Elofson and co-workers (6, 13) have furthermore found that, for diazonium concentrations above 10^{-3}M, the limiting current of the first wave reaches a constant value independent of concentration, and the occurrence of a polarographic maximum on the second one, which was interpreted by adsorption phenomena. In acidic medium, they have also observed a splitting of the second wave. They assigned the complicated shape of the polarograms to the irreversibility of the process. Using a stirred mercury cathode, the coulometric results obtained at the potential of the limiting current of the first or second wave were not reproducible.

Phenylmercuric chloride was isolated after electrolysis. Controlled potential electrolysis performed at a potential corresponding to the limiting current of the second wave corresponds to a four electrons process. A test reaction with ammonium phosphomolybdate indicates the presence of hydrazine in the electrolyzed solution.

Rüetschi and Trümpler (10) have reported a constant-current method using a mercury-pool cathode and a flowing catholyte, leading to good yields of phenylhydrazine, but did not attempt to investigate the mechanism of this process.

Any attempt to carry out electrochemical synthesis of aromatic hydrazines should be preceded by a critical evaluation of the mechanisms involved and elucidation of the role of adsorption. In particular it should be proved whether the hydrazines formed at very negative potentials operative when the constant current electrolysis is performed are generated in an electrochemical process or by a chemical reduction of diazonium salts by means of the hydrogen formed at the electrode surface.

In the present work, diazonium fluoborates instead of chlorides have been used, in order to avoid the chemical decomposition of the diazonium ions in the presence of halide ions.

Experimental

Reagents.—Stable *p*-methyl- and *p*-methoxyphenyldiazonium fluoborates have been prepared and purified by methods described in the literature (21). High purity commercial products have been used for preparation of supporting electrolytes (KCl, $NaClO_4$) and buffer solutions (McIlvain and Sörensen) in doubly distilled water.

Apparatus and techniques.—Tacussel instrumentation has been used for all the electrochemical measurements: Three electrode d-c and superimposed a-c polarograph (PRG3), potentiostats (PRT20, PRT40), integrator (IG5N), function generator (GSTP, UAP4), and recorder (EPL). A Telequipment storage oscilloscope DM60 has been used for cyclic voltammetry.

For the coulometric measurements and controlled potential electrochemical reductions, we have used a divided thermostated cylindric cell. The auxiliary electrode was a platinum grid, parallel to the mercury cathode and separated from it by an inner glass cylinder fitted with a sintered glass disk.

The outer compartment contained the mercury-pool cathode, the tested solution, the saturated calomel electrode (SCE) as reference and the fittings enabling deoxygenation. A relatively slow stirring of the mercury pool is particularly important at the outset of the electrolysis, because of the adsorption phenomena which can cause the partition of the mercury cathode into small balls isolated from each other by the adsorbed film. On the other hand, it is necessary to limit the duration of the electrolysis with a large mercury pool cathode, in order to limit the extent of the chemical side reactions. For the polarographic studies, a thermostated cell was used including SCE, fittings enabling deoxygenation and a platinum wire as an auxiliary electrode. All deoxygenations were done with pure nitrogen ("U" grade from "L'Air Liquide") and the nitrogen flow was kept over the solutions during the measurements.

Procedure.—0.1M $NaClO_4$ has been used as supporting electrolyte. As diazonium fluoborates are not stable in more basic media, McIlvaine and Sörensen buffers pH 1-7 were used. 0.01M stock solutions of diazonium fluoborates were kept oxygen free and stored at 4°C. All the electrochemical measurements were carried out at 4°C, except for coulometric measurements which were performed both at 4°C and 25°C.

Chemical identification of the products.—Preparative electrolysis were performed in a 500 ml cell, using a 44 cm^2 mercury-pool cathode.

p-Ditolylmercury has been separated from the acidic electrolyzed solution by $CHCl_3$ extraction, and recrystallization from benzene. This product has been identified by its melting point (lit. 244°-246°C, found 246°C) microanalysis (C% = 43.32, H% 3.92—Theor. = 43.19, 3.66) and ^{13}C NMR spectrum

$$\overset{5}{C}H_3\text{—}\overset{4}{}\overset{3}{}\text{ }\overset{2}{}\overset{1}{}\text{—Hg—}\text{—}CH_3$$

δ(ppm): C_2 = 137.48, C_3 = 129.48, C_4 = 138.06, C_5 = 20.95

J(Hg-C_2): 89.71 ppm-J(Hg-C_3): 102.96 ppm

N,N'-Di-*p*-tolylhydrazine has been separated by diethyl ether extraction after elimination of *p*-ditolylmercury and neutralization by sodium carbonate. The diethyl ether solution was dried over magnesium sulfate and saturated with gaseous hydrogen chloride. The resulting white hydrochloride was identified by infrared spectrometry, microanalysis, and NMR. This hydrazine is not electrochemically reducible under experimental conditions used.

p-Tolylhydrazine has been identified in the solution resulting from the controlled potential electrolysis by derivatization with 2,4-dinitrobenzaldehyde. The red hydrazone was recrystallized from acetic acid, and characterized by means of elemental analysis, infrared, NMR, and mass spectrometry; it was identical with the product obtained by reaction of 2,4-dinitrobenzaldehyde with commercial *p*-tolylhydrazine.

Moreover, *p*-tolylhydrazine is electroactive and shows a complex oxidation wave between 0.2 and 0.3V *vs.* SCE in the acidic medium used for the preparative electrolysis. This oxidation wave has been used, after calibration, for the determination of the concentration of hydrazine produced in electrolysis.

Results and Discussion

The following results have been predominantly obtained in experiments with *p*-methylphenyldiazonium fluoborates. The behavior of the p-methoxy derivative is analogous in all aspects with the exception of those obtained in controlled potential electrolysis which are discussed separately.

D-C and superimposed a-c polarography.—Compounds studied are reduced at concentrations of the diazonium salt larger than about 1 × 10^{-4}M in four waves (i_1-i_4, Fig. 1) in d-c polarography, and four corresponding peaks (i_{s1}-i_{s4}, Fig. 1) in a-c polarography. At concentrations lower than 1 × 10^{-4}M, wave i_2 and peak i_{s2} are missing.

The electrocapillary and *i-t* curves (Fig. 2) show a strong adsorption occurring at potentials between $(E_{1/2})_1$ and $(E_{1/2})_3$. The shapes of the *i-t* and electrocapillary curves, as well as values of half-wave potentials of waves i_1 and i_2, are not dependent on pH or concentration changes.

Wave i_1 (Table I and II) increases linearly with increasing concentration of the diazonium salt up to 1 × 10^{-4}M and becomes independent of concentration at higher values.

This observation together with the effect of temperature and a-c polarographic curves indicates that at concentrations above 1 × 10^{-4}M the height of this wave is governed by adsorption. Wave i_1 is thus typical Brdicka prewave.

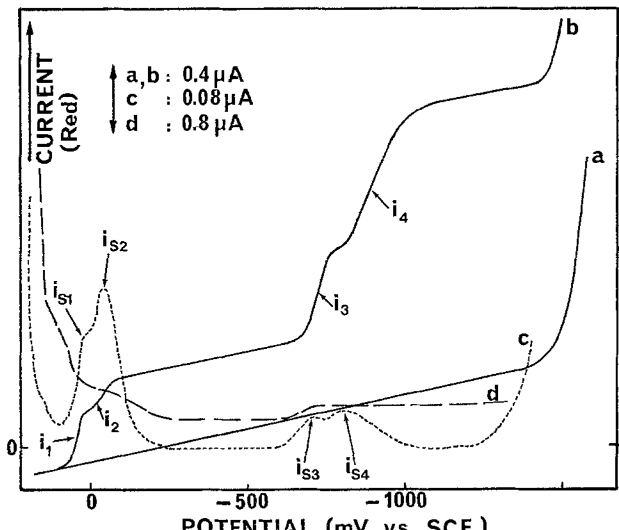

Fig. 1. D-C polarograms (a; b) and a-c polarograms (c: ϕ = 0g) (d: ϕ = 150g) of an aqueous solution of paratolyldiazonium fluoborate. McIlvain buffer, $NaClO_4$ 10^{-1}M, C = 2 × 10^{-4}M. pH = 5, T = 4°C, h = 65 cm, τ = 2 sec, F = 15 Hz, ΔV = 20 mV. $E_{1/2}{}^{i_1}$ = +50 mV; E_{S1} = +45 mV; $E_{1/2}{}^{i_2}$ = −45 mV; E_{S2} = −45 mV; $E_{1/2}{}^{i_3}$ = −730 mV; E_{S3} = −775 mV; $E_{1/2}{}^{i_4}$ = −910 mV; E_{S4} = −900 mV (vs. SCE).

Table I. Data obtained by d-c polarography of p-methylphenyldiazonium fluoborate

[a] ΔV = amplitude of the superimposed alternative signal.
[b] F = frequecy of the superimposed a.c.
[c] ϕ decreases with increasing concentration of the diazonium salt.
[d] E_s = potential corresponding to the sunmint current i_s.

The total height of waves i_1 and i_2 is a linear function of concentration and corresponds to a transfer of one electron.

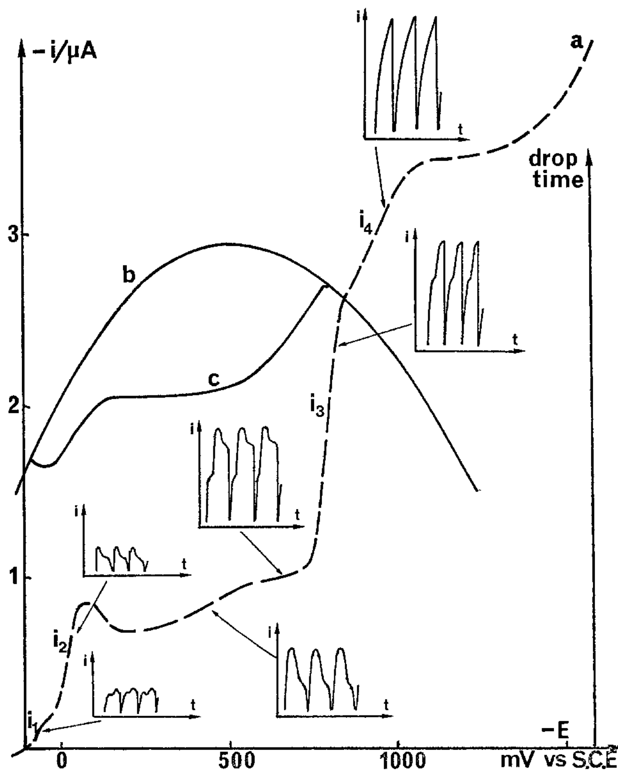

Fig. 2. D-C polarogram (a), electrocapillary curves (b: solvent; c: diazonium solution), and (i, t) curves. pH = 4, T = 4°C, h = 65 cm, τ = 2 sec. Buffered paratolyldiazonium solution (McIlvain buffer) $NaClO_4$ 10^{-1}M, $C = 3 \times 10^{-4}$M.

Independence of half-wave potential $(E_{1/2})_2$ of the concentration of diazonium salt, logarithmic analysis yielding a slope of 59 mV, and agreement of the sharp peak ($\Delta E_{S/2}$ = 100 mV) potential obtained by a-c polarography with the half-wave potential obtained by d-c polarography indicate reversible, single electron process.

This wave i_1 corresponds to a process

$$\mathrm{R{-}\overset{+}{N}{\equiv}\overset{-}{N}\ (free)} + e^- \rightleftarrows \mathrm{R{-}\overset{-}{N}{=}\dot{N}|\ ,Hg(ads.)}$$

where one-electron reversible reduction of the diazonium cation yields the adsorbed radical. Wave i_2 then corresponds to a reversible reduction of the diazonium cation through the adsorbed film, yielding a free radical

$$\mathrm{R{-}\overset{+}{N}{\equiv}\overset{-}{N}(free)} + e^- \rightleftarrows \mathrm{R{-}\overset{-}{N}{=}\dot{N}|\ (free)}$$

Wave i_3 is proportional to the concentration of the diazonium salt and its height is equal to the sum of limiting currents $i_1 + i_2$ and corresponds thus to a transfer of a second electron. Dependence of i_3 on the height of the mercury column similarly as the electrocapillary and i-t curves (Fig. 2), as well as the a-c polarograms obtained at ϕ = 150g (Fig. 1), show that the transfer of the second electron occurs on a surface from which the radical was desorbing. Logarithmic analysis and the shape of a-c polarographic peaks indicate that the electrode process is irreversible and the dependence of the half-wave potential of wave i_3 on pH indicates that proton transfer must occur beteen the transfer of the first and second electron.

The height of wave i_4 is twice that of wave i_3. The wave is diffusion controlled and corresponds to a two electron process. Broader and lower a-c polarographic peaks indicate an irreversible process; pH dependence of the half-wave potential of wave i_4 is a proof that

between tthe transfer of the second and third (and fourth) electron a proton transfer must occur.

Cyclic voltammetry.—The cyclic voltammogram recorded using a triangular potential sweep from + 0.1V to − 1.3V and back to + 0.1V *vs.* SCE shows, at concentrations of the diazonium salt smaller than 2 × 10^{-4}M, four cathodic peaks i_{P6}, i_{P1}, i_{P2}, and i_{P3} (Fig. 3, Table III).

Peak i_{P6} corresponds probably to the reduction of the product resulting from the oxidation of the mercury electrode at the starting potential E_1. This assumption is supported by observation that peak i_{P6} does not appear when the starting potential is slightly more negative.

At sweep-rate slower than 5 $Vsec^{-1}$ only the reduction peak i_{P2} is observed. This peak occurs in the potential range where d-c polarographic waves i_1 and i_2 were observed. At sweep-rate higher than 5 $Vsec^{-1}$ another very broad reduction peak i_{P3} is observed in the same potential range where d-c waves i_3 and i_4 occur. Reduction in this peak i_{P3} is completely irreversible, as no corresponding anodic peak is observed. At sweep rates higher than 5 $Vsec^{-1}$ anodic peak $i_{P2}{}^a$ is observed, indicating reversibility of the process taking place in peak i_{P2}. Peak i_{P1} is observed only at concentrations of the diazonium salt higher than about 1.5 × 10^{-4}M, this peak is ill separated from peak i_{P2} and is difficult to measure, but seems to be independent of concentration of the diazonium salt. It may be the adsorption prewave to the process occurring at peak i_{P2}. Indication of a corresponding anodic peak seems to be in agreement with this assumption.

The peak-current i_{P2} increases linearly with the concentration of the diazonium salt up to about 1 × 10^{-4}M. Deviations from linearity at higher concentrations (Fig. 4) indicate diffusion-controlled electrode process perturbated by adsorption (22, 24), in agreement with conclusions reached for d-c curves i_1 and i_2. Dependence of the peak potential of peak i_{P2} on concentration of the diazonium salt (Table III) may be due to adsorption and to a consecutive chemical reaction, second order (or higher) in the product of the one-electron transfer (25).

The peak current i_{P3} at sweep rates higher than 5 $Vsec^{-1}$ shows also a nonlinear dependence on diazonium salt concentration. The greater deviation from linearity for i_{P3} than i_{P2} is attributed to the desorption process occurring in this potential range (Fig. 2C). The origin of the dependence of the peak potential of i_{P3} on concentration of the diazonium salt may be similar to that of peak i_{P2}, even when the characteristics (Table III) of these two dependences are different.

Dependence of the reduction peak i_{P2} and the oxidation peak $i_{P2}{}^a$ on the rate of scanning (Table III, Fig. 5) indicates that a single oxidation-reduction couple is involved. At sufficiently high sweep rates the system is reversible, as indicated by the increase in ratio $i_{P2}{}^a/i_{P2}$ (Fig. 6) and by variation of the potential of peak i_{P2} with logarithm of the scanning rate (Fig. 7) (25, 26). At slower sweep rates the characteristics indicate the presence of an irreversible chemical reaction following the uptake of the first electron. The

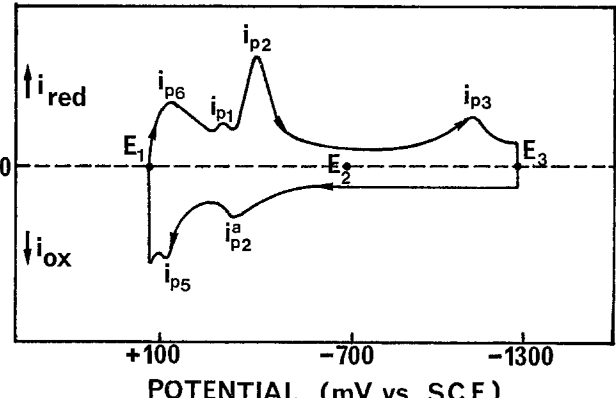

Fig. 3. General shape of the cyclic voltammogram of an aqueous solution of paratolyldiazonium fluoborate. pH = 5, T = 4°C. Buffered paratolyldiazonium solution (McIlvain buffer) $NaClO_4$ 10^{-1}M, $C \leq 2 \times 10^{-4}$M. 2 $Vsec^{-1} \leq v \leq$ 100 $Vsec^{-1}$. E_{P1} = +100 mV, E_{P2} = −700 mV, E_{P3} = −1300 mV *vs.* SCE.

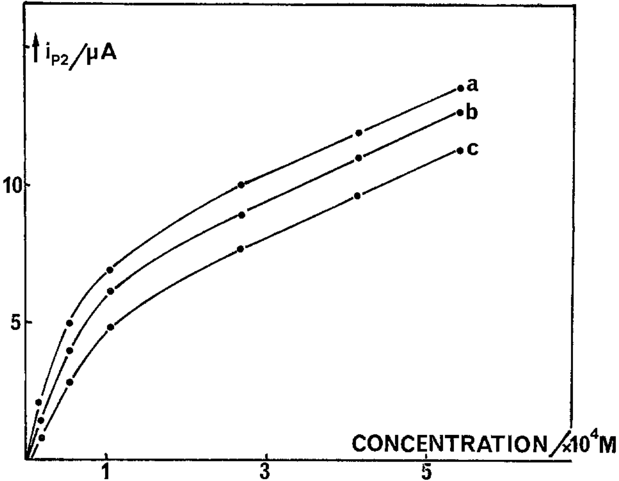

Fig. 4. Evolution of peak i_{P2} with the concentration of the solutions. Paratolyldiazonium solution $NaClO_4$ 10^{-1}M. pH = 4, T = 4°C, E_1 = +100 mV *vs.* SCE. (a): v = 100V × sec^{-1}; (b): v = 50V × sec^{-1}; (c): 20V × sec^{-1}.

role of adsorption is reflected in the large slopes of the dependence of the peak-potential on v (Fig. 7).

As frequently observed the shape of the cyclic voltammograms depends on the potential range applied and the direction of the sweep (Fig. 8)

Complete sweeping range: (E_1 = 100 mV, E_3 = − 1.3V *vs.* SCE). For a forward sweep starting from E_1 toward E_3 (Fig. 8A), the voltammogram has been described above (Fig. 3). For a forward sweep starting from E_3 toward E_1, i_{P2} and i_{P3} are notably lowered, i_{P4} disappears, and i_{P5} is much increased (compare Fig. 8B and Fig. 8A).

Shortened sweeping range: (E_1 = 100 mV, E_2 = − 700 mV, E_3 = − 1.300V *vs.* SCE). When the forward sweep starts from E_3 toward E_2, the peak i_{P3} is not ob-

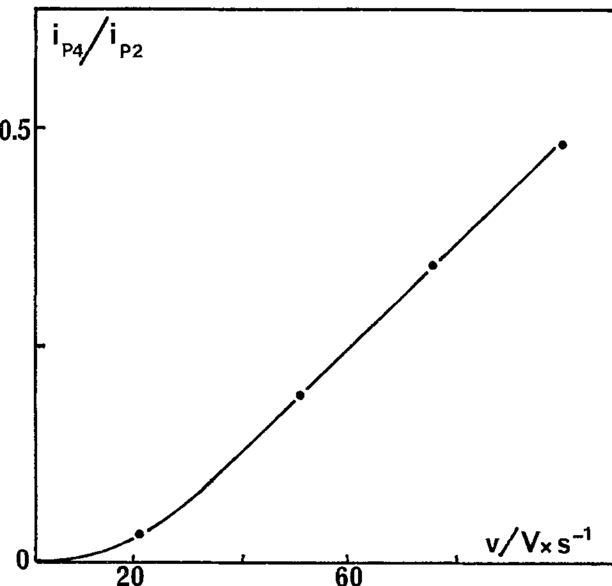

Fig. 6. Evolution of the ratio $i_{p2}{}^{a}/i_{p2}$ with the sweep rate. Paratolyldiazonium solution C = 1.25 × 10^{-4}M, pH = 4, T = 4°C, $NaClO_4$ 10^{-1}M, $E_1 = +100$ mV vs. SCE.

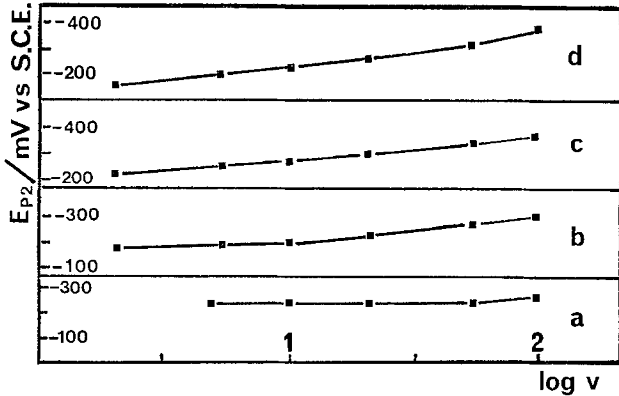

Fig. 7. Variation of peak potential E_{p2} with the sweep rate: $E_{p2} = f$ (log v) $NaClO_4$ 10^{-1}M. pH = 4, T = 4°C, E_1 = +100 mV vs. SCE. Paratolyldiazonium concentration: (a) C = 1 × 10^{-5}M; (b) C = 5 × 10^{-5}M; (c) C = 10 × 10^{-5}M; (d) C = 53 × 10^{-5}M.

