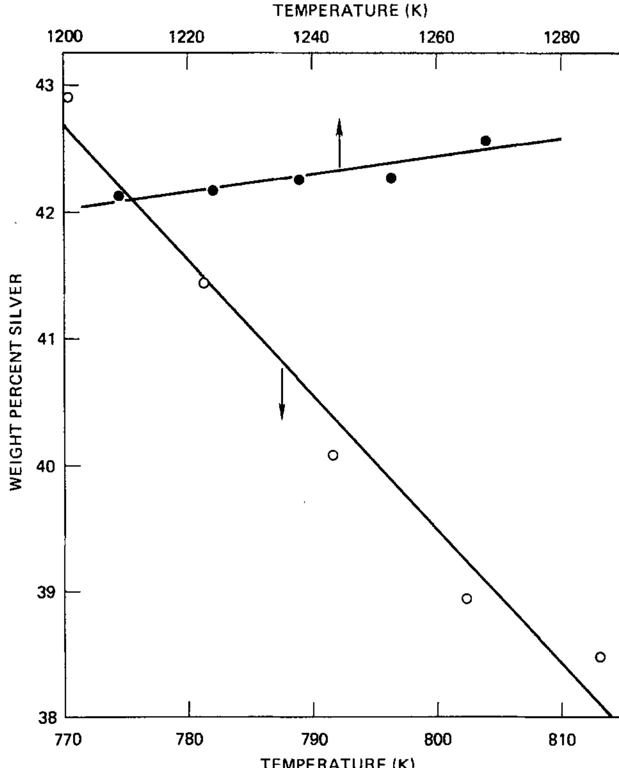

Fig. 1. Experimental composition-temperature curves for the 48 a/o Ag melt at two different average temperatures.

Table III. Experimental Soret coefficients for three melts

	1239	-0.14×10^{-3}	

* Defined by Eq. [1].

Ag composition. It should be noted that the σ data do not tend toward zero at infinite temperature.

Experimental Uncertainties

A lower bound for the error can always be obtained from the individual uncertainty limits for the various experimentally determined quantities. This sort of analysis is summarized in Table IV. This table is, in part, based on the assumptions that σ varies at T^{-2} and X_{Ag} in the composition and temperature ranges of interest. Uncertainties calculated in this way are shown with some of the data points in Fig. 3. These estimates should be compared to the σ variation, and this indicates that the σ variation is not obscured by these uncertainties.

A realistic assessment of the systematic experimental errors is generally much more difficult. In the present case, four major possibilities have been considered: (*i*) the times chosen might have been insufficient for the attainment of a true steady state, (*ii*) the system might be inherently subject to convective remixing errors, (*iii*) some runs might have been spoiled through mechanical agitation during the final quench, and (*iv*) the higher-temperature data might have been more affected by remixing during quenching.

Convective remixing occurs in a Soret experiment when the column is heated from the bottom and the Rayleigh number exceeds some critical value (9). When the column is heated from the top, it is inherently stable unless the Soret segregation causes the heavier component to migrate to the hot end, overcoming the density gradient caused by differential thermal expansion. In these experiments the denser component, Ag, migrates to the cold end and the test columns should always have fallen in Velarde and Schechter's (9) inherently stable quadrant II. The

$X_{Ag}\,X_{Te}$	6.4	6.4	Includes sample-to-sample composition variation
Total	~30	~50	

normal Rayleigh numbers estimated for typical conditions varied from 1×10^7 for the 60 a/o Ag melt to 4×10^6 for the 24 a/o melt.

Horizontal temperature gradients can also produce convective remixing, but experimental data indicate that this is not as serious a problem in a Soret experiment as it is in an isothermal mass diffusion experiment. Agar and Turner (10) who used a 10 mm diam Soret cell showed that horizontal temperature gradients influenced their results when the combined (thermal plus Soret density gradients) yielded Rayleigh numbers less than about 10^6. The minimum Rayleigh number for our experiments was 4×10^6 and this takes no credit for the large enhancement from the Soret effect. The data of Winter and Drickamer (11) on Pb-Sn, Cd-Sn, and Zn-Sn solutions also support this conclusion. These authors, who used 3 mm diam capillaries, found that their results for the Pb-Sn and Cd-Sn systems were in good agreement with earlier data obtained with 10 mm diam columns. Convective errors became significant for ~2% density differences (Zn-Sn) but the density difference for Ag-Te is comparable to that of Pb-Sn.

It has been shown that convection reduces the steady-state segregation and that σ values calculated from short-time data tend to exceed the apparent steady-state values (12). The usual kinetic equation, which should fit data for times greater than about 0.2 θ, is (12)

$$\frac{\sigma_t}{\sigma_\infty} = 1 - \frac{8}{\pi^2} \exp\left(-\frac{t}{\theta}\right) \quad [2]$$

where σ_t = apparent value of σ calculated from data, σ_∞ = steady-state value, t = time, $\theta = a^2/\pi^2 D_{12}$, a = cell height, and D_{12} = effective diffusion coefficient for the solution. Figure 3 shows that the test data for the 32.4 a/o Ag melt taken at about 740 K fit the equation reasonably well. The diffusivity derived from the data, ~1×10^{-5} cm²/sec, also seems reasonable, sug-

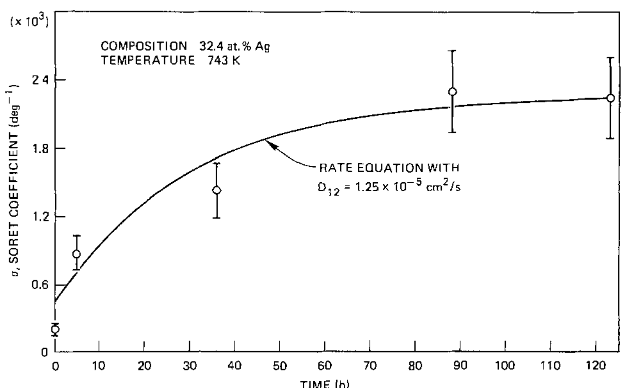

Fig. 3. Variation of the apparent Soret coefficient at the 32 a/o Ag melt with time.

gesting that the times chosen were sufficient for attaining steady-state conditions.

Data from two runs on the 60 a/o Ag composition at 1012 K also support this point of view. The σ values for 6.3 and 88 hr indicate a θ of about 12 hr and a diffusivity of 3.5×10^{-5} cm^2/sec. This is similar to the D derived by Glazov and Burkhanov for molten Cu_2Te (6). Other data (Fig. 2) on the 32 a/o Ag composition indicate that the two "steady-state" σ values fall below the general experimental trend, possibly by as much as 30%. Also the two points at 5 and 36 hr seem to show that θ increases with time. This suggests that convection could have influenced some of the experiments.

Inadvertent mechanical agitation of the sample capsules during the final quench could lead to occasional low σ values; this probably happened 10-20% of the time. This intermittent difficulty was compensated by weighing the higher σ values more heavily than the lower ones. A more elaborate experimental apparatus would also have been useful in this regard.

A final point is that data taken at high temperatures may be more subject to convective remixing than those from lower temperatures. At higher temperatures, the thermal diffusivity increases, but this is compensated by the viscosity decrease and the net effect should be to produce a Rayleigh number which does not vary strongly with temperature. On this basis, the test samples should have remained in Velarde and Schechter's (9) stable second quadrant, although moving closer to the unstable third quadrant because the stabilizing influence of the Soret effect is diminished at elevated temperatures. The much higher thermal diffusivity (1, 3) of the low Ag melts would lower their Rayleigh numbers relative to the compositions near Ag_2Te, and thus the low-Ag melts should be less stable. The viscosity variation, which should be smaller than the diffusivity change, is unknown.

Discussion

In the first part of this section, thermodynamic data for the system are critically reviewed and used to derive $d \ln \gamma_{Ag}/d \ln X_{Ag}$ values for calculating the experimental heat of transport, Q_{Ag}^* (8)

$$Q_{Ag}^* = -RT^2 \left(1 + \frac{\partial \ln \gamma_{Ag}}{\partial \ln X_{Ag}} \right) \sigma \qquad [3]$$

A fairly extensive examination was required because the two sets of experimental activity data (13, 14) are in conflict. In the second part of the section, the Q_{Ag}^* values are compared with some theoretical formulas to see how well theory can account for the observed temperature and composition variations.

Thermodynamic factor.—Both Zaleska (13) and Predel and Piehl (14) have reported activity data for liquid Ag-Te solutions. Zaleska (13) obtained silver activities from emf measurements on concentration cells, while Predel and Piehl (14) made measurements of the Te pressure over the solutions and obtained Ag activities from a Gibbs-Duhem integration. The agreement is poor for silver concentrations greater than about 10 a/o, and for solutions containing more than about 35 a/o Ag the two sets of data do not even give the same sign for the deviations from Raoult's law. Calorimetric data for the system support the Zaleska (13) values.

Thermodynamic data for the compound Ag_2Te cover a wide temperature range, appear to be internally consistent, and can be used as a valuable check on the measurements for liquid solutions of other compositions. The specific heat data (15-17) cover the range 16-1500 K, and the absolute entropy, S_{298}, given by Mills and Richardson (16) was used in the calculations. The high temperature specific heat data of Blachnik and Gunia (17), which are in good agreement with the Mills and Richardson (16) results at lower temperatures, were employed in calculating H_T-H_{298} and S_T-S_{298}. These calculations also require values for the two-solid-state enthalpy increments for the ($l \rightarrow i$) and ($i \rightarrow h$) phase transitions (18) and the enthalpy of fusion. Three values for the ($l \rightarrow i$) ΔH are available (16-18) and an average, 2.96 kJ/g atom of alloy, was used in the calculation. Castanet and Bergman (19) have reported ΔH for the ($i \rightarrow h$) phase transition and there are two experimental values for the enthalpy of fusion (17, 19). The average of these two values, 3.41 kJ/g atom of alloy, was used in the calculations. Several direct measurements of the heat of formation of the low (20), intermediate (21, 22), and high (19) temperature forms of Ag_2Te have been reported and two values (14, 20) have been published for the enthalpy of formation of the Ag_2Te liquid solution. Kiukkola and Wagner (23) also obtained values for ΔG_f° at 523 and 573 K, and Knudsen cell studies of the vaporization of the solid compound (24, 25) can be extrapolated to make an estimate of the tellurium activity at the melting point.

One convenient way to test the consistency of these results is to use the C_p-T data in combination with the enthalpies of the transitions to convert all of the experimental heats of formation to values corresponding to 1g atomic weight of the low temperature phase. Values for the two elements were taken from the literature (26). Excluding the Predel and Piehl value, and including the two values derived from ΔS° and ΔG° (23), the ΔH_{298} values calculated for the low temperature form range from -12.39 (22) to -11.28 kJ/g atom (21) and the experimental value (20) is -12.01 kJ/g atom. The Predel and Piehl (14) value is about -15.9 kJ/g atom.

The overall compilation of data for Ag_2Te show at least two interesting features. First, the specific heat data for the liquid compound (17), when combined with literature data for the liquid elements (26), indicate that the temperature coefficient of the heat of formation should be only about 1.5%/100°. The results of Castanet and Bergman (19) showed that ΔH is approximately independent of temperature. Second, the absolute S values for Ag, Te, and Ag_2Te indicate that ΔS for formation of the liquid solution, 1.25 J/g atom deg, is much less than the ideal value. This result seems to support the idea (19) that this solution is not a random one. The calorimetric ΔS falls along the trend of the Zaleska (13) values and is considerably greater than the ΔS given by Predel and Piehl (14), -6.6 j/g atom deg.

The calorimetric data for Ag_2Te yield a value for ΔG for formation of the liquid solution from the two liquid components, and the magnitude of this ΔG is about a factor of 2 larger than ΔG calculated from a_{Te} and a_{Ag} as given by Predel and Piehl (14). The Zaleska (13) data do not extend to the Ag_2Te composition. The problem with the activity data (14) seems to arise mostly because there is only one a_{Te} data point for tellurium contents less than 40 a/o, and it appears to be too high. This conclusion is supported by Knudsen cell data (24, 25) which indicate $10^{-3} < a_{Te} < 10^{-2}$ at the melting point of Ag_2Te, and by making a rough estimate of a_{Te} at the miscibility gap. For the assumptions that in silver rich, metallic solutions a_{Ag} follows Raoult's law and a_{Te} obeys Henry's law, the entropy of mixing is ideal, and using the experimental integral heat of mixing (19), one obtains $a_{Te} \sim 4 \times 10^{-3}$ for solutions containing between 9 and 30 a/o Te. The assumptions employed in this estimate are obviously not correct, but the intent is only to demonstrate that a_{Te} must be very low in Ag-rich melts. The Predel and Piehl (14) data indicate $a_{Te} \approx 0.2$ for a 40 a/o solution, and if these two results are even approximately correct, the activities of both components must vary quite rapidly near the Ag_2Te composition. Blachnik and Bolte (27) have noted that this is the case in some selenide systems. This analysis implies that the thermodynamic factor (Eq. [3]) is very

large near the Ag_2Te composition, and Q^* values derived for the two silver-rich melts (Table III) are thus subject to large uncertainties.

The evidence showing that the a_{Ag} values of Predel and Piehl (14) are probably not correct does not establish the validity of the Zaleska (13) values, but further examination of the data for solutions in the 0-60 a/o Ag range at least shows that the results are internally consistent. This test involved using the Predel and Piehl (14) a_{Te} data with the experimental heats of mixing (13, 19, 28) and ΔS values to calculate a_{Ag}. The tellurium activity data are consistent with values calculated from the phase diagram and should not vary much with temperature (14, 28, 29). The enthalpy data are principally due to Castanet *et al.* (19, 28) but Maekawa (30) and Zaleska (13) have reported results which support Castanet *et al.* The Predel and Piehl (14) enthalpy data, which appear to be too large at the Ag_2Te composition, were not used. The ΔS values were chosen by plotting (*i*) the ΔS values tabulated by Zaleska (13), (*ii*) the ΔS computed from $\bar{S}_{Ag}$ (13) and $\bar{S}_{Te}$ (28), and (*iii*) the ΔS values computed from specific heat data for Ag, Te, and Ag_2Te. This produced a curve which is nearly ideal for solutions containing less than 45 a/o Ag. This experimental line then falls well below the ideal values for more silver-rich compositions. The Predel and Piehl (14) ΔS values show this same general variation, but the negative departures from ideal mixing are much larger.

The two sets of activity coefficient values are compared in Fig. 4. The heat of mixing data were used to adjust the Zaleska (13) values to 1281 K. The agreement is excellent, and both sets of values were used in defining the γ_{Ag}-X_{Ag} variation. The deviative (Eq. [3]) is small (~ -0.2) for the 18, 24, and 32 a/o Ag melts and increases rapidly ($+0.3$ for 48 a/o and $+0.9$ for 60 a/o Ag) at higher silver contents. It should be noted (Fig. 4) that the activity data imply that Henry's law is only valid for very low silver contents. Also the increase which begins at about 45 a/o Ag must lead to a very rapid activity variation in the vicinity of the Ag_2Te composition.

The effects of composition and temperature on the heat of transport.—The data presented here represent a survey of the Soret effect in Ag-Te solutions over an unusually large temperature range. As shown in Fig. 5, Q^* tends to increase with the Ag content of the melts, and the temperature dependence is strong. Measurements on the 26-60 a/o Ag melts show that Q_{exp}^* decreases at higher temperatures and approaches zero at about 0.8 to 0.9 of the normal boiling points. One measurement (Fig. 1) also suggests that Q^* becomes negative at still higher temperatures.

These variations can be discussed by using the theoretical framework presented by Huntington (31). In general, the heat of transport should contain three terms, two of which can be temperature dependent

$$Q_{exp}^* = Q_{int}^* + Q_{Th}^* + Q_{el}^* \qquad [4]$$

where Q_{int}^* = intrinsic, temperature independent term which would be present in all liquids, Q_{Th}^* = contribution from the internal Thompson field to the motion of a charged species, and Q_{el}^* = component due to atom-charge carrier interactions. Detailed calculations for liquid metals (8) show that the electronic and intrinsic terms are usually both significant while the Thomson contribution can be neglected. This is not necessarily the case for semiconducting solutions. The possible magnitudes of the three terms for the semiconducting Ag-Te melts are discussed in the following paragraphs.

Bhat and Swalin (32) have discussed application of various models for calculating Q_{int}^* for liquid metal solutions and concluded that the theory developed for dense gases is more successful than the Wirtz-Brinkman model. There does not seem to be any unique way to making this test in the present case, since diffusion and viscosity data are not available and the dense gas theory should not apply when the molar volumes are greatly different. An earlier theory (11) based on differences in the heats of vaporization does give the sign of the heat of transport, but the calculated Q_{int}^* values are too large. This theory was also modified to include the activation energies, $\Delta U^{\pm}$, for diffusion or viscous flow (11)

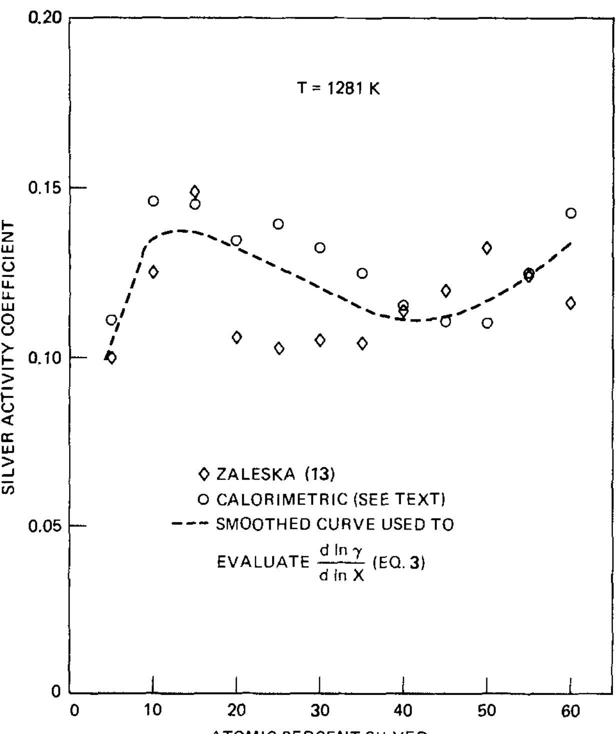

Fig. 4. Silver activity coefficients for Ag-Te solutions at 1281 K. The dotted line was used to evaluate the thermodynamic correction factor (Eq. [3]).

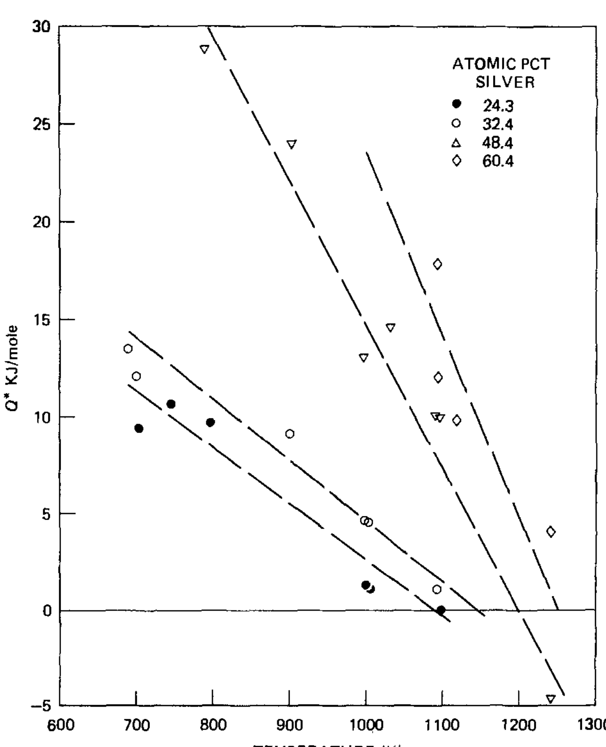

Fig. 5. Temperature dependence of the heats of transfer of four Ag-Te solutions.

$$Q_{int}^* = \frac{M_{Ag}\overline{V}_{Te} + M_{Te}\overline{V}_{Ag}}{2\overline{M}}\left(\frac{\Delta U_{Ag}^{\pm}}{\overline{V}_{Ag}} - \frac{\Delta U_{Te}^{\pm}}{\overline{V}_{Te}}\right) \quad [5]$$

where $\overline{V}_i$ = partial molar volume of component i and M_i = mass of component i. This formula, which is fairly successful for liquid metals, probably can explain the composition dependence of Q_{int}, because the activation energy difference term should be different for Ag-rich and Te-rich solutions. The general trend of this variation is similar to the liquidus curve for the system.

The Thomson field contribution is given by (31)

$$Q_{Th}^* = eZ_{es}\zeta_T T \quad [6]$$

where e is the magnitude of the electronic charge, ζ_T the Thomson coefficient, and Z_{es} is the effective charge number of the moving ion seen by the electrostatic field. The Seebeck coefficients, S, data of Dancy (3) can be described by equations of the form

$$S = S_o - \Lambda T \quad [7]$$

so that with the Kelvin relationship Eq. [12] becomes

$$Q_{Th} = -9.6 \times 10^4 Z_{es}\Lambda T^2 \text{ J/g atom} \quad [6a]$$

The chief trouble is in deciding what value to assign to Z_{es}. In a metallic solution, it ought to be positive and Huntington (31) has argued that it should be taken as the full ion charge. This is not so clearly the case for Ag-Te solutions, since one could imagine negatively charged Te ions playing a role. At any rate the potential importance of this term can be seen by assuming that Z_{es} is unity. For the eutectic (33% Ag) melt Λ is about 7×10^{-8} μV/deg^2, and this leads to a Q_{Th}^* of about -6.7 kJ/mole at 1000 K. The experimental value at this temperature is about $+4.8$ kJ/mole deg, so this contribution is large enough to explain the observed negative temperature coefficient.

It is also possible that the third component, Q_{el}^*, could be responsible for the temperature dependence of Q_{exp}^*. For liquid alkali and noble metal solutions, Murarka *et al.* (8) have shown that Q_{el}^* is negative and proportional to temperature, and that the average of the temperature coefficients calculated for seven cases is about -8 J/g atom deg. This kind of calculation would not apply to an Ag-Te solution, but some general guidance can be gained by referring to the two-band treatment which Huntington applied to Pt (31). The analysis shows that Q_{el}^* is larger than for single-band metals and that the coefficient is proportional to, among other factors, the Seebeck coefficient. The sign of the contribution is governed by the Seebeck coefficient and the ratio of elective masses of holes and electrons, and turns out to be positive for Pt. Then, since the transport property data indicate that the Ag-Te melts are hole conductors, Q_{el} could have the sign and magnitude required to explain the experimentally observed negative temperature coefficients.

To examine these possibilities in more detail, Q_{Th} was computed by assuming that Z_{es} in Eq. [6a] was unity, and the remaining part of the heat of transport was plotted as a function of temperature. The quantities ($Q_{int}^* + Q_{el}^*$) obtained in this fashion can be adequately described by a linear temperature variation and the calculation shows that Q_{Th}^* probably is not responsible for all of the temperature dependence. The linear temperature coefficients obtained in this fashion are larger than those calculated by Murarka *et al.* (8) and increase with the Seebeck coefficients of the melts. This is roughly what was expected from the theory.

The principal conclusion drawn from this work is, therefore, that there is a correlation between the temperature dependence of the Soret segregation and the electronic transport properties of the melts. This correlation involves one or both of the thermoelectric properties, S and ζ_T, and the dominant effect could be experimentally identified if the precision of the results could be improved.

ABSTRACT

The photoelectrochemical properties of the polycrystalline TiO_2 doped with 3d transition metals (Cr, Mn, V, Cu, Ni, and Zn) have been investigated. The electrodes doped with Cr, Mn, V, and Cu show the visible light photoresponses. It is concluded that the visible light photoresponse is based on the impurity band formed near the π^* conduction band of the TiO_2 in energy position, in analogy with the Co-doped TiO_2 electrode reported previously. The cathodic photocurrent of the O_2 reduction was also observed for the doped and undoped electrodes. From the good agreement of the spectral dependences of the anodic and cathodic photocurrents, it is judged that both type photocurrents are brought about by the same photoexcitation process. The observed large cathodic photocurrents for the electrodes that give the visible light photoresponse are attributable to the d-orbitals of the doped metal as the active site, by which the impurity band is formed in the bulk. A mechanism for the photosynthesis is also suggested from the simultaneous appearance of the photo-oxidation and photoreduction currents on an electrode.

TiO_2 is suitable for the anode material of the photoelectrolysis of water from the point of view of the stability in aqueous solution, but its large bandgap brings about only small efficiency in using the solar spectra. Recently, it has been reported that the TiO_2 electrode is improved by doping with various elements. Cr and Mn-doped TiO_2 single crystals bring about the visible light response, and the u.v. response increases by doping with Al(1, 2). Polycrystalline TiO_2 doped with Al and Be show the interesting property that the quantum efficiencies to the u.v. light increase like the TiO_2 single crystal electrode doped with Al(3, 4). Moreover, there is a report that Ni, Cr, Cd, and Zn-doped polycrystalline TiO_2 electrodes give the visible light response (5).

In our laboratory, it is found that the polycrystalline TiO_2 prepared at high temperature and the Co-doped polycrystalline TiO_2 show the visible light response (6). The polycrystalline-type electrode is more suitable for the photoanode than the single crystal in preparation cost and in ease of the preparation process. In the present paper, the photoelectrochemical properties of the polycrystalline TiO_2 doped with 3d transition metals are studied. In our results, the visible light response was observed for the Cr, Mn, V, and Cu-doped electrodes, but not for the Zn-doped electrode, and was very small for the Ni-doped electrode. Moreover, the large cathodic photocurrent was also observed for some electrodes. A mechanism for these phenomena is proposed and qualitatively confirmed in the present paper. From the simultaneous appearance of the anodic and cathodic photocurrents, a possible mechanism for the photosynthesis is also suggested.

Experimental

All the electrodes are prepared by the thermal decomposition of the aqueous solutions of 3d metal salts on the Ti metal substrate (99.6%). The nitrates were used for Mn, Cu, and Zn, and the oxide (CrO_3) for Cr. $VOCl_2$ dissolved in the diluted HNO_3 was used for V. The preparation method is the same as that described in a previous paper (6), but H_2O_2 was not used in the present study. The samples were prepared at either 500° or 600°C as the final heat-treatment. No oxide other than TiO_2 was observed in x-ray analysis for the electrodes with the coating concentration less than about 2.5×10^{-7} mole/cm^2. As for the electrodes used in this study, almost all of the metals in the coating metal salts will be doped in the formed TiO_2 layer. All the electrodes are denoted as TiO_2/M in this paper.

The electrolyte was pre-electrolyzed 1M KOH. An Hg/HgO electrode was used as the reference electrode and electrode potentials cited in this paper are referred to this electrode. The spectral dependence of the cathodic photocurrent was measured in the O_2 saturated electrolyte, and that of the anodic photocurrent was done in air. Both photoresponses of the anodic and cathodic currents were fast (<0.3 sec) for all the electrodes used in the present study, analogous to the Co-doped TiO_2 electrode (6). The other measurements were conducted in the same way as in the previous paper (6). The irradiation intensity is not corrected. However, a sequence of measurements is done with the same experimental setup, so that the irradiation intensity has been kept constant during the measurements.

Results

TiO_2/Cr, TiO_2/Mn, TiO_2/V, and TiO_2/Cu electrodes.—The potential sweep voltammograms for the TiO_2/Cr(2.5×10^{-9} mole/cm^2) and TiO_2/Mn(2.5×10^{-8} mole/cm^2) electrodes are shown in Fig. 1 and 3, respectively. The spectral dependences of the photocurrents for the TiO_2/Cr and TiO_2/Mn electrodes are shown in Fig. 2 and 4, respectively. The photocurrents were determined by the differences between the stable illumination current and the dark current as described in the previous paper (6). The u.v. photocurrents for both electrodes, as the figures show, are based on the original photoexcitation process of the TiO_2. The observed large photocurrents due to the visible light for

the TiO_2/Cr and TiO_2/Mn electrodes are attributable to the Cr and Mn impurity bands formed in the TiO_2 lattice as described in a later section. Relatively large cathodic photocurrents were also observed for both types of electrodes in the O_2 saturated 1M KOH, but not in the Ar saturated one. The cathodic photocurrents, therefore, are based on the O_2 reduction. This observed cathodic photocurrent is not attributable to the increase of the photoconductivity as described in a later section. Good agreement of the spectral dependences of the anodic and cathodic photocurrents show that photoelectrochemically reactive electrons and holes are produced by the same photoexcitation process.

The spectral dependences of the photocurrents for the TiO_2/V and TiO_2/Cu electrodes are shown in Fig. 5 and 6, respectively. It is concluded that the photo-

currents due to the visible light for the TiO_2/V and TiO_2/Cu electrodes are based on the V and Cu impurities doped in the TiO_2 lattice, respectively. The TiO_2/V electrode prepared at 500°C showed no visible light photoresponse. The u.v. light responses for the both electrodes are due to the fact that the photoexcitation process in the original bandgap of the TiO_2 is the same as for the TiO_2/Cr and TiO_2/Mn electrodes.

TiO_2/Ni, TiO_2/Zn, and TiO_2/Fe electrodes.—The TiO_2/Ni electrode shows the very small response to the visible light near the original TiO_2 bandgap energy as well as the variation in the u.v. spectral dependence of the photocurrent, but the TiO_2/Zn electrode shows no visible light response. These results are different from those reported by Monnier *et al.* (5). These differences are probably due to the preparation method of the electrode, but this is not clear.

The visible light response was not observed for the TiO_2/Fe electrode with 2.5×10^{-8} Fe mole/cm², but was observed for the electrode with 2.5×10^{-6} Fe mole/cm² as shown in Fig. 7. It is judged that the visible light photocurrents of the latter electrode are not due to the Fe impurities doped in the TiO_2 lattice, but are due to the Fe_2O_3 formed on the top of the surface, since the spectral dependences of the photocurrents agree with that of the Fe_2O_3 electrode reported earlier (7-11). The good agreement of the spectral dependences of the anodic and cathodic photocurrents shows that the photoproduced electron in the conduction band and hole in the valence band of the Fe_2O_3 react with the solution species under the cathodic and the anodic biases, respectively.

Discussion

The large cathodic photocurrent is not attributable to the increase of the conductivity by the photon. This is confirmed by the following result. The TiO_2 (single crystal)/Cr electrode as described in a later section, whose surface layer is only doped, also gives the large cathodic photocurrent as Fig. 11 shows, while non-doped TiO_2 (single crystal) gives no cathodic photocurrent. If the observed cathodic photocurrent is based on the photoconductivity, this doped electrode will not

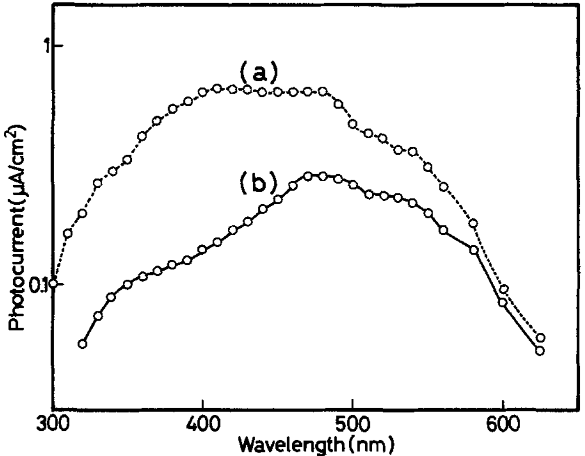

Fig. 7. Spectral dependences of the photocurrents at the TiO_2/Fe (2.5×10^{-6} mole/cm²) electrodes prepared at 600°C. The cathodic and anodic photocurrents were measured at −0.5 and 0V, respectively. (a) Cathodic photocurrent, (b) anodic photocurrent.

give the cathodic photocurrent, because the impurity band or sites formed only in the surface layer do not affect the photoconductivity.

The electrodes used in this study will contain the surface states and the recombination centers as well as the formed impurity band. The visible light response of the Cr-doped electrode used in this study agrees with that reported by Ghosh *et al.* (1), in which Cr is doped in the bulk of the TiO_2 single crystal. This agreement shows that the visible light responses in the doped electrodes used in this study also are mainly based on the impurity levels in the TiO_2 bulk, but not the surface states. These formed impurity levels are broad in their energy positions as the spectral dependences of the photocurrents show, therefore they seem to form a band, *i.e.*, an impurity band. The surface states will be mainly formed on the surface by these impurity level edges. These will act in the electron transfer from the electrode surface to the solution species. On the other hand, many recombination centers also will be formed by the doping, but will be situated in the deep levels and not participate in the formation of the impurity band. These recombination centers will bring about the relatively small photocurrents at the doped electrodes used in this study.

Table I shows the onset potentials of the anodic photocurrents in air for the various electrodes used in the present study. The onset potentials of the doped electrodes (except for the TiO_2/Fe and TiO_2/Mn electrodes) are almost the same as that of the undoped TiO_2 electrode, as the table shows. Therefore, the electrodes doped with Cr, V, and Cu are favorable for the anode in the photoelectrolysis of water by sunlight from the viewpoint of the high visible light response, but some improvements are necessary in order to obtain the large photocurrent. As stated above, the visible light response is based on the formed impurity band throughout the TiO_2 layer, which is situated near the

Table I. Onset potential of the anodic photocurrent

Sample		Preparation temp.	Onset potential
TiO_2		500°, 600°C	−0.70

π^* conduction band (6) in the energy position as described in detail in a later section.

The spectral dependences of the cathodic and anodic photocurrents for the polycrystalline TiO_2 electrode heated at 600°C are shown in Fig. 8. The cathodic photocurrents for the TiO_2/Zn and TiO_2/Ni electrodes show similar spectral dependences to the TiO_2 electrode, but these are very small, as shown in Table II. The ratios of the maximum cathodic photocurrent (i_{mc}) to the maximum anodic photocurrent (i_{ma}) obtained from the figures of the spectral dependences are listed in Table II for the various electrodes. These photocurrents are brought about by the u.v. light, and therefore based on the photoproduced electron in the π^* conduction band and the photoproduced hole in the π valence band of the TiO_2 (6). The high cathodic photocurrents for the Cr, Mn, V, and Cu-doped electrodes are noteworthy. The flatband potential will give no effect on the cathodic photocurrent, because the onset potentials of the TiO_2, TiO_2/Zn, and TiO_2/Ni electrodes are almost the same as those of the TiO_2/Cr, TiO_2/Cu, and TiO_2/V electrodes, but very different in the above ratio. It is concluded that the high O_2 reduction photocurrent is attributable to many surface states formed on the surface by the dopants, which easily reduces the O_2 molecule. That is, these surface states will be the active sites for the O_2 reduction. The active site will be the d-orbital of the dopant (Cr, Mn, V, and Cu) as discussed previously. The photoproduced electron in the π^* conduction band of the TiO_2 will flow to the O_2 molecule adsorbed at the active site through the impurity band, if the impurity band is formed near the π^* conduction band in the same energy position as the Co-doped TiO_2 (6). This is a reasonable energy position in a theory of electron transfer. Therefore, it is predictable that the impurity band is situated near the π^* conduction band for all the TiO_2/M electrodes which show the visible light response. Figure 9 shows the model for the cathodic and anodic photocurrents on the TiO_2/M electrodes (M: Cr, Mn, V, and Cu).

Table II. Ratio of the maximum cathodic photocurrent to the maximum anodic photocurrent

Sample		Preparation temp.	Ratio i_{mc} (μA)/ i_{ma} (μA)
TiO_2		600°C	0.6/16 = 0.04
TiO_2/Cr	(2.5×10^{-9} mole/cm²)	600°C	6.8/4.2 = 1.6
	(2.5×10^{-8} mole/cm²)		1.4/1.5 = 0.9
TiO_2/Mn	(2.5×10^{-8} mole/cm²)	500°C	1.5/1.7 = 0.9
	(2.5×10^{-8} mole/cm²)	600°C	0.8/1.6 = 0.5
TiO_2/V	(2.5×10^{-8} mole/cm²)	600°C	3.4/3.6 = 0.9
TiO_2/Cu	(2.5×10^{-7} mole/cm²)	600°C	5.8/13 = 0.4
TiO_2/Zn	(2.5×10^{-6} mole/cm²)	600°C	0.09/16 = 0.006
TiO_2/Ni	(2.5×10^{-7} mole/cm²)	600°C	0.24/2.6 = 0.09

It is confirmed by the following experiment for the TiO_2/Cr electrode that the impurity band is situated near the π^* conduction band in energy position. In this experiment, the TiO_2 (single crystal)/Cr electrode, which was prepared by coating the isopropyl alcohol solution with metal oxide and then heating in the same way described in the experimental section, was used. The electrode was heated at 600°C in air as the final heat-treatment. If the impurity band is situated near the π^* conduction band, the visible light photoresponse will be observed for the cathodic current but not for anodic current as illustrated in Fig. 10, because the impurity band is formed only on the electrode surface region. The photoproduced electron by the visible light cannot flow into the bulk under the anodic bias, but into the solution under the cathodic bias. The spectral dependences for this type of electrode are shown in Fig. 11. The clear cathodic photocurrent due to the visible light was observed, but only the small anodic

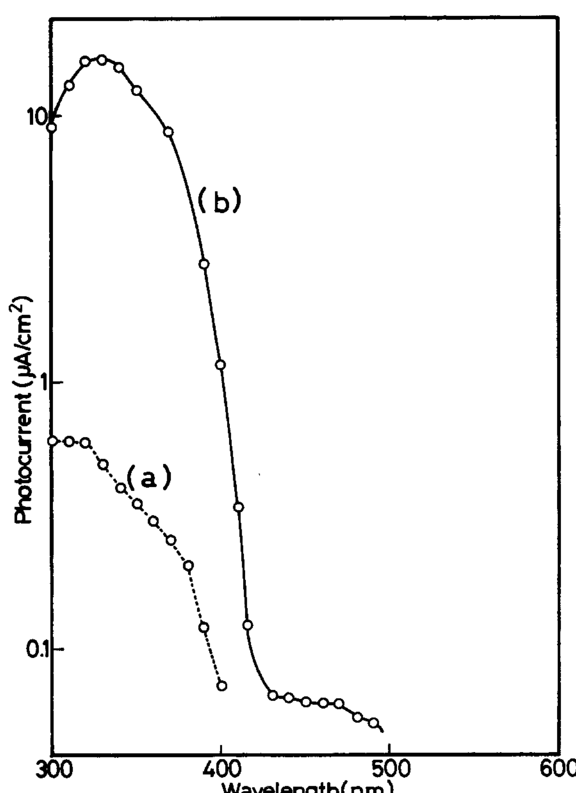

Fig. 8. Spectral dependences of the photocurrents at the TiO_2 prepared at 600°C. The cathodic and anodic photocurrents were measured at −0.8 and 0V, respectively. (a) Cathodic photocurrent, (b) anodic photocurrent.

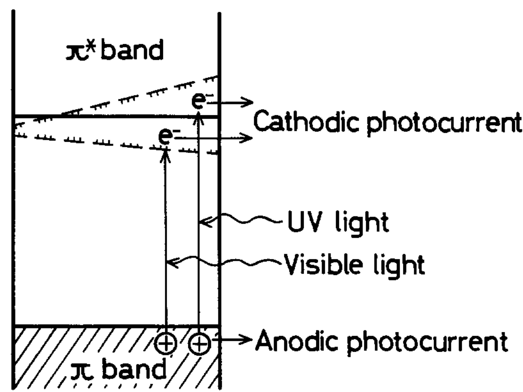

Fig. 9. Model of the photoexcitation process at the electrode giving the visible light photoresponse.

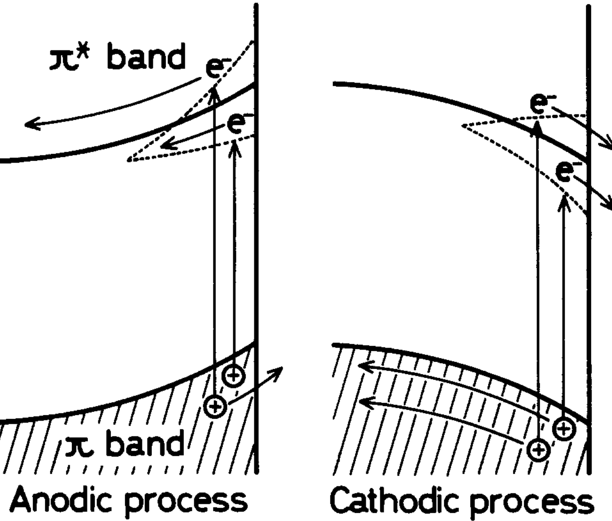

Fig. 10. Cathodic and anodic photoprocess at the TiO_2 (single crystal)/Cr. The larger visible light response for the cathodic photocurrent than the anodic photocurrent is brought about.

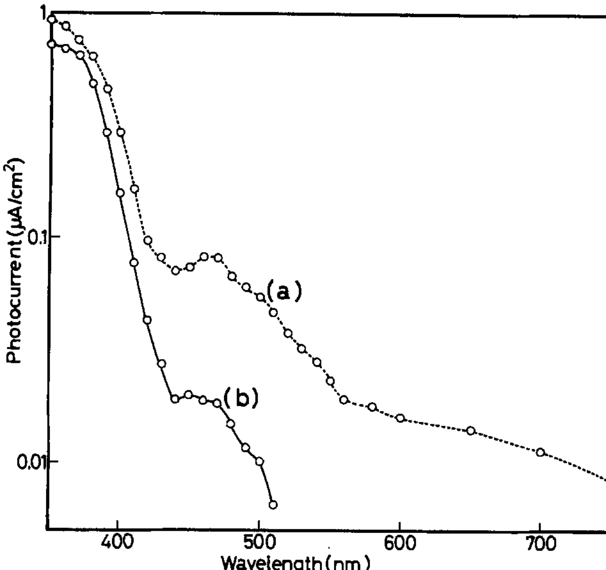

Fig. 11. Spectral dependences of the photocurrents at the TiO_2 (single crystal)/Cr(2.5×10^{-9} mole/cm^2) electrode prepared at 600°C. (a) Cathodic photocurrent, (b) anodic photocurrent.

photocurrent due to the visible light with the wavelengths near the bandgap energy of the TiO_2 was observed. This result agrees with the expectations as stated above very well. The small visible light response for the anodic current reflects that the impurity band slightly interacts with the π^* conduction band. The same type electrodes doped on their surfaces with the other transition metal (Mn, V, Cu) also gave the similar spectral dependences in which the visible light responses of the anodic photocurrents are small, but not stable. From the energy position of the impurity band, it is estimated that this band will consist mainly of the d-orbital of the impurity transition metal. Therefore, the d-orbital on the top of the impurity band will act as the active site for the O_2 photoreduction on the electrode surface.

The simultaneous appearance of the both cathodic and anodic photocurrents at the TiO_2 electrodes reflects that the photoreduction by the photoproduced electron and the photo-oxidation by the photoproduced hole possibly proceed on the same surface at the same time in the potential region near the flatband potential, and give a photosynthetic mechanism. In particular, the above two reactions will rapidly proceed on the TiO_2 surface doped with Cr, Mn, V, and Cu. This mechanism is essentially different from that of the photosynthesis proposed on the platinized TiO_2 in which the reduction proceeds on Pt and the oxidation on the TiO_2 (12, 13), but similar to that suggested by Schrauzer *et al.* (14) and Inoue *et al.* (15).

Conclusions

In the electrodes used in the present work, the Cr, Mn, V, and Cu-doped TiO_2 electrodes show the visible light response. From the results of the experiment in which the single crystal TiO_2 coated by Cr was used, it is confirmed that the impurity band is formed near the π^* conduction band of the TiO_2. It is found that TiO_2 electrodes also give the O_2 reduction photocurrent, and that in particular the doped TiO_2 electrodes which show the visible light response bring about the large O_2 reduction photocurrent. The good agreement of the spectral dependences of the anodic and cathodic photocurrents show that both photocurrents are brought about by the same photoexcitation process. The large O_2 reduction photocurrent is based on the d-orbital of the impurity metal by which the impurity band will be formed in the bulk. That a photosynthesis of the photoreduction by the photoproduced electron and the photo-oxidation by the photoproduced hole simultaneously proceed on the same surface is suggested from the simultaneous appearance of the both cathodic and anodic photocurrents.

Semiconductor Electrodes

XXXIII. Photoelectrochemistry of n-Type WSe_2 in Acetonitrile

Henry S. White, Fu-Ren F. Fan, and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The photoelectrochemical behavior of n-type WSe_2 single crystal electrodes in acetonitrile solutions containing several redox couples (I^-/I_3^-, Br^-/Br_2, Cl^-/Cl_2, thianthrene$^{0/+}$, $Ru(bpy)_3^{2+/3+}$ was investigated. Electrodes with discontinuities in the van der Waals' surface show large dark currents and recombination of electrons with photo-oxidized solution species. Pretreatment of such a surface with Cl^- passivates these dark active sites and increases the photocurrent density. The observed photopotentials at WSe_2 for redox couples with potentials, V_{redox}, more positive than 0.5V *vs.* SCE show behavior consistent with Fermi level pinning; the onset potential of photocurrents increases linearly with increasing V_{redox} while the photopotential remains constant. The energy position at which pinning occurs depends on the density of surface states and the concentration of solution species. The characteristics of a photovoltaic cell based on the n-WSe_2/Cl^-, Cl_2^-/Pt system is also described.

The performance of photoelectrochemical devices for conversion of solar to chemical and electrical energy can be critically limited by processes occurring via intermediate energy levels at the semiconductor/liquid interface (surface states). Surface recombination and Fermi level pinning are two such processes that generally are detrimental to efficient energy conversion. In either case the photoelectrochemical results are somewhat different from expectations based on the idealized model (1) of the semiconductor electrode/solution interface. A number of investigations of the dependence of potential distribution (2) and charge transfer kinetics (3) on surface states have been carried out. The surface pretreatment or modification procedures can influence the distribution and density of surface states at energies located within the bandgap and thus cause changes in the electrochemical behavior (4, 5).

Recently, Tributsch and co-workers have introduced photoelectrochemical cells based on layer-type transition metal dichalcogenides (5). These and later investigations (6-11) have shown that the observed photopotentials in aqueous (5f, 9) and nonaqueous (6-8) solutions are smaller than the expectations based on the ideal junction model. Lewerenz (10) and Tributsch (11) and co-workers have also recently investigated the role of surface morphology on conversion efficiencies of layered semiconductors in aqueous solutions. We report here an investigation of n-type WSe_2 electrodes in acetonitrile (MeCN) solutions. The effect of the nature of the surface and pretreatment procedures on the electrochemical response and a photovoltaic cell based on the photogeneration of chlorine at n-type WSe_2 immersed in an MeCN solution containing Cl^-/Cl_2 is described.

Experimental

Semiconductor electrodes.—N-type WSe_2 single crystals were generously donated by Dr. Barry Miller and Dr. Frank DiSalvo of Bell Laboratories. Electrical contacts were made to the back of each crystal by rubbing In/Ga alloy into the crystal to which a copper lead was contacted with silver epoxy cement (Allied Products Corporation, New Haven, Connecticut). A clean new crystal face ($\perp$ C-axis) was exposed by sticking adhesive tape on the front side and gently pulling off the top surface layer. To obtain electrodes with only the van der Waal's surface ($\perp$ C-axis) exposed, a very minute surface area was carefully chosen that was free from any edges or face defects; these are known to provide recombination centers (10, 11). Such electrodes are designated "type S" in this paper. No electrodes were prepared with only the surface $\parallel$ C-axis exposed, since the crystals were only ~1-2 mm thick along this plane and are difficult to mount without leaking. Electrodes were prepared from several crystals that had visible edges (discontinuities in the otherwise smooth van der Waal's plane) exposed to the solution. These electrodes are designated "type E." Scanning electron micrographs of type S and type E WSe_2 electrodes are shown in Fig. 1. The surface defects represented roughly 5%-10% of the total surface area of type E electrodes.

The crystal sides and back and the copper lead were completely covered with 5 min epoxy cement; this was then covered with silicone rubber sealant (Dow Corning Corporation, Midland, Michigan). For long-term stability measurements involving strong oxidants, such as Cl_2, the electrode was covered with a preactivated photo-cure epoxy cement that is used in dental restorative work (Caulk Nuva-Fil, D.A., Milford, Delaware). The exposed areas of the crystal faces in both types of electrodes were between 0.010 and 0.070 cm^2.

Unless noted otherwise, before each experiment the electrodes were etched in 12M HCl for 15-30 sec, rinsed thoroughly with distilled water, and dried under vacuum for 1 hr. The electrodes were then stored inside an He-filled dry box (Vacuum Atmospheres, Hawthorne, California) and used within one day.

Chemicals.—All electrochemical grade tetralkylammonium salts were purchased from Southwestern Chemical Company (Austin, Texas). Tetrabutylammonium perchlorate (TBAP), tetrabutylammonium bromide (TBABr), tetramethylammonium chloride (TMACl), and tetrabutylammonium iodide (TBAI) were crystallized at least twice from acetone-ether and dried under vacuum for 2 days. Tetraethylammonium chloride (TEAC) was recrystallized from MeCN-ether and dried as above. Thianthrene (Th) (Aldrich Chemicals) was either sublimed three times or recrystallized from benzene twice. $Ru(bpy)_3(ClO_4)_2$ was prepared and purified as previously described (12). After purification the reagents were stored inside the dry box. I_2 (Fisher Scientific Company), Br_2 (MCB), and Cl_2 (Matheson Gas Company) were used without

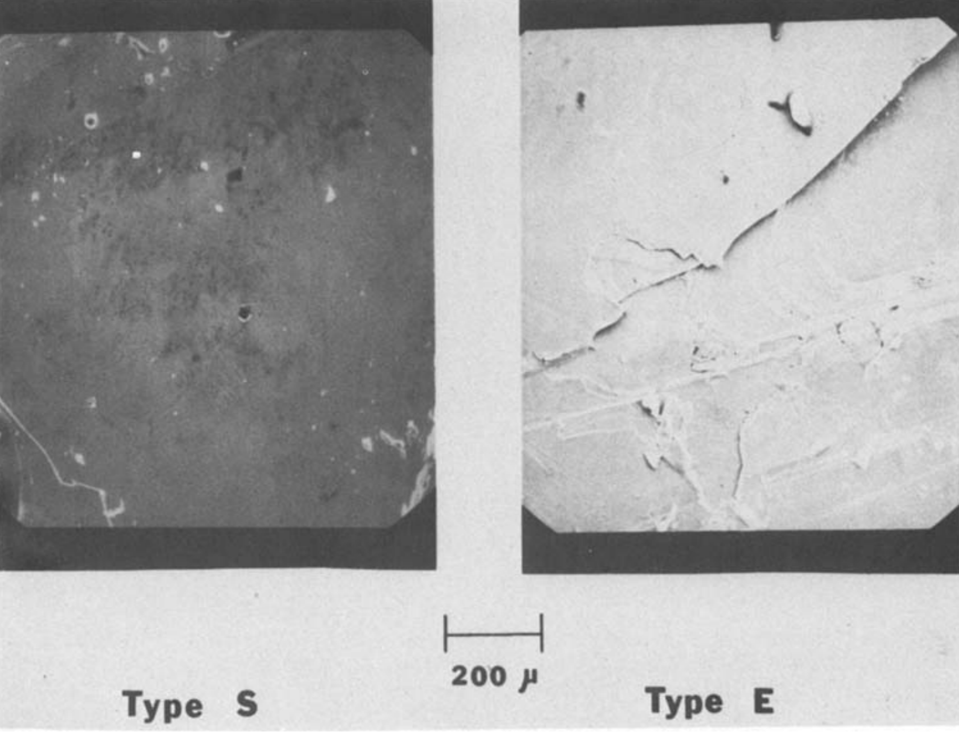

Fig. 1. Scanning electron micrographs of WSe_2 electrodes: (a) type E; (b) type S. Magnification 100×.

further purification. MeCN was purified and dried as previously described (13) and stored inside the dry box.

Electrochemical apparatus.—Voltammetric measurements were made in a two-compartment cell (30 ml) equipped with an optically flat Pyrex window. The working and reference electrodes were separated from the auxiliary electrode, a Pt flag (~8 cm^2), by a medium-porosity frit. Along with the semiconductor electrodes the main compartment contained a Pt disk (0.025 cm^2) sealed in glass that was used to check the purity of the electrolyte and to locate the potential of the reference electrode with respect to the potential of a known reversible redox couple. The reference electrode was a polished silver wire inside a glass cylindrical compartment containing only the supporting electrolyte and separated from the main solution by a medium-porosity frit. All potentials reported here are referenced to an aqueous saturated calomel electrode (SCE). Single compartment, two-electrode cells, also equipped with optically flat Pyrex windows, were used as photovoltaic (solar) cells.

The electrochemical cell and solutions were prepared before each experiment within the dry box. All ground glass joints were sealed with silicone-based vacuum grease to permit the cell to be removed from the inert atmosphere for study. When the experiment required opening of the electrochemical cell outside of the dry box, prepurified N_2 was blown over the top of the solution until the cell was reclosed.

The cyclic voltammograms were obtained with a Princeton Applied Research (PAR) Model 173 potentiostat and PAR Model 175 Universal programmer and recorded on a Houston Instruments Model 2000 X-Y recorder. Capacitance measurements were made using a PAR Model HR-8 lock-in amplifier. Solar cell current-voltage curves were made by measuring the voltage across a variable load resistance with a Keithley Model 179 TRMS digital multimeter.

The light source used for photoelectrochemical studies was an Oriel Corporation (Stamford, Connecticut) 450W xenon lamp. A red filter was used to eliminate wavelengths below 590 nm. Neutral density filters (Oriel Corporation) were used to vary the light intensity. The full, filtered xenon lamp power output was ~150 mW/cm^2 as measured with an E. G. and G. (Salem, Massachusetts) Model 550 radiometer/photometer and a Scientech 361 power meter.

Results

Capacitance measurements and cyclic voltammetry in the absence of redox couple.—Capacitance measurements on several n-WSe_2 electrodes in MeCN containing only TBAP (0.2M) resulted in two distinct types of behavior. The capacitance *vs.* potential curve of a type S electrode, Fig. 2, closely resembles behavior typical of a fairly large bandgap n-type semiconductor, where at potentials positive of the flatband potential, V_{FB}, the space charge region is depleted of electrons and contains ionized donors at some constant concentration (1). This region extends up to potentials of 1.3V *vs.* SCE. At potentials more negative than −0.4V, the capacitance becomes constant indicating the onset of degeneracy. The voltammetric behavior of the same electrode in MeCN-0.2M TBAP is shown in Fig. 3. In the dark a small current, ~0.2 mA/cm^2, begins at 0.6V. Under illumination, the photocurrent begins at ~0.5V and increases steadily at more positive potentials. At ~1.0V, the photocurrent is ~1.0 mA/cm^2. On the reverse

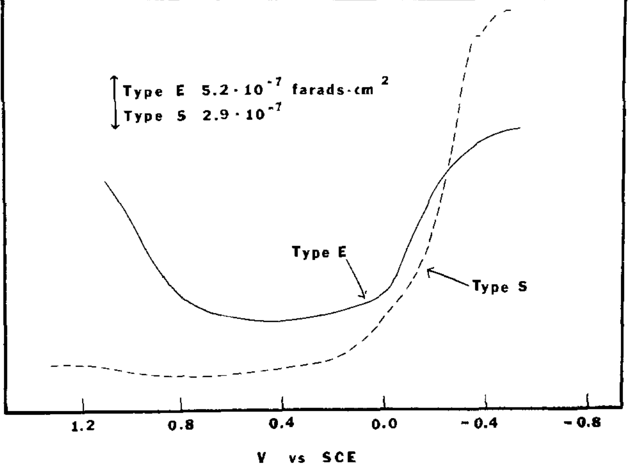

Fig. 2. Differential capacitance curve for type E and type S WSe_2 electrodes in MeCN containing 0.2M TBAP. Scan rate, 5 mV/sec; applied a-c voltage, 5 mV rms. Frequency, 1000 Hz.

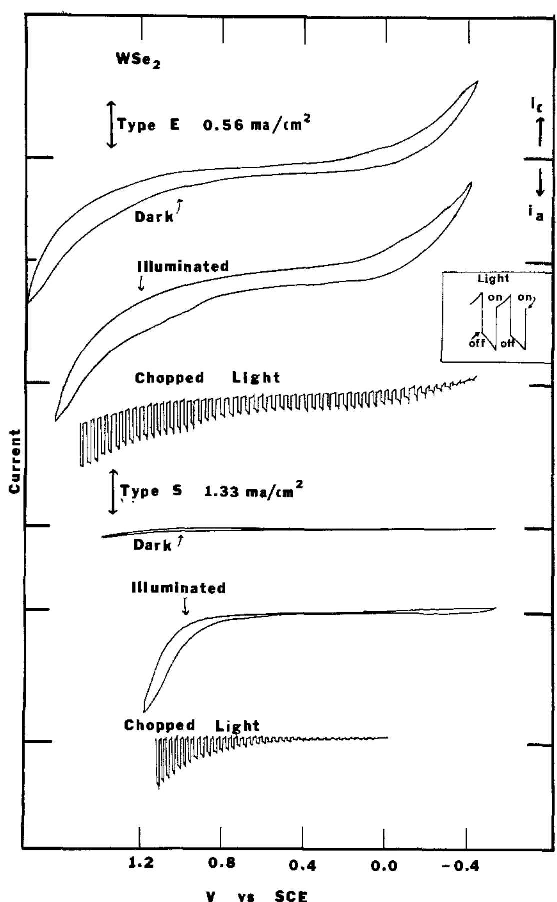

Fig. 3. Voltammetric behavior of type S and type E electrodes in MeCN-0.2M TBAP. Scan rate, 100 mV/sec, except for chopped light scans, 10 mV/sec.

scan, under illumination, a small cathodic current, ~0.2 mA/cm^2, begins at 0.0V. This same cathodic current is observed if the light is turned off on the reverse scan and increases with more positive switching potentials. The anodic photocurrent and induced dark current are probably due to the oxidation and re-reduction of the crystal surface caused by traces of H_2O in the acetonitrile (5e). Further purification of the solvent by addition of Al_2O_3 significantly reduced these currents.

The capacitance behavior of a type E WSe_2 electrode, also shown in Fig. 2, is typical of electrodes with discontinuities in the van der Waal's surface. The branch toward negative potentials is similar in shape to the type S electrodes. However, at potentials more positive than 0.7V, the capacitance increases sharply indicating either deep surface states, inversion of the space charge region, or the occurrence of a faradic process. As Tributsch has already pointed out (5e), inversion of the space charge region in a semiconductor with a bandgap of 1.4 eV is unlikely within this potential region. If space charge inversion due to thermal activation of electrons into the conduction band were responsible for this increase in capacitance, both type S and type E electrodes should show this behavior. The voltammetric behavior of the same crystal (type E) in a blank solution is shown in Fig. 3. A dark anodic current is observed that is approximately five times larger than on the type S electrode (compare at 1.0V). Under illumination, a photocurrent begins at −0.3V and is fairly constant until 0.7V where a sharp increase in anodic currents begins. The net photocurrent density at 1.0V is ~0.6 mA/cm^2, which is ~60% the current density at the type S electrode. The V_{FB} values and donor densities of these crystals were estimated from the capacitance measurements. Mott-Schottky plots for the two crystals described above are shown in Fig. 4a and 4b. The results for several crystals are summarized in Table I. V_{FB}, for WSe_2 in MeCN, estimated by extrapolating to the potential where $1/C_{sc}^2 = 0$, was always in the range of −0.2 to −0.4V *vs.* SCE. The apparent donor densities, n_D, for type E electrodes were 3-7 times larger than for type S electrodes. As can be seen in the Mott-Schottky plots, the apparent capacitance values were highly dependent on the frequency of the applied alternating voltage. Frequency dispersion of the capacitance due to dielectric relaxation should be negligible in a covalent-type material like WSe_2. It is possible that the dispersion observed here is due to small changes in the effective electrode surface due to corrosion. The values of n_D listed in Table I are from measurements in the range 500-1000 Hz. A value of 10 for the dielectric constant of WSe_2 was used in all calculations (14).

Table I. Estimates of flatband potentials and donor densities for n-WSe_2

Crystal, WSe_2	V_{FB} (V *vs.* SCE)	n_D (cm^{-3})
Type S	−0.22	1.3×10^{18}
	−0.36	2.0×10^{18}
	−0.42	1.8×10^{18}
Type E	−0.26	8.5×10^{18}
	−0.4*	5.6×10^{19}

* Measured *vs.* Ag quasi-reference electrode and corrected to SCE with accuracy of ∼±0.1V.

Voltammetric behavior of various redox couples at n-WSe_2.—Types S and E electrodes showed distinctly different voltammetric behavior. Recall that type E electrodes are those that have visible edges or discontinuities in the van der Waal's plane exposed to the solution. These edges have been associated with the face parallel to the main C-axis (|| C-axis) (15) where empty conduction band orbitals are exposed to the solution. The results are summarized in Tables II and III.

Oxidation of I^- and Br^-.—The type S electrode shows negligible dark current in the vicinity of I^- oxidation on Pt (Fig. 5a). Upon illumination, the potential for onset of photocurrent, V_{on}, was 0.0V and attains a saturation current at ∼0.2V. The chopped light voltammogram clearly indicates that little back-reaction (reduction of photo-oxidized products) occurs beyond the onset potential. The dark current at the type E electrode in the presence of I^- (Fig. 5b) was smaller (*i.e.,* about one-tenth) than in the blank solution (Fig. 3). V_{on} was ∼0.07V more negative than the V_{on} at the type S electrode. This difference in onset potential is approximately the difference in the measured flatband potentials for these crystals. The maximum photocurrent densities were about the same for both type S and type E electrodes. However, on scan reversal, a much larger reduction peak centered at −0.07V was found with the type E electrode.

The oxidation of Br^- (as TBABr) on WSe_2 followed behavior similar to that found for I^- (Fig. 6a and 6b).

Table II. Voltammetric data for various redox couples at WSe_2

Couple	Pt* V_{pa}	Pt* V_{pc}	Type S** V_{onset}	Type S** V_{pc}	Type E† V_{onset}	Type E† V_{pc}
I^-/I_2	0.35	0.1	0.00	—	−0.07	−0.08
Br^-/Br_2	0.69	0.25	0.05	−0.35	0.02	−0.12
Cl^-/Cl_2	1.09	0.82	0.55	—	0.21	−0.02
$Th^{0/+}$	1.26	1.20	0.60	0.76	0.67	0.75
$Ru(bpy)_3^{2/3+}$	1.33	1.27	0.91	0.96	—	—

* All values in V *vs.* SCE; E_{onset} = potential of photocurrent onset.
** Under illumination; negligible dark anodic currents at type S electrodes.
† Under illumination; no well-defined peaks in dark except for thianthrene oxidation, V_{pa} = 1.35V; V_{pc} = 1.15V.

Table III. Comparison of current densities at type S and type E WSe_2 electrodes in solutions containing various redox couples

Redox couple	Type S Dark* (mA/cm^2)	Type S Illuminated (mA/cm^2)	Type E Dark (mA/cm^2)	Type E Illuminated (mA/cm^2)
I^-	<0.1	0.66	<0.1	0.71
Br^-	<0.1	5.0	<0.1	1.1
Cl^-	<0.1	6.0	0.1	2.0
Th	<0.1	3.2	2.4	2.4

* Dark current measured at potential of oxidation peak on Pt. Photocurrent measured at peak potential for type E electrodes. Measured at current plateau for type S electrode except for Br^- where i_{photo} was measured at 0.8V.

The V_{on} for the type E electrode was about 30 mV more negative than for the type S electrode. A much larger difference existed, however, in the total photocurrent densities. The current density at the type S electrode was about 4-5 times larger than that at type E.

Oxidation of Cl^-.—The voltammetric behavior for the oxidation of Cl^- at the two WSe_2 electrodes are shown in Fig. 7a and 7b. At the type S electrode, V_{on} is 0.55V. Again, no dark current or back-reaction is seen at this electrode. The oxidation of Cl^- on the type E electrode is strikingly different. V_{on} was 0.34V more negative at this crystal. This difference in onset potential cannot be accounted for by the small difference in flatband potential (∼50 mV). The cyclic voltammogram at the type E electrode shows a large reduction peak centered at 0.17V in the dark on scan reversal. This peak probably corresponds to the reduction of chlorine generated in the dark on the anodic scan. Under illumination, this reduction peak occurred at a potential about 0.2V more negative. No reverse reduction peak was observed in the dark on the type S electrode since no dark anodic current flowed. However, under illumination, a similar cathodic current was observed at potentials more negative than 0.0V.

Thianthrene.—The voltammetric behavior for the oxidation of thianthrene (Th) at the two WSe_2 crystals is shown in Fig. 8a and 8b. While under illumination, the onset potential and waveforms are almost identical at the two electrodes; in the dark a striking difference exists. With the type E electrode, a large quasi-reversible peak is located at approximately the same potential as on Pt. The current density in the dark is equal to the photocurrent density. On the type S electrode, no dark anodic current is observed. On scan reversal following an anodic scan under illumination, a cathodic peak is observed at both type E and S electrodes.

Oxidation of thianthrene in the presence of halide.—The photo-oxidation of Th with small amounts of halide species (10-15 mM) added to the solution was studied to determine the effect of halide ions on the photoelectrochemical behavior of WSe_2. The cyclic voltammograms obtained in the dark at the type E electrode in mixed Th/halide solutions is shown in Fig. 9. The previously observed dark quasi-reversible wave due to Th oxidation and $Th^{+\cdot}$ reduction is noticeably absent in the presence of I^-, Br^-, or Cl^-. A comparison of the cyclic voltammograms under illumination of thianthrene alone and with either I^- or Br^- in solution shows little change in the peak potentials due to Th photo-oxidation. In the presence of Cl^-, however, these peaks, which were centered around 0.75V *vs.* SCE, are absent (Fig. 10), and instead, a new pair of oxidation and reduction waves centered at 0.52V appeared. These peaks were not present in solutions containing Cl^- alone and therefore are assigned to the oxidation and reduction of Th. From these results, it appears that Cl^- induces a 230 mV shift in V_{on} for the oxidation of thianthrene. To demonstrate that this effect results from the interaction of Cl^- with the surface discontinuities, the experiment illustrated by Fig. 11 was undertaken. A fresh type E electrode was prepared and the dark and photo-oxidation of Th was observed (curves a, b). The electrode was then removed and dipped into an MeCN solution of 7.0 mmoles TEACl in the dark without any external electrical connection. After 30 sec, the electrode was removed, rinsed thoroughly with MeCN, and placed back into the original Th-containing solution. The resulting cyclic voltammograms (curves c and d) showed an immediate decrease in the dark current and a negative shift (∼180 mV) of the onset potential for photocurrent. The maximum photocurrent for Th oxidation increased by about 25% following this surface treatment. This improved photocurrent-potential curve re-

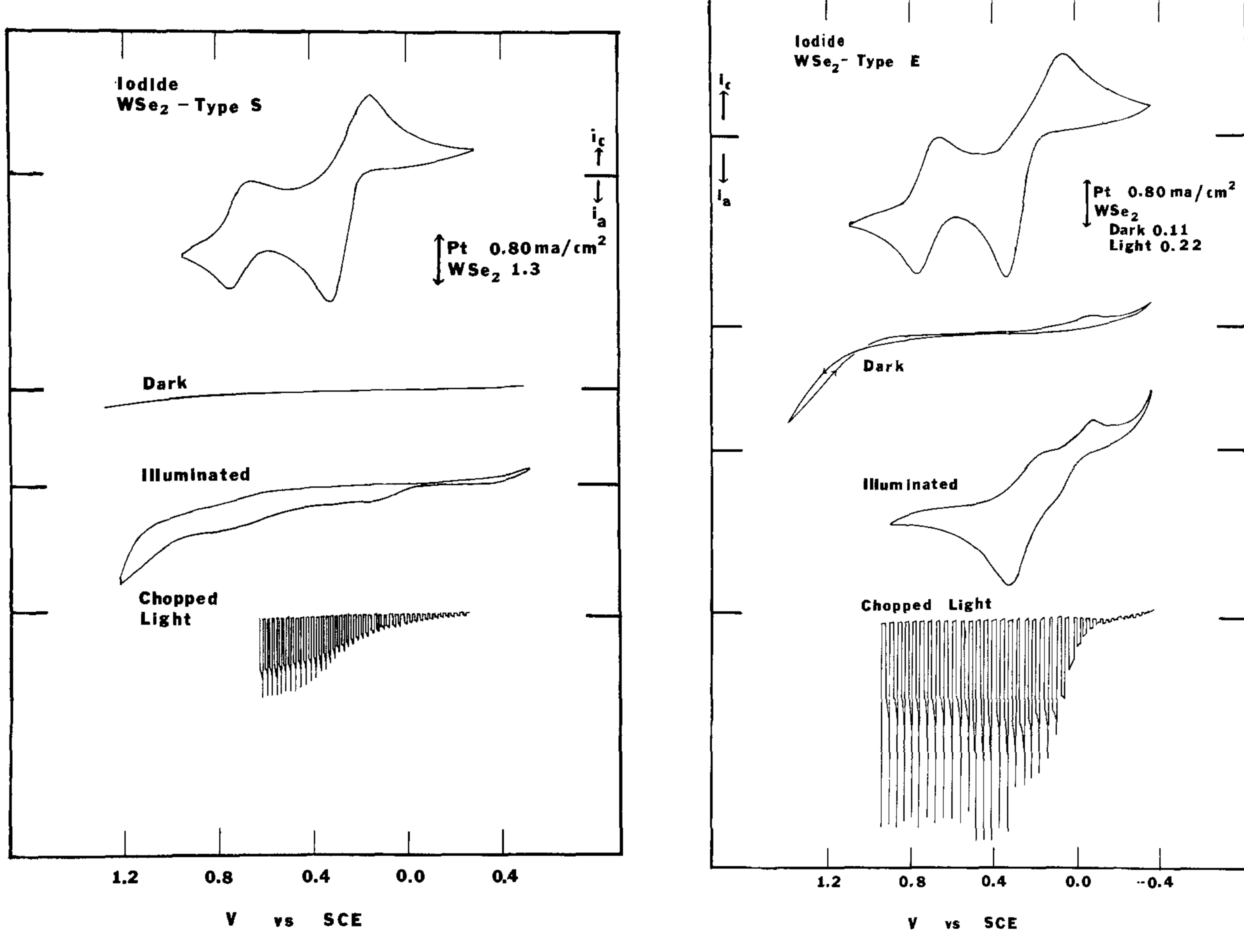

Fig. 5. Voltammetric behavior of iodide in MeCN containing 0.2M TBAP and TBAI. (a) Type S, [I⁻], 10 mmoles; (b) type E, [I⁻], 15 mM. Scan rate, 100 mV/sec, except for chopped light scan at 10 mV/sec.

mained unchanged for at least 30 min of continuous cycling. When a similar experiment was carried out with a type S electrode, no changes in the dark oxidation current (which was negligible) or the photocurrent was found by a Cl^- pretreatment. Note that the decrease in dark current for the type E electrode on treatment with Cl^- takes place without any possibility of photo-oxidation occurring during the exposure of the electrode to Cl^- so that the formation of a light-induced complex between the electrode and Cl^- is unlikely. The observed effect can be ascribed to interactions of the Cl^- with surface discontinuities leading to modification or passivation of these sites.

Photovoltaic cell based on WSe_2/Cl^-, Cl_2, (MeCN)/Pt.—Schneemeyer and Wrighton have previously reported photovoltaic cells based on the generation of Cl_2 at illuminated MoS_2 (6) and $MoSe_2$ (7) in MeCN. Similar cells employing type S WSe_2 photoanodes were constructed to test the efficiency and stability of this material. The *i-V* characteristics for several electrodes in cells saturated with TEACl and with Cl_2 bubbled through the solution are shown in Fig. 12. The open-circuit photovoltage, V_{oc}, and short-circuit photocurrents, i_{sc}, for several electrodes are listed in Table IV.

At low photovoltages the photocurrents at several electrodes appear remarkably high, representing quantum efficiencies of 1 (or even more) under short-circuited conditions. A sharp drop in photocurrent (~30%-40%) is observed with increasing load resistance in the first 100 mV of the photo *i-V* curve (Fig. 12). To determine if these unusually high currents are due to a photoinduced corrosion process, a WSe_2 crystal (11.5 mg) was placed in contact with a Pt electrode and immersed in a 2.0M TEAC solution saturated with Cl_2. After 60 hr under illumination (~80 mW/cm^2) the crystal remained unchanged with no weight loss (±0.1 mg). While this experiment may not reproduce the actual conditions of a PEC cell, photoinduced corrosion does not appear to be the major cause of the high short-circuit currents. Other causes for this result, such as the focusing or scattering of the incident radiation onto the very small area electrode by the surrounding glass or sealant to cause a higher effective light flux on the electrode, have been considered. Probing experiments with the small beam of an He-Ne laser show that this is a small effect. At this time, the actual cause of these anomalous currents is unclear.

V_{oc} depended strongly on the amount of Cl_2 bubbled through the solution. The highest V_{oc} values listed for the 1.9M Cl^- solutions (Table IV) were produced by optimizing the Cl^-/Cl_2 ratio. No attempt was made to measure exactly the amount of Cl_2 dissolved in the solution. As shown in Fig. 13, V_{oc} drops considerably as excess Cl_2 is added to the solution. In a regenerative photocell with an inert metal electrode and without an external power supply the photocurrent can be limited by either processes at the photoanode or at the metal cathode. Thus, at low concentrations of Cl_2 the photocurrent was limited by mass transfer to the platinum cathode, while at high Cl_2/Cl^- ratios, the photovoltage was limited by the solution redox potential (as discussed below). When the photocurrent did not increase with higher concentrations of Cl^- or Cl_2, addition of Cl^- to the solution increased V_{oc}. The i_{sc} value increased steadily with Cl^- concentration up to 1.6M. Additional increases in Cl^- concentration had no effect on i_{sc} or V_{oc}.

In a 1.9M Cl^- solution, V_{oc} approached a constant maximum value at light intensities ≥30 mW/cm^2. The short-circuit photocurrent increased linearly with light intensity up to 120 mW/cm^2, where it also reached a saturation value.