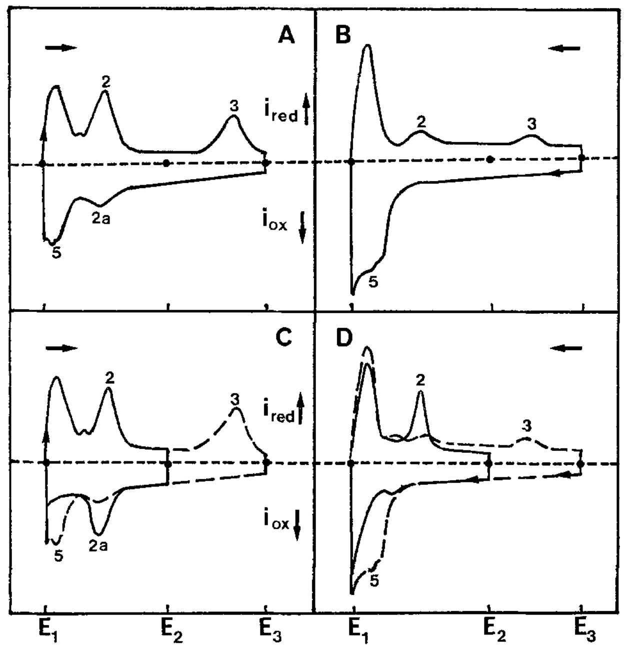

Fig. 8. Evolution of a cyclic voltammogram with sweeping range and direction of sweeping. Paratolyldiazonium solution C = 1.25 × 10^{-4}M, pH = 4, T = 4°C; $NaClO_4$ 10^{-1}M. (A) v = 50V × sec^{-1}, forward sweep from E_1 to E_3; (B) v = 50V × sec^{-1}, forward sweep from E_3 to E_1; (C) v = 50V × sec^{-1} [forward sweep from E_1 to E_2 (solid line)]; [forward sweep from E_1 to E_3 (dashed line)]; (D) v = 50V × sec^{-1} [forward sweep from E_2 to E_1 (solid line)]; [forward sweep from E_3 to E_1 (dashed line)].

served. When the forward sweep starts from E_2 toward E_1, the peak i_{P5} disappears and the peak i_{P2} increases (Fig. 8D). When the forward sweep reversed from E_1 toward E_2, the peak i_{P4} is again observed, and is much higher than when the sweeping range is extended up to E_3 (Fig. 8C). Oxidation peak i_{P5} appears and disappears simultaneously with peak i_{P3} when the sweeping conditions are modified. Peak i_{P5} is therefore due to oxidation of the species resulting from the reduction step i_{P3}.

A solution of the primary hydrazine $Ar-\overline{N}H-\overline{N}H_2$ in a buffered aqueous solution leads to a cyclic voltammogram showing an oxidation peak identical with i_{P5} when the forward sweep starts from E_3 toward E_1. The formation of hydrazine by the electrochemical reduction of the diazonium salt is therefore highly probable at the potential of the peak i_{P3}.

Controlled potential electrolysis.—Controlled potential electrolysis was carried out at low concentrations of the diazonium salt (7 × 10^{-4}M) on a small mercury pool cathode (area 5 cm^2) to carry out coulometry and at higher concentrations (1.2 × 10^{-2}M) with a large mercury pool electrode (area 44 cm^2) and large volume of the solution (300 ml) for electrosynthetic studies.

Coulometric measurements at potentials corresponding to limiting currents i_1 or i_2 yield $n = 1$. After exhaustive electrolysis all waves i_1-i_4 disappear simultaneously and no oxidation or reduction wave is formed. The product of the first electron uptake is thus electroinactive under conditions used, probably due to a consecutive chemical reaction such as formation of organomercury compounds.

When the coulometric electrolysis was carried out at the limiting current of wave i_3 the value of n obtained was significantly smaller than 2 (Table IV). This indicates competitive chemical reaction of the product of the one-electron reduction, such as formation of organomercury compounds. Such a reaction is faster for p-methyl than p-methoxy derivative (Table IV) and is slower at 4°C than at 25°C. Products formed at the limiting current of wave i_3 yield neither oxidation nor reduction waves.

Table IV. Coulometric measurements

Ar	Wave i_1 Q_1		Wave i_2 Q_2		Wave i_3 Q_3		Wave i_4 Q_4		Hydrazine yield	
	$t = 25°C$	$t = 4°C$	$t = 25°C$	$t = 4°C$	$t = 25°C$	$t = 4°C$	$t = 25°C$	$t = 4°C$	$t = 25°C$	$t = 4°C$
CH_3—	1	1	1	1	1.3	1.8	2.4	3.5	5%	36%
CH_3—O—	1	1	1	1	1.7	1.9	3.6	3.8	32%	65%

Similarly, electrolysis at the limiting current of wave i_4 yields the value of n smaller than 4 (Table IV), the value of n being larger for p-OCH_3 than p-CH_3 derivative and in both cases larger at 4°C than at 25°C. Solution of the electrolysis product yields an oxidation wave, identical in wave-shape and half-wave potential with the wave of a corresponding hydrazine Ar—NH—NH_2 recorded under identical conditions.

The height of anodic wave in the solutions electrolyzed at the limiting current of wave i_4 was used to determine yields of the hydrazine (Table IV). These yields were higher for the p-OCH_3 than for the p-CH_3 derivative and in both instances higher at 4°C than at 25°C.

All these experiments indicate that the radical formed in the reduction of the p-methyl derivative is more reactive toward metallic mercury than the corresponding p-methoxy derivative.

Electro-oxidation at the potential corresponding to the limiting current of the oxidation wave of the hydrazine Ar—NH—NH_2 yielded a solution in which the current-voltage curve obtained with a DME resembled that obtained with a dilute solution of the diazonium salt. The possibility of oxidation of the hydrazine partly to a diazonium salt is being further investigated.

Preparative electrolysis in more concentrated solutions of diazonium salts at the potential corresponding to the limiting current of waves i_1 and i_2 yielded the diaryl derivative Ar—Hg—Ar in 90% yield.

Electrolysis at the limiting current of wave i_4 at low temperature (4°C), with a moderate stirring of the mercury pool (*cf.* Experimental) in a buffer of pH 2 yielded 10% of the mercury derivative Ar—Hg—Ar, 8% of the symmetrical hydrazine Ar=NH—NH—Ar, and 57% of the primary hydrazine Ar—NH—NH_2 for p-CH_3 and 80% for p-OCH_3 derivatives. When conditions of electrolysis (stirring, temperature) were not optimized, up to 30% of the symmetrical hydrazine was formed.

Conclusion

Experimental evidence indicates the following sequence of reactions

$$Ar-\overset{+}{N}\equiv N + e \rightleftarrows (Ar-\overset{-}{N}=\overset{\cdot}{N})\text{ads} \qquad i_1 \qquad [1]$$

$$Ar-\overset{+}{N}\equiv N + e \rightleftarrows (Ar-\overset{-}{N}=\overset{\cdot}{N})\text{free}, \qquad i_2 \qquad [2]$$

$$2Ar-\overset{-}{N}=\overset{\cdot}{N} + Hg \rightarrow Ar-Hg-Ar + \overset{-}{N_2} \qquad [3]$$

$$Ar-\overset{-}{N}=\overset{\cdot}{N} + H^+ \rightleftarrows Ar-\overset{+}{N}H=\overset{\cdot}{N} \qquad [4]$$

$$Ar-\overset{+}{N}H=\overset{\cdot}{N} + e \rightarrow Ar-\overset{-}{N}H-\overset{-}{N}\square, \qquad i_3 \qquad [5]$$

$$2Ar-\overset{-}{N}H-\overset{-}{N}\square \rightarrow Ar-\overset{-}{N}H-\overset{-}{N}H-Ar + \overset{-}{N_2} \qquad [6]$$

$$Ar-\overset{-}{N}H-\overset{-}{N}\square + 2H^+ \rightleftarrows Ar-NH=NH_2^{2+} \qquad [7]$$

$$Ar-NH=NH_2^{2+} + 2e \rightarrow Ar-NH-NH_2 \qquad i_4 \qquad [8]$$

$$Ar-NH-NH_2 + H^+ \rightleftarrows Ar-NH-NH_3^+ \qquad [9]$$

Thus the present paper demonstrates formation of a primary hydrazine derivative by a direct electrochemical reduction of the corresponding diazonium fluoborate.

Lower temperature and the presence of electropositive substituents on the phenyl ring favor formation of hydrazine and minimize the importance of competitive chemical side-reactions. The scaling-up of the electrochemical synthesis of hydrazines and behavior of other substituted aromatic diazonium fluoborate are under investigation.

Influence of pH on the Potential Dependence of the Efficiency of Water Photo-oxidation at n-TiO_2 Electrodes

P. Salvador

Instituto de Catálisis y Petroleoquímica, C.S.I.C., Serrano, 119, Madrid-6, Spain

ABSTRACT

The measurement of photocurrent *vs.* electrode potential at different electrolyte *p*H shows the quantum efficiency for water photo-oxidation to be *p*H dependent. These results are interpreted in terms of surface OH^- groups and physisorbed OH^- ions acting as intermediates in a double mechanism of hole trapping and charge transfer at the semiconductor/electrolyte interface. The experimental data are analyzed according to Wilson's model for the electrochemical behavior of semiconducting photoexcited electrodes, which introduces as new parameters surface electron transfer and surface recombination rates. This analysis leads to a maximum density of surface centers for charge transfer of the order of 10^{14} cm^{-2}.

The use of n-type wide-bandgap semiconducting materials as photoelectrodes in photoelectrochemical cells has been widely developed since Füjishima and Honda (1) reported in 1972 that water could be photoelectrolyzed at an n-TiO_2 electrode illuminated with u.v. light.

It is well established that water photoelectrolysis in a photoelectrochemical cell (pec) is the result of two processes. First, photons are absorbed by the semiconductor (SC) and generate electron-hole pairs. Those pairs generated within the depletion layer are separated by the electrostatic field, the electrons migrating toward the bulk and the holes toward the surface. The efficiency for the photogeneration of holes at the surface is controlled by the electronic and optical parameters of the SC (2). In a second process the holes reaching the surface react with electrons transferred from reducing species in the electrolyte. The global reaction is

$$2H_2O + 4h^+ \rightarrow O_2\uparrow + 4H^+$$

The mechanisms by which the electron exchange between the SC and the electrolyte takes place are not well understood. If O_2 evolution is considered to proceed by electron tunneling through the Helmholtz layer from the electrolyte energy levels to the SC surface, only isoenergetic electron transfer is possible. Since the equilibrium redox level of the O_2/OH^- couple lies at the middle of the forbidden band TiO_2 (3), very small overlapping with the valence band should be expected, and very low photocurrents for O_2 evolution should be obtained. However, it is observed experimentally that quantum efficiencies near 100% can be reached (4), which suggests that a different mechanism to that of direct injection of electrons from the electrolyte to the valence band must dominate the charge-transfer process. Most authors explain such a high charge transfer efficiency as being due to surface states overlapping filled states of water molecules (1, 5). The nature of these surface states is not well known. They could be preexisting states on the SC surface inherent to the nature of the solid, *e.g.*, structural defects. However, as suggested by Wilson (6), they could also be considered as electrolyte states sufficiently bound to the surface, so that the isoenergetic restriction on charge transfer could be relaxed.

In this paper we present experimental results dealing with the influence of the electrolyte *p*H on the O_2 evolution photocurrents at TiO_2 electrodes. These results provide some new information about the mechanism of charge transfer at the SC/electrolyte interface and on the nature of the surface sites active in water photo-oxidation.

Key words: interface charge transfer, photoelectrolysis of water, solar energy conversion.

Experimental

The rutile used in this work was obtained from an anatase powder (99.9%, Degussa) by heating at 800°C for several hours. Rutile powder, pressed into a disk of 1 cm^2 area and 0.05 cm thickness, was sintered in air at 1200°C for 2 hr and then reduced in H_2 atmosphere at 800°C for 20 min. One side of the disk was aluminum-metallized, and a copper wire was attached to it with Ag epoxy. The contact was then sealed with epoxy resin.

The cell, built of Pyrex glass with a quartz window, consisted of the photoelectrode, a platinized Pt counterelectrode, and an SCE reference electrode. Electrolytes, from *p*H 6.4-13.3, were prepared from a 0.5M Na_2SO_4 solution to which different quantities of a 0.1M KOH solution were added. Bidistilled water and reagent grade chemicals were used. The photoelectrode was illuminated with a 150W Xe lamp followed by a Bausch and Lomb grating monochromator. Steady-state current *vs.* potential curves were obtained, point by point, with a microammeter and a $10^9\Omega$ digital millivoltmeter. To minimize possible diffusion effects near the electrode surface, the electrolyte was mechanically stirred during the experiments.

Mott-Schottky plots were used to estimate donor concentrations. Capacitance measurements of the photoelectrode/electrolyte/Pt system were carried out with a General Radio 1650A impedance bridge at 1 kHz. The electrode potentials are given *vs.* SCE.

The photon flux reaching the electrode was determined by means of a calibrated E.G. & G. 4000B silicon photovoltaic detector. Reflection losses at the cell window and electrode surface were estimated to be of the order of 10%.

Results

Photocurrent pH dependence.—Figure 1 shows typical photocurrent *vs.* electrode potential curves, at 360 nm, for different *p*H values. The photocurrent efficiency, η, is defined as

$$\eta = \frac{i_{(light)} - i_{(dark)}}{qI_o}$$

where $i_{(light)}$ and $i_{(dark)}$ are current densities under il-

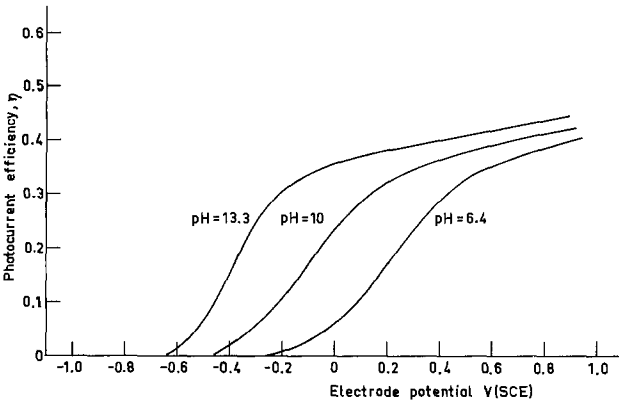

Fig. 1. Steady-state current *vs.* potential curves for TiO_2 at different electrolyte *p*H, under illumination with u.v. light (λ = 360 nm). The *p*H of the electrolyte (0.5M Na_2SO_4 solution) was adjusted by addition of KOH.

lumination and at dark, respectively, I_o represents the flux of photons absorbed by the electrode ($I_o \simeq 12 \times 10^{15}$ cm^{-2} · sec^{-1}), and q is the electronic charge.

At constant electrode potential, η depends on the electrolyte *p*H. On the other hand, the potential of zero efficiency shifts toward negative values when the *p*H is increased. This shift is about -0.4V for a *p*H increase of 7 units, which is in agreement with the flatband potential shift of -0.059V/*p*H unit expected for metal oxides (7). To compare quantum efficiencies for different *p*H values the curves in Fig. 1 are replotted by referring the voltage scale to the flatband potential (V_{FB}). Figure 2 shows a plot of η *vs.* the band bending ($V - V_{FB}$). Flatband potentials for different *p*H values were calculated by taking $V_{FB} = -0.9$V *vs.* (SCE) for pH = 13.3 (7) and assuming that $dV_{FB}/d_{pH} = -0.059$V. The V_{FB} values so obtained agree quite well with those measured from the Mott-Schottky plots. It can be seen in Fig. 2 that for a constant value of the band bending η increases with increasing *p*H. This effect has a tendency to decrease as the bands are flattened ($V \rightarrow V_{FB}$). For high band bending the *p*H effect seems to disappear.

Donor concentration.—For N_D a value of 10^{19} cm^{-3} was taken, which represents the average value of the donor concentration calculated from capacitance measurements ($N_D = 8.7 \times 10^{18}$ cm^{-3}) and from photocurrent spectral distribution ($N_D = 1.4 \times 10^{19}$ cm^{-3}) (8).

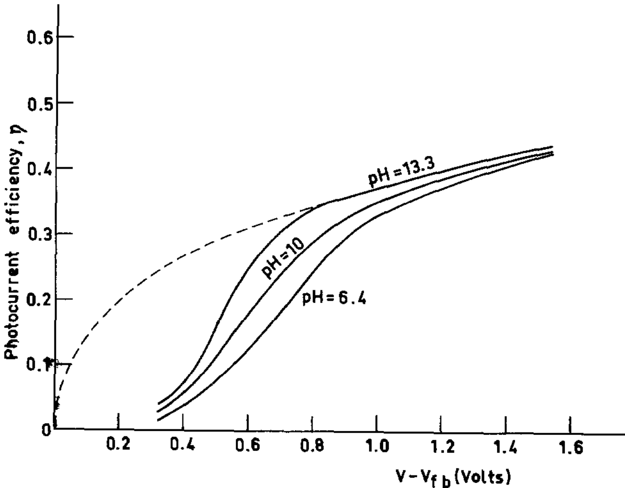

Fig. 2. Plot of photocurrent efficiencies *vs.* band bending from data of Fig. 1. Dotted line represents the theoretical quantum efficiency for negligible electron-hole bulk recombination (Eq. [18]).

Discussion

The TiO_2/electrolyte interface.—It is well known that TiO_2 has a great tendency to hydration. According to Munuera *et al.* (9), in a fully hydrated anatase, the amount of adsorbed water is approximately equivalent to a monolayer of hydroxyl groups. About half a monolayer ($\simeq 5 \times 10^{14}$ H_2O/cm^2) corresponds to molecular water loosely bound to the surface. Two-thirds of the remaining water ($\simeq 3 \times 10^{14}$ OH/cm^2) is composed of acidic OH groups and the remaining one-third (about 2×10^{14} cm^{-2}) are the OH^- ions, most strongly attached to the surface, with a marked basic character.

When TiO_2 is in equilibrium with an aqueous medium (electrolyte) the above situation changes. Besides the chemisorbed OH groups, OH^- and H^+ ions, whose bulk concentrations depend on *p*H, are specifically adsorbed. The point of zero zeta potential (pzzp) represents the *p*H at which the net surface charge is zero, or the concentration of adsorbed OH^- and H^+ ions is the same. For TiO_2 pzzp $\simeq$ 5.8 (7), *i.e.*, at this *p*H the potential drop in the Helmholtz layer due to adsorbed H^+ and OH^- ions is zero. Any increase of the *p*H above the pzzp means an increase of the number of OH^- ions adsorbed, the net surface charge becoming negative. The opposite happens for *p*H $<$ 5.8, *i.e.*, the net surface charge becomes positive because of the excess of adsorbed H^+ ions. In the first case, the potential drop across the Helmholtz layer is negative, while it is positive in the second case. The result is that the flatband potential shifts by about 0.06V per *p*H unit (7).

As a first approximation the Helmholtz layer can be considered as a flat capacitor, whose capacity is (10)

$$C_H = \frac{Q_S}{\phi_H} \qquad [1]$$

where Q_S is the net charge adsorbed and ϕ_H the potential drop in the Helmholtz layer. $Q_S = q \cdot \Delta N_{ad}$ (electronic charge times the surface ion excess) and $\phi_H = \Delta V_{FB}$, so expression [1] becomes

$$C_H = \frac{q \cdot \Delta N_{ad}}{\Delta V_{FB}} \qquad [2]$$

It must be remarked that Q_S is the result of an excess of both physisorbed and chemisorbed OH^- ions. Therefore, we must write $\Delta N_{ad} = \Delta N_{chem} + \Delta N_{phys}$, distinguishing the excess of surface OH^- groups, ΔN_{chem}, from the excess of physisorbed OH^- ions, ΔN_{phys}.

The experience with metals (11) shows that the overall differential capacitance of the double layer has a constant value determined by the oriented sheet of water dipoles in direct contact with the surface. The situation with semiconductors could be different. Recent experiments on TiO_2 electrodes (12) seem to show a small systematic variation of the Helmholtz layer capacitance with *p*H, from 64 ± 20 μ**F** · cm^{-2} for pH = 2.7 to 31 ± 10 μ**F** · cm^{-2} for pH = 13. However, in view of the large standard deviations, any conclusion about these variations is unwarranted. In any case, taking for C_H an average value, we can write

$$\frac{\Delta N_{ad}}{\Delta pH} = \frac{\Delta N_{ad}}{\Delta V_{FB}} \frac{\Delta V_{FB}}{\Delta pH} = \frac{C_H}{q} \frac{\Delta V_{FB}}{\Delta pH}$$
$$= 1.8 \times 10^{13} \text{ cm}^{-2}/pH$$

According to this, for an increase of the electrolyte *p*H from 6.4 to 13.3, the surface excess of OH^- ions increases by 1.2×10^{14} cm^{-2}.

The mechanisms of charge transfer.—Among the mechanisms proposed to explain the generation of photocurrents upon absorption of u.v. light by TiO_2, the most acceptable is, in our opinion, that in which

surface OH^- groups and Ti^{3+} ions act as hole traps and donor centers, respectively

$$p^+ + OH^-_{surf} \rightarrow OH^o_{surf} \quad [3]$$

$$e^- + Ti^{+4} \rightarrow Ti^{+3} \quad [4]$$

where OH^o_{surf} denotes adsorbed OH radicals. Reaction [4] represents the bulk majority carrier process. Under high enough anodic polarization electron and holes are efficiently separated by the electric field. Holes reach the hydrated surface

$$p^+ + Ti^{+4} - OH^- \rightarrow Ti^{+4} - OH^o \quad [5]$$

while the electrons migrate toward the bulk. However, near the flatband potential electrons can reach the surface where they could recombine with the holes

$$e^- + Ti^{+4} - OH^o \rightarrow Ti^{+3} - OH^o \rightarrow Ti^{+4} - OH^- \quad [6]$$

If reaction [5] prevails over [6], oxygen is evolved possibly according to the following reaction between surface OH^o radicals

$$2(Ti^{+4} - OH^o) \rightarrow 2(Ti^{+4} - \square) + H_2O_2$$
$$\rightarrow 2(Ti^{+4} - \square) + H_2O + 1/2\, O_2\uparrow \quad [7]$$

Where $\square$ denotes OH vacancies at the surface. Afterward the vacancies will be filled by physisorbed OH^-

$$Ti^{+4} - \square + OH^-_{phys} \rightarrow Ti^{+4} - OH^-_{surf} \quad [8]$$

and the initial state of the surface is reestablished. Experiments of irradiation of hydrated TiO_2 powders give evidence that both H_2O_2 (13, 14) and OH^o radicals (15) are formed on the TiO_2 surface, which point in favor of the mechanisms proposed in [5] and [7].

On the other hand, although OH^o radicals seem to be loosely bound to the surface (16) and can diffuse bidimensionally, leading to reaction [7], the rehydroxylation process should be too slow to explain the very high turnover number for O_2 evolution. However, this difficulty disappears if instead of surface OH^o radicals, either physisorbed OH^- or water molecules are considered to participate in a process of charge transfer (17)

$$Ti^{+4} - OH^o_{surf} + OH^-_{phys}$$
$$\rightarrow Ti^{+4} - OH^-_{surf} + OH^o_{phys} \quad [9]$$

$$Ti^{+4} - OH^o_{surf} + (HOH)_{phys}$$
$$\rightarrow Ti^{+4} - OH^-_{surf} + OH^o + H^+ \quad [9']$$

$$2\, OH^o_{phys} \rightarrow H_2O_2 \rightarrow H_2O + 1/2\, O_2\uparrow \quad [10]$$

According to this alternative model, surface OH^- groups act as intermediates for hole trapping, while physisorbed OH^- ions must be considered as charge carrier electrolyte species, strongly bound to the surface, participating in a process of charge transfer between the SC and the electrolyte. Electron injection from these species to the SC (surface OH^o radicals) could happen directly without necessity of a tunneling process (18).

The photocurrent pH dependence.—Several photoelectrochemical reactions are known where electrolyte composition has a remarkable influence on the intensity of the photocurrents. For α-Fe_2O_3 electrodes, Kennedy and Frese (19) showed that the photocurrent depends on citrate concentration according to: $\Delta\eta \propto \ln\,[\text{citrate}]$. These authors assumed that the photocurrent's increase was proportional to the surface coverage of citrate ions, θ, which follows a Temkin isotherm (*i.e.*, $\theta = \text{const.} + kT \ln\,[\text{citrate}]$), but they do not propose any mechanism to explain this effect.

In an attempt to interpret the effect of Na_2S concentration in suppressing corrosion of CdS electrodes, Wilson (20) has given a mathematical model that treats adsorbed species as surface charge transfer states, which allows a quantitative approach to the role of adsorbed species in the charge transfer process at the SC/electrolyte interface. In addition to the semiconductor physical properties, Wilson's model takes into account, as new parameters to describe the behavior of the SC/electrolyte system, the surface recombination rate, S_r and the interface electron transfer rate, S_t (6).

At flatband potential S_r is defined by

$$S_r = \int_{E_v}^{E_c} v\sigma_r N_r(E)\, dE \quad [11]$$

where E_c and E_v are the energies of the low limit of the conduction band and of the upper limit of the valence band, respectively, v is the thermal velocity of the holes, σ_r is the hole capture cross section of the recombination centers, and $N_r(E)$ is the density of recombination centers at the surface. As the band bending increases the electrons are forced to migrate toward the bulk under the space-charge electrical field, and the surface recombination rate decreases. The voltage dependence of S_r is given by (6)

$$S_r = \int_{E_v}^{E_c} \frac{v\sigma_r N_r(E)\, dE}{1 + \exp\,(E - E_f)/kT} \quad [12]$$

where q is the electronic charge, k is the Boltzmann constant, T is the absolute temperature, and E_F is the energy Fermi level at the bulk for a given applied voltage.

S_t can be described in terms of a surface density of charge transfer centers, $N_t(E)$, their cross section for interaction with holes in the valence band at the electrode surface σ_t, and the surface hole thermal velocity, v (6)

$$S_t = \int_{E_v}^{E_c} v\sigma_t N_t(E)\, dE \quad [13]$$

From an electrochemical point of view, N_t is a density of intermediate states for charge transfer, which can be eventually identified with adsorbed species (20).

According to the charge transfer model proposed, in our case N_t should correspond to the density of adsorbed OH^- groups (*i.e.*, $N_t = N_{ad}$), this being proportional to the electrolyte pH, that is, to log $[OH^-]$. If for simplicity we suppose a single energy level for N_t, Eq. [13] can be written

$$S_t = N_{ad}\sigma_t v \quad [14]$$

The fraction of holes reaching the surface that contributes to the photocurrent, P, must be

$$P = \frac{S_t}{S_r + S_t} \quad [15]$$

where we have assumed that all the holes that reach the surface recombine either with bulk free electrons or with electrons from the electrolyte.

An estimation of P from the experimental data of Fig. 2 is not difficult. In fact, according to Eq. [15], P represents the number of holes crossing the interface, relative to the total number of holes, I, reaching the electrode surface

$$P = \frac{\eta I_o}{I} \quad [16]$$

Carrier lifetimes in TiO_2 seem to be determined by a diffusion controlled bulk recombination process, and the hole diffusion length for $(V - V_{FB}) > 0$ is negligible compared to the width of the depletion layer (8). In this case, the holes generated outside the depletion layer will not contribute significantly to the photocurrent. Moreover, as long as the hole lifetime, τ_p, is the reciprocal of the number of collisions between electrons and holes leading to recombination, the value

of τ_p should be larger in the depletion layer than in the bulk, exceeding the respective transit time value. Therefore, all the holes generated within the electrical field region should reach the interface, and I in Eq. [16] could be identified with the number of photons absorbed within the space charge layer

$$I = I_o [1 - \exp(-W\alpha)] \qquad [17]$$

α being the optical absorption coefficient and W the space charge layer width (21)

$$W = \left[\frac{2\epsilon\epsilon_o}{qN_D} (V - V_{FB}) \right]^{1/2} \qquad [18]$$

where ϵ is the dielectric constant of the semiconductor and ϵ_o the vacuum permittivity, the other parameters having been already defined. The dotted line in Fig. 2 is a plot of I/I_o *vs.* $(V - V_{FB})$ (Eq. [17]). α has been taken to be 10^5 cm^{-1} at $\lambda = 360$ nm.

From the data in Fig. 2, by applying Eq. [16], a plot of P *vs.* $(V - V_{FB})$ for the three different pH values used is obtained (Fig. 3). As can be seen, at a given pH, P decreases as $(V - V_{FB})$ decreases which was expected according to Eq. [12]. Moreover, for low band bending $S_r > S_t$, which is in agreement with the statement that, in this situation, surface recombination is the dominant reaction (6). By contrast, at high enough band bending, the influence of S_r virtually disappears, and a situation dominated by charge transfer is established. An intermediate situation is that for $S_r = S_t$ ($P = 0.5$), whose analysis is very simple. In fact, from Eq. [15], for $S = S_t$, we can write

$$\left(\frac{dP}{dpH}\right)_{pH=6.4} = \frac{1}{4S_t}\left(\frac{dS_t - dS_r}{dpH}\right)_{pH=6.4} \qquad [19]$$

From Fig. 3 a plot of P *vs.* pH for different values of $V - V_{FB}$ is shown in Fig. 4. As can be seen the dependence is practically linear.

Let us now analyze with detail the experimental data of Fig. 4 by using Eq. [19]. For $(V - V_{FB}) = 0.6$ and pH = 7.8 it is $P = 0.5$ and Eq. [19] becomes

$$\left(\frac{dP}{dpH}\right)_{(V-V_{FB})=0.6} = 0.06$$

$$= \frac{1}{4}\frac{1}{(S_t)_{pH=7.85}}\left(\frac{dS_t}{dpH} - \frac{dS_r}{dpH}\right)_{(V-V_{FB})=0.6} \qquad [20]$$

Equation [19] also applies for $(V - V_{FB}) = 0.5$ and pH = 12.3; therefore we can write

$$\left(\frac{dP}{dpH}\right)_{(V-V_{FB})=0.5} = 0.042$$

$$= \frac{1}{4}\left(\frac{1}{S_t}\right)_{pH=12.3}\left(\frac{dS_t}{dpH} - \frac{dS_r}{dpH}\right)_{(V-V_{FB})=0.5} \qquad [21]$$

According to Eq. [14], we know that $dS_t/dpH = dN_{ad}/dpH\sigma_t v$. The hole capture cross section of surface states is, according to Wilson (22), between 10^{-16} and 10^{-17} cm^2. This value is considerably smaller than that obtained from geometrical considerations if surface states were localized on single atoms, probably due to poor electronic or phonon coupling between the states and the semiconductor (22). A value of $v = 10^7$ cm/sec can be taken for hole thermal velocity. So, we have

$$\frac{d_{St}}{dpH} \simeq 1.8 \times 10^3 \text{ cm/sec} \qquad [22]$$

Experiments with electrodes with different doping levels seem to show that S_t does not depend on the voltage through the surface field. Therefore, Eq. [22] is considered to be valid for any $(V - V_{FB})$ value.

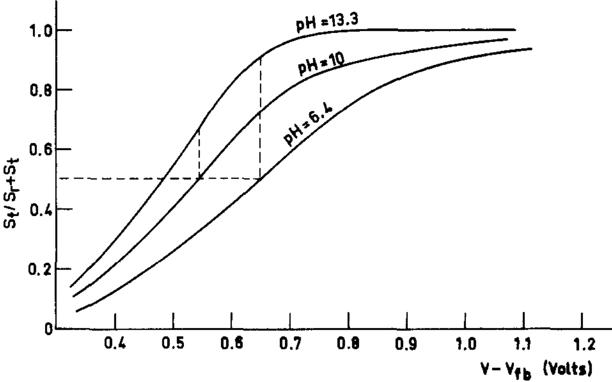

Fig. 3. Plot of the fraction P of holes contributing to the photocurrent (S_t), relative to the number of holes reaching the SC/electrolyte interface ($S_r + S_t$), vs. voltage, for different pH values, calculated from data of Fig. 2.

With respect to dS_r/dpH, the question arising is whether surface states involved in the charge transfer process are, to some extent, responsible for surface recombination. According to Wilson (22), adsorbed species could act as recombination centers, which means that S_r may be increased by adsorption ($dS_r/dpH > 0$). However, there is the possibility that recombination centers were related to preexisting surface states inherent to the solid on which adsorption takes place. In this case, it should be $dS_r/dpH < 0$. In both cases a linear dependence of S_r on pH should be expected. Finally, it could happen that $dS_r/dpH = 0$, *i.e.*, that surface recombination is unaffected by adsorption of electrolyte species.

Let us calculate S_t from Eq. [20] and [21] for different values of dS_r/dpH. This is shown in Table I. As can be seen the only values of dS_r/dpH leading to reasonable values of S_t are those for either $dS_r/dpH = 0$ or $dS_t/dpH > dS_r/dpH \gtrless 0$. However, the best agreement between $(S_t)_{pH} = 7.85$ and $(S_t)_{pH} = 12.3$ is obtained for $dS_r/dpH \simeq -10^{-3}$ cm/sec.

On the other hand, for small values of P, *i.e.*, for $S_r >> S_t$, derivation of Eq. [15] leads to the following approximation

$$\frac{dP}{dpH} = \left(\frac{1}{S_t}\frac{dS_t}{dpH} - \frac{1}{S_r}\frac{dS_r}{dpH}\right)\frac{S_t}{S_r} \qquad [23]$$

For pH = 7.85 and $(V - V_{FB}) = 0.35$, we have in Fig. 4 $P \simeq 0.1$, and Eq. [23] should apply. Therefore we can write

$$\frac{dP}{dpH_{(V-V_{BF})=0.35}} = 0.014 = \left[\left(\frac{1}{S_t}\right)_{pH=7.85}\left(\frac{dS_t}{dpH}\right) - \left(\frac{1}{S_r}\right)_{pH=7.85}\left(\frac{dS_r}{dpH}\right)\right] \times 0.11 \qquad [24]$$

that can also be used to calculate $(S_t)_{pH=7.85}$. The results are included in the last column of Table I. As we supposed that S_t does not depend on the applied voltage, the correct value of dS_r/dpH should be that giving the best agreement between the two values of $(S_t)_{pH=7.85}$ obtained from Eq. [20] and [23], respectively. This is reached again for $dS_r/dpH \simeq -10^{-3}$ cm/sec. According to Table I the corresponding values for S_t are $(S_t)_{pH=7.85} \simeq 10^4$ cm/sec and $(S_t)_{pH=12.3} \simeq 2 \times 10^4$ cm/sec. Therefore, the maximum value of S_t, for pH = 14, should be of the order of 10^4-10^5 cm/sec, corresponding to a maximum density of surface states for charge transfer $(N_{ad})_{max} \simeq 10^{14}$ cm^{-2}. This value is in quite good agreement with the density of bandgap surface states obtained by Wilson (22), which comes to reinforce the idea that these could be intermediates of the reaction leading to O_2 evolution.

Table I. Values of dS_r/dpH and S_t compared with Eq. [20], [21], and [23], calculated from experimental data of Fig. 4

	1	2	3	4	5
	$\frac{dS_r}{dpH}$ (cm/sec)	$(S_t)_{pH=7.85}$ $(V - V_{FB}) = 0.6$ (cm/sec)	$(S_t)_{pH=12.3}$ $(V - V_{FB}) = 0.6$ (cm/sec)	$(S_t)_{pH=12.3}$ $(V - V_{FB}) = 0.5$ (cm/sec)	$(S_t)_{pH=7.85}$ $(V - V_{FB}) = 0.35$ (cm/sec)
$\frac{dS_r}{dpH} > \frac{dS_t}{dpH}$	10^5	-4×10^5		-5.8×10^5	-1.6×10^4
	10^4	-3.4×10^4		-4.9×10^5	4.7×10^3
	5×10^3	-1.3×10^4		-1.9×10^4	8.3×10^3
$\frac{dS_r}{dpH} = \frac{dS_t}{dpH}$	1.8×10^3	0		0	1.07×10^4
$0 < \frac{dS_r}{dpH} < \frac{dS_t}{dpH}$	1.2×10^3	2.5×10^3	1.05×10^4	3.6×10^3	1.1×10^4
	10^3	3.3×10^3	1.1×10^4	4.7×10^3	1.1×10^4
	10^2	7.1×10^3		9.0×10^3	1.2×10^4

Column 3. Values of S_t obtained from column 2 by adding $S_t = 8 \times 10^3$ cm/sec.
Column 4. Values of S_t obtained from Eq. [21].
Column 5. Values of S_t obtained from Eq. [23].

On the other hand, the maximum value for S_r near flatband must be at least two or three orders of magnitude greater than S_t. This implies a density of states for surface recombination greater than N_{ad} and, probably, the participation of a new type of recombination center, unless $\sigma_r > \sigma_t$. However, if we assume that $\sigma_r = \sigma_t$, the fact that $0 > dS_r/dpH \simeq - dS_t/dpH$ seems to indicate that surface recombination centers are destroyed by adsorption of electrolyte species at about the same rate that surface states for charge transfer are formed.

Conclusions

The experimental results reported in this paper, concerning the pH dependence of the photocurrents associated with the process of water photo-oxidation at TiO_2 electrodes, have been used to postulate a mechanism of charge transfer at the SC-electrolyte interface. This mechanism involves two steps. The first step involves surface hydroxyls (basic OH^-) as traps for holes generated by light, giving rise to the formation of OH^o radicals according to the reaction

$$Ti^{+4} - OH^-_{surf} + h^+ \rightarrow Ti^{+4} - OH^o_{surf}$$

In a second step one electron is transferred from one physisorbed electrolyte species $(OH^-)_{phys}$ to an OH^o_{surf} radical

$$Ti^{+4} - OH^o_{surf} + OH^-_{phys} \rightarrow Ti^{+4} - OH^-_{surf} + OH^o_{phys}$$

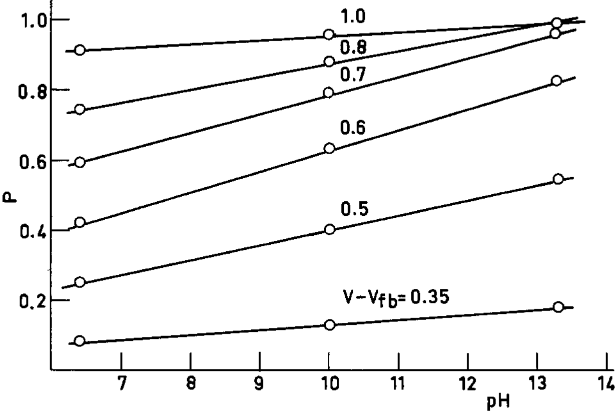

Fig. 4. Plot of P vs. pH for different values of $(V - V_{FB})$ from data of Fig. 3.

followed by reaction among absorbed OH^o_{phys} radicals and evolution of oxygen.

Adsorbed OH^- groups are considered as surface centers for charge transfer. The surface excess of these centers, N_{ad}, depends on the electrolyte pH, which accounts for the pH dependence of the photocurrent. A simple mathematical treatment of these results making use of surface recombination and surface electron transfer parameters as defined by Wilson (6), shows that the maximum surface concentration of such surface centers for charge transfer is of the order of 10^{14} cm^{-2}.

From a recent XPS study of hydrated rutile surfaces (23), evidence of two types of surface OH species (acid and basic) has been obtained. The O 1s and Ti 2p binding energies seem to indicate that the formation of OH^o radicals (reaction [1]) is easier from the basic OH^- groups singly bonded to Ti, because of the significant covalent character of this bond. An analogous conclusion about the role of chemisorbed basic OH^- in OH^o radical formation is also reached from experiments of photoadsorption-photodesorption of oxygen on TiO_2 hydroxylated surfaces (16). Accordingly, the density of surface centers active in hole capture should be of the order of 10^{14} cm^{-2} (9), which is in agreement with our maximum density of surface centers for charge transfer. On the other hand, it seems reasonable to believe that, due to the higher covalent character of the Ti-OH bond involving basic OH groups, the energy of their valence bonding orbitals should be lowered with respect to the O 2p level of surface oxygens doubly bonded to Ti. Therefore, the energy levels of these surface states should be somewhere in the bandgap, better overlapping the OH^-/O_2 redox level, and so allowing a more efficient isoenergetic charge transfer between SC and electrolyte.

With respect to the nature of surface recombination centers our experimental results do not allow any conclusion. It is probable that adsorbed OH^o radicals could behave as surface centers for recombination at or near the flatband situation (22). However, the participation of the other kind of centers, associated for instance to structural defects, in the process of surface recombination is necessary. This type of center seems to be blocked by adsorption of electrolyte species, thus contributing to a more rapid increase of the fraction of holes participating in photocurrent when the electrolyte pH is raised.

Ruthenium-Based Mixed Oxides as Electrocatalysts for Oxygen Evolution in Acid Electrolytes

R. S. Yeo,*[1] J. Orehotsky,* W. Visscher,* and S. Srinivasan*[2]

Department of Energy and Environment, Brookhaven National Laboratory, Upton, New York 11973

ABSTRACT

Ruthenium oxide, prepared by the thermal decomposition method, has the highest known initial electrocatalytic activity for oxygen evolution in acid electrolyte. However, this material is not stable in the electrolyte and at the same time exhibits a significant increase of oxygen overpotential with time, probably due to a chemical transformation of the oxide from a lower to a higher valence state. Efforts were made to stabilize ruthenium by preparing mixed oxides with Ir and/or Ta using the thermal decomposition method. The electrocatalytic activities for oxygen evolution on these oxides in $1N$ H_2SO_4 were determined using the potentiostatic method. The surface areas of these oxides were estimated using cyclic voltammetry. Dual Tafel slopes (approximately 30 and 40 mV) were found on most of these oxides. The ternary oxide ($RuIr_{0.5}Ta_{0.5}O_x$) exhibited a single Tafel slope of 30 mV, had the lowest overpotential, and showed minimum variation of overpotential with time.

Ruthenium oxide, produced by the thermal decomposition method (1), is one of the best electrocatalysts for chlorine evolution (2-5) and is being increasingly used as the anode in chlor-alkali cells (6). Ruthenium oxide exhibits the lowest overpotential initially for oxygen evolution (7-13) but this oxide is not stable in acidic environments and also the oxygen overpotential increases with time (14-16). Numerous plausible explanations have been proposed for these observations. The most likely one involves a consideration of the stoichiometry of this oxide material and of the associated valency state of the ruthenium cations.

Key words: electrocatalysis, oxygen evolution, ruthenium-based mixed oxides, defect oxides, dual Tafel slopes.

Ruthenium oxide produced by the thermal decomposition procedure is suggested to exist in a substoichiometric $RuO_x (x < 2)$ oxidation state (17-19) and the favorable electrocatalytic activity might then result from the mixed Ru^{3+}-Ru^{4+} cationic valencies present in this substoichiometric oxide. Since the metastable RuO_x is suspected to transform to the stable RuO_2 stoichiometry with its full complement of quadravalent ruthenium cations, the observed degradation during oxygen evolution conceivably could result from the gradual oxidation of the trivalent ruthenium cations. This explanation appears reasonable since RuO_2 is not a particularly attractive electrode material for oxygen evolution (20). It also implies that a nondegradable electrocatalytically active ruthenium oxide anode can be realized if the ruthenium cation can be stabilized in a mixed III-IV valency state.

Stabilization of mixed cation valency states frequently occurs in binary or ternary stoichiometric oxide compounds. Unfortunately, there are no reported oxide compounds where the ruthenium cations exist in the III-IV state (21). The objectives of this investigation were to fabricate several potentially promising equilibrium binary and ternary oxide compounds where the ruthenium cations hopefully exist in the mixed III-IV state and then to determine both the electrocatalytic activity and stability of these materials. Selecting the appropriate components for the binary and ternary compounds was a difficult task particularly because very little information is available about oxides that form compounds with ruthenium oxide (21-22) and, of the known compounds, the ruthenium cations usually exist in an oxidation state of four or more. Binary and ternary oxides containing ruthenium, iridium, and tantalum as the cationic constituents were used in this particular study. Tantalum was selected for its potential ability to stabilize the III-IV ruthenium valency state and for its corrosion resistance in an acid electrolytic medium (23). Iridium was chosen because of its reported electrochemical stability during oxygen evolution and because it is a possible agent for alloying tantalum and ruthenium oxides which appear to be immiscible as simple binaries.

Experimental

Electrode preparation.—Six titanium supported oxide electrodes of nominal compositions, RuO_x, IrO_x, $RuTaO_x$, $IrRuO_x$, $RuTa_{0.5}Ir_{0.5}O_x$, and $Ru_{0.5}TaIr_{0.5}O_x$ were prepared by the thermal decomposition method, similar to that reported in the patent literature (1) for the DSA anodes used in the chlor-alkali industry. The metal chloride salts were dissolved in the following manner: $RuCl_3 \cdot 1\text{-}3H_2O$ could easily be dissolved in either isopropyl alcohol or water, whereas $IrCl_3 \cdot 3H_2O$ was dissolved in isopropyl alcohol with addition of few drops of H_2O_2. Some difficulties were found in preparing an aqueous solution of $TaCl_5$. However, it could be dissolved in nonaqueous solvents (such as isopropyl alcohol). These metal chloride solutions were then mixed in the appropriate molar proportions to form solutions of the desired electrode compositions. The electrodes were formed by dipping titanium support structures into these solutions, heating the wetted structures over a hot plate to dryness, and then baking the structures in air at 350°C for 5 min. This dipping, drying, and baking procedure was repeated seven times. Each electrode was then heated in air at 350°C for 3 hr. The support structure consisted of a titanium foil 0.5 × 1.0 × 0.0025 cm, that was wet polished on number 600 Emery paper and then spot-welded to a 0.1 cm diam titanium wire. These titanium assemblies were cleaned in acetone and dilute hydrochloric acid before dipping into the appropriate solution for the thermal decomposition treatment. The titanium wire was then masked off with shrinkable Teflon tubing.