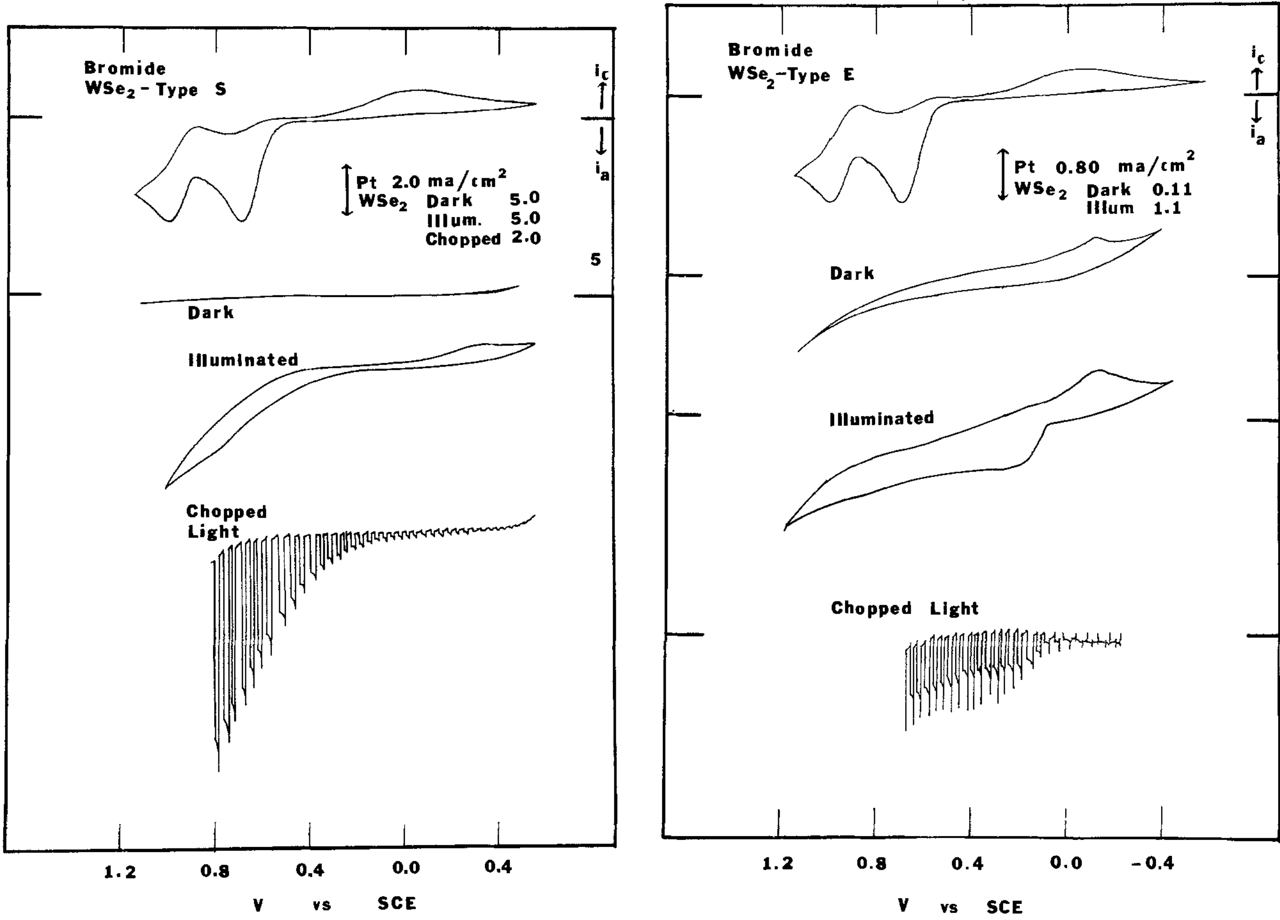

Fig. 6. Voltammetric behavior of bromide in MeCN containing 0.2M TBAP and 10 mM Br^-. (a) Type S; (b) type E. Scan rate, 100 mV/sec except for chopped light scan at 10 mV/sec.

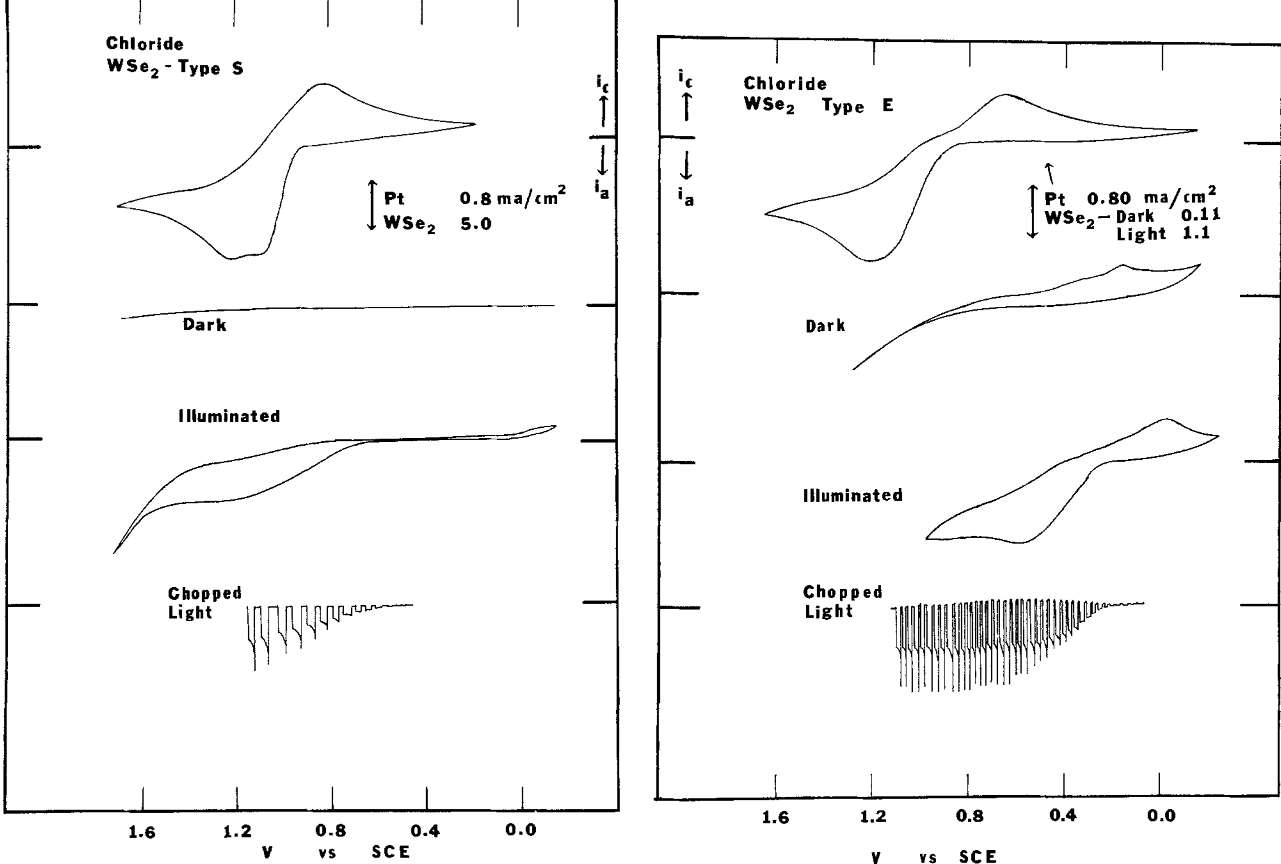

Fig. 7. Voltammetric behavior of chloride in MeCN containing 0.2M TBAP and 10 mM Cl^-. (a) Type S; (b) type E. Scan rate, 100 mV/sec except for chopped light scan at 10 mV/sec.

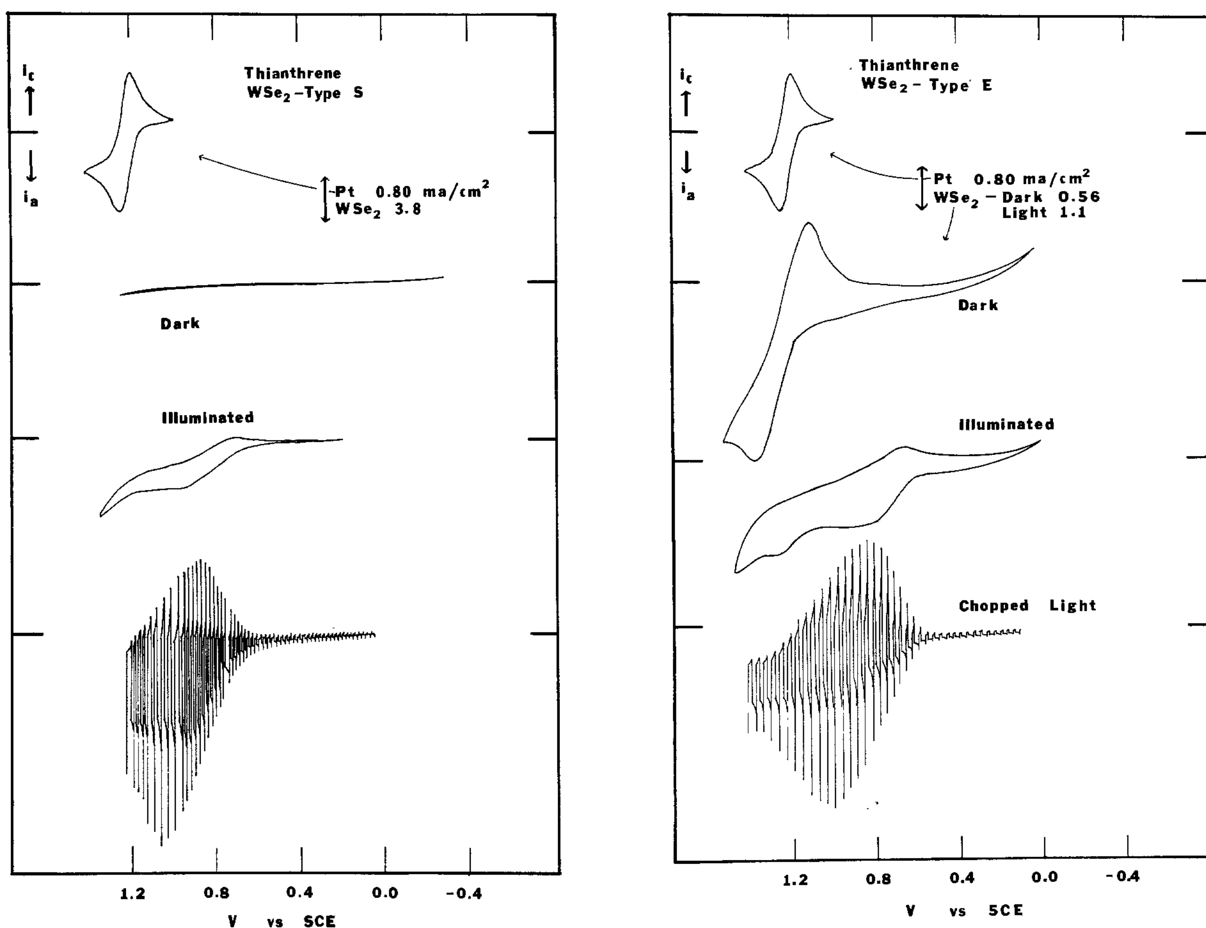

Fig. 8. Voltammetric behavior of thianthrene in acetonitrile solution containing 0.2M TBAP and 5 mM Th. (a) Type S; (b) type E. Scan rate, 100 mV/sec except for chopped light scan at 10 mV/sec.

Irradiation of the WSe_2 photoanode with the full output from a 450W xenon lamp (>590 nm and infrared filtered) focused onto the electrode surface yielded the i_{sc} and V_{oc} values listed in Table IV. Maximum power efficiencies under these conditions were estimated to be 7%-10.5%. No atempts were made to correct for solution absorption or reflections at the cell windows or the electrode surface. However, since the same photocurrent was found at ~80% of this light intensity, the power efficiencies at lower intensities would be ~2% higher.

The stability of n-WSe_2 (type S) against possible attack by Cl_2 generated at the surface was tested by allowing the photovoltaic cell to run for several hours (Fig. 14). After 7 hr, the short-circuit photocurrent had decreased by ~4% from its original stable value of 146 μA. This corresponds to 3.7C of charge passed which represents an amount of charge sufficient to consume an appreciable part of the 10 mg crystal, if corrosion were occurring. The electrode surface appeared unchanged after 7 hr.

Table IV. Characteristics of several photovoltaic cells: n-WSe_2 (type S)/(MeCN), Cl^-, Cl_2/Pt*

Electrode**	Conc. TEACl	Fill factor (max)	Power efficiency	i_{sc} (mA/cm²)	V_{oc} (mV)

Discussion

Dark and photocurrents. —The large differences in dark currents on the type S and type E electrode can be understood by a modified model used by Gerischer *et al.* for dark currents on MoS_2 (15). In this model, the d-orbitals parallel to the C-axis, in addition to forming the conduction band in the bulk material, are assumed to provide surface states at discontinuities of the type E electrode at energies in the upper part of the bandgap (11). Facile electron transfers can take place from the electroactive species into the conduction band via these mediating d-orbitals. When the exposed surface is free from edges, the layer of Se atoms block overlap between the conduction band and molecular orbitals of the species. In this case, electron transfer in the dark via the conduction band is allowed only by thermal excitation or by tunneling. This model seems to fit the behavior found for the oxidation of Th at WSe_2. In the dark, a small current (<0.2 mA/cm²) is observed on the type S electrodes. This dark current is no larger than the current observed for the same electrode in a solution containing only supporting electrolyte (0.2M TBAP). At the type E electrode, a large, mass transfer limited, dark current is observed for Th oxidation indicating that the current is not controlled by the number of dark oxidation sites on the crystal surface. Under illumination, both electrodes show similar voltammetric responses, with slightly higher photocurrents observed on the type S electrode. Thus for the type E electrode, the existence of the surface states allows Fermi level pinning and electron transfer to occur at potentials close to the standard potential of the redox couple. However, for a type S electrode, there are much lower densities of surface states near the conduction band. Fast electron transfer reactions do not occur in the dark for couples with potentials much more positive than the flatband

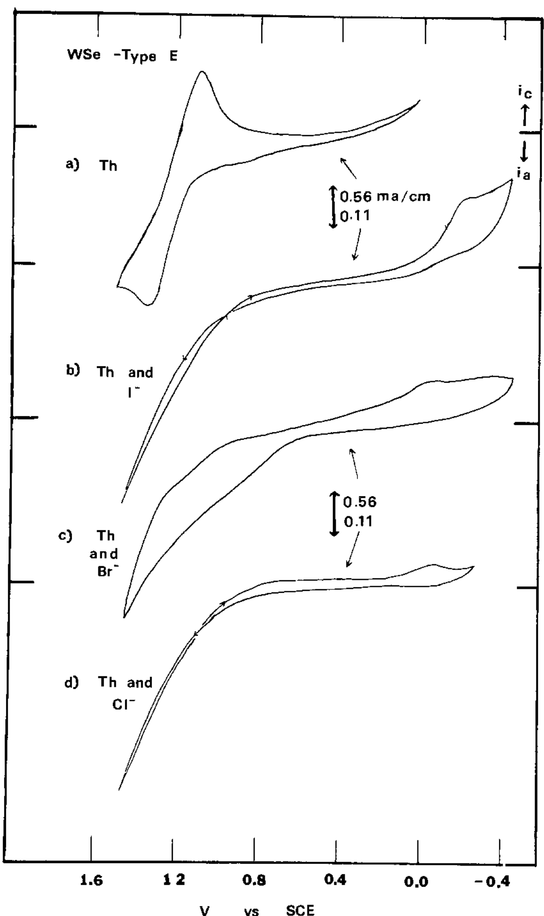

Fig. 9. Effect of bulk halide on dark currents at type E n-WSe_2 electrode. (a) 5 mmoles thianthrene (Th); (b) 5 mmoles Th and 15 mM TBAI; (c) 5 mM Th and 10 mM TBABr; (d) 5 and 10 mM TMACl. Scan rate 100 mV/sec. 0.2M TBAP as the supporting electrolyte.

potential. However, even with type S electrodes, Fermi level pinning at the bottom part of the bandgap may occur, as discussed later.

The photo-oxidation of halide species shows a slightly more complicated behavior. At the type S electrode, the dark anodic current in the presence of halides is about the same as the small dark current observed in a solution containing only supporting electrolyte. However, at the type E electrode, the dark current in the presence of halides is much smaller than that in the blank solution. Tributsch *et al.* have previously proposed an interaction of I^- with the surface in aqueous solutions (5f). The decrease in the dark oxidation currents on the type E electrode on the addition of halide ions similarly suggests a strong interaction of I^-, Br^-, and Cl^- with the surface states, composed of empty d-orbitals along the exposed edges. deactivating these previously dark active sites. This is confirmed by the decrease in the dark currents for Th oxidation (and $Th^{\cdot +}$ reduction) by the addition of I^-, Br^-, or Cl^-.

The total photocurrent densities for the oxidation of Cl^- or Br^- are 3-5 times larger at the type S electrode. Apparently while the dark active sites at the exposed edges are ineffective for the dark oxidation of Br^- or Cl^-, they remain rather efficient at trapping electrons and reducing photogenerated Cl_2 and Br_2. The total photocurrent density for the oxidation of I^- at the two electrodes was approximately the same.

The difference in behavior between Br^- or Cl^- and I^- probably reflects the stronger interaction of I^- with the electrode surface. The decrease in background current after treatment with halide (compare the dark currents at type E electrode before and after addition of I^-, Br^-, Cl^-) is important, since this current is presumably caused by oxidation of the surface lattice in the presence of trace amounts of H_2O in the acetonitrile (5e). Suppression of the crystal oxidation is equivalent to stabilization of these photoanodes and may be the reason for the stability observed in the aqueous iodide (5e, 9) and nonaqueous chloride (6, 7) cells employing layered materials. Further experiments are necessary to demonstrate if the halide pretreatments are sufficient for long-term stability.

Photopotentials.—From differential capacitance measurements, V_{FB} of n-type WSe_2 (both type S and E) in MeCN/TBAP alone was $-0.3 \pm 0.1V$ *vs.* SCE (Table II). The bandgap of these samples, determined from the action spectrum, is ~1.4 eV. After correction for the difference between Fermi level and the conduction bandedge, this places the edge of the valence band at ~1.0V *vs.* SCE. This is in good agreement with the flatband potential of p-type WSe_2, +1.0V *vs.* SCE, measured in MeCN (16).

The difference in potential for oxidation at Pt and illuminated WSe_2 (*i.e.*, the photounderpotential) *vs.* the standard potential for several redox couples is shown in Fig. 15. The standard potentials taken for I^-, Br^-, and Cl^- are the average of the reduction and oxidation peak potentials at Pt. The V_{on} for I^- and Br^- is approximately 0.2-0.3V positive of the measured flatband potential. This positive value of V_{on} suggests recombination is occurring and this can be attributed to the band of surface states lying directly below the conduction bandedge.

For couples with standard potentials more positive than 0.5V *vs.* SCE (Cl^-/Cl_2, Th/Th^+, and $Ru(bpy)_3{}^{2+/3+}$) the photopotential ($V° - V_{on}$) be-

comes almost constant at a value of ~0.4-0.5V. This limiting value can best be understood by Fermi level pinning (2a) at surface states located approximately 0.5 eV above the valence bandedge. V_{on} for redox couples with $V°$ more positive than 0.5V *vs.* SCE should increase linearly with increasing $V°$. For couples with $V°$ at potentials negative of the surface-state level (<0.5V), V_{on} is constant and the photopotential should increase as $V°$ becomes more positive, as seen in Fig. 15. Further evidence for the presence of surface states is the highly dependent nature of the photovoltage developed in the n-WSe_2/Cl^-, Cl_2(MeCN)/Pt cell upon the Cl_2/Cl^- ratio (Fig. 13). Based on the ideal model of the semiconductor-solution interface (1), V_{on} should be at V_{FB} and the Pt electrode would be poised by the redox couple so that a higher photovoltage is expected with higher Cl_2/Cl^- ratios, *i.e.*, a higher Cl_2/Cl^- shifts the solution redox potential to more positive values while the bandedges remain unaffected. However, the experimental results do not conform to this behavior. Upon addition of Cl_2, V_{oc} actually decreases (see Fig. 13). This could be attrib-

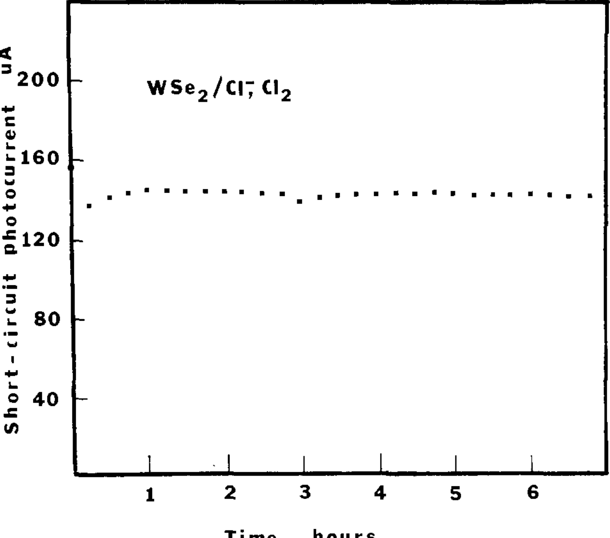

Fig. 14. Short-circuit photocurrent of WSe_2/Cl^- (1.9M), Cl_2/Pt PEC cell as function of time. Electrode area, 0.015 cm^2.

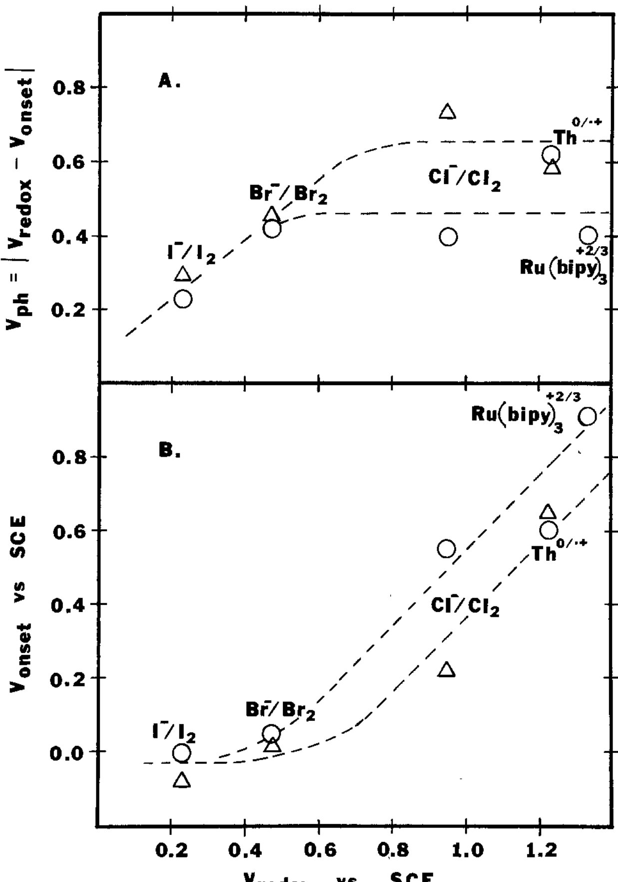

Fig. 15. (a) Comparison of photopotentials developed at type S (○) and type E (△) WSe_2 electrode for several redox couples in MeCN. (b) Comparison of onset potential of photocurrent at type S (○) and type E (△) electrodes for several redox couples in MeCN.

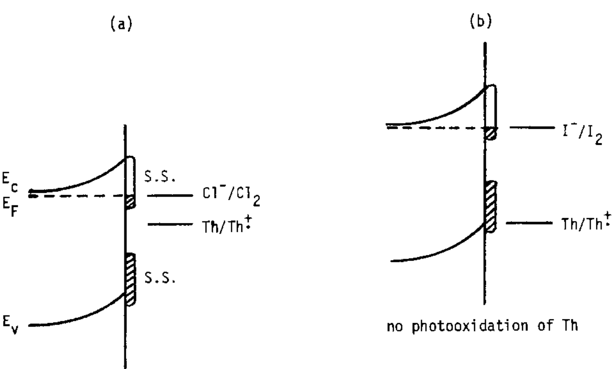
uted to a higher surface recombination rate at the higher Cl_2 concentration.

The shift in onset potential for Th oxidation at the type E electrode in the presence of Cl^- can also be explained by Fermi level pinning as shown in Scheme I (a). As the applied potential is biased in a positive direction, Cl_2 is initially generated and the Fermi level is pinned at the redox potential of Cl_2/Cl^- or, more likely, somewhat between the $V°$'s of the two redox couples. The result should be a more negative onset potential for thianthrene oxidation as is observed in Fig. 10. I^-/I_2 does not affect the onset potential for thianthrene oxidation, since at the potential where the Fermi level is pinned, *i.e.*, at the standard potential of I^-/I_2, the valence bandedge and the bottom surface



Scheme I. *E_c, conduction bandedge; E_F, Fermi level; E_V, valence bandedge; S.S., surface state.*

states are well beyond the potential of $Th/Th^{\cdot +}$ [see Scheme I (b)].

Conclusion

The results presented here indicate that the surface morphology of WSe_2 single crystals is a critical factor in determining their performance characteristics in photoelectrochemical cells. Both the photocurrent and photovoltage are dependent on the discontinuities in the surface plane. The application of layer-type semiconductors toward efficient solar conversion devices will depend on the ability to passivate recombination centers located at these surface discontinuities. Halide pretreatment can improve the photoresponse for the oxidation of thianthrene. Surface pretreatments with other electron-donating species may passivate recombination to a larger degree and is under investigation. The correlation of the density of surface states (surface discontinuities) with the observed photopotential lends support to the role of Fermi level pinning (2). Further results are required before an unambiguous relationship can be drawn between the density of surface states and the observed photopotential.

The stability and efficiency of the nonaqueous n-WSe_2/Cl^-, Cl_2/Pt photovoltaic cell confirm the original predictions of Tributsch (5a) on the performance of layered materials.

Semiconductor Electrodes

XXXIV. Photoelectrochemistry of p-Type WSe_2 in Acetonitrile and the p-WSe_2-Nitrobenzene Cell

G. Nagasubramanian and Allen J. Bard*

Department of Chemistry, University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The photoelectrochemical behavior of p-type WSe_2 single crystal electrodes in acetonitrile solutions containing a number of redox couples [*e.g.*, N,N,N',N'-tetramethyl-p-phenylene diamine (+ 1/0), methyl viologen (+ 2/+1), nitrobenzene (0/−1), phthalonitrile (0/−1)] was investigated. For couples with potentials in the bandgap region (*ca.* −0.4 to +1.0V *vs.* SCE), a linear increase of the photopotential with V_{redox} was observed. Couples located at more negative potentials (*i.e.*, above the conduction bandedge) also showed a photoeffect, with the photopotential pinned at ~ −0.95V; this was ascribed to surface state pinning or inversion. A PEC cell of the form p-WSe_2/$PhNO_2$, MeCN/Pt is described. Treatment of the p-WSe_2 electrode with iodide was shown to improve the efficiency of such cells.

In the preceding paper, the behavior of n-type WSe_2 in acetonitrile (MeCN) solutions was discussed (1). WSe_2 and other layer-type semiconductor materials, first proposed by Tributsch for photoelectrochemical (PEC) applications (2), have been extensively investigated recently (3-8). The results with n-WSe_2/MeCN were consistent with a flatband potential of ~ −0.3V *vs.* SCE and the existence of surface states which provide sites for surface recombination and lead to Fermi level pinning. Studies of p-type WSe_2 in MeCN were undertaken to confirm the location of the bandedges in WSe_2 and to ascertain if the behavior of a number of redox couples at this material was consistent with a pinning model.

A second goal of this work was the construction of a PEC cell for conversion of solar to electrical energy utilizing this material. Past research involving PEC cells in nonaqueous solvents such as MeCN have shown that while high stability can often be attained in such systems, the maximum light intensities that can be utilized are often limited by the low concentrations of the electroactive materials in the solution (9). However, nitrobenzene ($PhNO_2$) is miscible in all proportions with MeCN and should be a reasonable oxidant at a p-type semiconductor electrode. Cells with p-WSe_2 and $PhNO_2$ which appear stable and show monochromatic efficiencies ~4% are described here.

Experimental

Chemicals.—Nitrobenzene ($PhNO_2$) was purified following the procedure of Marcoux *et al.* (10). $PhNO_2$ was first passed through an activated alumina column and then vacuum distilled. MeCN was purified as previously described (11). The other redox couples were purified by recrystallization. All compounds were stored inside a helium-filled Vacuum Atmosphere Corporation (Hawthorne, California) glove box. Polarographic grade, tetra-n-butyl ammonium perchlorate (TBAP), dissolved and recrystallized from ethanol, thrice, and dried under vacuum ($<10^{-5}$ Torr) for 3 days was used as supporting electrolyte. The cell employed was a conventional single compartment cell of 25 ml capacity containing the p-WSe_2, a Pt working and counterelectrode and a quasi-reference electrode, which was an Ag wire immersed inside the solution and separated from it by a medium-porosity glass frit. The potential of this electrode was checked against an aqueous saturated calomel electrode (SCE) at regular intervals and was found to be constant. All potentials, unless specified otherwise, are given in V *vs.* SCE.

The p-WSe_2 single crystal generously donated by Dr. B. Miller and Dr. F. DiSalvo, Bell Laboratories, was used as the electrode. This was selected, after carefully verifying under microscope that the surface was quite free of exposed edges. A clean new crystal surface (⊥ C-axis) was produced by attaching adhesive tape and peeling off the surface layer. Gold was electroplated on one side of the pellet and the contact was found to be ohmic. A copper wire lead for electrical contact was attached to the gold-coated side with silver epoxy cement (Allied Product Corporation, New Haven, Connecticut) and was subsequently covered with 5 min epoxy cement. The assembly was mounted into 7 mm diam glass tubing and was held in position with silicone rubber sealant (Dow Corning Corporation, Midland, Michigan), which also served as an effective seal against the seepage of electrolyte solution to the rear of the semiconductor electrode. The exposed area of p-WSe_2 was 0.05 cm^2. The surface of the electrode was etched before use with 12M HCl for 5-10 sec and then rinsed thoroughly with distilled water and dried. The area of the Pt cylindrical wire, used as a counterelectrode, was 0.15 cm^2.

* Electrochemical Society Active Member.

Key words: capacitance, voltammetry, solar cells.

A Princeton Applied Research (PAR) Model 173 potentiostat and PAR Model 175 Universal programmer were used in all experiments, with positive feedback *iR*-compensation employed to compensate for solution resistance and internal resistance of the electrode. The *i-V* curves were recorded on a Model 2000 X-Y recorder (Houston Instruments, Austin, Texas). In solar cell experiments, the photovoltage and photocurrent between the working electrode and counterelectrode as a function of load resistance were measured with a Keithley Model 179 TRMS Digital Multimeter. The light sources were an Oriel Corporation (Stamford, Connecticut) 450W xenon lamp and a 2-mW spectrophysics Model 132 He-Ne laser. Differential capacitance was measured with PAR Model HR8 lock-in amplifier. All of the solutions were prepared and sealed in the glove box and removed for the experiments.

Results

Capacitance plots.—The location of the band energies is often estimated from Schottky-Mott plots of $1/C^2$ *vs.* V, where C is the capacitance of the semiconductor electrode (assumed to be the space charge capacitance) and V is the electrode potential. A typical plot for p-WSe_2 in a 0.1M TBAP/MeCN solution at 10 Hz and 10 kHz is shown in Fig. 1. This behavior was essentially unaffected by the addition of $PhNO_2$ to the solution. Analysis of the plot yields a flatband potential, V_{FB}, of 0.9V *vs.* SCE and a doping level of 4×10^{18} cm^{-3}. From this value and the bandgap energy, E_g of 1.4 eV, the location of the conduction and valence bandedge energies can be estimated, as shown in Fig. 2.

Cyclic voltammetry of various redox couples.—To study the effect of the redox couple in solution, on the behavior of p-WSe_2, the cyclic voltammetric (CV) response for a number of redox couples, in the dark and under illumination was investigated. The couples investigated and their standard potentials are shown in Fig. 2. From the location of the energy levels of these couples with respect to the bandedges, one would predict that a photocurrent for reduction could only be obtained for those with standard potentials in the range -0.4 to $+1.0$V *vs.* SCE (*e.g.*, TMPD/$\overset{+}{\text{TMPD}}\cdot$), if the "ideal" model of the interface applied (12). With this model, dark oxidation of the reduced forms of the couples with potentials above the conduction bandedge (< -0.4V *vs.* SCE), but not those in the gap, is expected. The experimental results for the different couples are summarized in Table I and details for some of these are discussed below. For TMPD (Fig. 3), a

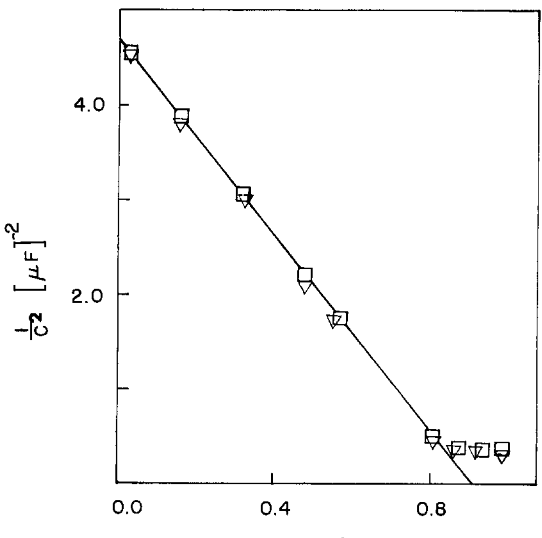

Fig. 1. Mott-Schottky plot of p-WSe_2 in MeCN containing 0.1M TBAP supporting electrolyte: (—□—□—) 10 kHz; (—▽—▽—) 10 Hz.

dark oxidation current is observed beginning at $\sim +0.2$V *vs.* SCE. The onset of photocurrent under chopped illumination, V_{on}, is $+0.55$V which is negative of V_{FB}. Similarly for TPPD, a dark two-step oxidation at potentials only slightly more positive than at Pt is observed and V_{on} for the small photocurrent is $+0.55$V. While these results are consistent with the usual semiconductor electrode model, with the presence of some surface states in the gap region accounting for the dark oxidation at energies above E_V, the behavior for couples above E_C requires the assumption of Fermi level pinning (13) or inversion (14). Consider the behavior of the $PhNO_2$ couple at p-WSe_2. The photoelectrochemical behavior was a function of both the con-

centration of $PhNO_2$ and that of $PhNO_2^{\cdot -}$. A cyclic voltammogram of $PhNO_2$ (0.2M) in MeCN at a Pt electrode (0.15 cm² area) (Fig. 4) shows the well-known wave for the reduction to the radical anion at −1.33V vs. SCE while only a small reduction current is found in the dark at p-WSe_2 (Fig. 4b); a small photocurrent is observed during the first scan (Fig. 4c). This photocurrent greatly increases during the second and subsequent scans under continuous illumination (Fig. 4d).

Clearly the presence of $PhNO_2^{\cdot -}$ in the solution greatly enhances the photocurrent for the reduction as illustrated in Fig. 5 where the effect of chopped illumination in a solution in which anion radicals were generated at the Pt electrode by the passage of 0.27 and 2.3C, is demonstrated. The effect of concentration of $PhNO_2^{\cdot -}$ (produced by electrogeneration) on the limiting cathodic photocurrent is shown in Fig. 6a. The photocurrent rises sharply at $PhNO_2^{\cdot -}$ concentrations up to 0.019 mM and then essentially levels off. The concentration of $PhNO_2^{\cdot -}$ at which this leveling off occurs depends somewhat on the $PhNO_2$ concentration. The magnitude of the maximum photocurrent at a given concentration of radical anion depends on the $PhNO_2$ concentration as shown in Fig. 6b. At low concentrations of $PhNO_2$, the current is limited by mass transfer of $PhNO_2$ to the electrode surface. At higher concentrations, the current saturates at a level governed by the light intensity. For irradiation with the full unfocused output of the 450W xenon lamp, this saturation occurred at ~0.2M $PhNO_2$. With $PhNO_2$ under these conditions, V_{on} was −0.4V vs. SCE; this represents reduction at potentials about 0.9V more positive than those at Pt.

For other couples with standard potentials corresponding to energies above E_C, similar photoeffects and underpotentials are observed (Table I). Note that with these V_{on} shifts more negative, as the standard potential becomes more negative so that the difference $V_{redox} - V_{on}$ is essentially constant at ~0.9V. Such behavior is characteristic of Fermi level pinning or in-

version (13, 14). However, recall that couples at more positive potentials showed a relatively constant value for V_{on}, or a value of $V_{redox} - V_{on}$ which was a function of V_{redox}. The behavior for all the couples is illustrated in Fig. 7 and discussed below.

p-WSe$_2$/PhNO$_2$, MeCN solar cells.—A number of electrochemical photovoltaic cells based on nonaqueous electrolytes have been described (9). A general problem found with such cells for possible application to solar to electrical energy conversion is that the solubilities of the reduced or oxidized species in solution are low and mass transfer to either the semiconductor or counterelectrode limits the current at levels appreciably below those corresponding to the incident radiation. Since $PhNO_2$ can be mixed in all proportions, with MeCN, and as shown in Fig. 6, its concentration can be adjusted so that the saturation current is controlled by the light flux, photoelectrochemical cells of $PhNO_2$ and p-type semiconductors in nonaqueous solutions are particularly interesting. A two-electrode cell containing a p-WSe_2 photocathode and a Pt gauze (40 cm^2 area) counterelectrode immersed in an MeCN solution containing 0.2M $PhNO_2$ and 0.019 mmoles $PhNO_2^{\cdot}$ was fabricated. The i-V characteristics of such a cell obtained with different load resistances is shown in Fig. 8a. The open-circuit photovoltage was 0.56V and the short-circuit photocurrent was 0.11 mA. From this plot, the fill factor was computed to be 0.56. With this value of fill factor, the overall optical to electrical energy conversion was ~2.0%. The photocurrent as a function of time is shown in Fig. 9. The photocurrent was fairly stable for at least 3 hr, at which time the experiment was terminated. The relatively low efficiency of the cell suggests that recombination processes at the p-WSe_2 surface (*e.g.*, the oxidation of photogenerated $PhNO_2^{\overline{\cdot}}$) are important. Previous studies of n-WSe_2 have shown that exposed edges on the van der Waals surface of the electrode act as such recombination centers and that treatment with I^- or other halide ions appears to passivate these edges (1). Such an iodide treatment is also effective in improving the performance of the p-WSe_2 cell. If the p-WSe_2 electrode is immersed for ~45 sec in MeCN solution of 4 mM tetra-n-butylammonium iodide (TBAI), then removed, rinsed with MeCN, and immersed into the solar cell containing 0.2M $PhNO_2$ and 0.019 mM $PhNO_2^{\overline{\cdot}}$, a much higher photocurrent is observed (vide Fig. 8a). Although the V_{oc} and fill factor are essentially unchanged, this increase in i_{sc} increases the maximum power efficiency (monochromatic) to 4.1%. The effi-

ciency is similarly increased by the direct addition of 3 mM TBAI to the MeCN/$PhNO_2$ solution in the cell.

The behavior of the PEC cell was also studied at higher light intensities by irradiation with the red-filtered light of a 450W xenon lamp or by direct sunlight. The variation of photocurrent and photovoltage as a function of light intensity is plotted in Fig. 10 for a MeCN solution containing 0.2M $PhNO_2$ and 0.02 mM $PhNO_2^{-}\cdot$. The photovoltage and photocurrent increased sharply at low light intensities, but became essentially saturated at higher intensities. Essentially, the same behavior was observed for solution containing 2.0M $PhNO_2$/0.02 mM $PhNO_2^{-}\cdot$ (Fig. 10) which suggests that the saturation of photocurrent at higher light intensities was not caused by limited mass transfer of $PhNO_2$ to the electrode. Hence, the cause of the saturation of short-circuit current is probably recombination at the p-WSe_2 surface. However, treatment with iodide (as in the previous case) produced higher photocurrents and removed the saturation effect. This treatment caused little change in the open-circuit photovoltages. The overall behavior of the intensity of the PEC cell at maximum red-filtered xenon lamp and in sunlight is shown in Fig. 8b. Note that as with irradiation with the He-Ne laser, treatment of the p-WSe_2 with iodide produces a higher photocurrent with only a marginal increase of fill factor and V_{oc}. The overall optical-to-electrical energy efficiency in full sun is ~2% with the iodide-treated electrode.

Discussion

The results of the photoelectrochemical experiments with the various redox couples, shown in Fig. 7, can be summarized as follows. The photopotential, V_{ph}, equal to $V_{redox} - V_{on}$, increases linearly with a slope near one, and then, at a potential near that corresponding to the conduction bandedge (~ −0.4V *vs.* SCE), it levels off at a constant value near 0.95V. Note that this parallels the behavior found with n-WSe_2/MeCN (1), except that for the n-type material the maximum photopotential was smaller (~0.5V) and that the leveling off occurred at potentials about 0.5V negative of the

valence bandedge. The results with n-WSe_2 were consistent with the onset of Fermi level pinning (13) by surface states at energies about 0.5 eV above the valence band. The existence of such states as recombination centers could also explain the low values of V_{ph} found with p-WSe_2 for $TPPD^{+\cdot}$ (*i.e.*, the fact that the line V_{ph} *vs.* V intersects at +0.6V rather than at V_{FB} for p-WSe_2). The leveling at negative potentials for p-WSe_2 could be ascribed to pinning by surface states just below the conduction bandedge, E_C. Such states were invoked to explain recombination in n-WSe_2/MeCN (1). However, because the onset of this pinning occurs at a potential very close to the V_{FB} value of n-WSe_2 (*i.e.*, the conduction bandedge), the inversion model, proposed by Kautek and Gerischer (14) for n-type layered compounds could also apply. In both cases, the injection of electrons, either into surface states or at the surface at energies corresponding to E_C, causes the development of a negative surface charge which then causes changes in the potential drop across the Helmholtz layer. Thus, the pinning effect should occur in the presence of reductants of energies near or above E_C. Recall that the addition of $PhNO_2^{-\cdot}$ greatly promoted the photoreduction of $PhNO_2$ at WSe_2, in agreement with this concept. The effect of the introduction of a reduced form with a redox level energy above E_C to shift the bandedges has been seen previously, *e.g.*, in solvated electron production in liquid ammonia at p-GaAs (15), and with a number of couples at p-GaAs (16) and p-Si (17).

Technical Notes

Moderate Temperature Na Cells

II. Transition Metal Diselenide Cathodes

K. M. Abraham* and L. Pitts

EIC Laboratories, Incorporated, Newton, Massachusetts 02158

Recently we described (1) a moderate temperature rechargeable Na cell which operates at ~130°C and utilizes a β-Al_2O_3 solid electrolyte in conjunction with a transition metal disulfide cathode. In that study, we investigated the cathodic cycling behavior of TiS_2, VS_2, and $Nb_{1.1}S_2$. In our continuing search for suitable cathode materials for the moderate temperature Na cell (1-3), we have made a preliminary evaluation of the suitability of the diselenides, VSe_2 and $TiSe_2$ as rechargeable cathodes. Our findings are presented in this paper. While there have been prior studies dealing with the structural chemistry of the Na intercalates of $TiSe_2$ and VSe_2 (4, 5), very little is known about the reversibility of the intercalation reaction. The available data on the structural chemistry of the Na intercalates of $TiSe_2$ and VSe_2 show that structural changes of the host lattice occur with Na intercalation. An understanding of the effects of these structural changes on cathode rechargeabilities in Na cells is of both scientific and practical interest. Vanadium diselenide has been shown to be a highly reversible cathode in secondary Li cells utilizing nonaqueous solvents (6, 7).

* Electrochemical Society Active Member.

Key words: secondary cell, diselenide cathodes, sodium anode.

Experimental

VSe_2 (99.8%) and $TiSe_2$ (99.8%), obtained from Cerac, Incorporated, Milwaukee, Wisconsin, were used without further treatment. Their x-ray powder pattern agreed quite well with literature data (6). The electrochemical cell incorporating a β-Al_2O_3 tube was of the same type described previously (1, 2). The metal selenide cathodes were fabricated in the form of pressed electrodes from a cathode mix consisting of ~50 weight percent (w/o) MSe_2, 40 w/o Shawinigan carbon (50% compressed), and 10 w/o Teflon, as described previously (1). The electrolyte was a 1M solution of NaI in 1.2-Bis(2-methoxy-ethoxy) ethane, (triglyme) (1). The assembled cell had the configuration

Liquid Na/β-Al_2O_3/Triglyme-NaI/MSe_2

The cells were cycled galvanostaticallly after thermostating them at 130°C (1-3).

Results and Discussion

Na/VSe₂ cell.—The open-circuit voltage (OCV) of the cell at 130°C was 2.32V. A cell was discharged slowly (0.5 mA/cm^2) to determine the capacity of the cathode and the shape of the discharge curve. Typical discharge curves are shown in Fig. 1. Initially, the cell rapidly polarized to 1.7V and the discharge proceeded with a voltage plateau at ~1.6V. The discharge showed a somewhat gradual but definite endpoint to 1.2V when a capacity equivalent to 1 Na/VSe_2 has been achieved. The cell exhibited 100% rechargeability in the first charge performed also at 0.5 mA/cm^2. With repeated cycling, the cathode utilization of ~1 Na/VSe_2 was maintained with 100% recharge efficiency. The cycling data for 24 cycles are shown in Table I. The cycling current from the fourth discharge onwards was maintained at 8 mA (1.0 mA/cm^2) with very little effect on cathode utilization. In some discharges, when the lower cutoff voltage was reduced to 1.0V, an additional capacity was obtained with a second voltage plateau at ~1.15V. While the additional capacity in the lower plateau region was not recharged, the deep discharge did not effect the rechargeability of the capacity in the higher plateau region. Since the electrolyte does not reduce at this lower voltage plateau, the additional capacity may correspond to further discharge of VSe_2 as was observed in the lower voltage discharge of Li/VSe_2 cells (6, 7). We have not investigated this further.

The x-ray powder pattern of the VSe_2 cathode, cycled 24 times and terminated at the end of discharge, exhibited, among others,[1] lines at 7.76 and 6.86Å. These lines agree quite well with the c lattice parameters of Na_xVSe_2 compositions described by Bloembergen *et al.* (5). These authors have identified two structural types in Na_xVSe_2 for $0 < x \leq 1$. In the type I rhombohedral structure, found for $0.5 \leq x \leq 0.7$, the lattice parameters, in the hexagonal description, were $a = 3.48$Å and $c = 3 \times 7.41$Å. In the type II rhombohedral structure, found in $Na_{1.0}VSe_2$, the lattice parameters were $a = 3.73$Å and $c = 3 \times 6.88$Å. In Na_xVSe_2 for $0.8 \leq x \leq 0.9$ a mixture of both type I and type II structures was found. In the region $0 < x \leq 0.5$, a two phase mixture of VSe_2 and type I Na_xVSe_2 was present together. The x-ray data of our cycled cathode show the presence of Na_xVSe_2 compositions with both the type I and type II structures. The data indicate also that the cycling reactions involve Na intercalation and deintercalation as shown in Eq. [1]

$$VSe_2 + xNa^+ + xe^- \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftharpoons}} Na_xVSe_2 \quad [1]$$

[1] Many of the expected lines in the x-ray pattern were absent due to interference from the carbon and Teflon present in the electrode. Other lines observed were at 3.41, 3.01, 2.68, 2.63, 2.34, 2.08, and 2.0Å.

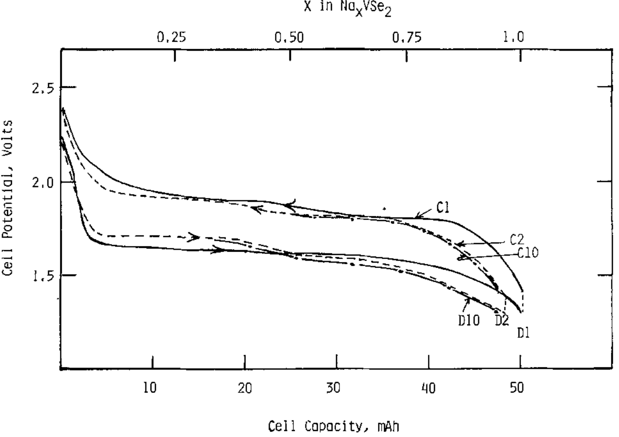

Fig. 1. Galvanostatic discharge and charge curves of the cell, liquid Na/β-Al_2O_3/triglyme, NaI/VSe_2 at 130°C. Curves D1, D2, and D10 are the 1st, 2nd, and the 10th discharges and curves C1, C2, and C10 are the corresponding charges. Current: 4 mA for the 1st and 2nd cycle; 8 mA for the 10th cycle.

A break in the discharge curve, which becomes more pronounced in the second discharge and thereafter, is observed at $Na_{0.48}VSe_2$. In agreement with the work of Bloembergen *et al.*, the first plateau in the discharge may correspond to the two phase region of VSe_2 and type I Na_xVSe_2. In the second plateau then, the discharge involves further Na intercalation into the Na_xVSe_2 phase(s) and both type I and type II phases may coexist at high values of x. Unlike the VS_2 cathode where the rechargeability was limited to the Na compositional range $\sim 0.3 < x \leq 1.0$ (1), the VSe_2 cathode is reversible for the entire range of $0 < x \leq 1.0$. In Na_xVS_2, the phase at $x < 0.3$, is a second state compound in which Na occupies every other layer. The Na in this phase becomes irreversible as cycling continues. Such a phase is absent in Na_xVSe_2 and may explain the superior reversibility of VSe_2.

Preliminary data on the rate capability of VSe_2 was obtained from the potentiostatic discharge of a cathode held at 1.3V *vs.* Na^+/Na. A capacity of 0.72 Na/VSe_2 was obtained at current densities $\geq$5.0 mA/cm^2. Since the present work was not aimed at optimization of cathode structure, rates considerably higher than these should be possible. The relatively high rate capability of the VSe_2 cathode in Li cells has already been reported (6).

Na/TiSe₂ cell.—The cell had an OCV of 2.29V at 130°C. Some typical discharge curves are shown in Fig. 2. To 1.1V cutoff, a capacity of 1 Na/$TiSe_2$ was obtained in the first discharge. The discharge at 0.5 mA/cm^2 proceeds in two distinct potential plateaus at ~1.75 and ~1.40V. A definite endpoint is reached

Table I. Cycling data for Na/VSe_2 cell at 130°C

Cycle No.	Discharge* capacity mA-hr	Discharge* capacity Utilization, Na/VSe_2	Charge capacity mA-hr	Charge capacity % of discharge

* Current: 4 mA (0.5 mA/cm^2) for cycles 1-3.
: 8 mA (1.0 mA/cm^2) for cycles 4-24.

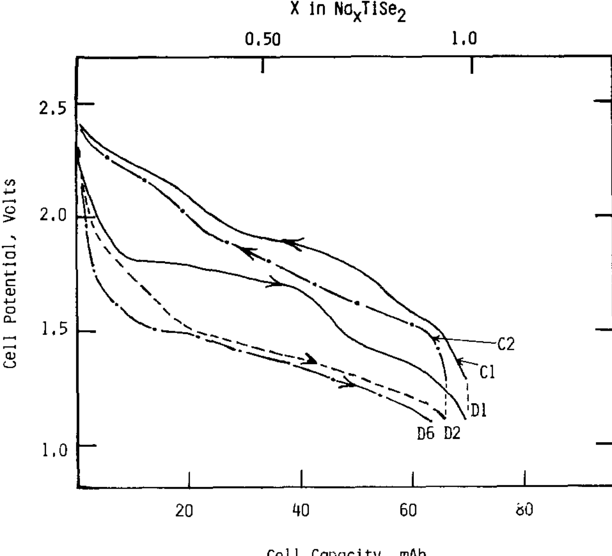

Fig. 2. Galvanostatic discharge and charge curves for the cell, liquid $Na/\beta\text{-}Al_2O_3$/triglyme, $NaI/TiSe_2$ at 130°C. Curves D1, D2, and D6 are the 1st, 2nd, and the 6th discharges and curves C1 and C2 are the 1st and 2nd charges. Current: 4 mA.

after a capacity of 1 $Na/TiSe_2$. The recharge at 0.5 mA/cm^2 was 100% efficient in the first charge. The second and subsequent discharges, however, proceeded at lower potentials than in the first discharge, although the capacity in the sixth discharge was still 0.88 $Na/TiSe_2$ to 1.1V cutoff. Apparently, a structural change of the $TiSe_2$ host lattice occurs in the first cycle with very little change thereafter. X-ray powder pattern of cycled cathodes showed only broad patterns and no useful information regarding mechanisms of cycling reactions or structural changes during discharge was obtainable this way. Nevertheless, the cycling data have demonstrated the reversibility of $TiSe_2$ in Na cells. The discharge of the cathode is accompanied by phase changes and a gross structural change of the host lattice apparently occurs after the first cycle.

In conclusion, we find that VSe_2 is useful as a rechargeable cathode for Na cells. It appears to be suitable for moderate rate applications. The specific energy of the Na/VSe_2 couple based on the observed cell voltage (1.6V) and capacity is 185 W-hr/kg. The performance of $TiSe_2$ is somewhat inferior to that of VSe_2.

Anodic Oxidation of Polysilicon

Pier Luigi Buldini and Quintilio Zini

C.N.R. Istituto LAMEL, Via de' Castagnoli 1, 40126 Bologna, Italy

Donatella Ferri

Istituto Chimico, Facoltà di Ingegneria, Università di Bologna, Bologna, Italy

The electrical characteristics of semiconductor devices are primarily determined by the impurities incorporated into the body of the semiconductor and by their spatial distribution. The widest applied method for determining impurity profiles in semiconductor involves successive measurements following the removal of controlled amounts of semiconductor. Radio-tracer counting (1-2), differential sheet resistivity measurements (1, 3), or chemical methods (4-5) can be used in conjunction with the sectioning to determine the impurity profile.

Semiconductor oxidation followed by etching of the oxide is a very useful technique for sectioning. Removal by anodic oxidation is reproducible, practically does not cause impurity redistribution, and can be carried out in a simple cell without the necessity of any expensive facilities. Several papers appeared dealing with the variables affecting anodic oxidation of silicon (6-8). Due to increasing interest in polysilicon technology, this paper makes a comparison between mono- and polysilicon anodic oxidation.

Key words: spectrophotometry, analysis, silicon, profiles.

Experimental

Mechanically polished n- and p-type silicon slices of different resistivity and orientation were used. In order to obtain a significant comparison between mono- and polysilicon anodic oxidation, a number of slices having the same characteristics were selected from each of the ingots. A number of slices belonging to each selected group were analyzed for monocrystalline data and on the remaining slices, polysilicon was chemical vapor deposited and analyzed. Chemical vapor deposition was performed at 650°C with anhydrogen flux of 62 liters/min and a silane flux (5% in hydrogen) of 280 ml/min, if measured at room temperature and atmospheric pressure. For avoiding polysilicon inhomogeneities, 2000Å layers were deposited and their thickness was checked by masking a small side area in order to provide a reference surface and then measuring

the resulting step. Polysilicon grain size was found to be about 100Å.

The slices were carefully cleaned in trichloroethylene-acetone-methanol (9), and just before anodizing they were etched in 10% hydrofluoric acid for about 10 min, rinsed in running doubly distilled water, and blown dry. A 3000Å thick aluminum layer was evaporated onto the back of the wafer to ensure a good uniform electrical contact.

An Electronic Measurements, Incorporated, Regatron C633CM power supply, capable of delivering 300 mA at 500V, was used to power the cell. A projection lamp was used to provide sufficient and uniform intensity of illumination (15 mM cm^{-2}) of the sample. The cathode was a stainless steel ring situated as shown in Fig. 1 in order not to impede both the continual mixing of the solution and the illumination.

Anodization was carried out at constant current (corresponding to about 4 mA cm^{-2} of slice surface) and variable voltage in an electrolyte of ethylene glycol containing 0.05M potassium nitrate and 10% of water (4, 8). The cell was kept at room temperature (20°-23°C). The range of oxide layers grown were sufficient to consume 50-400Å of silicon.

After the predetermined net forming voltage was reached, the electrolyte was removed and the cell was rinsed in running doubly distilled water. The wafer surface was scrubbed lightly during the rinse to ensure complete removal of the ethylene glycol. Any ethylene glycol residues prevent uniform removal of the oxide. After the oxide removal as described below, the cell was again rinsed in doubly distilled water and blown dry. Another oxidation step could now take place. During multiple runs, the electrolyte was rejected after every oxidation in order to avoid changes in the electrolyte characteristics.

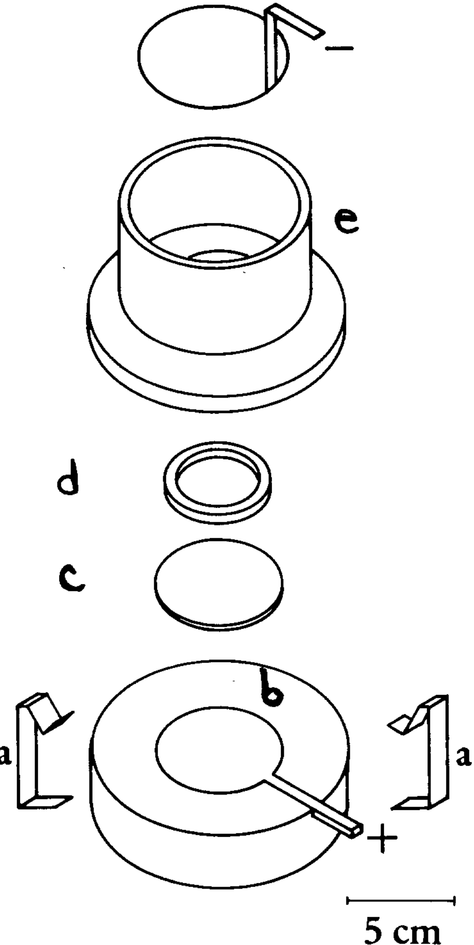

Fig. 1. Anodization cell (a—clamps, b—insulator, c—silicon slice, d—silicone packing, e—Plexiglas upper part of variable size according to the oxidized area).

A method for accurately measuring the thickness of silicon removed during anodization was previously reported (4). The method is based on the spectrophotometric determination of silicomolybdic complex when reduced to molybdenum blue and in the described conditions it is not subject to phosphates interference.

Normal precautions for trace analysis were taken throughout and polyethylene vessels and volumetric equipment were exclusively used to avoid any silica contamination.

The oxide removal was obtained by pipetting 1 ml of 0.1M hydrofluoric acid onto the slice surface and after 10 min (in order to assure the complete dissolution of the oxide) 5 ml of sulfuric acid solution, containing 1.25 ml of concentrated sulfuric acid per 100 ml of solution, were added to the cell. The solution was then transferred to a polyethylene volumetric flask and the cell was washed 2-3 times with 5 ml of doubly distilled water each time, and these washings were transferred to the same flask. 5 ml of ammonium heptamolybdate solution, containing 1.6g $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ per 100 ml H_2O, were added to the flask and after 6 min (in order to assure a complete molybdosilicic acid formamation) 5 ml of a 10 mg Fe(II) ml^{-1} reducing solution [prepared by dissolving 70g of iron(II) ammonium sulfate in 1000 ml of 1.25% sulfuric acid solution] and 5 ml of sodium fluoride solution, containing 2.4g NaF per 100 ml H_2O, were also added. After diluting to 50 ml with doubly distilled water, the absorbance of this solution was read at 828 nm against water. Spectrophotometric measurements were performed on a Perkin-Elmer Model 554 spectrophotometer.

A calibration curve was prepared by adding aliquots of standard silicon solution to 1 ml of 0.1M hydrofluoric acid solution and proceeding as above. The calibration curve is linear and reproducible from 10 μg Si $liter^{-1}$ to 800 μg Si $liter^{-1}$. The method permits determinations as low at 10 μg Si $liter^{-1}$, with a standard deviation better than ±4%. When using a cell having an anodization area of about 5 cm^2 (*i.e.*, 25 mm diam), a thickness of 5Å of silicon can be determined. When using this method it is not necessary to remove the wafer from the cell, so it is possible to easily monitor the progress of the anodization from run to run.

To check the uniformity of oxidation and the removal of the surface layers, the physical profile of the treated surface was tested with a Talysurf 10 (Rank Precision Industries, Leicester, England); the obtained results agree within a few percent with those obtained via the chemical method.

Results and Discussion

The different rates for monocrystalline silicon anodic oxidation as a function of dopant type, resistivity, and crystalline orientation are shown in Fig. 2. Every reported datum represents the mean value with standard deviation of sixty analyses on each of 5-7 samples for net forming voltages of 50, 100, and 150V. Data obtained on "reference" monocrystalline slices (Fig. 2) and those coming from the deep oxidation of the monocrystalline substrate of the polysilicon samples (not shown) were found equal. It can be seen that crystalline orientation does not seem to influence the anodic oxidation, as previously reported (8), while the conductivity type and resistivity (especially for the n-type) do influence anodic oxidation rate.

Figure 3 shows a comparison between mono- and polysilicon anodic oxidation rates. In spite of the fact that the polycrystalline silicon is undoped, the substrate seems to influence anodic oxidation especially at low dopant concentrations. Reported data do not take in account the mono-/polysilicon interface zone, where the anodic oxidation shows intermediate char-

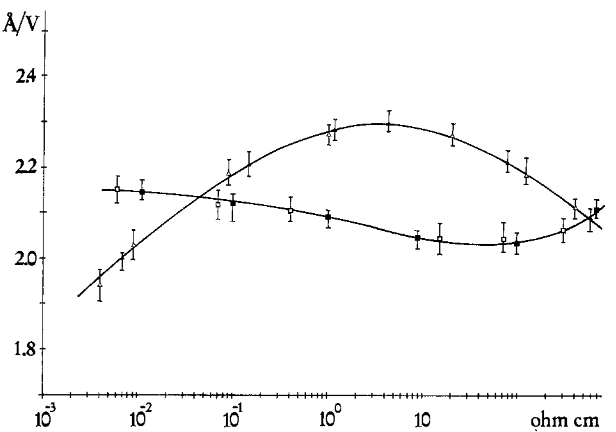

Fig. 2. n- and p-type monocrystalline silicon anodic oxidation rates: ▲ n-type Si(111), △ n-type Si(100), ■ p-type Si (111), □ p-type Si(100). Conditions as reported in the text.

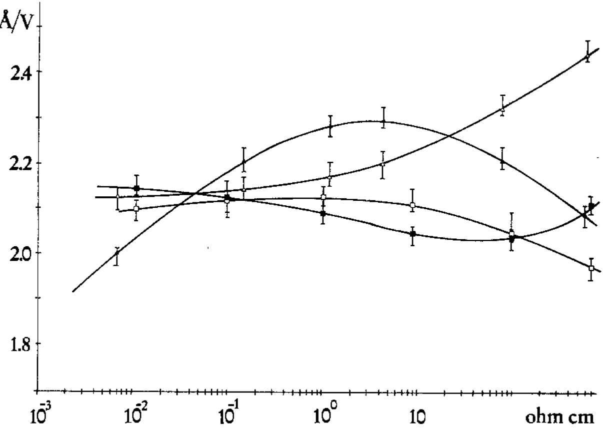

Fig. 3. n- and p-type monocrystalline and polycrystalline silicon anodic oxidation rates: ▲ n-type Si(111), △ polysilicon on n-type Si(111), ■ p-type Si(111), □ polysilicon on p-type Si(111). Conditions as reported in the text.

acteristics with respect to poly- and monocrystalline regions.

Another interesting feature, especially when performing automatic anodic oxidation, is the behavior of the initial drop voltage across the cell. Because the initial drop voltage depends on the electrolyte/wafer contact resistance, it is expected to increase with the wafer resistivity. This fact is confirmed for monocrystalline silicon, while polycrystalline silicon is influenced by the substrate resistivity and moreover shows the same behavior both on p- and n-type substrate. Figure 4 shows the initial voltage drop variation both for mono- and for polycrystalline silicon as a function of silicon resistivity.

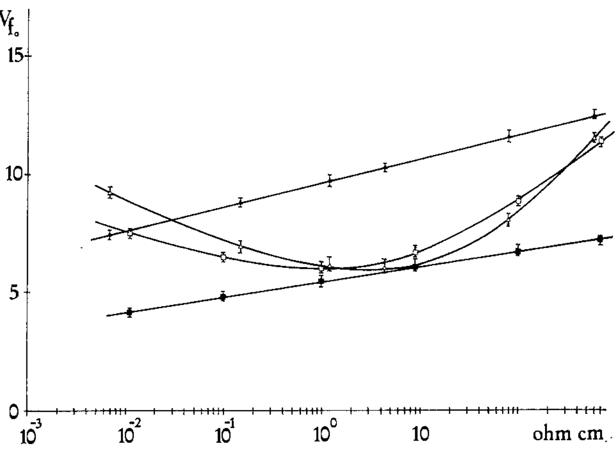

Fig. 4. n- and p-type monocrystalline and polycrystalline silicon initial drop voltage: ▲ n-type Si(111), △ polysilicon on n-type Si(111), ■ p-type Si(111), □ polysilicon on p-type Si(111). Conditions as reported in the text.

Preliminary results on amorphous silicon layers, obtained by B^+ and P^+ ion implantation at high dose on monocrystalline silicon, show a similar behavior with respect to polysilicon.

Acknowledgments

The authors wish to thank Prof. D. Nobili for his helpful discussions and the MOS Development Labs of SGS-ATES (Agrate Brianza, Italy), for supplying and checking polysilicon samples.

Manuscript submitted April 25, 1980, revised manuscript received Dec. 5, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

All Dry Lithography Processes and Mechanistic Studies with Poly(methacrylonitrile) and Related Polymers

H. Hiraoka*

IBM Research Laboratory, San Jose, California 95193

ABSTRACT

Poly(methacrylonitrile) and related polymers have been found to be uniquely suited for all dry lithographic processes. The polymer patterns are generated by thermal treatment followed by oxygen plasma removal. Poly(methacrylonitrile) and copolymer(acrylonitrile-methacrylic acid) yield patterns with positive tone, while poly(α-chloroacrylonitrile) provides negative tone patterns. Oxygen plasma etch rate differs for the exposed and the unexposed parts. The polymer patterns, after heat-treatment, become highly CF_4 plasma etch resistant, providing well-defined SiO_2/Si patterns. Thus, with 2 μm thick films of poly(methacrylonitrile) exposed to electron dose of 5×10^{-6} C/cm^2, 1.5-1.8 μm deep SiO_2/Si patterns are generated with high resolution by all dry processes; the resist patterns of 1.5 μm width, depth, and spacing are obtained at 5×10^{-6} C/cm^2 with the wall angle of 65°. Mechanistic studies including EPR, ESCA, and mass spectroscopic measurements were carried out to provide a mechanism.

A dry development process for photoresists and electron beam resists may be an attractive alternative to resists developed by wet methods from points of view including pollution, safety, high process yields, high throughput, and high resolution. Vapor development of poly(olefin sulfones) exposed to electron beams has been reported (1). It is also noted that even poly(methyl methacrylate) showed very shallow troughs after electron beam exposures at a dose of 10^{-4} C/cm^2 (2). Poly(olefin sulfones) and poly(methyl methacrylate) are, however, highly susceptible to plasma degradation and provide poor plasma etch resistance. They are, therefore, not suitable for all dry processes. Thermal development of poly(α-cyanoethylacrylate) has been reported (3); at a dose of 10^{-5} C/cm^2 remaining film thickness of developed areas was about 20% of original film thickness at 160°C. Complete development by oxygen plasma was not attempted, but the wall angle obtained with poly(α-cyanoethylacrylate) was shallow, 35°, making it unsuitable for high resolution work. Recently, Smith and his co-workers reported a plasma developable negative tone photoresist (4). Similarly, Penn reported dry development of a negative tone photoresist (5). However, the nature of their plasma developable photoresists has not been disclosed. Dry development of x-ray resists have also been reported recently (6).

I wish to report here that poly(methacrylonitrile), poly(α-chloroacrylonitrile), and related polymers provide resist patterns, after electron beam exposure, with high sensitivity and high resolution upon dry development. The dry developed resist patterns are highly resistant to CF_4 plasma etching to the same degree as cresol-formaldehyde novolac resin. They thus provide well-defined SiO_2/Si patterns (7). Furthermore, poly(methacrylonitrile) and copolymer(acrylonitrile-methacrylic acid) can be made photosensitive to u.v. light by addition of photoactive compounds like 2,3,4-trihydroxybenzophenone-tris-[naphthoquinone-(1, 2)-diazide-(2)-5-sulfonate]. Their photoimages can be developed by dry methods, but they have only mediocre photosensitivity (8). EPR, ESCA, and mass spectroscopic studies have been carried out to understand the dry development processes for these materials.

Key words: polymers, plasma, etching, integrated circuits.

Experimental

Polymeric materials.—Poly(methacrylonitrile) was obtained from Polysciences, Incorporated. Poly(α-chloroacrylonitrile) was prepared from the monomer using potassium persulfate as a catalyst (9). Copolymers of acrylonitrile-methacrylic acid and of acrylonitrile-methyl methacrylate were synthesized from the freshly distilled monomers using benzoyl peroxide as a catalyst.

Resist film preparations.—The polymers were dissolved in their suitable solvents; poly(methacrylonitrile) in cyclohexanone, the copolymers in 2-methoxymethanol, and poly(α-chloroacrylonitrile) in dimethylformamide. For lithographic studies, a photoactive compound like 2,3,4-trihydroxybenzophenone-tris-[naphthoquinone-(1, 2)-diazide-(2)-5-sulfonate], was added to the polymer solutions at concentrations up to about 20 weight percent (w/o) solid. The polymer films were spin-coated onto silicon wafers to a film thickness of 1-3 μm. The resist films of poly(methacrylonitrile) and of copolymer (acrylonitrile-methacrylic acid) were prebaked at 120°-130°C for 30 min, while the resist films of poly(α-chloroacrylonitrile) and copolymer (acrylonitrile-methyl methacrylate) were prebaked at 90°C for 20 min.

Electron beam exposures.—Electron beam exposures were carried out with a Vector Scan electron beam exposure system in our laboratory. For preliminary re-

sults exposures were conducted with an ISI scanning electron microscope used in conjunction with a micromicroammeter and a lab timer. For the mass spectroscopic studies a Varian Auger scanning electron gun was used at a current level of 5 μA; mass spectra were taken with a UTI quadrupole mass analyzer (10). The gaseous products formed during the thermal treatments were studied with a Hitachi-Perkin Elmer mass spectrometer.

U.V.-light exposures.—U.V.-light exposures for photoimage generation were carried out with a medium pressure mercury lamp and a photomask which cuts off the shorter wavelength light below 3000Å. The exposure times required for dry development appear to be 3-4 times longer than for the conventional wet development.

Thermal development.—Thermal development of the polymer patterns was carried out both in vacuum and in air at 150°-200°C for poly(methacrylonitrile), and at 100°-200°C for copolymer(acrylonitrile-methacrylic acid). The copolymer required much shorter times and lower temperature for thermal development than poly(methacrylonitrile). The presence of air during the thermal development did not influence the development at temperatures below 180°C. At higher temperatures some deterioration took place in unexposed parts of the resist films. The exposed samples were kept in air without any appreciable deterioration for a few weeks at room temperature prior to thermal development.

Plasma development and etching.—The wafers with thermally developed polymer patterns were placed in oxygen or CF_4 plasma; in the plasma the gas pressure was about 100 Pa, and the sample holder had a bias potential of -45V. After the plasma development, SEM pictures of polymer patterns were taken with an ISI Super II scanning electron microscope. For SiO_2/Si patterns the wafers with resist patterns were exposed to a CF_4 plasma for several minutes; then, the wafers were again exposed to an oxygen plasma to remove the remaining resist films. The SiO_2/Si patterns thus obtained were photographed with the SEM.

EPR study.—Powders of the polymer samples were sealed in a quartz tube in vacuum for EPR measurements. The electron beam exposures were carried out at liquid nitrogen temperature through a thin aluminum window with a Febetron, pulsed electron beam systems of Field Emission Corporation, which operated at 600 keV. The EPR spectra were taken with a spectrometer operating in the X band.

ESCA study.—ESCA measurements were carried out at room temperature under a vacuum better than 4×10^{-7} Pa using a Hewlett-Packard 5650B ESCA spectrometer which had resolution better than 1 eV. The samples were flooded with thermal electrons during the data collection to neutralize the charge effect. The reported binding energies were referenced to the $Au_{4f7/2}$ transition at 83.9 eV used to calibrate the instrument.

Results

Lithographic Studies

Poly(methacrylonitrile).—Typical results obtained with poly(methacrylonitrile) are presented in Fig. 1. After electron beam exposures at doses of 1×10^{-5}, 5×10^{-6}, and 1×10^{-6} C/cm^2, the wafers were heated at 155°-200°C for 20 min to 3 hr. Figure 1(a) shows the polymer patterns developed by 3 hr heating at 155°C, and Fig. 1(b) presents the polymer patterns obtained by 20 min heating at 200°C; in both cases the electron beam dose was 5×10^{-6} C/cm^2. These pictures demonstrate that the 1.5-2.8 μm deep polymer patterns were obtained from original film thicknesses of 2-3 μm without any appreciable thickness loss of the unexposed parts. Figure 1(a) reveals line patterns of

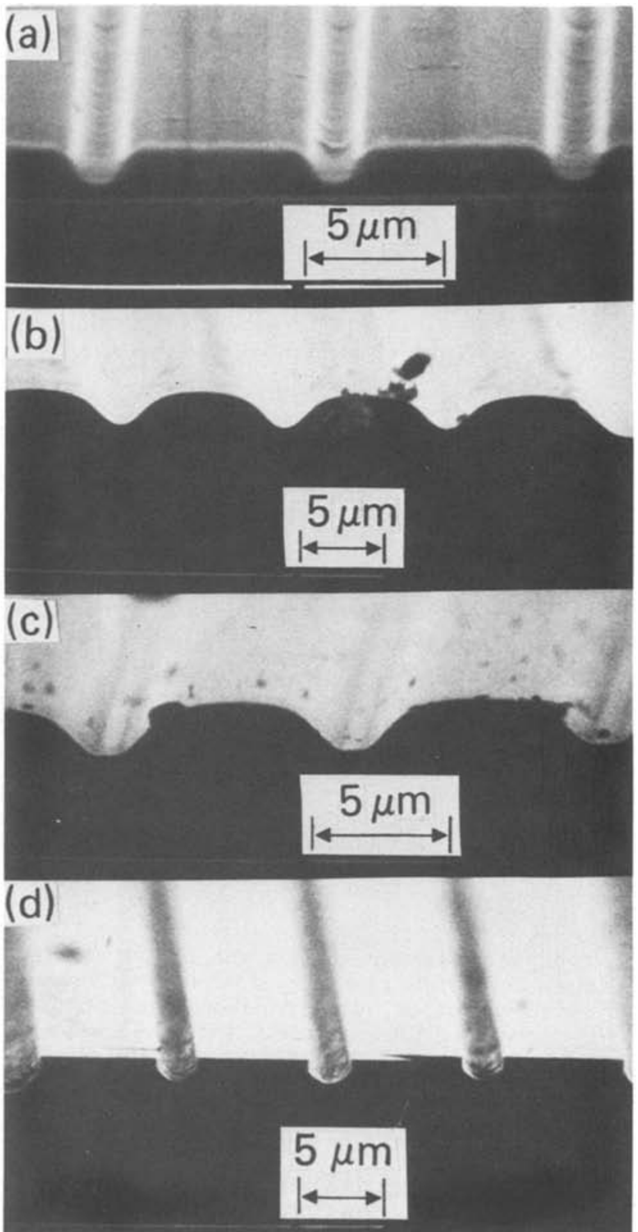

Fig. 1. (a) Thermally developed polymer patterns of poly(methacrylonitrile) after electron beam exposure at a dose of 5×10^{-6} C/cm^2 and heat-treatment at 155°C for 3 hr in vacuum; (b) the same as in (a) except heat-treatment at 200°C for 20 min; (c) oxygen plasma developed polymer patterns of (b); (d) SiO_2/Si patterns obtained by CF_4 plasma etching with (c).

1.5 μm width and depth. Although the lines are 6 μm apart, this spacing may be reduced to about 1.5 μm. The wall angle of the line patterns in Fig. 1(a) is 65°, while the wall angle in Fig. 1(b) is 45°. Clearly high temperature development loses resolution and wall angles. These wall angles obtained with poly(methacrylonitrile) in dry development were steeper than those shown in the SEM pictures reported previously with poly(α-cyanoethylacrylate) (3) and with the plasma developable negative working photoresist (4).

Wafers with thermally developed polymer patterns were placed in the oxygen plasma for about 5 min in order to completely develop the images. The resulting polymer patterns from the ones in Fig. 1(b) are shown in Fig. 1(c). The electron beam exposed area had 1.6 times faster oxygen plasma etch rate than the unexposed area. A similar observation was reported previously (11). The comparison of Fig. 1(b) with Fig. 1(c) indicates that there is no change in the wall angle after the oxygen plasma exposure.