For comparative purposes, two proprietary oxygen evolution anode electrocatalysts WE-3 and E-50, provided by the General Electric Company, were also studied. These two materials were supplied in a finely divided powder form and they were fabricated into electrodes by Teflon bonding (24) onto a 52 mesh platinum screen. The dimensions of the screen were 0.8 × 1.2 cm.

Electrochemical studies.—The kinetic parameters for oxygen evolution were determined on the resulting electrodes in 1*N* H_2SO_4 solution at 25°C from steady-state potentiostatic measurements employing a PAR 371 potentiostat.[3] For each measurement, the current interruptor technique (25) was used to correct for the *IR* loss in the electrolyte. The electrolyte was prepared from analytical grade sulfuric acid and double distilled water. Nitrogen was continuously bubbled through the electrolyte. A platinum foil served as the counterelectrode and saturated calomel electrode (SCE) was employed as a reference. The entire electrochemical assembly was housed in a Teflon cell previously described (26).

The surface areas of the electrodes were crudely estimated using the cyclic voltammetric technique, as described in the Results section. The estimated surface areas were used to convert current readings to apparent current density values.

The time variation of electrocatalytic activity of these titanium supported materials during oxygen evolution was evaluated galvanostatically. Each electrode material was maintained at a constant current of 50 mA while the resulting potential was monitored as a function of time.

[3] The time taken to reach a pseudosteady current at each potential varied from 5 to 10 min.

Results

The Tafel plots for oxygen evolution on the various electrode materials are presented in Fig. 1 and 2, whereas the Tafel parameters are summarized in Table I. The performance of RuO_x electrode is better than that of IrO_x and of the binary oxide electrodes ($IrRuO_x$ and $RuTaO_x$). On the other hand, the electrocatalytic activity of RuO_x improves as it forms a ternary oxide ($Ru_{0.5}Ir_{0.5}TaO_x$ and $RuIr_{0.5}Ta_{0.5}O_x$) by alloying with both iridium and tantalum. Further, the electrocatalytic activity of the E-50 electrode is less than that of the WE-3 and the mixed oxide electrodes. The $RuTa_{0.5}Ir_{0.5}O_x$ electrode showed a single Tafel slope of 30 mV, while all the remaining electrode materials exhibited dual Tafel slopes (Fig. 1 and 2, Table I). The initial Tafel slope is typically about 30 mV for all the electrodes expect IrO_x and the proprietary E-50 anode for which initial Tafel regions had a slope of

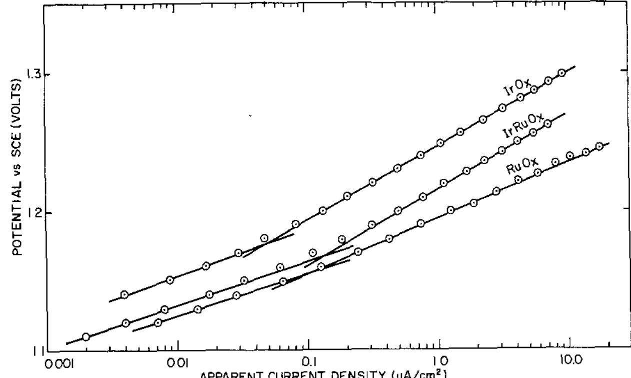

Fig. 1. Tafel plots for oxygen evolution on IrO_x, $IrRuO_x$, and RuO_x in 1.0*N* H_2SO_4 at 25°C.

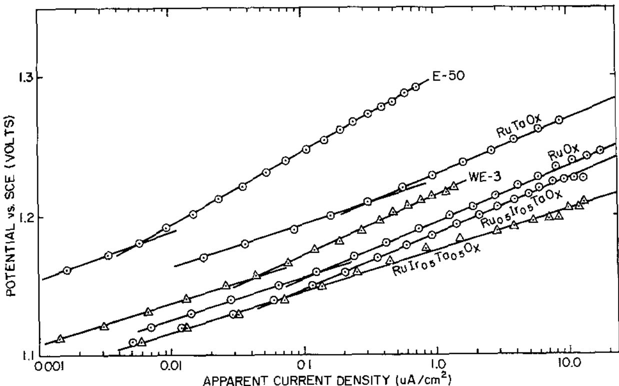

Fig. 2. Tafel plots for oxygen evolution on RuO_x, $RuTaO_x$, $Ru_{0.5}Ir_{0.5}TaO_x$, and $RuIr_{0.5}Ta_{0.5}O_x$ in 1.0*N* H_2SO_4 at 25°C.

Table I. Kinetic parameters for oxygen evolution in 1*N* H_2SO_4 at 25°C

Electrode	Tafel slope, mV		Apparent exchange current density, A/cm²	
	Low η	High η	Low η	High η
RuO_x	32	42	7×10^{-13}	1×10^{-11}
$RuTaO_x$	30	40	7×10^{-14}	2×10^{-12}
$RuIrO_x$	30	40	4×10^{-14}	2×10^{-10}
$Ru_{0.5}Ir_{0.5}TaO_x$	30	40	4×10^{-12}	2×10^{-11}
$RuIr_{0.5}Ta_{0.5}O_x$	30	—	1×10^{-12}	—
IrO_x	35	55	4×10^{-13}	3×10^{-11}
WE-3	30	42	4×10^{-13}	9×10^{-12}
E-50	35	55	5×10^{-14}	2×10^{-12}

about 35 mV. The second Tafel slope is about 40 mV for all the electrodes except IrO_x, $RuIrO_x$, and E-50, which have a second Tafel region with a slope of 55 mV. The surprising and noteworthy feature of the Tafel plots is that the overpotential for oxygen evolution is greater for the RuTa and RuIr oxides and less for the ternary RuIrTa oxides than it is for ruthenium oxide. This aspect of the data is reflected in the apparent exchange current densities, which have been determined for each electrode by a Tafel slope extrapolation and are also presented in Table I.

The active surface areas of the electrode were estimated using cyclic voltammetry (27). Initially, a potential sweep at 50 mV/sec was performed on each electrode between the hydrogen and oxygen evolution regions and a typical response is presented in Fig. 3. The voltammetric profiles are generally void of any distinctive features and the display did not indicate any obvious double layer charging region, reminiscent of the response on platinum which enables the calculation of true surface area. Cyclic voltammograms, limited to a 50 mV potential range, were employed to obtain a crude estimate of the surface areas of each electrode. The best results, where the anodic and cathodic currents were equal in magnitude and the capacitative current was linear with the sweep rate, were obtained when these limited range cyclic voltammograms were performed around the rest potential of each electrode. A typical sequence of cyclic voltammograms at various sweep rates and the associated current dependence on the sweep rate are presented in Fig. 4 and 5, respectively. The apparent capacitances and the roughness factors of each electrode were evaluated from these cyclic voltammograms and the results are listed in Table II. The roughness factors were determined by assuming a double layer capacitance of $2(10^{-5})$ f/cm² for a smooth surface. It is interesting to note that the roughness factor of these mixed oxide electrodes increases progressively from single to binary to ternary oxides. Also, the roughness factors of both E-50 and WE-3 electrodes are at least ten times higher than that of the mixed oxide electrodes prepared by thermal decomposition method.

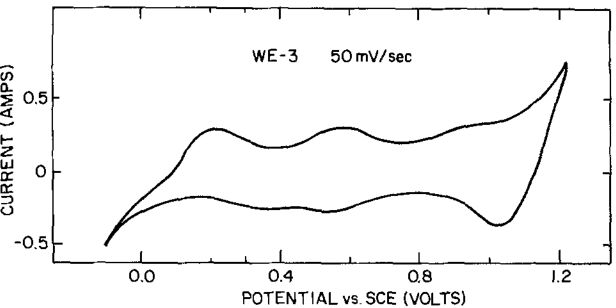

Fig. 3. Cyclic *i-V* curve for WE-3 electrode in N_2-saturated 1.0*N* H_2SO_4 at 25°C.

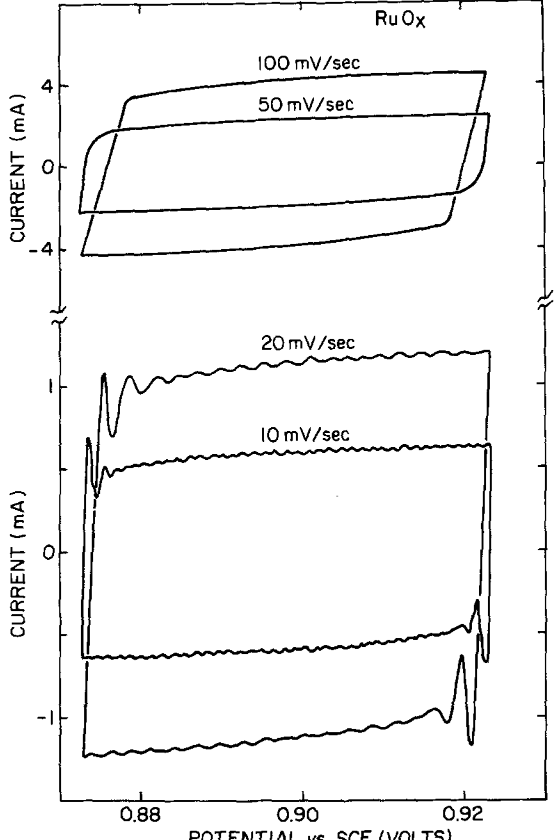

Fig. 4. Cyclic voltammograms for RuO_x electrode in N_2-saturated 1.0*N* H_2SO_4 at four sweep rates and at 25°C.

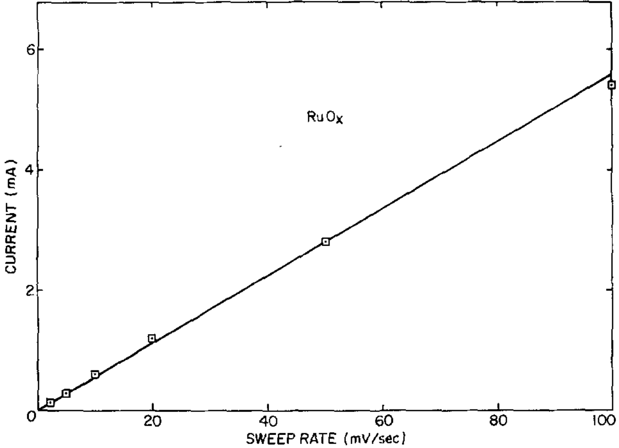

Fig. 5. Capacitative charging current (from Fig. 4) vs. sweep rate.

The time variations of overpotentials for oxygen evolutions on materials at a constant current are presented in Fig. 6. The normalized overpotential is the ratio of overpotential at time *t*, to the initial overpotential at time zero. These plots illustrate that the electrocatalytic activities of both the binary and ternary oxides are considerably more stable than that of ruthenium oxide.

Discussion

Any comparison of the electrocatalytic activity of these anode materials is critically dependent on an accurate determination of the surface area. The surface area of each electrode material was estimated from the limited range cyclic voltammograms. The resulting apparent surface areas, determined by this technique, were unexpectedly and incredibly large. This is evident from our reported roughness factors (Table II), which are sometimes orders of magnitude larger

Table II. Measured capacitance and calculated roughness factor of various electrodes

Electrode	Capacitance, f/cm^2	Calculated roughness factor
IrO_x	0.04	2×10^3
RuO_x	0.056	3×10^3
$RuTaO_x$	0.16	8×10^3
$RuIrO_x$	0.16	8×10^3
$RuIr_{0.5}Ta_{0.5}O_x$	0.2	1×10^4
$Ru_{0.5}Ir_{0.5}TaO_x$	0.4	2×10^4
WE-3	4.0	2×10^5
E-50	4.0	2×10^5

than the values of 10-700 commonly reported in the literature for thermally decomposed ruthenium oxide (3, 20, 27, 28). The magnitude of our roughness factors are unacceptably high and are not considered to be correct even though the limited range cyclic voltammograms are inversely symmetric and the charging current is linearly related to the sweep rate. The apparent surface areas determined from the cyclic voltammograms are thus considerably higher than the true surface areas, making the calculated exchange current densities considerably smaller than the true current densities which could not be determined. The abnormally large roughness factor probably results from pseudocapacitance, though one may assume that this pseudocapacitance is directly related to the true surface area. The reproducibility of the experiments were supportive of this assumption since different electrodes of the same oxide material with significantly different roughness factors have identical and superimposable potential-apparent current density plots. This suggests that the relative values of the surface areas and roughness factors determined by the cyclic voltammograms are correct even though their absolute values may be incorrect and establish that of all the materials examined for oxygen evolution the two ternary oxides are the best electrocatalysts for oxygen evolution over the entire current range tested.

As is seen from Table II, the surface roughness of both WE-3 and E-50 electrodes are about 100 times larger than that of either RuO_x or IrO_x. The high surface areas of these electrodes probably accounts for the low cell potentials in water electrolyzers using these anode catalysts (29). Also, the better electrocatalytic activity of WE-3 over that of E-50 is consistent with the results reported elsewhere (29).

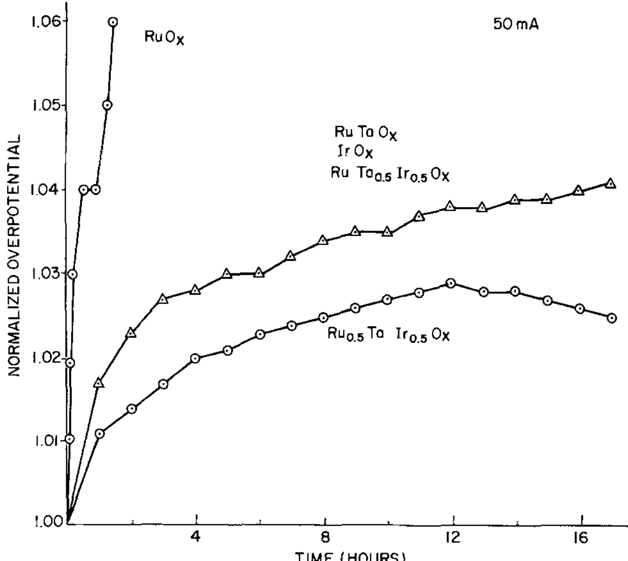

Fig. 6. Normalized overpotential vs. time for various electrodes at 25°C. Normalized overpotential $= \eta_t/\eta_0$, where η_t and η_0 are overpotential at time t and zero, respectively.

The kinetic parameter that is free from uncertainties in the surface area and can be presented clearly and unambiguously is the Tafel slope. A dual Tafel slope was observed on all the oxide electrodes except for $RuTa_{0.5}Ir_{0.5}O_x$. Dual Tafel slopes have been observed previously (30) for oxygen evolution on thermally decomposed ruthenium oxide where the initial Tafel slope was reported to be between 30 and 40 mV depending on the pH of the electrolyte. The second Tafel slope was reported to be about 80 mV in an acid electrolyte and this is not at all consistent with our results on ruthenium oxide. The dual 30 and 40 mV slopes, apparent in most of our oxide electrodes containing ruthenium cations, are not consistent with any predicted values associated with the various mechanisms commonly proposed for the oxygen evolution reaction (31). Various mechanistic reaction sequences, consistent with a 30 and 40 mV dual Tafel slope response, are currently being investigated.

Finally, the time variation of overpotential for oxygen evolution at a constant current of 50 mA (Fig. 6) clearly shows that the binary and ternary oxides are electrocatalytically more stable than ruthenium oxide. The time dependence of the overpotential was approximately the same for the other oxide stoichiometries except $Ru_{0.5}TaIr_{0.5}O_x$ which appeared to have a very slight stability advantage.

In conclusion, it is shown that the electrocatalytic activity of ruthenium oxide can be improved and stabilized in acid electrolyte by alloying with iridium and tantalum, probably because the ruthenium cations in these mixed oxides can exist in the III-IV state and remain in such mixed valencies over long periods of time. The existence of III-IV ruthenium cations and its relationship to the electrocatalytic activity awaits a detailed study of both the surface states and the phase diagram of the IrTaRu oxide system.

Acknowledgments

The authors wish to thank Dr. C. R. Davidson and Mr. J. H. Russell of the General Electric Company, Wilmington, Massachusetts for the supply of the proprietary catalyst (E-50 and WE-3) and for their helpful discussions. This work was carried out under the auspices of the United States Department of Energy. Dr. J. Orehotsky and Dr. W. Visscher were Visiting Scientists at BNL in the summer of 1979 from Wilkes College, Wilkes-Barre, Pennsylvania and the Technological University, Eindhoven, The Netherlands, respectively.

Ring Disk Electrodes with an Impinging Jet

D-T. Chin* and Ravi R. Chandran

Department of Chemical Engineering, Clarkson College of Technology, Potsdam, New York 13676

ABSTRACT

When a jet of electrolyte is impinging perpendicularly on a stationary circular electrode, there is a region of "uniform accessibility" similar to that on a rotating disk electrode. The objective of this study is to develop the impinging jet into a practical tool for electroanalytical applications. This geometry is attractive because there is no mechanical movement and the electrode can be easily adopted for the process streams and closed systems requiring pressure other than the ambient atmospheric pressure. A theoretical and experimental investigation has been made to determine the feasibility of a ring disk arrangement with an impinging jet. The reduction of ferricyanide ion and the cyclic voltammetry of a Cu^{2+}/Cu reaction were used to determine the mass transfer characteristics and the collection efficiencies of platinum and nickel ring disk electrodes located within the uniform accessible regime of the impinged surface. It is found that the rotating ring-disk theory could be used as a first approximation in the numerical computation.

In recent years, the impinging jet has been recognized as an important research tool because it offers a high rate of heat and mass transfer. Among the practical applications are glass toughening, drying of paper, solids leaching, and welding processes. It is commonly used in electrochemical machining and in erosion corrosion.

The impinging jet electrode is composed of a circular disk electrode embedded on a flat plate and a submerged circular jet of electrolyte incident at 90° on the electrode surface. Chin and Tsang (1, 2) have carried out a theoretical and experimental study of mass transfer to an impinging jet electrode; their results can be summarized by the following correlations

(*i*) for laminar flow ($Re < 2000$, $0.1 < r_1/d < 0.5$, and $0.2 \leq H/d \leq 6$)

$$Sh_{disk} = 1.51\, Re^{1/2}\, Sc^{1/3}\, (H/d)^{-0.055} \qquad [1]$$

(*ii*) for turbulent flow ($4000 < Re < 16{,}000$, $0.1 < r_1/d < 1$, and $0.2 \leq H/d \leq 6$)

$$Sh_{disk} = 1.12\, Re^{1/2}\, Sc^{1/3}\, (H/d)^{-0.055} \qquad [2]$$

where Sh_{disk} is the Sherwood number based upon the inside diameter of the nozzle, d; Re is the Reynolds number based upon the nozzle diameter and the average velocity of the electrolyte within the nozzle; Sc is the Schmidt number; r_1 is the radius of the electrode; and H is the distance between the nozzle and the electrode surface. These equations confirm the fact that if the disk electrode radius is kept less than one-half of nozzle diameter in laminar flow, and less than one nozzle diameter in turbulent flow, the electrode possesses a "uniform accessibility" to the diffusing species. This property is similar to that of a rotating disk electrode (3). The pattern of fluid flow near the impinging jet electrode also resembles that of the rotating disk.

In view of the foregoing considerations, it is thought that by placing a set of concentric ring and disk electrodes on the impinged surface, one might offer electrochemists an alternative tool for the study of reaction

Key words: convection, mass transport, analysis, voltammetry.

intermediates. Such an arrangement has the advantage that the electrodes are stationary, and the geometry can be adopted for the continuous process streams and the closed electrochemical systems which require a pressure other than the ambient atmospheric pressure. The objective of this study is to determine the mass-transfer rate to the ring, and to measure the collection efficiency of the ring disk combination.