In order to transfer polymer patterns to SiO_2/Si substrate layers, the wafers with completely developed polymer patterns were placed in the CF_4 plasma for about 20 min. In order to remove remaining polymer layers, the wafers were placed again in the oxygen plasma for about 5 min. The SiO_2/Si patterns thus obtained are shown in Fig. 1(d). From the loss of the polymer film thickness and the depth of the substrate patterns obtained the relative etch rate of the silicon to the polymer layers in the CF_4 plasma is calculated to be 1.3. In our CF_4 reactive ion etching condition with −500V bias potential the relative etch rate of the heat-treated poly(methacrylonitrile) to cresol-formaldehyde novolac resin is 1.2. Vertical walls of the SiO_2/Si patterns shown in Fig. 1(d) indicate that the polymer becomes highly etch resistant during the CF_4 plasma exposure.

With a higher dose of electron beams thermally developed polymer patterns have a steeper wall angle, as described in more detail with copolymer(acrylonitrile-methacrylic acid).

Poly(methacrylonitrile) yields positive acting polymer patterns upon conventional wet development after electron beam exposure and has a sensitivity of about 1×10^{-5} C/cm^2 (12). The wall profiles of the developed polymer patterns of poly(methacrylonitrile) were not vertical with either dry or wet development. This is also apparent in the x-ray exposed films (12).

With addition of a photoactive compound to poly(methacrylonitrile) the polymer films become u.v.-light sensitive. They can be developed in a completely dry process as shown in Fig. 2. Here, the photoactive compound used is a diester of dihydroxybenzophenone with 1,2-diazo-naphthoquinone-5-sulfonic acid. More recent experiments show that the triester is the best suited for this dry development, followed by the diester; the monoester is the least sensitive for the dry development. The photoactive compound was admixed as 20 w/o solid, and the mixture was dissolved in cyclohexanone. The dry developed photoresist is not very sensitive; it took exposure times four times longer than a conventional wet development of AZ 1350J.[1] The thermal image development was carried out at 200°C for 20 min, resulting in 0.5 μm deep patterns as shown in Fig. 2(a). The resulting polymer patterns were completely developed in an oxygen plasma.

These experimental results indicate that the photosensitivity for dry development is derived from decomposition of the photoactive compounds exposed to u.v. light. Insofar as host resins do not thermally flow or decompose and are CF_4 plasma etch resistant, any resin making uniform films with the photoactive compound may become a dry developable photoresist. AZ 1350J becomes a dry developable positive working photoresist when the resist films are heated at 180°C for 15 min. AZ 2400[1] did not develop polymer patterns even though the resist films were treated exactly in the same way as AZ 1350J. The difference between AZ 1350J and AZ 2400 is clearly due to different photoactive compounds used. When copolymer(acrylonitrile-methacrylic acid) is admixed with 2,3,4-trihydroxybenzophenone-tris-[naphthoquinone-(1,2)-diazide-(2)-5-sulfonate], the resist films become a dry developable positive tone photoresist like AZ 1350J and poly(methacrylonitrile) admixed with the photoactive compound.

Copolymer(acrylonitrile-methacrylic acid).—Three different monomer ratios were used for the copolymer synthesis; [acrylonitrile]/[methacrylic acid] = 0.13/0.87, 0.5/0.5, 0.65/0.35. The polymerization was carried out at 60°-65°C. The polymer formed was dissolved in 2-methoxymethanol, filtered, reprecipitated in cyclohexane. The resist films were spin-coated from a 2-methoxymethanol solution onto silicon wafers and prebaked at 130°C for 30 min prior to electron beam exposures.

[1] Shipley Company Trademark.

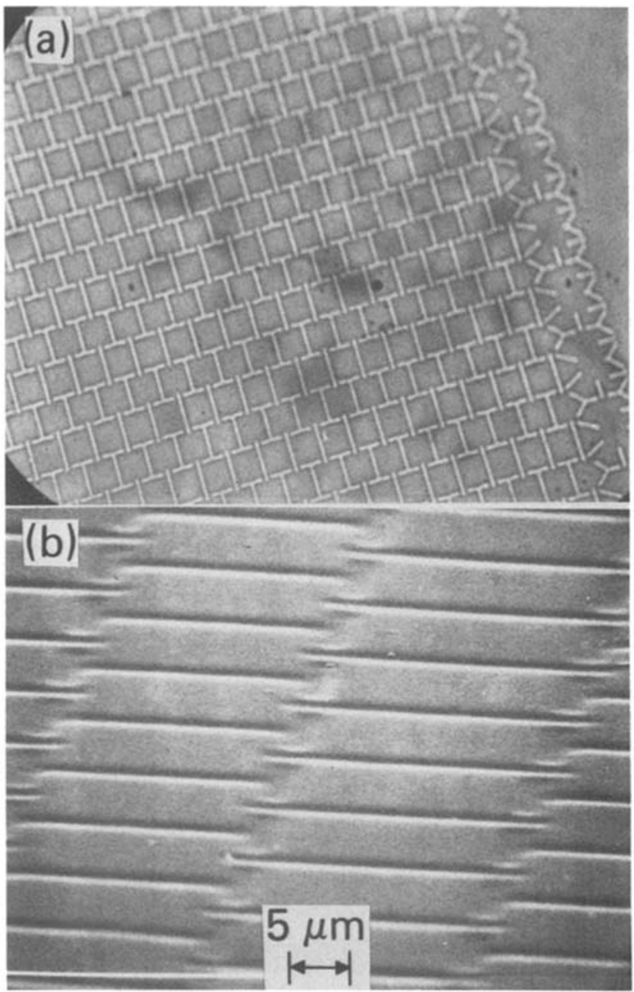

Fig. 2. All dry photolithography with a photo-sensitized poly-(methacrylonitrile) which contains a diester of dihydroxybenzophenone with 1,2-diazo-naphthoquinone-5-sulfonic acid; (a) polymer patterns, (b) SiO_2/Si patterns obtained with (a).

Among the copolymers with three different monomer ratios the equimolar copolymer is found to be the best suited for dry development. The copolymer with the higher methacrylic acid fraction does not have sensitivity for dry development, while the copolymer with the excess acrylonitrile fraction tends to have thermal flow in dry development at 100°-200°C. The polymer patterns of the equimolar copolymer shown in Fig. 3 were developed by 10 min heating at 200°C in vacuum. A steep wall angle can be obtained at high electron beam dose but the angle decreases markedly with decreasing dose; 73° at 1×10^{-5} C/cm^2 [Fig. 3(a)], 45° at 5×10^{-6} C/cm^2 [Fig. 3(b)], 15° at 1×10^{-6} C/cm^2 [Fig. 3(c)]. The SiO_2/Si substrate patterns were generated from these polymer patterns in the same way as described for poly(methacrylonitrile).

A copolymer of methyl methacrylate and acrylonitrile with the acrylonitrile content below 14% is reported to have a high electron beam sensitivity for conventional wet development (13). We observed that this copolymer(methyl methacrylate-acrylonitrile) was not suited for all dry processes because the resist films cannot stand in the CF_4 plasma; besides, depth of the developed resist patterns was shallow, although the images were recognizable even at 1×10^{-6} C/cm^2 due to color change caused by thermal treatment at 150°C.

Poly(α-chloroacrylonitrile).—The resist films of poly(α-chloroacrylonitrile) gave negative working polymer patterns upon electron beam exposure and dry development. For a dose of 6×10^{-6} C/cm^2 of 25 keV electrons, this material yielded relief images of

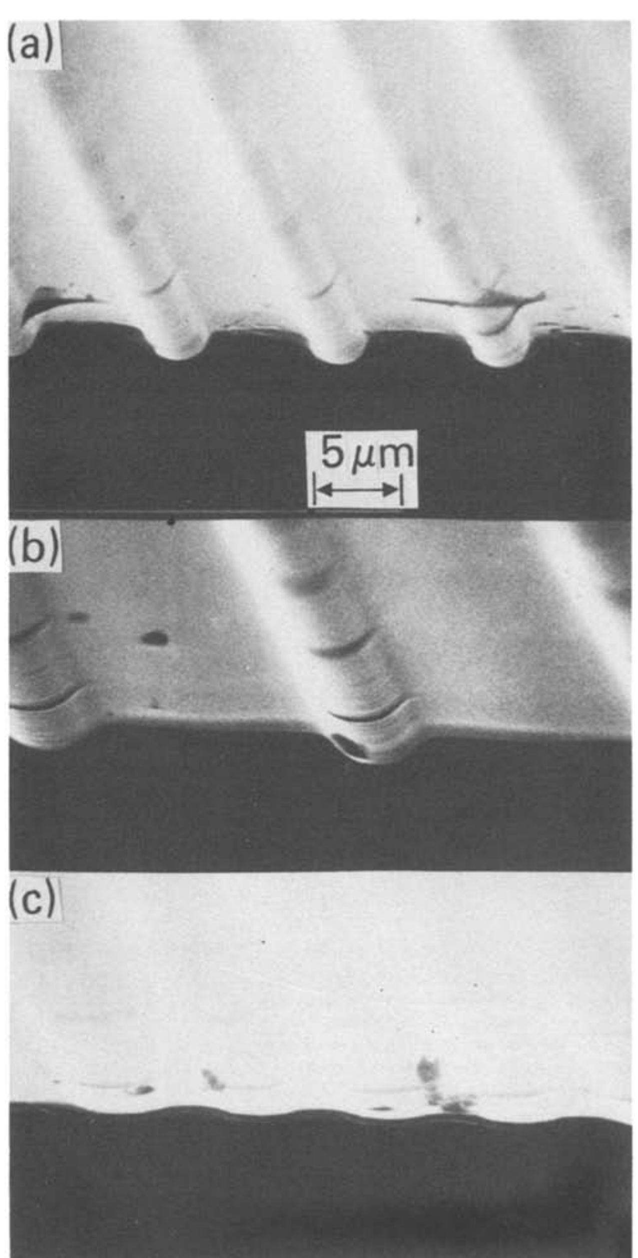

Fig. 3. Thermally developed polymer patterns of copolymer-(acrylonitrile-methacrylic acid) after heat-treatment at 200°C for 10 min; electron beam doses: (a) 1×10^{-5} C/cm^2, (b) 5×10^{-6} C/cm^2, (c) 1×10^{-6} C/cm^2.

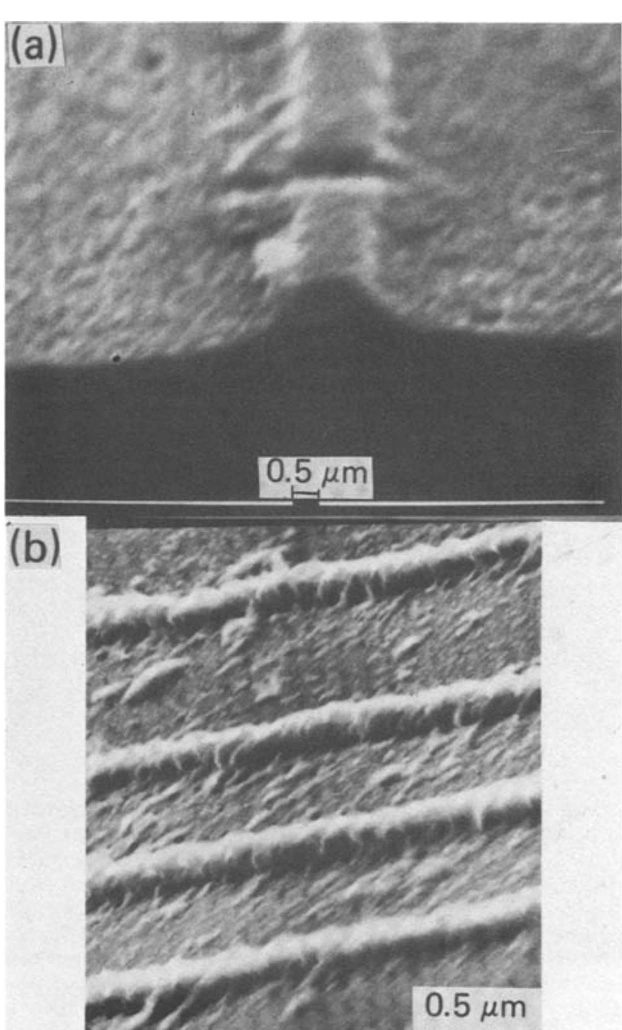

Fig. 4. (a) All dry processed SiO_2-Si patterns with poly(α-chloroacrylonitrile) after electron beam exposure at 6×10^{-6} C/cm^2, heat-treatment at 150°C for 20 min in vacuum, and subsequent oxygen and CF_4 plasma treatments; (b) polymer lines of poly(α-chloroacrylonitrile) after baking at 800°C for 40 min in vacuum; patterns were generated by wet development in aqueous acetone.

0.5 μm height after post-baking at 150°C for 20 min in vacuum. With this relief image of the resist film subsequent CF_4 plasma etching gave SiO_2/Si patterns of 1.5 μm height, as shown in Fig. 4(a). This result indicates either relatively higher etch resistance in the exposed parts than in the unexposed parts, or stronger etch resistance of the resist films over SiO_2/Si substrates.

We have already reported our ESCA studies of structural changes of poly(α-chloroacrylonitrile) and poly(acrylonitrile) upon u.v.-light, heat, and electron beam exposures (14). In unexposed areas both unzipping and hydrogen chloride elimination reactions took place in the thermal development, while in the exposed areas the conjugated double bond polymer chains are already formed in electron beam induced reactions and unzipping reactions play only a minor role in the development. This difference causes the negative tone resist patterns in the thermal development of poly(α-chloroacrylonitrile).

Poly(α-chloroacrylonitrile) also yields negative working images upon electron beam exposure and conventional wet development (15). Once polymer patterns were formed and post-baked, the lines are extremely stable upon thermal treatment because of the structural changes shown in the following

$$\sim\underset{\displaystyle CN}{\overset{\displaystyle Cl}{C}} - CH_2 \sim \xrightarrow[-\,HCl]{e^-} \sim \underset{\displaystyle CN}{C} = CH \sim \longrightarrow \approx \overset{\displaystyle CH}{C} \quad \overset{\displaystyle CH}{C} \sim$$
$$\sim C \overset{}{\underset{N}{}} C \underset{N}{} \sim$$

Figure 4(b) demonstrates that the polymer lines thus formed from poly(α-chloroacrylonitrile) are extremely stable even at 800°C. Such high heat resistance and consequent high etch resistance are the result of the conjugated ladder-type structure formed from poly(acrylonitrile) and related polymers (16).

Mechanistic Studies

In order to understand the chemical reactions involved in the dry lithographic processes described in the preceding section, we have carried out some mechanistic studies using mass spectroscopy, EPR, and ESCA.

Mass spectroscopic study.—The gaseous products formed during electron beam exposure were studied with a UTI quadrupole mass spectrometer. The mass

spectrum obtained with poly(methacrylonitrile) is shown in the upper line of Fig. 5, while the lower line of Fig. 5 is the background spectrum; mass peaks at 57, 56, 55, 43, 41, 39 are contamination peaks due to cracked diffusion pump oil. Removal of H_2, CH_3, CN, and HCN have clearly been observed. A small amount of carbon dioxide formed may be due to contamination. The gaseous products formed from poly(α-chloroacrylonitrile) during electron beam exposure are H_2, HCl, CN, and HCN, as already described in our previous report (14).

EPR study.—The powder of poly(methacrylonitrile) was irradiated in vacuum with 600 keV electron beam pulses through an aluminum window at 77 K. The free radicals generated were studied at 77 K with an EPR spectrometer. The EPR spectrum obtained with poly(methacrylonitrile) at 77 K is shown in Fig. 6(a). The features of the spectrum can be simulated by superposition of a 6-line spectrum (10G bandwidth, 20.5G coupling constant) and a broad singlet (13G bandwidth), as shown in Fig. 6(b). The 6-line spectrum belongs to a tertiary free radical shown below

$$\bullet C(CH_3)(CN)-CH_2\sim$$

which has an unpaired electron coupled to five hydrogen atoms. The broad singlet spectrum is not due to trapped free electrons; the trapped electrons usually give a sharp singlet signal at G = 2.0023. Although its origin is not clear, it may belong to an unpaired electron attached to the cyano group. The electronegativity of cyano groups is well known. Unlike poly(methyl methacrylate), methyl radicals were not observed, indicating that the CH_3 scission from the main chain may not be important; the CH_3 peak found in the mass spectrum may be due to a fragmentation of monomeric products. As long as air was excluded from the sample, the free radicals having the EPR spectrum shown in Fig. 6(a) are fairly stable; the essential features of the spectrum did not change even if the sample were brought to room temperature.

ESCA study.—ESCA measurements were carried out on thin films of poly(methacrylonitrile), which were exposed to electron beams, or u.v. light, and heat-treated. The core level signals of C_{1s} and N_{1s} are shown in Fig. 7 and 8, respectively. The exposure to u.v. light caused only small changes in the core level signals, as expected from the u.v.-absorption spectrum of the polymer. The u.v.-absorption spectra of the poly(methacrylonitrile) sensitized with the photoactive compounds show only the photo-bleaching of the sensitizer at 310-450 nm upon u.v.-light exposure. Electron beam exposures and heat-treatment, however, caused significant changes in both core level signals. Unexposed films of poly(methacrylonitrile) have two distinct C_{1s} core level signals at 286.5 and 285 eV, which belong to the carbon atom of the cyano group and to the main chain carbons and methyl group carbon, respectively. The loss of the cyano group carbon signal upon electron beam exposure is clearly demonstrated by the C_{1s} core level signals. This is in agreement with the loss of HCN as previously described in the mass spectroscopy study. However, the removal of the cyano group as HCN must be a minor part of its total disappearance, based on the N_{1s} core level signal observed.

The displacement of the C_{1s} core level signals to a lower binding energy indicates an increased electron density on the carbon atom. This is consistent with the formation of olefinic linkages. Electron beam exposure also caused a shift of the N_{1s} core level signal peak to a lower binding energy, although the whole spectrum broadened. As was reported earlier for poly(acrylonitrile) and poly(α-chloroacrylonitrile) (14), the N_{1s} core level signal is shifted to a higher binding energy by 1.5 eV upon cyclization through cyano groups to yield —C=N— linkages. The observed lower binding energy shifts of both core level signals of C_{1s} and N_{1s} indicate enriched electron density on the nitrogen as well as olefinic linkage formation. Subsequent heating of the exposed polymer films caused the shift of the N_{1s} core level signal to higher binding energy as shown in Fig. 8, probably due to cyclization through the cyano groups, while little change of the C_{1s} core level signal of the exposed samples was observed upon subsequent heat-treatment. The broadening of the N_{1s} core level signal at higher energies upon electron beam exposure may indicate an electron beam-induced cyclization to a small degree.

Discussion

The overall reactions of poly(methacrylonitrile) upon electron beam exposure may be summarized below

$$\sim C(CH_3)(CN)-CH_2\sim \;\longrightarrow\; \sim C(CH_3)=CH\sim \qquad [1]$$

$$\longrightarrow\; \sim C(CN)=CH\sim \qquad [2]$$

$$\longrightarrow\; \text{cyclic structure: } \sim C(CH_3)-CH_2-C(CH_3)\sim \text{ bridged by } -C=N-C- \qquad [3]$$

$$\longrightarrow\; \sim C(=C=N\bullet)-CH_2\sim \;\longleftrightarrow\; \bullet C(CH_3)(CN)-CH_2\sim \qquad [4]$$

Reaction [1], [2], and [3] may play only minor roles, and reaction [4] is probably the major reaction of poly(methacrylonitrile) upon electron beam exposure which would lead to an unzipping reaction upon heating. Reactions [1], [2], and [3] result in some residual resist layer in the thermally developed polymer patterns. In Fig. 1 this is about 10%-20% of the original resist thickness.

Different from poly(methacrylonitrile), electron beam exposure of poly(α-chloroacrylonitrile) causes elimination of hydrogen chloride from the main chain

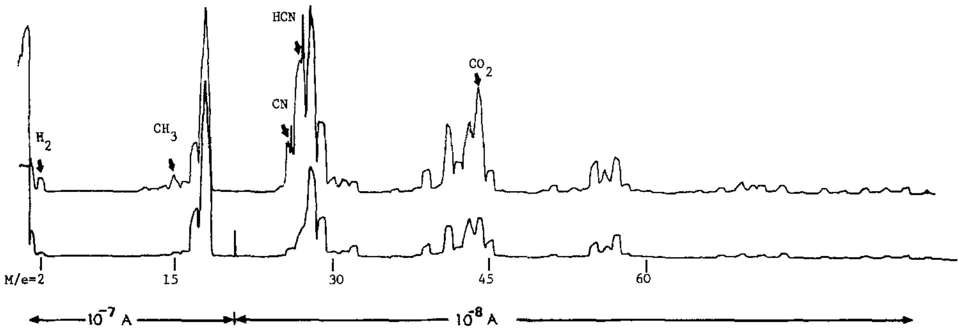

Fig. 5. Mass spectrum of gaseous products formed during electron beam exposure of poly(methacrylonitrile); the upper line is for products, and the background is shown by the lower line.

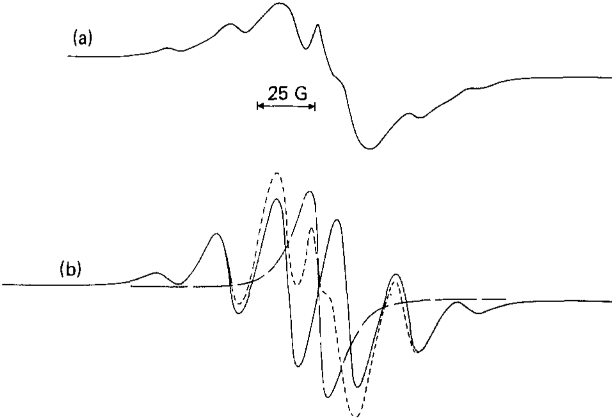

Fig. 6. (a) The EPR spectrum obtained with poly(methacrylonitrile) after electron beam exposure at 77 K in vacuum; (b) the solid 6-line spectrum (10G bandwidth, 20.5G coupling constant) and the solid single-line spectrum (13G bandwidth) are combined together in the dashed line to simulate the experimental spectrum shown in (a).

as the major reaction, resulting in a conjugated double bond main chain; here the main chain scission is a minor reaction. The conjugated main chain thus formed undergoes only cyclization to yield the conjugated ladder-type structure upon subsequent heating. In an unexposed area, however, thermal development causes both elimination of hydrogen chloride and the main chain scission. This difference of the reactions in electron beam exposed areas from unexposed areas causes relief images in the resist films upon thermal development.

Copolymer (acrylonitrile-methacrylic acid) undergoes anhydride formation to a small degree in the prebaking process, as evidenced by appearance of its new u.v.-absorption band at 240 nm. Upon electron beam exposure the main chain scission takes place in both acid and anhydride sections (10). The subsequent thermal development causes an unzipping reaction in electron beam exposed areas, while in unexposed areas the cyclization suggested by Grassie (17) and anhydride formation may occur, resulting in the generation of polymer patterns as shown in Fig. 3.

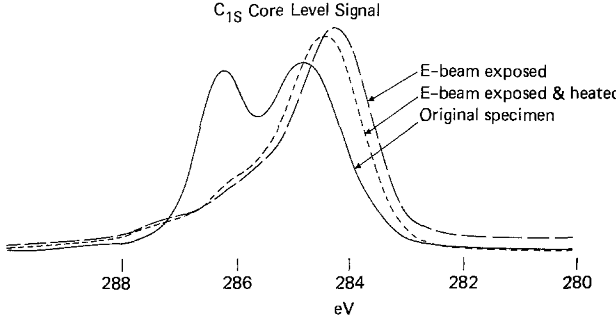

Fig. 7. The C_{1s} core level signals of poly(methacrylonitrile)

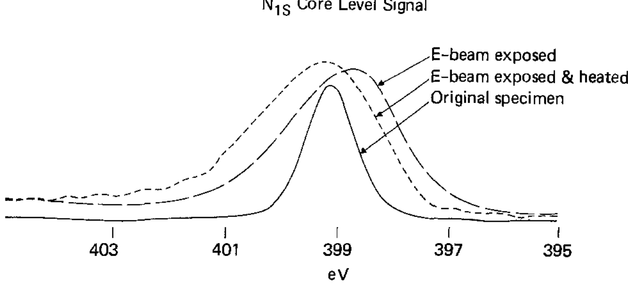

Fig. 8. The N_{1s} core level signals of poly(methacrylonitrile)

With copolymer (methyl methacrylate-acrylonitrile), the main chain scission takes place in the methyl methacrylate section in both electron beam exposed areas and unexposed areas upon heating. This results in only shallow polymer patterns in thermal development. Besides, the methyl methacrylate section suffers severe degradation in a CF_4 plasma.

Conclusions

All dry processes for photo- and electron beam lithography are still in a stage of infancy, although all dry photolithography has been claimed to be in a production stage for specific applications (4). All dry processes are important not only because of possible economic advantages but also because of ecological and safety aspects. Poly (methacrylonitrile) and related polymers appear to have unique properties for use in dry development. After heat-treatment which causes chemical rearrangements of the main polymer chains, the polymer films become highly CF_4 plasma etch resistant and hence are suitable for dry processes. The major problem appears to be the control of the wall profiles of polymer patterns. With high dose and low temperature development steep wall angles can be obtained. The resolution may be limited at present to polymer lines 1.5 μm wide and deep with 1.5-2 μm spacings.

Optical Characterization of Tungsten Silicide Thin Films

M. Delfino* and W. I. Lehrer

Fairchild Camera and Instrument Corporation, Research and Development Laboratory, Palo Alto, California 94304

ABSTRACT

The optical constants of tungsten silicide formed by thermally reacting chemicaly vapor deposited tungsten on <100>, <111>, and polycrystalline silicon substrates are reported. The substrate and thermal annealing temperature, unlike the annealing time, are shown to have a marked effect upon the optical properties of the silicide. The ellipsometric charts necessary for determining the thickness and refractive index of oxides grown or deposited on the silicides are constructed.

Tungsten disilicide (WSi_2) shows considerable promise as a low resistivity electrical interconnect and gate electrode material in integrated circuit technologies. The refractory metal silicide can be obtained by rf diode sputtering (1, 2), *E*-beam co-depositing (3), or chemically vapor depositing (CVD) (4) the metal onto silicon and its subsequent conversion by thermal annealing. For very large scale integrated circuit (VLSI) applications, it is generally necessary to cover the silicide with an oxide layer for stability and controllability requirements. This necessitates that nondestructive methods such as ellipsometry be used for measuring the oxide thickness and uniformity. Consequently, the optical constants of the silicide must be known.

This paper reports measurements of the optical constants of WSi_2 formed by reacting CVD tungsten on single crystal <100>, and <111> substrates and polycrystalline silicon films over the temperature range of 600°-900°C. The dependence of the optical properties on the substrate and on the annealing times is investigated. Finally, the ellipsometric charts used in annealing oxide thickness and refractive index are constructed and are shown to be in excellent agreement with thickness measurements made by selective etching and profilimetry.

Experimental Procedures

Studies were conducted on 3 in. diam wafers of 4-6 Ω-cm, n-type <100>, and 1-5 Ω-cm, p-type <111> Czochralski grown silicon. The samples were etched in 1:10 (HF:H_2O) for 20 sec, rinsed in deionized water, and blown dry with nitrogen prior to tungsten depositions. Polycrystalline silicon was deposited at 600°C at a rate of 375Å min^{-1} to a thickness of 3000Å on 2000Å of thermal oxide prepared by oxidizing the <111> material in dry oxygen at 1000°C. Tungsten films were deposited at a rate of 100Å min^{-1} on all three different substrates maintained at 600° ± 5°C in a Unipak VIII CVD reactor at atmospheric pressure in 80 liter min^{-1} dry hydrogen. For the gaseous tungsten source, a hydrogen flow of 8 liter min^{-1} was passed over resublimed WCl_6 (Alfa) maintained at 170° ± 5°C with a corresponding vapor pressure of 2.3 to 6.2 × 10^{-6} atm. The tungsten depositions on the polycrystalline silicon were performed in the same reactor immediately following the silicon deposition, thus minimizing the effects of a native oxide interface between the tungsten and silicon. Thermal annealing of the films was done in quartz tubes under 3 liter min^{-1} of dry hydrogen for 30 min.

Several methods were employed for characterizing the films. Scanning electron micrographs (SEM) of the cleaved samples and profilimetry using a Dektak after etching were employd to estimate film thickness and to evaluate surface topography. Auger electron spectroscopy (AES) depth profiles were used to establish chemical composition and to verify film thickness. Low-angle x-ray diffraction was done with CuKα radiation using a Phillips diffractometer in order to determine crystal structure. Resistivity was measured by the usual four-point probe method. Ellipsometric measurements were made with a Rudolph Model 436-200E ellipsometer at angles of incidence, ϕ = 70.0° and 75.0°. The light source was a 5 mW He-Ne laser (λ = 6328Å).

Results and Discussion

The 800Å thick tungsten films were found to form silicide layers which were approximately 2000Å thick. The surfaces exhibited a metallic luster and were free of cracks as examined by SEM. AES depth profiles showed a silicon to tungsten ratio of nominally 2:1 throughout the film thickness. In all samples, some oxide $\lesssim$ 20Å was detected at the surface, presumably in the form of a native tungsten-silicon oxide. No other contaminants were found. X-ray diffraction did not show any evidence of crystallinity in the 600°C films corresponding to either tungsten or silicide. At 900°C, the silicides formed on all three substances were identified as the tetragonal phase of WSi_2, space group I4/mmm ($D_{4h}{}^7$) with the lattice parameters a_0 = 3.21, and c_0 = 7.83Å (5). The x-ray diffraction results are summarized in Table I. The relative intensities have

been normalized to the most intense peak, *i.e.*, the (101) reflection of the silicide formed on the polycrystalline substance. Interestingly, the (004) reflection is absent in the silicides formed on the single crystal substrates and the other reflections are significantly less intense relative to that of the polycrystalline substrate. Thus the nature of the crystallinity of the silicide depends on that of the silicon substrate and/or the interfacial native oxide.

The resistivity as a function of annealing temperature is shown in Fig. 1. The annealing time is 30 min. At 800°C and below, the resistivity of the silicides formed on the <100> and <111> silicon substrates is essentially identical, whereas the silicide grown on polycrystalline silicon has a lower resistivity. As this temperature is increased, a change in slope is noted in all three samples suggesting the onset of a phase change resulting in similar resistivities at 900°C. Increasing the thermal annealing time to 120 min had a negligible but decreasing effect on the resisivity values. The resistivity minima of $\sim 3 \times 10^2$ μΩ-cm at 900°C is slightly lower than that reported for sputtered WSi_2 annealed at 975°C for 30 min in nitrogen (2). The lowest resistivity that we have obtained was 2.2×10^2 μΩ-cm for silicide formed at 900°C on the <100> silicon substrate.

The refractive index n, and the extinction coefficient k, were calculated from the ellipsometric paramters ψ (azimuth angle) and Δ (relative phase difference) from the following equations (6)

$$n^2 - k^2 = \sin^2\phi + \sin^2\phi \tan^2\phi \left[\frac{\cos^2 2\psi - \sin^2 2\psi \sin^2\Delta}{(1 + \sin 2\psi \cos\Delta)^2}\right] \quad [1]$$

$$2nk = \sin^2\phi \tan^2\phi \left[\frac{\sin 4\psi \sin\Delta}{(1 + \sin 2\psi \cos\Delta)^2}\right] \quad [2]$$

where ϕ is the angle of incidence. These equations assume an oxide-free surface, an air ambient, and $k > 1$. For transparent surface films less than ~20Å these equations are still valid within experimental uncertainties, if both $n > 1$ and $k > 1$. The single surface reflectivity is obtained from n and k by the relation

$$R = \frac{(n - 1^2) + k^2}{(n + 1)^2 + k^2} \quad [3]$$

The dependence of the measured optical constants on annealing temperature is shown in Fig. 2-4. The error bars reflect the reproducibility of a minimum of three measurements at two angles of incidence on a given sample. The measured optical constants of the as-deposited tungsten on thermal oxide are shown for comparison. These values are different than those reported (7) for bulk single crystal tungsten, presumably because our measurements were done on thin amor-

phous films of tungsten. Based on our data, and the value for the complex refractive index for single crystal silicon of $3.862\text{-}0.0335i$ (8), a silicide reaction appears to have occurred at 600°C on all three substrates. The dependence of the optical constants of the <100> and <111> substrate silicides on annealing temperature is nearly identical, whereas that of the polycrystalline substrate silicide is markedly different. A change in slope is observed as 800°C is exceeded in all three samples, but of opposite sign in the polycrystalline substrate silicide. Increasing the annealing time to 120 min had no effect on the extinction coefficient, and a small essentially negligible decrease on the refractive index. It should be emphasized that these measurements assume homogeneity throughout the film thickness, and are most sensitive to the surface properties, *i.e.*, the light is virtually completely attenuated within the first 200Å. Furthermore, the measured optical constants are found to be essentially invariant with respect to thickness for film thickness > 1000Å.

The ellipsometric chart necessary for determining the thickness and refractive index of transparent films on WSi_2 was constructed from the calculated values of $\bar{\Psi}$ and $\bar{\Delta}$ from the Leberknicht-Lustman relation (9) given as

$$\tan \bar{\psi} \exp(i\bar{\Delta}) = \tan \psi \exp(i\Delta)$$

$$\left\{ 1 - \left[\frac{i4\pi \cos\phi \sin^2\phi\alpha}{\left(\lambda - \frac{\lambda}{\tilde{n}^2}\right)\left(\cos\phi - \frac{\sin^2\phi}{\tilde{n}^2}\right)} \right] \right\} \qquad [4]$$

where $\tilde{n}_2 = n_2 - ik_2$ is the complex refractive index of WSi_2, shown in Fig. 2 and 3, as calculated from the measured ellipsometric parameters ψ and Δ at the wavelength λ. The film property coefficient is

$$\alpha = d^2 - \frac{d^2}{n_1^2} - \frac{n_1^2 d^2}{\tilde{n}_2^2} + \frac{d^2}{\tilde{n}_2^2} \qquad [5]$$

where d is the film thickness of refractive index n_1. If the film is absorbing, then n_1 is complex.

As an example, the dependence of ψ and Δ on the properties of thermal oxide ($n_1 = 1.46$) and vapox (1.44) on WSi_2 annealed at 900°C is shown in Fig. 5. For film thickness less than ~700Å, it is virtually impossible to distinguish between the oxide refractive indexes. The ellipsometric chart when applied to a variety of oxide film thickness was found to be in excellent agreement (±5%) with thickness determination done by selective removal of the oxide followed by profilimetry. In cases where a large number of samples of identical silicide characteristics are employed it was found that removal of the oxide and subsequent measurement of the optical constants of the silicide resulted in accuracies as high as ±1% in film thickness.

Summary

It appears that CVD tungsten on <100>, <111>, and polycrystalline silicon substrates react to form silicides at temperatures as low as 600°C. On the basis of the AES and SEM data the extent of silicide film thickness is invariant with respect to thermal annealing conditions. The silicides are amorphous transforming to crystalline WSi_2 at temperatures exceeding 800°C, but the nature of the crystallinity appears to be enhanced for the silicides on the polycrystalline silicon substrate. This may be a result of the absence of a native oxide at the tungsten silicon interface, since the presence of oxide is known to inhibit the silicide reaction kinetics. For native oxide on <100> silicon, the reaction rate is initially limited to localized nucleation of WSi_2, whereupon formation of a continuous layer of WSi_2, the kinetics become diffusion limited (1). An alternate explanation is that the grain size of the silicon substrate plays an active role in the reaction kinetics. The electrical resistivity and optical properties of the silicides are found to depend strongly on the substrate and thermal annealing temperature but not the annealing time. Construction of the ellipsometric charts proved useful for estimating the thickness and refractive index of oxides on silicides by nondestructive means.

High Resolution Doping Profiles in $Pb_{1-x}Sn_xTe$ Thin Film Structures

D. L. Partin

General Motors Research Laboratories, Physics Department, Warren, Michigan 48090

ABSTRACT

The fabrication of thin laser structures by molecular beam epitaxy has placed stringent demands upon the techniques for characterizing these structures. An electrochemical etch originally developed by Norr is shown to be capable of well-controlled etching of sub-micron dimensions from $Pb_{1-x}Sn_xTe$ surfaces. This allows material parameters, such as the doping level, to be measured as a function of depth.

The application of molecular beam epitaxy (MBE) techniques to the growth of lead-salt diode laser structures has resulted in attainment of micron-dimensioned structures with improved performance (1, 2). However, characterization of the grown layers becomes increasingly difficult as their dimensions become smaller. It is therefore useful to investigate a chemical etching system which has the capability of removing thin layers of these materials in a well-controlled manner. When used successively, it would then enable depth profiles of a variety of material properties to be measured, such as the doping level, defect density, etc.

The etching system investigated in this work was originally developed for use on PbTe by Norr (3). It consists of 45 ml H_2O, 20 ml ethanol, 35 ml glycerol, and 20g KOH. The sample is the anode and the cathode is platinum. This solution does not attack the sample (<0.002 μm/min) with no applied potential. At relatively low voltages ($\sim$1V) it attacks the (100) surface preferentially at defects, and is therefore used to measure dislocation density. At 10V the etching is uniform, producing a polished surface.

This etching system was chosen because it appeared to offer potential for controlling the amount of material removed by controlling the etching time. The other well-known polishing solution for $Pb_{1-x}Sn_xTe$ is a solution of Br_2 in HBr. The material removal rate can be made small ($\sim$0.1 μm/min) by diluting the solutions with water. However, x-ray photoelectron spectroscopy (XPS) studies of PbTe polished with this dilute solution showed that almost all tellurium of the etched layer remains on the surface (4). This makes this etching solution unsuitable for the present purpose.

Experimental Techniques

In this work, 50 ml of Norr etching solution were used in a beaker which was magnetically stirred at 200 rpm. The cell voltage was 10.0V, and the solution temperature was 25°C unless noted otherwise. The samples were mechanically polished single crystals with a (100) orientation. After Norr etching to obtain damage-free surfaces, Apiezon wax was used to coat part of the sample surface. The sample was then etched for a controlled length of time. After removing the wax, the resulting step height on the sample surface was measured with a Sloan Dektak film thickness profiler. In a few cases an interference microscope was used to check the Dektak results, and agreement within 5% was obtained.

Key words: epitaxy, etch, laser, spectroscopy.

Experimental Results

Figure 1 shows the results of etching studies on PbTe doped p-type with Tl to a level of 1×10^{19} cm^{-3}. The initial etch rate is rapid followed by a relatively slow, linear etch rate. The graph and the inset table show that etched depths in the range 0.1-2.5 μm are readily obtained, which covers the range of practical interest.

When a voltage pulse is applied to the sample, a blue film appears in a fraction of a second. This film disappears in roughly 1 sec after the cell potential is reduced to zero, indicating that the film dissolves into the etching solution. However, if the sample is removed from the solution while etching and immediately rinsed with deionized water, the film is still present. Examination of the film with Auger electron spectroscopy in combination with Ar-ion sputtering indicated that the film consists of roughly equal amounts of Pb, Te, and O (Fig. 2). The atomic concentrations were obtained by normalizing the Auger signals by the elemental sensitivity factors which is generally accurate within a factor of 2. The depth scale was approximated by assuming that the sputtering rate in the oxide was the same as that in the PbTe substrate, which was separately determined. Some of the oxide may have dissolved before the etching solution was rinsed from the sample. Other elements were looked for in the film, such as potassium or carbon, but none was found within the instrumental sensitivity (typically 1%).

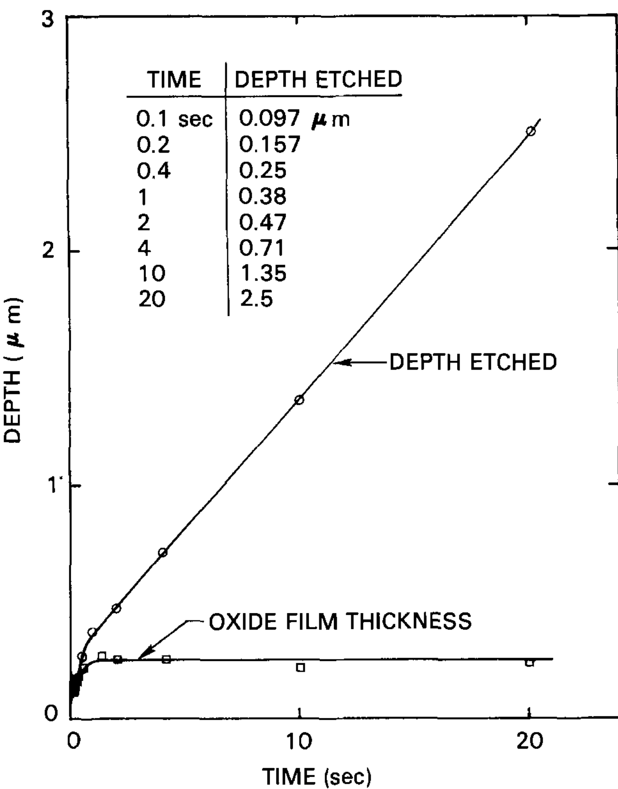

Fig. 1. Calibration curve for PbTe:Tl etched with the Norr etch at 25°C and 10V applied potential.

Thus, when a 10V potential is applied to the film, there appears to be an initial period of rapid oxide film growth. After about 1 sec of film growth, the film interference color observed visually appears to remain constant, implying that the film thickness remains constant. Therefore, growth of the oxide film at the film/substrate interface is occurring at the same rate as dissolution of the film at the film/solution interface.

Film Growth Model

These observations can be made more quantitative with a simple model. The total depth etched, D, after time t is given by

$$D = T + Ct \qquad [1]$$

where T is the oxide thickness and C is the rate of dissolution of the oxide film at the film/solution interface (Fig. 3). Differentiating gives

$$\frac{dD}{dt} = \frac{dT}{dt} + C \qquad [2]$$

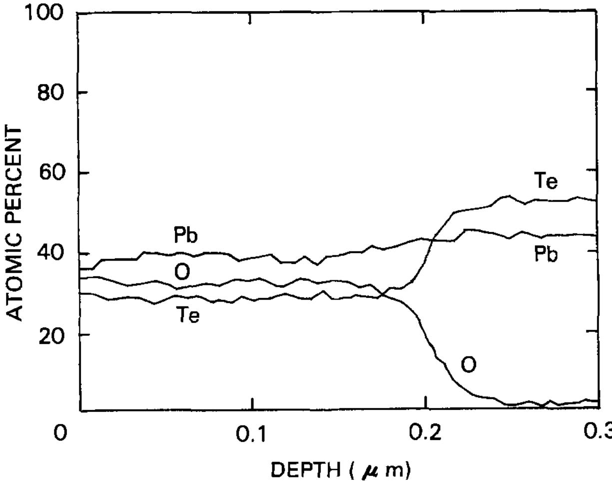

Fig. 2. Auger depth profile of oxide film formed by the Norr etch

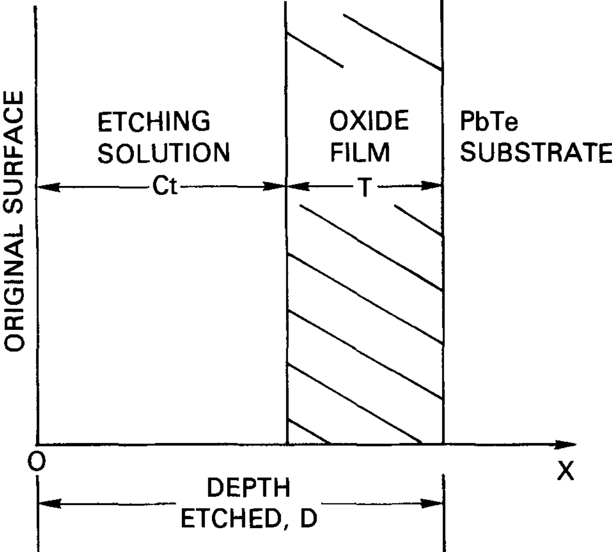

Fig. 3. Schematic showing the total depth etched, *D*, as the sum of the oxide film thickness, *T*, and the depth of dissolved material, *Ct*.

As noted above, the oxide thickness becomes constant after about 1 sec, so that

$$\frac{dD}{dt} = C, \quad t > 1 \text{ sec} \qquad [3]$$

Thus, using the linear portion of the "depth etched" *vs.* time curve in Fig. 1, the constant $C = 1.13 \times 10^{-5}$ cm/sec. Using this value of C in combination with Eq. [1] and the "depth etched" curve of Fig. 1, the oxide film thickness can be calculated as a function of etching time. This data is plotted in Fig. 1, and shows rapid film growth until the thickness stabilizes, as expected. The limiting thickness is 0.25 μm, which is in good agreement with the oxide thickness shown in Fig. 2.

The current which flows through the etching solution is related to the depth etched into the substrate. The number of substrate atoms oxidized per unit area and time is $N_s dD/t$, where N_s is the number density of atoms in PbTe (2.94×10^{22} cm^{-3}). Thus, the current density through the oxide, J, is given by

$$J = qBN_s \frac{dD}{dt} \qquad [4]$$

where B is the average number of electrons required to oxidize PbTe atoms. The oxide species are known to be PbO and TeO_2 (5, 6). Thus, Pb is formally in the +2 valence state in PbTe and PbO, but Te changes from the −2 state to the +4 state, which requires 6 electrons. This implies a theoretical value of 3 for B. For comparison with experiment, Eq. [4] may be expressed in integral form

$$Q = \int_0^t J dt = qBN_s D \qquad [5]$$

where Q is the total charge per unit area which passed through the oxide in time t. Using an oscilloscope, Q was measured *vs.* etching time t. From the known dependence of D on t (Fig. 1), an experimental value of B could be determined. Over the range of etching times from 0.1 to 20 sec, the value of B obtained was 3.4 ± 0.2, which is in reasonably good agreement with the theoretical value of 3 determined above.

Sensitivity to Experimental Variables

The etching results shown in Fig. 2 are for PbTe doped p-type with Tl at a level of 1×10^{19} cm^{-3}. The lead salts can also be doped n-type or p-type by making them metal-rich or chalcogenide-rich, respec-

tively. The etch rate for Pb-rich PbTe ($n = 6 \times 10^{17}$ cm^{-3}) or Te-rich $Pb_{0.86}Sn_{0.14}Te$ ($p = 1.5 \times 10^{18}$ cm^{-3}) was determined for several etching times, and always found to agree with the data for Tl-doped PbTe ($p = 1.0 \times 10^{19}$ cm^{-3}) (Fig. 1) within about 10%. This implies that the etch rate remains constant through a heterojunction or p-n junction in the $Pb_{1-x}Sn_xTe$ system, at least for x in the range 0-0.14, which covers most of the range used in practical devices.

The sensitivity of the etch rate to variations in etching solution composition or temperature is shown in Table I. All data shown is for a 2 sec etch on Tl-doped PbTe. The addition of 20% extra ethanol or glycerol leaves the etch rate essentially unchanged, while water and KOH change it by ~50%. This may imply that OH^- is the species that conducts current through the oxide film and supplies oxygen at the PbTe/oxide interface. It should be noted that hydrogen cannot be observed with Auger electron spectroscopy. Therefore, its presence in the oxide film (Fig. 2) could not be confirmed.

The potassium concentration in the Norr etching solution is very high, and some of it may be left behind on the etched surface. After etching, the samples are rinsed in ethanol, water, dilute nitric acid, and then water. The nitric acid is believed to be effective in gettering the potassium from the surface. This was tested by studying the surface concentration of potassium with secondary ion mass spectroscopy (SIMS), which is extremely sensitive to alkali metals. This technique yields only relative concentrations, but it was found that samples cleaned with the Norr etch and rinsed in the above sequence of reagents had only 2-5% as much potassium on their surfaces as samples which were rinsed in ethanol and water only. This was so even when the sample was rinsed for 3 sec in nitric acid diluted to 0.1 volume percent with water.

The nitric acid rinse also affected the thermoelectric voltage measured on the etched surface of lightly doped samples. PbTe samples ($n = 6 \times 10^{17}$ cm^{-3}) which did not have a nitric acid rinse had thermoelectric voltages which were ~20% lower than samples rinsed in 0.1-1% nitric acid. Since potassium is expected to be an acceptor impurity in PbTe, this probably means that it compensates donors near the surface of PbTe. Thus, the removal of potassium from the surface is necessary if the Norr etch is to be useful for depth profiling of carrier concentrations.

Carrier Concentration Profile

The carrier concentration profile of a diode laser will be shown to illustrate the usefulness of this etching system (Fig. 4). The substrate consisted of PbTe doped p-type with Tl at 2×10^{19} cm^{-3}. A 4.7 μm thick Tl-doped PbTe active region was then grown by molecular beam epitaxy. This was followed by a 0.7 μm thick Bi-doped region. The growth was carried out at 2 μm/hr deposition rate and 350°C substrate temperature. Other aspects of the growth technique are being reported elsewhere (7).

Table I. Sensitivity of etch rate to variations

Variation	Depth in 2 sec (μm)	Normalized depth
Standard (25°C)	0.47	1.00
20% extra water	0.75	1.60
20% extra ethanol	0.50	1.06
20% extra glycerol	0.48	1.02
20% extra KOH	0.66	1.40
35°C	0.77	1.64
45°C	0.91	1.94

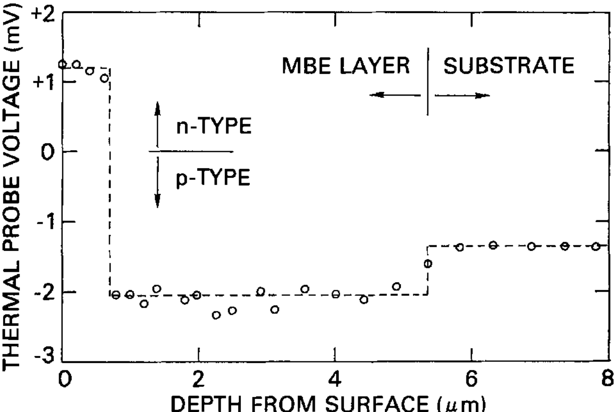

Fig. 4. Thermal probe voltgae as a function of depth through a laser structure.

The carrier concentration is determined from the thermoelectric voltage generated by a metal probe held 9°C above a room temperature contact at the back of the sample. The measurement is repeated after each etching step to obtain the profile shown in Fig. 4. The thermoelectric voltage in the active region corresponds to a hole concentration of $\sim 4 \times 10^{18}$ cm^{-3} at 77 K. The electron concentration in the Bi-doped region is 1×10^{19} cm^{-3}. Of particular interest is the abrupt change in voltage between depths of 0.6 and 0.8 μm. This implies that the measurement technique is capable of 0.2 μm resolution or better, which is adequate to profile micron-dimensioned structures.

Conclusions

An electrochemical etch is shown to reproducibly remove $Pb_{1-x}Sn_xTe$ to depths in the range 0.1-2.5 μm. The etch rate as function of time can be well understood in terms of the formation of an anodic oxide film which is soluble in the etching solution. The etch rate is not sensitive to conductivity type, doping level, or Sn concentration in the range $0 \leq x \leq 0.14$. This makes this etching system useful for depth profiling the doping level of MBE-grown heterostructure diode lasers.

ABSTRACT

We present two developments in low energy ion beam etching. First, we have extended the usable ion energy range for broad beam ion etching down to tens of electron volts by using a single extraction grid of very fine aperture size. High ion current densities (up to 1.0 mA/cm^2) are achieved below 100 eV ion energy while maintaining a collimated beam with low energy spread (about 10 eV). Second, we have applied this capability to reactive ion beam etching (RIBE) of Si and SiO_2 and we introduce a quantitative parameter which characterizes the effectiveness of ion bombardment in enhancing chemical etching. This parameter is obtained from etch rate measurements using Ar and CF_4 gases over the ion energy range 20-1500 eV. Step edge profiles are also examined.

In this paper we present two developments in low energy ion beam etching. First, we have extended the usable ion energy range for broad beam ion etching down to tens of electron volts by replacing the conventional dual grid ion extraction system with a single grid of very fine aperture size. High ion current densities (up to 1.0 mA/cm^2) are achieved at low ion energies (down to 20 eV) while maintaining a collimated beam with low energy spread (about 10 eV). Second, we introduce a quantitative parameter which characterizes the effectiveness of ion bombardment in enhancing chemical etching, the basis of reactive ion etching (RIE). The ion enhancement parameter is obtained from the energy dependence of the etch rates of a material using reactive and inert gases. We have measured the etch rates of Si and SiO_2 with Ar and CF_4 gases over the energy range 20-1500 eV. We find, for example, that in etching SiO_2 with CF_4 at an ion energy of 200 eV, the ion enhancement parameter is about 3, indicating that for each substrate atom removed by physical sputtering, two additional atoms are removed by enhanced chemical etching. Above an ion energy of 500 eV this enhancement parameter decreases to unity, indicating that ion enhancement of chemical etching has reached its maximum effectiveness. These measurements may be used to optimize etch rate selectivity in reactive ion beam etching (RIBE).

We also compared the step edge profiles obtained using CF_4 etching of SiO_2 with those obtained with Ar ion etching. Inert gas ion etching usually leaves sloping walls and may cause trenching and redeposition on mask edges. These problems are minimized by using a reactive ion beam etching process at an energy low enough to cause little physical sputtering. Ion beam systems operate at two orders of magnitude lower pressure than a glow discharge RIE system, reducing the effect of neutrals. The mean free path of ions and etch products exceeds the chamber dimensions, minimizing loading effects, contamination by backscattering, and chemical effects of the sample holder. The ion energy spread is low, and the energy and current density may be independently controlled and measured. These advantages provide an incentive to extend the useful energy range to below 100 eV and to take advantage of the selectivity available with chemically reactive species. These two topics are addressed here, beginning with the limits encountered when the ion energy is decreased.

Key words: reactive ion etching, ion bombardment, etch rate ratio, ion current, space charge, extraction.

Theory—Limit on Ion Current Density at Low Energy

Ion beam etching is usually carried out using broad beam electron bombardment ion sources (1). Figure 1 shows the general configuration. This diagram shows a single extraction grid, whereas typically a dual grid system is used. A low voltage magnetically enhanced discharge is maintained between the thermionic cathode and surrounding anode, and ions are extracted through the grid system to form a directed beam. The ion energy is close to the anode potential V_a. The beam is aimed at the material to be etched, and normally a flow of electrons is supplied from a neutralizer filament to avoid surface charging effects (1). The conventional dual grid configuration is shown in Fig. 2a. In this design the screen grid potential differs from the discharge plasma potential by the magnitude of the discharge voltage V_d, and the accelerator grid is held negative to prevent backstreaming of electrons into the discharge chamber. Further details of operation are given in Ref. (1, 2). These ion sources easily generate ion current densities of 0.5 mA/cm^2 at 500 eV, but such high ion energies may cause device damage, knock-on penetration of contaminants, or intermixing of layers. Lower ion energies are desirable, but below about 100 eV the ion current density is space charge limited to only a few hundredths milliamperes per square centimeter. Since this current density corresponds to less than one tenth monolayer of bombardment per second, practical ion etching cannot be carried out below 100 eV with a dual grid system.

The space charge limit on current flow may be stated as follows. The maximum current density obtainable from an ion source (1) is related to the ion acceleration voltage V and the acceleration distance d by

$$j_{max} \propto V^{3/2}/d^2 \quad [1]$$

In a dual grid system (Fig. 2a) V is the potential difference between the discharge plasma and the accelerator grid, and d is approximately the distance between the plasma sheath and the accelerator grid. To

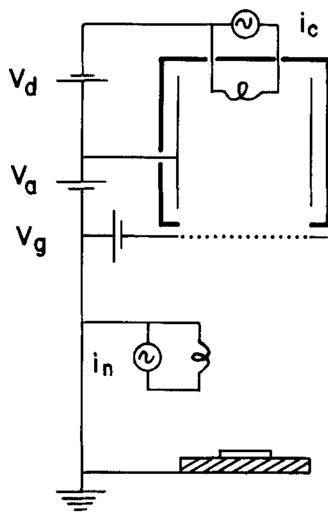

Fig. 1. Diagram of single grid ion source, showing cathode current i_c, discharge voltage V_d anode voltage V_a, grid voltage V_g, neutralizer current i_n, and sample on a grounded holder.

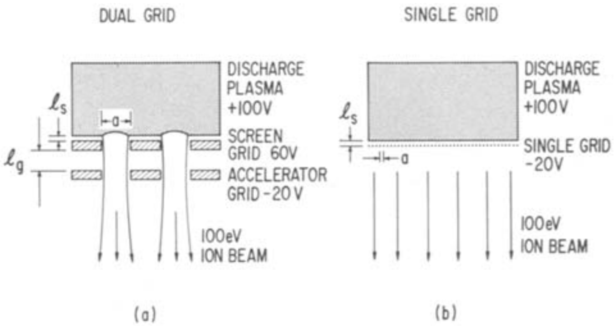

Fig. 2. Comparison of the extraction grid region of (a) dual grid ion source and (b) single ion source, showing the grid aperture diameter a, discharge sheath thickness l_s, grid spacing l_g, and potentials typical for generating a 100 eV ion beam.

generate a low energy ion beam, V must be decreased, and since d is fixed by the grid spacing (typically 1 mm or greater), j_{max} decreases also. The relationship is shown in Fig. 3, in which the maximum current density obtained from a dual grid ion source is plotted as a function of $V^{3/2}$. Therefore, while a current density of 3.0 mA/cm^2 is obtained at an ion energy of 1500 eV ($V^{3/2} = 67{,}000$), only 0.05 mA/cm^2 is obtained at 100 eV ($V^{3/2} = 1153$). This space charge limitation on ion current density is a ceiling above which a dual grid source cannot operate, even by increasing the ion density in the source.

In order to maintain high current density at low ion energy, we use a single extraction grid (3) (Fig. 2b) which overcomes the space charge limitation of a dual grid system. The single grid is formed from a material with a very fine aperture size a. The aperture size must be comparable to or less than the thickness of the plasma sheath l_s for effective operation. With this condition satisfied, ions leave the discharge plasma in almost parallel trajectories. with a certain fraction passing through the grid as a collimated beam. Although the grid is bombarded by ions, sputtering damage is minimized by operating at low ion energy.

The single grid differs markedly from the dual grid system by maintaining high current density at low ion energy. The acceleration distance d is now equivalent to the sheath thickness l_s, which is on the order of 0.1 mm. As the ion energy is decreased, d is no longer fixed, and the sheath thickness l_s decreases to keep the ion current density equal to the space charge limit. Therefore almost constant current density is maintained down to about 20 eV ion energy.

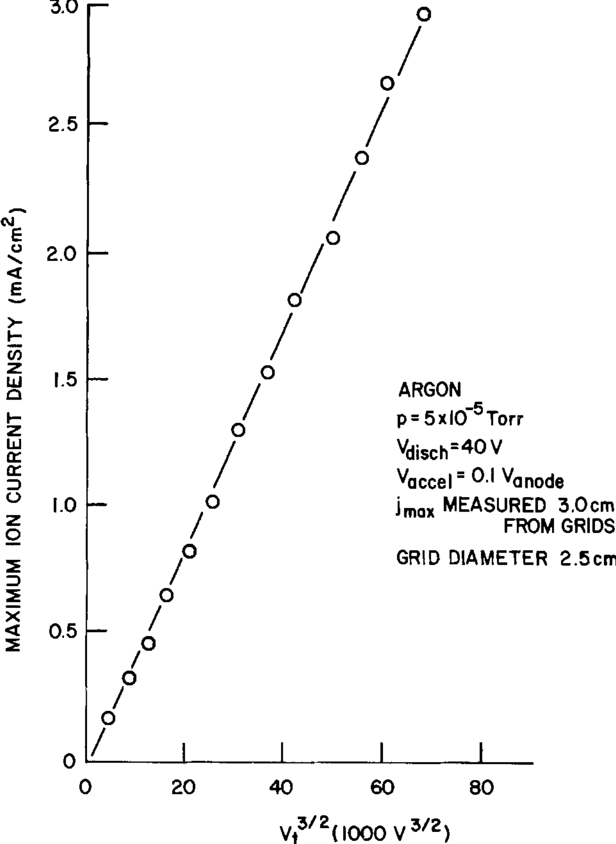

Fig. 3. Maximum current density obtained from a dual grid ion source as a function of $V_t^{3/2}$, illustrating the space charge limit on current density. V_t is the total potential difference between the discharge plasma and the accelerator grid.

Experimental Procedure

Single grid ion source.—We have tested the single grid design on two ion sources of 3.5 and 7.5 cm beam diameter by simply replacing the grid system with a single grid of electroformed nickel mesh of 0.2 mm aperture size and 82% transparency (100 lines per inch). The 3.5 cm source is shown schematically in Fig. 1. Cathode and neutralizer filaments are tungsten. Typical operating parameters which generate a 100 eV argon beam are: sample chamber pressure = 10^{-2} Pa (8×10^{-5} Torr), discharge voltage = 40V, discharge current = 0.2A, anode voltage = 100V, grid voltage = −20V, grid current = 3 mA, beam current = 7 mA, current density at grid = 0.73 mA/cm^2, current density 14 cm from grid = 0.32 mA/cm^2, and ion energy = 95 ± 5 eV.

The current density and energy distribution in the ion beam are measured using a retarding grid analyzer. The analyzer measures the ion current which reaches a collector plate after passing through a positively biased mesh grid. The voltage on this retarding grid is swept to trace out the energy distribution of the ions. Another negatively biased grid is used to screen out electrons from the analyzer. Measurements confirm that current densities up to 1.0 mA/cm^2 can be obtained at ion energies as low as 20 eV. This result demonstrates that the sheath thickness adusts itself to maintain the beam current density independent of ion energy. The ion current density is now determined by the ion density in the source and is not limited by grid geometry. Thus a wide range of operating conditions is available at low ion energy, as shown in Fig. 4. In this figure the operating range of the dual grid source is shown for ion energies up to 200 eV. This curve is the low energy portion of Fig. 3. Also shown is the operating range of the single grid. With the single grid, ion energies much higher than 200 eV are not suitable be-

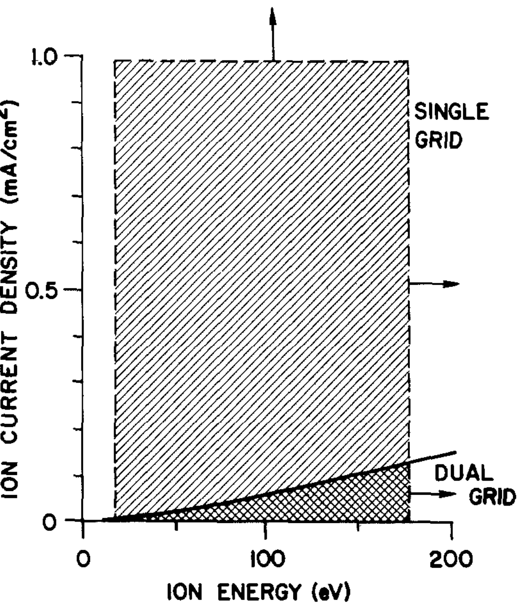

Fig. 4. Comparison of the low energy operating range of the single grid and the dual grid ion source.

cause of ion bombardment of the grid. Current densities above 1.0 mA/cm^2 can be obtained, but are limited eventually by overheating of the grid. Energy analyzer measurements indicate an energy spread of about 10 eV, similar to that obtained with a dual grid source. We have operated the single grid source as low as 20 eV ion energy, but below this value the ion energy spread becomes comparable to the average ion energy, and the beam can no longer be considered almost monoenergetic. Over the entire operating range shown in Fig. 4, however, the energy spread remains far smaller than the broad energy distributions found in rf glow discharge systems, and the current density is much higher than a dual grid system can generate. Thus quantitative measurements of etch rates can be carried out with current densities on the order of 1.0 mA/cm^2 over a wide range of low energies by using the single grid design.

A convenient feature of the single grid design is that it may be easily used on an existing dual grid ion source. The discharge chamber remains unchanged, while the low energy performance of the ion source is greatly improved. Finer mesh grids up to 333 lines per inch were also tested, but these developed holes during operation. With care, a 100 mesh grid can be used for 5-10 hr operation including several exposures to air.

Etch rates of Si and SiO_2 with Ar and CF_4.—We have measured the etch rates of Si and SiO_2 using Ar and CF_4 gases in the ion source, over an ion energy range of 20-1500 eV. The 3.5 cm diam single grid source was used for ion energies below about 200 eV, and the 2.5 cm diam dual grids were used on the same ion source for higher ion energies. Ion source parameters were similar to those listed above, except that with CF_4 a discharge voltage of 70V was used. The sample chamber was evacuated to an initial pressure of typically 5×10^{-5} Pa (4×10^{-7} Torr), then raised to an Ar or CF_4 pressure of 1-5 $\times 10^{-2}$ Pa (0.8-4 $\times 10^{-4}$ Torr) for etching. Etch rate measurements were made using a coated quartz crystal rate monitor located 14-20 cm from the ion source and were supplemented by step measurements on masked Si and oxidized Si wafers. Several measurements were also made using a larger diameter (7.5 cm) single grid source. Ion current density and energy were measured above the sample using a retarding grid analyzer. Current densities of typically 0.1 mA/cm^2 were used, with etch times of 10-90 min. These measurement times were longer than time constants associated with the rate monitor temperature or the establishment of steady etching conditions (4).

Etch rates were divided by the ion current density to calculate the etching yield in atoms/ion for each ion/sample combination. Argon ion current densities were corrected for the resonant charge exchange process (2, 5) which converts a fraction of the energetic beam ions to energetic neutrals. This fraction increases with background pressure and causes the measured ion current density to underestimate the total energetic particle flux striking the sample. Correcting for this process allows measurements at different pressures to be reliably compared. Current density values with CF_4 were not corrected for charge exchange since this process should not be significant for CF_3^+ ions (the dominant species) passing through mostly CF_4 gas.

To examine the step edge profiles generated by low energy RIBE, several wafers of oxidized Si were coated with a 1 μm thick photoresist pattern. After etching with CF_4 at 200 eV ion energy, the photoresist was removed and the steps were examined by scanning electron microscopy. The step profiles were then compared with steps etched using 500 eV argon ions.

Results

Etching yields are given in Fig. 5 as a function of ion energy, for Si and SiO_2 using Ar or CF_4. To convert these yields to etch rates, in the case of Si a yield of 1 atom/ion means that in an ion beam of current density 1.0 mA/cm^2, the Si etch rate is 12.5 Å/sec. For SiO_2, a yield of 1 atom (either Si or O) per ion means that in an ion beam of current density 1.0 mA/cm^2, the SiO_2 etch rate is 9.5 Å/sec. For reference, the asterisk in Fig. 5 indicates the maximum chemical etching yield of SiO_2 by a single CF_3^+ ion to yield SiF_4 plus CO and CO_2, according to the equation

$$4CF_3 + 3SiO_2 \rightarrow 2CO + 2CO_2 + 3SiF_4$$

This maximum yield is 0.75 SiO_2 molecules, or 2.25 atoms (Si or O) per CF_3^+ ion. The significance of this value is discussed in the next section. The data obtained with the single grid ion source are shown as circles and those taken with the dual grid are shown as triangles. These measurements merge smoothly at 200 eV in the case of Ar/SiO_2, but for CF_4/SiO_2 there is a significant difference in etch rates measured by

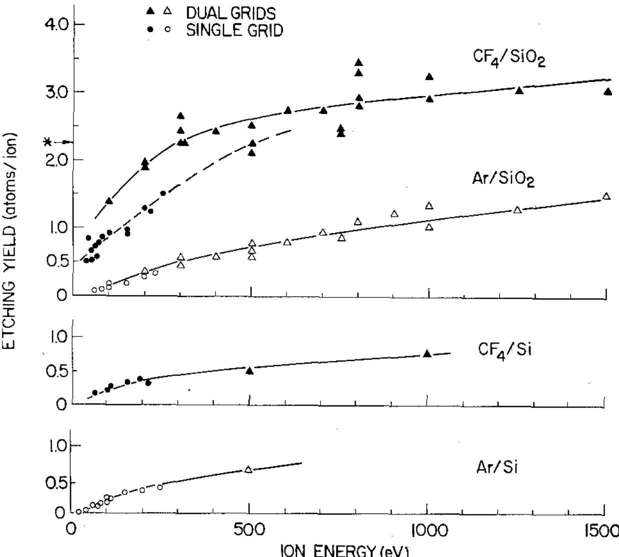

Fig. 5. Etching yields (atoms/ion) as a function of ion energy for four ion/material combinations: CF_4/SiO_2, Ar/SiO_2, CF_4/Si, and Ar/Si. Circles are measurements taken with the single grid ion source, and triangles are taken with the dual grid system. The asterisk indicates the maximum CF_4/SiO_2 chemical etching yield of 2.25 atoms/ion.

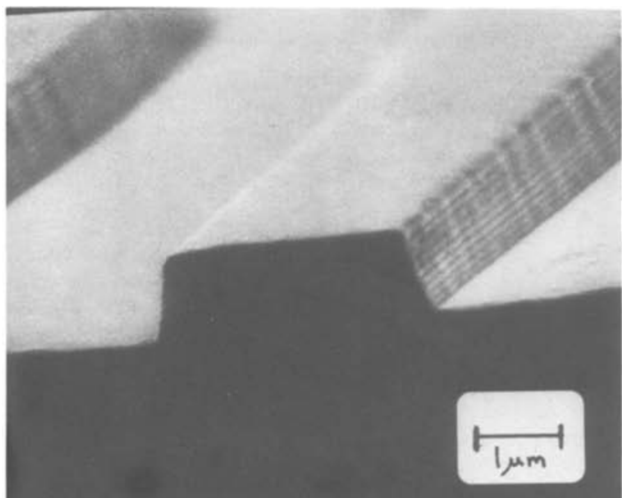
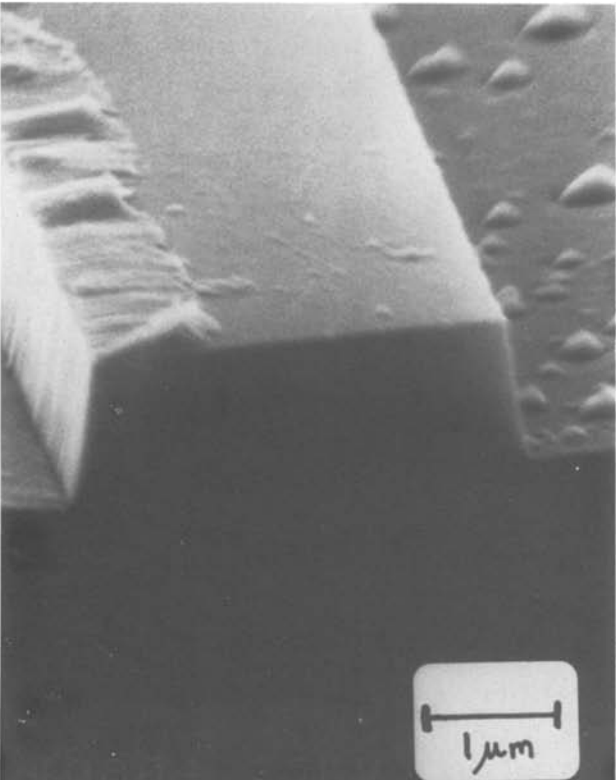
these two grid systems. This difference appears to be caused by a mild rate of deposition of polymeric material from the CF_4 discharge, which competes with the etching process, especially at low ion energy. The multiple data points shown at the same ion energy in Fig. 5 were obtained from different samples, using various values of gas pressure and ion current density to assess the overall reproducibility of the process.

Step edge profiles are shown in Fig. 6. The initial photoresist mask shape is shown in Fig. 6a. A 1 μm deep step in SiO_2 etched with CF_4 at 200 eV is shown in Fig. 6b, and a 0.5 μm deep step in SiO_2 etched with Ar at 500 eV is shown in Fig. 6c. The step edge profile obtained with CF_4 has almost vertical walls with no evidence of trenching. This indicates directional, anisotropic etching with mostly volatile products. The wall is not quite vertical because of the sloping mask shape (Fig. 6a) and the slight divergence angle of the ion beam (about 10°). Since the mask is etched at about 1/5 the rate of the SiO_2, the lateral movement of the step edge contributes to a slightly sloping wall. The step edge profile obtained with Ar (Fig. 6c) shows a sloping wall with a shallow trench formed by reflected ions. This shape evolves when etching is by purely physical sputtering, causing partial redeposition on the wall of the step. Although this redeposited material may be simultaneously removed by sputtering, it has the effect of decreasing the etch rate of the sloping wall, contributing to a shallower slope. Also with Ar sputtering, the photoresist mask and the SiO_2 substrate etch at similar rates. The mask edge therefore moves a greater distance laterally than in etching with CF_4 to the same depth, again contributing to a sloping step edge. Trenching can be more severe than shown in Fig. 6c, as shown in Ref. (6). Also redeposition on mask edges can leave unwanted fringes (7, 8). These artifacts of inert gas ion etching are minimized by using low energy RIBE.

A fringe is evident in Fig. 6b, but this is not due to redeposited sputtered material. The deposit on the top of the step is the polymer coating obtained when using CF_4 in the ion source. The polymer coated the side of the photoresist and then fell onto the top surface of the SiO_2 when the photoresist was removed. The formation of this polymeric coating on the sample being etched caused wide variations in the measured etch





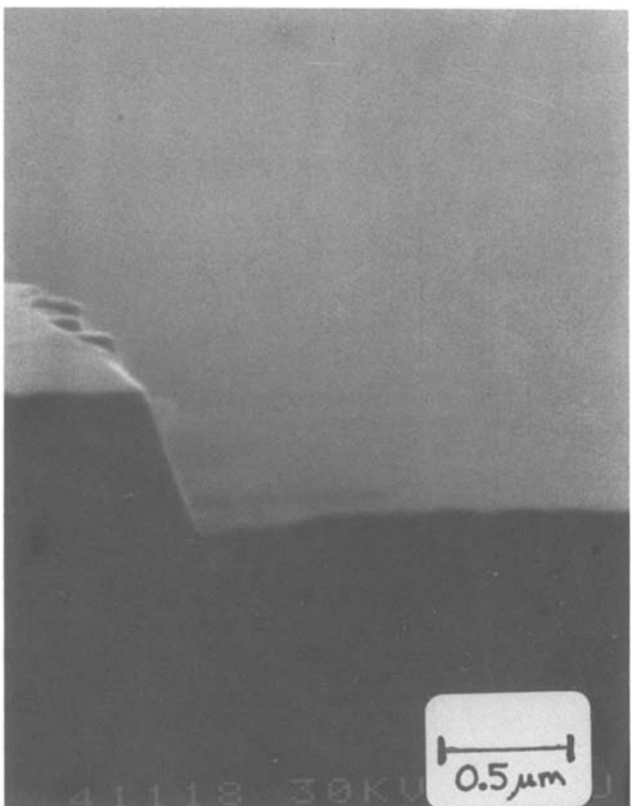


Fig. 6. Scanning electron micrographs showing: (a, upper left) 1 μm thick photoresist pattern on 1 μm thick SiO_2, prior to ion beam etching. (b, lower left) Etched step in SiO_2 after 200 eV CF_4 etch to a depth of 1 μm, after removal of photoresist, showing near-vertical walls and polymer residue. rate of CF_4/SiO_2 at ion energies below 100 eV and probably accounts for the roughness of the etched surface in Fig. 6b. Under certain operating conditions the deposition process dominated and showed a positive deposition rate exceeding the etch rate. Competition from this deposition process was minimized by operating at low gas pressure ($<10^{-2}$ Pa) and large distances from the ion source (>10 cm). Preliminary etch rate measurements using the larger diameter (7.5 cm) ion source were inconclusive because net deposition always occurred below 100 eV ion energy. The larger diameter source acts as a broad area vapor source for deposition on the sample. When CF_4 was used in either ion source, an insulating coating also formed inside the discharge chamber. This coating gradually increased the resistance of the discharge circuit and after several hours operation the discharge would be extinguished. Cleaning the anode surface quickly restored normal operation. The complications which arise from the deposition of polymeric material on both the sample and the discharge chamber surfaces may possibly be eliminated by using a different gas mixture. However, above ion energies of 200-300 eV, etch rates with CF_4 did not seem to be affected by polymer deposition. Also, when using argon the operation of the ion source was straightforward, and reproducible etch rates were obtained at ion energies as low as 20 eV (Fig. 5).

The ratio of etching yields between CF_4/SiO_2 and Ar/SiO_2 is plotted in Fig. 7. Also shown is the ratio of the slope of the CF_4/SiO_2 etch yield curve to the slope of the Ar/SiO_2 curve. This ratio is defined as the ion enhancement parameter p, to be discussed in the following section.

Discussion

Comparison of etching results.—The etch rate measurements (Fig. 5) over the range 20-1500 eV demonstrate several points. The etch rates of Ar/SiO_2, CF_4/Si, and Ar/Si are very similar. Etching of Si or SiO_2 by Ar is a purely physical sputtering process, and etching of Si by CF_3^+ ions has been shown to be almost entirely by physical sputtering (4). These results also indicate that in RIBE there is a low concentration of F radicals involved in etching, in contrast to glow discharge systems (9). We find, therefore, that when CF_4 is used in the ion source, the dominant etching species is CF_3^+ ions and that etching by neutral species is less important. This assumption is reasonable in a system which exposes the sample to a collimated ion flux extending far from the ion source, whereas neutral etching species are spread over a wide solid angle upon leaving the source. Since mean free paths are long in the ion beam system, gas phase reactions and loading effects should be negligible.

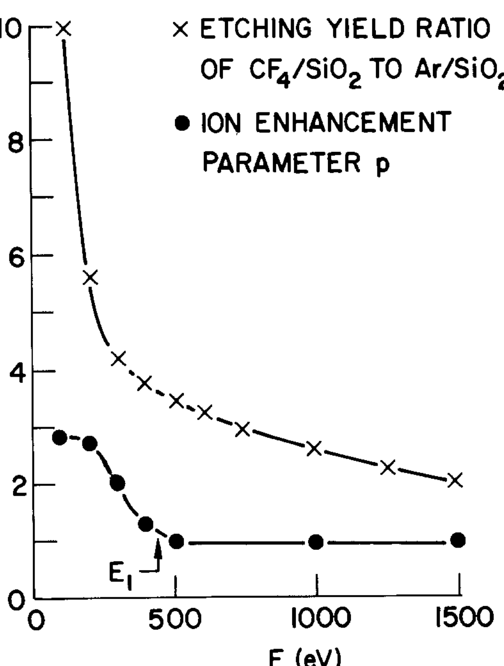

Fig. 7. Ratio of etching yields of CF_4/SiO_2 to Ar/SiO_2 as a function of ion energy, obtained from data of Fig. 5, and the ion enhancement parameter p (the ratio of the slopes of the etching yields of CF_4/SiO_2 to Ar/SiO_2), as a function of ion energy. The energy E_1 is the energy at which the ion enhancement of chemical etching is saturated.

The CF_4/SiO_2 etch rate curve (Fig. 5) represents the etch rate of SiO_2 by CF_3^+ ions, apart from the undesirable effect of polymer deposition. We can estimate the magnitude of this deposition effect by comparing the etch rates obtained with the single grid (circles) and dual grid system (triangles). Due to differences in open area fraction and beam diameter, the single grid exposes more than three times the area of discharge plasma to substrate line of sight than does the dual grid system. Therefore the deposition flux should differ by at least a factor of three for these two measurements. With this in mind, we can estimate that if polymer deposition were completely absent, the CF_4/SiO_2 etch rate should be only slightly higher than the curve obtained with the dual grids.

In the following discussion we will consider the CF_4/SiO_2 etch rate curve obtained with the dual grids to be an accurate measurement of the SiO_2 etch rate by CF_3^+ ions. The CF_4/SiO_2 etch rates measured here are consistent with SiO_2 etch rates obtained in glow discharge RIE (9) when reasonable assumptions are made for ion energy and current density, which are not directly measurable in RIE. Also, recent etch rate measurements of SiO_2 in ion beams of other fluorocarbon gases are in good agreement with the results presented here. Meusemann (8) reports SiO_2 etch rates in CHF_3 and in CF_4 + 4% O_2 giving etching yields of about 3.1 atoms/ion at 1000 eV, in agreement with Fig. 5. Horiike *et al.* (10) report SiO_2 etch rates in C_2F_6 over a range of ion energies, but give no values of ion current density. Using Eq. [1] we can estimate the values used and arrive at etching yields consistent with Fig. 5. The general agreement between etching yields of SiO_2 in different fluorocarbon gases supports our interpretation that the main etching species in these cases is the CF_3^+ ion. Step edge profiles shown in Ref. (8, 10) are also nearly vertical, with no trenching.

Model of ion enhanced chemical etching.—The etch rate of SiO_2 using CF_4 is significantly higher than with argon because of the combined effect of ion bombardment and chemical etching. In RIE, much progress has been made in understanding the etching effects of neutral radicals (F, CF_3), reactive ions (CF_3^+), and the role of ion bombardment (4, 9). However, experiments with finely focused ion beams (4) are not easily extended to low ion energy and large sample areas, and studies in glow discharge RIE systems (9, 11) lack direct measurements of ion energy and current density on which to base a model. Low energy RIBE is a more well-defined process, in which ion energy and flux are easily measured and controlled, allowing us to model the effects of ion bombardment in chemical etching.

In this section we introduce a quantitative parameter which characterizes the effect of ion bombardment in enhancing chemical etching. To describe this parameter, we focus on the CF_4/SiO_2 etching yield curve of Fig. 5. This curve is shown schematically in Fig. 8 as y_n, the net etching yield, which is made up of three components:

1. A physical sputtering yield, y_s: This component is the etching yield due to sputtering by CF_3^+ ions. Since the CF_4/Si, Ar/SiO_2, and Ar/Si yields are close, we expect the sputtering component of the CF_4/SiO_2 etching yield to be similar to these curves.

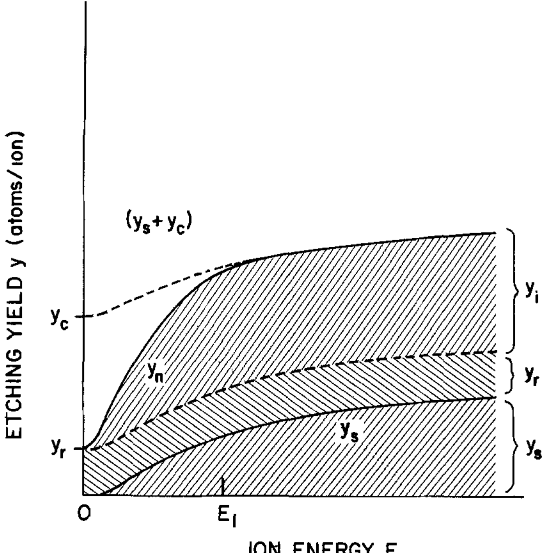

Fig. 8. Schematic diagram of the components involved in RIBE. y_s is the physical sputtering yield, y_r is the residual chemical etching yield, y_i is the ion enhanced chemical etching component, y_c is the maximum chemical etching yield, and y_n is the net etching yield. The energy E_1 is indicated, at which point the ion enhancement of chemical etching is saturated.

2. A residual chemical etching yield, y_r: This component requires only low energy ion impact (< 20 eV) and not sputtering. Its magnitude is given by the extrapolated zero-energy intercept of the CF_4/SiO_2 curve and equals approximately 0.4 atoms/ion. Considering the F atom content of CF_3^+, the maximum etching yield of SiO_2 by purely chemical etching is 2.25 atoms per CF_3^+ ion, as described earlier. This value is labeled by an asterisk in Fig. 5 and is indicated by y_c in Fig. 8. Therefore the residual chemical etching yield y_r is well below its potential value of y_c. If the residual chemical etch rate were at its maximum, the sum of this value plus the physical sputtering yield would be the curve $(y_s + y_c)$ in Fig. 8. This curve represents the maximum yield possible due to both sputtering and chemical etching, assuming no other etching species are present.

3. An ion enhanced chemical etching yield, y_i: After subtracting the residual chemical etching component y_r and the sputtering component y_s from the net CF_4/SiO_2 etching yield y_n, there remains a component which is the ion enhanced chemical etching yield y_i. This component increases with energy in a manner similar to the sputtering component y_s and is approximately a multiple of y_s at low energy. At an energy E_1, y_i reaches a value of $(y_c - y_r)$. Above E_1, y_i remains constant, indicating that ion enhancement of the chemical etching process has saturated. At high energy, therefore, the net etching yield follows the sum of the sputtering yield y_s and the maximum chemical etching yield y_c.

The energy dependence of these etching yields suggests the following interpretation of ion enhanced chemical etching. Ion impact increases the reactivity of the chemical etching process from a low value at low energy (< 20 eV) to its full value at some high energy E_1. Above this ion energy the CF_4/SiO_2 etching yield should follow the curve $(y_s + y_c)$. The data of Fig. 5 show that below 500 eV the CF_4/SiO_2 etching yield rises rapidly with energy, as does y_n in Fig. 8. Above 500 eV the CF_4/SiO_2 etching yield follows a similar slope to the Ar/SiO_2 curve. Although the Ar/SiO_2 curve cannot be equated directly to the sputtering component y_s of CF_4/SiO_2 etching, they are expected to be very similar. Therefore, above 500 eV the CF_4/SiO_2 etching yield follows the sum of a sputtering component and the maximum chemical etching yield (the asterisk in Fig. 5).

The physical picture is that in CF_3^+ etching of SiO_2 the rate of formation of volatile etch products is limited by the number of active sites available on the SiO_2 surface. This point is confirmed by a low value of the residual chemical etching yield y_r. The creation of more active sites adds to the chemical etching yield, a contribution proportional to the number of additional sites. Physical sputtering creates active surface sites by removing atoms and creating surface defects. We expect the number of additional sites to be approximately proportional to the sputtering yield, or equivalently to the sputtering component of the CF_4/SiO_2 etch rate, y_s. It is therefore reasonable that the ion enhanced chemical etching component y_i be a multiple of the sputtering component y_s, at least at low ion energy where the enhancement has not saturated. The multiplying factor is the ratio of the slope of the net etching yield curve y_n to the slope of the sputtering component y_s. We define this ratio as the ion enhancement parameter p. The parameter p gives a quantitative measure of the ion enhanced chemical etching process. From the CF_4/SiO_2 and Ar/SiO_2 etching yield curves of Fig. 5 we obtain values of the parameter p as a function of energy. These results are shown in Fig. 7. A value of $p = 2$ (at 300 eV, for example) means that in addition to residual chemical etching, each departing sputtered atom (Si or O) leaves behind enough active sites to cause on the average one additional atom to be removed by chemical etching (formation of volatile products). The enhancement parameter p shows a high value at low energy, decreasing to unity above about 500 eV ion energy. Since the shape of the low energy portion of the CF_4/SiO_2 etching yield curve is not precisely known, the energy dependence of p in Fig. 7 should be regarded as a trend. We find that the enhancement of chemical etching by ion bombardment saturates at an ion energy E_1 of approximately 500 eV.

The energy dependence of the ion enhancement parameter p (Fig. 7) illustrates several phenomena. At ion energies below E_1, ion impact has a multiplicative effect on the etching yield. Ions in the range of 100-200 eV are effective at stimulating additional chemical etching, and the ratio of the net etching yield to the sputtering yield is high. Above E_1, at 500-1000 eV, chemical etching has been increased to its maximum effectiveness, and individual ions do not have as great a multiplicative effect on the etching yield. The yield becomes the additive sum of sputtering plus maximum chemical etching. The energy E_1 is consistent with CF_3^+ ions penetrating the SiO_2 surface, dissociating and depositing their energy within the top few layers. This process generates maximum chemical reactivity, whereas at lower energies the molecular ion would dissociate on the surface, but active sites may not be available to complete the reaction with the substrate.

Having measured the enhancement parameter p for a given ion/material combination, we can now choose an energy for ion beam etching which optimizes the ratio between chemical etching and sputtering. For example, in etching a vertical structure as shown in Fig. 6b, it is important to minimize the sputtering component of etching to reduce mask erosion and redeposition of sputtered material. Simultaneously, the chemical etching component should be maximized to gain highly anisotropic etching. From Fig. 7 it looks most attractive to carry out the etching at the lowest ion energy, where the enhancement parameter p is maximized. However, at very low energy the net etching rate may be too low for practical applications (Fig. 5). An optimum etching energy would be closer to E_1, around 300-500 eV for CF_4/SiO_2. Here the net etching yield is high, and the etching yield ratio between chemical etching and sputtering is still high. Little would be gained by increasing the ion energy above 1000 eV, because the net etching yield does not increase significantly, while the sputtering yield rises by more

than a factor of two. The ratio between the net etching yield and the sputtering yield (Fig. 7) decreases gradually as the ion energy is increased above E_T. High ion energy sacrifices selectivity while generating more substrate damage. Similar considerations apply to applications in which a reactively etched film is to be removed down to an underlying nonreactive substrate. Here again, the sputtering yield should be minimized to avoid overetching, and an energy near E_1 would be optimum for high selectivity combined with short etching time.

We have demonstrated that low energy ion beam etch rate measurements give quantitative information on the process of reactive ion etching. From the energy dependence of etching yields, an ion enhancement parameter p is obtained which characterizes the effectiveness of ion bombardment in stimulating chemical etching. This parameter guides the choice of the optimum ion energy for practical RIBE applications.

For low energy ion beam etching, the single grid modification to a broad beam ion source can be used to obtain high ion current density at low ion energy. This capability extends practical ion beam etching down to tens of electron volts. In addition to the application to RIBE discussed in this paper, such low energy ion beam etching is appropriate for surface cleaning applications prior to thin film deposition, or in conjunction with analytical techniques where surface damage is to be minimized.

Amorphous Transparent Conductors: The CdO-SnO_2 System

F. T. J. Smith and S. L. Lyu

Eastman Kodak Company, Research Laboratories, Rochester, New York 14650

ABSTRACT

In the CdO-SnO_2 system both end members and the phases Cd_2SnO_4 and $CdSnO_3$ have been reported to be useful transparent conductors. The present report concerns amorphous sputtered films having compositions ranging from 20 to 80 mole percent CdO in SnO_2. We have determined the properties of both as-deposited and annealed films as functions of both film composition and sputtering conditions. From these results, the optical and electrical properties of the films have been correlated with film structure and composition. The optimum conditions for obtaining highly conductive and transparent films are described. Films having a transmission of 80%-90% in the visible and a sheet resistance of less than 5 Ω/sq can be deposited under these conditions.

Materials having both a high degree of transparency in the visible and a high electrical conductivity have found a wide variety of applications, usually in the form of thin films (1). The most commonly used materials are based on oxides of Cd, In, Sn, and Sb, with most attention having been paid to SnO_2 and the In_2O_3-SnO_2 system.

In the CdO-SnO_2 system both end members have been reported to be useful transparent conductors. Films of CdO have been used, for example, as transparent electrodes on selenium photovoltaic cells (2), as heating elements (3), and as transparent electrodes on CdS (4). Films of SnO_2 doped with various donors have been used even more widely (1). The phases Cd_2SnO_4 (5) and $CdSnO_3$ (6) have also been reported to be transparent conductors. Films of the intermediate phases exhibit the highest ratio of visible-wavelength transmission to sheet resistance, and properties superior to those of the best indium-tin oxide films have been reported for Cd_2SnO_4 films (7). It has been reported that sputtered films having compositions close to that of the phase Cd_2SnO_4 are amorphous when deposited onto amorphous substrates at room temperature and crystalline when deposited onto substrates heated to 400°-500°C (5).

Most of the previous work has been concerned with the properties of crystalline films having compositions close to that of Cd_2SnO_4 (7, 8). About amorphous films, on the other hand, little information exists. Nozik (5) reported the properties of four as-deposited films obtained by using various power levels and oxygen con-

Key words: films, conductance, transmittance.

centrations in the sputtering gas. He found electron mobilities in the range 5.8-24 cm^2/V sec and resistivities of 2.6×10^{-3} to 10 Ω-cm. Haacke *et al.* (9) reported a mostly amorphous film to have a mobility of ~27 cm^2/V sec and a resistivity of ~6.2×10^{-2} Ω-cm. Such high mobilities are not generally observed in materials which lack long-range order.

We report in detail the properties of amorphous films and in particular the effects of target composition and sputtering atmosphere on these properties. We will also report the results of post-deposition anneals on film properties. We have observed a minimum resistivity for as-deposited amorphous films of 3.3×10^{-4} Ω-cm compared with a lowest reported value of 4.8×10^{-4} Ω-cm for as-deposited polycrystalline films (8). A resistivity of 1.5×10^{-4} Ω-cm has been reported for polycrystalline Cd_2SnO_4 films annealed and reacted with CdS in an argon atmosphere (9); however, the film composition resulting from this process was not reported.

Experimental Methods

The sputtering system consisted of an rf diode with the target placed horizontally below the substrates as shown in Fig. 1. So that target compositions could be changed easily, the sputtering target used was a shallow dish 20 cm in diameter filled with the powdered oxides mixed in the appropriate ratio. Substrates were loaded through an airlock, thus avoiding exposure of the target to the atmosphere. This avoided the problems of absorption of moisture and oxygen which would have been expected as a result of repeated exposure of a target with a large surface area to the atmosphere between runs. As a result we observed a high degree of reproducibility of film properties after initial outgassing and presputtering of new targets. For example, over several series of 20 runs under the same conditions, all sheet resistance values were within 8% of the mean value. In earlier experiments with indium-tin oxide in this system, we obtained essentially identical properties with films sputtered under the same conditions from either a loose powder or a hot-pressed target. This confirms that the physical form of the target is not a major concern with this equipment.

The sputtering system was enclosed in a stainless steel cylinder pumped by an oil diffusion pump with a cold trap. A pressure of 1×10^{-7} to 5×10^{-8} Torr was measured in this cylinder between runs. During sputtering, a throttle valve of fixed diameter was used to limit pumping speed. Both argon and oxygen of high purity were introduced to the chamber through metering valves to form the sputtering atmosphere. A stainless steel cup could be rotated into position over the target in place of the substrates. Deposition onto this cup was always carried out for 30 min to equilibrate the system before deposition onto the substrates.

The substrates used were 5 cm diam disks of fused quartz 0.5 mm thick and polished on both sides. They were cleaned with ammonia-hydrogen peroxide and hydrochloric acid-hydrogen peroxide mixtures before use. The substrates were clamped into recesses in a massive aluminum and copper disk which was water cooled. The substrate surface did not exceed ~100°C during a typical deposition procedure.

Optical measurements were made at near-normal incidence by using a Cary 14 two-beam spectrophotometer in the visible and near-infrared range, and a Beckman AR10 spectrometer in the 2-10 μm range. Measurements were made with an uncoated substrate in the reference beam of the Cary 14 and were corrected for absorption due to the substrate in the case of measurements made with the Beckman instrument. Sheet resistance was measured using a four-point tungsten probe, and both sheet resistance and Hall coefficient were measured by the van der Pauw method. For the van der Pauw measurements the films were etched into a cloverleaf pattern by masking them with photoresist and etching in dilute hydrochloric acid. Silver paste or simple pressure contacts were used, and the measurements were made using an a-c current and a d-c magnetic field of 4.3 kθe. Film thickness was measured with a mechanical profilometer to determine the average height of an etched film edge.

Results and Discussion

A series of films 5-10,000Å thick were deposited from a target containing 67 mole percent (m/o) CdO and 33 m/o SnO_2 to find sputtering conditions giving a maximum ratio of transmission to sheet resistance. The sputtering power, total gas pressure, oxygen-argon ratio, and target-substrate spacing were systematically varied. For example, Fig. 2 shows the conductivity and transmission at 550 nm as functions of the sputtering power for films deposited using an argon plus 1.2% oxygen atmosphere at a total pressure of 2×10^{-2} Torr. The target-substrate spacing was 3.5 cm. The transmission shown was obtained by averaging interference fringes and is only weakly dependent on sputtering power, whereas the conductivity increases rapidly with increasing power up to 400W and then levels off. Sputtering powers above 2 W/cm^2 were not used because they resulted in arcing, powder levitation, and overheating at the target surface. Similar problems

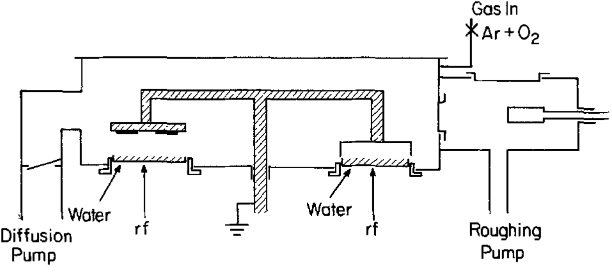

Fig. 1. RF diode sputtering system

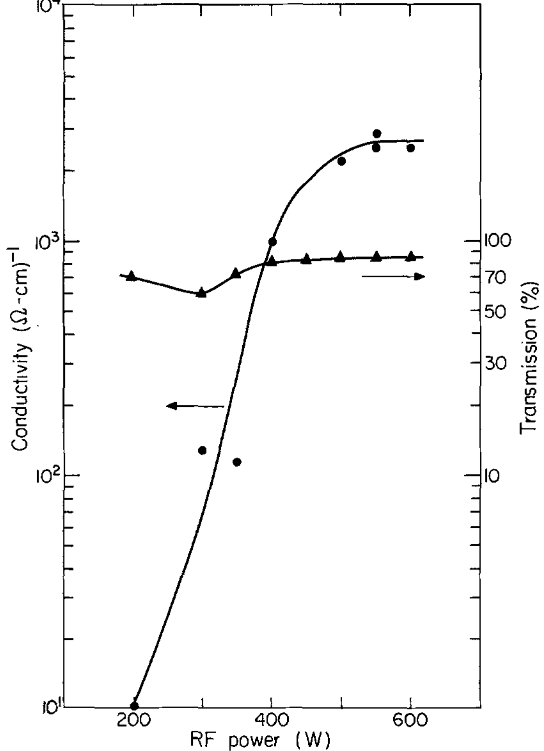

Fig. 2. Dependence of conductivity and optical transmission at 550 nm on the sputtering power. Film thickness ~7000Å, target 30 m/o SnO_2, oxygen content of sputtering atmosphere 1.2%.

with powder targets at high power densities have been reported (9), and direct evaporation of CdO at higher powers has been reported to result in changes in film composition (10). From this series of experiments, we found the optimum deposition conditions to be a sputtering power of 500W (1.6 W/cm^2), a target-substrate spacing of 3.5 cm, and a sputtering atmosphere of argon plus 0-10% oxygen at a total pressure of 2×10^{-2} Torr. All further experiments were therefore carried out under these conditions; only the compositions of the target and of the sputtering atmosphere were varied.

The deposition rate decreased with increases in the amount of SnO_2 in the target and showed a maximum at 2% oxygen in the sputtering atmosphere. The results for three target compositions are shown in Fig. 3. The deposition rate increased with the amount of CdO in the target, indicating a higher sputtering efficiency for CdO than for SnO_2. This difference apparently increases with oxygen level up to ~3%, since the curves of Fig. 3 diverge up to this point. It would therefore be expected that the target surface would change in composition, becoming depleted of cadmium oxide, during an initial target equilibration process. In support of this we observed that the color of the target surface changed from red-brown to gray during the first few hours of use. Once a steady state has been reached, Cd and Sn must be removed in the ratio in which they are present in the target. On the other hand, because of differences in sticking coefficient between Cd and Sn on surfaces of various types and temperatures, the film composition need not be identical with that of the target. Sputtering was carried out on a new target for at least 8 hr before the films, the properties of which are reported here, were deposited. Also, when changes were made in the oxygen level in the sputtering atmosphere, presputtering was carried out for at least 2 hr under the new conditions. After these conditioning processes, film properties were highly reproducible over a series of more than 50 deposition runs including several changes in sputtering gas composition. This confirms that a steady state had been reached in each case.

To determine film compositions, a series of deposits were made from targets containing 25, 30, and 50 m/o SnO_2 in sputtering atmospheres containing 0-6% oxygen. These were analyzed using an electron microprobe. The results are shown in Fig. 4. Films sputtered from the 30 and 50 m/o SnO_2 targets contained substantially less Cd than the target, whereas films from the 25 m/o SnO_2 target contained somewhat more. In general the Cd/Sn ratio increased with increases in

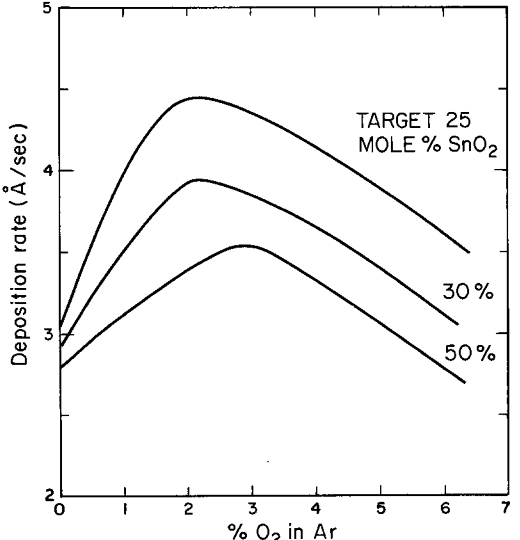

Fig. 3. Deposition rate at 500W power as a function of sputtering atmosphere for three target compositions.

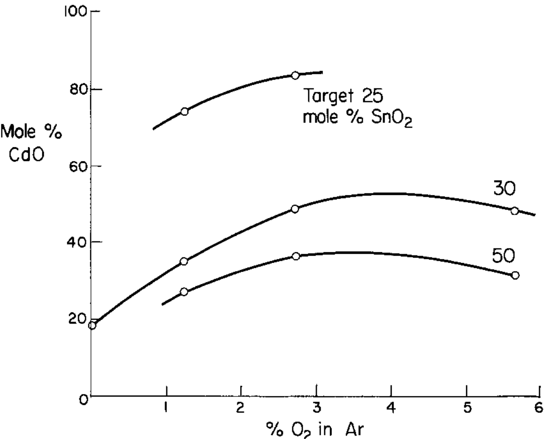

Fig. 4. Results of microprobe analysis of films deposited at 500W from three different target compositions.

the oxygen content of the sputtering atmosphere. These compositions were found to be extremely uniform across each sample. The compositions shown in Fig. 4 cover a range on both sides of the phases $CdSnO_3$ (50 m/o SnO_2) and Cd_2SnO_4 (33 m/o SnO_2).

With polycrystalline films, significant variations in properties such as conductivity would be expected over such a wide range of compositions. In particular, it has been reported that good conductivity is obtained only from single-phase Cd_2SnO_4 films (7). Lloyd has obtained films having Cd/Sn ratios in the range 0.7-3.5 as a result of heating the target at high powers and thus directly evaporating CdO. It is not reported whether these films were amorphous or crystalline; however, at the power levels used, heating of the substrate would probably have resulted in crystalline films. A distinct downward trend in resistivity was reported at high powers and Cd/Sn ratios. A similar trend has been reported for indium-tin oxide films (11) and attributed to effects of substrate heating on the film structure rather than compositional changes. At a deposition rate of 200 Å/min from argon + 20% oxygen and a Cd_2SnO_4 target, Lloyd obtained Cd/Sn ratios of 1.2-2.3 and conductivities of 5-50 $(\Omega\text{-cm})^{-1}$. Because deposition rates are dependent on geometry and even on substrate, it is difficult to make such a comparison; however, by extrapolation from our results we would expect to obtain a Cd/Sn ratio of 0.5 and a conductivity of 2500 $(\Omega\text{-cm})^{-1}$ for amorphous films deposited from such a target in an argon plus 1.5% oxygen mixture. The conductivity is shown in Fig. 5 for films 5-8000Å thick deposited from the three targets at various oxygen levels. The conductivity decreases rapidly at oxygen levels above 2%, but is not strongly dependent on the target composition itself. Thus, in contrast with these results for polycrystalline films, the conductivity for amorphous films is determined primarily by the oxygen level in the sputtering atmosphere rather than the Cd/Sn ratio in the film. Films deposited from the 50 m/o SnO_2 target at 3% O_2 or from the 30 m/o SnO_2 target at 1% O_2 both contain ~35 m/o CdO; however, their conductivities are 20 and 2000 $(\Omega\text{-cm})^{-1}$, respectively.

X-ray diffraction patterns could not be obtained from any of these films even for film thicknesses of up to 2 μm. This result is consistent with previous reports (9) that films sputtered onto amorphous substrates at temperatures below 400°C are amorphous. In attempts to crystallize the films, they were annealed in nitrogen for 30 min at various temperatures. No crystallization occurred for anneal temperatures up to 600°C. At higher anneal temperatures, the film spalled from the substrate. Both 400°C annealed and as-deposited film surfaces were examined by SEM. They appeared to be smooth even at a magnification of 10,000×, in contrast with sputtered polycrystalline indium-tin oxide films

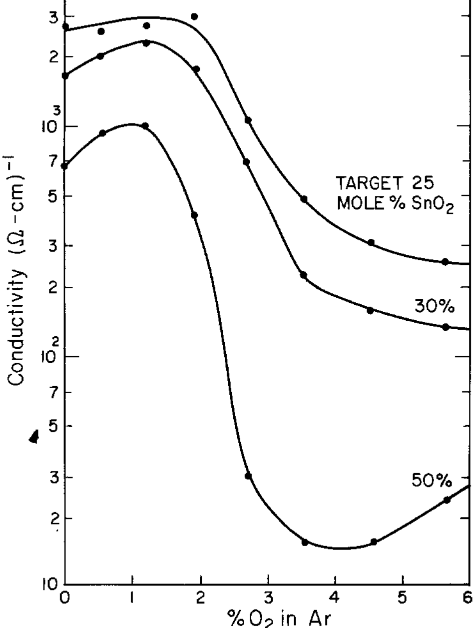

Fig. 5. The conductivity as a function of sputtering atmosphere for films 5-8000Å thick deposited at 500W.

on which a rough dimpled surface could be seen under the same conditions.

Annealing did result in major changes in both electrical and optical properties of the less-conductive films. After the films were annealed in nitrogen at 300°-600°C, the conductivity of films deposited at the highest oxygen levels was drastically increased, but films deposited at below 2% oxygen were much less affected. At 400°C this increase was complete in ~15 min, and no further change occurred with longer anneals of up to 10 hr. The conductivity of films annealed at 400°C for 30 min is shown in Fig. 6. These curves may be compared with the data for as-deposited films shown in Fig. 5. The highest conductivities before annealing were obtained for films sputtered from the 25 m/o SnO_2 target at ~1.5% O_2. A maximum value of 3000 (Ω-cm)$^{-1}$ was obtained compared with a previously reported maximum value for as-deposited amorphous films of 385 (Ω-cm)$^{-1}$ (5). After annealing, the 30 m/o SnO_2 target also sputtered at 1.5% O_2 gave the most conductive films. The large increase in conductivity resulting from nitrogen annealing specimens deposited at a high oxygen level was not reversible by annealing in oxygen. Annealing any of the films in oxygen at 400°C for 30 min after a prior nitrogen anneal at the same temperature resulted in only a 5%-10% reduction in conductivity. Thus, it is unlikely that these large changes in conductivity can be attributed simply to changes in the degree of oxidation of the film.

Since the increase in conductivity on annealing did not result from recrystallization of the films, it could be attributed to an increase in mobility resulting from some more subtle structural change. Alternatively, it could be the result of an increase in carrier concentration due to separation or dissolution of an amorphous second phase. For crystalline films Haacke reported that 750°C anneals reduced the CdO content (9). To discriminate between these two possibilities, Hall-effect measurements were made on the films both before and after annealing.

All of the films were found to be n-type. The Hall mobilities for films deposited at various oxygen levels are shown in Fig. 7. The most unexpected aspect of the results is the relatively high mobility, in the range 15-50 cm^2/V sec. These mobilities are as high as or higher than values reported elsewhere for crystalline films (9). Our results are, however, comparable with those reported by the same authors for their amorphous films. Normally electron mobilities of much less than 1 cm^2/V sec are measured in amorphous films (12), and the Hall effect is usually anomalous. One possible explanation is that the films are not amorphous, but of extremely small grain size, too small to give an observable x-ray diffraction pattern. The grain size would then, however, have to be less than 20Å. The Hall mobility after a 400°C 30-min anneal in nitrogen is shown in Fig. 8. The values for films from the 25 and 30 m/o SnO_2 targets were not appreciably changed. The shape of the curve for films from the 50 m/o SnO_2 target is, however, quite different. Possibly the changes in these tin-rich films result from dissolution or precipitation of crystalline SnO_2, although no evidence for this was seen in x-ray diffraction patterns.

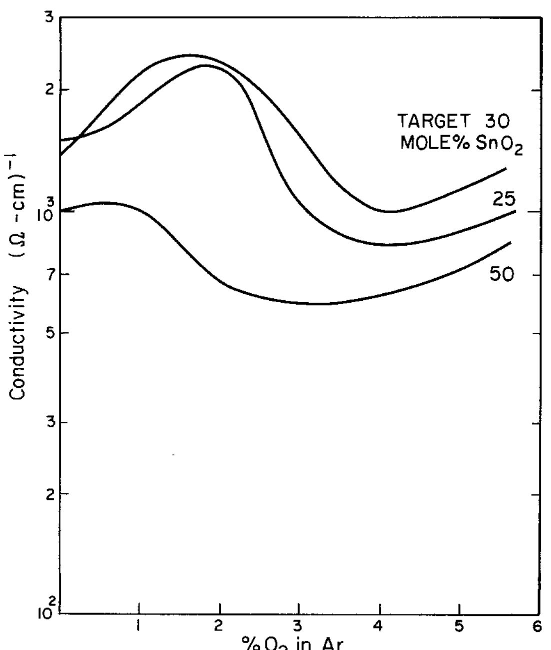

Fig. 6. The conductivity as a function of sputtering atmosphere for films 5-8000Å thick deposited at 500W and annealed in nitrogen at 400°C for 30 min.

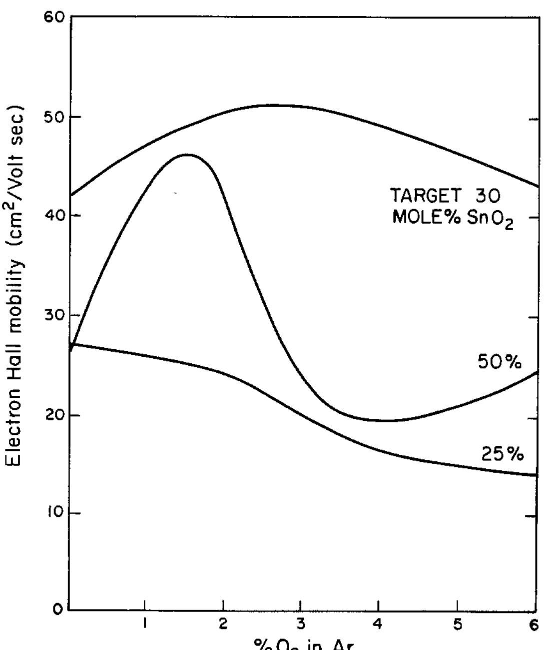

Fig. 7. The electron mobility as a function of sputtering atmosphere for films 5-8000Å thick deposited at 500W.

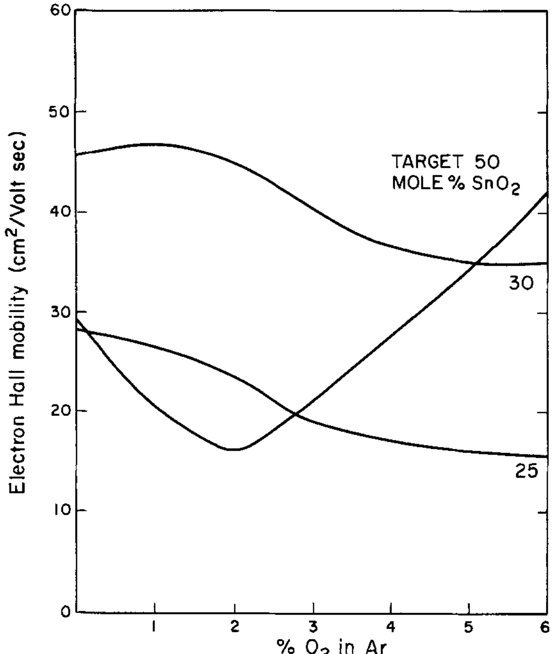

Fig. 8. The electron mobility as a function of sputtering atmosphere for films 5-8000Å thick deposited at 500W and annealed in nitrogen at 400°C for 30 min.

The electron concentrations obtained from Hall measurements, assuming a Hall factor of unity, are shown in Fig. 9. A maximum value of $6.5 \times 10^{20}/cm^3$ was obtained for the as-deposited films. This is very close to the value $7 \times 10^{20}/cm^3$ measured for tin-doped indium oxide films deposited in the same sputtering system. The effect of a 400°C anneal in nitrogen on the electron concentration in films deposited from the 30 m/o SnO_2 target is also shown in Fig. 9. After annealing, the electron concentration was only weakly dependent on the oxygen level in the sputtering atmosphere. Similar behavior was seen for films deposited from the

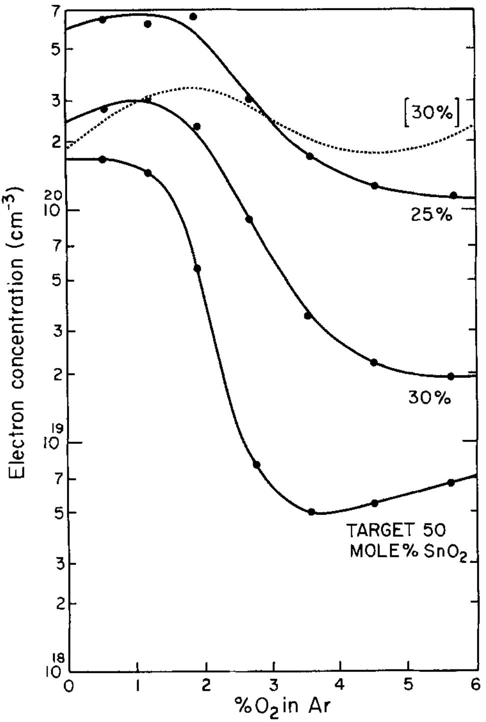

Fig. 9. The electron concentration as a function of sputtering atmosphere for films 5-8000Å thick deposited at 500W. The dashed curve refers to films from the 30 m/o SnO_2 target annealed in nitrogen at 400°C for 30 min.

other targets. Thus, the effect of annealing on the conductivity of films deposited at a high oxygen level results almost entirely from an increase in the electron concentration. As discussed above, this is apparently not simply due to a reduction in oxygen content of these films, since annealing in oxygen instead of nitrogen has little effect.

All of the sputtered films were highly transparent. Their color varied with composition from pale yellow for films of high SnO_2 content to reddish at high CdO level. Transmission spectra are shown in Fig. 10 for a 6950Å thick film sputtered from the 30 m/o SnO_2 target at 2.7% oxygen. This spectrum is similar to that reported previously for amorphous films (5) except that the absorption edge is shifted to somewhat shorter wavelengths. The transmission is 80%-90% throughout most of the visible range, ~10% higher than previously reported for amorphous films (5). Annealing this film in nitrogen at 400°C for 30 min raised its carrier concentration from 8×10^{19} to $3 \times 10^{20}/cm^3$. The spectrum measured after this anneal is also shown in Fig. 10. At short wavelengths the absorption edge is shifted to higher energies. A similar shift is observed with crystalline indium oxide films (13) and cadmium oxide films (14) and results from the Burstein mechanism. In amorphous materials, however, such shifts have usually been attributed to the effect of annealing in reducing the density of state tailing into the bandgap (15).

Summary

Our results can be summarized as follows.

1. Highly transparent and conductive amorphous films can be deposited onto unheated amorphous substrates from targets consisting of powdered cadmium and tin oxides mixed together. Films having a transmission of 80%-90% in the visible region and a sheet resistance of less than 5 Ω/sq can be deposited under appropriate conditions. These properties are comparable to those achieved with as-deposited crystalline films in the CdO-SnO_2 system. Control of the oxygen level in the sputtering atmosphere is critical to achieving this result.

2. Annealing in nitrogen increases the conductivity of films deposited at high oxygen levels, but does not greatly affect those deposited under optimum conditions. This increase is due to an increase in electron concentration.

3. The target composition is not critical for these amorphous films, but the optimum is 25%-30% SnO_2 in CdO.

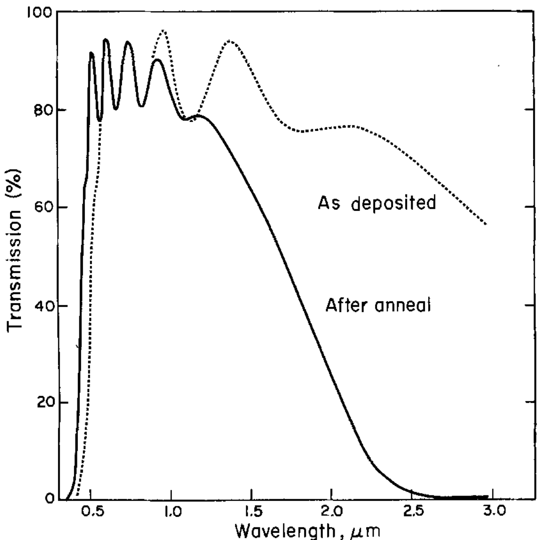

Fig. 10. Optical transmission of a 6950Å thick film deposited at 500W from a 30 m/o SnO_2 target. Dashed curve is for the same film after annealing in nitrogen at 400°C for 30 min.

Thermal Decomposition of InP and Its Influence on Iso-Epitaxy

H. Temkin,* V. G. Keramidas,* and S. Mahajan*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The effects of rapid thermal degradation of InP substrate on the quality of epitaxially grown layers are generally underestimated. Scanning photoluminescence, photocurrent, and etch pitting techniques have been used to evaluate the influence of InP substrate decomposition on the quality of epitaxially grown layers. Growth on substrates protected with an InP cover piece results in epitaxial layers with localized regions of low luminescence and high dislocation density. These are present even in layers with a very good surface morphology. The use of source-piece protection, in conjunction with a shallow In meltback prior to epitaxy, eliminates the deleterious effects of thermal decomposition. The incorporation of these steps into the growth of device wafers greatly improves the yield of InP/InGaAsP light emitting diodes.

The attractiveness of InGaAsP/InP quaternary alloy for use in fiber communications is now well established. In particular, light emitting diodes (LED's) operating in the region of zero dispersion of silica fibers, *i.e.*, between 1.27 and 1.32 μm, can provide much higher data capacity than comparable GaAlAs devices (1). However, liquid phase epitaxy of InP and InGaAsP is not as well established as that of GaAs and its alloys. The recent research effort in this area has been directed mainly towards improvements in the growth of the quaternary alloy (2), without much attention being given to problems related to InP itself.

The rapid thermal degradation of the InP substrate prior to growth appears to be one of the main problems in the reproducible preparation of high quality InP epitaxial layers (3). Among the techniques commonly used to prevent or remove such damage are the use of a polished InP cover piece (4), which protects the substrate before growth and an *in situ* In etch (5, 6). The combination of the two methods, labeled as "perhaps over cautious," has also been reported (7).

In this work, the application of photoluminescence (PL), photocurrent scanning, and etch pitting techniques to evaluate the effectiveness of substrate protection measures is described. The role of defects caused by the thermal decomposition of InP in device yield and performance will be discussed. We demonstrate that the use of an InP cover piece alone, while assuring an excellent surface morphology of epitaxial layers, results in a large density of macroscopic defects which are not visible by Nomarski-contrast microscopy but clearly seen as areas of lower photoluminescence efficiency. In addition, dislocation pits with the density exceeding that of the underlying substrate are observed. Similarly, it is difficult to achieve good growth reproducibility with a pure In meltback alone.

Experimental Details

Thermal decomposition studies and the liquid phase epitaxy were carried out on {100} oriented InP substrates doped with Sn ($n \approx 1 \times 10^{18}$ cm^{-3}) and S ($n \approx 1 \times 10^{19}$ cm^{-3}). The dislocation densities in the respective substrates are $\sim 1 \times 10^4$ and $< \sim 1 \times 10^3$ cm^{-2}. All the substrates were polished with 0.5% bromine-methanol to an optically smooth finish. Single layers of InP and double heterostructure (DH) InP/InGaAsP wafers were prepared by conventional techniques (8), with the substrate protected by an InP cover piece prior to growth. The DH wafers consisted of a 5 μm thick buffer layer followed by a 0.8 μm thick

* Electrochemical Society Active Member.

Key words: crystal growth, defects, photoluminescence.

InGaAsP active layer ($\lambda_p = 1.3$ μm) and a 2 μm thick confining layer. After the growth, the substrate side of the wafer was thinned to ~100 μm by Br-methanol polishing. The contact metallization was subsequently applied through shadow masks. The scanning apparatus used is similar to that recently described by Johnston *et al.* (9) and has a spatial resolution of 5-10 μm, limited by the laser beam size.

Results

As demonstrated in Fig. 1(a), iso-epitaxial layers grown on substrates protected by an InP cover piece show very good surface morphology under Nomarski-contrast microscopy. Only in some isolated areas very small (<5 μm diam) dissociation pits and associated In droplets with local density of less than $10^4/cm^2$ can be seen. These shallow pits are probably formed during the short time when the wafer is exposed to high temperature following the termination of growth. Figure 1(b) shows the same area, identified by a "knee" in the lamellae, subjected to the Huber etch for 45 sec to reveal dislocations. The etch pits are either isolated or form pairs, very likely due to the presence of small dislocation half loops. To ascertain whether the dislocations observed in Fig. 1(b) result from the replication of defects present in the bulk of the underlying substrate, the epitaxial layer and the portion of the substrate contiguous to the epi-substrate interface have been removed. The subsequent Huber etching of the substrate indicates significantly lower dislocation density and an absence of very small dislocation half loops.

In addition to the microscopic defects, the PL scan reveals a number of randomly distributed dark spots. Figure 2 shows a picture obtained on a 5 μm thick epitaxial layer. The scan covers an area of 0.25 mm^2, equal in size to a single LED. While the upper right part of the scanned area is uniformly bright, a number of irregularly shaped dark regions can be seen in the remainder of the photograph. The smallest imaged defects are approximately 7-10 μm in diameter, their apparent size limited by the extent of the laser beam. The largest dark feature is about 150 μm long. The difference in PL efficiency between bright and dark areas is no more than a factor of 2. In order to investigate the effects of thermal treatment we have subjected the substrate (protected with InP cover) to a temperature cycle corresponding to melt homogenization prior to the growth. The cycle consists of a rapid rise to 675°C and holding this temperature for 90 min. After this thermal treatment the surface remains flat and featureless under examination at high magnification (×700) with a Nomarski-contrast microscope. Morphological changes can be seen on intentional scratches, in which fine In droplets appear. The thermal

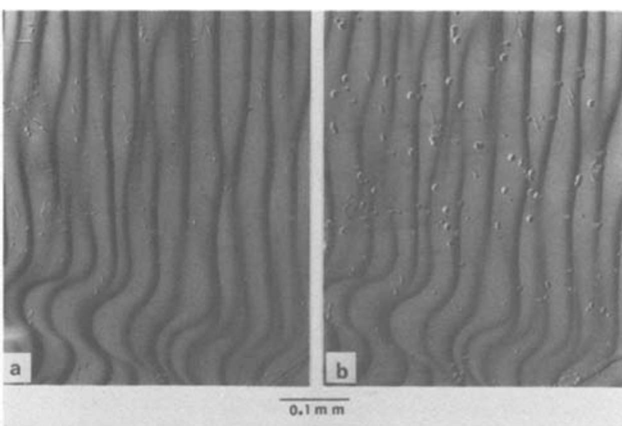

Fig. 1. Optical micrograph of an epi-layer grown with neither the source-piece protection nor the meltback. (a) As-grown surface, and (b) same area as in (a) except that the epi was Huber etched for 45 sec to reveal dislocations.

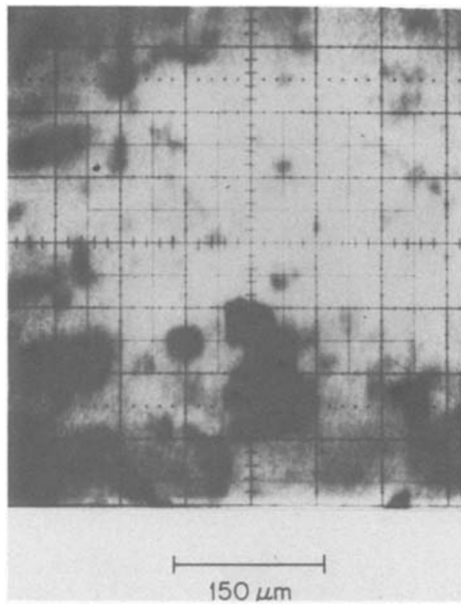

Fig. 2. Photoluminescence scan of the epitaxial layer of InP grown with substrate cover and without In meltback.

etch pits, identical to those described by Lum and Clawson (3), can be found only in a part of the substrate not covered with InP during the high temperature treatment. The PL scan however, reveals a number of dark areas, up to 150 μm in diameter, without corresponding morphological features. These defects, absent in substrate wafers not subjected to an intentional heat-treatment, are similar to those shown in Fig. 2. In addition, the overall PL efficiency (band-edge emission) of the heat-treated substrate decreases by about a factor of 2.

The effects of thermal dissociation on device performance were investigated on single diodes fabricated from different wafers. Since in a DH wafer the buffer layer is covered by other epitaxial layers, it cannot be examined by a PL scan. The defects in the buffer layer can, however, be imaged by a modified photocurrent scan technique, schematically shown in Fig. 3. The photoluminescence generated by the scanning laser beam at the surface of the InP substrate (top of the device) is transmitted through the wafer and is detected by the LED operating as a photodetector. Defects within the substrate and the buffer layer, *i.e.*, in the region above the p-n junction, that act as nonradiative recombination centers, In inclusions, etc., will result in regions of low photocurrent. Unlike the case of conventional photocurrent scan, direct injection of the scanning beam into the depletion region is not required. This photocurrent scan is similar in principle

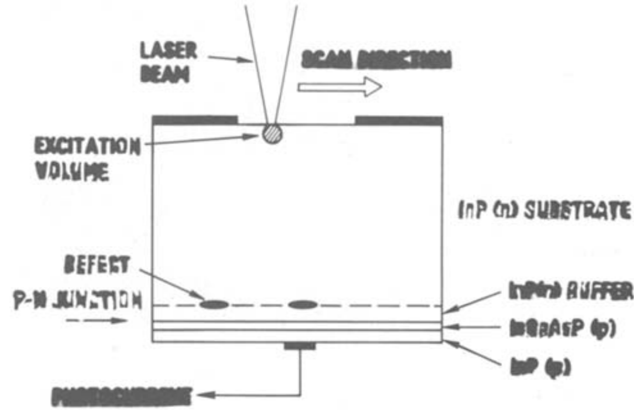

Fig. 3. Schematic diagram of a single chip photocurrent scan. Defects above the p-n junction can be imaged by this technique.

to the recently proposed technique of transmission cathodoluminescence (10). Similar, but not identical, results can be also obtained with the electron beam excitation (11).

Figure 4 shows the result of a photocurrent scan of an individual LED chosen for its low power output from a wafer grown with a cover piece and without In meltback. The bright key-shaped outline is defined by the top metallization. Inside its 200 μm diam opening, in addition to a number of smaller defects, a large and not fully resolved dark feature can be seen. Their dimensions and density are very similar to the defects imaged by PL scan on epitaxially grown InP buffer layers and thermally treated substrates. Examination of the quaternary layer by the PL scan of the epi-side did not reveal any nonuniformities, suggesting that the observed defects are confined to the InP layers. A large density of defects can be invariably found in diodes with low electroluminescence output. Typically, the power output of these diodes is a factor of 2-5 lower than the best devices obtained from the same wafer.

If the substrate is not covered, a very deep In meltback, up to 25 μm, is required to remove thermal damage. In our experience, however, even with such a deep etch the density of In inclusions exceeds that found in iso-epitaxial layers grown with the substrate cover and a shallow meltback. Once a thermal etch pit which gives rise to an In inclusion is formed, as discussed in Ref. (3), its removal by In etch is very difficult. Furthermore, since the In etch is crystallographic in nature, it is equally difficult to retain the flat surface essential for the growth of uniform epitaxial layers. Finally, the deep meltback frequently results in melt carryover and wipe-off problems. These difficulties of deep In etch become more severe for large area growth ($\gtrsim 1$ cm^2).

The defects of the type described above can be eliminated by an *in situ* In meltback, 2-5 μm deep, of the covered InP substrate immediately before growth commences. The PL scan of InP buffer layer and laser-induced current scan of devices grown with this additional In etch do not show any large defects of the type shown in Fig. 2 and 4. In addition, great reduction in the dislocation density is achieved. Figure 5(a) shows the surface of an epitaxial layer grown on low dislocation density S:InP, using the two substrate protection measures. The surface morphology is somewhat better than that shown in Fig. 1(a). Figure 5(b) shows the same area, indicated by black arrows, Huber etched for 45 sec. The evident microscopic perfection of this iso-epitaxial layer is made possible by the combination of InP cover piece and shallow In meltback. In the growth experiments in which only part of the protected substrate was subjected to a meltback, only that portion did not contain excess dislocations and dislocation loops.

Implementation of these two growth procedures resulted in a large increase of device yields. In the device wafers grown with the substrate cover but without meltback, a very large variation of LED power output was observed, with only about 30% of the diodes clustered at the high power end of the distribution histogram. This percentage increased to 80-90% in devices obtained from wafers grown with the addition of the meltback procedure.

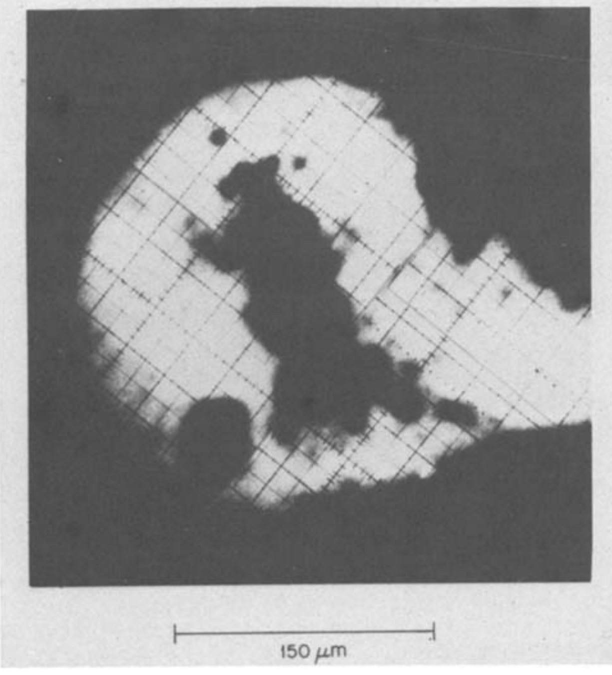

Fig. 4. Photocurrent scan of an LED chip. Bright key-like shape is defined by the n-metallization, as discussed in the text.

Discussion

The results presented here can be rationalized if it is assumed that a shallow and discontinuous layer of degraded material is formed at the surface of InP on heating. It has been observed that thermal treatment at temperatures higher than 370°C readily degrades the stoichiometry of near-surface InP due to phosphorous out-diffusion (12). When an epitaxial layer is grown on such a surface without meltback, the formation of a degraded layer is expected. The presence of such a thermally degraded layer near the substrate-epitaxial layer interface has been studied in n-GaAs, where the loss of As through thermal annealing has been accompanied by changes in the optical and electrical characteristics of the material. For instance, a reduction in the electron concentration in Se- and Te-doped GaAs has been observed upon annealing (13). Furthermore, photoluminescence studies of thermally degraded layers show great reduction of near bandgap luminescence efficiency and spectral changes associated with formation of As vacancies (14). Since these layers were very shallow, from 0.1 to 0.8 μm, their delineation by etching was not possible. The presence of a similar degraded layer on thermally treated InP is therefore plausible.

Two possibilities exist regarding the origin of dislocations observed in Fig. 1(b). First, the condensation of point defects inherited by an epi-layer during growth may result in formation of dislocations and dislocations loops. Second, thermal decomposition-induced defects in the substrate may aggregate to produce the observed shallow defects, which can then be replicated in the epi-layer. The second mechanism is more likely since it is consistent with the PL scan results and growth experiments in which only a portion of the substrate was etched with In.

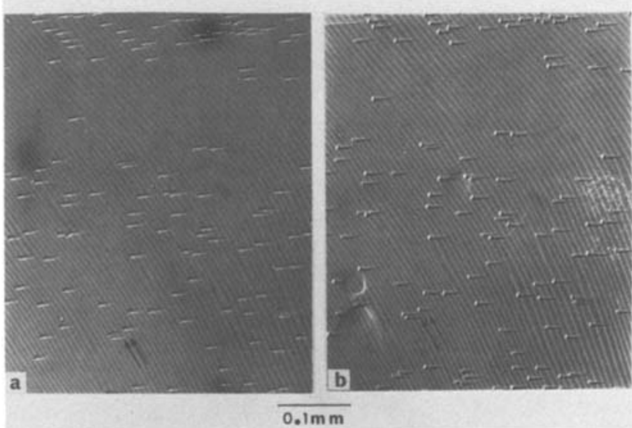

Fig. 5. Optical micrographs of an epi-layer which was protected by a source piece and the substrate melt-back. (a) As-grown surface, and (b) after Huber etching for 45 sec.

The use of substrate cover and In meltback works best when employed together. The InP cover piece greatly reduces the thermal decomposition of the substrate, as shown by the excellent surface morphology, by providing local phosphorus overpressure. However, in spite of good morphology, thermal decomposition is still present as demonstrated by areas of low luminescence in epitaxial layers. This residual shallow layer of dissociated substrate material is subsequently removed by a light In etch.

Defect-Revealing Etches on GaAs: A Comparison of the AHA with the A/B and KOH Etches

Wilfried R. Wagner, L. I. Greene, and L. I. Koszi*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

AHA etch-revealed features on {100} N^+ GaAs wafers were compared to defects revealed by the well-characterized A/B and molten KOH etches on the same sample areas. It was demonstrated that the AHA etch technique reveals dislocation line segments, growth striae, and microdefects as does the A/B etch. Unlike the A/B etch the AHA etch did not result in a "memory" effect. A 1:1 correlation between molten KOH-induced dislocation etch pits and AHA-revealed dislocation line segments was demonstrated.

Today, highly doped Bridgeman-grown GaAs represents the most commonly utilized substrate for GaAlAs-GaAs LPE. In this material only line dislocations can presently be characterized with confidence using various defect-revealing etches. A defect microstructure is known to exist (1, 2) in this material but has not been characterized in any detail. Oscillations in the rates of dopant incorporation during growth arising from constitutional supercooling (3) are revealed as the etched striae (4, 5) but the defect microstructure often observed in combination with such striae (5) has not been investigated as well. Defect-revealing etches are useful in determining substrate quality, evaluating the results of epitaxial growth, and monitoring processing steps. However, it is necessary to know and understand the behavior of each etchant thoroughly. Because of the unique characteristics of defect-revealing etches they can only be used with confidence if they have been well calibrated (5) and compared with other etches. The A/B etch (6), now commonly used in the GaAs industry, initially yielded irreproducible results until its "memory" (7) characteristic was understood. This etch determines defects/volume rather than defects/area as do most other etches.

One of us (LIG) reported on a new defect-revealing etch (8) effective on all orientations of conducting GaAs. Ammonium-hydroxide anodic (AHA) etching occurs by anodic electrochemical dissolution in a solution consisting of reagent grade ammonium hydroxide added to distilled water in sufficient quantities to reach a pH level between 10.6 and 13.4. Current densities between 0.1 and 2 mA/cm² and etching times between 1 and 5 min are sufficient to delineate defects. The AHA etch is particularly sensitive to changes in the electronic properties of GaAs such as the impurity atmospheres of dislocations and dopant segregation in growth striae. The simplicity, safety, and ease of use makes this a desirable etching technique. In this paper we present the results of an etch-to-etch calibration of the AHA etch vis-a-vis the A/B (5) and molten KOH (9) etches.

Procedures

Individual defects were mapped by etching a numbered grid on the back of selected {100} substrates by means of a photomask matrix grid. The map on the

* Electrochemical Society Active Member.
Key words: etching, "memory" effect, microdefects.

back of the wafer and the etched wafer front were superimposed by utilizing a Zeiss Universal microscope equipped with a "Photochanger" coupled to an infrared sensitive TV camera. The image on the TV monitor shows the strong image of the transmitted matrix pattern on the bottom surface (Fig. 1) while the photographed image is due to the infrared filtered reflected light from the etched top surface (Fig. 3a). Careful alignment ensured that identical wafer cross sections were viewed in both images. A specific wafer area could then be relocated easily by finding its grid position on the TV monitor. The use of Nomarski interference contrast was found to be essential in resolving etch features.

The etchants used were the AHA etch (8), the A/B etch (6), and the molten KOH (9) etch. All etched surfaces were of the {100} orientation from Si-doped ingots. AHA etching was done at room temperature in an electrolyte consisting of DI water and NH_4OH, usually at a pH of 11.5 and at 25 mA current for 30 sec. Following Stirland (2), A/B etching was done at

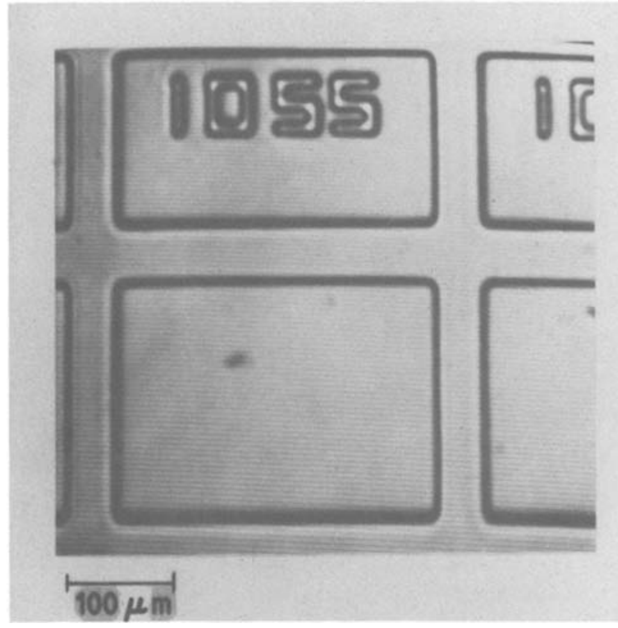

Fig. 1. The TV monitor image of a section of a specimen corresponding to the photomicrograph of an AHA etched surface shown in Fig. 3a.

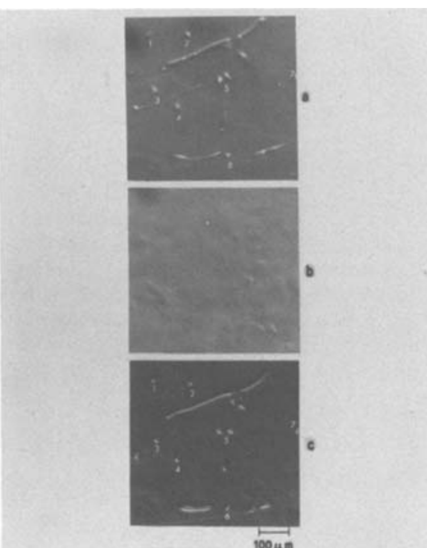

Fig. 2. Photomicrographs of an AHA-A/B etching sequence: (a) the AHA-etched surface; (b) the repolished surface; (c) the A/B-etched surface.

room temperature for a few minutes only. A/B etching was stopped when the Nomarski interference contrast of the first-revealed dislocations was similar to that of the AHA etch-revealed dislocations. In this manner complications arising from the "memory effect" (7) are avoided.

The molten KOH etch was utilized at 300°C for 30 min. A fresh KOH solution was always used and the samples were dipped into the solution as soon as the temperature set point was reached, approximately 15 min after the power was turned on. Experimental problems were common with this technique. Frequently, a solid crust would form over the solution; breaking this crust caused occasional samples to fracture. Defect-revealing etching did not take place on samples that were in contact with the precious metal crucible used to contain this corrosive etch. The exact composition of this etch is ill defined. KOH has a literature melting point of 360°C, yet the anhydrous, reagent-grade KOH we used was liquid already at 250°C. This chemical is extremely hygroscopic, therefore we suspect that this etch actually consists of a concentrated aqueous solution where the water is derived from atmospheric moisture. Defect-revealing etching did not occur in a dry nitrogen atmosphere.

The different etches were successively used on the same samples. The initial surface preparation on each sample consisted of a Syton-Peroxide (S-P) chemomechanical polish which had been used satisfactorily for liquid phase epitaxy applications. The subsequent polishing between each etch application was the same but did not result in as fine a surface because polishing was stopped as soon as the etchant-induced morphology was no longer visible.

The occurrence of a "memory" effect resulting from prolonged etching with the AHA etch was investigated by repeated sequential etching on the same area. Initially an array of dislocations was located on an AHA-etched surface by the technique described above. Then, to demonstrate the action of the A/B "memory" effect, the sample was A/B-etched without repolishing and the resultant morphology recorded after 5, 10, and 20 min of cumulative etching time. Next, again without repolishing the sample, the wafer was AHA-etched and the resultant morphology was recorded on the same area after 1, 3, 6, and 12 min of cumulative etching time.

Results

Calibrating the AHA etch against the AB etch.—Figures 2-4 demonstrate the correlation between the AHA and A/B etchant-revealed defects on three types of etch features, namely dislocations, "growth" striae, and microdefects. In Fig. 2a seven similar line features resulted from AHA etching (Fig. 2c). In Fig. 2c all seven defects mapped in Fig. 2a could be identified again. Both etchant-induced defect morphologies are similar. In Fig. 3 the etch features of interest consist of the "growth" striae. Using the defect contrast calibrated in Fig. 2 as location markers, in Fig. 3a the AHA etch reveals a stria superimposed on the sets of line defects at locations 1 and 2. Neither etch induced stria at location 3.

The AHA etchant-revealed defects visible in Fig. 4a are especially complex. In Fig. 4a the AHA-revealed line defects and striae are partially obscured by the dense background of a "microdefect" structure. With this sample, as defect registration was not considered essential, nearly 2 mils of sample thickness were polished off to achieve a specular surface before the A/B etch was applied. The results of the A/B etch are shown in Fig. 4b. A similar microdefect morphology of equivalent density is again found to exist in the same area.

Calibrating the AHA etch against the molten KOH etch.—An elegant correlation of the two etches is presented in Fig. 5. A {100} surface that had been etched

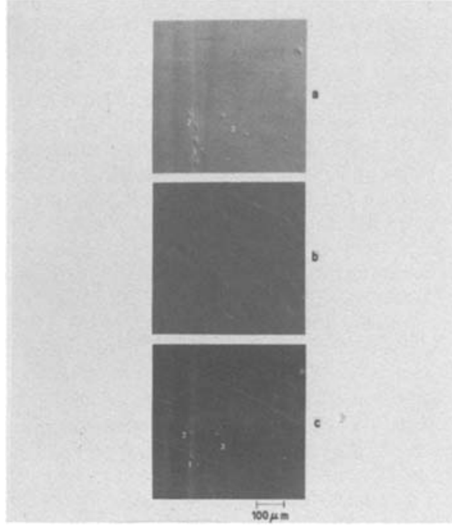

Fig. 3. Photomicrographs of an AHA-A/B etching sequence: (a) the AHA-etched surface; (b) the repolished surface; (c) the A/B-etched surface.

with molten KOH was cleaved, exposing a {110} cleavage plane. Then the cleavage plane was etched with the AHA etch. To every KOH-generated etch pit which was (substantially) intersected by the cleavage plane, an AHA-revealed line feature was traced. No other AHA-induced feature could be correlated with the KOH etch. The KOH etch did not reveal striae or microdefects.

Testing for the "memory" effect.—The effects of a series of etch sequences on the same six dislocations are shown in Fig. 6. In Fig. 6a six dislocations that were initially identified with the AHA etch and subsequently etched for 5 min with the A/B etch are shown. In Fig. 6b and c the etch morphology after 10 and 20 min of cumulative room temperature A/B etching is shown. The typical A/B dislocation traces can be seen to extend as a function of total etching time from the AHA-induced pits. Upon changing back to the AHA etch in Fig. 6d, e, and f, a pit can be seen to appear at the end of each A/B-induced dislocation trace. As a function of time, these pits do not elongate as was seen to occur with the A/B etch traces, but simply become more pronounced.

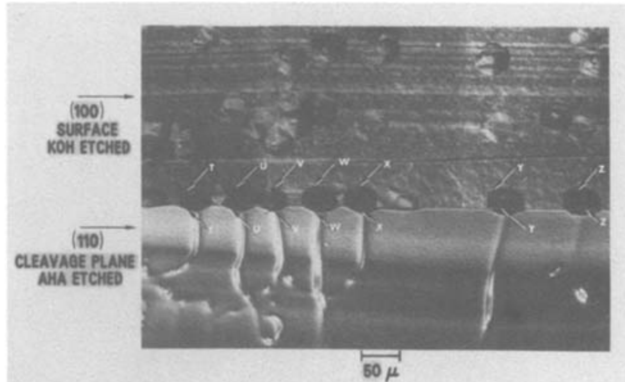

Fig. 5. A photomosaic of a molten KOH-etched specimen with an AHA-etched cleavage face.

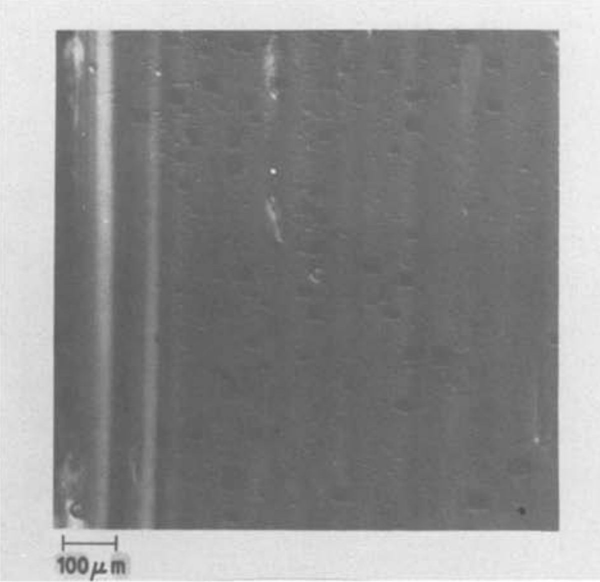
Discussion

It is well known that the A/B-induced morphology shown in Fig. 2c is the result of dislocations that existed in the material that was removed by the etch (1, 2, 5, 7). AHA-induced line features, as shown in Fig. 2a, were previously correlated with existing dislocations with an x-ray topograph (8). Molten KOH-induced etch pits, as are illustrated in Fig. 5, have been shown to result from the intersection of a dislocation with a free surface (10). We have demonstrated here that the use of the AHA etch results in a characteristic morphology at the same locations at which the other etches revealed the existence of dislocation line segments. The AHA-induced etch pits that begin to be visible in Fig. 6d prove that the AHA etch reveals dislocations intersecting the surface at the actual point of emergence. Dislocations near the surface are also revealed by the AHA etch. Pits Y and Z in Fig. 5 both have the AHA-revealed dislocations leading to the apex of the pit, but this dislocation "contrast" is different from that associated with pits T-X. The weaker relief suggests dislocation line segments underneath. The electrolytic etches are particularly sensitive to the impurity atmosphere surrounding dislocations (11). Because of this, a faint defect trace can be resolved for a "submerged" dislocation.

It was demonstrated in Fig. 3 that both the AHA and the A/B etch will reveal the same striae, but the relief is not the same, although our setting of the Nomarski contrast made it appear so. Given the nature of the two



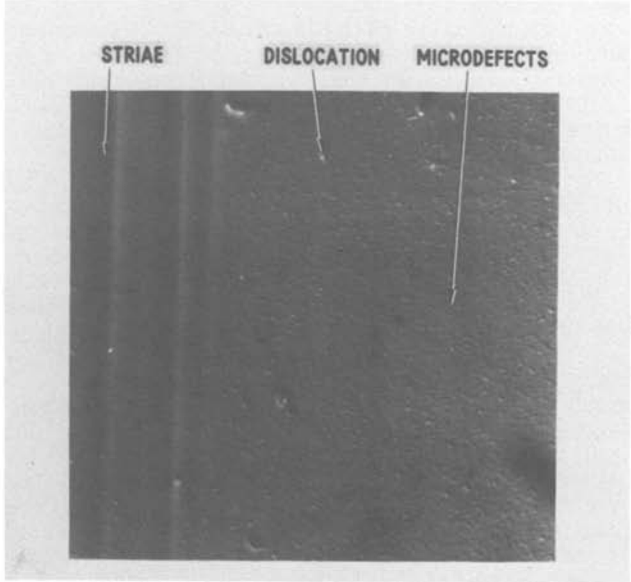


Fig. 4. Photomicrograph of an AHA-A/B etching sequence: (a, left) the AHA-etched surface; (b, right) the A/B etched surface

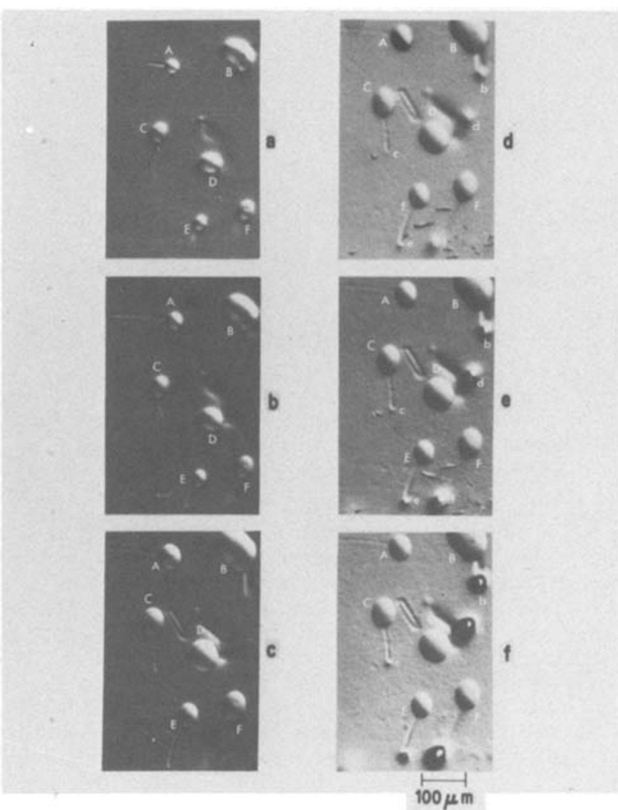

Fig. 6. Photomicrographs of an AHA-A/B-AHA etching sequence: (a) after 1 min AHA and 5 min A/B etching; (b) after 5 more minutes A/B etching; (c) after 10 more minutes A/B etching; (d) after 1 more minute AHA etching; (e) after 3 more minutes AHA etching.

etches, *i.e.*, that the A/B etch preferentially removes perfect material (7) while the AHA etch is thought to be primarily sensitive to the electronic nature of the material (11), the striae relief of both etches is opposite, *i.e.*, AHA-induced ridges were correlated to A/B-induced troughs.