Theoretical Analysis

In order that the ring disk combined with the impinging jet can be used to quantitatively study the reaction intermediate, one must have a knowledge of the collection efficiency at the ring electrode. The collection efficiency, N, is defined as the fraction of a material produced at the disk electrode, being collected at the ring electrode. Let us consider that a species Red is generated at the disk electrode according to the reaction

$$\mathrm{Ox} + ne^- \rightarrow \mathrm{Red} \quad [3]$$

This species will be carried by convective diffusion to the ring electrode, where the reverse reaction occurs

$$\mathrm{Red} \rightarrow \mathrm{Ox} + ne^- \quad [4]$$

One may control the potential of the ring electrode such that reaction [4] is limited by the transport of Red to the ring surface. Let us assume that there is an excess inert salt in the electrolyte such that the effect of migration due to the electric field can be neglected. We use the coordinate r as the radial distance from the axis of the impinging jet, and the coordinate z as the perpendicular distance from the impinged surface (Fig. 1). The steady-state axial symmetrical convective diffusion equation for the transport of Red takes the form

$$v \frac{\partial C}{\partial z} + u \frac{\partial C}{\partial r} = D \frac{\partial^2 C}{\partial z^2} \quad [5]$$

where C is the concentration of Red in the flowing electrolyte; D is its diffusivity; and u and v are the velocity components in the r- and z-directions, respectively. The boundary conditions to the differential equation are

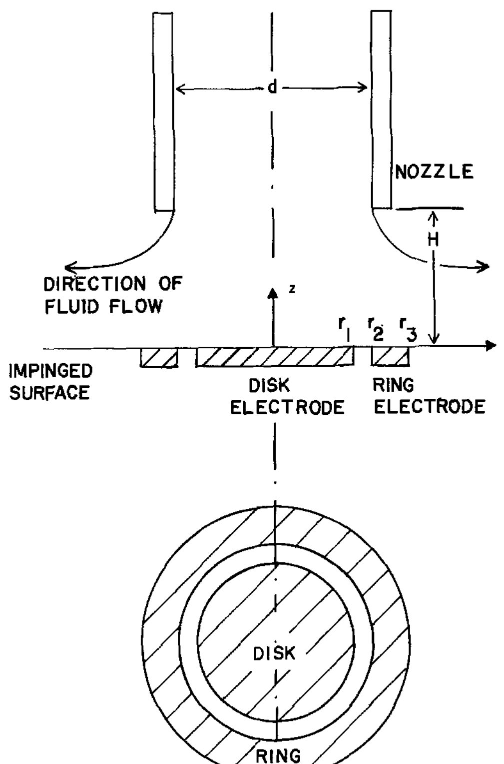

Fig. 1. Ring disk electrodes with an impinging jet

(i) In the bulk of the electrolyte ($r, z \rightarrow \infty$)

$$C = 0 \quad [6a]$$

(ii) On the disk electrode surface ($z = 0$, $r < r_1$)

$$\frac{\partial C}{\partial z} = \frac{i_{\mathrm{Disk}}}{nFD} \quad \text{or} \quad C = C_{\mathrm{Disk}} \quad [6b]$$

(iii) On the surface of the insulating annulus ($z = 0$, $r_1 < r < r_2$)

$$\frac{\partial C}{\partial z} = 0 \quad [6c]$$

(iv) On the ring electrode surface ($z = 0$, $r_2 < r < r_3$)

$$C = 0 \quad [6d]$$

(v) On the insulation plane ($z = 0$, $r > r_3$)

$$\frac{\partial C}{\partial z} = 0 \quad [6e]$$

For the simplicity of the analysis, we shall assume that the diffusion domain is confined to the stagnation region near the nozzle axis, where the flow boundary layer thickness is uniform, and the radial and the vertical velocity components have the following forms (4, 5)

$$\left.\begin{aligned} u &= ar\phi'(\eta) \\ v &= -2\sqrt{a\nu}\,\phi(\eta) \end{aligned}\right\} \quad [7]$$

where η is the dimensionless vertical coordinate defined as $z\sqrt{a/\nu}$, and a is an unspecified hydrodynamic constant. The values of a depend upon the nozzle Reynolds number and the dimensionless nozzle height. The stream function, $\phi(\eta)$, has been obtained by Homann (4); its Taylors series expansion for small η has been found as (1, 2)

$$\phi(\eta) = 0.656\eta^2 - 0.16667\eta^3 + 3.6444 \times 10^{-3}\eta^6 - 3.9682 \times 10^{-4}\eta^7 + \ldots \quad [8]$$

At high Schmidt numbers (on the order of 1000), the thickness of the concentration boundary layer is much smaller than the thickness of the hydrodynamic boundary layer. Thus, the first term in the Taylors series expansion of $\phi(\eta)$ would give sufficient accuracy to the solution of the convective diffusion problem, and Eq. [5] can be simplified to

$$1.312\, a \sqrt{\frac{a}{\nu}}\, z \left(r \frac{\partial C}{\partial r} - z \frac{\partial C}{\partial z} \right) = D \frac{\partial^2 C}{\partial z^2} \quad [9]$$

Introducing a new dimensionless vertical coordinate defined as

$$\zeta = \left(\frac{a}{\nu}\right)^{1/2} \left(\frac{1.312\nu}{3D}\right)^{1/3} z \quad [10]$$

Equation [9] becomes

$$3\zeta \left[r \frac{\partial C}{\partial r} - \zeta \frac{\partial C}{\partial \zeta} \right] = \frac{\partial^2 C}{\partial \zeta^2} \quad [11]$$

The boundary conditions to Eq. [11] can be obtained from Eq. [6] as

(i) On the disk ($r < r_1$),

$$\left.\frac{\partial C}{\partial \zeta}\right|_{\zeta=0} = \left(\frac{\nu}{a}\right)^{1/2} \left(\frac{3D}{1.312\nu}\right)^{1/3} \frac{i_{\mathrm{Disk}}}{nFD} \quad \text{or} \quad C|_{\zeta=0} = C_{\mathrm{Disk}} \quad [12a]$$

(ii) On the insulating annulus ($r_1 < r < r_2$),

$$\left.\frac{\partial C}{\partial \zeta}\right|_{\zeta=0} = 0 \quad [12b]$$

(*iii*) On the ring ($r_2 < r < r_3$)

$$C|_{\zeta=0} = 0 \quad [12c]$$

(*iv*) In the bulk of the electrolyte

$$C \Big|_{\substack{\zeta\to\infty \\ r\to\infty}} = 0 \quad [12d]$$

Equations [11] and [12] are identical to the convective diffusion problem on the rotating ring-disk electrode for which an exact solution has been obtained by Albery and Bruckenstein (6) and Smyrl and Newman (7). Thus the collection efficiency for the rotating ring-disk electrode is also valid for the ring disk electrode with the impinging jet

$$N = \frac{\text{Total ring current}}{\text{Total disk current}}$$

$$= (A^3 - B^3)^{2/3} \left[\frac{\sqrt{3}}{4\pi} \ln \frac{1+\theta^3}{(1+\theta)^3} - \frac{3}{2\pi} \tan^{-1}\left(\frac{2\theta-1}{\sqrt{3}}\right) + \frac{3}{4}\right] + \frac{\sqrt{3}}{4\pi} \ln \frac{1+A^3\psi^3}{(1+A\psi)^3}$$

$$+ \frac{3}{2\pi} \tan^{-1}\left(\frac{2A\psi-1}{\sqrt{3}}\right) + \frac{1}{4} - A^2 \left[\frac{\sqrt{3}}{4\pi} \ln \frac{1+\psi^3}{(1+\psi)^3} + \frac{3}{2\pi} \tan^{-1}\left(\frac{2\psi-1}{\sqrt{3}}\right) + \frac{1}{4}\right] \quad [13]$$

where

$$\left.\begin{array}{l} A = r_3/r_1, \quad B = r_2/r_1 \\ \theta = (B^3 - 1)^{1/3} \\ \psi = \dfrac{1}{A}\left(\dfrac{A^3 - B^3}{B^3 - 1}\right)^{1/3} \end{array}\right\} \quad [14]$$

Notice that Eq. [13] is only a function of the geometry ratios, r_3/r_1 and r_2/r_1; it is independent of the nozzle height as well as the flow conditions in the nozzle. Albery and Bruckenstein have tabulated the values of N for common values of r_2/r_1 and r_3/r_1 (6).

Experimental

Cell construction and experimental setup.—The construction details of the impinging jet cell are shown in Fig. 2. The cell was made of a Plexiglas tube 15.24 cm in diameter and 10.16 cm in length. The cell had a fixed Plexiglas bottom-plate of 1.26 cm thick and a removable Plexiglas upper plate of 1.26 cm thick. A counterelectrode with a 1.26 cm hole in the center was mounted inside the cell on the bottom plate which had an opening of 9.4 cm to accommodate the nozzle. The nozzle was 0.95 cm ID × 1.26 cm OD × 20.32 cm long and was machined to have a tapered end. The electrolyte flowed through the nozzle and impinged perpendicularly on the working electrode surface as shown in the figure. A second nozzle which had a dimension of 0.635 cm ID × 1.26 cm OD, was also used in the experimental investigation. The nozzle height was adjusted by moving the nozzle up and down and by tightening the nut of the male connector. A Starret micrometer depth gauge (Model 445D-RL) with 0.00254 cm (0.001 in.) precision was used to measure the nozzle height. At 5.08 cm from the bottom plate, a hole was provided to accommodate a Luggin capillary tube. The capillary was connected to an external reference electrode compartment (Fig. 3) with a rubber tubing. A hole of 1.27 cm in diameter was provided on the upper plate for the exit of the electrolyte.

The cell was so designed such that it could adopt different diameters of ring and disk electrodes by changing the electrode adopter. The stationary working electrode with the adopter was mounted on the upper plate over an opening of 4.45 cm in diameter. Four different sizes of ring and ring disk electrodes were used. Two of the electrodes were platinum ring-platinum disk made by Pine Instruments Company; the other two were nickel ring electrodes embedded on a fiberglass resin. The dimensions of these electrodes are listed in Table I.

Figure 3 shows the complete experimental setup. The flow system consisted of a solution tank, a gear pump, a set of rotameters, a flow damper, and the impinging jet cell. These components were connected together with one-half in. polypropylene tube and one-half in. nylon tube fittings. The solution tank was an 11 liter PVC tank; an epoxy gear pump with a Hastelloy-C shaft and a Buna-N impeller were used to circulate the electrolyte. A bypass nylon needle valve and three other nylon needle valves in the upstream of three rotameters were used to control the flow rate of the electrolyte. Three Gilmont F-1500 shielded rotameters were used to measure the flow rate; they were composed of a glass tube and a glass ball to avoid the corrosion problems. The Plexiglas flow damper in the downstream of the rotameters was used to eliminate any turbulences in the electrolyte before it flowed into the impinging jet cell. The electrolyte flowed into the cell through the nozzle tube. It impinged normally on the working electrode and then returned to the storage tank via the exit on the top plate of the cell. All the experiments were performed at a constant room temperature of 24° ± 1°C.

Mass-transfer measurements.—The limiting current measurements for the reduction of ferricyanide ion were used to determine the rate of mass transfer to the ring and the disk electrodes. The solutions used were 0.01M $K_3Fe(CN)_6$ and 0.01M $K_4Fe(CN)_6$ in a 1M NaOH or 0.5M Na_2SO_4 supporting electrolyte saturated with nitrogen. A Pine Instruments RDE3 potentiostat was used to sweep the potential of the working electrodes

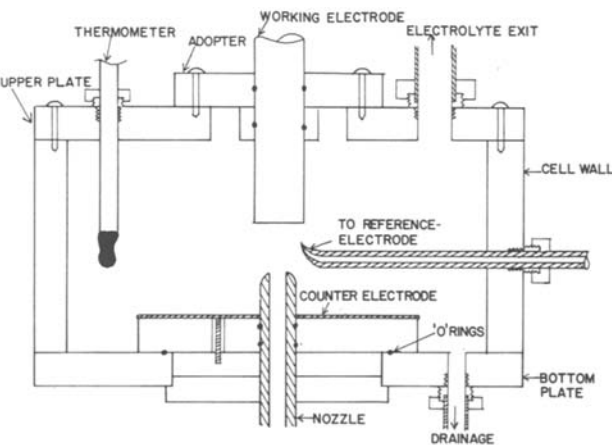

Fig. 2. Schematic diagram of the impinging jet cell

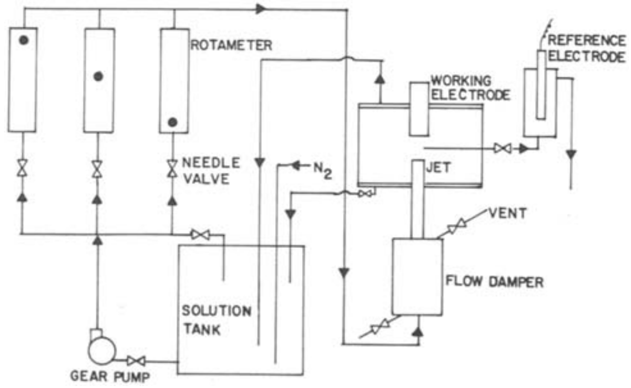

Fig. 3. Schematic diagram of experimental setup

Table I. Dimensions of the ring and the ring disk electrodes

Electrode	Material	r_1 (cm)	r_2 (cm)	r_3 (cm)
DT-9 ring disk	Platinum	0.383	0.399	0.409
DT-21 ring disk	Platinum	0.250	0.276	0.358
N1R1 ring	Nickel	—	0.318	0.635
N1R2 ring	Nickel	—	0.159	0.635

from 0.25V to −1.0V with respect to a saturated calomel reference electrode. The resulting currents were recorded on a X-Y recorder (Hewlett-Packard 7000 A). In this way the polarization curves and the limiting currents were determined for various flow rates and electrode sizes. The details of the experimental procedures are described in Ref. (8).

Measurement of collection efficiency.—The limiting current measurements for the reduction of ferricyanide to ferrocyanide on the platinum disk electrode, and the oxidation of ferrocyanide to ferricyanide on the platinum ring electrode were used to determine the collection efficiency. A nitrogen-saturated solution containing 0.01M $K_3Fe(CN)_6$ and 0.5M Na_2SO_4 was used for the measurements. The potential of the central disk electrode was swept between 0.2 and −1.1V *vs.* SCE, whereas the ring potential was controlled at 1.1V *vs.* SCE. The disk and the ring currents were recorded as functions of the disk potential on two separate X-Y recorders (Hewlett Packard 7000 A and Linseis 1700). The collection efficiency was calculated as the ratio of the ring current (minus any blank current when the disk electrode was at open circuit) to the disk current.

Feasibility test.—To test the ability of the ring disk electrodes with the impinging jet to detect the reaction intermediates, a triangular voltametric sweep was carried out for the Cu^{2+}/Cu reaction. The electrolytes used were: (*i*) 0.01M $CuCl_2$ plus 0.5M HCl; and (*ii*) 0.01M $CuSO_4$ plus 0.5M H_2SO_4. These solutions were saturated with nitrogen before and during the experiments. The potential of the central platinum disk electrode was scanned between 0.4 and −0.4V *vs.* SCE in the chloride solution and between 0.2 and −0.2V *vs.* SCE in the sulfate solution. To detect the formation of any intermediate Cu^+ ion during the scan, the potential of the platinum ring electrode was maintained at 0.4V *vs.* SCE for the chloride system and at 0.58V *vs.* SCE for the sulfate system. These potential values were the limiting current potentials for the oxidation of cuprous ion to cupric ion (9) at the ring electrode.

Results and Discussion

Mass transfer to ring electrodes.—A set of experiments were first performed to determine the mass transfer characteristics of the ring electrode with the limiting current measurements. The typical results for four different sizes of ring electrodes are shown in Fig. 4 and 5 in the form of $i_{lim,ring}$ *vs.* $Re^{1/2}$ for two different nozzle heights. All the data were obtained within the stagnation regime of the impinging jet (r_3d < 0.67). It is seen that the limiting current density follows a linear relationship in both laminar and turbulent flow regimes, and the straight lines can be extrapolated to the point of origin. This shows that the limiting current density is proportional to $Re^{1/2}$ and thus to the square root of linear velocity of the electrolyte in the nozzle. Each set of data has different slopes in laminar and turbulent regions, and there is a transition flow region in between. The flow transition appears to be in the range of the nozzle Reynolds numbers between 2000 and 4000. This behavior is similar to mass transfer to a circular disk electrode on the impinged surface (1). However, for the disk electrode there is a uniform accessibility and the mass transfer rate is independent of the electrode radius, whereas the limiting current density to the ring decreased with increasing r_3/r_2 ratios. This is because the ring electrode behaved as

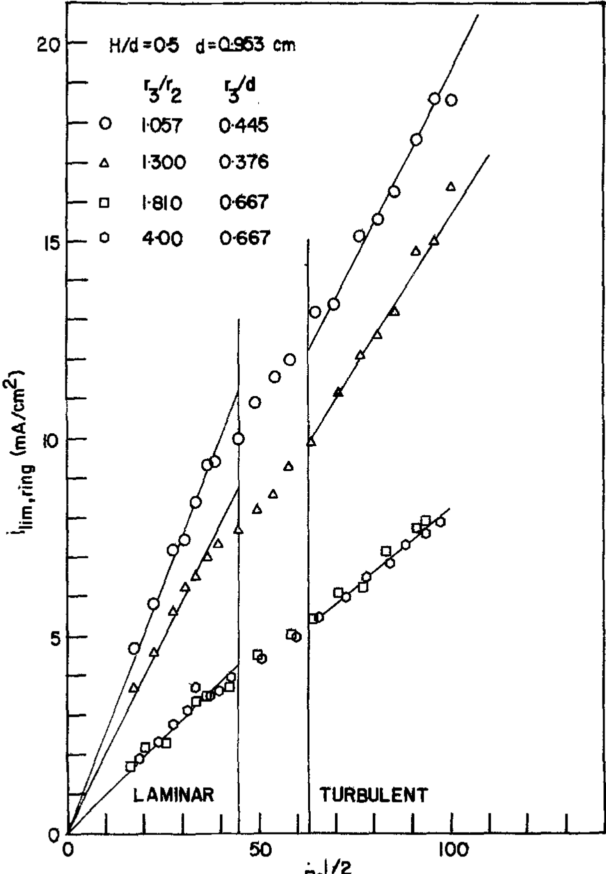

Fig. 4. Dependence of the limiting current density of four different sizes of ring electrodes on the nozzle Reynolds number for H/d = 0.5 and d = 0.95 cm.

though the central portion of a disk was rendered nonreactive, and the electrode was no longer uniformly accessible to the diffusing ion. The local mass transfer rate was maximum at the inner edge and decreased along the radial direction toward the outer edge. The average mass transfer rate to the ring would be higher than that to a disk. The data for the two ring electrodes with r_3/r_2 = 1.8 and 4.0 seem to fall on a single curve as shown in Fig. 4 and 5. This indicates that as the width of the ring increased, the average mass-transfer rate decreased and eventually became the same as that of a disk electrode whose radius would be equal to the outer radius of the ring.

Figure 6 shows the dependence of the limiting current density of a ring electrode on the dimensionless nozzle height for a range of H/d between 0.5 and 6. There was a slight decrease in the mass-transfer rate at various Reynolds numbers; however, the dependence was very small.

For a rotating ring electrode, the mass-transfer rate is related to a geometrical factor, γ, defined as (3, 10)

$$\gamma = \frac{(r_3^3 - r_2^3)^{2/3}}{r_3^2 - r_2^2} \qquad [15]$$

It has been found that the ratio of the average limiting current density of a rotating ring electrode to the limiting current density of a rotating disk electrode is equal to γ (10). In the present study, an attempt has been made to normalize the limiting current density of the ring electrode with the limiting current density of a disk electrode having the same radius as the outer radius of the ring under the same flow conditions. The results are plotted in Fig. 7 as a function of the Reynolds numbers for four different sizes of ring electrodes over a range of H/d from 0.5 to 6. The values of $i_{lim,disk}$ used in the figure were calculated from Eq. [1]-[2].

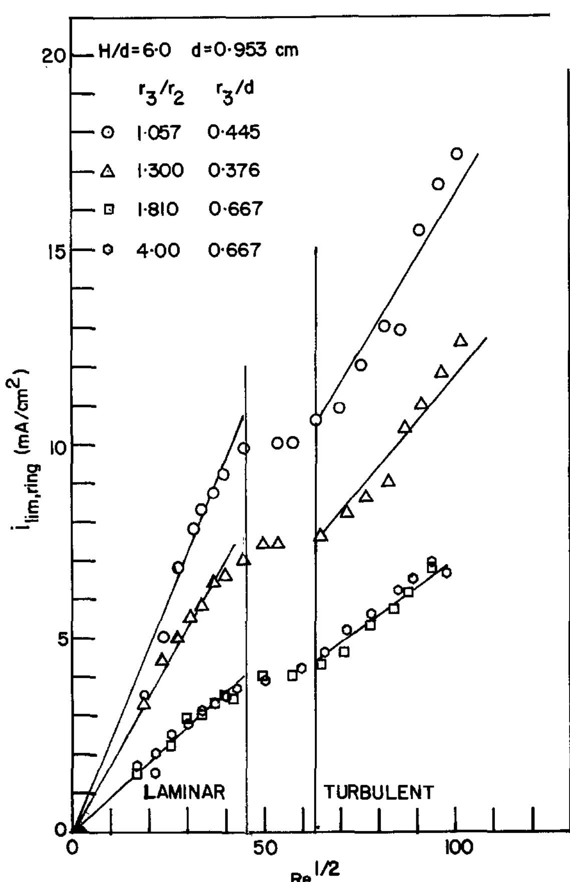

Fig. 5. Dependence of the limiting current density of four different sizes of ring electrodes on the nozzle Reynolds number for $H/d = 6.0$ and $d = 0.953$ cm.

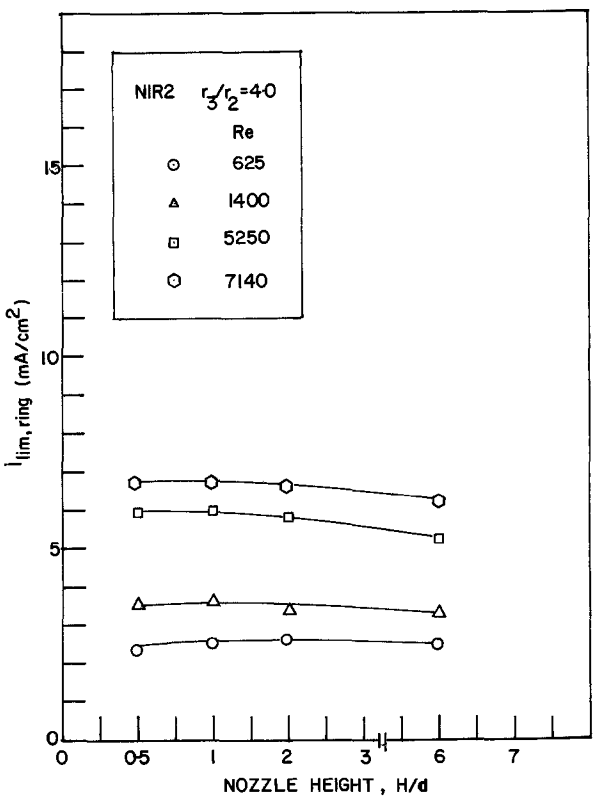

Fig. 6. Dependence of the limiting current density of the N1R2 ring electrode on the dimensionless nozzle height, H/d.