Our data confirms that the KOH etch is only effective in revealing dislocations intersecting the free surface. This suggests that the KOH etch is principally sensitive to strain, while the A/B etch is also sensitive to chemical effects such as the impurity atmosphere near dislocations and impurity segregation or variations in stoichiometry at striae. Similarly, the AHA etch appears to be principally sensitive to variations in the electronic structure of the material. For this reason, dislocations and striae are revealed by the A/B etch in semi-insulating GaAs while this material is not normally etched at all by the AHA etch, but in N^+ GaAs striae are revealed much stronger with the AHA etch than with the A/B etch.

The nature of the defect microstructure revealed by the AHA etch in Fig. 4a and by the A/B etch in Fig. 4b is not understood. It may be composed of small dislocation loops or stacking faults. We do not believe that these microdefects correspond to the "S" pits described by Stirland and Augustus (1) because neither the observed defect morphology nor the wafer doping level correspond to their findings. The large rectangular pits visible in Fig. 4a occur as a result of local accelerated etching possibly at microdefect sites and are found after prolonged etching. These are also not well understood, presumably they are initiated by localized conductivity fluctuations. Prolonged etching was necessary in this particular sample to achieve resolution of both the dislocations and striae in addition to the microdefects.

The growth of the A/B etch-induced dislocation traces as a function of time in Fig. 6a-c is a clear illustration of the A/B "memory" effect. It is not unexpected to observe such relatively long dislocation traces because the A/B etch removes approximately 2.5 μm/min at room temperature. Eventually, these traces form a dense network of lines across the entire sample. With the AHA etch such a "memory" effect does not take place. As AHA etching is continued (Fig. 6e and f) the AHA etch features have become more pronounced but new etch features do not occur. The AHA-induced dislocation etch morphology visible in Fig. 6f is essentially identical to the original AHA-induced morphology still visible in Fig. 6a. (For brevity, a figure depicting the original, AHA-etched surface was omitted.) After 12 min of AHA etching, areas adjacent to the six dislocations shown had already degraded into the large rectangular pits discussed above, indicating that the specimen was completely etched. Nevertheless, prolonged AHA etching did not result in new dislocation traces and therefore a misleading defect determination.

The effect of the AHA etch on p-type (Zn-doped $2 \times 10^{18}/cm^3$) GaAs is somewhat different. The observed defect morphology was identical to n-type material; dislocations, microdefects, and striae were revealed precisely the same, but accelerated etching effects were never observed on this type of material. Etching could be continued apparently indefinitely, therefore new dislocation traces would eventually appear. This is, of course, a "memory" effect. In practice, only a prolonged etching, continued long after dislocation traces were readily resolved, would result in an erroneous defect determination.

Conclusion

The AHA technique reveals defects on GaAs such as dislocations, growth striae, and microdefects. The resultant defect morphology is similar to that of the A/B etch but the etch is readily effective on conducting GaAs only. All defects revealed by the molten KOH or A/B etches are also revealed by the AHA etch. There is no "memory" effect associated with the AHA etch but prolonged etching may result in large pits at the sites of defects.

Detection of Structural Defects in N-type InP Crystals by Electrochemical Etching under Illumination

A. Yamamoto, S. Tohno, and C. Uemura

Ibaraki Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Tokai, Ibaraki 319-11, Japan

ABSTRACT

An experimental study has been made of the detection of structural defects in n-type InP crystals by electrochemical etching under illumination. Under illumination, presence of structural defects such as mechanical damage or grown-in defects on the crystal surface led to a decrease of dissolution rate of the surface. This enabled structural defects to be revealed as etch hillocks. Surface damage introduced during handling processes of the crystal was detected with high sensitivity. By observing etch hillocks, detailed information was obtained regarding fine structure and distribution of dislocations or dislocation clusters in nominally undoped crystals. It was found that novel defects, which were not involved in nominally undoped crystals ($n = 1\text{-}5 \times 10^{16}$ cm^{-3}), were involved in highly sulfur-doped crystals ($n = 4 \times 10^{18}$ cm^{-3}) with low dislocation densities (EPD $\lesssim 10^3$ cm^{-2}).

The interest in InP has increased recently since InP crystals have been used as substrates for InGaAsP-InP lasers emitting in the 1.0-1.6 μm wavelength region. It is well known that a poor quality substrate is a major source of imperfections in epilayers. Therefore, to enhance the reliability of InP-based devices, it is essential to lower defect content in InP crystals. Simultaneously, it is desirable to evaluate InP crystals accurately by simple and convenient methods.

Chemical etching techniques have been widely used to detect structural defects in III-V compound crystals. For GaAs crystals, it has been found that the chemical etching using the AB etchant (1) or the photoetching using the modified AB etchant (2) produce etch hillocks at defects. Such etch hillocks give us more useful information with regard to the fine structure of defects than the "orthodox" etch pits (3). We have found previously (4) that, in the electrochemical etching of n-type GaAs under illumination, etch hillocks can be produced by employing suitable current density and incident light intensity. The detection of structural defects in n-type GaAs by electrochemical etching has been studied by Factor and Stevenson (5).

For InP crystals, on the other hand, chemical etchants that produce etch hillocks have not been reported. Also, few studies have been made of anodic dissolution or electrochemical etching of InP.

In this work, we studied anodic dissolution of n-type InP under illumination and, on the basis of that, detected structural defects in n-type InP crystals by electrochemical etching under illumination. As a result, it was proved that electrochemical etching under illumination was able to reveal handling damage or grown-in defects as etch hillocks with high sensitivity and high resolution. It was also found that novel defects, which were hardly detected by the conventional chemical etching technique, were involved in highly sulfur-doped InP crystals.

Experimental

The apparatus used for the study of anodic dissolution and electrochemical etching of n-type InP under illumination is schematically illustrated in Fig. 1. The anodic current was pulsed at a frequency of 30 Hz and with a 10% duty cycle. Measurements of potential were made of InP electrodes against a saturated calomel electrode (SCE). The InP sample was illuminated with an incandescent lamp of 60W, and the light was introduced to the sample surface by using a low-loss quartz rod. For the electrolyte, a solution of 1 mole/liter NaOH (6) was employed. The electrolyte was kept at 25°C and dry N_2 gas was slowly bubbled during experiments.

Most of samples used were InP single crystals with <100> or <111>P orientation grown by the liquid encapsulation Czochralski (LEC) method. The nominally undoped crystals with carrier concentration of $1\text{-}5 \times 10^{16}$ cm^{-3} were grown in our laboratory. The sulfur-doped crystals with carrier concentration of 4×10^{18} cm^{-3} were purchased from Varian Associates (USA). For the study of carrier concentration dependence of dissolution rate, heavily sulfur-doped crystals ($n = 2 \times 10^{19}$ cm^{-3}) grown by the synthesis solute-diffusion (SSD) method (7) were also used. The InP wafers of 0.5 mm thickness were cut from the single crystal rods. They were mechanically lapped with SiC slurry

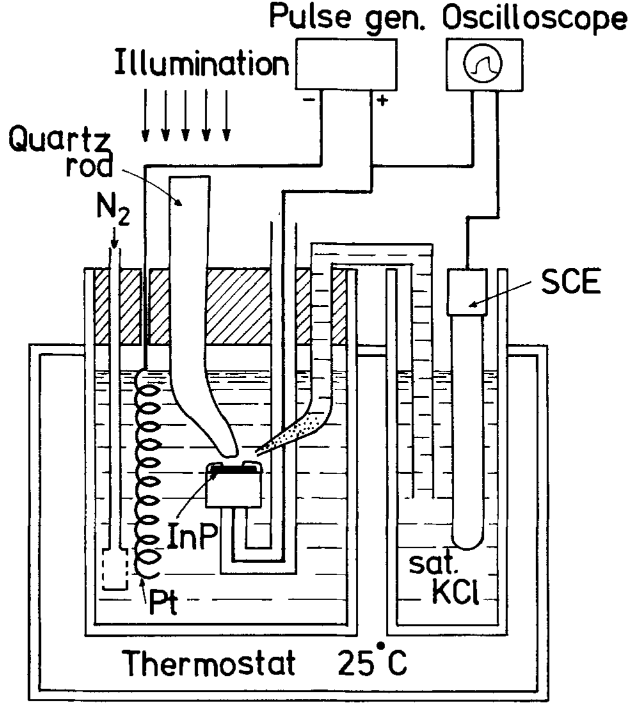

Fig. 1. Apparatus used for the study of anodic dissolution and electrochemical etching of n-type InP under illumination.

Key words: InP, structural defect, anodic dissolution, electrochemical etching.

(No. 4000) and then mechanically polished with fine abrasive alumina (0.3 μm particle size). After being degreased and rinsed with deionized water, they were chemically polished in a 2% Br-methanol solution.

The sample was fixed by the sample holder shown in Fig. 2. The InP wafer was cemented with an adhesive wax to the Teflon electrode holder and coated with Apiezon wax. The exposed area of the InP surface was 5-10 $\times$ 10^{-2} cm^2. Ohmic contact to the wafer was made by rubbing Ga-In eutectic on the rear surface of the wafer.

To calibrate etch hillocks produced by the electrochemical etching, the sample surface was also chemically etched with a solution of 2 H_3PO_4 + 1 HBr (Huber etch) (8), which has been currently used to reveal dislocations in InP crystals. Etched patterns were examined by the Nomarski technique. Profiles of etched surface were determined by Dektak (an instrument for mechanical measurement of roughness and waviness, manufactured by Sloan Instruments Corporation).

Results and Discussion

I-V Characteristics of n-Type InP Electrodes

Current density-dissolution potential (*I-V*) characteristics of n-type InP electrodes were studied to understand the anodic behavior and, furthermore, to find conditions for preferential etching for the detection of structural defects. Dissolution potentials of InP electrodes under the dark and illumination conditions were measured as a function of current density. By employing a pulsed current of 10% duty ratio, the potential became completely stable and was measured with high reproducibility.

Figure 3 shows the *I-V* curves for a chemically polished InP sample and a mechanically polished one. The samples are nominally undoped (100) InP crystals with carrier concentration of 1 $\times$ 10^{16} cm^{-3}. In the dark, the surface damaged mechanically exhibits less noble dissolution potential than the undamaged one. This fact indicates that the presence of defects leads to an increase in reactivity of the InP surface. This increase is due to the hole generation at defects introduced by mechanical polishing. From this fact, it is obvious that etch pits are produced at defect sites on the surface when the electrochemical etching is carried out in the dark. By illuminating the surface, dissolution potential of the undamaged surface is drastically shifted to a more active value, whereas that of the damaged one is slightly changed. Under illumination, consequently, the undamaged surface is more reactive than the damaged one. Such smaller dissolution rates

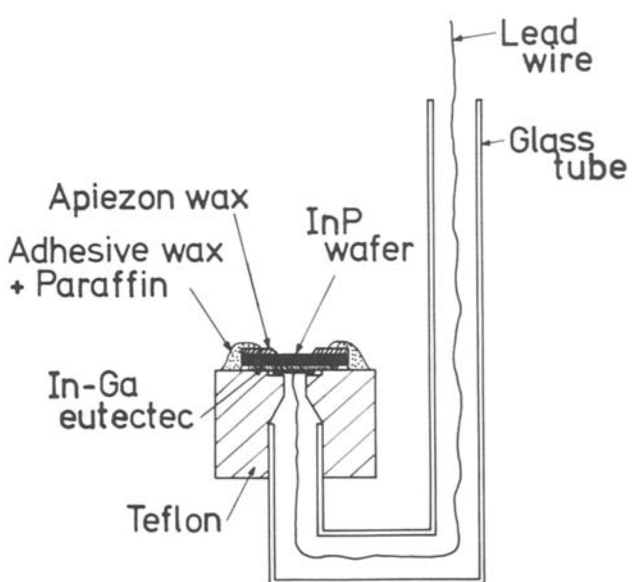

Fig. 2. Cross section of sample holder

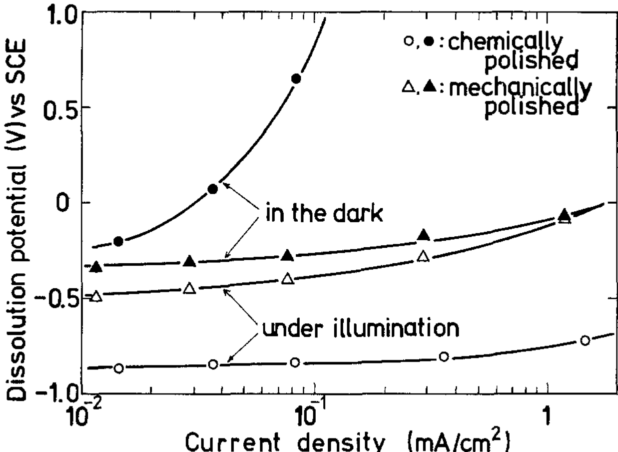

Fig. 3. Dissolution potential-current density curves for <100>-oriented InP electrodes polished chemically or polished mechanically with abrasive alumina (0.3 $\mu m\phi$).

of the damaged surface under illumination is due to lower hole concentration at the surface, because defects introduced by mechanical polishing act as recombination centers of holes generated by incident light. This fact suggests that etch hillocks can be produced at defect sites by the electrochemical etching under illumination.

Figure 4 shows the *I-V* curves for <100>-oriented InP samples with different carrier concentrations. All samples were chemically polished in a Br-methanol solution before measurements. In the dark, the sample with higher carrier concentration shows less noble dissolution potential, *i.e.*, higher dissolution rate. This result is similar to those for other semiconductors (4, 9, 10) and cannot be explained by taking into account only the hole concentration in the bulk of the sample. Under illumination, the sample with higher carrier concentration shows lower dissolution rates because of its smaller increase in dissolution rate by illumination. Such a smaller increase in dissolution rate by illumination, as well as the higher dissolution rate in the dark, for the sample with higher carrier concentration may be explained by the decrease of contribution rate of hole to the anodic dissolution process (9). The sample with carrier concentration of 2 $\times$ 10^{19} cm^{-3} is electrochemically polished even in the dark, and the *I-V* curve for this sample is scarcely influenced by the introduction of mechanical damage. These facts show that the detection of defects by electrochemical etching is impossible for such heavily doped samples. From the facts mentioned above, it also seems that n-type InP with carrier concentrations of about 10^{19} cm^{-3} needs no holes in the dissolution reaction (10).

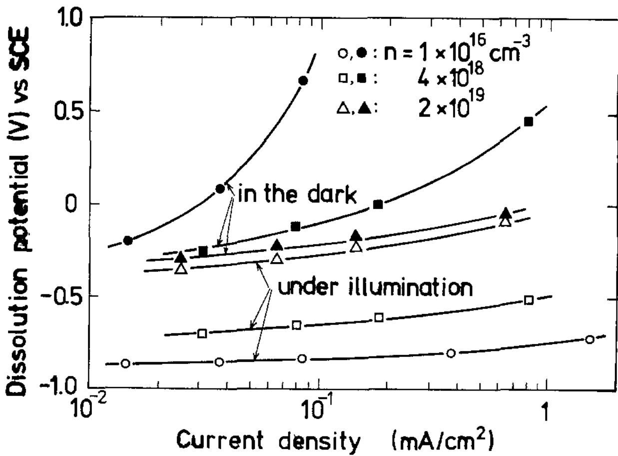

Fig. 4. Carrier concentration dependence of dissolution potential-current density curve for <100>-oriented InP electrodes.

It can be seen from the carrier concentration dependence of the dissolution rate shown in Fig. 4 that growth striations in the crystal are detected as a rugged feature on the etched surface, because they are due to local fluctuations of carrier concentration in the crystal.

Detection of Handling Damage and Grown-In Defects

Handling damage.—Surface damage introduced during preparation or handling processes of the samples must be completely removed in order to evaluate grown-in defects accurately. It is well known that damage is introduced by cutting, lapping, or mechanical polishing of the crystal (preparation damage). Such damage can be removed by the chemical polishing as a final preparation process. Damage is also introduced in the handling process of the sample after the chemical polishing (handling damage). The handling damage is not so heavy as the preparation damage and, therefore, is considerably difficult to detect. In this work, the detection of handling damage by electrochemical etching under illumination was investigated.

Figures 5 and 6 show the handling damage revealed by electrochemical etching under illumination. The samples are nominally undoped crystals ($n = 1 \times 10^{16}$ cm^{-3}) with <100> orientation. Linear and dot-like features are produced when the surface was rubbed with a filter paper [Fig. 5(a)]. These features consist of elevated structures (etch hillocks) as seen from Fig. 5(b). Band-like hillocks are produced when the surface was held with a Teflon tweezer, as shown in Fig. 6(a) and 6(b). Before the electrochemical etching, no features such as scratches are observed on the surface. As can be seen from the results in Fig. 5 and 6, however, the electrochemical dissolution rate at the damaged portions on the surface is remarkably decreased. These results suggest that the recombination velocity of holes at the damaged portions is extremely increased in spite of no changes in the surface morphology. On the other hand, no features are produced by the chemical etching with the Huber etch or a Br-methanol solution. Therefore, it is concluded that the detection sensitivity of electrochemical etching to defects is higher than that of chemical etching.

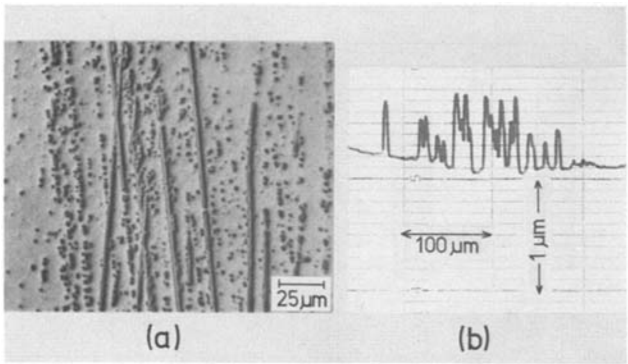

Fig. 5. Surface damage introduced by rubbing with a filter paper: (a) electrochemically etched pattern; (b) profile of the etched surface.

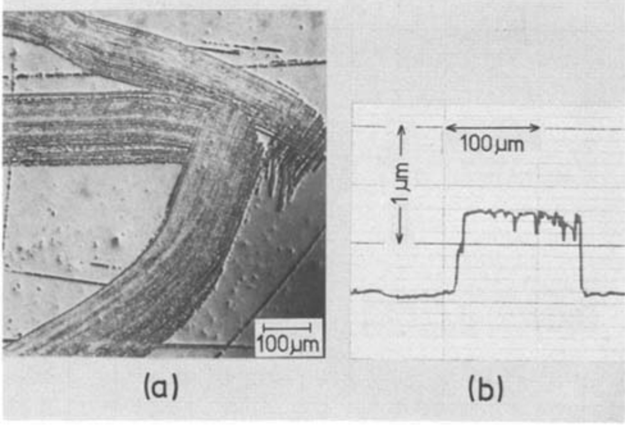

Fig. 6. Surface damage introduced by holding with a Teflon tweezer: (a) electrochemically etched pattern; (b) profile of the etched surface.

Detection of the handling damage for the samples of 4×10^{18} cm^{-3} is successfully performed as in the case of the samples of 1×10^{16} cm^{-3}. For the samples of 2×10^{19} cm^{-3}, on the other hand, the detection is unsuccessful, that is, no etch hillocks are formed and the samples are electrochemically polished. This result agrees with that expected from the *I-V* curves.

As described above, it is confirmed that etch hillocks can be produced at damaged portions on the n-type InP surface by the electrochemical etching under illumination, and is also found that light damage such as handling damage can be detected with high sensitivity by this technique.

Grown-in defects.—Detection of grown-in defects was carried out for the samples prepared carefully to eliminate any surface damage. The samples investigated are nominally undoped (n = 1-5 $\times 10^{16}$ cm^{-3}) and sulfur-doped ($n = 4 \times 10^{18}$ cm^{-3}) crystals grown by the LEC method.

Defects in nominally undoped crystals.—A typical electrochemically etched pattern produced on the (100) surface is shown in Fig. 7(a). Dot-like features are observed and they consist of elevated structures (etch hillocks) as shown in Fig. 7(b). The surface shown in Fig. 7(a) was then chemically etched with the Huber etch to reveal etch pit patterns. The result and the correspondence between the etch hillocks and the etch pits are shown in Fig. 7(c) and 7(d), respectively. Good correspondence between both is evident. Therefore, it is concluded that the etch hillocks are due to dislocations because the Huber etch produces dislocation pits. The correspondence, however, is not completely perfect. A few pits which do not correspond

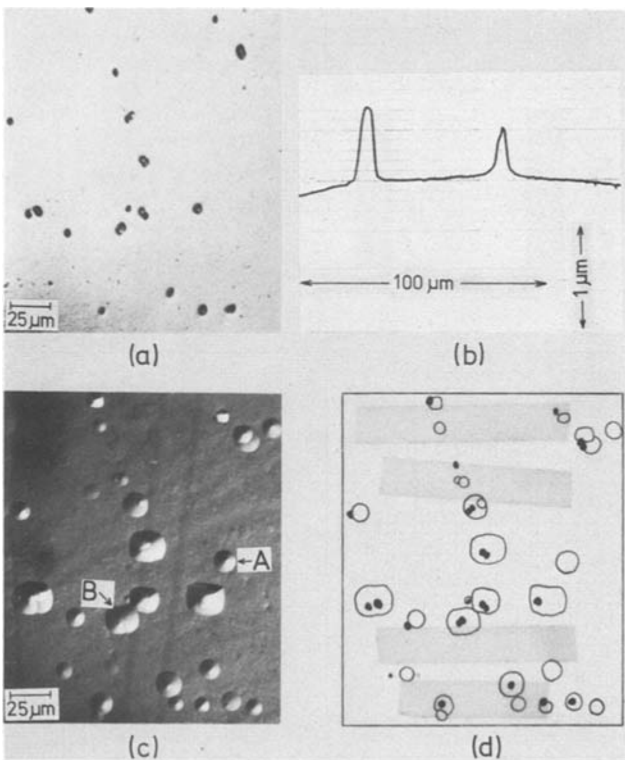

Fig. 7. Detection of dislocations on the (100) surface of nominally undoped crystal: (a) electrochemically etched pattern; (b) profile of the etched surface; (c) etch pit pattern revealed with the Huber etch; (d) correspondence between etch hillocks (a) and etch pits (c).

to the etch hillocks, such as the pit denoted by "A" in Fig. 7(c), are observed. The numbers of such pit were found to increase with increasing the time of the chemical etching. This fact indicates that these pits are due to dislocations laid at deeper portions beneath the original surface. Several rectangular pits are observed in Fig. 7(c) and each pit corresponds to two hillocks lying very close to each other as seen in Fig. 7(d). One of the rectangular pits, denoted by "B" in Fig. 7(c), has no apex and resembles a saucer-pit rather than a dislocation-pit. These facts suggest that the defects responsible for the rectangular pits are not line defects (linear dislocations) but isolated defects such as dislocation loops.

Figure 8 shows the electrochemically etched pattern produced on the (111)P surface. Linear hillocks, which are not found on the (100) surface, are observed on the (111)P surface in addition to dot-like hillocks. This is in contrast with the results for GaAs (2, 3) in which dot-like hillocks mainly exist on the (111)As surface and linear hillocks on the (100) surface. The linear hillocks on the (111)P surface show the existence of dislocations comparatively parallel to (111) planes in InP crystals. The straight line denoted by "S" in Fig. 8 is a growth striation. It should be noted that the revelation of growth striations in the crystals of such low doping levels ($\sim 10^{16}$ cm^{-3}) shows the high detection sensitivity of electrochemical etching to inhomogeneity in the crystal.

In some of the crystals investigated, defects consisted of clustered etch pits, *i.e.*, clustered dislocations were observed when the surfaces were etched with the Huber etch. A typical result is shown in Fig. 9(a). Figure 9(b) shows such defects revealed by electrochemical etching under illumination. Although these defects are observed as mere clusters of pits in Fig. 9(a), it can be seen from Fig. 9(b) that they consist of the following three regions: a ball-shaped nucleus, a region of inseparably concentrated dislocations around the nucleus, and an outermost region in which dislocations are scattered. The nucleus is not always found in all cases. Defect II in Fig. 9(b) is an example in which the nucleus is not found. The region of inseparably concentrated dislocations is star-like and is extended to [110] directions. Seki *et al.*[1] have observed this type of defect in etch pit patterns and found from Auger analysis of the etched surface that the composition of the crystal is In-rich at the portions involving these

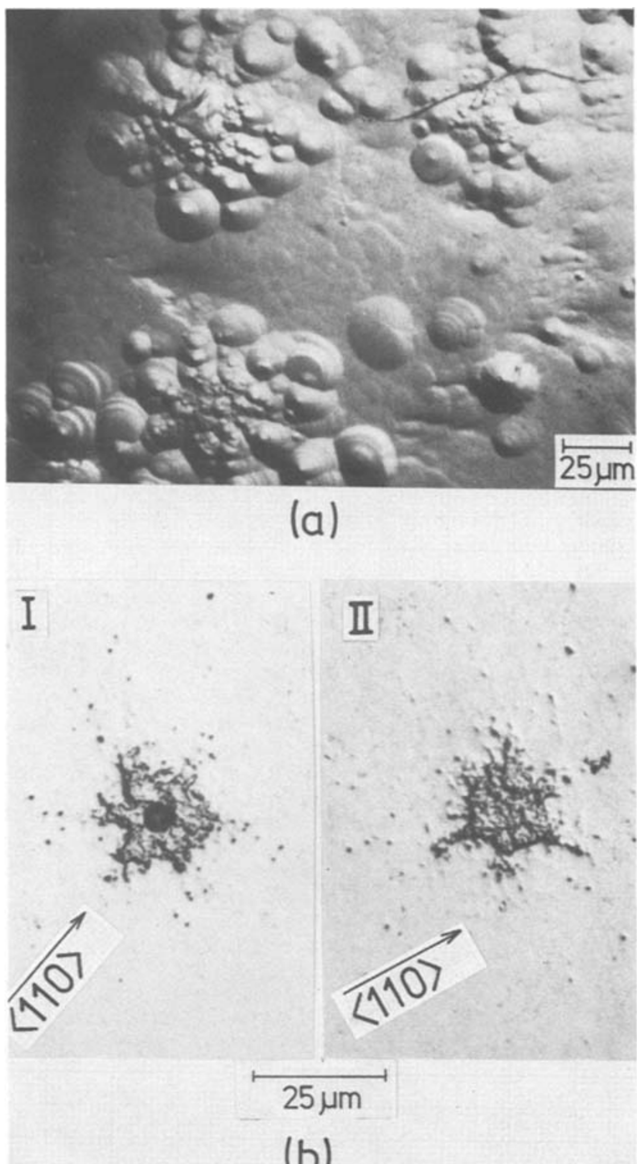

Fig. 9. Clusters of dislocations observed in nominally undoped crystal: (a) chemically etched pattern; (b) electrochemically etched pattern.

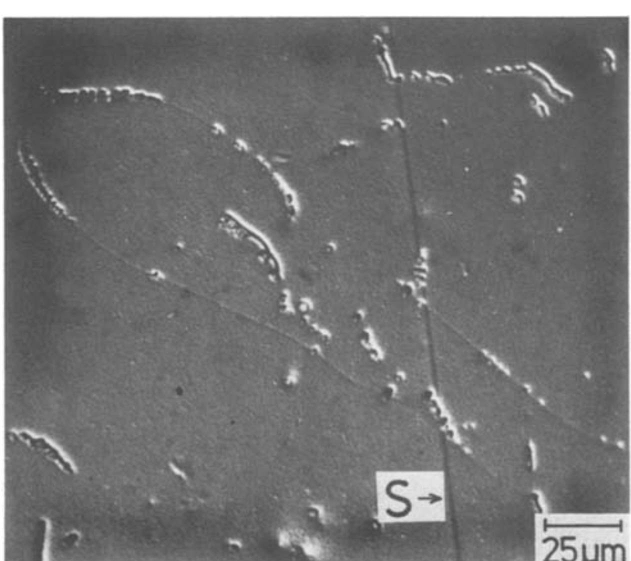

Fig. 8. Electrochemically etched pattern produced on the (111)P surface of nominally undoped crystal.

defects. On the other hand, similar defects to those revealed here have been observed in GaP crystals pulled from Ga-rich melts and they have been attributed to the defects caused by Ga inclusions (11). From these results, it is reasonable to interpret that the defects shown in Fig. 9 are caused by In inclusions and the ball-shaped nucleus is an In inclusion. The nucleus in the defect II in Fig. 9(b) is thought to either have been already removed during the preparation process of the sample or have been buried below the surface.

As described above, major defects detected in nominally undoped InP crystals are dislocations and dislocation clusters including In inclusions. The observations of etch hillocks produced by the electrochemical etching under illumination give more detailed information on the structure and distribution of these defects than those of etch pits.

Defects in S-doped crystals.—The samples investigated were cut from S-doped wafers having average etch pit density (EPD) of $\lesssim 10^3$ cm^{-2}. The distribution of EPD in the wafer was not uniform, that is, EPD depended largely on the portion of the wafer. The samples having EPD from zero to more than 10^4 cm^{-2} were prepared. Sorts or densities of defects newly detected in

the samples were found to be different depending on EPD in the sample.

The results obtained for the samples having high EPD ($\gtrsim 10^3$ cm^{-2}) are described. Figure 10(a) shows a typical pattern produced electrochemically on the (100) surface. Etch pits observed on the surface were formed by using the Huber etch before the electrochemical etching. In this sample, no other defects are observed except for dislocations and growth striations. Figure 10(b) shows the surface profile of the pit-free region in Fig. 10(a) traced perpendicularly to the striae. Growth striations are due to local fluctuations of doping levels in the crystal. From the *I-V* curves in Fig. 4, it can be seen that the dents and bulges in Fig. 10(b) correspond to the regions of lower doping levels and of higher doping levels, respectively.

The results obtained for the samples having EPD of nearly zero are described and discussed. Figure 11(a) shows the electrochemically etched pattern produced on the (100) surface of the dislocation-free sample. In contrast to the result for the higher EPD sample [Fig. 10(a)], ellipse-shaped or dash-like features are observed in this figure. The density of these features was found to drastically decrease with increasing EPD in the sample. The density on the surface shown in Fig. 11(a) is about 10^5 cm^{-2}. These features are distributed parallel to <110> direction, as seen from Fig. 11(b). When the surface shown in Fig. 11(a) is etched with the Huber etch (etched depth ≈ 2 μm), these features disappear leaving the vestiges "A'"-"D'" only for the relatively large features "A"-"D" as shown in Fig. 11(c). Mahajan *et al.* (12) have observed similar features to the ellipse-shaped ones in the transmission cathodoluminescence (TCL) images for highly zinc-doped (100) crystals and have interpreted them as impurity clusters. In the TCL images, however, the fine structure of the ellipse-shaped features and the presence of the dash-like features have not been revealed. This may be due to the relatively low resolution of the TCL image.

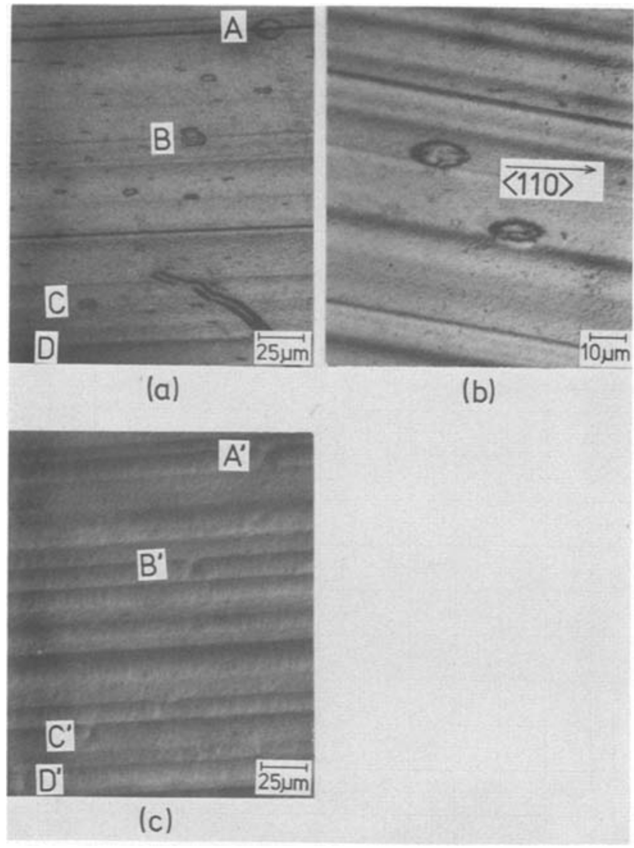

Fig. 11. (100) surface of S-doped crystal ($n = 4 \times 10^{18}$ cm^{-3}), dislocation-free, after electrochemical etching: (a) electrochemically etched pattern; (b) magnification of (a); (c) variation of the etched pattern (a) by chemical etching with the Huber etch (etched depth is about 2 μm).

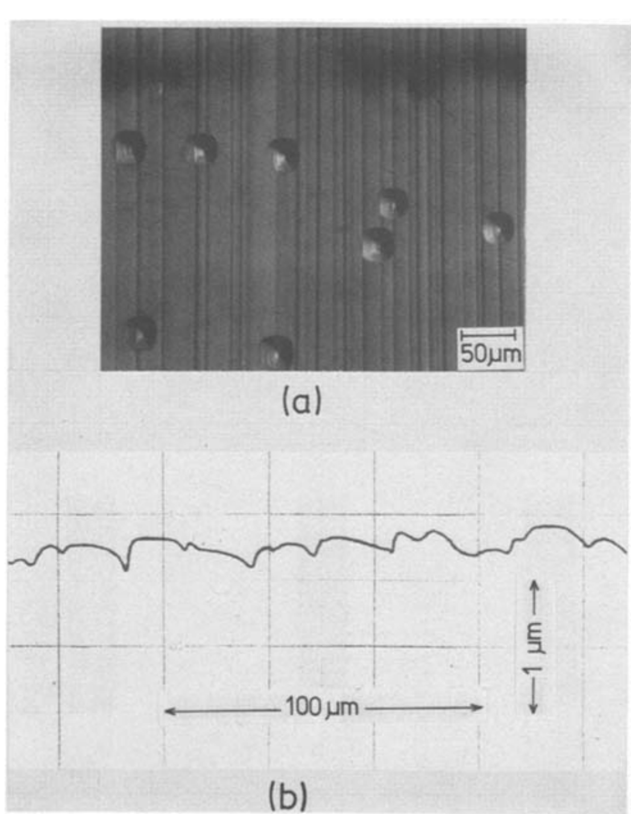

Fig. 10. (100) surface of S-doped crystal ($n = 4 \times 10^{18}$ cm^{-3}) having dislocation density of about 10^4 cm^{-2} after electrochemical etching: (a) electrochemically etched pattern; (b) surface profile of the pit-free region. The etch pits observed in (a) were produced with the Huber etch before electrochemical etching.

Figure 12(a) shows the electrochemically etched pattern produced on the (111)P surface of dislocation-free sample. Dot-like features of density about 10^4 cm^{-2} are observed. Figure 12(b) is a magnification of Fig. 12(a). In this figure, relatively large features denoted by "A" and "B" and a small one denoted by "C" are observed. When the surface in Fig. 12(b) is etched with the Huber etch (etched depth ≈ 2 μm), saucer-pits "A'" and "B'" are produced at the features "A" and "B," respectively, and, on the other hand, the feature "C" disappears leaving a faint vestige "C'," as shown in Fig. 12(c). This result suggests that the features "A" and "B" are due to different origins from that of the "C." The origin of feature "C" seems to be similar to that of the feature observed on the (100) surface [Fig. 11(a)], because both features disappear after the chemical etching.

As described above, it was found, with the assistance of electrochemical etching under illumination, that novel defects, which were not observed in the crystals with high dislocation densities, were involved in the dislocation-free crystals doped with sulfur. Although these defects are somewhat larger in size than the microdefects observed in GaAs:S or GaAs:Te (13), we believe that their presence is closely related with high-impurity doping and/or with reduction of grown-in dislocations. Interpretation of structural defects by electrochemical etching alone is difficult, however. Further investigations to reveal fine structures of the defects detected in this work with transmission electron microscope (TEM), in combination with the detection of the defects by the electrochemical etching, are now in progress.

(111)P surface of S-doped crystal ($n = 4 \times 10^{18}$ cm^{-3}), dislocation-free, after electrochemical etching: (a) electrochemically etched pattern; (b) magnification of (a); (c) variation of the etched pattern (a) by chemical etching with the Huber etch (etched depth is about 2 μm).

Summary

Anodic dissolution and electrochemical etching of n-type InP under illumination were studied in order to detect structural defects in n-type InP crystals.

The presence of structural defects led to a decrease of dissolution rates of the crystal surface under illumination. This enabled us to reveal defects as etch hillocks. Surface damage introduced during treatments with a filter paper or a tweezer were detected with high sensitivity. Major grown-in defects detected in nominally undoped crystals ($n = 1\text{-}5 \times 10^{16}$ cm^{-3}) were dislocations and dislocation clusters caused by In inclusions. By the observations of the etch hillocks, more detailed information was provided regarding the structure and distribution of these defects than by those of the etch pits. In sulfur-doped crystals ($n = 4 \times 10^{18}$ cm^{-3}) with low dislocation densities (EPD $\lesssim 10^3$ cm^{-2}), ellipse-shaped or dash-like defects were observed on the (100) surface and dot-like defects on the (111)P surface. Such defects were hardly detected by the chemical etching technique. The density of these defects were decreased drastically with increasing dislocation density in the crystal. The presence of these defects was thought to be closely related with high-impurity doping and/or reduction of grown-in dislocations.

Through these investigations, it was demonstrated that electrochemical etching under illumination had the ability to reveal inhomogeneity in n-type InP crystals, including structural defects, with high sensitivity and high resolution.

Studies of Phosphorus Pile-Up at the Si-SiO_2 Interface Using Auger Sputter Profiling

S. A. Schwarz,[1] R. W. Barton, C. P. Ho,* and C. R. Helms*

Stanford Electronics Laboratories, Stanford University, Stanford, California 94305

ABSTRACT

We have used Auger sputter profiling to investigate in detail the pile-up of phosphorus at the Si-SiO_2 interface, which occurs during thermal oxidation of heavily doped silicon. We find that, in the early stages of oxidation, the interfacial region acts as a sink for phosphorus. As oxidation proceeds, the "pile-up" within 50Å of the interface saturates and the phosphorus concentration in the silicon near the interface begins to rise. High temperature nitrogen anneals had little effect on the pile-up, indicating that existence of the pile-up cannot be explained by a simple diffusion mechanism. We also observed the pile-up to be greatly diminished in a heavily boron-compensated sample. We discuss possible mechanisms which may be responsible for this effect.

During the thermal oxidation of heavily phosphorus-doped silicon, the phosphorus, which is relatively insoluble in SiO_2, is rejected by the oxide and pushed into the silicon where it diffuses away from the interface. This process was first described in detail by Grove *et al.* (1). If oxide growth and diffusive transport are the only operative mechanisms in the process, the phosphorus concentration near the Si-SiO_2 interface should be no more than twice the bulk concentration for typical conditions, as illustrated in Fig. 1. However, a magnified view of the interfacial region, obtained using Auger sputter profiling, shows an anomalous buildup of phosphorus near the interface as illustrated in the inset in Fig. 1. This phosphorus pile-up has been observed by several groups (2-6) and is the subject of this paper.

The pile-up phenomenon has implications for device performance. We will show that the rapid uptake of phosphorus at the interface has a significant effect on the doping level near the interface, especially during the early stages of oxidation. This may be particularly important for VLSI devices in which thin oxides, high doping levels, and shallow junctions may be present. The phosphorus pile-up is also one of a class of related interfacial phenomena which are of current practical interest. Other phenomena include dopant-enhanced oxidation (7-9), oxidation-enhanced diffusion (10), and doped oxide-source diffusion (11).

In this paper, we investigate the evolution of the phosphorus pile-up during oxide growth for a variety of oxidation conditions. We also examine the effects of high temperature N_2 anneals and boron compensation. We find that the driving force for phosphorus pile-up is an equilibrium property of the interface, and is not due to the oxidation process itself. The interface acts as a sink for phosphorus, which may be represented as a sharp minimum in the chemical potential for that region. A vacancy mechanism model is also presented which is consistent with our experimental results and also accounts, to some extent, for the related phenomena mentioned above.

The paper is organized as follows. We begin by describing the Auger sputter profiling (ASP) technique. Experimental details and results appear next, and then we discuss these results and examine several physical mechanisms which could account for our observations. The thermodynamic model is also discussed. A Summary follows. The vacancy mechanism model is discussed in the Appendix.

Auger Sputter Profiling

The Auger sputter profiling (ASP) technique has been discussed in detail elsewhere (12). We briefly describe here the details of the ASP technique as it applies specifically to these studies.

Our experiments were performed in a Varian 2730 Spectrometer with a base pressure of $\sim 10^{-9}$ Torr. Electrons from the integral gun of the variable-aperture cylindrical mirror analyzer struck the sample at an angle of 30° to the surface normal. The 4.5 keV electron beam was operated at currents less than 10 μA rastered over a 200 $\times$ 200 μm square to minimize effects of electron-stimulated desorption and electron beam-induced diffusion (2, 4, 13). Sputtering was performed using a pseudorandom rastered ion beam at beam energies af 1 keV or less at an angle of incidence of 49°. Neon was used so that a liquid N_2 cryopanel could be employed to minimize the partial pressure of contaminant gases. We have previously shown that, with these experimental parameters, the measured

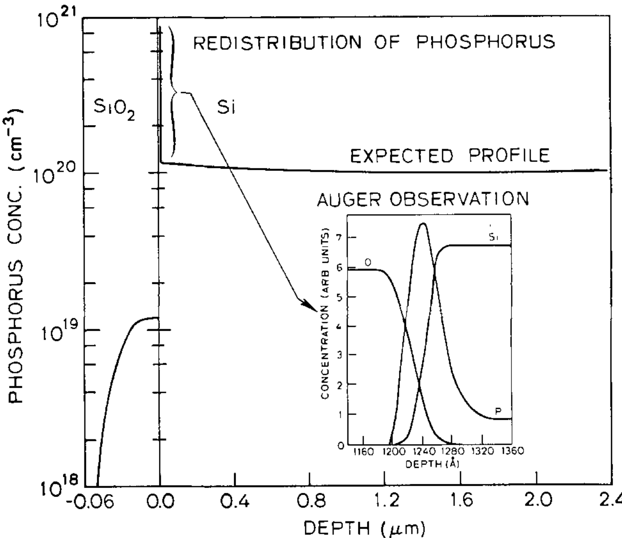

Fig. 1. Illustration of the phosphorus pile-up effect at the Si-SiO_2 interface for a bulk concentration of 10^{20} cm^2 and a sample oxidized at 1150°C for 10 min. Except for the delta-function-like contribution near the interface, the profile shown has been calculated using traditional diffusion redistribution theory. Note, the falloff in phosphorus concentration at the surface of the oxide is due to evaporation of phosphorus. The insert shows an actual measurement from this work of the near interface region, indicating the anomalous pile-up observed.

width of the interface is not seriously affected by electron escape depth broadening (5) or ion knock-on mixing (14).

A typical set of derivative spectra obtained during profiling of the phosphorus-rich Si-SiO_2 interfacial region are illustrated in Fig. 2. As we sputter through the oxide, two peaks appear in the featureless SiO_2 spectrum—a weak elemental Si peak at 108 eV and the P_{LMM} peak at ~120 eV. The phosphorus peak grows rapidly and then decreases to a steady value in the silicon bulk. The phosphorus peak is observed to shift gradually to higher energies during the profile. The phosphorus peak in P_2O_5 is generally found at ~110 eV. The 3 eV energy shift shown in Fig. 2 could be attributed to a single phosphorus-oxygen bond or to a more complex interfacial structure.

Although, generally, the Auger spectroscopy technique can be sensitive to elements in concentrations below 10^{19} cm^{-3}, the practical sensitivity in these studies is limited by the overlap of the Si 108 eV and P 120 eV spectra. Because the silicon derivative spectrum has a small positive slope in the vicinity of the P (LMM) spectrum, peak-to-peak measurements of this spectrum alone will not detect phosphorus below 4×10^{19} cm^{-3} (as calibrated by ion implanted standards). In fact, assuming that the silicon background remains the same, all peak-to-peak determinations of phosphorus concentration will be underestimated by the same amount; this is shown in Fig. 3. Most measurements presented here, however, are for concentrations in excess of 10^{20} cm^{-3}, for which the sloping background will add only a small correction to the peak-to-peak concentration.

When the peak-to-peak height of the Si_{LVV} (92 eV), P_{LMM} (120 eV), and O_{KLL} (502 eV) transitions are plotted as a function of depth, a profile (5) similar to that of the inset in Fig. 1 is obtained. The distance over which the Si_{LVV} signal rises from 10% to 90T of its final value is termed the interface width. In lightly doped samples, the interface width is ~25Å and does not vary with the oxide thickness (15). In heavily doped samples, we have shown that the interface width increases significantly (5).

It is interesting to compare the Auger sputter profile of phosphorus in Fig. 4 with depth profiles of the same sample obtained elsewhere using the SIMS (secondary ion mass spectroscopy) technique. In Fig. 4, we compare the data of Dobrott (16) (20 keV O_2 + sputtered) and Evans (17) (8 keV Cs + sputtered) with our own (1 keV Ar + sputtered). It is observed that the SIMS technique, as applied in their studies, has greater sensitivity to phosphorus but poorer depth resolution due to the high ion sputtering energies.

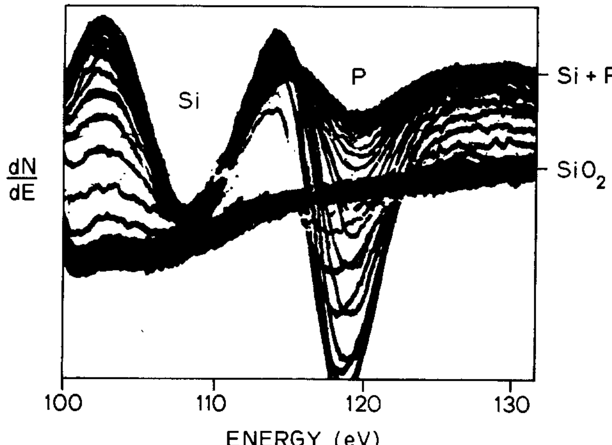

Fig. 2. Oscilloscope photograph of Auger spectra being recorded during profile from an electron energy of 104-134 eV. For elemental silicon, there is a weak LVV peak that is present at ~108 eV, and the phosphorus LMM transition appears at 120 eV. The sloping background in the vicinity of the phosphorus peak causes errors in quantitative analysis that are illustrated in Fig. 3.

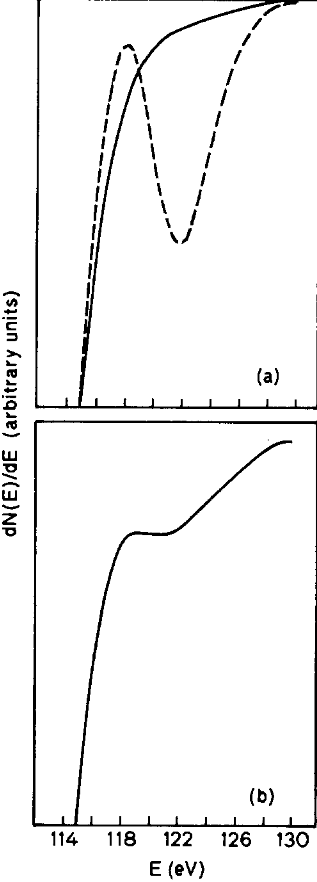

Fig. 3. Examples of phosphorus Auger spectra taken from an implanted standard in silicon. (a) The solid line is the silicon spectrum for a sample without phosphorus, the dotted line is a spectrum for a sample with 1×10^{20} cm^{-3} phosphorus. (b) Auger spectrum for 4.0×10^{19} cm^{-3} phosphorus. Due to the sloping background, a simple peak-to-peak measurement would erroneously indicate zero concentration.

Results

Heavily doped Si (111) and (100) samples were prepared by thermal deposition and drive-in from a $POCl_3$ source. The resultant phosphorus profiles were flat to within 10% to a distance of 1 μm into the silicon. Oxidations were performed in dry O_2 at 900° and 1150°C with 30 sec push-pulls in O_2.

Three sets of experiments were performed. First, the effect of oxidation time and therefore oxide thickness on the pile-up was measured at an oxidation temperature of 900°C for (100) oriented samples. Second, the effect of subsequent postoxidation N_2 anneals was determined. Finally, the effect of an additional electrically compensating dopant, boron, on the pile-up effect was measured.

A series of experiments were performed to examine the evolution of the pile-up during oxidation. Si (100) samples with bulk phosphorus doping 2×10^{20} cm^{-3} (as measured by ASP calibration from ion-implanted standards) were oxidized in dry O_2 at 900°C for various lengths of time. The oxidation times used in these experiments are tabulated in Table I. Oxide thicknesses were determined from previous calibrations (18) by the time required to sputter to the interface and are also listed in the table. The resultant interface widths, again the 10-90% width of the Si_{LVV} transition, appear in the third column of the table. As previously reported, the interface width appears to increase with oxide thickness. This effect is not observed in undoped samples (17).

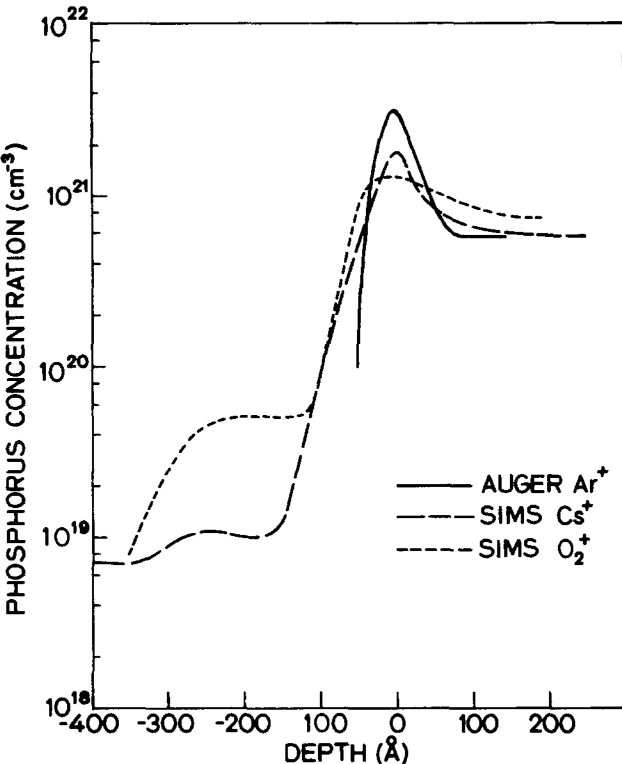

Fig. 4. Comparison of SIMS and Auger profiles of phosphorus pile-up. Auger data are shown as the solid line; SIMS data from Dobrott (13) (20 keV O_2^+ sputtering) are shown as the short dashed line; SIMS data from Evans (14) (8 keV Cs^+ sputtering) are shown as the long dashed line. The broadening observed in the SIMS experiments is due to the higher ion energies used. The SIMS technique does have higher sensitivity to phosphorus; the deviation in the phosphorus levels from the two SIMS profiles in the SiO_2 may be due to the presence of SiH which has the same mass as phosphorus.

The phosphorus profiles from the samples of Table I are collectively illustrated in Fig. 5. This figure shows the phosphorus profiles as a function of depth measured from the outside surface of each sample. Each phosphorus peak is situated at the Si/SiO_2 interface as shown in Fig. 3. The sample oxidized for 90 min, for example, has an oxide 550Å thick and so shows the phosphorus peak at a depth of 550Å. The peak heights shown were reproducible to within ~20%.

We see in Fig. 5 that a pile-up is just beginning to form in the 1 min oxide. The next profile, for a 10 min oxidation, illustrates an important phenomenon. Much more phosphorus is present in the pile-up region than can be accounted for by the displacement of phosphorus from 70Å of oxide. The concentration of phosphorus on the silicon side of the pile-up is observed to dip below the bulk doping level. Thus, we find that the interface is acting as a sink for phosphorus, with phosphorus diffusing from the bulk of the Si to the interface where it is immobilized. Succeeding profiles in Fig. 5 show that, for oxide thicknesses greater than

Table I. Data for 900°C dry oxidation of Si (100) samples with initial P doping of $\sim 2 \times 10^{20}$ cm^{-3}

750	1760	51

* 10-90% width of the Si_{LVV} (92 eV) profile.

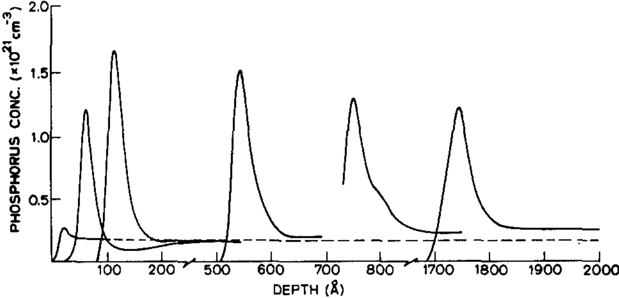

Fig. 5. Evolution of phosphorus pile-up for sampes of bulk concentration 2×10^{20} cm^{-3} oxidized at 900°C. Depth is measured from the surface of the oxide in all cases. From right to left, each profile corresponds to oxidation times of 1, 10, 20, 90, 200, and 750 min, respectively, with oxide thicknesses of 20, 70, 120, 550, 750, and 1760Å, respectively (see Table I). The peak in phosphorus concentration occurs on the silicon side of the interface for each case.

200Å, the peak phosphorus concentration is no longer increasing, *i.e.*, the pile-up has saturated. As the oxide thickness increases, the phosphorus level on the silicon side of the pile-up rises above the bulk doping level. Thus, any further phosphorus which is rejected by the growing oxide redistributes in the silicon bulk in a manner consistent with previous models (1) of phosphorus accumulation.

As a further check of the concentration dip effect, we examined a less heavily doped sample ($\sim 5 \times 10^{-19}$ cm^{-3}) which was oxidized concurrently with the 10 min heavily doped (2×10^{20} cm^{-3}) sample of Fig. 5. A comparison of these two profiles is shown in Fig. 6. The oxide thickness of the heavily doped sample is slightly larger, consistent with the oxidation enhancement model of Ho *et al.* (8). In the less heavily doped

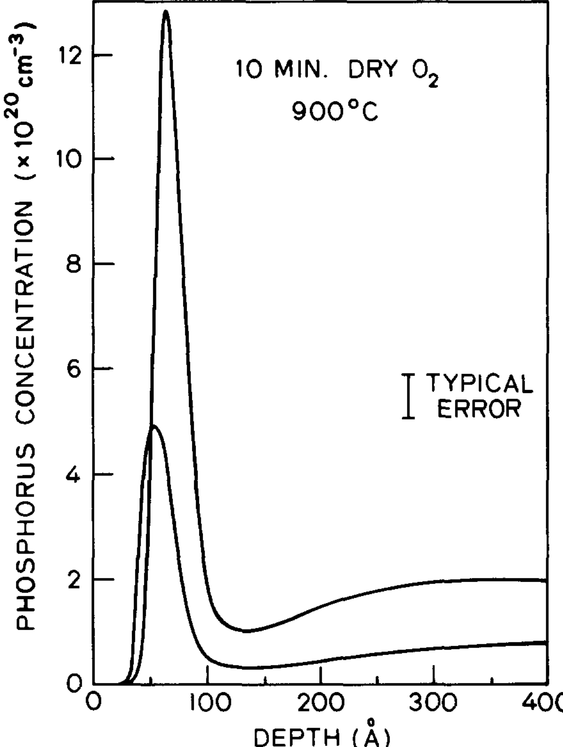

Fig. 6. Illustration of the depletion of phosphorus that occurs in the near interface region for short oxidation times. Two curves are shown for samples of phosphorus concentration 2×10^{20} cm^{-3} and 8×10^{19} cm^{-3}, with oxides grown at 900°C for 10 min. (The 2×10^{20} curve is identical to the curve with peak second from the left in Fig. 6.) An obvious depletion (dip) in the phosphorus is observed.

sample, we again observe a prominent concentration dip.

In order to determine whether or not the observed phosphorus distribution is related to the motion of the Si/SiO_2 interface, or is instead an inherent property of the interface, we measured the effect of N_2 annealing on phosphorus pile-up. One sample with a bulk doping level of 2×10^{20} cm^{-3} was oxidized for 10 min at 1150°C (thickness of 450Å) and later annealed for 14 min at the same temperature. Assuming conventional values for the phosphorus diffusion constant (19), the phosphorus that is observed at the interface after oxidation should be able to diffuse back into the bulk of the silicon after only 0.1 sec at 1150°C. As shown in Fig. 7, however, no significant change in the phosphorus distribution was detected after the postoxidation anneal. The diffusion length of phosphorus under the conditions of the anneal was 3300Å.

In a further test, a sample grown at 900°C for 10 min (thickness of 48Å) was annealed at 900°C for 8.75 hr. The sample prior to the anneal showed a depletion of phosphorus on the silicon side of the phosphorus pile-up (see Fig. 5 and 6). After the anneal, the phosphorus pile-up had grown to the height of that in the sample oxidized for 20 min, and the depleted area had redistributed itself into the bulk so as to be undetectable. The diffusion length for this anneal was ~1500Å.

One of the heavily phosphorus doped (~6×10^{20} cm^{-3}) samples was further subjected to a 60 min boron deposition at 1100°C from a diborane source. The residual oxide was etched, and the sample was oxidized in dry O_2 for 4 hr at 900°C. An Auger sputter profile indicated a bulk boron doping level of ~2×10^{21} cm^{-3} (5 atomic percent), well above the solid solubility limit. The sputter profile also indicated that the phosphorus pile-up had almost completely disappeared. The peak phosphorus concentration was roughly 10% larger than the bulk concentration. The interface width, as measured by the 10-90% width of the Si_{LVV} profile, was ~80Å, much broader than the typical width of a similar sample with no boron present. Ho (9) has reported that the oxidation rate of this sample is much reduced by boron compensation. The possible implications of these results will be discussed in the Appendix.

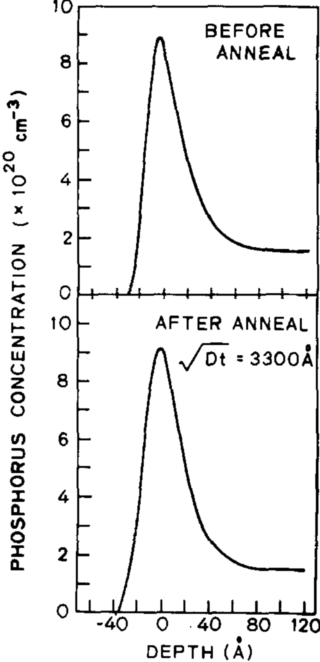

Fig. 7. Illustration of the effect on annealing on the pile-up effect for a sample of concentration 2×10^{20} cm^{-3} oxidized for 10 min at 1150°C in dry O_2 and annealed at the same temperature for 14 min. The profile before annealing is shown in (a); after the anneal is shown in (b). The annealing has had very little effect on the pile-up.

Discussion

As has been pointed out previously, the measured phosphorus profiles are not consistent with a simple diffusion-redistribution model, as these models would predict a much smaller peak concentration with the pile-up region extending much further into the silicon.

A model put forth in a previous paper from this laboratory suggested that the pile-up may be caused by the formation of a $P^+V^=P^+$ complex that would diffuse slowly and therefore cause a high concentration of phosphorus to build up near the interface. Our present data is inconsistent with this model in two ways. First, the depletion of phosphorus in the silicon in the near interface region for short oxidation times (see Fig. 6) clearly cannot be explained by this mechanism. Second, these complexes would tend to diffuse back into the bulk of the silicon during the N_2 anneal; the pile-up, however, does not decrease during the anneal and, in fact, increases for some initial conditions. This mechanism therefore cannot account for the pile-up observed.

Our data can only be explained by considering the interface as a sink for phosphorus during both oxidation and anneal. This behavior is therefore a property of the interface and not a direct consequence of the oxidation process itself. The behavior of the Si-SiO_2 interface as a sink for phosphorus implies that the chemical potential for phosphorus has a sharp minimum at the interface.

There are several mechanisms which can account for this chemical potential sink at the interface. Since the phosphorus is positively charged in the silicon, it might be attracted to a negative electrical potential at the interface. Since the phosphorus is a different size than silicon and will have, in general, a different bonding geometry, it might reduce the interfacial strain energy. The phosphorus might also form a chemical species at the interface (an SiP or an SiP_xO_y) which is not observable in the bulk. And, finally, the phosphorus might accumulate where vacancies, with which it is normally paired, have been depleted. A vacancy mechanism model is described in the Appendix.

Summary

We have used Auger sputter profiling to investigate the pile-up of phosphorus at the Si-SiO_2 interface which occurs during the thermal oxidation of heavily doped silicon. We find that, in the early stages of oxidation, the interfacial region acts as a sink for phosphorus. As oxidation proceeds, the pile-up saturates and the doping level in the silicon near the interface begins to rise. High temperature anneals had little effect on the pile-up, indicating that the existence of the pile-up cannot be explained by a simple diffusion mechanism. We also observed the pile-up to be greatly diminished in a heavily boron compensated sample. A vacancy mechanism model is proposed which is consistent with these results.

APPENDIX

A Vacancy Mechanism Model

In the recent work of Fair and Tsai (19), Ho *et al.* (7-9), and Ghoshtagore (11), in which heavily phosphorus-doped samples were investigated, vacancy mechanism models were used in each case to explain experimental results. These models will be considered briefly below. Phosphorus has long been known as a substitutional diffusant, indicating that the redistribution of phosphorus in silicon will certainly be affected by the concentration of vacancies. We find that, given the known pairing tendency of phosphorus with charged vacancies, a localized pile-up at the interface may result if the interface acts as a sink for vacancies. In this section, we first discuss the models just mentioned as they pertain to the phosphorus pile-up. We then describe our vacancy mechanism model and some of its implications.

Recently, Fair and Tsai (19) examined the effect of the phosphorus doping level, or alternatively the Fermi level position, on the phosphorus diffusivity. An increased concentration of vacancies is expected in heavily doped samples due to the production of charged vacancies. Fair and Tsai demonstrated a significant change in phosphorus diffusivity which occurs when the Fermi level crosses a position 0.11 eV below the conduction bandedge. They surmised that this level corresponds with the production of doubly charged vacancies $V^=$.

Ho *et al.* (7-9) investigated the effect of the phosphorus doping level on the oxidation rate of silicon. They found that the oxidation rate was significantly enhanced when the Fermi level rose above the 0.11 eV position. The oxidation rate correlated well with the expected concentration of vacancies. On the assumption that oxygen moves into vacant sites at the interface, the interface may well be acting as a vacancy sink. As a further test of their model, they compensated several heavily phosphorus doped samples with boron in order to bring the Fermi level down below the $V^=$ level. In these samples, the oxidation rate was much reduced, as illustrated in Fig. 8. The rightmost compensated sample in this figure was profiled using ASP, as discussed in the text. While the phosphorus pile-up was absent, the extreme doping levels in this sample render any interpretation suspect.

Ghoshtagore (11) has investigated the redistribution of phosphorus into silicon from a heavily doped oxide as a function of annealing times and temperatures. He showed that the redistribution process could be described using a surface barrier constant K such that the diffusive flux of phosphorus at the interface is balanced by a factor KC_B where C_B is the bulk phosphorus concentration near the interface. The factor K, when plotted as a function of temperature on an Arrhenius plot (11), exhibits an activation energy of $\sim$3.8 eV. The diffusion constant of phosphorus exhibits the same activation energy within experimental error. These results indicate that phosphorus entering the silicon from the oxide may be activated by a vacancy mechanism.

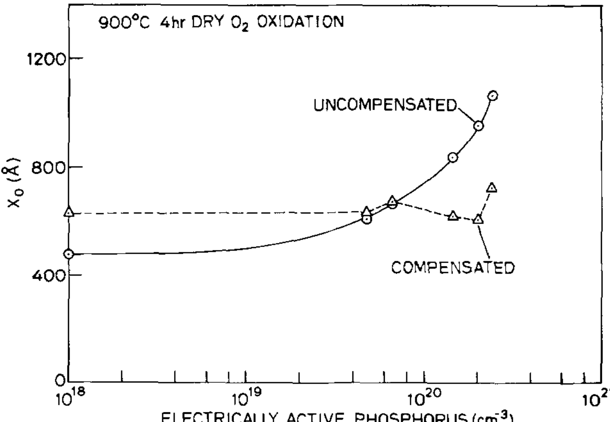

Fig. 8. Oxide thickness (oxidation rate) vs. phosphorus concentration of phosphorus-doped Si compensated and uncompensated by a constant boron diffusion [Ref. (9)].

We now propose a simple extension of these vacancy models which may provide a mechanism for the phosphorus pile-up. Phosphorus atoms, positively charged in the silicon lattice, are expected to pair up with negatively charged vacancies (19) due to coulombic attraction. These PV pairs then travel in tandem through the crystal. If the interface acts as a sink for vacancies or as a preferential binding site for phosphorus, PV pairs arriving at the interface may lose their vacancy, thus immobilizing the phosphorus atom. This could account for the concentration dip effect (Fig. 6) which occurs during the initial stages of oxidation. Immobilized phosphorus atoms at the interface may be activated, as in Ghoshtagore's work, by a vacancy mechanism and hence escape from the interface. In fact, activation may simply occur when an unpaired vacancy contacts the phosphorus atom.

As the oxidation proceeds, a steady-state condition will be reached where the immobilization of phosphorus is balanced by its activation. A detailed calculation would have to account for the immobilization site density at the interface, the probabilities associated with vacancy consumption and activation, the altered vacancy concentrations near the interface, as well as any other chemical or field effects which may be operating. Thus, a generalized thermodynamic model (20) may provide a simpler description of these effects. However, the vacancy mechanism model may provide some qualitative insight into a variety of experimental results. One implication of the model is that the pile-up should be greatly diminished when the Fermi level is a distance kT or greater below the $V^=$ level. This could account for the absence of the pile-up in the boron compensated sample. In a previous study by Johannessen *et al.* (4), the pile-up ratio was monitored as a function of the bulk doping level. This ratio showed an apparent decrease as the Fermi level dropped below the $V^=$ level. (This level crossing occurs at a phosphorus concentration of $\sim 1 \times 10^{20}$ cm^{-3} at 900°C according to Fair and Tsai.) These results are somewhat questionable, however, as the low concentration data may have been affected by the peak-peak height measurement error discussed in the text. Further annealing experiments as well as investigations of other dopants will help to clarify the mechanisms involved.

An X-Ray Lithography System

W. D. Buckley and G. P. Hughes

Perkin-Elmer Corporation, Norwalk, Connecticut 06856

ABSTRACT

A full field, short exposure time x-ray lithography system which is capable of submicron lithography on silicon wafers is described. The optimum system configuration is determined and a new high flux x-ray lithography source is identified. The overall system performance is summarized including resolution, exposure time, overlay capability, mask stability and technology, experimental x-ray resist evaluation, and evaluation of source radiation effects on silicon MOS integrated circuits.

X-ray lithography is a candidate technology for the fabrication of silicon integrated circuits with submicron minimum feature size. The lithographic performance of an x-ray lithography system is determined by the interaction of the exposure source, the aligner, the mask technology, and the photoresist (Fig. 1). This paper discusses an approach to one such system and reports its performance including evaluation of radiation damage.

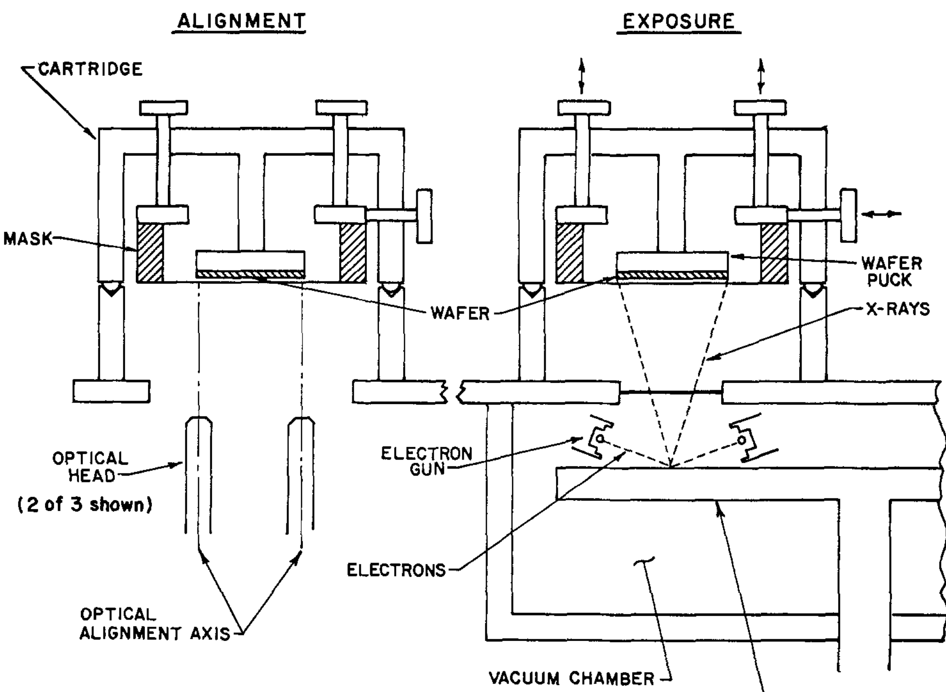
The system is based on a electron beam generated x-ray source with a water-cooled rotating anode. Since exposures are performed in helium at atmospheric pressure, a thin Be window separates the source vacuum chamber from the exposure chamber. A compatible mask technology has been developed based on titanium mask membranes and gold absorbers. The fabrication, patterning, and stability of these masks is described in Ref. (1). Similarly, an optical aligner has been developed compatible with optically opaque or transparent masks. The principle and performance of this aligner is described in Ref. (2).

Key words: x-ray, lithography, tungsten source.

System Considerations

In any lithography system, the parameters of practical interest are the resolution, linewidth control, exposure time, and overlay capability. In an x-ray lithography system the dependent parameters are controlled by the independent parameters, source diameter (s), mask to wafer distance (d), exposure distance (D), and source power (P). System design consists of optimizing the geometric factors to satisfy the conflicting requirements of high resolution and short exposure time.

Table I lists typical system parameters for a 3 in. wafer exposure system. The mask-to-wafer separation of 50 μm is chosen so as to minimize the possibility of mask damage during exposure and is large enough to ensure an effectively infinite mask life.



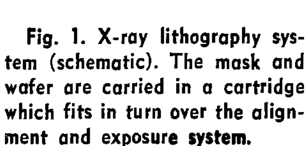


Fig. 1. X-ray lithography system (schematic). The mask and wafer are carried in a cartridge which fits in turn over the alignment and exposure system.

Table I. System parameters: geometric limitations

Parameter	Has impact on	Control parameters	Limiting value
d = Mask to wafer gap	Mask life		50 μm
D = Wafer to source distance	Exposure uniformity (±5%)	$D \geqq 3$x wafer radius	$D \geqq 12$ cm
	Minimum exposure time	D, window thickness, resolution	$D = 15$ cm
S = X-ray source diameter	Resolution (0.5 μm)	Penumbral $\frac{S}{D} d$	$S \leqq 0.15$
	Linewidth variation (>5%)		$S \leqq 0.15$ cm
	Variation in d (1 μm)	$\frac{S}{D} \Delta d$	
	Temperature corrections (±1°C)	$\frac{S}{D} \Delta d$	
	Wafer Out of flat 5 μm	$\frac{S}{D} \Delta d$	

The optimum exposure distance ($D = 15$ cm) is determined by the consideration of exposure flux uniformity and the exposure time. Since the wafer is illuminated by a quasi-point source of x-rays, the exposure flux at the wafer decreases radially. In order to ensure an exposure uniformity within ± 5% across the wafer, it is necessary that the exposure distance be greater than three times the wafer radius. For the 15 cm exposure distance used here, the flux uniformity is ± 3%.

The exposure time is determined by the radiation flux and absorption in the vacuum window, mask membrane, helium atmosphere, and photoresist, and by the photoresist sensitivity. In addition two other factors are important.

First, for a fixed wafer diameter, as the exposure distance increases the diameter of the vacuum window can be reduced. In principle a thinner window can be used and, because of reduced absorption, the exposure time is decreased.

Second, it is usual to consider the effects of exposure distance variations at constant source power. However, it is more useful to examine these effects at constant resolution. This perspective has a major effect on the permissible power since the electron beam diameter can vary with exposure distance.

The exposure time (τ) relation can be written [Ref. (3)]

$$\tau = \tau_0 \frac{D^2}{P_B} \exp(\mu_1 t + \mu_2 D) \quad [1]$$

where τ_0 is independent of P_B and D. The absorption coefficients of the vacuum window and helium atmosphere are μ_1 and μ_2, respectively, and t is the thickness of the vacuum window.

The required thickness (t) of a vacuum window is related to its diameter (V) by the relation

$$t = AV \quad [2]$$

where A is a constant, characteristic of the window material. The diameter of a circular window required to expose a circular area of diameter W is given by

$$(V - S) = \frac{x}{D} (W - S) \quad [3]$$

where x is the source to window distance. Combining Eq. [2] and [3] we may substitute

$$t = \frac{x}{D} (W - S) + S \quad [4]$$

in Eq. [1].

It is usual to consider the effects of variations in the source-to-wafer distance D while maintaining the beam power, P_B, constant. It is more useful to examine the variation of exposure time at constant resolution. **This innovation has a** major effect on the permissible power since the electron beam spot size can vary with the exposure distance.

The source diameter is related to the resolution (p) by the relation

$$p = \frac{Sd}{D} \quad [5]$$

For a high power rotating anode x-ray source, the maximum power is related to the spot diameter (s) by a relation of the form [Ref. (5, 6)]

$$P_B = BS^{3/2} \quad [6]$$

where B is a constant, characteristic of the anode material.

Combining Eq. [1], [4], [5], and [6], it can be shown that the exposure time is given by

$$\tau = \frac{\tau_1}{B} \left(\frac{d}{p}\right)^{3/2} D^{1/2} \exp\left(\mu_1 A \frac{x}{D} (W - S)\right) \exp \mu_2 D \quad [7]$$

where $\tau_1 = \tau_0 \exp(\mu_1 AS)$.

The situation is summarized in Fig. 2. In calculating these curves, use was made of the experimentally determined exposure time and sensitivity for COP photo-

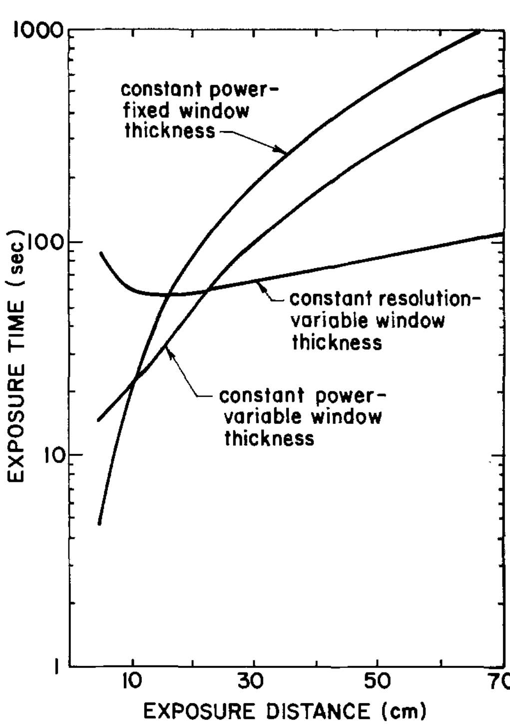

Fig. 2. Various relationships between exposure time and source-to-wafer distance. The conventional model assumes a constant window thickness and derives the exposure time for constant power.

resist. For all the curves, a 5 μm Mylar mask, a helium exposure atmosphere, and a 5 cm source-to-vacuum window distance were assumed. A source power of 10 kW was used for constant power calculations and a Be window of thickness 25 μm for constant window thickness. Similarly, 1 μm resolution was assumed for the constant resolution curve. A value of 5×10^{-4} was used for the constant A based on our experimental data and a recent publication (5). The value of the constant B was based both upon theoretical considerations and upon the specifications of commercially available rotating anode sources (Fig. 3).