It is interesting to note that the ratio became independent of the Reynolds number and the dimensionless nozzle height; it was only a function of the geometrical factor, γ. A linear regression analysis for all the data obtained ($1 < \gamma < 3$; $r_3/d < 0.67$; $0.5 \leq H/d \leq 6$; $1400 < \mathrm{Sc} < 1600$) resulted in the following empirical correlation for mass transfer to the ring electrode with an impinging jet

$$\frac{i_{\mathrm{lim,ring}}}{i_{\mathrm{lim,disk}}} = \frac{\mathrm{Sh_{ring}}}{\mathrm{Sh_{disk}}} = \begin{cases} 0.790\,\gamma \ (300 < \mathrm{Re} < 2000) \\ 0.938\,\gamma \ (2000 < \mathrm{Re} < 11{,}000) \end{cases} \quad [16]$$

Here $i_{\mathrm{lim,disk}}$ and $\mathrm{Sh_{disk}}$ are the average limiting current density and the average Sherwood number of a disk electrode whose radius is equal to the outer radius of the ring; these values are calculated from Eq. [1] or [2] obtained previously by Chin and Tsang (1). Figure

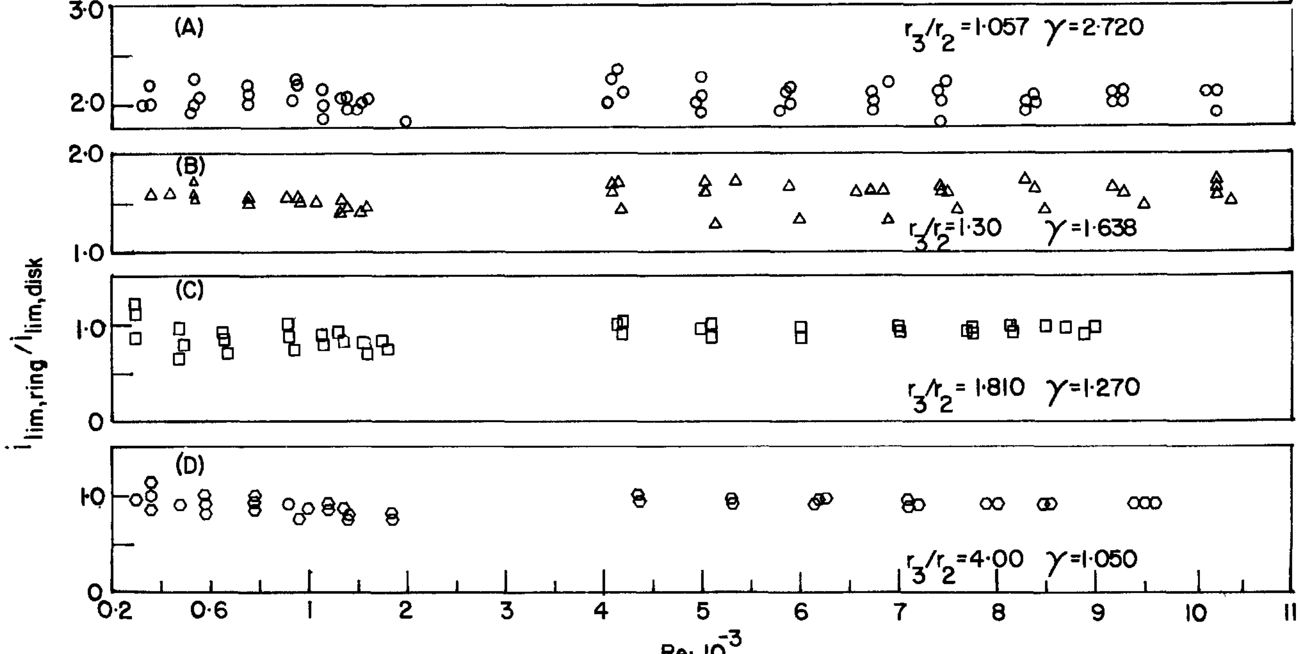

Fig. 7. Dependence of $i_{\mathrm{lim,ring}}/i_{\mathrm{lim,disk}}$ or $\mathrm{Sh_{ring}}/\mathrm{Sh_{disk}}$ on the nozzle Reynolds number, for four different sizes of ring electrodes. The values of $i_{\mathrm{lim,disk}}$ and $\mathrm{Sh_{disk}}$ are calculated from Eq. [1]-[2].

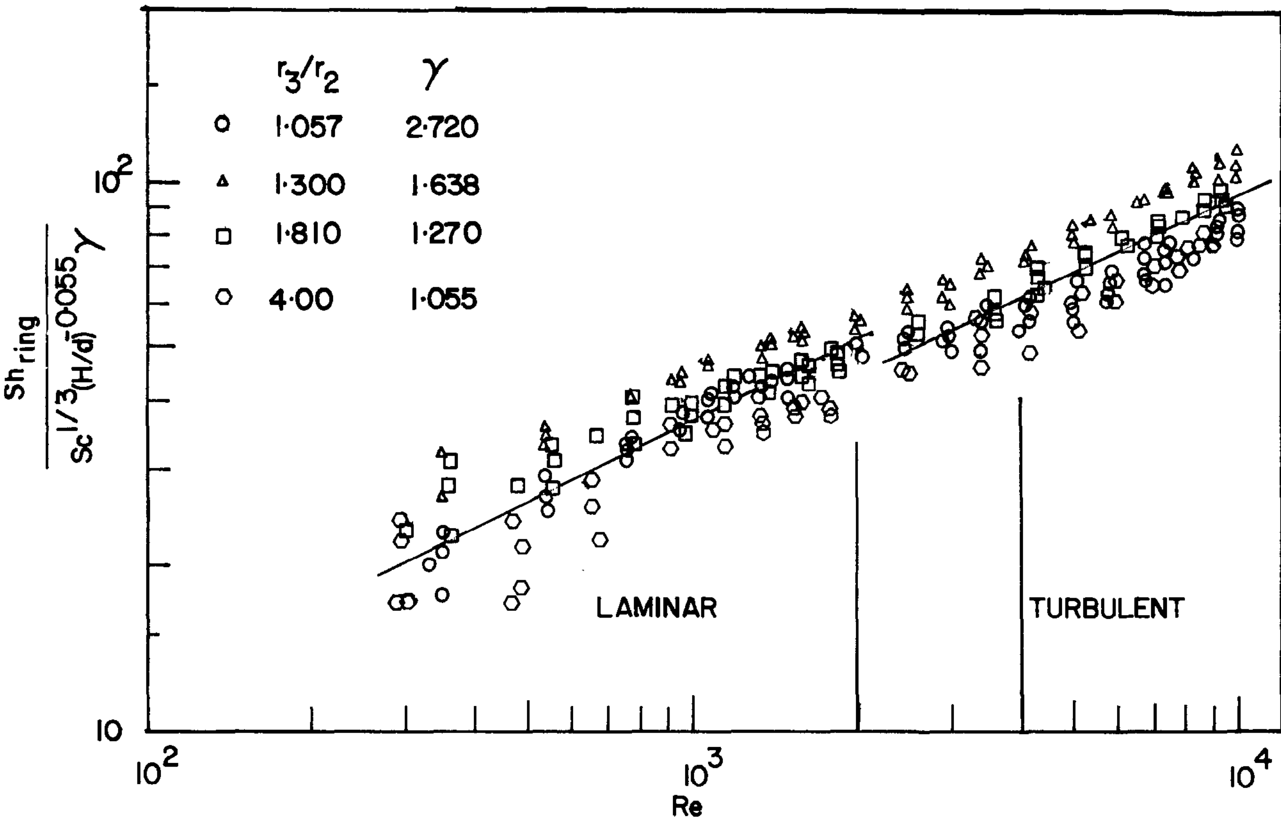

Fig. 8. Summary of mass-transfer data of the impinging jet ring electrodes for $0.5 \leq H/d \leq 6$, and $r_3/d < 0.67$. The solid lines represent the empirical correlation of Eq. [16].

8 shows a log-log plot of $Sh_{ring}/Sc^{1/3}(H/d)^{-0.55}\gamma$ *vs.* Re for both laminar and turbulent flows. It is seen that Eq. [16] as represented by the straight lines correlated the data well; the agreement was within ± 15%.

Collection efficiency.—Figure 9 shows the typical recorder traces obtained during the collection efficiency measurements with the DT21 platinum ring disk electrodes in a solution containing 0.01M $K_3Fe(CN)_6$ and 0.5M Na_2SO_4. The disk potential was swept toward the cathodical direction, whereas the ring potential was kept at a limiting current potential for the oxidation ferrocyanide to ferricyanide. Figure 9A shows the disk current *vs.* disk potential for two different Reynolds numbers; the corresponding ring currents are shown in Fig. 9B. The blank current (or background current) at the ring while the disk was at the open circuit is also shown in the figure. The collection efficiency was calculated from the ratio of the ring current minus any blank current, to the disk current. In most cases, the flat portion of the curves in the range of disk potential between −0.3 and −0.9V *vs.* SCE, was used for the calculation. Since there were fluctuations in the recorded current readings, the maximum and the minimum values of the fluctuations were noted, and the average values of the ring and the disk currents were used to compute the average collection efficiency. Four other ratios, $I_{ring,min}/I_{disk,max}$, $I_{ring,max}/I_{disk,min}$, $I_{ring,min}/I_{disk,min}$, and $I_{ring,max}/I_{disk,max}$, were also computed. Here the suffixes, min and max, denote the minimum and the maximum values of the ring and the disk currents on the flat portion of the recorder traces. These ratios were used to give a statistical representation of the collection efficiency data. It was found that the average collection efficiency was equal to the ratios, $I_{ring,min}/I_{disk,min}$ and $I_{ring,max}/I_{disk,max}$. The fact was supported by the observations during the experiments that the maximum ring current occurred when the disk current reached the maximum of its fluctuations, and conversely the minimum ring current occurred when the disk current was minimum. This suggests that the ratio of the average ring current to the average disk current renders a true representation of the collection efficiency of the ring disk electrodes.

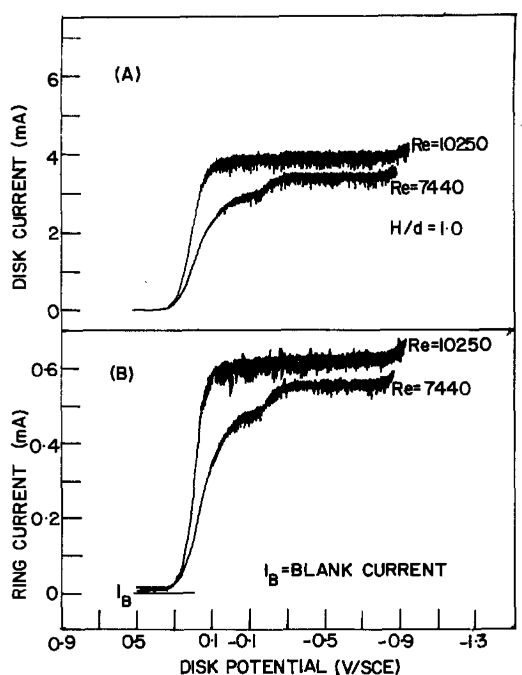

Fig. 9. Recorder traces of the disk and the ring currents as a function of the disk potential for the DT21 platinum ring disk electrodes. The reduction of ferricyanide was carried out at the central disk electrode, whereas the ring potential was kept at 1.1V *vs.* SCE to reoxidize any ferrocyanide ions reaching the ring electrode. The scan rate of the disk potential was 0.25 V/min, and $H/d = 1.0$.

In this way, the collection efficiency for two different sizes of platinum ring disk electrodes (DT9 and DT21) was measured over a range of Reynolds numbers from 300 to 11,000 and for the dimensionless nozzle heights

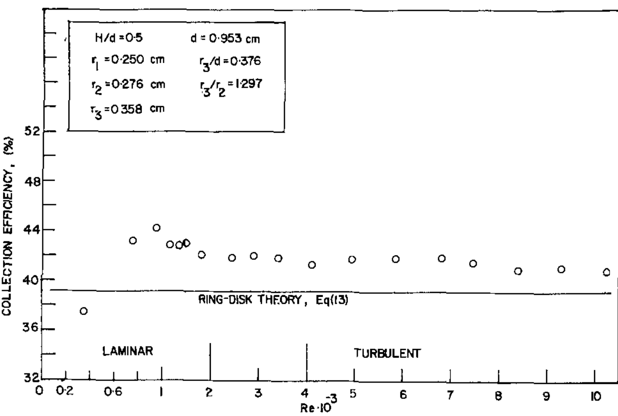

Fig. 10. Dependence of the collection efficiency on the Reynolds number for the DT21 platinum ring disk electrodes.

between 0.5 and 6.0. Figures 10 and 11 show the typical results obtained at $H/d = 0.5$ as a function of Reynolds numbers. The data points in the figures are the experimental average collection efficiencies calculated from $I_{ring,ave}/I_{disk,ave}$. For comparison, the ring disk theory of Eq. [13] is plotted as the solid horizontal lines. Although there is a scatter in the data, the experimental collection efficiency does not appear to depend on the Reynolds number. For the DT21 electrodes (Fig. 10), the experimental values are consistently higher than the theory prediction, whereas for the DT9 electrodes (Fig. 11), the experimental values are smaller than the theory. However, the difference is small, and the agreement between the ring disk theory and the experiment is within ± 10%.

Figure 12 shows the dependence of the experimental collection efficiency on the dimensionless nozzle height, H/d, for various Reynolds numbers and r_3/d ratios. It is seen that for the two different sizes of ring disk electrodes shown in the figure, the collection efficiency remained constant in the region of $0.5 < H/d < 2$. At higher values of H/d, the collection efficiency slowly decreased with increasing H/d ratios. This trend was true for both laminar and turbulent flows.

The effect of r_3/d ratio on the collection efficiency was checked by using two different nozzle diameters, and the results are shown in Fig. 12A and B. It appears that an increase in the r_3/d ratio tended to lower the collection efficiency. During the course of completing the present work, a similar paper was published by Du Duc (11) who used an impinging jet ring disk electrode with $r_3/d = 1.55$ and a range of H/d from 0.03 to 3.0. In his experiments, the ring electrode and the part of the disk electrode were located outside the uniform accessible regime of the impinging jet, and the collection efficiency was found to be much smaller

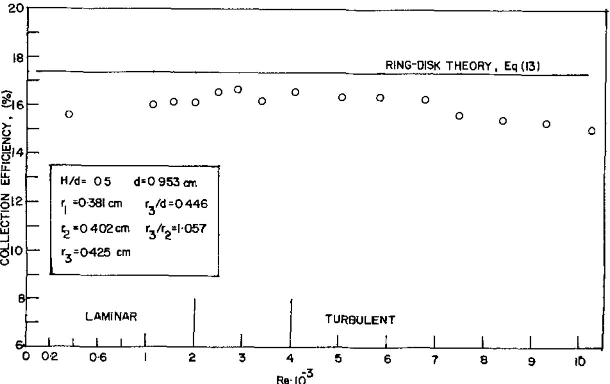

Fig. 11. Dependence of the collection efficiency on the Reynolds number for the DT9 platinum ring disk electrodes.

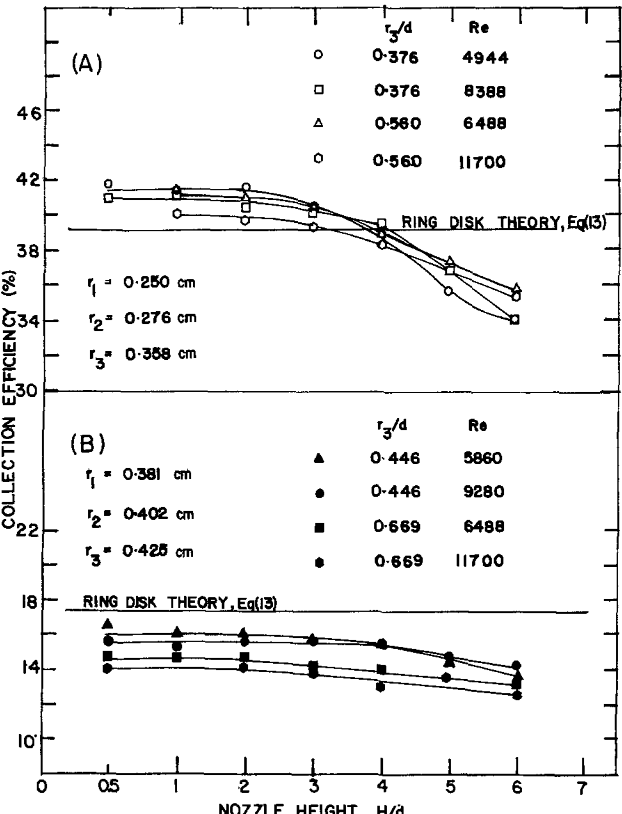

Fig. 12. Collection efficiency as a function of the dimensionless nozzle height for two different sizes of ring disk electrodes at various Reynolds numbers and r_3/d ratios.

than the prediction of the ring disk theory. The present results for $H/d \leq 2.0$ as well as those of Du Duc (11) are summarized in Table II. It appears that if one limits the dimensionless nozzle height to less than 2.0 and the ratio of r_3/d to less than 0.6, the ring disk theory can be used as a first approximation for the prediction of the collection efficiency. However, in view of the complexity of fluid flow in an impinging jet, it is suggested that a cell with fixed H/d, r_1/d, r_2/d, and r_3/d ratios be constructed, and a simple redox reaction, such as the reduction of ferricyanide to ferrocyanide ions be used to calibrate the collection efficiency. The ring disk theory of Eq. [13] can be then used to check the accuracy of the calibrations.

Feasibility test.—The feasibility of the ring disk electrode with an impinging jet to detect a reaction intermediate was tested by detecting an intermediate Cu^+ species in a Cu^{++}/Cu° reaction.

Figure 13 shows the test carried out in a 0.01M $CuCl_2$/0.5M HCl solution with the DT21 platinum ring disk electrodes. The disk and ring currents are plotted against the disk potential for $H/d = 1$ and Re = 6970. The disk current exhibited two reaction waves during the cathodic sweep. The first wave corresponded to the reduction of Cu^{++} to Cu^+; within this potential range there was an increase in the ring current which reached a plateau when the disk current reached the limiting current for the Cu^{++}/Cu^+ reaction. The ratio of the ring current to the disk current gave the collection efficiency and the value agreed with the previous measurements using the ferricyanide/ferrocyanide reaction. The second wave corresponded to the reduction of Cu^+ to Cu; within this potential range the ring current correspondingly decreased to zero. In the anodic sweep, the copper deposited during the cathodic sweep started to dissolve into the electrolyte, and the disk current increased. It reached a maximum and then sharply decreased once all the copper was dissolved into the electrolyte. There was a correspond-

ing increase in the ring current, which simultaneously reached a maximum with the disk current. Again, the ratio of the ring current to the disk current agreed with the measured collection efficiency. This indicates that the main dissolution product of copper in $CuCl_2$-HCl solution is Cu^+.

Figure 14 shows the cyclic voltammetry of the DT21 platinum ring disk electrodes in a 0.01M $CuSO_4$-0.5M H_2SO_4 solution. In the cathodic sweep the disk current had only one reaction wave. The ring did not detect any Cu^+ species and had a zero ring current. The reason for this is that Cu^+ formed in $CuSO_4$-H_2SO_4 solution was very unstable and immediately converted to Cu. During the anodic sweep, the disk current increased. It reached a maximum and then decreased when all the copper was dissolved. The ring did detect some Cu^+ during the anodic sweep but the ring current was very small as indicated by the μA-scale in Fig. 14B. This implies that the main dissolution product of Cu in $CuSO_4$-H_2SO_4 solution is Cu^{++} and the very small amount of Cu^+ might be the result of a secondary chemical reaction between Cu^{++} and Cu (9). Thus the impinging jet was capable of differentiating the Cu^{++}/Cu reaction in the $CuCl_2$-HCl solution from that in the $CuSO_4$-H_2SO_4 solution.

Conclusions

A theoretical and experimental study has been made to determine the feasibility of a ring disk arrangement with an impinging jet for electroanalytical applications. The reduction of ferricyanide ion and the cyclic voltammetry of a Cu^{2+}/Cu reaction were used to measure the mass transfer rates and the collection efficiencies of four different sizes of ring disk electrodes over a range of Reynolds numbers from 300 to 11,000. It is found that if one limits the nozzle height to 0.5-2.0 nozzle diameters and the outer radius of the ring electrode to less than 0.6 nozzle diameter, the collection efficiency would be independent of the Reynolds number and the nozzle height for both laminar and turbulent flows. Within these ranges, the rotating ring disk theory can be used as a first approximation in the prediction of the collection efficiency.

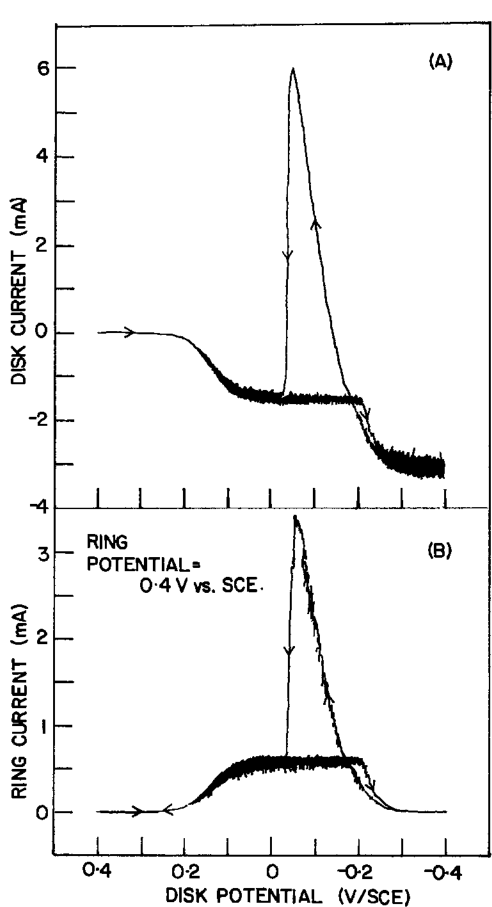

Fig. 13. Cyclic voltammetry curves of the DT21 platinum ring disk electrodes in 0.01M $CuCl_2$-0.5M HCl solution at H/d = 1.0 and Re = 6970. The disk potential was scanned at a rate of 0.25 V/min, and the ring potential was maintained at 0.4V vs. SCE.

Oxidation of HCOOH and CH_3OH on Platinum Modified by Foreign Metal Adatoms in 85% Phosphoric Acid

R. R. Adzic,[1] W. E. O'Grady,* and S. Srinivasan*

Brookhaven National Laboratory, Upton, New York 11973

ABSTRACT

The use of underpotentially deposited metal atoms as electrocatalysts suggests a promising route for enhancing the kinetics of oxidation of organic fuels. The electro-oxidation of formic acid and methanol was studied on underpotentially deposited metal atoms on platinum in 85% phosphoric acid. The rates of these reactions were greatly improved. Due to adsorption of phosphate ions, formic acid oxidation rates on underpotentially deposited metal atoms are lower than in perchloric acid. The electrocatalytic activity of the investigated underpotentially deposited metals for formic acid oxidation follows the order Pb > Bi > Tl: for methanol oxidation during the cathodic scan the rates are higher for lower lead concentrations, which is probably due to lower concentration of adsorbed lead and/or oxide. It is proposed that the enhanced reaction rates with underpotentially deposited metal atoms are due to inhibition of hydrogen adsorption and hence of formation of poisoning intermediates such as COH.

The interest in the more efficient use of organic fuels has increased considerably after the energy crisis of 1973. For this reason, the attention of a number of electrochemists has focused on electrochemical energy conversion including the direct oxidation of organic molecules. The oxidation reactions of HCOOH and CH_3OH are of particular interest because these molecules are potential fuels for fuel cells and represent "model molecules" for reactions which serve as a basis for studies of more complex ones. It was recently shown (1-3) that foreign metal adatoms have a striking catalytic effect on these reactions on several noble metals in 1M $HClO_4$. In this work, the results obtained for the oxidation of formic acid and of methanol on platinum modified by foreign metal adatoms in 85% H_3PO_4, which is one of the most attractive electrolytes for practical fuel cells, are reported.

Experimental

The measurements were made in a three-compartment Pyrex cell. The working electrode was 2 cm^2 Pt foil. The counterelectrode was also Pt, while the reversible hydrogen electrode served as the reference. The working electrode was first polished to obtain a mirror finish, washed, cleaned with 1:1 volume ratio H_2SO_4-HNO_3, and then rinsed with triply distilled water.

The acid was purified using essentially the procedure of Ferrier *et al.* (4) and Huang *et al.* (5). H_2O_2 was added to reagent grade 85% H_3PO_4 (Mallinckrodt) and this solution was heated to 90°C until gas evolution ceased. The acid was then heated to 160°C to reduce the water content and destroy any remaining traces of H_2O_2. The water content was adjusted and the acid was preelectrolyzed for 24 hr.

Results

Underpotential deposition of Pb, Bi, and Tl on Pt in 85% H_3PO_4.—Figure 1 shows the underpotential deposition (UPD) of Pb. This metal was added in the form of perchlorate, which introduced some $HClO_4$ and H_2O into the electrolyte. This, however, negligibly changed the concentration of H_3PO_4. The UPD of Pb considerably suppresses hydrogen adsorption on Pt, but apparently less than in 1M $HClO_4$. The suppressed hydrogen adsorption peaks are seen in Fig. 1. This behavior and a large pseudocapacitance associated with lead adsorption/desorption process indicate a somewhat smaller electrosorption valence for Pb_{ad} in this electrolyte. Larger currents for desorption of some other adatoms in the presence of specific adsorption of anions have been ascribed to a desorption of anions which accompanies the UPD (6). It appears that both effects might be present in this particular system. The desorption of Pb_{ad} occurs at less positive potentials than in $HClO_4$. It appears that these differences are due to the interference of a specific adsorption of phosphate ions with the UPD of Pb. The shift of the lead

desorption peak to less positive potentials is equivalent to a reduction in bond strength between metal adatoms and the substrate surface. The interaction of phosphate anions with platinum is stronger than with lead adatoms which hence causes a decrease in bond energy.

Figures 2 and 3 display the UPD of Bi and Tl. The differences found with the UPD of Pb in 1M $HClO_4$ and 85% H_3PO_4 are also found for the UPD of Bi and Tl. These include a shift of desorption peaks to less positive potentials, *i.e.*, a diminishing of the underpotential deposition effect and a change of the electrosorption valence. The latter looks negligible with Bi. The peak at 1.3V in Fig. 3 is due to the redox reaction Tl^+/Tl^{3+}.

Oxidation of HCOOH on Pt and Pt modified by foreign metal adatoms.—Figure 4 shows the oxidation of HCOOH on Pt in 85% and 40% H_3PO_4. The voltammogram obtained in 40% H_3PO_4 is essentially the same as that obtained in 1M $HClO_4$ and H_2SO_4 (1, 6). The oxidation currents are, however, much smaller in 85% H_3PO_4. A very small peak in the anodic scan is noteworthy. The second anodic peak is also different. The lower activity of Pt in 85% H_3PO_4 arises mainly from the decreased H_2O concentration. The specific adsorption of phosphate ions seems to have a smaller influence.

Figure 5 shows the oxidation of HCOOH on Pt partially covered by lead adatoms (full line). Approximately a 60-fold increase of the peak current in the anodic scan is seen in comparison with the curve for Pt (dashed line). The effect is similar in magnitude to the one observed in 1M $HClO_4$ (1, 2). The peak at 0.85V is a new feature. It falls exactly between the peak for desorption of Pb and the onset of oxide for-

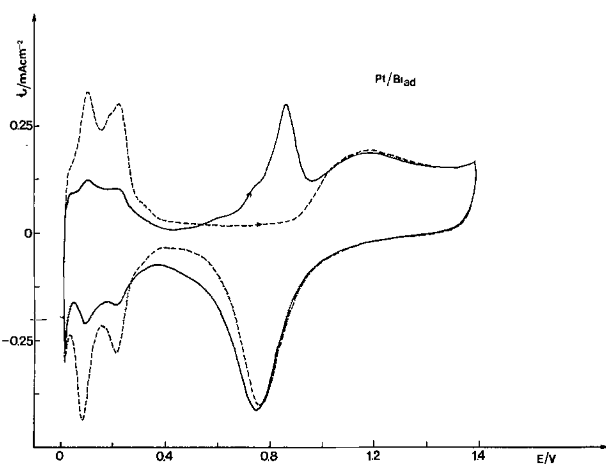

Fig. 2. Underpotential deposition of Bi on Pt in 85% H_3PO_4 (full line). Pt in the absence of Bi (dashed line). Sweep rate 100 mV/sec, $1 \times 10^{-3}M$ Bi^{3+}.

mation on Pt (Fig. 1). It appears that after desorption of Pb adatoms, the Pt surface is not completely covered by strongly bound intermediates and thus the oxidation of HCOOH is facilitated. In 1M $HClO_4$, there is no such window because a complete desorption of Pb coincides with the onset of oxide formation on Pt (1, 2).

Figure 6 displays the results obtained with Bi adatoms. The peak in the anodic scan is increased considerably. It appears, however, at more positive potentials than the peak on Pt without Bi_{ad}. This is caused by an excessive coverage of Bi adatoms at less positive potentials. At smaller concentrations of Bi the peak indeed shifts to less positive potentials. The current at the peak is, however, smaller because it appears at a lower overpotential for HCOOH oxidation. As with Pb adatoms, a second peak in anodic scan appears, but at ~1.0V in this case.

Figure 7 shows the effects of Tl adatoms which are considerable, although smaller than the effects of Pb and Bi. There is agreement with the data obtained in 1M $HClO_4$ (1, 2). The smaller current density of the peak in the cathodic direction is due to the formation of a high coverage of Tl_{ad}. This decreases the available oxide-free and intermediate-free Pt surface which is otherwise available for the oxidation of HCOOH.

Steady-state measurements (Fig. 8) show striking catalytic effects of Pb adatoms consistent with the linear sweep voltammetry. At 0.4V the effect amounts to three orders of magnitude. A similar effect has been found in 1M $HClO_4$ (1-3).

Oxidation of CH_3OH.—Figures 9 and 10 show voltammetry curves for the oxidation of CH_3OH on Pt in 85% H_3PO_4 and the effect of a progressive decrease of cathodic and anodic potential limits, respectively. A small oxidation current is seen in the double layer region of Pt for the sweep encompassing the whole potential range. The main oxidation peak coincides with the onset of oxide formation on Pt. Figure 9 shows a surprising current jump when the sweep is reversed at 0.2V which gradually diminishes at more positive potentials. This current spike is not at present clearly understood. It might be connected with the oscillatory phenomena observed in oxidation of organics (26). The currents associated with the sweeps reversed at potentials outside the hydrogen adsorption

are higher than for the sweep which encompasses the whole potential range. The indication is that H_{ad} on Pt has a role in producing strongly bound intermediates in oxidation of CH_3OH on Pt.

A progressive decrease of anodic potential limit (Fig. 10) shows that an incomplete oxidation of strongly bound intermediates leads to a decrease of catalytic activity of Pt.

Figure 11 displays the effect of Pb adatoms on this reaction. The effect is smaller than for oxidation of HCOOH. It is, however, larger than in 1M $HClO_4$ (3), probably caused by desorption of Pb adatoms before the oxide formation on Pt in 85% H_3PO_4. This view is confirmed by the appearance of the second peak for oxidation of HCOOH (Fig. 5). Platinum is protected from adsorption of strongly bound intermediates by Pb adatoms and after Pb desorption clean Pt surface is available for the oxidation of CH_3OH, since the adsorption of COH can be kinetically controlled. New peaks (solid line) occur at 0.35, 0.5, and 0.8V and the shoulder at 0.65V. The first two peaks and the shoulder are partly caused by the desorption of Pb adatoms. The peak at 0.8V is clearly the catalytic effect, which shifts the oxidation of CH_3OH by 0.2V to less positive potentials. In the cathodic direction an inhibition is ob-

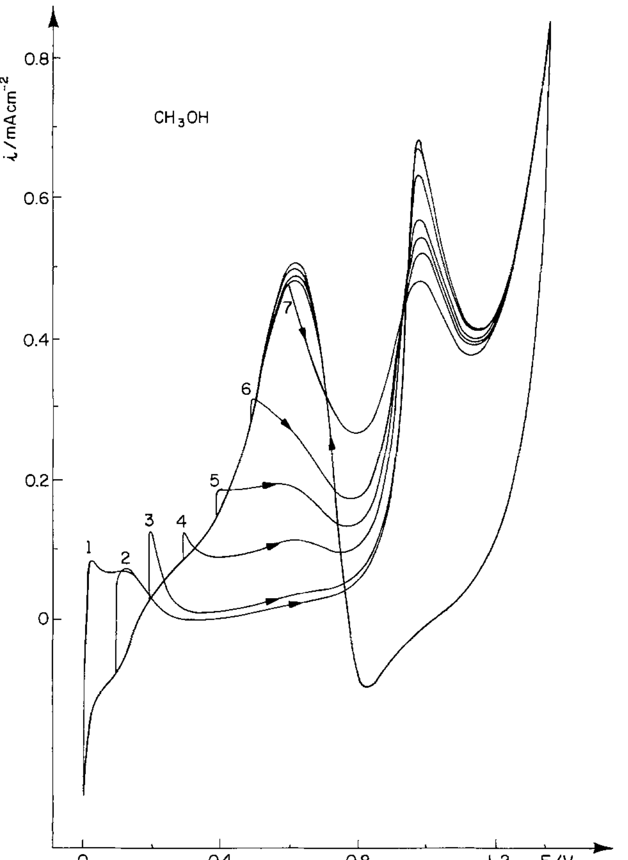

Fig. 9. Oxidation of CH_3OH on Pt in 85% H_3PO_4. Effects of a progressive decrease of cathodic potential limit. 0.5M CH_3OH; sweep rate 100 mV/sec.

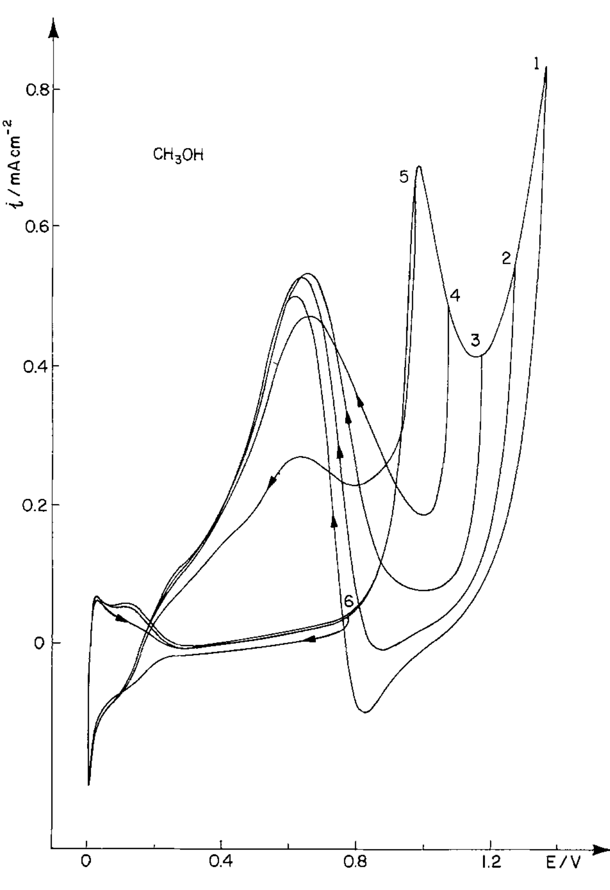

Fig. 10. Oxidation of CH_3OH on Pt. Effects of a progressive decrease of anodic potential limit. Other data as in Fig. 9.

served, caused by an excessive coverage of Pb adatoms formed simultaneously with oxide reduction on Pt. At this high concentration of Pb^{2+} ($C_{Pb^{2+}}$), a very small portion of the Pt surface is lead- and oxide-free in the cathodic scan. Only on such a surface can the oxidation of CH_3OH occur. For smaller $C_{Pb^{2+}}$, *i.e.*, smaller θ_{Pb}, both effects are less pronounced (Fig. 11).

Discussion

Oxidation of HCOOH.—The oxidation of HCOOH on Pt has been given considerable attention. The results of various authors differ in details of the reaction mechanism, but agree about the main feature of the reaction, *i.e.*, the formation of strongly bound intermediates which are difficult to oxidize. These intermediates block the surface and reduce the reaction

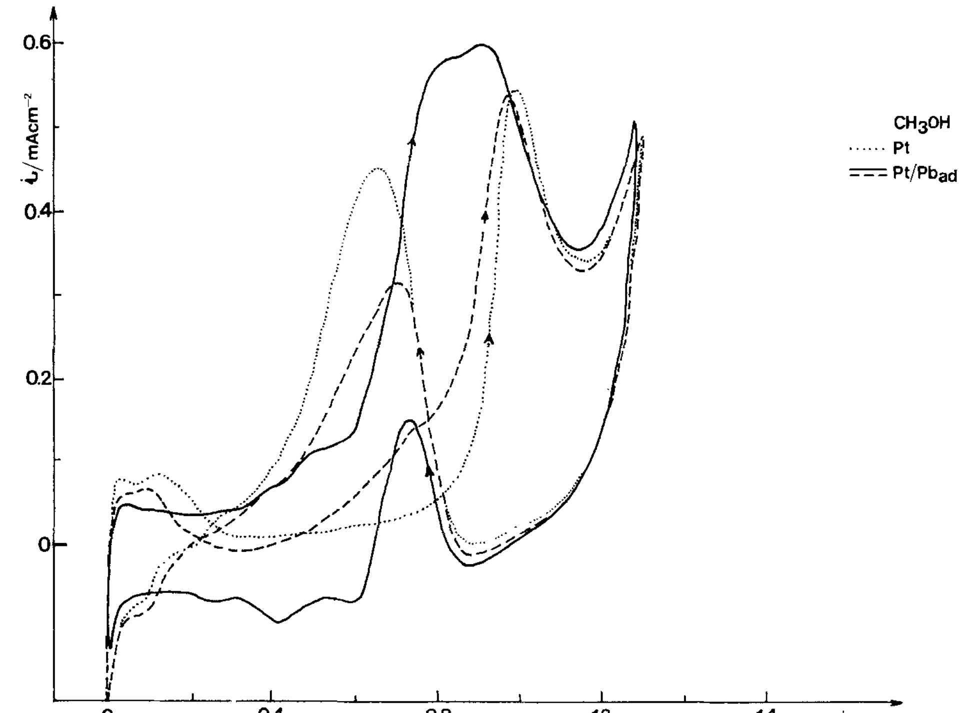

Fig. 11. Oxidation of CH_3OH on Pt (dotted line) and Pt with Pb adatoms (full line and dashed line with 1×10^{-3} and 1×10^{-4}M Pb^{2+} in electrolyte). 0.5M CH_3OH; 100 mV/sec.

rate. According to a majority of authors, the strongly bound intermediate is the species $\underset{***}{C}OH$. [See, for example, the recent reviews by Capon and Parsons (7) and McNicol (8).] In parallel with the reaction leading to the formation of the strongly bound intermediate, a direct oxidation to CO_2 takes place. This apparently occurs only on a small fraction of the surface covered by $\underset{***}{C}OH$.

As pointed out above, it appears that there is no major difference between the oxidation of HCOOH in 85% H_3PO_4 and $1N$ $HClO_4$, or H_2SO_4. The shape of the voltammogram in 40% H_3PO_4 is the same as in these electrolytes, which suggests the same reaction mechanism. The mechanism given by Capon and Parsons (6) is supported by catalytic effects of foreign metal adatoms. According to these authors, the reaction commences with the oxidative dehydrogenation

$$HCOOH \rightarrow \underset{*}{C}OOH + H^+ + e \qquad [1]$$

followed by further oxidation of carboxy ad-radical

$$\underset{*}{C}OOH \rightarrow CO_2 + H^+ + e \qquad [2]$$

The ad-radical $\underset{*}{C}OOH$ also reacts immediately with hydrogen adsorbed on the Pt surface to form the strongly bound intermediate

$$\underset{*}{C}OOH + 2H_{ad} \rightarrow \underset{***}{C}OH + H_2O \qquad [3]$$

The species $\underset{***}{C}OH$ has been postulated by several authors (6, 9). The role of H_{ad} in its formation has been clearly illustrated in the work by Capon and Parsons (6). Catalytic effects of foreign metal adatoms provide evidence for the participation of H_{ad} in the formation of $\underset{***}{C}OH$ (1-3).

The species $\underset{***}{C}OH$ can be oxidized at higher positive potentials in a reaction with H_2O or OH_{ad} (the peak at 0.9V). On the basis of several sets of data (6, 10, 11), it appears that the reaction with OH_{ad} is more probable

$$\underset{***}{C}OH + Pt(OH) \rightarrow \underset{**}{C}(OH)OH + Pt \qquad [4]$$

$$\underset{**}{C}(OH)OH + Pt(OH) \rightarrow \underset{*}{C}OOH + Pt + H_2O \qquad [5]$$

$$\underset{*}{C}OOH + Pt(OH) \rightarrow CO_2 + Pt + H_2O \qquad [6]$$

In order to explain all the features of the oxidation of HCOOH on Pt, Capon and Parsons (6) postulated an additional strongly bound intermediate, the species $\underset{**}{C}(OH)$ which requires two sites for adsorption. Its oxidation is slow and it eliminates the sites for adsorption of HCOOH causing the peak at 0.5V. It probably occurs in a disproportionation reaction

$$HCOOH + \underset{*}{C}OOH \rightarrow \underset{**}{C}(OH)_2 + CO_2 + H + e \qquad [7]$$

The existence of such species have also been confirmed by the effects of foreign metal adatoms.

Figure 4 is in agreement with the above considerations based on the analysis of behavior in $1N$ acid electrolytes. Smaller currents for oxidation of HCOOH are, however, obtained in 40% and especially in 85% H_3PO_4. This is due to the competitive adsorption of phosphate ions which are more strongly adsorbed than ClO_4^-, or SO_4^{2-} (12, 13). A relatively strong specific adsorption of phosphate ions can easily decrease the adsorption of HCOOH and decrease the reaction rate along the main reaction pathway. It has been shown that Cl^- has a detrimental effect on this reaction (15). A shift of the second anodic peak to more positive potentials and its somewhat different shape in 85% H_3PO_4 is caused by the shift of the initial oxide formation on Pt in this electrolyte. This corroborates the view that OH_{ad} is necessary for the oxidation of $\underset{***}{C}OH$, rather than adsorbed H_2O. A progressive decrease of cathodic and anodic potential limits supports the mechanism outlined by Eq. [1]-[5].

The adatoms of Pb, Bi, and Tl suppress hydrogen adsorption on Pt (Fig. 1-3). Thus, these adatoms eliminate reaction [3], *i.e.*, the formation of $\underset{***}{C}OH$ species. This is the primary origin of the catalytic effects of these adatoms. Furthermore, these adatoms also suppress the adsorption of $\underset{**}{C}(OH)_2$ intermediate by decreasing the number of nearest neighbor pairs of Pt atoms necessary for its adsorption. At potentials close to 0.0V, the coverages of Pb, Bi, and Tl adatoms are close to $\theta_M \approx 1$. The oxidation of HCOOH does not take place on such a surface. Hydrogen adsorption is completely suppressed and this prevails into part of the hydrogen adsorption region. At more positive potentials, θ_M commences to decrease and a clean Pt surface is exposed to HCOOH. The reaction can now proceed along the direct oxidation pathway. As long as $\theta_M > 0.5$, the surface is protected from adsorption of $\underset{**}{C}(OH)_2$ species because pairs of nearest neighbor Pt sites are not available. An even distribution of adatoms on the Pt surface is required which appears to be the case for these systems (3).

As θ_M decreases below 0.5, $\underset{**}{C}(OH)_2$ commences to adsorb, which decreases the reaction rate. This causes the appearance of the peak in Fig. 6-8, *i.e.*, a decrease of the current, although the overpotential increases.

In the presence of foreign adatoms, the current associated with reaction [1], which appears to be the rate-determining step (6, 15) can be written in the following way

$$i = k(1 - \theta) \exp{(1 - \alpha)\mathbf{F}E/RT} \qquad [8]$$

where θ is total coverage of adsorbed species

$$\theta = \theta_M + \theta_{\underset{**}{C}(OH)_2} \qquad [9]$$

Reaction [2] seems to be fast (6, 15) and therefore the coverage of COOH should be negligible. Consequently, it is not taken into account in Eq [9].

If one adatom blocks one Pt site for adsorption of $\underset{**}{C}(OH)_2$ then for $\theta_M < 0.5$

$$\theta_{\underset{**}{C}(OH)_2} = 1 - 2\theta_M \qquad [10]$$

In this case Eq. [8] becomes

$$i = k\theta_M \exp{(1 - \alpha)\mathbf{F}E/RT} \qquad [11]$$

When $\theta_M > 0.5$ on the basis of the above discussion, it follows that the rest of the surface will be free from $\underset{**}{C}(OH)_2$. Therefore

$$\theta = \theta_M \qquad [12]$$

and the current from Eq. [8] is now

$$i = k(1 - \theta_M) \exp{(1 - \alpha)\mathbf{F}E/RT} \qquad [13]$$

A semiquantitative calculation based on this model shows that the experimental voltammetry curve for Pt in 1M $HClO_4$ can be satisfactorily reproduced (2, 3). The same is valid for 85% H_3PO_4, except for the peak at 0.85V which has been explained earlier in the text.

Striking catalytic effects obtained in steady-state measurements (Fig. 8) support the view that in the

presence of adatoms, the poisoning intermediate $\underset{***}{\mathrm{C}}\mathrm{OH}$ is not formed, at least by reaction [3]. This species can, however, be formed in the reaction of COOH with HCOOH as shown by reaction [7]. Although lead adatoms are more strongly bound to the surface than $\underset{***}{\mathrm{C}}\mathrm{OH}$, as shown by specular reflectance spectroscopy (16), a certain adsorption equilibrium of these two species is established. Besides the equilibrium adsorption of $\underset{**}{\mathrm{C}}(\mathrm{OH})_2$ takes place at a lower coverage of adatoms. For these reasons, the Pt electrode has lower activity in the steady state than in the transient measurements. The activity is, however, still high and may be of practical interest.