The constant power, constant window thickness curve is dominated by the inverse square law term and, over most of the range, the exposure time is proportional to D^2. This is the basis of the conventional exposure time curve. When the window thickness variation is included, the square law term is significantly modified. Over most of the range illustrated, the exposure time is approximately proportional to D. Finally, for the constant resolution curve, an entirely different conclusion is apparent. An optimum exposure distance exists for which the exposure time is at a minimum. For greater distances the exposure time is approximately proportional to $D^{1/2}$ in agreement with Eq. [7]. In addition, the exposure time is only a weak function of exposure distance and, over the distance range illustrated, the increase is less than 50% above the minimum.

The optimum exposure distance can be derived from Eq. [7]. If the effect of the helium atmosphere is ignored, the optimum exposure distance (D_{opt}) is given by

$$D_{opt} = 2\,Aa\,\lambda^3\,(W - S) \qquad [8]$$

where $\mu_1 = a\lambda^3$ and λ is the exposure wavelength.

The minimum exposure time is obtained at the optimum exposure distance which, for an aluminum source and a 3 in. wafer, is approximately 15 cm.

Because the exposure time is insensitive to exposure distance, other system requirements will determine the distance. However, in general, a shorter distance is preferred in order to minimize power requirements.

The optimum source spot diameter is determined by the desired resolution and by the maximum permissible linewidth variation. In order to provide process latitude for 1 μm lithography, and to have the capability of extending to the sub-micron regime, a penumbral resolution limit of 0.5 μm was selected. This requires a 1.5 mm spot diameter, a 15 cm exposure distance, and 50 μm mask-to-wafer separation.

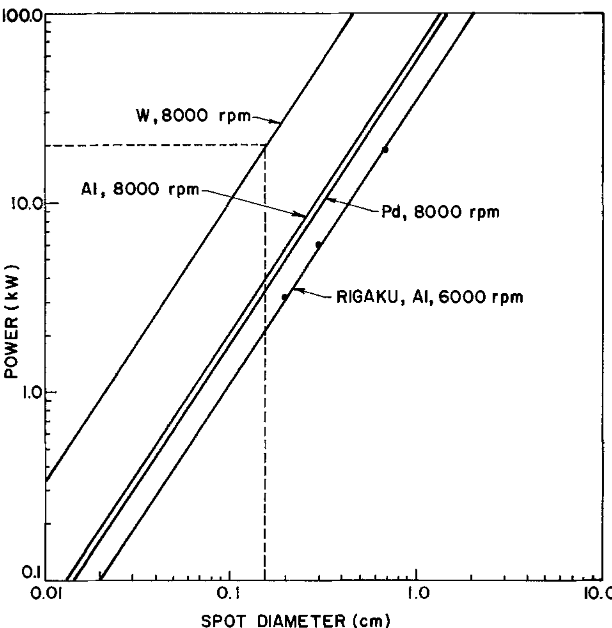

Fig. 3. Input power vs. spot diameter for water-cooled, rotating anode x-ray anodes.

Linewidth variations can arise from variation in the wafer surface and from uncontrolled or controlled variations in mask-to-wafer separation. For a 1.5 mm spot linewidth variations are 80Å per μm variation in gap.

Deliberate variations in the gap are part of the alignment procedure. These variations cause linear magnification changes at the image plane due to the inherent nature of point source imaging. The magnitude of the change, at a radius R, is given by the relation $\Delta R/R = \Delta d/D$. For the system geometry chosen this results in a magnification change of about 0.25 μm per μm of gap variation at the periphery of a 3 in. wafer. This effect can be used to compensate for linear magnification changes in the mask or wafer which can occur due to thermal or wafer processing effects (4). It can also compensate for linear magnification changes in the mask and, in so doing, considerably relax mask stability requirements.

Uncontrolled variations in the gap between exposures can result in image distortions which will limit the overlay precision. The magnitude of these distortions is given by the relation above and amounts to about 0.25 μm per μm of uncontrolled gap variation at the periphery of a 3 in. wafer. In order to minimize this effect a "bed of nails" wafer chuck was used. This reduces the chance of particle entrapment by simultaneously reducing the total contact area between the chuck and wafer and distributing this area over an array of small studs. The chuck surface was polished flat and served as a reference surface for the back of the wafer. In this manner the front surface profile of the wafer was controlled.

As a result of the discussion above one defines the geometrical parameters of the system as $d = 50$ μm, $D = 15$ cm, and $S = 0.15$ cm. The source power is the only unspecified independent parameter. Its value is determined by the maximum permissible power input to the specified source size for the anode material chosen.

The maximum power dissipation P of a rotating anode can be expressed as a function of the maximum allowable temperature rise, ΔT, (5, 6) by

$$P = \pi^2\,(\rho C_V K s^3 v)^{1/2}\,\frac{\Delta T}{16} \qquad [9]$$

where v is the surface velocity of the anode, K is the thermal conductivity, C_v is the specific heat, ρ is the density, and s is the spot diameter. The quantity (ΔT) is limited by melting or by the fatigue failure limit.

The equation predicts that the maximum power is proportional to the 3/2 power of the spot diameter. This relationship has been confirmed in the literature and by commercially available Al_K rotating anode sources. In Fig. 3, the data points are for x-ray sources available from Rigaku. The line labeled Rigaku-Al obeys the theoretical power law. The highest power commercial source uses a 250 mm diam Al target rotating at 8000 rpm. A projection for this source is also shown in Fig. 3. Also shown in Fig. 3 is the calculated power dissipation for a Pd anode (7).

It is apparent (Fig. 3) that the maximum power dissipation for an Al source and a 0.15 cm spot diameter is about 3.5 kW. Reference to Fig. 2 indicates an exposure time of approximately 100 sec. This consideration led us to evaluate alternate anode materials with the objective of increasing the power and reducing the exposure time. It was confirmed experimentally that a tungsten source is as efficient as aluminum in exposing both COP and PMMA resist. However, as shown in Fig. 3, the tungsten source can dissipate about six times more power than either the aluminum or pal-

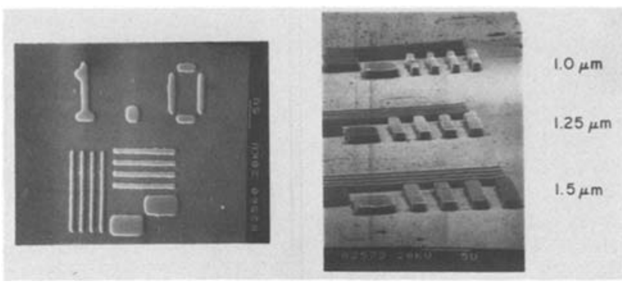

Fig. 4. X-ray lithography in PMMA [1 µm using a tungsten M-line (W_m = 7Å)] irradiation source. Resolution is not limited by photoelectron range.

ladium source (for a constant spot size) and results in a projected exposure time of less than 20 sec.

The lithographic capability of a tungsten M line (7Å) source is illustrated by Fig. 4, a scanning electron micrograph of resolution patterns with 1 µm thick PMMA film. One micron resolution in COP was also demonstrated and reported previously (8).

Table II summarizes the projected characteristics of an x-ray lithography system based on a tungsten source and a resist with the sensitivity of COP. For this system exposure time is not a limiting parameter. The table specifies a 3 in. wafer although the performance parameters are relatively insensitive to wafer size.

It is informative at this point to compare this system with conventional lithographic tools. It is customary to describe the performance of lithographic tools by the vague term resolution. However, King and Goldrick (9) have shown that the modulation transfer function (MTF) is a useful concept in describing the performance of photolithographic tools. MTF is a plot of the image modulation as a function of the spatial frequency of the mask pattern. Current practice is to associate an MTF value of 60% with the minimum feature size achievable in production.

For an x-ray lithography exposure system the modulation of the aerial image at the wafer plane is determined by the system penumbra and the mask contrast. The "system" MTF is the product of the MTF of the imaging system and the MTF of the mask.

Rao has shown how to calculate the MTF of an x-ray lithography system (10). Figure 5 compares the MTF of an F3 projection aligner and the x-ray lithography system described above. The large improvement in MTF obtained with the x-ray system is apparent. However, it is important to remember that the overall system MTF is determined by the product of the MTF of the imaging system and the MTF of the mask. For an optical system, with a high contrast mask, the mask MTF is essentially 100% and the system MTF dominates. For the x-ray system the mask contrast is less and dominates for features larger than about 0.5 µm.

Figure 6 illustrates the measured mask contrast and MTF for a gold absorber and a tungsten source. As can be seen the contrast depends on the accelerating voltage of the electron beam x-ray source due to continuum radiation. For 20 kV accelerating voltage the contrast is degraded by continuum radiation and W_L radiation generated by the source. Experimental mea-

surements indicate that continuum radiation is the predominant source of contrast reduction. For an 8 kV source a gold thickness of 0.5 µm results in an MTF of 60% and at 20 kV 0.7 µm of gold is necessary. For these masks, linewidths of 0.5 µm and greater have an MTF of 60%, limited by the absorber since the imaging system MTF is 100% (Fig. 4). Thicker gold increases the mask contrast and reduces the minimum feature size toward 0.3 µm. Clearly, the higher MTF possible with an x-ray system should result in better linewidth control in the presence of exposure nonuniformities. In addition, the absence of the multiple reflections characteristic of optical systems (11) should also aid in linewidth control.

System Performance

An experimental system has been constructed (Fig. 7) consisting of a tungsten anode x-ray source with a

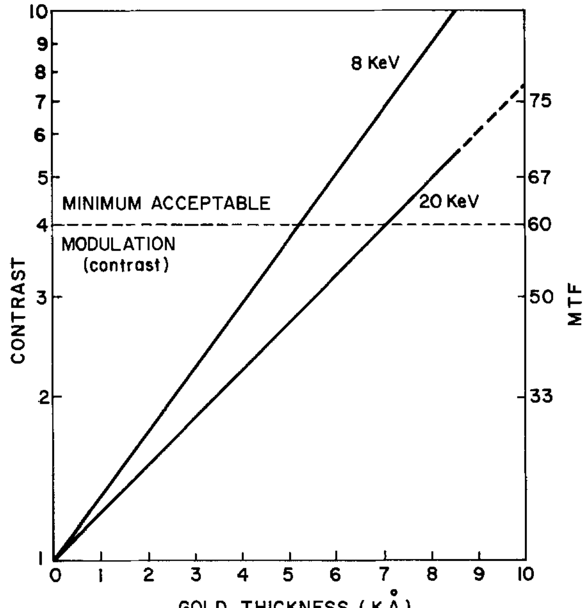

Fig. 6. The contrast of an x-ray mask using a gold absorber and a tungsten M line source. The lower energy excitation reduces bremstrahlung radiation and produces approximately theoretical contrast.

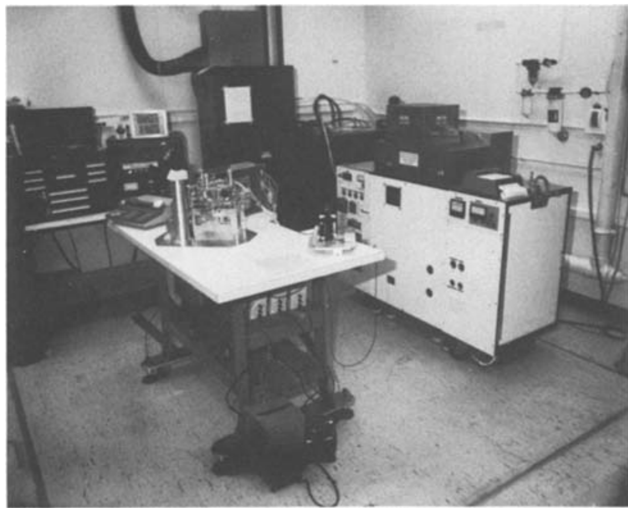

Fig. 7. An experimental x-ray lithography system. The alignment system with the removable cartridge is on the left and the exposure system on the right.

ring cathode electron gun. For this system the source power is limited to 10 kW by a low anode rotational speed (2000 rpm). This system has operated reliably at Perkin-Elmer for more than a year. A similar system at a customer facility has experienced less than 2% down time and has exhibited no evidence of flux output degradation in this time period. The exposure time is longer than predicted since a nonoptimum system configuration was used. For COP resist an exposure time of about 1 min is typical.

The use of a tungsten anode simplifies the electron gun design. Since tungsten deposition on the anode from the gun filament is not an issue, direct line of sight from the filament to the anode is acceptable. Consequently, we have constructed a ring cathode electron gun by adapting the design of a linear cathode gun from a conventional x-ray tube. This configuration is not optimized for x-ray lithography and is presently limited to a minimum spot size of about 2.5-3 mm. Although larger than our ultimate goal of 1.5 mm, this spot size results in an overall system MTF of 60% for linewidths greater than 0.7 μm which is quite adequate for sub-micron lithography.

The PBS resist is somewhat slower than COP but appears capable of developing finer features. Patterns consisting of 0.75 μm lines and spaces and isolated 0.5 μm geometries of either polarity can be replicated (Fig. 8). A statistical comparison of 1 μm features on a mask and patterns printed on a wafer indicates a 100% yield as measured at 50 locations. Extensive determination of critical linewidth control has not yet been undertaken. Preliminary measurements on COP resist indicate a linewidth standard deviation of about 0.1 μm for a 2 μm feature.

We have evaluated the exposure characteristics (Fig. 9) of several conventional u.v. and experimental photoresists. Experimental resist EK88 prepared by Eastman Kodak is attractive. This negative resist is almost twice as sensitive as COP with better resolution in thicker layers. The resist γ is about 1.25 compared to $\gamma = 1$ for COP. Figure 10 is a scanning electron micrograph of 1 μm lines and spaces in EK88. The initial resist thickness of 1 μm was exposed and developed to a final thickness of about 0.5 μm.

Radiation damage evaluation has been performed by a major semiconductor manufacturer using both discrete MOS devices and MOS integrated circuits. X-ray lithography was simulated by exposing completed MOS devices to 1, 3, and 10 times the PBS exposure dose. All devices exhibited parametric changes but the differences for the different doses were small. Discrete device results indicate that radiation effects are removed by a conventional aluminum alloy process for all exposure doses. Similar experiments were performed on an integrated circuit chosen for its expected sensitivity to radiation damage. Radiation effects were removed by an additional aluminum anneal of the finished circuits. No significant behavior difference was observed between the irradiated devices and a control group.

The mask technology utilizes a titanium membrane (1). Experiments so far indicate that this material is stable to better than 0.2 μm (the measurement precision) over at least 5 months. An optical aligner has been evaluated (2) using these masks. In its present form this experimental system has achieved an overlay error standard deviation of less than 0.5 μm. Data analysis indicates that ⅛ μm overlays are achievable in a reconfigurated system.

Conclusion

An x-ray proximity lithography system with a well-developed source, mask, and alignment system has been described. The fundamental problems of x-ray lithography have been addressed and shown to be tractable. The use of a high brightness x-ray source with conventional E-beam resist has reduced exposure times to less than a minute. Experimental resists result in exposure times comparable to optical lithography systems. The use of ductile titanium mask substrates with gold absorber layers has yielded high contrast, low distortion masks. The mask and bright exposure source in conjunction with an optical alignment system have been used to demonstrate the feasibility of x-ray lithography as a high resolution tool.

An X-Ray Lithography Alignment System

W. D. Buckley, M. P. Eisenberg, G. P. Hughes, D. H. Kittell, and J. L. Kreuzer

The Perkin-Elmer Corporation, Norwalk, Connecticut 06856

ABSTRACT

The design, operation, and performance of an experimental alignment system which is suitable for use with an x-ray lithography exposure system will be described. The system consists of optical, mechanical, and electronic subsystems and permits alignment of either opaque or transparent masks by means of an optical alignment detection and transfer system. A computer assisted procedure permits mask to wafer overlay with a mean plus standard deviation of less than 0.5 μm. The alignment algorithm automatically compensates for linear magnification changes in the mask or wafer by varying the mask to wafer separation. A data reduction scheme is described which identifies the major sources of misalignment and permits the analysis of wafer overlay data in terms of rigid body alignment errors in six degrees of freedom. The component evaluation of the system along with the system data analysis indicate that a second generation system should have overlays of less than one-third that of the prototype.

In another publication (1) we have described an x-ray lithography exposure system capable of submicron lithography. In order to fully exploit this capability, an alignment system with an overlay accuracy of one-half to one-third the minimum feature size is required. In addition, the alignment system must be compatible with the overall lithography system and mask technology. A mask technology based on titanium membranes has been described (2). The use

Key words: x-ray, lithography, alignment.

of this mask technology mandates that the aligner be capable of aligning optically opaque masks.

Since x-ray lithography is based on point source projection imaging, the gap between the mask and wafer results in a magnification of the mask pattern. The image on the wafer is enlarged by an amount $\Delta = Rd/D$ where d is the mask-to-wafer gap, R is the radial distance from the wafer center, and D is the exposure distance. Consequently, in order to minimize magnification changes between consecutive exposures the mask-to-wafer separation must be controlled.

The cumulative overlay error of one level to another will be influenced by in plane wafer distortions. However, recent studies (3-6) have shown that these changes manifest themselves principally as a linear change in wafer dimensions. Similar changes will result from thermal differences between exposures. Consequently, the magnification of an x-ray system can be used to advantage if the proximity gap can be fine-tuned to compensate these effects.

Alignment System

An alignment system based on optical detection and an optical alignment transfer standard can satisfy all of the requirements defined above.

The basis of the approach is illustrated in Fig. 1. The center of the wafer alignment target is located in space on the axis of an optical alignment channel by means of precise lateral and vertical alignment positioners. The wafer is then displaced a known distance, typically 50 μm, in order to provide the mask-to-wafer separation. Next the mask is inserted and the alignment procedure is repeated. Since the location of the wafer alignment target is retained in the transfer standard at the optical axis location, it is not necessary to view the wafer during mask alignment. Therefore either transparent or opaque masks can be aligned. In order to locate the mask parallel to the wafer, three alignment channels are used.

The overall alignment system consists of an optical detection system, a mechanical positioning system, a mensuration system, and a computer assisted alignment algorithm.

The optical system detects both lateral and vertical position of the alignment target simultaneously by means of a combined interferometer objective. A point in space is thus defined along the optic axis which serves as an alignment transfer standard and permits the alignment of opaque masks.

Lateral alignment is accomplished by means of a microscope ($NA = 0.60$) and prism assembly. As shown in Fig. 2 the prism assembly includes a beamsplitter and the overall effect is to generate two images rotated 180° relative to each other. When the center of the alignment target is not coincident with the axis of the optical system, a double image is seen. If the alignment target center is brought into coincidence with the optic axis, the two images coincide and a single image is seen, as illustrated in Fig. 3. The subsequent insertion of an opaque mask prevents viewing of the wafer alignment target directly, however, mask-to-wafer alignment is then accomplished by aligning the mask to the viewing optics.

A white light interferometer is used to define the position of the alignment mark in the z direction, *i.e.*, along the optic axis. The interferometer is operated in a null fringe mode in which a single interference fringe fills the entire viewing field. This interferometer yields a unique signature, characteristic of the surface being viewed when the two path lengths are nearly equal, and a minimum signal at the point of precise equality. The axial location of the alignment target can be determined to a small fraction of a micron.

In the experimental alignment system a Leitz "Mirau" interference objective is used to implement the white light interferometer. In this device the beamsplitter and reference mirror are combined in an assembly that mounts directly on the objective. Consequently, the same optical channel can be used for both lateral and vertical alignment.

In order to evaluate the alignment scheme, a single channel optical alignment system was established using conventional microscope components and interference objectives. Experimental repeatability tests were run for both alignment axes. The test involved performing the appropriate alignment, then displacing the stage an unknown amount and repeating the alignment without viewing the position sensor readout. The position of the stage after each alignment was recorded and the alignment procedure was repeated ten or more times. The mean and standard deviations were computed for each data set. This repeatability experiment was performed both on an x-ray mask and on ten substrates which were supplied by a commercial silicon device manufacturer and represented different stages of circuit fabrication. Each of the silicon devices was coated with 1.0 μm of photoresist in order to simulate a realistic alignment situation. The results are shown in Table I. In all cases the precision of the system was 0.25 μm or better.

The mechanical positioning mechanism is capable of positioning the mask and wafer at the required point in space defined by the optical channel. It is necessary to control both mask and wafer with six degrees of freedom. The basic building block of the mechanical positioning system is the lever reduction machine. It consists of a differential screw mechanism in conjunction with a lever. The differential screw is loaded against the long side of the lever, which is mounted to a base by two rotary flexures. Fine adjustment is obtained by directly turning the differential screw, whereas coarse adjustment is obtained by turning a knob threaded about the screw. The threads are selected so that one complete turn of the fine adjustment results in a 25 μm displacement at the short end

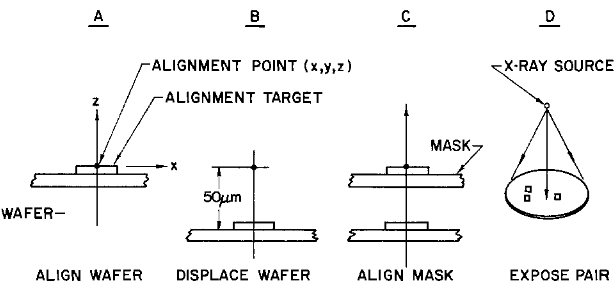

Fig. 1. Simplified single channel alignment procedure. Three channels are needed to set the mask and wafer parallel as shown on the right.

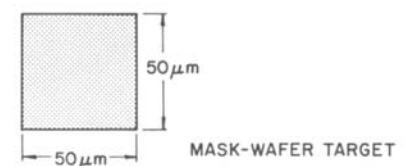
of the lever. The total range is about 600 μm. The lever pivot flexure bearing was selected for its ability to pivot with minimal lost motion or stickslip effects. (The average backlash is less than 0.03 μm.) At the short end of the lever is a push rod. This assembly is axially stiff but flexible in all other directions. It is designed to provide axial motion with minimal cross-coupling to other directions.

A mensuration system is included in order to permit full characterization and control of the mask or wafer position. Each control axis has a corresponding position sensor. This is an eddy current, noncontacting proximity-positioning-detecting device,[1] which exhibits good linearity over the design range of ± 300 μm. The combination of a lever reduction machine and gauge permits deliberate movements as small as 0.01 μm for each control axis.

[1] Kaman Proximity Gauge Model I.U., Kaman Sciences Corporation, Colorado Springs, Colorado.



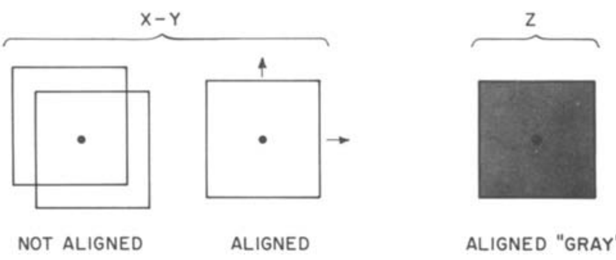


Fig. 3. An alignment target as seen through an optical channel. The left-hand side illustrates lateral alignment relative to the optic axis indicated by the dot. The right-hand target illustrates the axial alignment signal. Correct positioning along the optic axis is achieved when a minimum brightness fringe is observed.

The temporal stability of a single control axis was measured at a fixed knob setting by recording the gauge reading as a function of time. The results obtained are illustrated in Fig. 4. The experiment was performed in a laboratory environment over a period of about 30 min. The results obtained represent cumulative drift due to mechanical and thermal effects as well as the stability of the gauge and gauge control and readout circuits. Approximately 26 min elapsed before the accumulated drift read 0.1 μm.

As a general conclusion, the mechanical positioning mechanism gauge combination exhibited excellent linearity, backlash, and temporal stability characteristics and has been used for all the mechanical motions required for alignment.

The alignment system was divided into an optical subsystem and a mechanical subsystem as shown schematically in Fig. 5. The mechanical subsystem or cartridge mounts on top of the optical subsystem and is located by means of a ball bearing and groove arrangement.

The optical assembly contains the three optical channels required to provide the overall alignment capability. This assembly, referred to as the optical head, contains a total of six mechanical positioning mechanisms. Three are used to move the optical channels in order to locate the individual channels over their respective alignment targets. The other three change the position of the cartridge relative to the optical head by moving the mounting grooves in which the bearings rest.

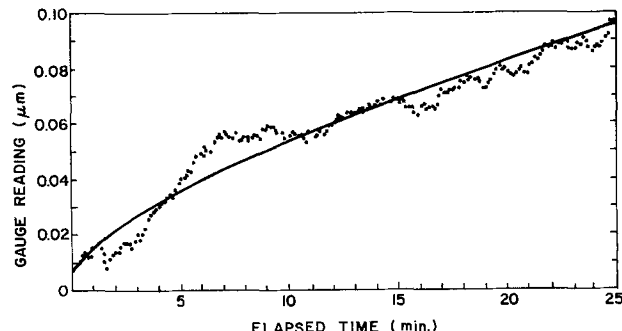

Fig. 4. Temporal stability of the positioning mechanism as measured by an eddy current sensor. The drift is representative of the entire system including the gauges and thermal effects.

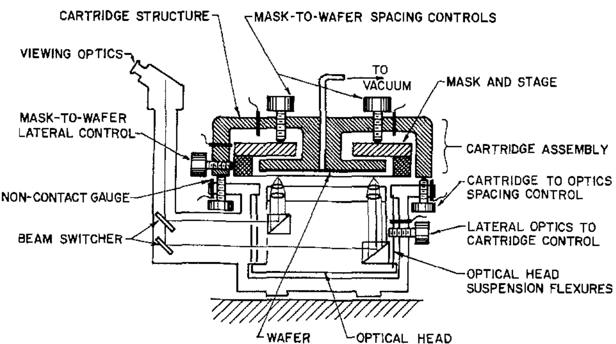

Fig. 5. Schematic diagram of the alignment cartridge. Mask and wafer are aligned separately to three optical channels (two of which are shown). In order to expose, the cartridge is removed together with the mask and wafer, and placed over the exposure source.

The cartridge contains a fixed wafer stage and a mask stage. The mask stage is mounted on three vertical and three horizontal mechanical positioning mechanisms and is kinematically constrained. Auxiliary clamps are not required to maintain the position of the mask after alignment.

The alignment procedure requires that the optical head be first aligned to the wafer. Next, the cartridge is removed to permit installation of the mask, and the mask is then aligned to the optical channels. Since the alignment transfer standard is the axis of the optical channels, they are not disturbed after the first alignment. Subsequent alignments are by means of the mask stage position controls. Successful alignment requires accurate replacement of the cartridge after loading the mask. This can be done within an rms error of less than 0.05 μm. Exposures are performed by placing the cartridge containing the mask and wafer over the exposure source.

Alignments are performed with calculator assistance. The calculator interrogates the gauges and aids the operator through the alignment procedure. The alignment algorithm compensates for mask-to-wafer scale differences and determines the appropriate mask-to-wafer separation. The system is designed so that all alignment steps consist of nulling a digital voltmeter readout. Figure 6 is a photograph of the complete alignment system.

Aligner Evaluation

The aligner evaluation was performed using oxidized silicon wafers and a titanium x-ray mask. A double exposure technique was used. The wafer was first coated with COP resist and the aligner was used to set the mask to wafer spacing and center the mask over the wafer. After exposure by means of the x-ray source, the resist image was developed and the underlying oxide was etched. The resist was then stripped and the wafer was recoated. In subsequent experiments, the mask was aligned to the image defined in the oxide and then exposed. After development, the position of the resist image relative to oxide image was used to determine the overlay performance of the aligner.

Since the same mask was used for the overlay, the evaluation was independent of mask-to-mask distortions. In addition, since the wafer was not subject to high temperature processing after the oxide etch, wafer distortions did not affect the results. In order to read the overlay errors a vernier mask pattern was used. Overlay was achieved by shifting the mask laterally 300 μm to produce an overlay image. The central vernier pattern had a resolution of 0.2 μm.

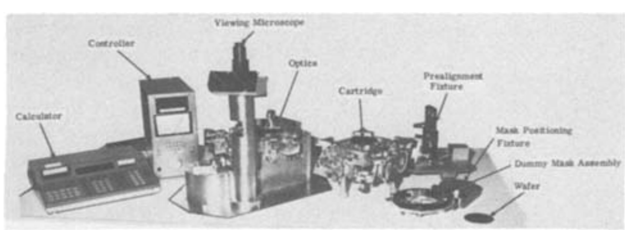

Fig. 6. Mask/wafer aligner system

Figure 7 is an example of a double exposure overlay on a 3 in. wafer. The dots on the wafer represent the location on the wafer where the vernier patterns were read and the vectors represent (to the scale drawn) the magnitude and direction of the measured misalignment. In this example, the mask was misaligned toward the lower left, however, the displacement vectors lie on diameters with a common center to within the measuring accuracy. This is an indication that the mask is undistorted and stable. Figure 8 summarizes

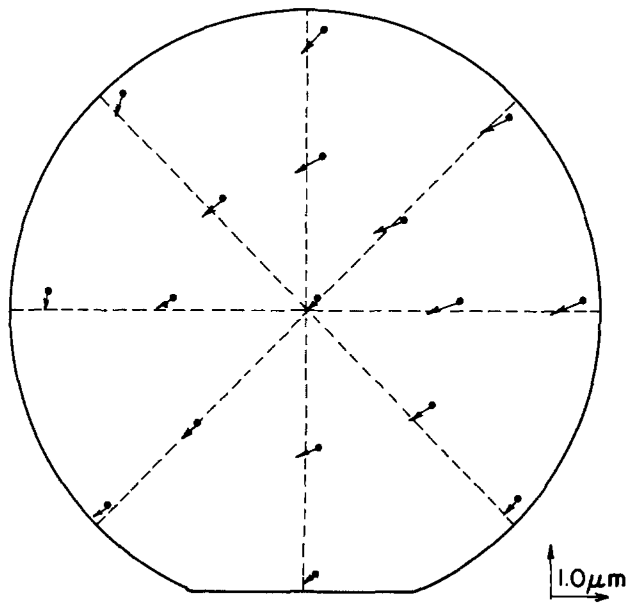

Fig. 7. Overlay performance using titanium mask. The arrows represent (to scale) the displacement vector at each location. The dashed lines are diameters with a common center. All the vectors lie in the lines indicating that the mask is stable, *i.e.*, behaving as a rigid body.

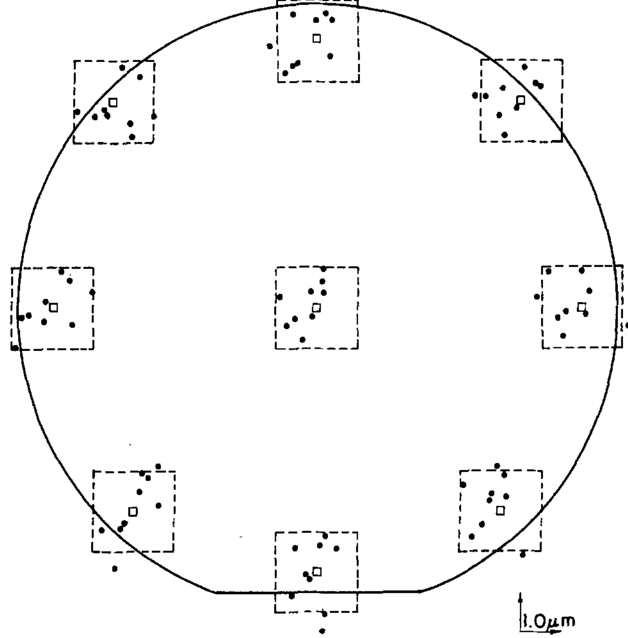

Fig. 8. Composite of double exposure overlays for 9 wafers. The dots represent a single wafer. The boxes are consistent with an alignment error with a standard deviation of less than 0.5 μm.

the results for 8 wafers. The data points represent the heads of all of the displacement vectors. The boxes are $\pm$ 1.0 μm misalignment limits.

The alignment precision can be estimated from Fig. 9 which is a histogram of the overlay errors at 17 data points on each of nine wafers. The curve illustrates the percentage of data points within a particular overlay error.

Both the histogram and the curve indicate that the alignment accuracy has a standard deviation of about 0.5 μm. In these initial experiments no attempt was made to control the temperature or to vary the mask-to-wafer gap to compensate for scale changes. This simplification permitted data analysis and overlay error source determination.

Alignment Error Analysis

X-ray lithography alignment consists of aligning a mask relative to a wafer in six degrees of freedom. Assuming the mask and wafer are rigid bodies, errors in alignment can be represented by a set of rigid body alignment error terms as shown in Fig. 10. These errors include translational errors (ϵX, ϵY), mask-to-wafer spacing error (ϵZ), in-plane rotational errors ($\epsilon\theta_z$), and mask-to-wafer tilt ($\epsilon\theta_x$, $\epsilon\theta_y$). The rigid body errors act in combination to produce overlay errors (ΔX, ΔY) on the wafer. In order to relate the rigid body errors to the displacement errors the coordinate system of Fig. 11 has been adopted. At any coordinate (X, Y) the total displacement error on the wafer due to the rigid body error terms is given by

$$\Delta X = \epsilon X + \left(\frac{X}{D}\right)\epsilon Z + \left(\frac{XY}{D}\right)\epsilon\theta_x + \left(\frac{X^2}{D}\right)\epsilon\theta_y + (Y)\epsilon\theta_z \quad [1]$$

and

$$\Delta Y = \epsilon Y + \left(\frac{Y}{D}\right)\epsilon Z + \left(\frac{XY}{D}\right)\epsilon\theta_y + \left(\frac{Y^2}{D}\right)\epsilon\theta_x + (X)\epsilon\theta_z \quad [2]$$

Using these equations and the overlay displacement errors, a best fit set of rigid body terms can be computed for each overlay wafer. Figure 12 represents the result of subtracting the vectors determined by the best fit overlay data from the measured overlay error vectors. The standard deviation of the X and Y components of these residuals is $\pm$ 0.1 μm which is the reading error of the vernier targets. Thus the alignment errors as shown in Fig. 7 can be represented, within our measuring accuracy, by the rigid body error terms implying that there is no measurable wafer or mask distortion.

Another measure of the alignment performance can be represented by Table II which details the mean and standard deviation of the rigid body error for the wafer overlays in Fig. 8. The effect of these rigid body

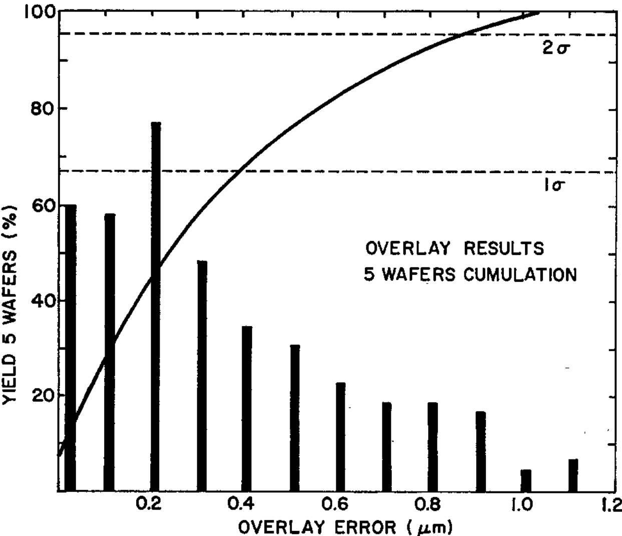

Fig. 9. Histogram of the alignment data. Alignment has been achieved with a 0.5 μm standard deviation in a nontemperature-controlled environment.

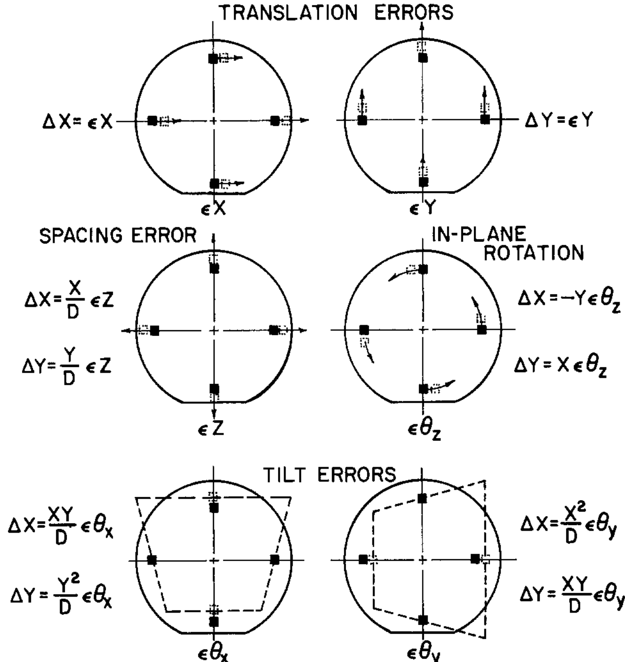

Fig. 10. Rigid body misalignment errors. These terms are used to evaluate aligner performance.

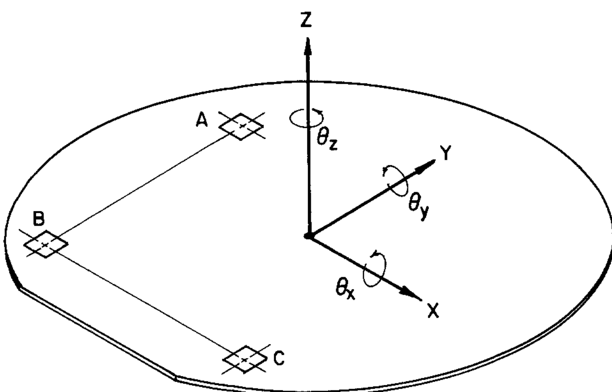

Fig. 11. The coordinate system used for overlay data reduction. Alignments are made by an optical channel located at each of point A, B, and C.

Table II. Alignment performance of nine wafers

	Rigid body error terms		Calculated error on wafer at 1.5 in. radius	
	Mean	S.D.	Mean	S.D.
Translation				
ϵX (μm)	−0.17	0.37	−0.17	0.37

[a] Includes temperature variation contribution.

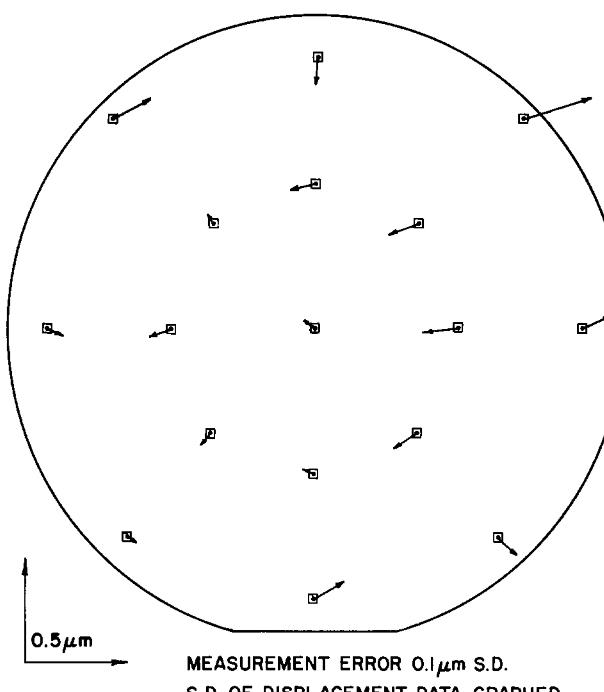

Fig. 12. Residual misalignment vectors for one wafer after rigid body error compensation. These residuals have the same standard deviation as the measuring error indicating that there is no measurable mask instability.

terms on the edge of a 3 in. wafer is also included. Note that the mean values are all small and thus represent no systematic alignment error. The standard deviation is consistent with the histogram of Fig. 9. The standard deviation of the axial alignment term (ϵz) is a major contributor to the overall alignment error. This result is not surprising since these data were obtained without correcting for magnification changes which result from the poorly controlled thermal environment. The use of the linear scale change capability should significantly reduce this term.

Conclusion

The basic concept, approach, and elements of an optical alignment system suitable for x-ray lithography have been described. An experimental alignment system has demonstrated overlay performance with a standard deviation of less than 0.5 μm, using optically opaque x-ray mask and 3 in. silicon wafers. This performance is limited by the aligner and not by mask or wafer stability. Readily implemented improvements including a temperature controlled environment, high resolution viewing optics, and linear magnification change compensation should result in an overlay standard deviation of better than ⅛ μm.

X-Ray Lithography Mask Technology

W. D. Buckley, J. F. Nester, and H. Windischmann

The Perkin-Elmer Corporation, Norwalk, Connecticut 06856

ABSTRACT

A high yield process will be described for fabricating large area free-standing membranes of thickness down to 0.5 μm for use as an x-ray lithography mask substrate. The choice of material, method of preparation, and technique for separating the membrane from its substrate will be discussed. Techniques for generating x-ray absorber patterns with submicron feature size are reported. These methods result in absorber geometries which are uniquely suited to x-ray lithography mask applications. Measurements of the mask patterning distortion and the temporal dimensional stability of a completed x-ray mask are reported.

X-ray lithography is a proximity mask replication technique that permits the definition of submicron features on silicon wafers or other substrates. Like its counterpart, u.v. proximity printing, it utilizes a patterned photomask. However, because soft x-rays are the exposing radiation there are significant differences in the photomask technology (1, 2). The ideal x-ray mask support should meet many difficult, seemingly contradictory, criteria. It should be relatively thin, yet rugged, flat and dimensionally stable, have a low atomic number and a favorably located absorption edge relative to the source wavelength; be fabricable in large area with low defect density and uniformly thin; have isotropic mechanical properties, be optically transparent, relatively inexpensive, and impervious to process chemicals commonly encountered in the semiconductor industry. In addition the absorber must be

Key words: x-ray, titanium mask, electroplating.

deposited with low intrinsic stress so as not to induce pattern distortions.

Since x-ray lithography permits the choice of a range of exposing wavelengths the mask technology must be selected in the context of the overall system selection. In this paper a mask technology is described which is compatible with the x-ray exposure system described in Ref. (3) and the alignment approach described in Ref. (4). The x-ray lithography mask chosen consists of a thin (~ 1 μm) titanium membrane stretched on a support ring. The desired pattern is defined on the membrane by a gold absorber.

In order to be useful for submicron lithography the membrane must be dimensionally stable in order to permit overlay of sequential mask patterns. In addition, the membrane must have a smooth surface morphology to permit submicron absorber definition and to avoid defects. These requirements constrain the choice of fabrication process and pattern definition technology. In the following discussion, membrane fabrication, tensioning, patterning, and dimensional stability are described.

Membrane Fabrication

Titanium membranes are produced by electron beam evaporation onto a glass substrate. In order to ensure membrane dimensional stability the deposition conditions are chosen to produce bulk strength films (5) of uniform thickness with isotropic physical characteristics, zero intrinsic stress, and smooth surface morphology.

Films are deposited onto 12.5 cm diam photomask quality soda lime glass. This glass is chosen because of the close match of its thermal expansion coefficient with titanium and because the high quality surface minimizes defects. The combination of high rate (100 Å/sec), high deposition temperature (350°C), and matched expansion coefficient produces large area bulk strength films with low intrinsic stress. The evaporation system geometry is chosen to ensure membrane thickness variations of less than 2% across a 8.6 cm active diameter.

A gold parting agent is used to facilitate separation of the titanium membrane from the glass substrate. The choice of parting agent, its thickness, and deposition temperature are critical to the membrane fabrication process and to the membrane surface morphology. Because gold has a relatively low recrystallization temperature (150°C) it must be deposited at low temperature to minimize grain growth which has a deleterious effect on the titanium surface morphology. Similarly a thin gold film (< 500Å) is used to minimize the effect of grain growth during titanium deposition. A titanium surface with features smaller than 0.2 μm is obtained by minimizing the heat cycle. The lower limit of gold parting layer thickness is determined by the interdiffusion kinetics of the Au-Ti system. It has been observed (6, 7) that the Au-Ti system is susceptible to significant intergranular diffusion at temperatures above 300°C. Furthermore, the diffusion rate is ambient dependent. Faster diffusion occurs in vacuum than in air possibly due to oxide formation at the titanium grain boundaries which act as interdiffusion barriers (8). Therefore, to assist peeling, it is necessary to minimize the elapsed time in vacuum after the completion of titanium deposition. The use of a gold parting layer results in a peeling yield of greater than 90% for 1 μm thick titanium films 12.5 cm in diameter. We have demonstrated that films as thin as 0.4 μm can be peeled successfully by this technique.

Table I presents a comparison of the transmission characteristics of various materials for the tungsten M-line (6.983Å). As can be seen the titanium must be significantly thinner than other materials to transmit 50% of the W_m radiation. On the other hand, titanium is fabricable in large area, free-standing form and can be tensioned to any desired value independent of the fabrication process parameters and are tough.

Table I. Comparison of the x-ray transmission of various membrane materials at the W_m line (6.983Å)

Membrane material	Thickness required for 50% transmission at W_m line (μm)
Titanium	1.1
Beryllium	41.8
Silicon	9.6
SiO_2	5.0
Si_3N_4	5.7
SiC	6.8
BN	7.9
Polyimide	9.0
Mylar	8.6

The titanium film is removed from the glass by mechanical peeling as illustrated in Fig. 1. A thin flexible ring is attached to the titanium by means of double-sided adhesive tape. Peeling proceeds under water until the membrane is free-standing on the flexible ring. The water acts as a surfactant to reduce peeling forces at the film-glass interface. Separation occurs at the weakly bonded gold glass interface and a titanium-gold film is obtained. The gold surface replicates the original glass substrate and is featureless at 10 KX magnification in an SEM. This surface is used for subsequent lithography and patterning. After separation the membrane is slack on its mounting ring, indicative of the absence of intrinsic stress.

The peeled membrane is tensioned and attached to a support ring. Figure 2 is a photograph of a 1 μm thick tensioned membrane and support ring with an 8.6 cm unsupported diameter suitable for exposing 7.5 cm diam silicon wafers. Figure 3 illustrates schematically the tensioning procedure. The membrane (M) mounted on its peeling ring (P) is placed symmetrically over the smoothly machined rim (A). Weights (W) are added at the periphery to apply a known tension to the membrane and the permanent support ring (T) is expoxied in place. Membranes are typically tensioned to approximately 10^4 psi. The tension in the membrane probably is not uniform since pinholes, a thickness nonuniformity (of ~2%) from center to edge and differentially friction along the bearing edge, A in Fig. 3, would result in an anisotropic tension field.

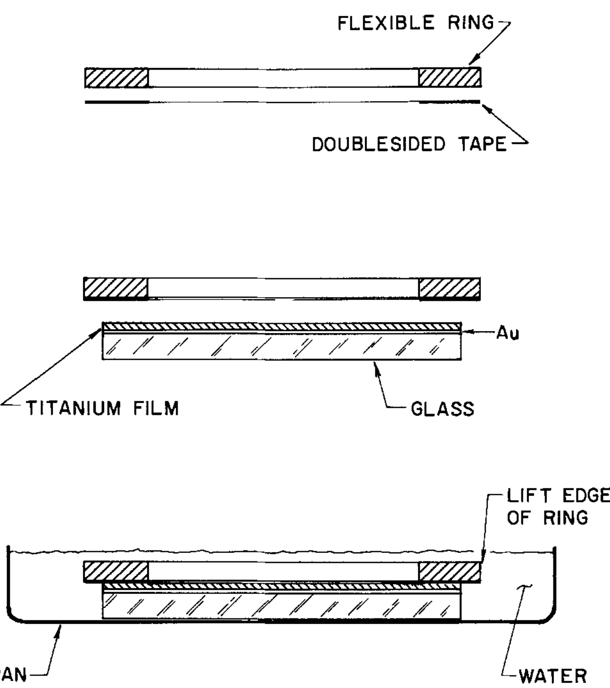

Fig. 1. Mechanical peeling of a titanium membrane from a glass substrate.

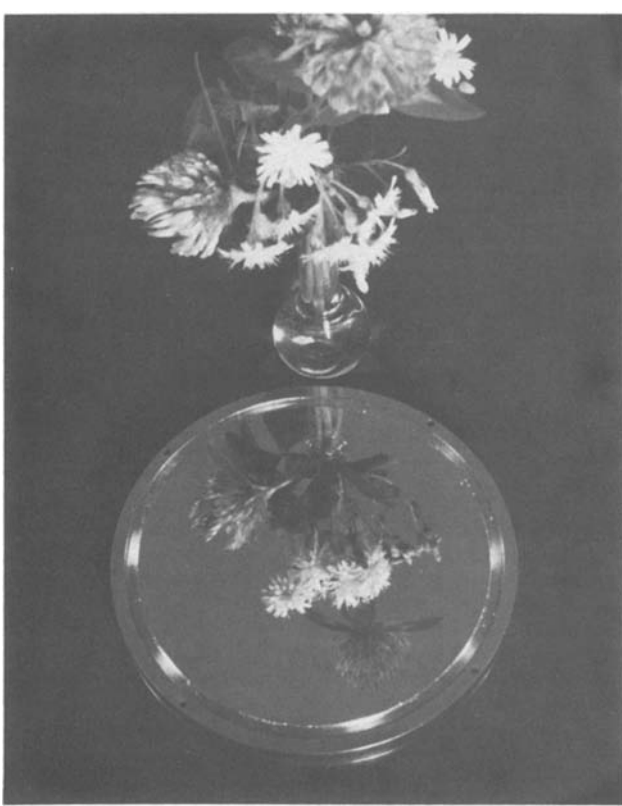

Fig. 2. 1 μm titanium membrane mounted on a rigid ring ready for patterning.

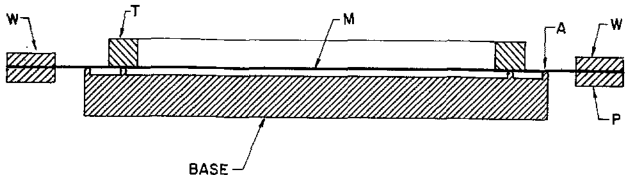

Fig. 3. Titanium membrane tensioning procedure. The support ring (T) is epoxied to the membrane (M).

However, within a ±2% precision (which represents a nonlinear in-plane distortion of <0.1 μm), our long-term stability tension measurements indicate that the dimensional stability does not appear to be compromised by these factors.

Mask Patterning

The tensioned membranes described above serve as substrates for the subsequent generation of a completed mask with the desired absorber pattern. Unlike optical photomasks, the absorber in an x-ray mask may have significant transmission. The x-ray transmission may be minimized by increasing the absorber thickness. However, the patterning process becomes progressively more difficult as the absorber thickness increases. Therefore, a practical compromise is necessary between the conflicting requirements of thick absorbers to produce high contrast and thin absorbers to facilitate high resolution patterning.

The choice of absorber thickness is influenced by the overall system configuration. For a tungsten-source M line (W_m) lithography system a contrast of 4:1 (analogous to that achieved by an optical system operating at 60% MTF) mandates a gold absorber thickness of at least 0.5 μm as shown in Fig. 4. In practice, a gold thickness of about 8000Å is used corresponding to an 8:1 contrast.

Submicron patterning of the absorber has been achieved by both additive and subtractive processing. Both of these processes require a photoresist thickness comparable to the absorber thickness. Submicron resist

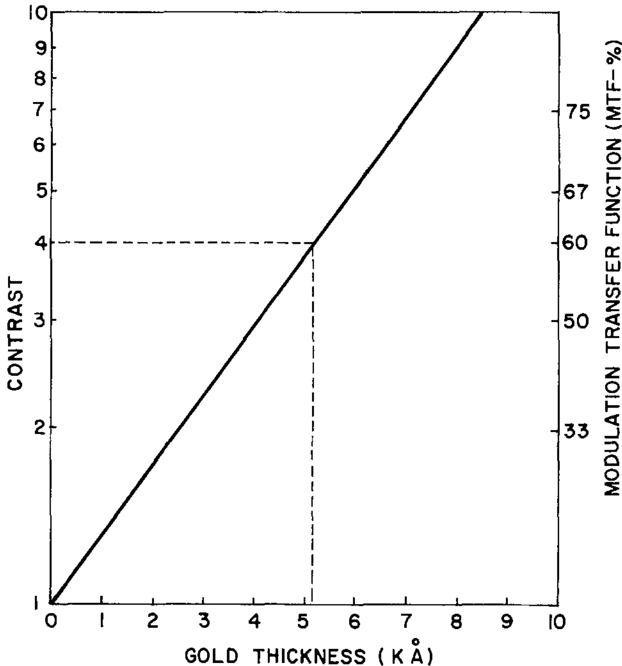

Fig. 4. Contrast and MTF dependence on gold absorber thickness. The dashed line indicates an MTF of 60% a value generally used to define the minimum feature size for practical lithography using optical systems.

pattern generation was achieved by electron beam lithography using an MEBES instrument.

Since it is difficult to achieve submicron pattern features in thick electron resist we have used tri-level or stencil processes. The additive stencil process is shown in Fig. 5. The tri-levels consist of 1 μm of PMMA on the membrane which is coated by 0.1 μm of evaporated Cr (or Al) on top of which is a 0.4 μm layer of electron resist (PBS). The PBS is electron beam patterned and the developed resist serves as an

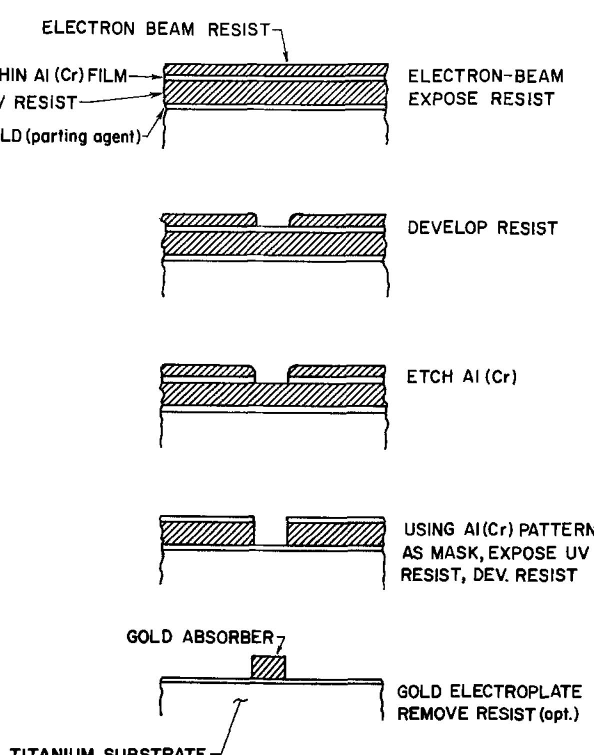

Fig. 5. Additive absorber definition process. The pattern is defined in the upper resist by electron beam lithography. This pattern is transferred to the thick lower resist by u.v. exposure. Subsequent absorber definition is by low stress gold plating.

etch mask for patterning the metal layer. The PBS is then stripped in an oxygen plasma and the metal stencil is transferred to the PMMA by deep u.v. exposure. After developing the PMMA in MIBK, and removing the masking metal by etching, the gold absorber is electroplated onto the thin parting layer which is used as a plating base. The final process step is removal of the PMMA in acetone. This process is attractive when Cr is used as the metal stencil since the electron beam resist patterning and metal etching use established photomask fabrication technology.

The electroplating process takes advantage of the conductivity of the titanium membrane. The plating apparatus is shown schematically in Fig. 6. In this scheme the entire mask is surrounded by an insulated housing with both surfaces of the membrane exposed to a conducting liquid solution. An internal electrode is placed in close proximity to the back-surface of the membrane. In this configuration gold plating occurs onto the front surface of the membrane through openings in the PMMA resist pattern. Since the current flow is perpendicular to the membrane plane, current distribution problems are avoided and uniform absorber thickness is obtained independent of position on the membrane surface. Figure 7 is a scanning electron micrograph of 1 μm lines and spaces produced by this process.

For an x-ray exposure system using a relatively short source to mask distance and a thick absorber, geometrical shadowing effects may result in linewidth variations as illustrated in Fig. 8. However, in the process described above, if a point deep u.v. source is located at the same source to mask distance as in the x-ray exposure system, then a leaning pattern is produced in the PMMA. Electroplating faithfully reproduces this profile in the absorber and eliminates the shadowing effects as illustrated in Fig. 8.

During exposure, x-rays absorbed in the titanium membrane produce photoelectrons which can cause spurious exposure of the x-ray resist. In order to minimize this effect of 1 μm thick coating of low atomic number material, such as PMMA, is applied to the unpatterned surface of the membrane. Figure 9 is a photomicrograph of a finished patterned x-ray mask.

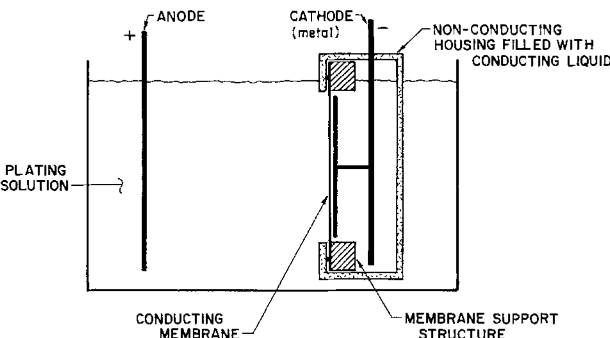

Fig. 6. Apparatus for electroplating a titanium mask membrane

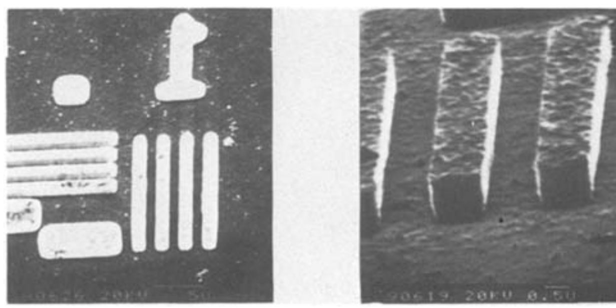

Fig. 7. 1 μm features × 1 μm thick electroplated gold test patterns on titanium x-ray mask.

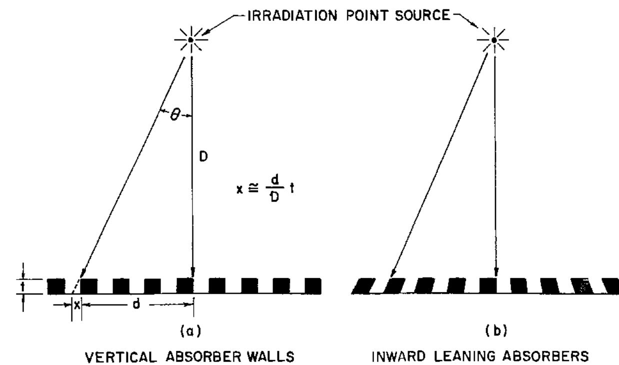

Fig. 8. Absorber definition technique which eliminates shadowing effects.

The subtractive version of the mask patterning process is similar to that described above except that a thick layer of absorber is deposited before stenciling layers are applied. Absorbed patterning proceeds by sputtering or ion etching.

In its present state of development a finished mask has an optically visible defect density of less than 20 cm^{-2} for defects greater than 0.5 μm. Straightforward improvements in cleanliness and process techniques are expected to lead to a notable improvement.

Mask Dimensional Stability

A practical x-ray lithography system mask must permit accurate overlay of successive mask layers. The dimensionless stability of the overall mask structure is thus critical. Dimensional instabilities include distortions introduced by the mask patterning process as well as those associated with the membrane itself.

In order to measure these distortions we have fabricated x-ray masks with vernier test patterns. These masks were patterned by means of a Micralign™ projection printer using a quartz master photoplate. The x-ray mask was subsequently compared with the original photoplate by using the optomechanical alignment system of the projection printer to read the vernier patterns. A patterned silicon wafer was also measured periodically to insure against changes in the measurement system. Using these methods the precision of our measurement technique was estimated to be ± 0.25 μm.

The x-ray alignment system (4) permits the detection and compensation of small linear scale changes in the x-ray mask by adjustment of the mask-to-wafer distance. Therefore, our major concern is with random or nonlinear dimensionless changes remaining after a single linear magnification correction. We have ana-

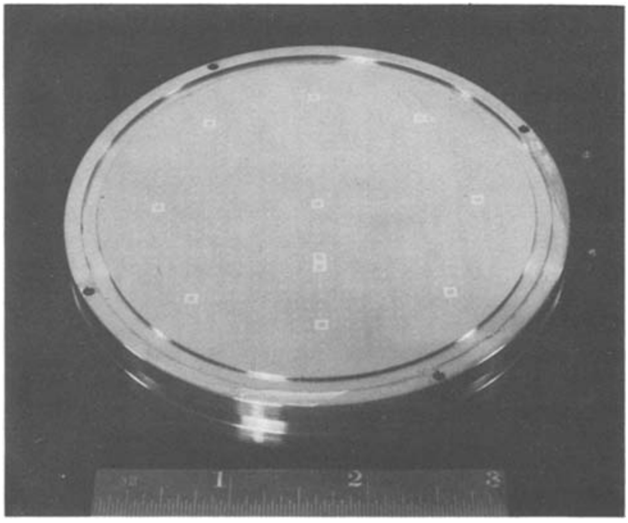

Fig. 9. Titanium x-ray mask with gold absorber pattern

lyzed our dimensional stability data in terms of linear and nonlinear distortions.

Figure 10 illustrates the average linear scale change of a 7.5 cm diam mask with time. The data indicates a small continuous shrinkage of the mask pattern with time. However, most of the shrinkage occurs in the first 1000 hr. This suggests that patterning of the stretched membrane after an initial aging could result in no further scale change (although the small scale change illustrated in Fig. 10 is, in fact, well within the compensating capability of the system).

Figure 11 illustrates the temporal variation of the residual nonlinear distortion term. It can be seen that this random term is small and within our measuring uncertainty at all times. It is important to note that these data include pattern distortions introduced by the fabrication process.

An x-ray multiple exposure technique was also used to measure the temporal stability of the x-ray mask. The x-ray lithography system was used to expose a silicon wafer and the pattern was etched in silicon dioxide. A second exposure using the same mask created an image in a new resist coating. (Unlike the Micralign measurement, these data do not include the pattern distortion since the mask is compared to itself rather than the master mask from which it was made.) The second exposure was offset from the first so that a vernier mask pattern could be used to measure misregistration. The vernier measurement uncertainty was approximately 0.1 μm. Misregistration was measured at seventeen locations in the wafer. The linear alignment errors were removed mathematically and the residual nonlinear errors are shown in Fig. 12. This figure summarizes the data for 8 wafers with an elapsed time of three weeks between exposures. The data shows that to within 1 standard deviation there is no nonlinear error, within the measuring precision.

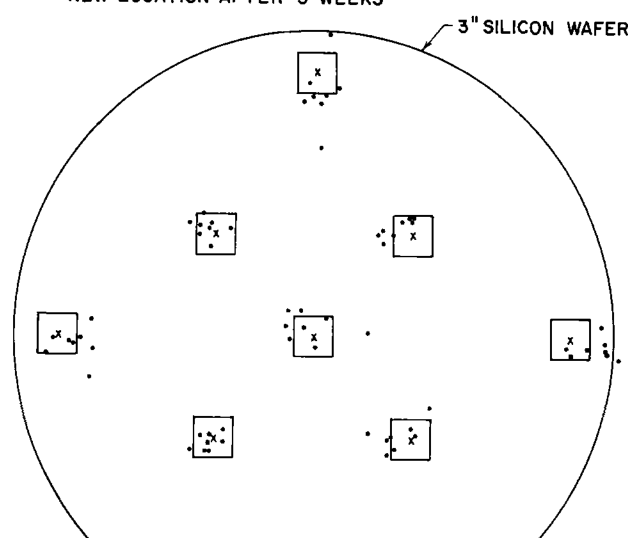

Fig. 12. Nonlinear dimensional change after 3 weeks for 8 wafers and a single mask. The data scatter is of the same magnitude as the measuring uncertainty.

Conclusion

Using a unique combination of materials and novel processing techniques we have developed a full field x-ray mask fabrication process. The masks are rugged, have a relatively high x-ray transmittance, are stable, and sufficiently blemish-free to be suitable for device fabrication.

ABSTRACT

A general relation for the growth and retrogrowth of oxidation-induced stacking faults (OSF) has been developed with three key observations from OSF experiments: (*i*) the growth rate of OSF is independent of their size and density, (*ii*) the ambient, pressure, and time dependences are explained by an oxidation rate dependence of the supersaturation of silicon self-interstitials in silicon which induces the fault growth, and (*iii*) the shrinkage of the faults in inert or oxidizing ambients is controlled by the same mechanism with activation energy of ~4.8 eV. To explain the oxidation rate dependence of interstitial supersaturation, a two-step oxidation model is proposed. In the first step, the lattice silicon atoms near the Si-SiO_2 interface oxidize to form SiO_2, but leave a substantial number of silicon atoms as interstitials near the interface. In the second step, these excess silicon atoms flow interstitially mostly into the oxide where they react with oxygen atoms until the oxidation is essentially complete, while a small fraction flows into the bulk silicon. The balance of the reactions in the two steps determines the silicon interstitial supersaturation in silicon which controls the growth rate of OSF. The correlation between the OSF and other oxidation-induced phenomena, *e.g.*, oxidation-enhanced diffusion (OED), and oxide fixed charge, Q_f, formation is also discussed based on the model. The correlation supports the postulate that these phenomena are caused by oxidation via the same point defect mechanism.

Thermal oxidation of silicon is known to induce growth of stacking faults in silicon (1). The presence of stacking faults has been found to cause adverse effects on the performance of integrated circuits, *e.g.*, current leakage in junction diodes and bipolar transistors, storage time degradation in MOS devices, dark current nonuniformity in CCD's, etc. (2-4). There have been successful efforts to reduce the density and size of oxidation-induced stacking faults (OSF), resulting in significant improvement in yield and performance of integrated circuits (5, 6). Understanding the OSF growth kinetics and its relation to processing steps is fundamental to further optimization of IC processes. More importantly, since OSF growth is induced by the oxidation process, a detailed understanding of OSF growth as well as of other oxidation-related process phenomena, *e.g.*, oxidation-enhanced diffusion (OED) and the formation of interface charges, may shed new light on oxidation kinetics.

From the abundant experimental data reported in literature (1), many important characteristics of OSF growth can be inferred. The density of OSF is influenced strongly by imperfections in the silicon wafer and is generally not affected by the oxidation process, exceptions result from the chlorine-assisted gettering oxidations (6). The size of OSF following oxidation, on the other hand, is essentially determined by the oxidation conditions. The growth of OSF consists of two different regimes, commonly referred to as growth and retrogrowth regimes. In the growth regime, in short oxidations at low temperatures, OSF expand with time. In the retrogrowth regime, in long oxidations at high temperatures, OSF shrink. The shrinkage of OSF is also observed when the wafers with OSF are annealed in neutral ambients at high temperatures (7, 8). It is shown in later sections that the shrinkage of OSF in both neutral and oxidizing ambients is similar and appears to be controlled by the same mechanism. The growth of OSF follows a time dependence of $t^{0.8}$ and an activation energy of 2.3 eV for most oxidation conditions (1). The OSF growth rate varies strongly with different oxidation ambients including different oxygen and steam pressures as well as chlorine-containing ambients (6, 9, 10).

This paper proposes a general equation relating the growth/retrogrowth of OSF to oxide growth rate. The basis of the general relationship is a model of point defect generation at the Si-SiO_2 interface during oxidation. The general relationship is shown to explain experimental results under a wide range of oxidation conditions. In later sections, the details of the point defect generation model and its implications to other oxidation-induced phenomena, *e.g.*, oxidation-enhanced diffusion and the formation of oxide fixed charges, are discussed.

Growth of Oxidation-Induced Stacking Faults

TEM analysis shows that OSF are two-dimensional extrinsic defects lying in <111> planes and are bounded by Frank partial dislocations (11, 12). The

* Electrochemical Society Active Member.
[1] Present address: Bell Laboratories, Allentown, Pennsylvania 18103.

Key words: oxidation, stacking faults, point defects, interface.

extrinsic nature of OSF suggests that the faults grow by the climb of Frank partials via emission of silicon vacancies or absorption of silicon interstitials. In a first attempt to model the growth of OSF, Hu (13) postulated that thermal oxidation of silicon is not a complete process and thus produces excess interstitial silicon atoms near the Si-SiO_2 interface. More recently, Tiller (14-16) has shown that oxidation of silicon requires the creation of free volume at the Si-SiO_2 interface. The free volume can be generated in part by the flux of silicon interstitials away from the interface. In both cases, a supersaturation of silicon interstitials occurs in the silicon substrate near the Si-SiO_2 interface and OSF grow by absorbing these interstitials. The rate of absorption determines the growth rate of OSF. In equation [13] of Ref. (13), Hu gave the growth rate as

$$\frac{dr}{dt} = \pi a_0^2 D_I (C_I - C_I^*) \quad [1]$$

where r is the radius of the stacking faults, a_0 the capture distance of interstitials by the faults, D_I the diffusivity of self-interstitials in silicon, and C_I and C_I^* the extrinsic and intrinsic interstitial concentrations in silicon, respectively.

Equation [1] states that at a given temperature the stacking fault growth rate depends only on the excess interstitial concentration. Since it is reasonable to assume that identical oxidation conditions yield identical excess interstitial concentration, they should also yield identical stacking fault growth irrespective of the initial size of the faults. This growth behavior of OSF is in agreement with Shiraki's experiments (9) described below and will prove to be an important difference between Hu's model and a recent model proposed by Murarka (1).

In Shiraki's experiments, silicon wafers were oxidized in dry oxygen ambient. OSF of ~65 μm length were observed on the wafers after oxidation. The oxide was then completely etched away and these wafers together with similar wafers, which were not oxidized, thus having no visible OSF, were oxidized in dry oxygen ambients containing different concentrations of HCl. The change in length of OSF after oxidation is replotted in Fig. 1(a-d). As can be seen from the figures, OSF of different initial lengths (0 and 65 μm) grow with similar rates throughout the same oxidation step, indicating that the growth rate of OSF is nearly independent of size and is determined only by the oxidation conditions as implied by Eq. [1]. This is particularly true during the early growth. For long oxidations, there appears to be some size dependence, which is probably caused by the overlapping of large faults or other secondary factors not known at present.

In his recent model, Murarka (1) considered the OSF growth analogous to the three-dimensional crystalline growth at the surface of kinks. He adapted a model developed by Kahlweit (17) and derived an expression for the OSF growth as a function of time.

$$r = \frac{4}{\sqrt{3b}} (2\Omega D \Delta C_I)^{3/4} t^{3/4} \quad [2]$$

where b is the magnitude of the Burger's vector of the partials bounding the faults, Ω is the atomic volume of silicon, D is the self-diffusion coefficient of silicon, and ΔC_I is the supersaturation of silicon interstitials in silicon.

Recently, Leroy (19) has criticized Murarka's use of Kahlweit's model to explain the growth of OSF. We will not repeat Leroy's arguments, but we would like to make here two additional points against Murarka's model. (*i*) In Kahlweit's original model the growth rate of the three-dimensional nuclei is inversely proportional to the diameter of the growing nuclei. Following Murarka's adaptation of the model, the growth rate of OSF is expected to vary with size. This is in disagreement with Shiraki's experiments described above. (*ii*) At a given temperature and ambient, the supersaturation of interstitials, ΔC_I, is constant according to Murarka's original paper (1), or varies inversely with oxidation rate, following a power law, according to a more recent presentation by the same author (20). Both of these arguments are contradicted by observations of oxidation enhanced diffusion, OED, which also results from interstitial supersaturation (21, 22). Indeed, OED experiments indicate that ΔC_I varies proportionately with oxidation rate, following a power law, in agreement with the one proposed later in the present paper.

Retrogrowth and Shrinkage of Oxidation-Induced Stacking Faults

As mentioned earlier, OSF shrink during long oxidations (23) and neutral ambient annealing (7, 8) at high temperatures. This section will show that in both the neutral and oxidizing ambients, the shrinkage is controlled by the same mechanism.

Sugita *et al.* (7) have observed that OSF shrink with constant rate when the wafers are annealed at high temperatures in N_2 ambient. Claeys *et al.* (8) reported similar shrinkage, with the shrinkage rate slightly dependent on annealing ambient (N_2, H_2, or Ar). These data are compared to the results of Shiraki's experiments shown in Fig. 1(a-d). Shiraki's data indicate that the addition of HCl to the oxidation ambient reduces the rate of OSF growth. When the added HCl content is high enough, the OSF growth is totaly suppressed and the initial faults shrink with a rate similar to that of the shrinkage in N_2 ambients observed by Sugita *et al.* (7) and Claeys *et al.* (8). The activation energy of the shrinkage is also very similar for various cases and is independent of ambient. In fact, all shrinkage data follow an Arrhenius temperature dependence with an activation energy of approximately 4.8 eV. This strongly suggests that the retrogrowth of OSF for long oxidations and the shrinkage during neutral ambient annealing are controlled by the same activated process.

A Model for the OSF Growth/Retrogrowth

Following the discussion in the previous two sections two important characteristics of the OSF growth in silicon must be emphasized: (*i*) the growth rate of the oxidation stacking faults is nearly independent of their size and density, and (*ii*) retrogrowth of OSF during oxidation is similar to shrinkage during annealing in neutral ambients.

To explain both the growth and retrogrowth, we consider that the Frank loop partial bounding the faults act as a sink or a source of interstitials. During oxidation, silicon interstitials are produced at the Si-SiO_2 interface and diffuse quickly into the bulk silicon, supersaturating the interstitial concentration to a level higher than the interstitial concentration in equilibrium with the faults, C_I^S, which is defined as the concentration at which the faults neither grow nor shrink. The partial dislocation, acting as a sink, captures the interstitials within a domain of radius, a_0, and causes the fault to grow (Fig. 2). For neutral ambients or when the oxidation rate is small and the interstitial generation is negligible, the interstitial concentration in the bulk returns to the equilibrium level, C_I^*, which is lower than C_I^S. The dislocation then acts as a source of interstitials and the interstitials diffuse away from the faults causing the faults to shrink. Although the importance of interstitials in OSF growth/retrogrowth is widely recognized, the detailed mechanism of the interstitials absorption and emission is still controversial. Leroy (19) advocates a diffusion controlled model, while Hu (24) favors a reaction control model. As the present paper is focused on the general macroscopic behavior of OSF in differ-

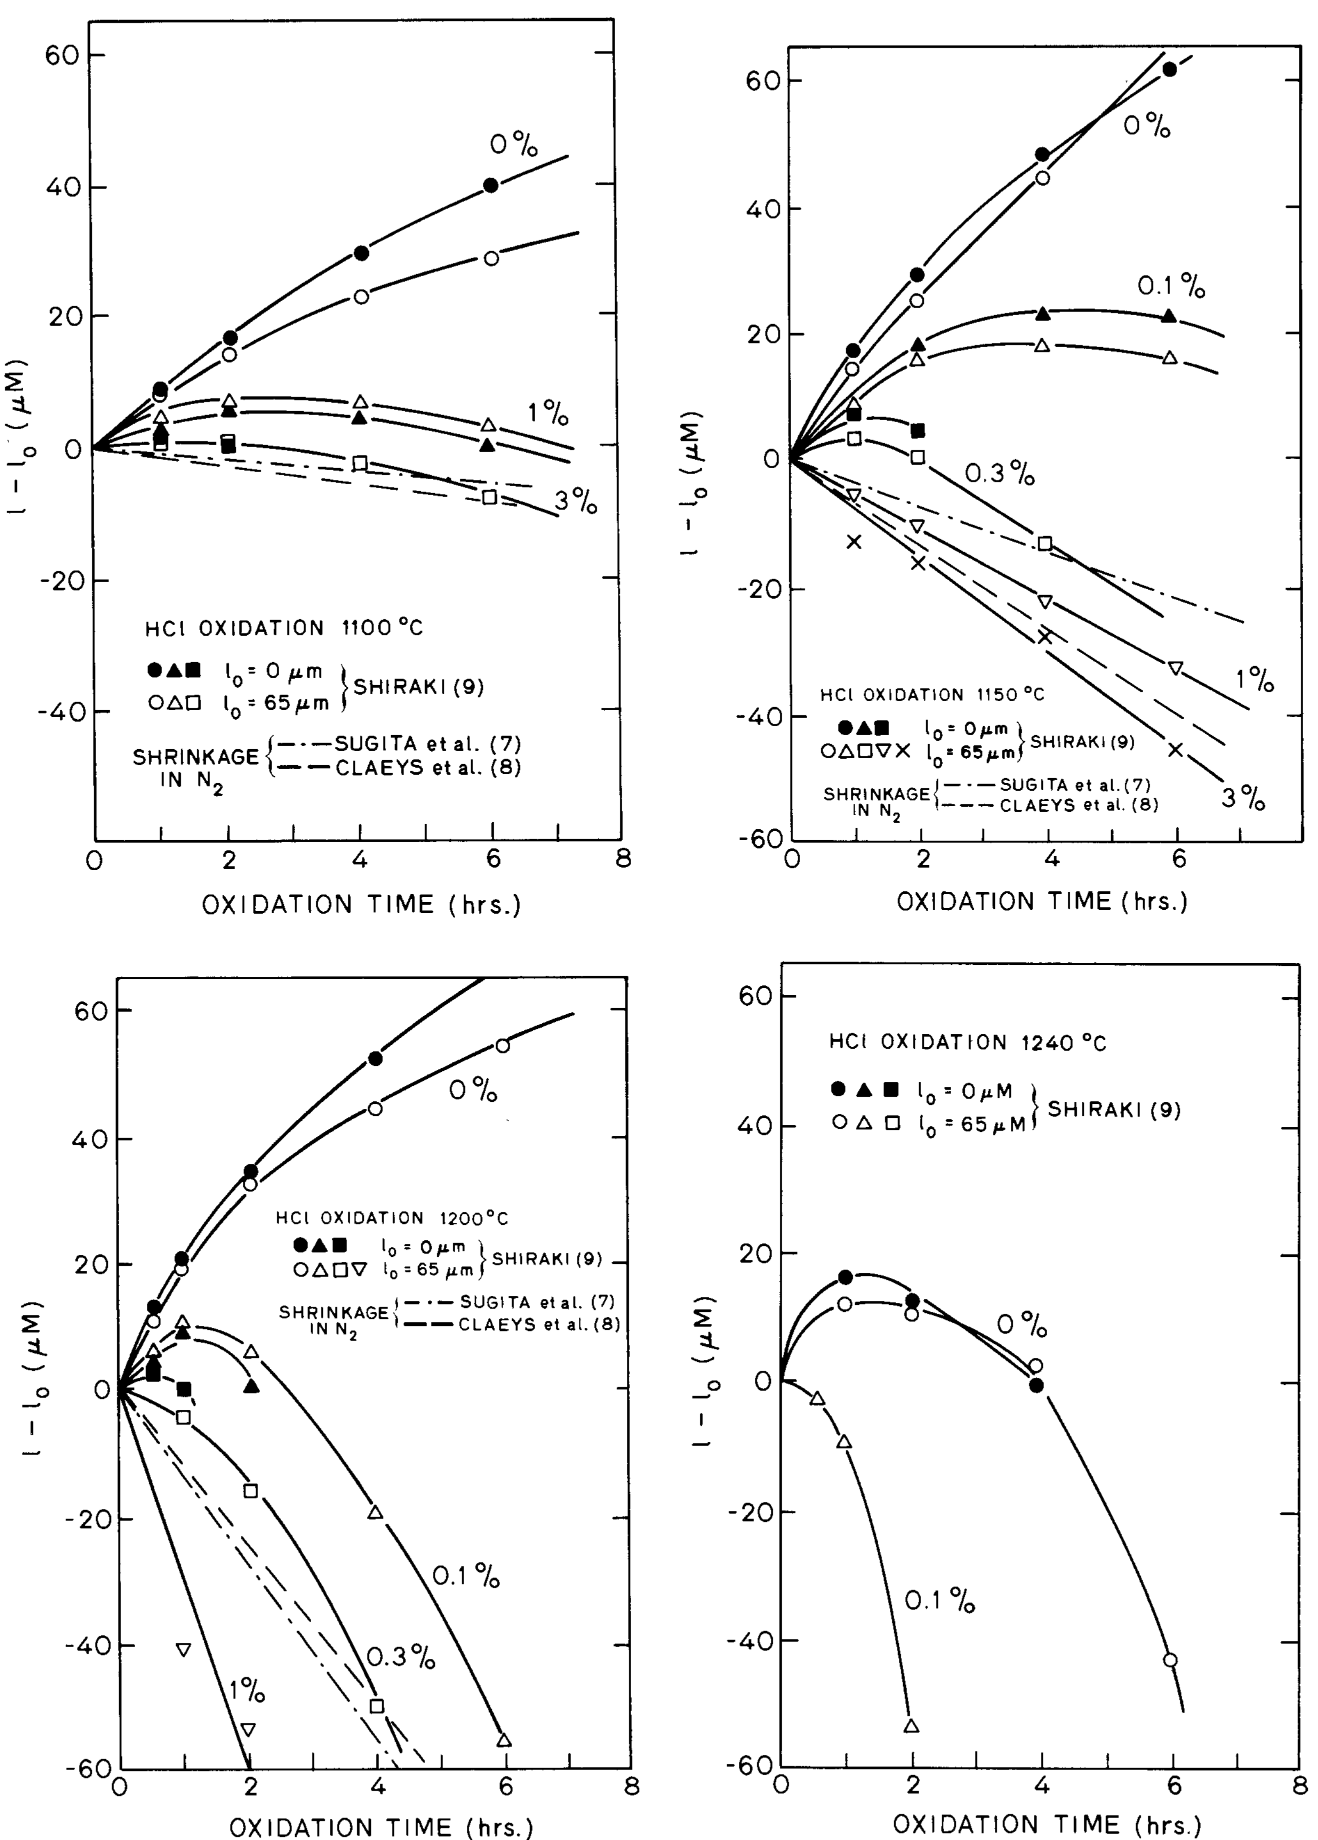

Fig. 1. Stacking faults of different initial lengths grow with similar rates in <100> silicon oxidations with different HCl concentrations at (a, top left) 1100°C, (b, top right) 1150°C, (c, bottom left) 1200°C, and (d, bottom right) 1240°C. Also shown are results of OSF shrinkage in N_2 ambient from Refs. (7, 8).

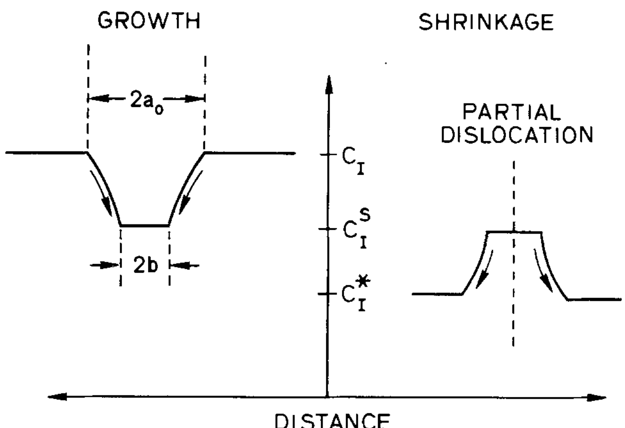

Fig. 2. The silicon interstitial distribution near the partial dislocation bounding the stacking faults during the growth and shrinkage of OSF.

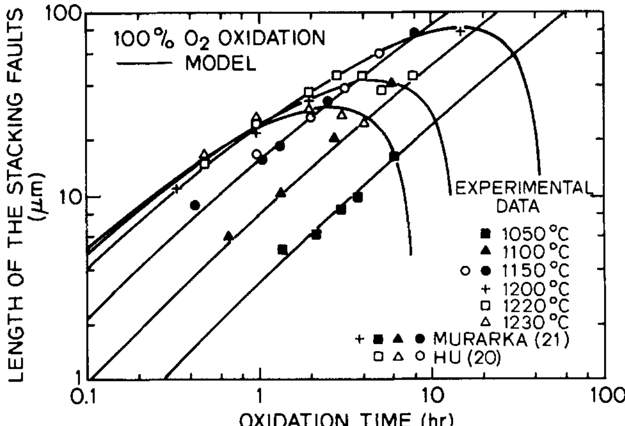

Fig. 3. Experimental data for OSF growth in 100% O_2 oxidation and comparisons with the model.

ent processing ambients, readers interested in more details on the microscopic models are referred to the above references. Both models, nevertheless, agree on the basic formulation of the OSF growth as follows

$$\frac{dr}{dt} = P(C_I - C_I^S) \quad [3]$$

where P is a proportionality factor, involving the diffusion of self-interstitials and the reaction energy barrier (19, 24).

The growth of OSF and, thus by implication, the interstitial supersaturation occurs only when the silicon is oxidized. In a later section, we discuss the possible mechanisms leading to the generation of interstitials at the $Si\text{-}SiO_2$ interface. It is also demonstrated later that the interstitial supersaturation can be related to the rate of oxide growth by the expression

$$C_I - C_I^* = K\left(\frac{dX}{dt}\right)^n \quad [4]$$

where K is a reaction constant related to the point defect generation process at the interface, and X is the oxide thickness.

Combining Eq. [3] and [4] gives a general relationship for the growth of OSF in silicon

$$\frac{dl}{dt} = K_1\left(\frac{dX}{dt}\right)^n - K_2 \quad [5]$$

$$K_1 = 2PK \quad [5a]$$

$$K_2 = 2P(C_I^S - C_I^*) \quad [5b]$$

where $l = 2r$ is the diameter of stacking fault, generally taken as the length of the fault.

A linear dependence ($n = 1$) in Eq. [4] was initially proposed by Hu (13) for OSF growth. However, as Hu pointed out later (23), the predicted time dependence of OSF growth based on the linear dependence disagrees with experimental results. Detailed comparison of Eq. [5] with experimental results shown in the next section gives the value of n to be 0.4. We believe that this sublinear dependence results from a particular point defect generation mechanism at the $Si\text{-}SiO_2$ interface. A model for the generation mechanism is discussed in a later section.

Comparison with Experiments

Figure 3 shows experimental data from Hu (23) and Murarka (25) for the OSF growth in dry oxygen at different temperatures in <100> silicon. At low temperatures (1050°-1150°C), only growth is observed while at higher temperatures both growth and retrogrowth occur. The length of OSF grown at low temperature shows a time dependence of $t^{0.8}$ which gives a dependence of $t^{-0.2}$ for OSF growth rate. The coefficient K_2 is insignificant at these temperatures and OSF growth is governed by the oxide growth, following Eq. [5]. For the temperatures and times shown in Fig. 3, oxidation is in the so-called parabolic oxide growth regime where dX/dt follows a $t^{-0.5}$ dependence (18). Thus, Eq. [5] yields a value of $n = 0.4$. With the known oxidation rate at these temperatures, K_1 is directly obtained from the data in Fig. 3. At higher temperatures, however, K_2 becomes significant and retrogrowth occurs during oxidation. K_1 and K_2 are then simultaneously obtained by a least squares fit. The extracted values for K_1 and K_2 are plotted in Fig. 4 as a function of temperature. Both appear to follow an Arrhenius temperature dependence with different activation energies

$$K_1 = 1.58 \times 10^{10} \exp(-2.4\ \text{eV}/kT)\ (\mu\text{m/hr})^{0.6} \quad [6]$$

$$K_2 = 6.45 \times 10^{17} \exp(-4.8\ \text{eV}/kT)\ (\mu\text{m/hr}) \quad [7]$$

These data are for OSF growth in <100> silicon in dry O_2 ambient and will be different for other orientations. The calculations using Eq. [5] with the now known n, K_1 and K_2 show good agreement with the experimental data in the complete range of temperatures and times as demonstrated in Fig. 3.

In the absence of oxidation, the interstitial concentration returns to the equilibrium level, C_I^*, and the stacking faults shrink with the rate

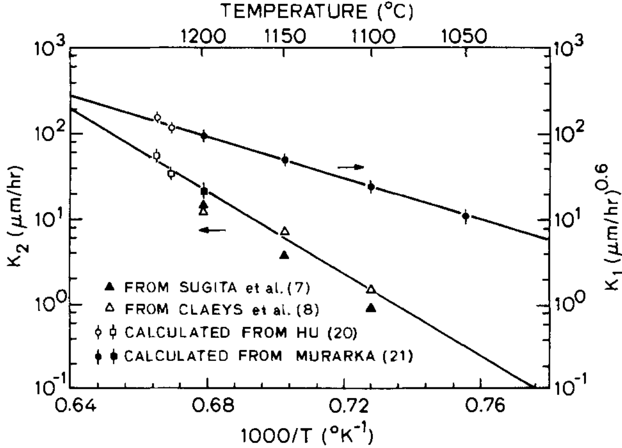

Fig. 4. The extracted data for the OSF growth constant K_1 and retrogrowth constant K_2 from the data in Fig. 3. Note the good agreement between the extracted K_2 and the measured shrinkage rates in N_2 from Refs. (7, 8).

$$\frac{dl}{dt} = -K_2 \qquad [8]$$

This allows an independent calculation of K_2. In Fig. 4 the OSF shrinkage rates in N_2 ambient from Sugita *et al.* (7) and Claeys *et al.* (8), are compared with the calculated K_2 from the dry O_2 experiments. Claeys *et al.* (8) also observed that the OSF shrinkage is different in different neutral ambients (Ar and H_2 as compared with N_2), which suggests that C_I^* is affected by the annealing gas ambients. They attributed the effect to nitridation possibly occurring at the interface during the N_2 annealing.

The difference in the activation energies of K_1 and K_2 is significant and can explain the strong temperature dependence of OSF retrogrowth. Figure 5 plots separately the growth and retrogrowth rates. At low temperature, the growth rate is seen to dominate. As the temperature increases, because of the larger activation energy of K_2, the retrogrowth rate increases more rapidly than the growth rate and, at sufficiently high temperatures, the retrogrowth dominates. This is in agreement with experimental findings (23, 25).

The 2.4 eV activation energy of K_1 includes the energy of interstitial generation at the Si-SiO_2 interface and of interstitial migration in silicon. Assuming an interstitial self-diffusion mechanism for silicon Seeger *et al.* (26) obtained 2.0 eV for the interstitial migration energy which leaves 0.4 eV for the activation energy of interstitial generation at the Si-SiO_2 interface.

The activation energy of K_2 involves the formation and migration of interstitials near the stacking faults. The calculated 4.8 eV activation energy of K_2 is close to that of silicon self-diffusion, which lies between 4.78 and 5.13 eV (27-29) and suggests the same formation and migration energies of the interstitial near the faults as in the bulk away from the faults.

Since K_1 involves only the migration of interstitials and the interstitial generation at the Si-SiO_2 interface, whereas K_2 involves only the formation and migration of interstitials near the faults, both are expected to be rather independent of oxidation ambients.[2] Hence Eq. [5]-[7] form a general relationship and can be readily applied to OSF growth under any different oxidation conditions. In the following subsections, we discuss the growth/retrogrowth of OSF for oxidations with different oxygen and steam pressures and compare the proposed general model to the experimental results available in the literature.

Oxygen partial pressure oxidations.—The growth of OSF is found to vary with different partial pressures of oxygen for otherwise similar oxidation conditions (25, 30). The partial pressure of oxygen results in different oxidation rates whereas the oxidizing species and interface kinetics are the same regardless of the pressure. Hence the different OSF growth at different oxygen pressures should provide an important test for the generality of Eq. [5].

For long oxidations, such as those used in OSF experiments, the oxide growth is dominated by a parabolic growth regime (18), in which the oxidation rate follows a $t^{-0.5}$ time dependence with actual value determined by the oxidant's partial pressure. The stacking fault growth rate at different oxygen pressures will then have a $t^{-0.2}$ time dependence, but different overall value, following Eq. [5] with $n = 0.4$ and assuming K_2 is negligibly small. Thus the length of OSF grown in different oxygen pressures will vary, but the same $t^{0.8}$ time dependence will always be observed. This is consistent with experimental data reported by Murarka (25) as shown in Fig. 6. The different lengths are also explained by the specific dependence of oxidation rate on oxygen pressure. Figures 7a, b, and c show more complete comparisons with data of OSF growth and retrogrowth during oxidations in different pressures at various temperatures and times. Calculations utilizing the present model show generally good agreement with these experimental data that come from many workers (9, 23, 30).

Atmospheric and high pressure steam oxidations.—OSF grow to a greater size in steam ambients than in dry oxygen ambients for the same oxidation temperature and time (23, 31). Figure 8 shows a comparison between experimental data from Ref. (23, 31) and calculations by Eq. [5]. Since the values of K_1 and K_2 used in Eq. [5] are obtained from data for dry oxidation only, the good agreement between experimental and calculated data shown in Fig. 8 suggests that the basic point defect process at the interface is the same for dry and steam ambients and is controlled primarily by the rate of oxide growth as postulated earlier in Eq. [4].

[2] One exception is chlorine-containing oxidation in which Cl atoms possibly affect the silicon point defect generation at the Si-SiO_2 interface.

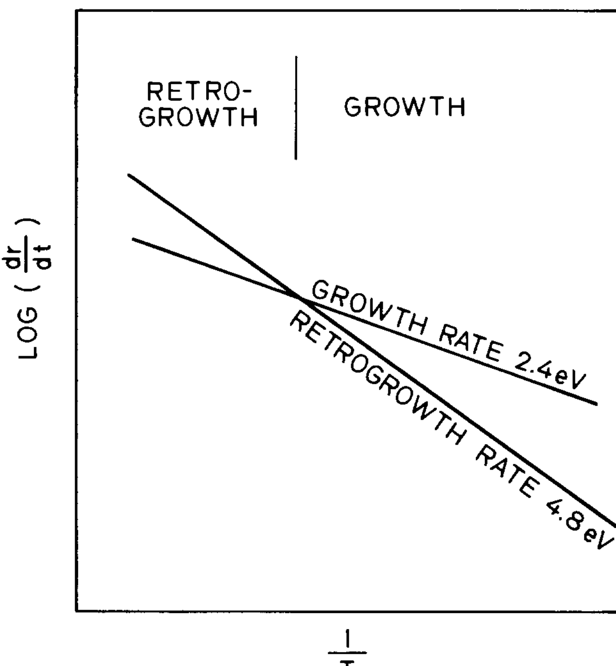

Fig. 5. At low temperatures, OSF growth rate is larger than retrogrowth rate. As the temperature increases, because of its larger activation energy, retrogrowth rate increases more rapidly and becomes dominant at high temperatures.

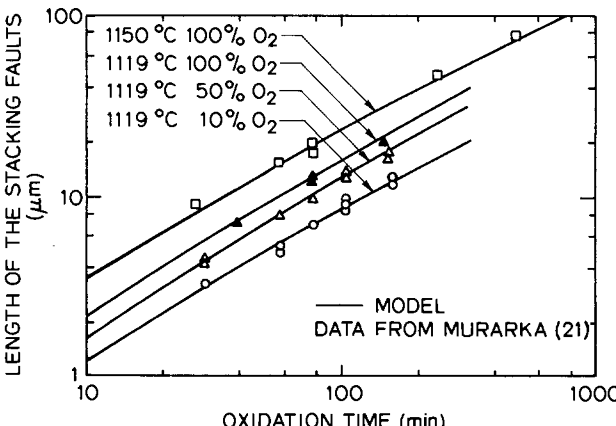

Fig. 6. The stacking faults growth in different O_2 partial pressures. These curves show the same time dependence, $t^{0.8}$, illustrating the same oxidation rate dependence of OSF growth.

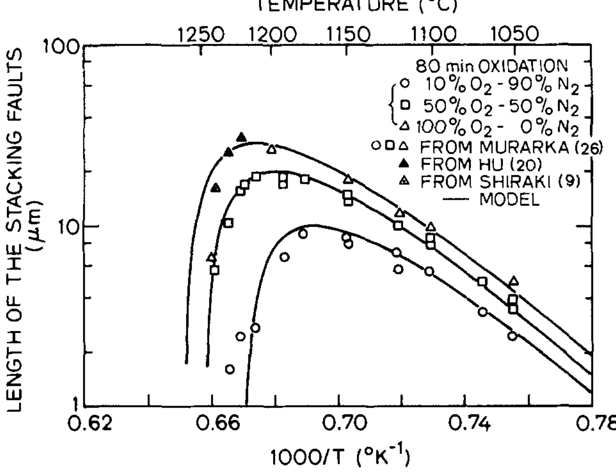

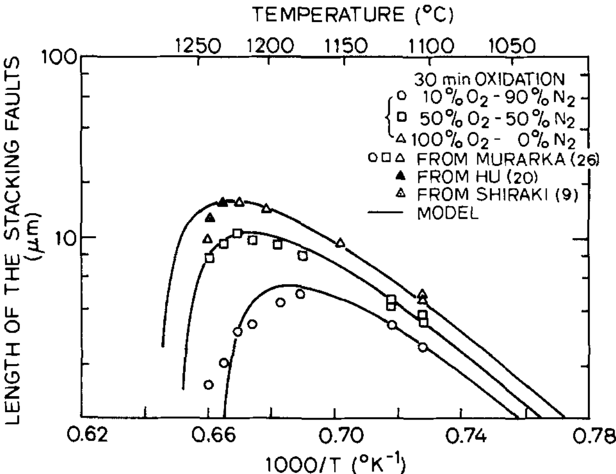

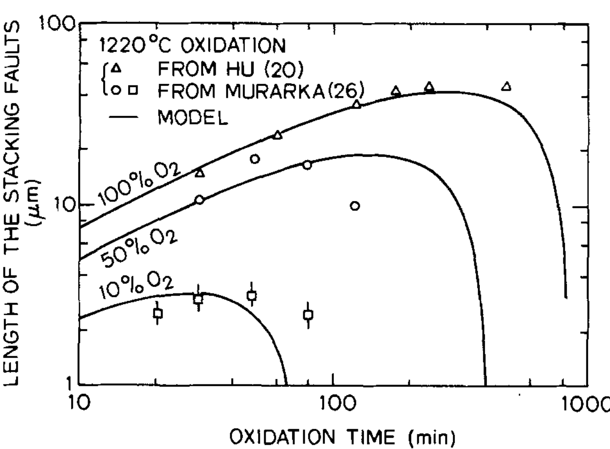

Fig. 7. The experimental results of OSF growth in different O_2 partial pressures and comparisons with the model. (a, top left) The temperature dependence for 80 min oxidation, (b, top right) 30 min oxidation, (c, bottom left) time dependence in 1200°C oxidation.

Tsubouchi *et al.* (32) reported that much smaller OSF result when the same thickness of oxide is grown in high pressure steam than in atmospheric steam (Fig. 9a and b). This supports strongly the sublinear oxidation rate dependence in Eq. [5]. It is rather obvious that if the oxidation rate dependence was linear, similar sizes of OSF would grow for the same thickness of oxide regardless of different ambients used at the same temperature. Calculations using the proposed model again show good agreement with experimental data both at atmospheric and high pressures.

Chlorine-containing oxidations.—The addition of HCl in the oxidation atmosphere suppresses the growth

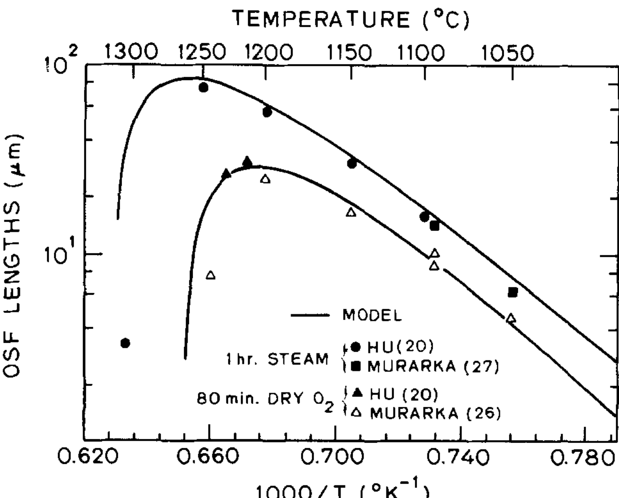

Fig. 8. The OSF growth in steam ambient as compared to that in dry O_2 ambient. The larger size of faults grown in steam ambients is explained by the oxidation rate dependence of OSF growth.

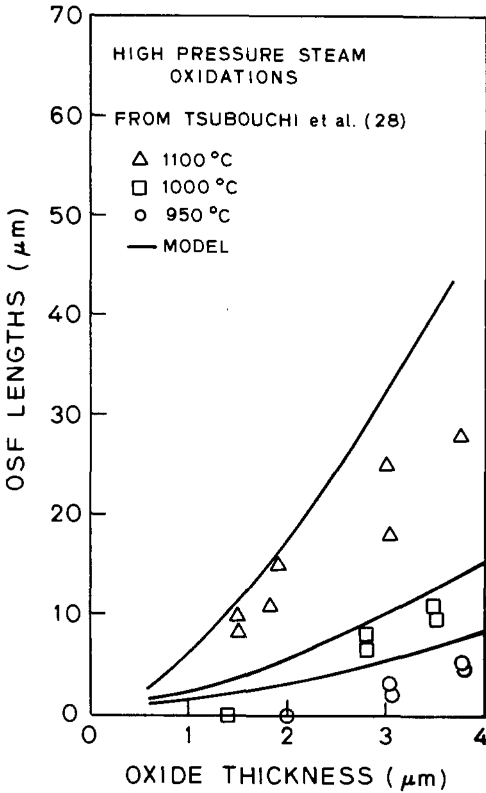
of OSF (Fig. 1). A similar effect has been observed for oxidations with other chlorine-containing atmospheres, *e.g.*, TCE (33) and C33 (6).

It can be seen from Fig. 1 that the presence of chlorine primarily reduces the growth rate of OSF while leaving the retrogrowth rate generally unaffected. This can be understood by considering a reaction of chlorine with silicon interstitials at the interface (forming silicon chlorides), which reduces the supersaturation of silicon interstitials in silicon during oxidation. The reaction at the interface, acting as a sink for both chlorine and excess silicon atoms, may partly explain the experimentally observed chlorine pile-up at the interface during oxidation (34).

Retrogrowth time (t_R) and temperature (T_R).—As mentioned in the earlier sections, there exists a time during oxidation at certain temperature when OSF begin to shrink with time instead of growing; this retrogrowth time is denoted as t_R. Also for a fixed duration of oxidation there exists a temperature at which OSF grow to a maximum length, this temperature is defined as retrogrowth temperature, T_R. It can be seen from Fig. 3 and 7 that both t_R and T_R are strong functions of oxidation temperature, time, and ambient.

At a given temperature, T, the retrogrowth begins during oxidation when the OSF growth rate decreases to 0, *i.e.*, $\partial r/\partial t|_T = 0$. Hence t_R can be calculated from Eq. [5] by deriving the oxide growth rate at which the above condition is obtained, as follows

$$\frac{dX}{dt_R} = \left(\frac{K_2}{K_1}\right)^{1/n} = \left(\frac{K_2}{K_1}\right)^{2.5} = 1.06 \times 10^{19} \exp(-6.0 \text{ eV}/kT_R) \ (\mu\text{m/hr}) \quad [9]$$



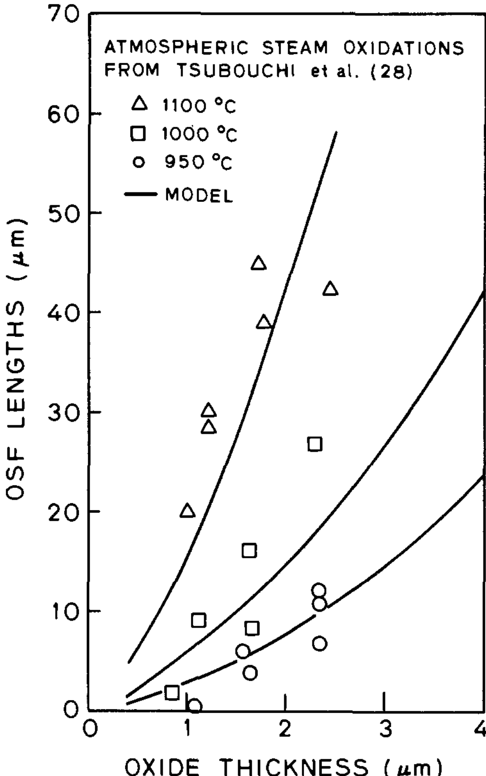


Fig. 9. The OSF growth in steam oxidations at (a, left) atmospheric pressure and (b, right) high pressure. Note the reduction of OSF sizes when the same oxide thickness is grown at high pressures instead of atmospheric pressure.

for <100> silicon. K_1 and K_2 are independent of oxidation ambient while the oxidation rate is strongly ambient and time dependent. Thus, from Eq. [9], t_R is expected to vary at different oxidizing ambients. Equation [9] can also be used for the calculation of T_R. An example graphical solution of this equation, for a 1 hr oxidation at different ambients, is shown in Fig. 10. While dX/dt at a fixed time is strongly ambient dependent, K_1 and K_2 are not. Thus, the temperature at which retrogrowth begins, defined by the intersection of the $(K_2/K_1)^{2.5}$ and $(dX/dt)_t$ curves, increases with increasing $(dX/dt)_t$. A certain similarity between Fig. 10 in the present paper and Fig. 10 in Ref. (25) should be noted here. The similarity, however, is only superficial since the plotted quantities and the theory behind them are different in the two cases. Since we have discussed our objections to Murarka's theory earlier in this paper, we will make no further comment at this point.

T_R can also be calculated utilizing Eq. [5] with the condition for maximum OSF growth for a given oxidation time, $\partial r/\partial T|_t = 0$. The calculations are compared in Fig. 11 with experimental results from Ref. (23 and 25) with generally good agreement.

Point Defect Generation at the Si-SiO_2 Interface

From the fact that stacking faults grow during oxidation, it is clear that the oxidation reaction is a source of point defects, assumed here to be self-interstitials, that induce the fault growth. While the Deal-Grove model (18) for oxidation explains very well the basic phenomenology of oxide growth, it provides little insight into its relationship with point defect generation process. In this section we discuss a model for the generation of interstitial point defects near the Si-SiO_2 interface and the subsequent distribution of these defects. This model is based on two key postulated mechanisms: (*i*) a two-step oxidation reaction and (*ii*) a segregation of excess silicon at the interface (16).

Two-step oxidation.—The average spacing between silicon atoms in SiO_2 is about 1-3 times the average spacing of silicon atoms in the Si lattice. If the Si-SiO_2 interface moves into the bulk Si with a velocity, V, during oxidation, the oxide thickens at a rate of 2.25V, which means that free volume must be created at a rate of 1.25V per unit area, otherwise the interface would be severely strained and oxidation would be retarded (14). The free volume may be supplied by a flux of vacancies from the bulk silicon to the interface, a flux of silicon interstitials from the interface to the bulk oxide or silicon, or a viscous flow of the oxide. If the free volume is to be entirely supplied by point defect fluxes, extremely large fluxes would be needed, which is unlikely. However, if less than 45% (1/1.25) of the silicon at the interface is oxidized and the rest of the silicon (55%) is placed at interstitial sites in the oxide, free volume would not be immediately needed. Since oxidation is experimentally found

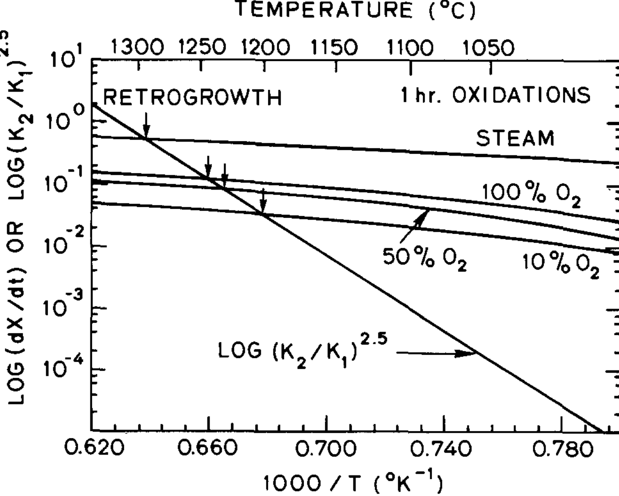

Fig. 10. The arrows indicate the temperature at which retrogrowth will occur for 1 hr oxidation in different ambients, calculated using Eq. [9]. The retrogrowth temperature increases for oxidations with increasing oxidation rates.

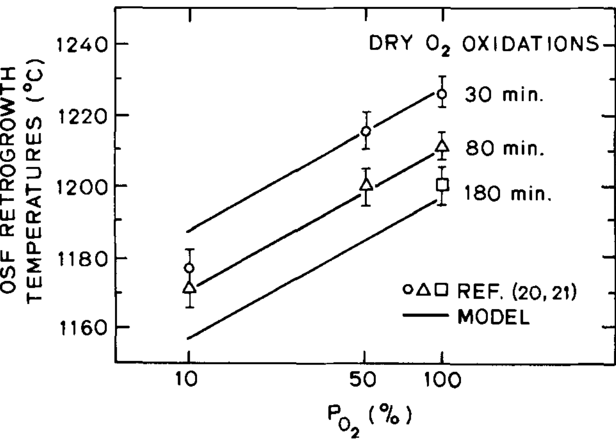

Fig. 11. For the same duration of oxidation, the retrogrowth of stacking faults occurs at lower temperatures at lower O_2 partial pressures. The calculations are from Eq. [5] with the condition, $d\tau/dT|_t = 0$.

to be more than 99% complete (35), the majority of these interstitial silicon atoms have to be oxidized in other reactions. Hence, the postulated initial oxidation and boundary motion reflect a localized intermediate mechanism for interstitial generation rather than a macroscopic observable fact.

The formation of interstitials at the interface can also be understood from the interface match between the Si and SiO_2 phases. It is pointed out by Tiller (16) that for low temperature oxidation, α-cristobalite is the preferred form for SiO_2 to initially form during thermal oxidation. The <100> α-cristobalite phase matches the <100> silicon quite well if 4 silicon atoms per unit cell (1/2 of total) become interstitials and diffuse either into bulk silicon or into the oxide. Based on observed results of OSF growth and the near completeness of oxidation, it seems most likely that the dominant fraction of these interstitials are consumed in subsequent oxidation rather than moving into bulk silicon.

From both the consideration of free volume and interface match at the Si-SiO_2 interface, it appears unlikely that the oxidation reaction immediately consumes all the silicon atoms in place at the interface. During oxidation, a substantial number of excess silicon atoms move away from the interface and become excess Si atoms near the interface; the fraction in the oxide is not directly observable whereas those which flow into bulk silicon affect OSF growth. Subsequent reactions of excess silicon with oxygen in the oxide then determine the silicon point defect distribution both in the oxide and in the silicon near the interface. In essence, oxidation of silicon is visualized as a two-step reaction in which point defects play an important role. In the first step, lattice silicon atoms located at the interface react with oxygen and form SiO_2

$$Si_L + (1-\gamma)O_2 \rightarrow (1-\gamma)SiO_2 + \gamma Si_I \quad [10]$$

where Si_L and Si_I represent the lattice silicon and the excess silicon at the interface, respectively, and γ indicates the fraction of excess silicon at the interface. We expect γ to range between approximately 0 and 0.55 based on considerations of free volume and interface mismatch. As oxidation proceeds, the concentration of excess silicon at the Si-SiO_2 interface builds up rapidly; some atoms can escape into bulk silicon and become silicon self-interstitials while others flow into the bulk oxide and quickly react with incoming oxygen near the interface. To avoid continuous buildup of excess silicon at the interface, the total flux away from the interface should equal the rate of generation of excess silicon. Thus

$$G = J_1 + J_2 \quad [11]$$

where G is the generation rate and J_1 and J_2 are the interstitial fluxes into bulk silicon and oxide, respectively. Based on the previously mentioned physical observations it is expected that G and J_2 are considerably larger than J_1 and the dimensions over which the fluxes persist differ by orders of magnitude. Specifically, J_2 being the intermediate reaction product persists only for a few monolayers. On the other hand, J_1 represents the flux which reaches deep into bulk silicon (Fig. 12).

From the reaction [10], the rate of generation of interstitials per unit area at the Si-SiO_2 interface is proportional to the velocity of interface movement, V, as given by

$$G = \frac{\gamma V}{\Omega} = \frac{a\gamma}{\Omega}\left(\frac{dX}{dt}\right) \quad [12]$$

where Ω is the unit volume of silicon. The interface velocity is related to the overall oxidation rate through the well-known ratio $a = 0.44$.

The extrinsic silicon interstitials in silicon may recombine with vacancies or may be absorbed by stacking faults and other defect structures existing in the silicon substrate. These effects are approximated by an infinite sink of interstitials at an effective distance L_S from the interface.[3] Then

$$J_1 = D_I \frac{(C_I - C_I^*)}{L_S} - C_I\left(\frac{dX}{dt}\right) \quad [13]$$

where D_I is the diffusion coefficient of silicon interstitials in bulk silicon and C_I is the concentration of silicon interstitials near the interface in bulk silicon. $C_I(dX/dt)$ is the convective flux due to the interface movement and is generally negligible. Since the excess silicon that flows from the interface into bulk silicon would be lost for further oxidation, J_1 should be much smaller than G and J_2, because oxidation is experimentally found to be more than 99% complete (35). This is further supported by the calculation of the flux of interstitials from the interface to the faults during a typical growth of OSF. For 1 hr oxidation at 1200°C OSF grow with an average rate of ~20 μm/hr and absorb interstitials at a rate of $[d(N_0\pi r^2)/dt]/\pi r^2 \sim 6 \times 10^{15}$ atoms/hr-cm^2, for OSF of 10 μm size. Here,

[3] This distance L_S is of the order of 25 μm based on the work of Taniguchi *et al.* (36) on oxidation-enhanced diffusion.

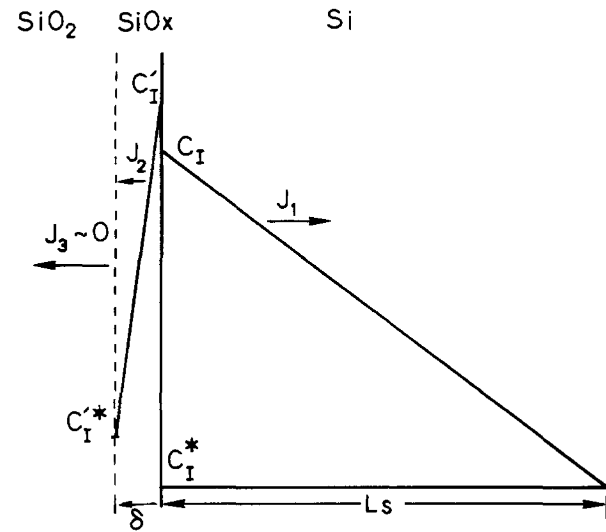

Fig. 12. Interstitial fluxes at the Si-SiO_2 interface during oxidation. J_1 reaches deep into bulk silicon, while J_2 is determined by the re-oxidation of excess silicon in oxide and persists only for a few monolayers.

$N_0 = 1.5 \times 10^{15}$ cm^{-2} is the number of atoms per unit area of OSF. The oxidation rate, on the other hand, is ~ 2 μm/hr, which produces excess silicon atoms at the interface at a rate of $\sim 2.6 \times 10^{18}$ atoms/hr-cm^2, from Eq. [12] with $\gamma = 0.55$. The detailed form of J_1 is thus not important for determining the interstitial generation at the Si-SiO_2 interface.

Experimentally, excess silicon atoms are found in bulk oxide only very near the interface (37, 38), which indicates that the excess silicon atoms generated during oxidation are quickly oxidized near the interface. This reaction determines the flux J_2 into the bulk oxide. The oxidation of these excess silicon atoms in the oxide is important for determining the net interstitial generation. Without it, the interstitial supersaturation would be linearly dependent on oxidation rate as proposed by Hu (13). The existence of the second oxidation reaction reduces the exponent of the power law dependence, as empirically found from the OSF data described in earlier sections. The reaction of the excess silicon with oxygen in the first layers of the oxide is assumed to follow a general reaction of the form

$$\mathrm{Si} + \frac{x}{2}\mathrm{O_2} \rightarrow \mathrm{SiO}_x \qquad [14]$$

where x is a parameter to be determined and may represent a mixture of several different SiO_x-type reactions. The postulated SiO_x, if different from SiO_2, is further oxidized later to SiO_2. J_2 can now be expressed as

$$J_2 = k'[\mathrm{O_2}]^{x/2}(C_{I}' - C_{I}'^*) \qquad [15]$$

where k' is the SiO_x reaction constant, $(C_I' - C_I'^*)$ the concentration of excess silicon interstitials in the oxide near the interface and $[O_2]$ the concentration of oxygen at the interface. J_2 can be directly related to the overall oxidation rate through the experimentally observed relation involving the oxygen concentration at the Si-SiO_2 interface (18)

$$\frac{dX}{dt} = k[\mathrm{O_2}] \qquad [16]$$

where k is the overall reaction coefficient of silicon oxidation at the interface. It then follows that

$$J_2 = \frac{k'}{k^{x/2}}\left(\frac{dX}{dt}\right)^{x/2}(C_I' - C_I'^*) \qquad [17]$$

Neglecting J_1, Eq. [11] is reduced to

$$\frac{a\gamma}{\Omega}\left(\frac{dX}{dt}\right) = \frac{k'}{k^{x/2}}\left(\frac{dX}{dt}\right)^{x/2}(C_I' - C_I'^*) \qquad [18]$$

and thus

$$C_I' - C_I'^* = \frac{a\gamma k^{x/2}}{\Omega k'}\left(\frac{dX}{dt}\right)^{1-x/2} \qquad [19]$$

Segregation of Excess Silicon at Si-SiO_2 Interface

Equation [19] gives the concentration of excess silicon interstitials in the oxide immediately adjacent to the silicon-oxide interface. During oxidation, silicon interstitials exist in both bulk oxide and silicon near the interface. Because of the different chemical potential of silicon atoms in the two phases, segregation of excess silicon atoms should result, leading to different concentrations at the respective sides of the interface (16). Since oxidation is a relatively slow process, the segregation is assumed to be near equilibrium and the interstitial concentrations are related by an equilibrium segregation m_I

$$m_I = \frac{C_I - C_I^*}{C_I' - C_I'^*} \qquad [20]$$

Combining Eq. [19] and [20], the concentration of extrinsic interstitials in bulk silicon near the Si-SiO_2 interface during oxidation is obtained as

$$C_I - C_I^* = \frac{a\gamma m_I k^{x/2}}{\Omega k'}\left(\frac{dX}{dt}\right)^{1-x/2} \qquad [21]$$

which is in the same form as Eq. [4]. In an earlier section, the value of n was obtained from experiments as 0.4, which gives a value of x equal to 1.2. Then

$$C_I - C_I^* = \frac{a\gamma m_I k^{0.6}}{\Omega k'}\left(\frac{dX}{dt}\right)^{0.4} \qquad [22]$$

and

$$C_I' - C_I'^* = \frac{a\gamma k^{0.6}}{\Omega k'}\left(\frac{dX}{dt}\right)^{0.4} \qquad [23]$$

SiO_x represents several different possible phases in the transition region between Si and SiO_2. The value of 1.2 determined here for x suggests that SiO is possibly the more dominant phase in this region.

Orientation dependence.—The growth of OSF depends strongly on the crystalline orientation of the silicon substrate surface. Under the same oxidation conditions, OSF grow more than two times faster in <100> than in <111> silicon (23). A significant decrease in OSF growth rate is also observed for off-axis orientation (39).

In Eq. [21] we expect the segregation coefficient, m_I, to vary with different orientations (16), in a way similar to impurity segregation at the Si-SiO_2 interface (40, 41) and thus be partly responsible for the orientation dependence of OSF growth. Indeed, the OSF data imply that $m_{<100>} > m_{<111>}$, which is the same as that of measured impurity segregation coefficient (40, 41).

Relation to Other Oxidation-Related Phenomena

The diffusion of commonly used impurities in silicon, *i.e.*, B, P, and As, is enhanced by oxidation (40, 42, 43). Oxidation-enhanced diffusion (OED) of impurities shows dependence on temperature (40, 42, 43), ambient (43), and orientation (40), similar to that of the OSF growth and is believed to be also caused by the supersaturation of silicon interstitials in bulk silicon. Assuming that the enhancement of impurity diffusivity is proportional to the interstitial supersaturation, in a separate paper (21), we demonstrate that the enhancement is directly related to oxidation rate in the manner expressed by Eq. [22]. The oxidation rate dependence of OED also explains the variation of OED in different ambients, temperatures, and times. The similar orientation dependence of OED and OSF further supports that both are caused by the same point defect mechanism.

The formation of oxide-fixed charges, Q_f, at the Si-SiO_2 interface during oxidation is mostly believed to be related to the excess unoxidized silicons in the bulk oxide (44). From Eq. [23], it is then expected that even at the same temperature, different Q_f will form in different oxidation conditions. Murarka (45) recently reported that different Q_f indeed result from oxidations at different oxygen partial pressures at the same temperatures (the higher the pressure, the larger the Q_f). This is in qualitative agreement with Eq. [23] which predicts higher concentration of interstitials in bulk oxide for oxidations with higher oxidation rates.

Conclusion

Thermal oxidation of silicon induces growth of stacking faults in silicon. A general relationship between OSF growth rate and oxidation rate has been developed which quantitatively explains the different growth and retrogrowth of oxidation stacking faults under various oxidation conditions, namely, temperature, time, ambient, and orientation.

The growth of oxidation stacking faults is caused by the supersaturation of silicon interstitials in bulk silicon during oxidation. The driving force for the genera-

tion of point defects at the Si-SiO_2 interface is thought to be the free volume requirement and interface mismatch. A model has been proposed for the point defect generation at the Si-SiO_2 interface in which oxidation is visualized as a two-step reaction involving generation, re-oxidation, and segregation of excess silicon. This point defect generation model forms the physical basis for the general relationship between OSF growth and oxidation rates.

The Oxidation Rate Dependence of Oxidation-Enhanced Diffusion of Boron and Phosphorus in Silicon

A. Miin-Ron Lin,*[,1] Dimitri A. Antoniadis,*[,2] and Robert W. Dutton

Integrated Circuits Laboratory, Stanford University, Stanford, California 94305

ABSTRACT

Oxidation-enhanced diffusion (OED) of boron and phosphorus has been found to vary with oxidation rate. The measurement technique uses a grating pattern of parallel nitride and oxide stripes on the silicon surface, which allows three different drive-in conditions to be achieved on the same wafer, namely, inert and oxidizing conditions with two different oxidation rates. Because of the close proximity of the profiles diffused under different conditions on the wafers, the relative change in the diffusivity of dopants could be accurately determined by means of spreading resistance measurements. The results show that impurity diffusion in oxidizing ambients is enhanced and the enhancement clearly depends on oxidation rates, the higher the rate, the larger the enhancement. Oxidation-enhanced diffusion is caused by the supersaturation of extrinsic point defects generated at the Si-SiO_2 interface during oxidation. The present work indicates that the supersaturation is directly related to oxidation rate by a sublinear power-law dependence, similar to that observed for the growth of oxidation-induced stacking faults. The oxidation rate dependence is used as a basis to formulate a general model which explains the variation of OED under different oxidation conditions, namely, temperature, time, ambient, and pressure.

It has been well established (1, 2) that diffusion of boron, phosphorus, and arsenic is enhanced during thermal oxidation of silicon. The oxidation-enhanced diffusion (OED) has been shown to depend on oxidation ambient (3) and temperature (1) as well as on orientation of the silicon substrate (1). It is generally accepted that thermal oxidation of silicon results in the generation of excess silicon point defects in the Si-SiO_2 interface during oxidation (4, 5). Some of these extrinsic point defects flow into the bulk silicon and supersaturate the point defect population there. Since substitutional impurities are known to diffuse by interactions with lattice point defects (6), the supersaturation results in the enhancement of impurity diffusivity.

Because the supersaturation of point defects is a direct result of oxidation, the level of supersaturation is expected to vary under different oxidation conditions, particularly with the rate of oxidation. In the present paper, we report experimental results on oxidation-enhanced diffusion of boron and phosphorus in dry oxygen ambient and demonstrate that OED of both impurities varies with oxidation rate. A quantitative model is presented that relates OED to the rate of oxidation by expressing the supersaturation point defects as a power law of oxidation rate.

The supersaturation of lattice point defects (self-interstitials) was originally suggested by Hu (4) as also causing the growth of oxidation stacking faults (OSF) in silicon during oxidation. The OSF growth shows dependence on oxidation ambient and temperature as well as substrate orientation (7), similar to that observed for OED. In a separate paper (8), we demonstrate that the OSF dependence can be explained by an oxidation rate dependence of point defect supersaturation, similar to that reported here.

Experiments

The starting materials for the experiments are p- and n-type 2 in. wafers of Czochralski <100>-oriented silicon with a resistivity of 10-20 Ω-cm. The wafers were oxidized in steam at 1000°C for 27 min to grow about 1900Å of oxide. Boron and phosphorus were implanted through the oxide into p- and n-type silicon wafers, respectively, to avoid the formation of the junctions. The dose for both impurities was low (6×10^{13} atoms/cm^2 at 60 keV for B and 8.5×10^{13} atoms/cm^2 at 160 keV for P) to avoid diffusion enhancement by high carrier concentration effects (9). The implanted wafers were annealed at 900°C for 30 min to activate the implanted dopants and 500Å of CVD silicon nitride was then deposited on the wafers at low temperature. Another layer of CVD oxide was used to pattern the nitride and oxide into parallel stripes (Fig. 1), which define three different regions repeated across the silicon wafer: (*i*) the first region labeled I with the nitride and oxide layers, (*ii*) the second region labeled II with only oxide, and (*iii*) the final region labeled III with the silicon surface directly exposed. Each of the three regions has a width of 500 μm and extends along the entire wafer. When the patterned wafers are thermally processed in dry oxygen ambient at high temperatures (900°-1200°C), the surface pattern allows three different drive-in conditions to be achieved on the same wafer. In region I, because of the nitride, the silicon surface is not oxidized and the impurities in the region diffuse under nonoxidizing conditions during the thermal process. In the other two regions, silicon is oxidized, but the rate is different because of the presence of the initial oxide in region II. The diffusion of impurities in both regions is enhanced, but by a different magnitude owing to the different oxidation rates. These different diffusivities result in different impurity profiles in the three regions on the same wafer.

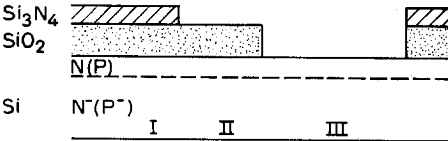

Fig. 1. The surface pattern of parallel nitride and oxide stripes that allows three different drive-in conditions on the same wafer; nonoxidizing in region I, and oxidizing in other regions with faster oxidation rate in region III. Each region has a width of 500 μm.

Key words: point defects, interstitialcy, spreading resistance.

The impurity profiles were characterized by means of spreading resistance measurements. Small samples (5 × 5 mm) were cut from the processed wafers and beveled on a block of 16 or 34 min angle so that the bevel edge was perpendicular to the surface stripes (Fig. 2). Because of the small stripe width, each bevel contains all three regions and thus the different impurity profiles are exposed side by side on the same bevel surface.

The probes used in the spreading resistance measurement have a small separation (25 μm) and thus the probe tracks can be located well within each stripe. The accurate control of both the lateral and transverse movement of the probes (better than 3 μm) allows one to match the three neighboring profiles measured on the same bevel surface to within 150-300Å, depending on the bevel angle. As a result, a small difference in the diffusion of impurities can be accurately determined. This measurement technique has been successfully used to study the OED of phosphorus and arsenic (2).

Figure 3 shows a series of measured spreading resistance profiles in phosphorus-implanted silicon. The profiles in the two oxidized regions (II and III) show different locations of the silicon surface which is expected, because different oxide thickness has been grown in the two regions. Also shown in the plots is the initial profile measured on a separate sample. The difference between the initial and diffused profiles indicates the extent of the impurity diffusion during the thermal oxidation. At all temperatures, both profiles in the oxidized regions (II and III) are farther apart from the profile in region I, clearly showing enhanced impurity diffusion in the oxidized regions. The data also indicate that the enhancement increases with decreasing temperature, consistent with the results of our previous works (1, 2).

At the two higher temperatures (1100° and 1200°C), the diffusion enhancement in the two oxidized regions is different, as evidenced from the different profiles in regions II and III. The difference becomes small at 1000°C and is almost nonexistent at 900°C. This follows closely the ratio of average oxidation rates in the two oxidized regions deduced in Table I from the ratio of the oxide thickness grown in these regions.

Analysis

Measured spreading resistance profiles have been analyzed by the process simulation program SUPREM (10) and a computer program (11) which converts impurity profiles into spreading resistance profiles. The advantage of comparing directly spreading resistance profiles instead of extracting impurity profiles is discussed elsewhere (2). The technique allows the accurate determination of very small differences in diffusivity. Figure 4 shows the comparison between measured and calculated spreading resistance for the initial and diffused phosphorus profiles at 1100° and 1200°C. Because of the effects of probe penetration and bevel edge rounding in spreading resistance measurements

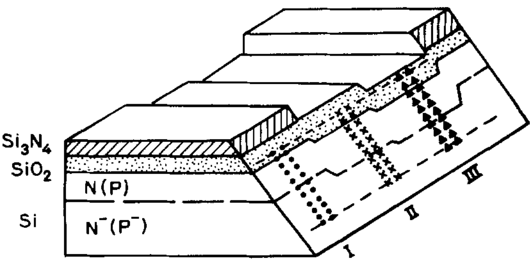

Fig. 2. The beveled spreading resistance measurement sample, which contains all three different regions. The close proximity of the profiles on the same bevel surface allows the relative depth of the neighboring profiles to be matched accurately.

Table I. The thickness of additional oxide grown during oxidation in oxidized regions II and III for phosphorus experiments

Ratio	1.33	1.79	2.47	4.99

* Region II has an initial oxide of thickness 1981A.

(12), the agreement near the tail and the surface of the profiles is rather poor. However, to determine the relative change in the impurity diffusivity, it is adequate to match the profiles within the resistance window, 1×10^4-$13 \times 10^4 \Omega$ shown in Fig. 4.

Table II lists the extracted diffusivities and the enhancement factors for boron and phosphorus in the three diffused regions for the processing temperatures, 900°-1200°C. The extracted diffusivities in region I agree well with the generally accepted low concentration (intrinsic) diffusivities in neutral ambients (13, 14). The diffusivity in the two oxidized regions (II and III) is enhanced with larger enhancement in region III where the oxidation rate was higher.

Since the same initial oxide thickness (~1900Å) was used in all experiments to achieve two different oxidation rates, the difference of oxidation rate in the two regions is small at low temperatures, where oxidation is dominated by linear growth, and increases at high temperatures where parabolic growth dominates. Results presented in Fig. 3 and Table II for the difference of impurity diffusivity in the two regions suggest that the oxidation-induced diffusion enhancement is related to the oxidation rate.

The diffusion enhancement during oxidation of silicon was originally explained by Hu (4) by a dual diffusion mechanism in which impurites are assumed to diffuse with vacancies and interstitials. Thus an increase in the concentration of either vacancies or interstitials would cause the enhancement of impurity diffusion. For the purpose of this paper we assume that the impurity diffusivity, D, is generally given by direct superposition of the two mechanisms. Then

$$D = D_{AV} + D_{AI} \quad [1]$$

where D_{AV} and D_{AI} are the vacancy and interstitialcy motivated impurity diffusivities. These are respectively related to the concentrations of vacancies, C_V, and self-interstitials, C_I, by

$$D_{AV} = d_{AV}C_V$$

$$D_{AI} = d_{AI}C_I \quad [2]$$

Denoting intrinsic values by "*," the proportionality factors, d, can be related to the intrinsic diffusivities and point defect concentrations by

$$d_{AV} = \frac{D_{AV}^*}{C_V^*}$$

$$d_{AI} = \frac{D_{AI}^*}{C_I^*} \quad [3]$$

The above equations are valid only if the intrinsic point defect concentration is nonzero. However, Eq. [2] are always valid.

During oxidation, the silicon self-interstitial concentration is supersaturated and impurity diffusion is enhanced via the interstitialcy mechanism by a magnitude proportional to the supersaturated interstitial concentration. Thus the total diffusivity of impurity during oxidation is simply

$$D = D^* + d_{AI}(C_I - C_I^*) \quad [4]$$

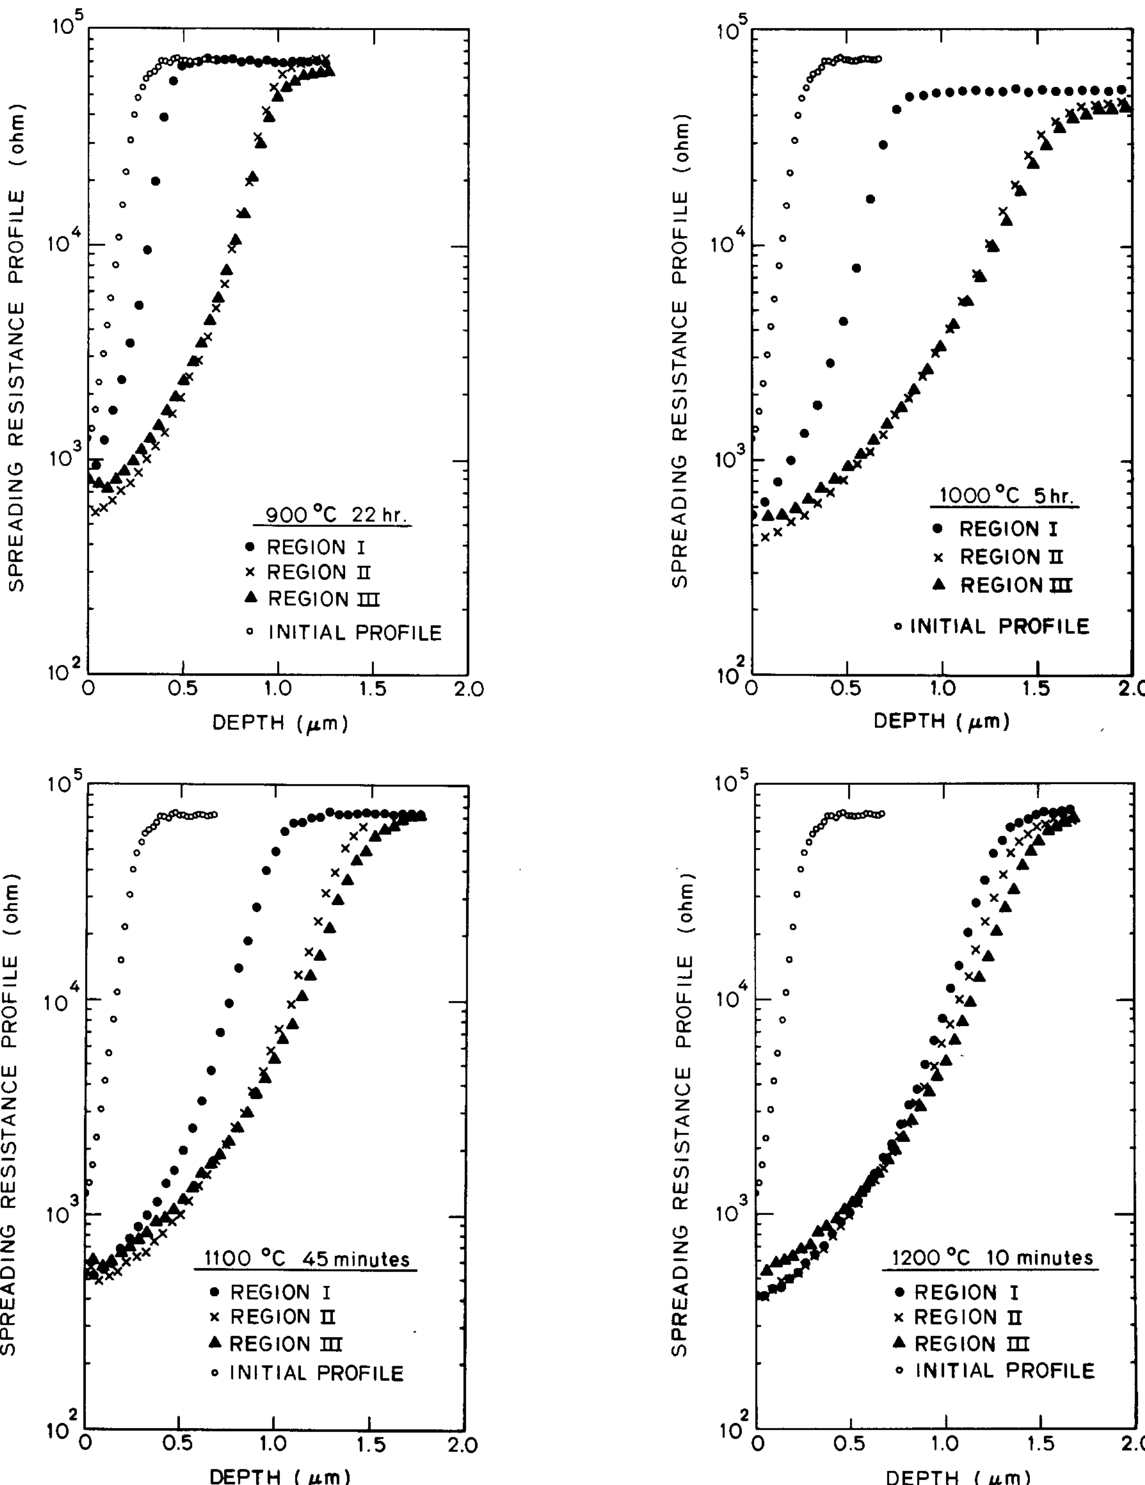

Fig. 3. The matched spreading resistance profiles of phosphorus in silicon at (a, upper left) 900°C, (b, upper right) 1000°C, (c, lower left) 1100°C, and (d, lower right) 1200°C, measured on the same beveled sample. The initial profile is measured on a separate sample. The depth resolution of the measurements is ~200Å. Only every other three measurement points are shown.

where D is the total diffusion coefficient, and $D^* = D_{AV}^* + D_{AI}^*$, is the intrinsic diffusivity in the neutral ambient.

In the absence of oxidation the interstitial concentration is probably low and the impurity diffusion is probably dominated by the vacancy mechanism. During oxidation excess silicon is produced at the Si-SiO_2 interface, part of which flows into the bulk silicon and raises the interstitial concentration above its equilibrium value, thus increasing the impurity diffusivity. The generation of the excess silicon at the interface is a result of the incompleteness of oxidation suggested by Hu (4), or of the free volume requirement and Si-SiO_2 interface mismatch suggested by Tiller (5). In both cases, the supersaturation of interstitials in silicon is related to the oxidation rate. The relation is assumed to be a power-law dependence of the form (15)

$$C_I - C_I^* = K\left(\frac{dX}{dt}\right)^n \quad [5]$$

where dX/dt is the rate of oxide growth, and the reaction constant, K, and the power exponent, n, are related to the point defect generation process at the Si-SiO_2 interface. Combining Eq. [4] and [5], one obtains

$$D = D^* + d_{AI}K\left(\frac{dX}{dt}\right)^n \quad [6]$$

for the impurity diffusivity during oxidation.

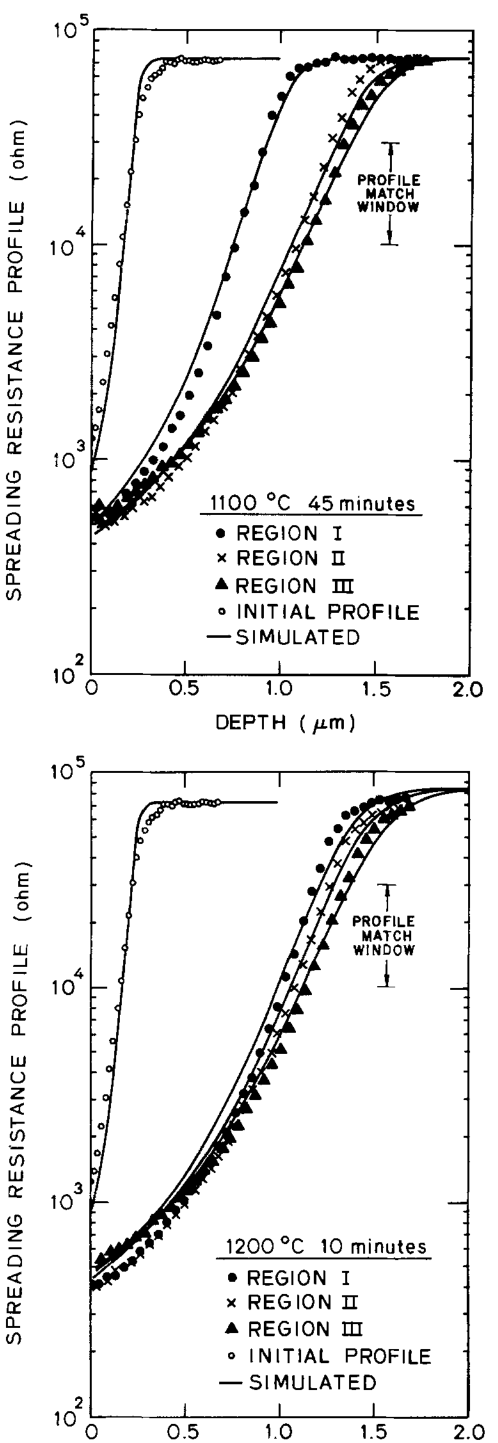

Fig. 4. The measured and calculated spreading resistance profiles of phosphorus-doped samples: (a) at 1100°C and (b) at 1200°C. The match between the measured and calculated spreading resistance profiles is emphasized within the resistance window, 1 × 10^4-3 × 10^4Ω (see text).

The above equation implies that generally D will be a function of time because dX/dt is time dependent. On the other hand, our experiments yield only an average diffusivity over the time of each experiment. However, as is shown in the Appendix, an average diffusivity, $<D> = 1/t \int_0^t D(\tau)d\tau$ produces exactly the same impurity profile as a time-varying $D(\tau)$ over the same time period, if $D(\tau)$ is independent of impurity concentration. Thus, the extracted diffusivities can be related to the oxidation rate by

$$\frac{<D>}{D^*} - 1 = \frac{d_{AI}K}{D^*t} \int_0^t \left(\frac{dX}{d\tau}\right)^n d\tau \qquad [7]$$

Assuming that the growth of oxide can be described by the Deal-Grove equation (16)

$$X^2 - X_o^2 + A(X - X_o) = Bt \qquad [8]$$

where X_o is the initial oxide thickness, and B and B/A are the parabolic and linear growth rates, Eq. [7] gives

$$\frac{<D>}{D^*} - 1 = \frac{d_{AI}K}{D^*t} \frac{B^{n-1}}{2(2-n)} [(2X + A)^{2-n} - (2X_o + A)^{2-n}] \qquad [9]$$

We define the diffusion enhancement ratio, DER, between regions III and II by

$$DER \stackrel{\Delta}{=} \left(\frac{<D>}{D^*} - 1\right)_{III} \Big/ \left(\frac{<D>}{D^*} - 1\right)_{II} \qquad [10]$$

Then using Eq. [9] and [10] we obtain

$$DER = \frac{(2X_{III} + A)^{2-n} - A^{2-n}}{(2X_{II} + A)^{2-n} - (2X_o + A)^{2-n}} \qquad [11]$$

where X_{III} and X_{II} are the final thicknesses in regions III and II. Comparison of Eq. [7] with the experimental results in Fig. 5 gives values of n between 0.4 and 0.6. Although the data in Fig. 5 are considerably scattered and do not allow accurate determination of n, the key fact that the value of n is less than 1 is easily deduced.

Recently, Tsukamoto *et al.* (17) reported that if the same thickness of oxide is to be grown at a given temperature, high pressure steam oxidation results in a much shorter impurity diffusion length than atmospheric pressure. At 950°C, one of the temperatures used in their experiments, the total diffusion enhancement can be estimated from our work to be larger than 4 and the diffusion is thus dominated by the extrinsic diffusion component. At high pressure the oxidation rate increases and the time needed to grow the same amount of oxide is reduced. But following Eq. [7], we expect the diffusion enhancement to increase also. If the diffusion enhancement was linearly proportional to the oxidation rate, instead of exhibiting sublinear dependence found in the present work, the increase in diffusion enhancement at high pressure would be the same as the reduction in oxidation time. Hence, the resultant impurity diffusion length would be almost independent of the pressure used. The fact that the impurity diffusion length is significantly reduced in higher pressure oxidation fur-

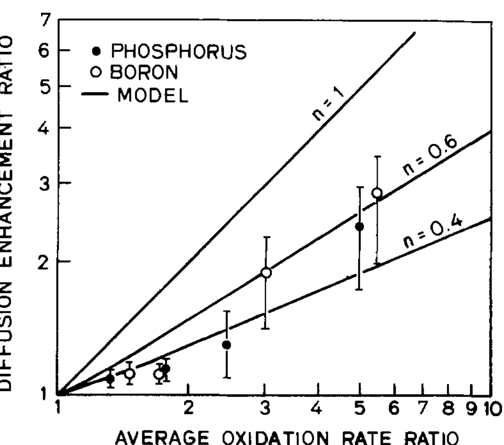

Fig. 5. The correlation between diffusion enhancements and average oxidation rates. The average oxidation rate is defined as the oxide thickness grown divided by the oxidation time.

* The data in parentheses are the diffusion enhancement factors, $<D>/D^*$.

ther supports the generality of the sublinear dependence found here.

Discussion

The growth of stacking faults during oxidation varies under different oxidation conditions, namely, temperature, time, ambient, and substrate orientation (18), in a manner similar to that observed for oxidation-enhanced diffusion. This strongly supports the hypothesis that both phenomena are caused by the same point defect mechanism (4, 19, 20). The OSF growth rate is proportional to the capture rate of interstitials, which is determined by the excess interstitial concentration in the bulk silicon during oxidation. We have demonstrated (8) that the variation of OSF growth under different oxidation conditions can be explained by a dependence of interstitial supersaturation on oxidation rate of the same form as Eq. [5] with the power exponent, $n = 0.4$, which is consistent with the value of n obtained from diffusion enhancements in Fig. 5. This provides another strong indication of the close correlation between stacking fault growth and oxidation-enhanced diffusion. The value of n, 0.4, is obtained from experimental data of OSF growth in a wide range of oxidation conditions (8) and will be used to represent oxidation rate dependence of OED for further discussion.

Using $n = 0.4$, the diffusion enhancement, $<D>/D^* - 1$, in Eq. [7] becomes

$$\frac{<D>}{D^*} - 1 = \frac{d_{AI}K}{D^*t} \int_0^t \left(\frac{dX}{d\tau} \right)^{0.4} d\tau \quad [12]$$

The oxidation rate decreases as oxidation time increases. It is thus expected from Eq. [12] that the diffusion enhancement will also decrease with oxidation time. Using the Deal-Grove oxidation equation (16) and assuming no initial oxide, Eq. [12] can be expressed as

$$\frac{<D>}{D^*} - 1 = G_E F(t) \quad [13]$$

$$G_E = \frac{d_{AI}K}{D^*} \left(\frac{B}{A} \right)^{0.4} \quad [13a]$$

$$F(t) = \frac{A^2}{3.2Bt} \left\{ \left(1 + \frac{4Bt}{A^2} \right)^{0.8} - 1 \right\} \quad [13b]$$

Here G_E represents the maximum diffusion enhancement and $F(t)$ expresses the reduction with time.

$F(t)$ is plotted in Fig. 6 to show the sensitivity of diffusion enhancement to oxidation time at different temperatures. From the figure, the reduction of diffusion enhancement for the oxidation times used in the experiments are to 88%, 74%, 68%, and 66% for temperatures, 900°, 1000°, 1100°, and 1200°C, respectively. The maximum enhancement factor G_E can then be determined by dividing the measured enhancement by the reduction factor. The results are shown in Fig. 7 which indicates essentially the same OED for boron and phosphorus, suggesting a similar diffusion mechanism for both impurities. The data also indicate a negative activation energy of ~ -1.2 eV, which suggests a continuous increase of diffusion enhancement at low oxidation temperatures. As the trend of integrated circuit technology is toward lower processing temperatures, oxidation-enhanced diffusion should continue to play an important role in impurity profile control.

An implication of the oxidation rate dependence of diffusion enhancement is that oxidation ambients having different oxidation rates result in different diffusion enhancements. For example, oxidation in wet and steam ambients is faster than in dry oxygen ambient and thus impurity diffusion is expected to be enhanced more in those ambients. On the other hand, in partial oxygen pressure ambients, the oxidation rate is reduced and diffusion enhancement should decrease accordingly. The ambient dependence of OED has been experimentally observed (3, 21) with the results in qualitative agreement with Eq. [12]. Detailed quantitative comparisons cannot be made at present, pending more comprehensive experimental data. On the other

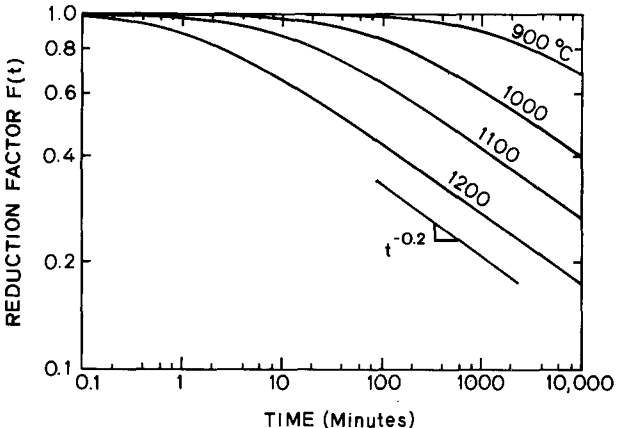

Fig. 6. The reduction factor $F(t)$ is calculated as a function of oxidation time. Oxidations used in the calculations start without initial oxide.

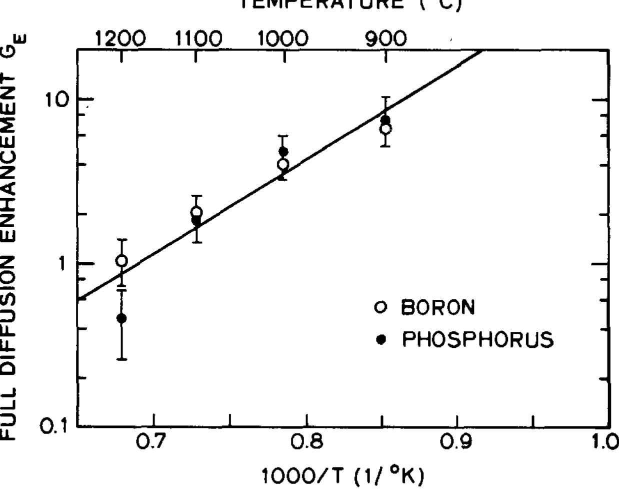

Fig. 7. The maximum diffusion enhancement factors G_E for boron and phosphorus at different oxidation temperatures.

hand, it has been demonstrated (8) that the sublinear oxidation rate dependence quantitatively explains the growth of OSF in a wide range of oxidation conditions. Thus, since oxidation-enhanced diffusion is closely related to OSF growth by the same point defect mechanism, we expect Eq. [5] and hence Eq. [12] to also largely explain the OED under different oxidation conditions.

An Example of Application

Today's integrated circuit technology is very much into VLSI (very large scale integration) where the lateral device dimensions are rapidly approaching micro- or submicrometer range. In order to optimize devices, the vertical dimensions need to be scaled accordingly. The vertical dimensions are, in most cases, dominated by impurity diffusion. This is particularly true in the formation of the oxide isolation commonly used in both the MOS and bipolar technologies, where long oxidations are used to produce sufficient oxide thickness to separate the active devices. These oxidations are increasingly done at low temperatures and high pressures to minimize the impurity diffusion. At these conditions, the oxidation-enhanced diffusion is clearly important.

Consider a case where 5000Å of oxide is to be grown. Equation [6] is used to calculate the impurity diffusion length, $2\sqrt{Dt}$, when the oxide is grown in dry oxygen, steam, or high pressure steam where the oxidation rate is further increased by a factor of 6, at different temperatures. The results plotted in Fig. 8 clearly show the reduction of impurity diffusion length in the two fast oxidizing steam ambients. Also shown in the figure is the diffusion length calculated with only intrinsic diffusivity. At high temperatures (>1100°C), the diffusion length is dominated by intrinsic diffusion and the reduction in diffusion length in the two steam ambients is mainly due to reduction in oxidation time. At low temperatures (<1000°C), however, extrinsic diffusion dominates and the reduction results from the sublinear oxidation rate dependence of the diffusion enhancement. It is important to also note in Fig. 8 that the reduction of the diffusion length toward decreasing temperatures is only gradual at low temperatures as compared to the rapid decrease when only intrinsic diffusion is considered. This is a result of the negative activation energy of oxidation-enhanced diffusion and emphasizes the importance of OED in impurity profile control at these temperatures.

Conclusion

The diffusion of ion-implanted boron and phosphorus in near-intrinsic <100> silicon has been studied experimentally in nonoxidizing and oxidizing conditions. The measurement technique uses a grating pattern of parallel nitride and oxide stripes on the silicon surface which allows three different diffusion conditions (inert and oxidizing with two different oxidation rates) to be achieved on the same wafer. Because of the close proximity of impurity profiles diffused under different conditions on the same wafer, the small relative change of impurity diffusivity was accurately determined by means of spreading resistance measurements. Results indicate that impurity diffusion is enhanced by oxidation and the enhancement is directly related to oxidation rate with higher enhancements at higher oxidation rates. The diffusion enhancement has a negative activation energy and consequently slows down the reduction of impurity diffusion length at low temperature processing.

Oxidation-enhanced diffusion is caused by supersaturation of lattice point defects during oxidation. The present work indicates that the point defect supersaturation depends on oxidation rate. The dependence is approximated by a power-law relation with an exponent ranging between 0.4 and 0.6 which is consistent with the oxidation rate dependence of the growth of oxidation stacking faults. The sublinear oxidation rate dependence of the diffusion enhancement explains the reduction of impurity diffusion length when growing the oxide in high pressure steam oxidation at low temperatures. It is also in qualitative agreement with the dependence of oxidation-enhanced diffusion in wet oxidation and reduced oxygen pressure oxidations, observed elsewhere (21).

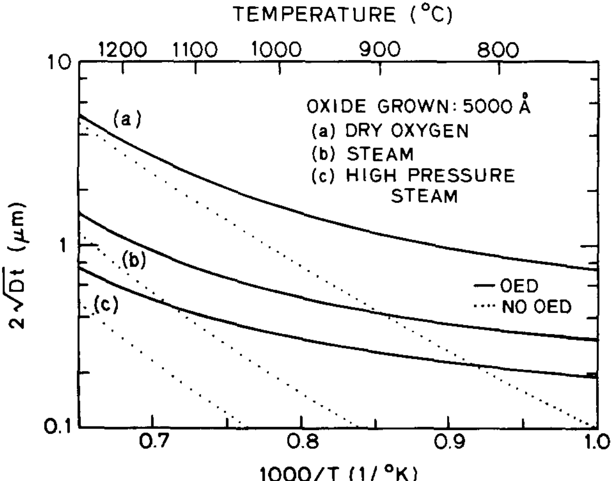

Fig. 8. Boron diffusion length during oxidation to grow 5000Å of oxide in dry oxygen, steam, or high pressure steom ambients at different temperatures.

APPENDIX

In the present experiments, the impurity concentration is kept below the intrinsic carrier concentration at the processing temperatures. The impurity diffusivity is thus independent of concentration and the impurity diffusion equation is

$$\frac{\partial C(x,t)}{\partial t} = D(t)\frac{\partial^2 C(x,t)}{\partial x^2} \quad \text{[A-1]}$$

with boundary conditions

$$\left.\frac{\partial C}{\partial x}\right|_{x=0} = 0 \quad \text{for neutral ambient drive-in [A-2]}$$

or

$$D\left.\frac{\partial C}{\partial x}\right|_{x=0} = \left(\frac{1}{m} - \alpha\right)\frac{dX}{dt}$$

for oxidizing ambient drive-in [A-3]

where $C(x,t)$ is the impurity concentration, m the segregation coefficient, and α the ratio of the consumed silicon to the thickness of oxide grown. dX/dt is the oxide growth rate.

Since D is a function of t only, by changing the variable t to $t' = \int_0^t D(t)dt$, the above equations are simplified to

$$\frac{\partial C(x,t')}{\partial t'} = \frac{\partial^2 C(x,t')}{\partial x^2} \quad [A\text{-}4]$$

with

$$\left.\frac{\partial C}{\partial x}\right|_{x=0} = 0 \quad [A\text{-}5]$$

or

$$\left.\frac{\partial C}{\partial x}\right|_{x=0} = \left(\frac{1}{m} - \alpha\right)\frac{dX}{dt'} \quad [A\text{-}6]$$

The solution to the above equations is a function of x and t' only. Hence the concentration, C, at a given x is determined by the value of $t' = \int_0^t D(\tau)d\tau$ and is independent of the detailed form of $D(\tau)$. In other words, a constant diffusivity, $\langle D\rangle = 1/t \int_0^t D(\tau)d\tau$ will produce exactly the same profile as the time-varying $D(\tau)$ over the same time period.

An Efficient Integration Technique for Use in the Multilayer Analysis of Spreading Resistance Profiles

H. L. Berkowitz* and R. A. Lux

U.S. Army Electronics Technology and Devices Laboratory, ERADCOM, Fort Monmouth, New Jersey 07703

ABSTRACT

The efficiency of multilayer analysis in calculating resistivity profiles from spreading resistance measurements depends on the rapid numerical evaluation of the well-known correction factor integral first introduced by Schumann and Gardner. We present a new approximate form for the correction factor which allows its numerical evaluation with only 22 integrand values for each evaluation of the integral. When this technique is used in our multilayer analysis program, we unfold spreading resistance profiles at the real time rate of less than 3 sec/point on a desktop computer. Its results match those of analytic evaluations of special two layer cases or with more elaborate numerical evaluations of graded structures to within 1%.

Two-probe spreading resistance measurement has become a widely used technique for determining impurity profiles in semiconductors (1-4). The conductivity of the material contacted by the probes is given by

$$R = C/(2a\sigma) \quad [1]$$

where R is the measured spreading resistance, a is the contact radius, and C is a correction factor which is a function of the conductivity profile of the material. The multilayer analysis technique of evaluating this correction factor was originally proposed by Shumann and Gardner (1) and later developed in more easily calculated forms (2-4); complete derivations are given in Ref. (2, 3). In this technique the correction factor is

$$C = \frac{8}{I}\int_0^\infty dx\left[\frac{J_1(x)}{x} - \frac{J_0(Dx)}{2}\right]\underline{I}(x)F(tx) \quad [2]$$

I is the total current flowing between the probes, where J_1 and J_0 are Bessel functions of the first kind, D and t are, respectively, the probe separation and layer thickness measured in probe radii, F (sometimes denoted by $1 + 2\theta$) is a function of all conductivities deeper than the contacted layer, and $\underline{I}(x)$ is the Hankel transform of the normal component of the current density $I(r)$ at a probe. F can be expressed by a recursion relation

$$F_{i+1} = \frac{F_i\sigma_{i+1} + \sigma_i\tanh(tx)}{\sigma_i + F_i\sigma_{i+1}\tanh(tx)} \quad [3]$$

which is equivalent to a form given by Choo (3). $\underline{I}(x)$ is given by

* Electrochemical Society Active Member.

Key words: resistivity profiles, spreading resistance measurements.

$$\underline{I}(x) = \int_0^a J_0(xr/a)I(r)rdr$$

Two forms of $\underline{I}(x)$ are found in the literature

$$\underline{I}(x) = \frac{I\sin(x)}{2\pi x} \quad [4]$$

which was first used by Shumann and Gardner (1) and

$$\underline{I}(x) = \frac{IJ_1(x)}{\pi x} \quad [5]$$

which was suggested by Severin (5) and used by Choo (6); the latter is used in the remainder of this paper. A complete discussion of the consequences of using either form is given in Ref. (7).

The calculation of a conductivity profile from a set of measured spreading resistances proceeds as follows. Starting at the deepest point, the value of the conductivity (and the resulting correction factor) is adjusted until the calculated spreading resistance agrees with the measured spreading resistance to the required accuracy. When this is achieved, the process is repeated at the next point, continuing until the entire set of measurements has been exhausted. The trial conductivity enters the calculation of the correction factor only through the function F. Hence during a numerical evaluation of C only the function F need be recalculated, the remainder of the integrand in Eq. [2] having been calculated once and stored as a numerical array.

Because the multilayer analysis scheme may require several evaluations of the correction factor per point an efficient technique for its evaluation is desirable. In this paper we introduce an approximation to the correction factor integral which can be evaluated rapidly. We then develop a numerical method which evaluates the approximate integral by sampling the integrand at only 22 points. We then compare this method with an analytic evaluation for special cases and with other numerical methods for a full multilayer case.

Approximation of the Correction Factor

The correction factor integral in Eq. [2] contains a term proportional to $J_0(Dx)/2$ which describes the voltage reduction at one probe due to the other probe. On physical grounds its effect can be significant only when the conductivity of the contacted layer is very high or when the spacing between probes is small, for which case Choo (3) showed that the primary effect of the J_0 term is to assure that the integrand vanishes at $x = 0$, even when F is singular at the origin.

In this section we show that it is possible to approximate the correction factor integral by an integral without a J_0 term by integrating from a nonzero lower limit

$$C_a = \frac{8}{\pi}\int_L^\infty dx\left(\frac{J_1(x)}{x}\right)^2 F(tx) \quad [6]$$

where L is given by

$$L = 2e^{-\gamma}/D \quad [7]$$

Here γ is Euler's constant, 0.577.... We demonstrate this by direct calculation of C and C_a in three cases which are amenable to analytic methods, namely (a) a conducting layer over an insulating substrate, (b) a conducting layer over a perfect conductor, and (c) a uniform semi-infinite slab. The appropriate forms of F are, respectively

$$F_A = \coth(tx), \quad F_B = \tanh(tx), \quad F_C = 1$$

For any multilayer case F must be within the envelope $\coth(tx)$ and $\tanh(tx)$. The test cases therefore represent the extreme cases and one intermediate case.

For thin conducting layers (*i.e.*, in the limit $t \to 0$), the first two forms can be approximated by

$$F_A = 1/(tx), \quad F_B = tx$$

allowing the integral in Eq. [2] to be evaluated analytically. For case (a) the function F_A has a pole at $x = 0$; the lower limit L is chosen so as to minimize the difference between C and C_a for this case. Equation [2] written as

$$C = \frac{8}{\pi t}\lim_{\epsilon\to 0}\int_0^\infty \frac{J_1(x)}{x}\left[\frac{J_1(x)}{x} - \frac{J_0(Dx)}{2}\right]\frac{dx}{x^{1-\epsilon}}$$

a special case of the Weber Schafheitlin integral (8), yields

$$C = \frac{2}{\pi t}(\ln(D) + 1/4) \quad [8]$$

The corresponding value of C_a is obtained by evaluating Eq. [6]

$$C_a = \frac{8}{\pi t}\lim_{\epsilon\to 0}\left[\int_0^\infty \frac{J_1^2(x)}{x^{3-\epsilon}}dx - \int_0^L \frac{J_1^2(x)}{x^{3-\epsilon}}dx\right]$$

which yields

$$C_a = \frac{2}{\pi t}[\ln(2e^{-\gamma}/L) + 1/4 + L^2/8\ldots] \quad [9]$$

where γ is Euler's constant, 0.577....

With L set at

$$2e^{-\gamma}/D = 1.12292/D$$

the fractional difference between C and C_a in this case is minimized; its magnitude can be estimated by evaluating the term of order L^2, namely

$$\frac{C - C_a}{C} \approx 0.14/((\ln D + 0.25)D^2) \quad [10]$$

Using this value of L, both C and C_a were evaluated for cases (b) and (c); results are shown in Table I. These three cases represent very different physical situations. The fact that the errors introduced by using C_a rather than C are smaller than 1% when D is greater than 10 suggests that the approximation is generally useful: in most probe arrangements D is greater than 30. The numerical procedure for evaluating C_a is much simpler than that necessary to evaluate C. The latter involves calculating the integrand at enough points to follow the rapid oscillations of the function $J_0(Dx)$. For example, when D is equal to 30, $J_0(Dx)$ has more than 30 zeros at values less than the first zero of $J_1(x)$.

The Numerical Integrator

In this section we describe a numerical integrator which has been tailored to take advantage of the properties of the integrand of [6] in order to minimize the required evaluations of F.

Our objective is to choose a set of numbers x_i and weights w_i such that C_a can be well represented by a numerical approximation.

$$C_n = \Sigma\, w_i F(tx_i) \quad [11]$$

The appropriate numerical integration technique was selected so as to accommodate the most singular case, $F = \coth(tx)$ taking care that other cases were treated with sufficient accuracy.

Based on properties of $(J_1/x)^2$, we divide the domain of integration into four regions

(A) $L \leq x \leq 0.1$

(B) $0.1 \leq x \leq 1$

(C) $1 \leq x \leq j_{1,1}$

(D) $j_{1,1} < x$

where $j_{1,i}$ is the ith zero of the Bessel function J_1 and $j_{1,0} = 0$, $j_{1,1} = 3.83171$. In cases of practical significance

Table I. Functional forms of correction factors with $L = 1.12292/D$

F	C	C_a	$\lvert 1 - C_a/C \rvert$
$1/xt$	$\frac{2}{\pi t}(\ln D + 0.25)$	$\frac{2}{\pi t}\left(\ln D + 0.25 + \frac{L^2}{8} + \ldots\right)$	$\frac{0.14}{D^2(\ln D + 0.25)}$
1	$\frac{8}{\pi}\left(\frac{4}{3\pi} - \frac{1}{4D}\left(1 + \frac{1}{8D^2} + \ldots\right)\right)$	$\frac{8}{\pi}\left(\frac{4}{3\pi} - \frac{L}{4}\right)$	$0.072/D$
xt	$4t/\pi$	$t(4 - L^2)/\pi$	$0.03/D^3$

L is restricted to the domain $0.001 \le L \le 0.1$. In each region we choose a numerical integrator which will assure adequate convergence of the integrals.

In region (A) we replace $(J_1/x)^2$ by 1/4. In this region the most difficult integrand that can arise will be proportional to coth (tx), which approaches $1/(tx)$ for small x. To treat the pole at $x = 0$, we choose $\ln x$ to be the integration variable; this segment of C_a is then

$$\frac{8}{\pi}\int_{x=L}^{x=0.1} \frac{x}{4} F(tx)\,d(\ln x)$$

We then apply a nine point Newton-Cotes integrator to the integrand. The nine points, equally spaced in $\ln x$, are given by

$$x_i = L\,(0.1/L)^{(i/8)}, \quad 0 \le i \le 8$$

This segment of C_n is

$$\frac{1}{4\pi}\ln(0.1/L)\sum_{0}^{8} w_{9,i}x_i F(tx_i) \qquad [12]$$

The weights $w_{9,i}$ for a nine point Newton-Cotes integrator are given in Ref. (9).

In region (B) the slowly varying $(J_1/x)^2$ is explicitly calculated. Again the most difficult integrand is proportional to $1/(tx)$, and we make the same transformation as in region (A). To achieve the same density of points in (B) as in (A), with $L = 0.001$, we use a five-point Newton-Cotes integration formula. This segment of C_n is then

$$\frac{2}{\pi}\ln(10)\sum_{0}^{4} J_1^2(x_i)F(x_i)\,w_{5,i}/x_i \qquad [13]$$

The weights $w_{5,i}$ are given in Ref. (9) and $x_i = 0.1(10)^{(i/4)}$.

In region (C), $(J_1/x)^2$ is falling rapidly; a five-point Newton-Cotes integrator in x rather than $\ln x$ provides adequate coverage. This segment of C_n is

$$\frac{2}{\pi}(j_{1,1} - 1)\sum_{0}^{3} (J_1(x_i)/x_i)^2 F(x_i) w_{5,i} \qquad [14]$$

Only four of the five points need be calculated, as $J_1(j_{1,1})$ is by definition zero.

In region (D), the rapid decrease in $(J_1/x)^2$ guarantees that the integral beyond the first zero, $j_{1,1}$, will make only a small contribution to the correction factor.

Using the mean value theorem

$$\int_{x=a}^{x=b} F(x)\,du(x) = F(\xi)\,(u(b) - u(a)) \qquad [15]$$

where $a \le \xi \le b$ and $du = (J_1/x)^2dx$, we approximate the integral between successive zeros of J_1 by choosing ξ to be the centroid of $(J_1/x)^2$ between zeros

$$\xi = \frac{\int_a^b J_1^2(x)\,dx/x}{\int_a^b (J_1(x)/x)^2dx} \qquad [16]$$

The approximation is exact if F varies at most linearly with x. We took five subintervals between successive zeros of J_1 to $j_{1,6}$, $x = 19.616$, and found that the integral truncated at this point was adequate for most integrands. [Albers (10) truncates at $x = 20$ and Choo (6) truncates at $x = 20.8$.] However, in cases where F is small in region (A) (for example when $F =$ tanh (tx)), an error of as much as 4% can be made due to this truncation. By using one additional point at the centroid of $(J_1/x)^2$ taken between 19.616 and infinity, this error can be reduced to below 1%.

This segment of C_n is then

$$\frac{8}{\pi}\Sigma\, w_{D,i}\, F(\xi_i) \qquad [17]$$

where the weights $w_{D,i}$ and ξ_i are shown in Table II. As the points at the region boundaries need be calculated only once, the complete integration requires only 22 evaluations of F.

Testing Procedures

The integration technique has been tested in the range $0.001 \le t \le 1$ and $10 \le D \le 1000$ for two layer cases where analytic results can be obtained and for representative multilayer distributions. We present the results of the two layer calculation and a sample multilayer case.

Test 1.—In the first test we compared C_n calculated using the 22 point integrator with C_a calculated analytically in the section Approximation of the Correction Factor.

$F(x)$ is replaced by tx, 1, and $1/(tx)$ in the cases now under consideration.

We evaluated C_n at 12 values of D between $D = 10$ and $D = 1000$ and list the maximum deviations in Table III. Maximum errors were found on comparing C with C_a and C_a with C_n. In all cases the maximum error occurs at $D = 10$.

In all cases we find agreement between the approximation and the numerical integrator to be better than 0.3%.

Table II. Centroids and weights used in region (D)

i	$a = j_{1,i}$	$b = j_{1,i+1}$	Centroid ξ_i	Weight $w_{D,i}$
1	3.83171	7.01558	5.23853	0.688546E-2

5	16.4706	19.6159	17.9861	0.173318E-3
6	19.6159	∞	39.3	0.4119E-3

Table III. Maximum deviations

F	$\frac{\lvert C - C_a \rvert}{C}$	$\frac{\lvert C_a - C_n \rvert}{C_a}$
tx	0.003	0.002
1	0.007	0.0008
$1/tx$	0.0006	0.0009

Test 2.—To measure the performance of our 22 point integrator for cases where analytic techniques were unavailable we constructed a Simpson integrator of 1597 points constructed as shown in Table IV.

This integrator was programmed in three versions to accommodate the various tests needed:

SIM which numerically integrates

$$\text{SIM} = \frac{8}{\pi}\int_0^{20}\left(\frac{J_1(x)}{x} - \frac{J_0(Dx)}{2}\right)\frac{J_1(x)}{x}F\,dx$$

SIMSG which evaluates the Schumann and Gardner correction factor

$$\text{SIMSG} = \frac{4}{\pi}\int_0^{20}\left(\frac{J_1(x)}{x} - \frac{J_0(Dx)}{2}\right)\frac{\sin(x)}{x}F\,dx$$

SIMT which corrects SIM for truncation error as described in the section The Numerical Integrator.

Truncating the integral at $x = 20$ allows us to compare our results with those of Albers (10), who generated spreading resistance data (*MD* in Table V) from model resistivity profiles by using the integration scheme of D'Avanzo *et al.* (4) over the interval $0 \leq x \leq 20$. Table V and Fig. 1 show one such data set calculated to represent the conductivity profile of a silicon wafer containing a Gaussian implant. Simulated spreading resistances were calculated from these conductivities for the case $a = 2$ μm, $D = 25$, $t = 0.015$ using SIMSG. We compared these to the set of resistances supplied by Albers. The largest fractional deviation found between the two data sets was less than 2 parts in 10^4. Spreading resistances were then calculated for the same data using the 22 point integrator, SIM, and SIMT. We find that agreement between the 22 point integrator and SIMT to be better than 5 parts in 10^3. This represents the total deviation between C and C_n for this case. A comparison between SIM and SIMT results indicate that the maximum relative deviation due to truncating at $x = 20$ for this case is about 2%.

Table IV. The 1597 point integrator

x, min.	x, max	Weights	Number of points
0	0.001	Trapezoidal	2
0.01	0.01	Simpson	199
0.01	0.1	Simpson	199
0.1	1	Simpson	199
1	20	Simpson	999

Table V. Summary of results calculating resistance as a function of depth in a layered medium using the various integrators mentioned in text. All calculations are based on the conductivity profile plotted in Fig. 1 and excerpted in this table for the case $a = 2$ μm, $D = 25$, $t = 0.015$.

The Gauss Laguerre Integrator

To demonstrate the value of the lower limit cutoff approximation, we repeated the tests performed on the 22 point integrator using another sparse point numerical integrator the Gauss Laguerre integrator (GL in Table V) of Choo *et al.* (11). This integrator retains the term in $J_0(Dx)$.

In Fig. 2 we plot the fractional deviation between C and the Gauss Laguerre integrated correction factors in the cases of the section Testing Procedures, Test 1.

We find that the deviations for these cases tend to cluster in a band of ± 5% with occasional excursions to 10% or 20%. This is due principally to the fact that for D greater than 10, $J_0(Dx)$ has more than 60 zeros in the interval of $0 \leq x \leq 20$. The 33 points used for the GL integrator cannot hope to cover it adequately.

Discussion and Conclusions

We have presented a new approximate form for the correction factor integral of Schumann and Gardner which facilitates the rapid and accurate evaluation of

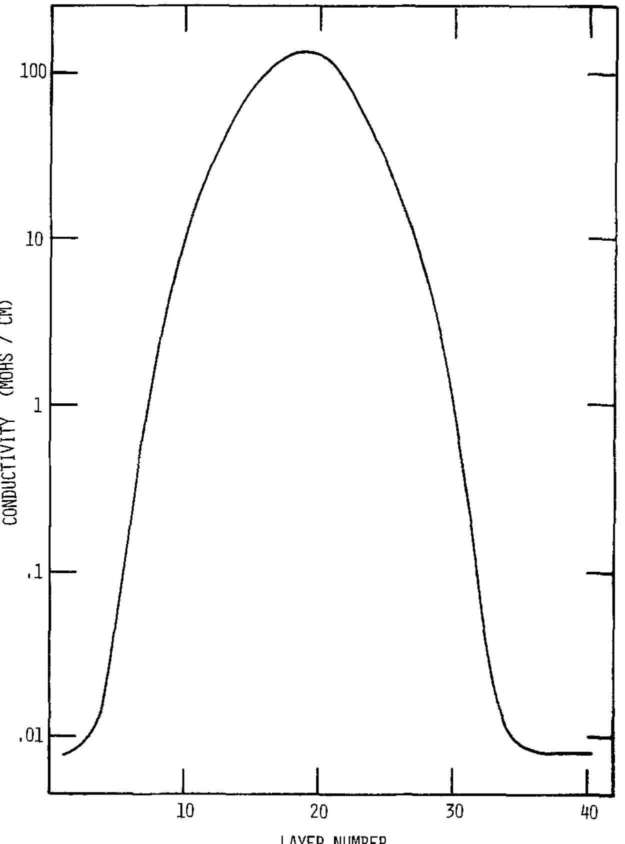

Fig. 1. Displays data supplied to us by Albers (10)

Fig. 1A. Plot of conductivity vs. depth for a model Gaussian implant.

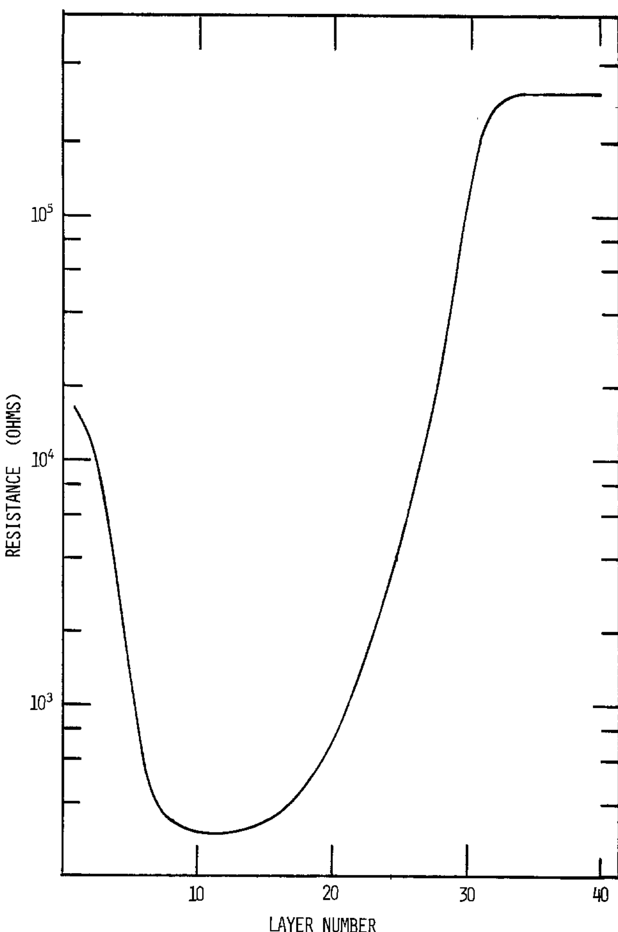

Fig. 1B. Plot of spreading vs. depth calculated by Albers using the integration scheme of D'Avanzo (4). The set shown here was calculated for $a = 2$ μm, $D = 25$, $t = 0.015$.

spreading resistance correction factors. This has been accomplished by eliminating the rapidly varying $J_0(Dx)$ term from the usual correction factor integral, Eq. [2].

Although we have presented the approximate integral of Eq. [2] only for $\underline{I}(x)$ satisfying

$$\underline{I}(x) = \frac{IJ_1(x)}{\pi x}$$

the approximation remains valid with the lower limit, L, given by Eq. [7] for all current density profiles whose Hankel transform satisfies Eq. [4b] of (5)

$$\underline{I}(x) = \frac{I\,\Gamma(\nu+1)J_\nu(x)}{2\pi(x/2)^\nu}$$

All of the commonly used forms of $\underline{I}(x)$ are special cases of the above.

The integrator of the section The Numerical Integrator was incorporated into a multilayer analysis program described elsewhere (12). The program was written in BASIC for an HP system 9845. The time to

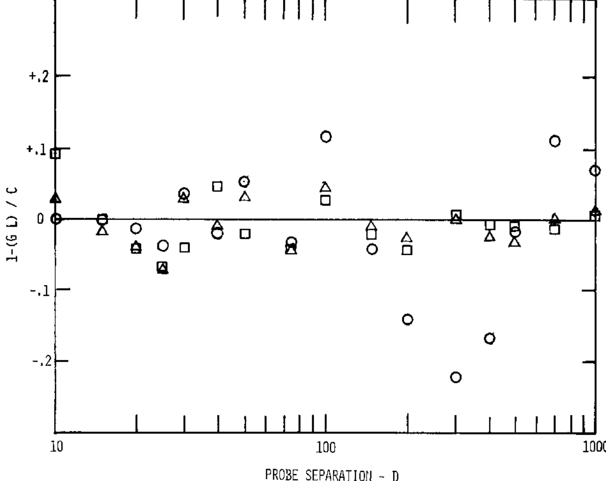

Fig. 2. Correction factors, GL, were calculated using the Gauss Laguerre integrator (11) for the Shumann and Gardner function, F, replaced by tx, 1, $1/tx$ and $10 \leq D \leq 1000$. Figure 2 shows a plot of the fractional deviation of GL from the analytically calculated correction factors, C of Table I. The squares, triangles, and circles refer to cases where F is set equal to tx, 1, $1/(tx)$, respectively.

calculate one point was generally less than 3 sec. As the time to measure a spreading resistance on modern equipment (*e.g.*, an ASR-100 probe) is about 6 sec the complete conductivity profile can be corrected as measurements are made.

Manuscript submitted April 14, 1980; revised manuscript received Nov. 6, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by the U.S. Army Electronics Technology and Devices Laboratory (ERADCOM).

Low Temperature CVD Growth of Epitaxial HgTe on CdTe

T. F. Kuech* and J. O. McCaldin†

California Institute of Technology, Pasadena, California 91125

ABSTRACT

Epitaxial layers of HgTe on CdTe substrates have been grown by a low temperature metal organic CVD technique at temperatures of 325°-350°C. Thin films of HgTe exhibiting good crystalline perfection were formed by the reaction of Hg vapor and dimethyl telluride. Similar techniques may provide an alternative growth method for the epitaxial growth of $Hg_xCd_{1-x}Te$ at low temperatures.

The semiconducting alloy system, $Hg_xCd_{1-x}Te$, is an important material for use in infrared detectors and imaging arrays. The bandgap of the material may be varied with composition over a wide spectral range from the visible ($x \simeq 0$) to over 30 μm ($x > 0.80$). Since the lattice parameters of HgTe and CdTe are nearly equal ($\Delta a/a = 0.003$), lattice matched epitaxial growth of $Hg_xCd_{1-x}Te$ for all values of x may be obtained on CdTe substrates. Epitaxial layers of $Hg_xCd_{1-x}Te$ on CdTe substrates have been grown by a variety of methods including vacuum deposition (1), sputter deposition (2), ion implantation (3), vapor deposition (4-5), close-spaced transport (6), and liquid-phase epitaxy (LPE) (7-9). Overall, LPE has proved to be the most useful of these methods. Epitaxial layers have been grown by LPE from both Hg and Te solutions. Recently, growth from Te solutions has produced good epitaxial layers with a minor amount of compositional variation across the layer (8). A change in composition can lead to undesirable variations in the spectral response of the material particularly in the long wavelength (high Hg content) regime. The relatively high temperatures used in Te solution LPE growth can also lead to the interdiffusion of the growing layer with the underlying substrate causing a vertical compositional grading in the $Hg_xCd_{1-x}Te$ layer. The extent of the interdiffusion increases rapidly with temperature making a low temperature growth technique desirable.

The use of chemical vapor deposition techniques, which have been very successful in silicon processing and the growth of III-V and some II-VI semiconductors, has previously not been reported in the case of $Hg_xCd_{1-x}Te$. The CVD growth of both HgTe and $Hg_xCd_{1-x}Te$ is difficult due to the large vapor pressures of the constituent elements, in particular Hg, required to be present to prevent thermal decomposition of the growing layer. In the case of pure HgTe at 500°C, the vapor pressure of Hg must remain between 0.16 and 7.0 atm to prevent decomposition or two-phase formation (10). The high Hg pressures required at these temperatures (500°C) for the growth and stability of the deposited layer have prevented the use of conventional open tube CVD reactors which operate at pressures less than or equal to 1 atm. If the substrate temperature is lowered, however, the required Hg pressures also decrease such that growth of HgTe at 325°C requires the Hg pressure to remain between 5×10^{-4} and 0.6 atm.[1] These pressures can be easily maintained by a source consisting of elemental Hg held at an appropriate temperature. However, the use of elemental Hg as a source does require the use of a hot wall reactor to prevent Hg condensation.

We are investigating CVD growth in the HgTe-CdTe system and present here the results for the CVD growth of epitaxial layers of HgTe on CdTe substrates. Epitaxial layers of HgTe were formed by the reaction of Hg vapor and the organic compound dimethyl telluride (DMT) according to the reaction

$$Hg + (CH_3)_2Te + H_2 \rightleftarrows HgTe + 2CH_4$$

Dimethyl telluride has been used previously, together with other metal-organic compounds, in the formation of CdTe, ZnTe, and a variety IV-VI compounds (11, 12). DMT has been used instead of H_2Te, which is a preferred source of Te. H_2Te is commercially unavailable probably due to its unstable nature. The use of DMT may introduce carbon as an impurity into the growing films.

The crystal growth was undertaken in a horizontal silica hot wall reactor, heated in a two-zone resistance furnace. This is shown schematically in Fig. 1. The left zone of the furnace was used to control the temperature of a boat of elemental Hg (triple distilled) which served as the source of Hg vapor. The Hg vapor pressure in the reactor was regulated by controlling the Hg source temperature. The right zone controlled the substrate temperature. DMT vapor was supplied by bubbling hydrogen through liquid DMT held at room temperature. The DMT vapor was introduced downstream from the mercury source to prevent surface contamination of the Hg. Typical H_2 flow rates through the DMT were 10-40 cm^3/min. Quartz baffles were installed in the reactor to insure good mixing of the Hg and DMT vapors prior to reaction. The hydrogen used as a carrier gas was purified in a Pd purifier and passed through a liquid nitrogen cold trap before entering the reactor. The apparatus operated at atmospheric pressure with total hydrogen flow rates of 0.4-0.6 liter/min.

$$(CH_3)_2Te + Hg + H_2 \rightarrow HgTe + 2CH_4$$

[1] These values are extrapolated from data given in Ref. (10).

Substrates of <110> CdTe were prepared by cleaving bulk single crystals of CdTe in air. The <110> CdTe substrate was used in most of this study due to the ease of sample preparation. However, substrates of <111>A CdTe etched in 1% bromine in methanol were also used.

The CdTe substrate was annealed in the reactor under an H_2 atmosphere for 30-60 min at 325°-350°C prior to the growth of the HgTe. This step was found necessary to insure good epitaxial growth of the HgTe. The growth of the HgTe was initiated by heating the Hg source to 270°-300°C followed by the introduction of DMT into the reactor. The substrate temperature was typically 325°-350°C during the growth period which lasted 10-120 min. This procedure gave growth rates of 0.3-0.6 μm/hr. After the growth period, the sample was quickly pulled from the furnace hot zone to prevent thermal decomposition of the HgTe layer. The growth procedure used here should not be considered to be optimal without further experimentation. Higher growth rates may be possible.

The growth morphology of the HgTe layers was examined by scanning electron microscopy (SEM). A variety of growth morphologies were observed depending on substrate crystal orientation and growth conditions. A typical HgTe growth on a <110> cleaved CdTe surface is shown in Fig. 2.

Figure 2(a) shows an HgTe layer grown over a tilt boundary in the CdTe substrate. This is evident in the surface morphology of the HgTe layer. Small terraces are found to be oriented along specific crystal directions in the substrate. Figure 2(b) shows an enlarged view of the HgTe surface. This reveals the faceting which occurs on the growing layer. This faceting may imply that the cleaved crystal face may not be the preferred growth direction. In LPE studies, the <111>A CdTe surface has been found to be the optimal surface for growth of $Hg_xCd_{1-x}Te$ (9), while previous vapor phase growth studies found the highest growth rate on the <111>B CdTe surface (4).

We have also obtained smoother growth morphologies than shown in Fig. 2 on the <110> cleaved surface as seen in Fig. 3. The HgTe layer shown growing over a cleavage step on the substrate surface is very smooth with little or no surface relief. The occurrence of different growth morphologies was found to be partly dependent on the quality of the substrate material.

The growth morphology on the <111>A surface of the CdTe is shown in Fig. 4. On this surface, the HgTe exhibits a triangular relief, characteristic of the symmetry of the underlying substrate. The <111>B face was not investigated.

The HgTe layers were also examined by helium backscattering and channeling measurements and glancing angle x-ray diffraction. In the helium backscattering experiment, a beam of 1.5 MeV helium ions impinges on the substrate and the energy distribution of the backscattered particles is measured at 170° from the direction of the incident beam. A typical backscattering spectrum of an HgTe layer is shown in Fig. 5. The curve labeled random corresponds to the case where the substrate is randomly aligned with respect to the ion beam. The high energy peak in the spectrum is due to scattering off the HgTe layer while the broad

Fig. 2. HgTe layer grown on a <110> cleaved CdTe surface. (a, top) HgTe layer grown over a tilt boundary in the substrate. (b, bottom) A higher magnification view reveals the faceting which occurs on the growing layer. The small terraces are orientated along specific crystal directions in the substrate. The SEM views are inclined 60° from the normal.

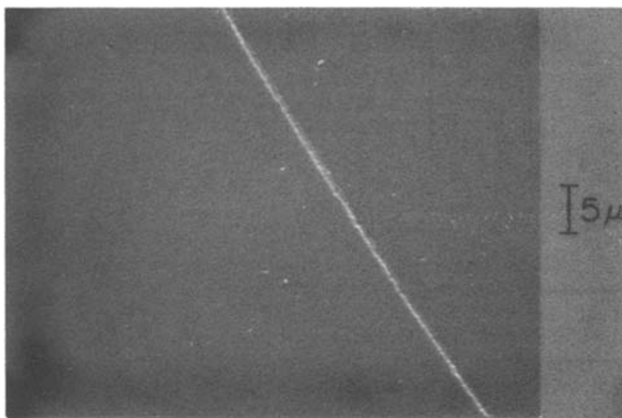

Fig. 3. HgTe layer on a <110> CdTe substrate possessing a smooth growth morphology. This layer was grown over a cleavage step in the substrate surface. Growth morphology was found to be partly dependent on substrate quality.

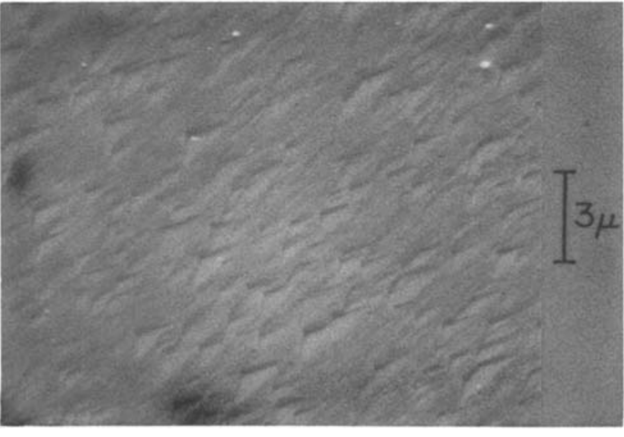

Fig. 4. HgTe layer grown on a <111>A CdTe substrate. The growing layer exhibits a triangular relief, characteristic of the underlying substrate. The polarity of the substrate was determined by chemical etching techniques.

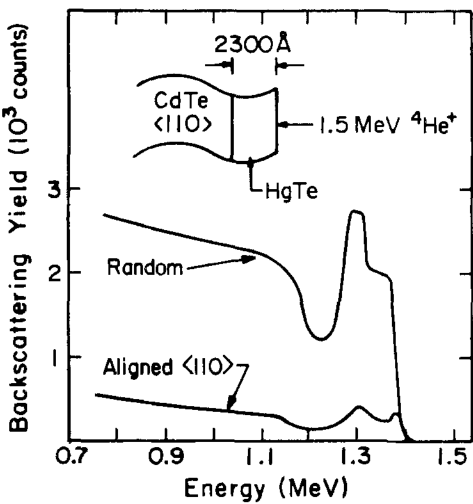

Fig. 5. The 1.5 MeV He^+ backscattering spectra of epitaxial HgTe layers. The random spectrum was used to determine the thickness of the HgTe layer. The aligned <110> spectrum indicates good epitaxial growth.

low energy part of the spectrum corresponds to scattering off the CdTe substrate. The thickness of the HgTe layer is easily obtained from the energy width of the HgTe peak (13). The curve labeled "aligned <110>" in Fig. 5 is the channeling spectrum of the HgTe layer. In this case, the ion beam is aligned along the <110> axis of the CdTe substrate. The ratio of the height of the HgTe peak in the channeled spectrum to random spectrum ($\chi_{min.}$) gives an indication of the crystal perfection of the HgTe layer which in this case is very good with $\chi_{min.} = 10\%$-15% and indicates epitaxial growth.

The thickness and hence the growth rate of the epilayer can be monitored by this technique. In Fig. 6, the HgTe peak from the random spectrum taken on two different growths is shown. The thicker film was grown with twice the vapor pressure of DMT in the reactor than in the case of the thinner layer. The growth rate was found to be proportional to the DMT pressure under the growth conditions used here. The variation of Hg pressure obtained by changing the Hg source temperature did not change the growth rate of the HgTe

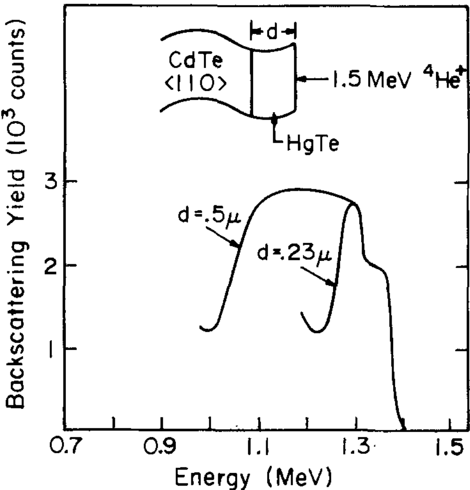

Fig. 6. The HgTe peak of the random backscattering spectrum taken on two different growths. The growth rate was obtained from the energy width of the HgTe peak.

for a given DMT pressure. The Hg source temperature was varied from 250°-300°C.

HgTe grown at temperatures greater than 350°C yielded poor results. At these temperatures the Hg and DMT vapors begin to react in the gas phase leading to undesirable film growth. Many metal organic compounds react easily at low temperatures, a fact which has necessitated the use of cold wall CVD reactors. This gas phase reaction sets an upper limit on the temperature range used in a hot wall reactor. The lower limit on the substrate temperature was found in this case to be 325°C. At temperatures below 325°C, the reaction between Hg and DMT is very slow leading to little or no HgTe growth.

In this study, we have demonstrated the use of a CVD technique for the low temperature growth of high quality HgTe epitaxial layers on CdTe substrates. However, the straightforward extension of this work to the growth of $Hg_xCd_{1-x}Te$ is not possible in the present arrangement. The reaction of dimethyl tellurium and dimethyl cadmium, the desired source of Cd, proceeds rapidly at low temperatures preventing the use of a hot wall reactor. The use of elemental mercury as a source of mercury vapor requires a hot wall arrangement. Dimethyl mercury could serve as an alternative source of mercury for use in a cold wall reactor. We are presently investigating the extension of this technique to the low temperature CVD growth of $Hg_xCd_{1-x}Te$.

Photoelectrochemical Behavior of n-GaAs Electrodes in Ambient Temperature Molten Salt Electrolytes: Device Characterization and Loss Mechanisms

P. Singh,* R. Singh,** K. Rajeshwar, and J. DuBow*

Department of Electrical Engineering, Colorado State University, Fort Collins, Colorado 80523

ABSTRACT

The use of molten-salt electrolytes in photoelectrochemical (PEC) devices is demonstrated by the n-GaAs|$AlCl_3$-BPC (1:1M ratio), ferrocene/ferricenium chloride|C system. Both single crystal and polycrystalline n-GaAs electrodes were employed. The performance parameters under illumination with a tungsten halogen lamp at 100 mW/cm^2 for PEC devices based on single crystal material were: Short-circuit current density (J_{SC}) = 4.9 mA/cm^2, open-circuit voltage (V_{oc}) = 611 mV, fill factor (FF) = 0.39, and conversion efficiency (η) = 1.2%. The corresponding values for the polycrystalline devices were: J_{SC} = 3.8 mA/cm^2, V_{oc} = 580 mV, FF = 0.33, and η = 0.7%. A marginal improvement in the performance parameters was observed on addition of benzene and methylene chloride. The factors limiting conversion efficiency in these PEC devices are J_{SC} and fill factor. The major loss mechanisms leading to poor J_{SC} and fill factors and thereby degrading cell output are identified as surface-state assisted carrier recombination and sluggish charge transfer at the n-GaAs/$AlCl_3$-BPC interface possibly arising from Cl^- ion adsorption on the n-GaAs electrode. Electrostatic means of minimizing surface state effects by inverting the semiconductor surface are discussed with the aid of energy band diagrams. It is shown that for n-type GaAs, inversion may be achieved by choosing a redox system such that its equilibrium potential lies positive of 0.59V *vs.* NHE. The use of molten-salt electrolytes and nonaqueous media in general, offers a greater flexibility in the choice of redox couples in this regard, since the onset potentials for electrode decomposition are more positive than values observed for aqueous media. The excellent PEC stability of n-GaAs electrodes in $AlCl_3$-BPC electrolytes is another manifestation of this effect.

Much attention has been focused in recent years on the prospect of utilizing photoelectrochemical (PEC) devices for conversion and storage of solar energy (1). An outstanding problem in PEC research is the photocorrosion undergone by the semiconductor electrode. The tendency of small bandgap semiconductors to undergo photocorrosion imposes severe limitations on their performance and lifetime in a PEC cell. The use of nonaqueous electrolytes has offered an attractive alternative in this regard (2). In a previous paper, we reported on the PEC characterization of n-GaAs electrodes in an aprotic room temperature molten salt electrolyte consisting of a mixture of $AlCl_3$ and n-butyl pyridinium chloride (BPC) (3). Cyclic voltammetry and capacitance-voltage measurements revealed that the semiconductor bandedges are optimally placed with respect to the stability limits of the electrolyte containing $AlCl_3$ and BPC in the 1:1M ratio. Photogenerated holes on n-GaAs electrodes were also seen to be utilized effectively in the ferrocene/ferricenium ion ($Fe(Cp)_2/Fe(Cp)_2^+$) redox reaction at the expense of the parasitic electrode dissolution process.

In the present paper, we describe the performance parameters of regenerative PEC cells based on the n-GaAs|1:1 $AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2Cl$|C system. Both single crystal and polycrystalline n-GaAs electrodes were examined in this study. Our results show that the above PEC system is capable of generating significantly high open-circuit potentials. Photopotentials as high as 680 mV have been observed under illumination with a tungsten halogen lamp at 100 mW/cm^2. The current densities (~2-7 mA/cm^2), however, were rather low compared to values typical of PEC cells based on aqueous electrolytes.

Key words: surface states, specific ion adsorption, surface inversion.

In an effort to probe the origin of the low current density, a systematic study of the various loss mechanisms in the n-GaAs|1:1 $AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2$|Cl|C cell was carried out. Factors relating to the effect of electrolyte conductivity, specific ion adsorption, hindrance to charge transfer at the semiconductor/electrolyte interface, and surface states, were of particular relevance in this regard. The deleterious effect of surface states on the photovoltaic performance was unequivocally demonstrated by a comparison of the dark and illuminated current-voltage characteristics of the above PEC system.

Finally, conclusions based on the present experimental data are extended to encompass aspects related to the design and operation of PEC systems in general. Ways in which the relative positions of semiconductor bandedges and redox couples may be optimized and the deleterious influence of surface states minimized by electrostatic means, are discussed with the help of energy band diagrams. It is proposed that carrier recombination via surface states, which is likely to be a major loss mechanism in PEC devices, may be reduced considerably by inverting the semiconductor surface.

Experimental

PEC devices were fabricated using single crystal (Te-doped, $<\bar{1}\bar{1}\bar{1}>$ and $<100>$ orientations) and polycrystalline (average grain size 0.1-0.5 mm) n-GaAs wafers obtained from commercial sources. The wafers were degreased with xylene, rinsed with methanol, and dried under nitrogen. They were then given a chemomechanical polish with 1% solution of bromine in methanol. Individual electrodes were scribed from these wafers after providing them with ohmic contacts consisting of thermally evaporated Ge-Au alloy on the back surface which was subsequently annealed in nitrogen at 450°C for 15 min. A Teflon-coated copper

wire was attached to the contacts using conducting silver epoxy. The entire back surface and the edges of the electrodes were covered with nonconducting epoxy resin. The electrodes were etched in 10% HCl for 15 min to remove any native oxide and the damaged surface layers. This was followed by etching in H_2SO_4:H_2O_2:H_2O (3:1:1) for 15 sec. The electrodes were rinsed with deionized water and etched for 30 sec in 6M HCl. After rinsing with deionized water and ethyl alcohol the electrodes were dried under vacuum and then transferred into the dry box. The geometric area of the electrodes was nominally 0.10-0.25 cm^2. A vitreous carbon plate (nominal dimensions: 1.5 × 15 × 30 mm) was used as the counterelectrode in the PEC devices.

Molten salt electrolytes consisting of $AlCl_3$-BPC in the 1:1M ratio were prepared according to procedures described elsewhere (3). Ferrocene ($Fe(Cp)_2$) was obtained from commercial sources and purified by extraction with petroleum ether and subsequent recrystallization. Ferricenium chloride ($Fe(Cp)_2Cl$) was prepared using standard procedures (4). Nominal concentrations of $Fe(Cp)_2$ and $Fe(Cp)_2Cl$ in the electrolyte were 0.2M and 20 mM, respectively. All manipulations with the electrolytes and redox chemicals were carried out in a dry box.

A 300W tungsten halogen lamp was used to illuminate the n-GaAs electrodes. The intensity of the light source was calibrated using a radiometer/photometer. The light intensities reported herein are not corrected for reflection and absorption losses in the cell and in the electrolyte.

Dark current-voltage measurements were performed using a PAR 173 potentiostat (Princeton Applied Research Corporation, Princeton, New Jersey) equipped with PAR 179 coulometer accessory. Three-electrode geometry was employed for these measurements. An aluminum wire immersed in the $AlCl_3$-BPC electrolyte (2:1M ratio) and separated from the main cell compartment by a fine-porosity glass frit was employed as the quasi-reference electrode. Photocurrent *vs.* potential data were obtained by using a Hewlett-Packard 721 A power supply in series with the PEC cell. The cell current was monitored by measuring the potential drop across a 10 kΩ resistor in series with the cell.

Results

Illuminated current-voltage characteristics.—Figure 1 illustrates the illuminated current-voltage characteristics for n-GaAs (single crystal) |1:1 $AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2Cl$|C PEC cells. Corresponding data obtained on polycrystalline n-GaAs wafers are also illustrated. The relevant performance parameters for these cells are assembled in Table I.

The relationship between short-circuit current density (J_{sc}) and light intensity is illustrated in Fig. 2a. A linear correlation is observed for light intensities up to approximately 1 sun (100 mW/cm^2). The variation of open-circuit voltage (V_{oc}) with light intensity is also shown in Fig. 2a. After an initial sharp increase, the rate of increase of V_{oc} with light intensity slows down in accordance with the behavior predicted by the equation (5)

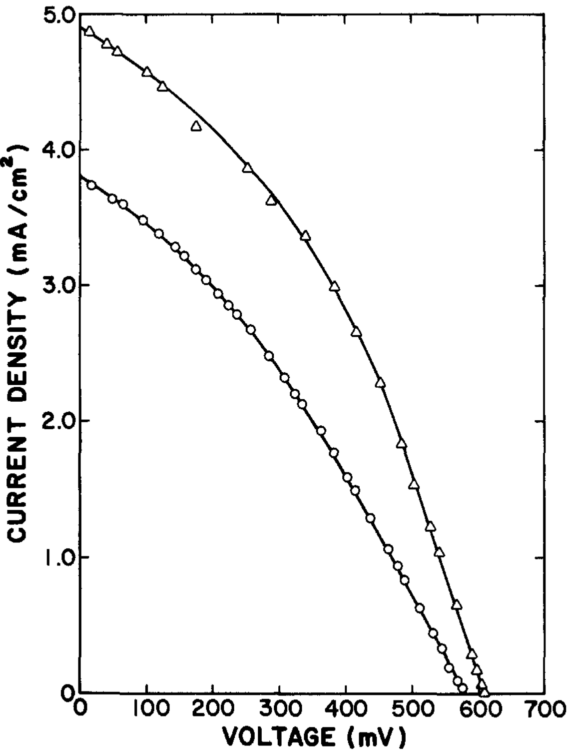

Fig. 1. Current voltage characteristics of n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2Cl$|C system. (△)—single crystal n-GaAs, (○)—polycrystalline n-GaAs. The light intensity in these experiments was 100 mW/cm^2.

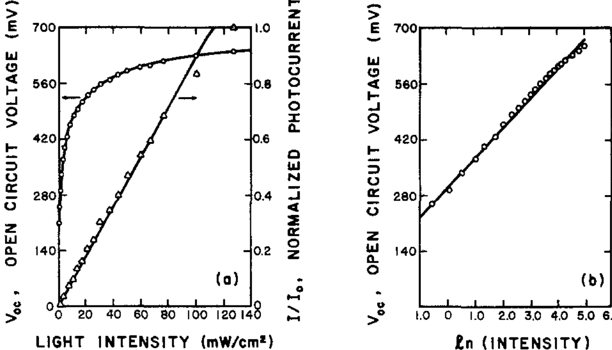

Fig. 2. (a) Relationship of open-circuit voltage and photocurrent with light intensity and (b) correlation of V_{oc} with logarithm of light intensity for the n-GaAs (single crystal)|$AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2Cl$|C system.

$$V_{oc} = (n\,kT/q)\ \ln\,[(J_{sc}/J_o) + 1] \qquad [1]$$

where n is the junction "ideality factor," J_o is the reverse saturation current density of the device, and the other terms assume their usual significance. The relationship between V_{oc} and logarithm of light intensity is illustrated in Fig. 2b. Values of n in the range 1.8-3.0

were extracted from the slopes of such plots for the devices examined in this study.

Effect of organic additives.—The illuminated current-voltage characteristics of the n-GaAs|1.1 $AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2Cl$|C system are shown in Fig. 3 in the presence of benzene (50% by volume) in the electrolyte. A comparison of the data, with and without the presence of benzene, is presented in Table I for single crystal and polycrystalline material. A slight improvement in J_{SC} values is apparent for the electrolyte containing benzene, although these values are still below current levels in n-GaAs PEC cells based on aqueous electrolytes (6, 7). The enhancement of J_{SC} values in the presence of benzene is consistent with recent work which shows that addition of benzene to $AlCl_3$-BPC molten salt electrolytes, results in an increase in the conductivity of the medium due to a sharp reduction in the viscosity (8). The slight improvement in fill factors for the devices utilizing mixtures of $AlCl_3$-BPC and benzene (Table I) is again consistent with a reduction in the series resistance brought about by the above effect.

Effects similar to those obtained with benzene were observed on addition of methylene chloride (50% by volume) to the 1:1 $AlCl_3$-BPC electrolyte.

Cell stability.—Long-term irradiation of n-GaAs electrodes was carried out in the 1:1 $AlCl_3$-BPC electrolyte and the photocurrents were monitored under short-circuit conditions. Figure 4 illustrates typical results. The incident light intensity in this experiment was 57 mW/cm². The constancy of the observed photocurrents indicates the excellent PEC stability of n-GaAs electrodes in the 1:1 $AlCl_3$-BPC electrolyte. (The slight fluctuations in the photocurrent in Fig. 4 are attributed to electrolyte stirring effects and variations in light intensity as a function of time.) Further confirmation is provided by stoichiometric data. For example, in the results shown in Fig. 4, a total amount of charge of 7776 C/cm² was passed through the electrode. This corresponds to 3.9g of GaAs decomposed per unit area assuming a decomposition reaction involving the transfer of three electrons. Since the electrode mass in this experiment was *ca.* 20.3 mg, even 5% of the total current that was passed would have resulted in complete consumption of the electrode. The enhanced stability of n-GaAs electrodes in the aprotic $AlCl_3$-BPC system may be understood if we note that the onset potentials for photocorrosion currents lie significantly positive of the values observed in aqueous electrolytes (3). This point is further illustrated by a comparison of the two cases as shown in Fig. 5.

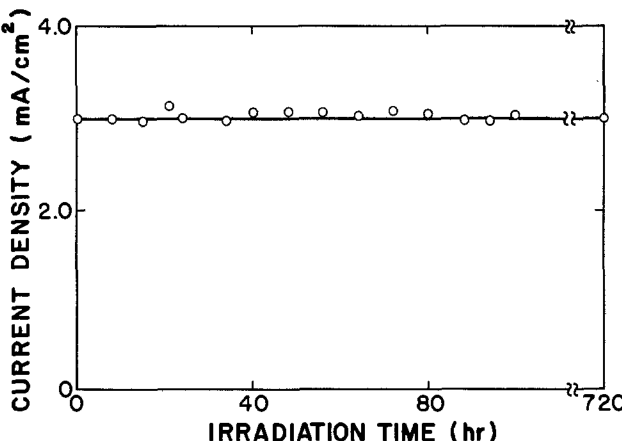

Fig. 4. Time dependence of short-circuit current density for n-GaAs (single crystal)|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2Cl$|C system. The light intensity was 57 mW/cm² and the 1:1 $AlCl_3$-BPC electrolyte contained 200 mM ferrocene and 20 mM ferricenium chloride.

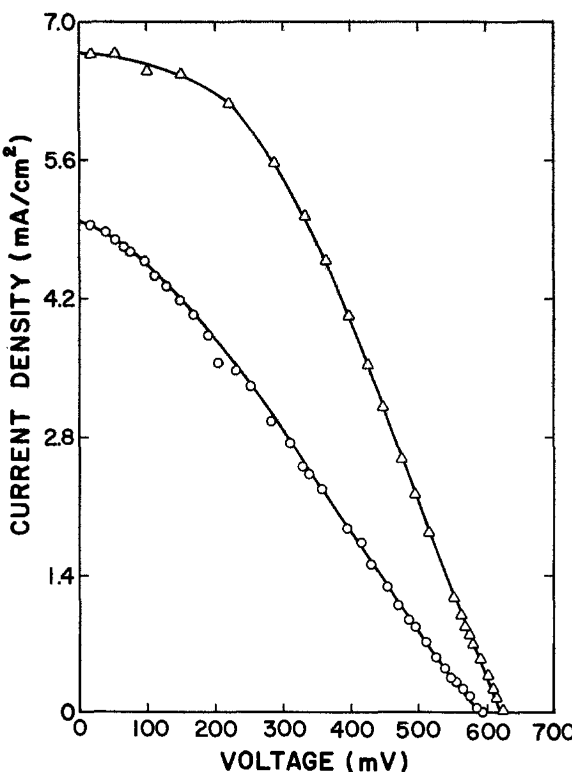

Fig. 3. Current voltage characteristics of n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2Cl$|C system in the presence of benzene (50% by volume) in the electrolyte. (△)—single crystal, (○)—polycrystalline n-GaAs. The light intensity was 100 mW/cm².

Discussion

The V_{oc} values observed for the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2/Fe(Cp)_2Cl$|C system in the present study, compare favorably with those observed by previous authors for PEC devices based on the n-GaAs/aqueous electrolyte interface (6, 7). Even higher V_{oc} values than

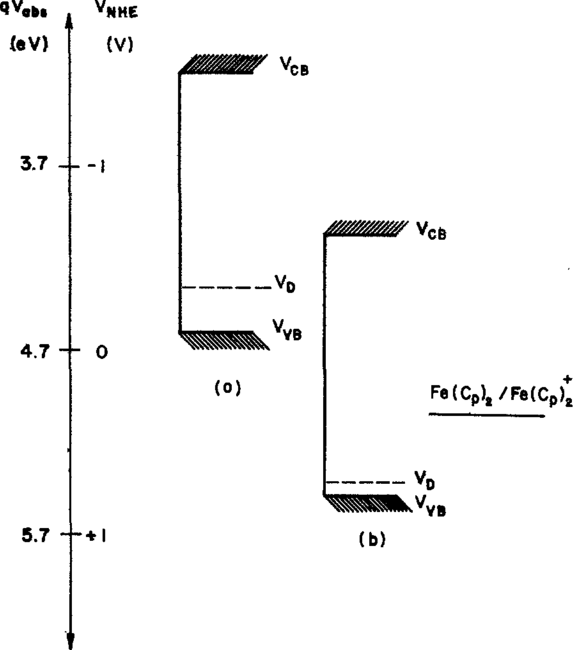

Fig. 5. Relative positions of potentials corresponding to n-GaAs bandedges (V_{CB} and V_{VB}) and onset potentials (V_D) for electrode decomposition for (a) aqueous electrolytes (pH = 12) and (b) $AlCl_3$-BPC (1:1M ratio) electrolyte. Relevant data were obtained from Ref. (3), (9), and (14). The redox level refers to the $AlCl_3$-BPC electrolyte only.

those shown in Table I were observed for some n-GaAs electrodes (750-800 mV) although difficulties were experienced in consistently reproducing this behavior. The overall conclusion from the present data is that high V_{oc} values can be realized with n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2Cl$|C devices and the main factors limiting conversion efficiency are fill factor and short-circuit current density. Mass transfer of electroactive species [$Fe(Cp)_2$ and $Fe(Cp)_2^+$] in the bulk electrolyte does not seem to be a limiting factor in the observed J_{SC} values as indicated by the linear correlation observed for J_{SC} with light intensity (Fig. 3a). The relatively minor effects noted above on addition of organic additives also seem to support this interpretation. Therefore, the factors limiting the magnitude of J_{SC} and fill factor are to be sought elsewhere. The following paragraphs amplify the possible role of surface states and specific ion adsorption effects in this regard.

Surface states.—Surface states have been implicated in previous studies on the semiconductor/electrolyte interface (2a, 10). A brief examination of their role in impairing PEC performance, however, would be relevant to the following analysis of the experimental data. Surface states at the semiconductor electrode/electrolyte interface, manifest themselves in the following ways:

(*i*) They act as charge storage centers and thereby modify the electrostatics (*i.e.*, the amount of band bending) and consequently the barrier height in the system. In the extreme case of high surface-state densities, Fermi level pinning ensues (11).

(*ii*) Surface states provide charge transfer paths between the charge carriers in the semiconductor and the electrolyte species in cases where there is not sufficient overlap between the semiconductor bandedges and the redox levels. For an n-type semiconductor, electron transfer from the semiconductor conduction band to the oxidized redox species represents a leakage current which detracts from the overall PEC performance of the electrode. The net result is that any change in the occupancy of the surface states on illumination, may result in a reduced anodic current flow (for an n-type semiconductor).

(*iii*) Surface states act as recombination-generation centers by interacting with the valence and conduction bands of the semiconductor. Sluggish charge transfer at the semiconductor/electrolyte interface, which leads to an accumulation of charge carriers at the surface (under illumination), may cause recombination losses via surface states to be significantly larger under illumination than in the dark.

It may be noted that in the preceding discussion no distinction has been made between "intrinsic" surface states (*e.g.*, dangling bonds, Tamm levels) and those brought about by interaction of electrolyte species with the semiconductor surface (11). Let us now examine the data in Fig. 6 in the light of the above discussion. Figure 6 is a comparison of the dark current-voltage characteristics and the current-voltage curves obtained by subtracting J_{SC} from the illuminated current-voltage data for the n-GaAs|1:1 $AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2Cl$|C system. For cases where carrier losses (for example, via recombination) are unchanged upon illumination, the two curves in Fig. 6 are expected to coincide (12). The large separation of the two curves in Fig. 6 is taken as direct evidence for the active participation of surface states as leakage current paths and recombination centers in the n-GaAs/$AlCl_3$-BPC system [effects (*ii*) and (*iii*) noted above]. Consequently, the rather poor short-circuit current densities observed in the present study for the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2Cl$|C system may be partially attributed to the deleterious effect of surface states (*vide infra*).

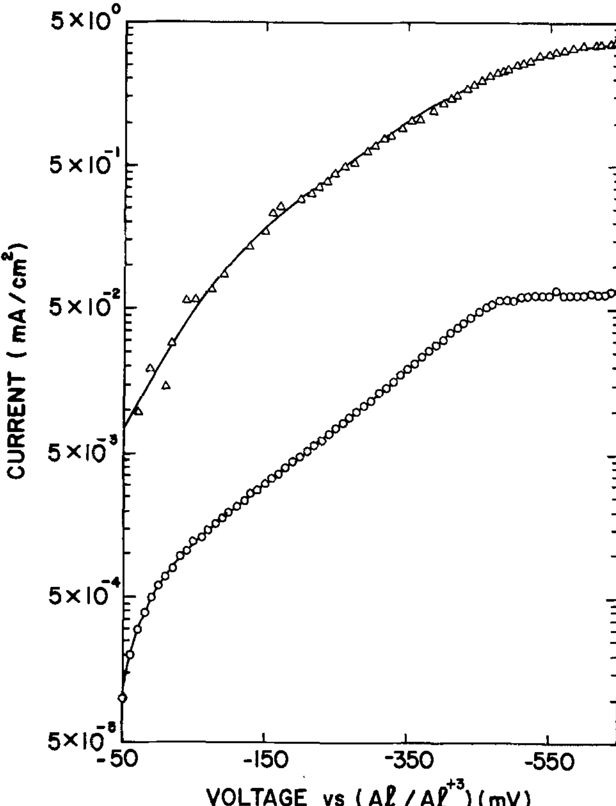

Fig. 6. Comparison of the dark current-voltage characteristics (0) and current-voltage behavior obtained by subtracting I_{SC} from illuminated current-voltage characteristics for the n-GaAs (single crystal) $AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2Cl$ C system. The illuminated current-voltage data were obtained at a light intensity of 100 mW/cm^2.

Further evidence for the effect of surface states on the photovoltaic performance of the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2Cl$|C system is found in the magnitude of the slope of V_{oc} *vs.* ln I plots (Fig. 2b). Ideal junctions with $n = 1$ should yield a slope of 25 mV (*cf.*, Eq. [1]). Slopes consistently greater than this value were observed for the present PEC system (the data shown in Fig. 3b yield a slope of ~75 mV). This behavior implies an n-value of greater than unity which in turn is indicative of recombination-generation dominated current-voltage behavior (13).

Specific ion adsorption.—Specific adsorption of electrolyte species on the semiconductor surface often leads to rather dramatic effects on the electrostatics at the semiconductor/electrolyte interface (14). The negative shift observed in flatband potentials with increasing pCl ($= -\log [Cl^-]$) for the n-GaAs/$AlCl_3$-BPC interface (3, 15) is consistent with specific adsorption of Cl^- ions on the n-GaAs surface. This adsorption effect could lead to sluggish charge transfer at the electrode/ electrolyte interface by partially blocking close approach of $Fe(Cp)_2$ molecules to the n-GaAs surface. This in turn enhances the carrier recombination losses as discussed above.

Adsorption of electronegative species on an n-type semiconductor surface, however, can also have a beneficial effect. For example, adsorbed Cl atoms may function as efficient electron traps and thereby induce an effective positive charge on the semiconductor surface at equilibrium. In the extreme case, the semiconductor surface may become inverted (*vide infra*) and thereby lead to an enhancement of the barrier height in the system. Such effects are well known in metal-insulator-semiconductor (MIS) devices (16). It is doubtful, however, whether Cl^- ion adsorption has such a favorable effect in the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2$/

$Fe(Cp)_2Cl|C$ system; the V_{oc} values are only 65-75% of the theoretical maximum output (3).

In the light of the present experimental data and recent studies on PEC systems in general (2a, 10), it appears that a major loss mechanism in these devices involves surface states. How can their effect be ameliorated? Previous studies on solid-state devices (17) have shown that for an inverted semiconductor interface, the electrostatic effect of surface states remains virtually independent of the cell potential (*i.e.*, no change in surface-state occupancy) over a wide range of applied bias. This contrasts the situation obtaining with a depleted semiconductor surface. The key to minimizing the deleterious influence of surface states, then, is to ensure the presence of an inversion layer on the semiconductor surface. The conditions to be fulfilled by semiconductor/electrolyte interfaces in general and by n-GaAs/electrolyte systems in particular, for the formation of an inversion layer, are analyzed below with the help of energy band diagrams.

Figure 7 illustrates the energy band diagram for an n-type semiconductor in contact with the electrolyte. The vacuum level is chosen as the reference in this diagram. V_{redox} is the redox (equilibrium) potential of the redox couple in the PEC system with respect to the reference level. V_{redox} may be converted to normal hydrogen electrode (NHE) or saturated calomel electrode (SCE) electrochemical scale by the equations (18)

$$V_{redox} = V_{redox}^{NHE} + 4.70 \quad [2]$$

$$V_{redox} = V_{redox}^{SCE} + 4.94 \quad [3]$$

The Helmholtz layer at the semiconductor/electrolyte interface is nominally 2-6Å thick. Inversion layers cannot usually be sustained on the semiconductor surface under these conditions which accounts for the relatively rare occurrence of inversion layer formation by effects similar to those noted above for specific ion adsorption (19). Deliberate introduction of an oxide layer or any other dielectric of tunnelable dimensions (~15-30Å depending on the semiconductor) is therefore necessary to ensure inversion layer formation. The interphase region shown in Fig. 7, therefore, represents a composite of the Helmholtz layer and the dielectric region. The total potential drop across the interphase, ΔV, then consists of two components: (*i*) ΔV_1, potential drop across the interphase region of thickness, d and dielectric constant, ϵ_i, and (*ii*) ΔV_2, potential drop across the interphase states and any fixed charges in the interfacial layer, *i.e.*

$$\Delta V = \Delta V_1 + \Delta V_2 = E_s d + \frac{q(Q_{ss} + Q_i)d}{\epsilon_i} \quad [4]$$

E_s is the electric field at the semiconductor surface, and Q_{ss} and Q_i are the charge densities in the surface states and in the interphase region, respectively.

An inspection of Fig. 7 leads to the equation

$$V_{redox} = \Delta V + \frac{\chi_s}{q} + \psi_s + \phi_n \quad [5]$$

χ_s is the electron affinity of the semiconductor, ψ_s is the surface potential of the semiconductor, and ϕ_n is the potential difference between the Fermi level and the conduction bandedge. For the semiconductor surface to be under inversion, the following condition must be satisfied (20)

$$\psi_s > 2\frac{kT}{q}\ln\left(\frac{N_D}{n_i}\right) \quad [6]$$

N_D is the donor density in the semiconductor, n_i is the intrinsic carrier concentration, and T is the temperature in °K. To ensure inversion at the semiconductor surface

$$V_{redox} > \Delta V + \frac{\chi_s}{q} + \phi_n + 2\frac{kT}{q}\ln\left(\frac{N_D}{n_i}\right) \quad [7]$$

For cases where ΔV is negligible, the condition for inversion at the semiconductor surface can be written as

$$V_{redox} > \frac{\chi_s}{q} + \phi_n + 2\frac{kT}{q}\ln\left(\frac{N_D}{n_i}\right) > 2\frac{kT}{q}\ln\left(\frac{N_D}{n_i}\right) + V_{FB} \quad [8]$$

V_{FB} is the flatband potential of the n-type semiconductor.

An analogous treatment for the case of a p-type semiconductor yields

$$V_{redox} < \frac{\chi_s}{q} + \frac{E_g}{q} - \frac{2kT}{q}\ln\left(\frac{N_A}{n_i}\right) - \phi_p - \Delta V < V_{FB} + \frac{E_g}{q} - 2\frac{kT}{q}\ln\left(\frac{N_A}{n_i}\right) - \Delta V \quad [9]$$

N_A is the acceptor density and ϕ_p is the potential difference between the Fermi level and the valence bandedge of the semiconductor.

For the case of n-GaAs with a carrier concentration of $2 \times 10^{17}/cm^3$ and an electron affinity of 4.06 eV (21), the condition expressed in Eq. [8] reduces to

$$V_{redox} > 5.29V \quad [10]$$

Therefore the redox potential needed to invert the n-GaAs surface must lie more positive than 0.59V on the NHE scale, provided the net potential drop across the interphase region is zero. (It may be noted in this regard that V_{redox}^{NHE} of the $Fe(Cp)_2/Fe(Cp)_2^+$ system is only 0.42V.) Two effects may impose restrictions on the choice of conditions for the formation of an inversion layer: (*i*) V_{redox} must lie at potentials more negative than the decomposition potential of the semiconductor (22) and (*ii*) in the presence of high surface-state densities and concomitantly high potential drops across the interphase region (14, 23), the Fermi level may become pinned at the interphase. It may not be then possible to obtain inversion on the

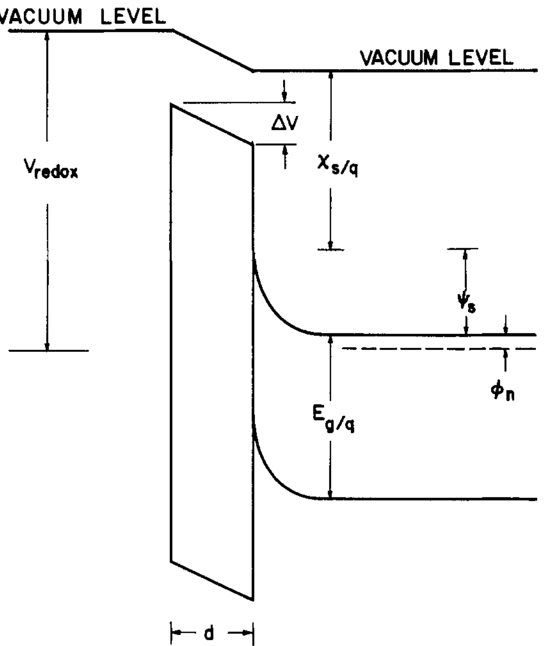

Fig. 7. Energy band diagram for an n-type semiconductor in contact with the electrolyte. See text for description of symbols.

semiconductor surface. The first restriction is rather severe for aqueous electrolytes since the decomposition potentials tend to be rather negative. On the other hand, for nonaqueous electrolytes in general and for molten salt electrolytes in particular, a greater degree of flexibility is rendered in the choice of V_{redox} by the favorable location of decomposition potentials (*cf.* Fig. 5).

Summary and Conclusions

1. Open-circuit voltages as high as 680 mV have been obtained with the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2Cl$|C system. These values are close to the highest observed to date on PEC systems in general. The overall solar conversion efficiencies in this system are admittedly low (~2%) relative to values observed for PEC systems based on aqueous electrolytes. No attempts, however, were made towards optimizing cell design. It is also worth noting that the performance parameters of PEC cells based on molten salt electrolytes are comparable to those observed for other nonaqueous electrolyte systems (24).

2. The cells demonstrate good PEC stability under short-circuit conditions. The electrode decomposition potentials in $AlCl_3$-BPC electrolytes lie significantly positive of values observed for aqueous media.

3. The main factors currently limiting conversion efficiency in the n-GaAs|$AlCl_3$-BPC, $Fe(Cp)_2$/$Fe(Cp)_2Cl$|C system are poor short-circuit current densities and fill factors. Addition of organic additives to the $AlCl_3$-BPC electrolyte marginally improves J_{SC} and fill factors.

4. The major loss mechanism leading to poor J_{SC} and fill factors have been identified as surface-state assisted recombination of charge carriers coupled with sluggish charge transfer at the n-GaAs/$AlCl_3$-BPC interface, presumably because of Cl^- ion adsorption on the electrode surface.