The smaller catalytic effect of Tl adatoms is due to its weaker bond with Pt, which is reflected in its electrosorption valence (18). Formic acid and its intermediates can therefore affect the adsorption of Tl in the same way as found with Cd (17). Also, partially charged Tl adatoms can induce the adsorption of phosphate ions which would also cause a decrease of the rate of oxidation of HCOOH.

Oxidation of CH_3OH.—The oxidation of CH_3OH apparently leads to the formation of the same strongly bound intermediates as during the oxidation of HCOOH. Frumkin and Podlovchenko (18) have shown that the chemisorption and dehydrogenation of CH_3OH results in formation of $\underset{***}{\mathrm{C}}\mathrm{OH}$. Kazarinov *et al.* (19), using a radiotracer technique, have shown that the oxidation of CH_3OH, HCHO, and HCOOH, in both acid and alkaline electrolytes, results in the formation of $\underset{***}{\mathrm{C}}\mathrm{OH}$ intermediates. This is in agreement with the results of Wieckowski (20), Breiter (21), Biegler (22), and Capon and Parsons (7). Vassilyev *et al.* (23) showed how $\underset{***}{\mathrm{C}}\mathrm{OH}$ could arise from a whole variety of organic molecule oxidations. Allen *et al.* (24) using ESCA identified a chemisorbed species as $\underset{***}{\mathrm{C}}\mathrm{OH}$. *In situ* identification of this apparently most important intermediate in oxidation of organics would also be desirable. A dehydrogenation of the methyl group leads to the formation of $\underset{***}{\mathrm{C}}\mathrm{OH}$ and the oxidation of 3H

$$CH_3OH \rightarrow \underset{***}{\mathrm{C}}\mathrm{OH} + 3H^+ + 3e \qquad [14]$$

The origin of the catalytic effect of Pb adatoms on this reaction can be explained by a so-called "third body" effect (25). Pb adatoms suppress the adsorption of $\underset{***}{\mathrm{C}}\mathrm{OH}$ to a certain extent. The oxidation of CH_3OH commences at potentials where θ_M is low, which is the cause of a relatively small catalytic effect. At higher temperatures, the effect should be larger if this explanation is correct, since the oxidation of CH_3OH would shift to lower overpotentials, where θ_M is high enough. In the oxidation of CH_3OH, HCOOH was detected in solution (26). The catalysis of its oxidation probably contributes to the effect observed with CH_3OH. The presence of HCOOH in solution is supported by the role of H_{ad} in oxidation of CH_3OH as seen in Fig. 9.

Motoo *et al.* (10) explained the enhancement of CH_3OH oxidation caused by Ru, Sn, and Ge (27) deposited on Pt as due to a coadsorption of oxygen by these metals. Adsorbed oxygen helps oxidation of $\underset{***}{\mathrm{C}}\mathrm{OH}$ intermediate. Osetrova *et al.* (11) have found that OH coadsorbed on Sn was the active species. Janssen and Moolhuysen (28) and McNicol *et al.* (29) have found that various adatoms modify the adsorption properties of Pt through a ligand effect. There is no indication that Pb, Bi, or Tl coadsorb oxygen or OH species. Except for Tl at low coverages, the electrosorption valence of Pb and Bi on Pt is close to their faradaic valence (18), which supports this view. The modification of uncovered Pt sites by these adatoms, the ligand effect, is not supported by the observation that the foreign metal adatoms do not effect hydrogen adsorption on such sites (17).

Conclusions

Underpotentially deposited metal adatoms on platinum enhance the rates of electro-oxidation of formic acid and of methanol with aqueous phosphoric acid as the electrolyte. The effects are more significant for formic acid oxidation than for methanol oxidation. From the cyclic voltammetric results, it is proposed that the underpotentially deposited metal adatoms (Pb, Bi, and Tl) inhibit the adsorption of atomic hydrogen and hence the formation of the poisoning intermediate. For formic acid oxidation, the electrocatalytic activities follow the order Pb > Bi > Tl. These results can be interpreted on the basis of the higher coverage of the adatoms at lesser positive potentials or due to a weaker bond between the adatoms and the substrate. The magnitudes of the effects of the adatoms are less in phosphoric acid electrolyte than those found previously in perchloric acid, probably due to the specific adsorption of phosphate ions. The use of underpotentially deposited metal atoms as electrocatalysts shows promise for improving the performance of direct organic fuel-air fuel cells.

ABSTRACT

Photomicroscopic, electron-microscopic, and surface analytical studies have been conducted on $Li(Si)/LiCl \cdot KCl/FeS_2$ electrochemical cells before and after discharge, and on individual anode and cathode components. Physical and chemical compositional changes were observed at both the anode and cathode interface that have significance in the discharge mechanism. Oxygen-rich species were found at the surface of the FeS_2 cathode particles and migration of sulfur away from the cathode during discharge was also observed. Thermal shock of FeS_2 single crystals confirmed the tendency for sulfur to move away from the bulk with the application of heat to the surface. Exposure of the Li(Si) alloy to atmosphere and/or thermal shock resulted in the formation of a lithium-rich surface in the carbonate or oxide form. These findings have significance to battery systems that must be stored for long time periods, as well as the possible source of resistive interfaces in charge and discharge cycles.

The Li/FeS_2 primary and Li/FeS secondary batteries are the subject of intense research in several laboratories (1-6). Primary battery applications require that the anode (Li alloys) and the cathode (pelletized FeS_2) be separated by an electrolyte-binder (EB) layer with no membrane separator between them (1). Stacks of these pelletized cells are placed in series to produce the desired operating voltage and the diameter is varied to yield the desired current drain. When operating as a primary power source, the cells normally sit in an inactive state until heated to operating temperatures greater than the melting point of the electrolyte, in times on the order of seconds (or less). Optimization of the operation of these batteries and development of design criteria for future high energy density batteries, must be preceded by a better understanding of the chemical and electrochemical reactions which proceed at each interface. To this end, we have conducted several studies on intact single cells and on individual anode, cathode, and electrolyte components. A typical single cell is discharged as variable currents from 0.1 to 1.0A producing a cell voltage of 1.5-1.9V for periods from minutes to hours using previously described techniques (1). These discharges do not normally consume the entire power capacity of the materials within each cell.

Key words: fused salts, electrode, electron spectroscopy, passivation.

In this paper, we report on the correlation of electron microscopic, photomicroscopic, and various electron spectroscopic surface analysis data to the study of the Li(Si) alloy/electrolyte-binder interface and the FeS_2/electrolyte-binder interface from single cells and battery discharges. Migration of components from both anode and cathode during heating and discharge is noted. Surface analysis of discrete anode and cathode components and of standard materials confirm many of these migration processes.

Experimental Section

The materials used for single cell testing were typical battery compositions (4). The anode pellet was made from an Li(Si) alloy of 40 or 45 weight percent (w/o) Li. Standard particle size was 76-422 μm (-40 to $+200$ mesh) yielding a typical pellet density of 1.0 g/cm^3.

The electrolyte-binder (EB) pellet, used to separate the anode and cathode, was composed of an $LiCl \cdot KCl$ eutectic (45/55 w/o) and a MgO binder (Maglite S, Merck Chemical Company, San Francisco, California). The finely divided MgO acts to immobilize the electrolyte when melted but does not react with either the anode or cathode. The mixture was composed of 70 w/o electrolyte and 30 w/o binder and formed to a density of about 1.7 g/cm^3.

The cathode powder was 64 w/o FeS_2, 16 w/o $LiCl \cdot KCl$ eutectic electrolyte, and 20 w/o EB. The EB used

in the cathode was 12 w/o SiO_2 binder and 88 w/o LiCl · KCl eutectic. FeS_2 was readily available as granular iron pyrite obtained from Matheson, Coleman, and Bell Manufacturing Company, Norwood, Ohio, with a particle size less than 295 μm (50 mesh). Pellets were formed to a density of 2.6 g/cm^3.

To assemble a cell, the pellets were stacked around a centering post and sandwiched between two stainless steel disks used as current collectors. The assembled cells were then placed between preheated platens to melt the electrolyte, and discharged for various times and at various temperatures and current densities on a standard single cell tester (6).

For microscopic studies, discharged cells were broken through the center and the exposed interface was smoothed with increasingly finer sandpaper. Optical examination before and after sanding showed that the integrity of the diffused material was preserved. Cells from any given series of discharges were assembled as a unit and examined simultaneously under both the optical and the scanning electron microscopes. The interfaces of particular interest in this study involve the electrochemically active Li(Si) anode and FeS_2 cathode with LiCl · KCl electrolyte and MgO binder (all 1 mm thickness).

All experimental apparatus except the Auger electron and x-ray photoelectron spectrometers was located in a "dry room" facility with an atmosphere containing less than 300 ppm water. This unique feature allows cells to be prepared, discharged, and microscopically examined in a relatively water-free environment.

The scanning electron microscope is an International Scientific Instruments Model Super III-A with a resolution of 70Å. Samples were examined under a 100 μA beam current with a 30 keV accelerating voltage. The electron probe microanalysis (EM) using energy dispersive x-ray spectroscopy (XRF) was performed with a Princeton Gamma-Tech XCEL-1000 analyzer. The analyzer used a lithium-drifted silicon detector with a measured resolution of 153 eV and 1000 counts/sec at 5.9 keV. For the elemental analysis, samples were examined under 3000× magnification exposing a surface area of 0.03 mm^2. The spectra were collected for 30 sec from five different spots on each pellet and then averaged. To quantify the amount of a given element, window integrals were used to measure x-ray counts; the number of counts being proportional to the amount of an element. The x-rays emitted by the element within a given energy range or window were first counted. The number of x-rays in a background window were simultaneously counted; the background window being selected to have the same width and close to the same energy as the elemental window but not containing any x-rays from the element. The elemental x-rays were then divided by the background x-rays resulting in a unitless ratio (S/S^o and Fe/Fe^o). The ratio reflects an atomic intensity uncorrected for the fluorescence atomic sensitivity.

The Auger electron spectroscopy (AES) data were taken with a Physical Electronics Auger system with a single-pass, cylindrical mirror analyzer. For a typical spectrum, the electron gun was operated at 2 kV and 5-20 μA and a beam diameter of *ca.* 0.1 mm was maintained. The pressure was maintained at 5×10^{-10} Torr. The cells were broken in a glove box in high purity argon and transferred quickly to the high vacuum chamber. Careful microscopic examination indicated no visible signs of contamination. This observation is supported by the fact that little or no carbon was observed in the AES spectra. Carbon peaks are typical of most contamination.

X-ray photoelectron spectroscopy (XPS) data were taken from a GCA McPherson ESCA 36 Photoelectron Spectrometer using a 127° electrostatic deflector as an electron analyzer. The x-ray source emitted $MgK\alpha$ radiation (1253.6 eV). The spectrometer was interfaced to a PDP 8/e minicomputer, which provided a summation average of the spectra as well as digital control of the analyzer. For all the spectra obtained, pressure was maintained in the 10^{-7}-10^{-8} Torr range.

Results and Discussion

Photomicroscopic and electron microscopic studies.—Figure 1 illustrates a typical voltage-time dependence of a single cell discharged at 100 mA/cm^2 and 520°C. Curve (a) is the total cell potential while curve (b) is the anode-to-reference potential and curve (c) is the cathode-to-reference potential. From these data, the following reproducible features are noted. A positive voltage excursion is observed during the first minute (seconds) of discharge followed by a nearly constant voltage response of 1.5-1.6V for the next several minutes. A decline in operating voltage is observed after about 20 min for anodes of this composition (*i.e.*, approximately 45 w/o). Small voltage changes observed during discharge have been shown to be due to compositional changes of the lithium alloy (3, 25). Polarization of the cathode is responsible for the steadily declining potential after about 30 min of discharge. Finally, the sharp decline in cell voltage occurs when the anode can no longer support the current drawn, *i.e.*, at about 85% of theoretical Li capacity. However, batteries built with these cells and tested at this current density typically experience end of life due to the internal temperature cooling to <352°C, normally expending less than 50% of the lithium capacity.

Significant compositional changes at the anode/electrolyte interface and at the cathode/electrolyte interface were indicated by study of the photomicrographs of cross-sectioned, discharged single cells. Figure 2 shows the photomicrographs of three single cells which were, (a) held at open circuit for 2 min, (b) discharged at 0.25A for 20 min, and (c) discharged at 0.25A for 80 min —all at 520°C.

Several features were evident in all photomicroscopy studies. These are summarized as follows: (*i*) a significant change in color and morphology was observed for the anode at the electrolyte interface following discharge; (*ii*) the FeS_2 particles which comprise the cathode material undergo an apparent phase transformation at their outer perimeter. The transformation is dependent upon the extent of discharge of the single cell and the temperature of the discharge; (*iii*) a new phase appears as a layer in the electrolyte-binder (EB) region following discharge. The thickness of this

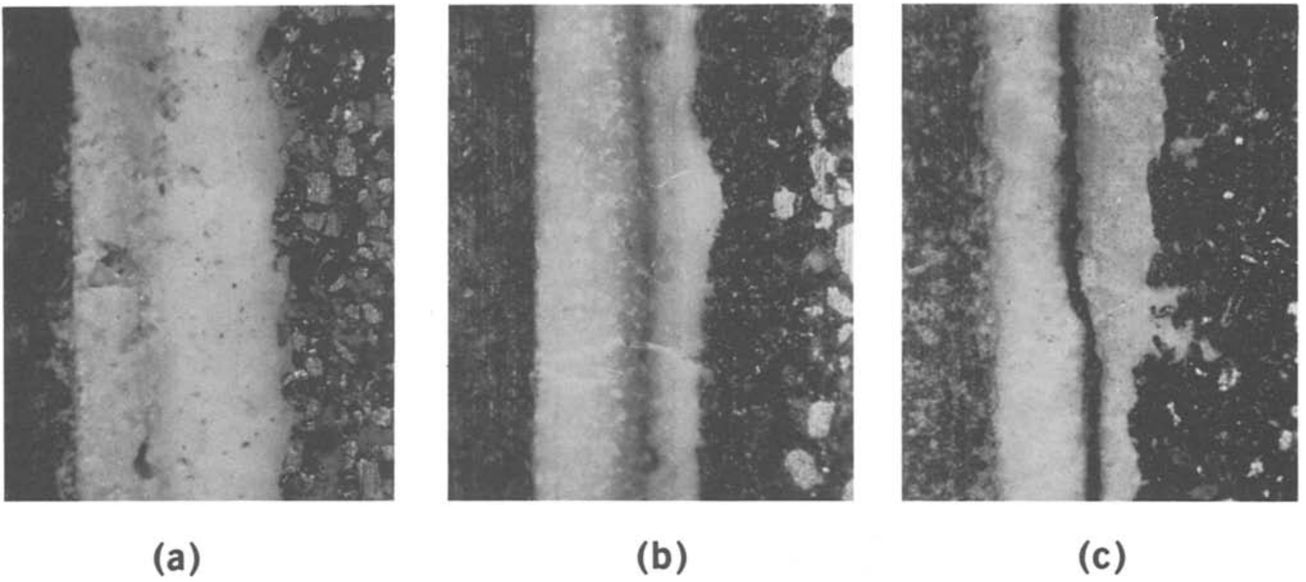

Fig. 2. Photomicrographs of the cross sections of three single cells which were (a) held at open circuit for 2 min at 520°C, (b) discharged at 0.25A for 2 min, and (c) discharged at 0.25A for 80 min. The anode layer is at the left, the EB layer at the center, and the cathode layer is at the right in each photograph.

layer and its proximity to the anode is a complex function of the discharge current, temperature, and voltage. This layer can be seen in the center of Fig. 2(b) and (c). From these photomicrographic studies, it was apparent that stoichiometric changes were occurring at each interface which may have significance for the performance of these and other lithium-metal sulfide batteries.

Electron microscopic studies of similarly discharged cells were conducted to further study the changes noted above. Figure 3 shows three photomicrographs and the corresponding x-ray fluorescence dot maps

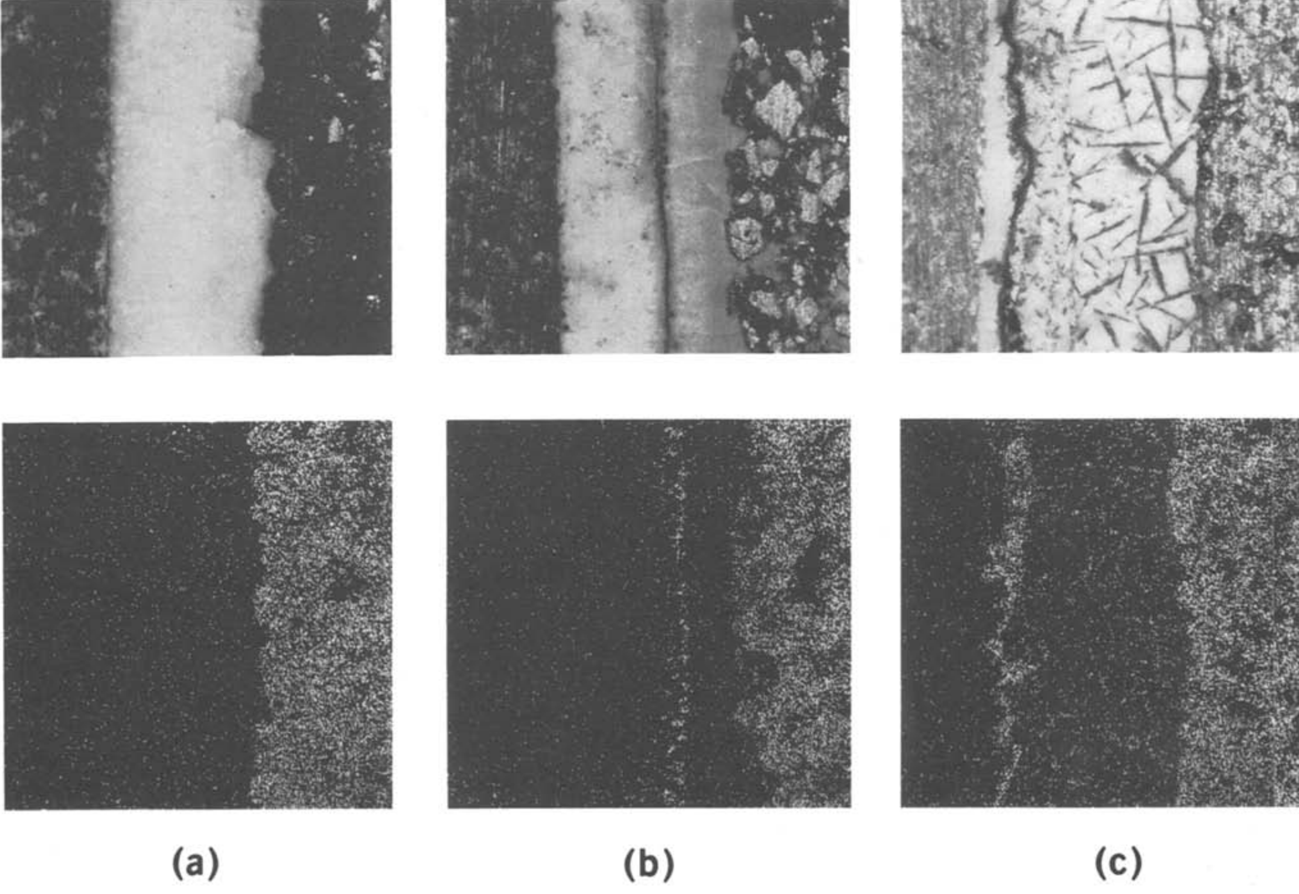

Fig. 3. Scanning electron micrographs and sulfur ($K\alpha$) x-ray fluorescence dot maps of cross sections of three single cells which were discharged at 1.0A for 20 min at (a) 440°C, (b) 520°C, and (c) 600°C. Again the anode, EB layer, and cathode are displayed from left to right.

for sulfur ($K\alpha$ radiation excited at 25 keV) as a function of discharge temperature, from 440° to 600°C. The new phase in the EB layer is transformed from a discrete band to more dispersed linear regions of new material as the discharge temperature increases. The sulfur density maps show the movement of sulfur from the cathode region into the EB layer. Iron (Fe, $K\alpha$) was also detected by the XRF method, in the same region as sulfur. Tables I and II give more information on the stoichiometric changes undergone at the cathode/EB interface. Table I shows the relative increase of both sulfur and iron in the EB layer as a function of discharge time. Table II shows the relative increase in each element with increasing discharge temperature. In all cases the concentrations of sulfur and iron show increases of a factor of two to four by increasing either time or temperature of discharge. TEM and x-ray analysis of the portions of the sulfur-rich phase in the EB layer of cells discharged under high current drain have indicated the presence of lithium sulfide and an Fe containing phase.

Further studies of compositional changes at the anode and cathode/electrolyte interfaces were carried out using Auger electron spectroscopy (AES). AES spectra were recorded on a point-by-point basis as a function of lateral position on nondischarged and discharged single cells and then compared with electron micrographs of similar regions of the single cell. The computation of relative atomic ratios for certain elements as a function of distance is shown in Fig. 4. We have recorded the sensitivity-corrected intensity of each element as a relative atomic ratio with respect to chlorine. Analysis of the data in this fashion removed many of the uncertainties in the relationship between intensity of the Auger signal and real concentration of the element (7). Chlorine was an ubiquitous component of each single cell. The cathode pellets are a mixture of FeS_2 and the LiCl · KCl eutectic, the EB layer is composed mainly of that same eutectic, and chlorine is found throughout the anodes of cells heated to high temperatures. Fluctuations of the elements noted below are not due to large changes in the chlo-

Table I. Relative sulfur ($K\alpha$) and iron ($K\alpha$) x-ray fluorescence (XRF) intensities in the EB layer of a single cell, discharged at 0.25A, 520°C for the times shown

Time (min)	S/S°	Fe/Fe°
2	1.3	0.94
10	3.4	1.0
20	6.3	1.2
40	7.2	1.4
80	9.8	2.7

Table II. Relative sulfur ($K\alpha$) and iron ($K\alpha$) XRF intensities in the EB layer of single cells discharged at 1.0A for 20 min at the temperatures shown

Temp (°C)	S/S°	Fe/Fe°
440	1.2	0.98
520	6.9	1.2
600	8.4	3.1

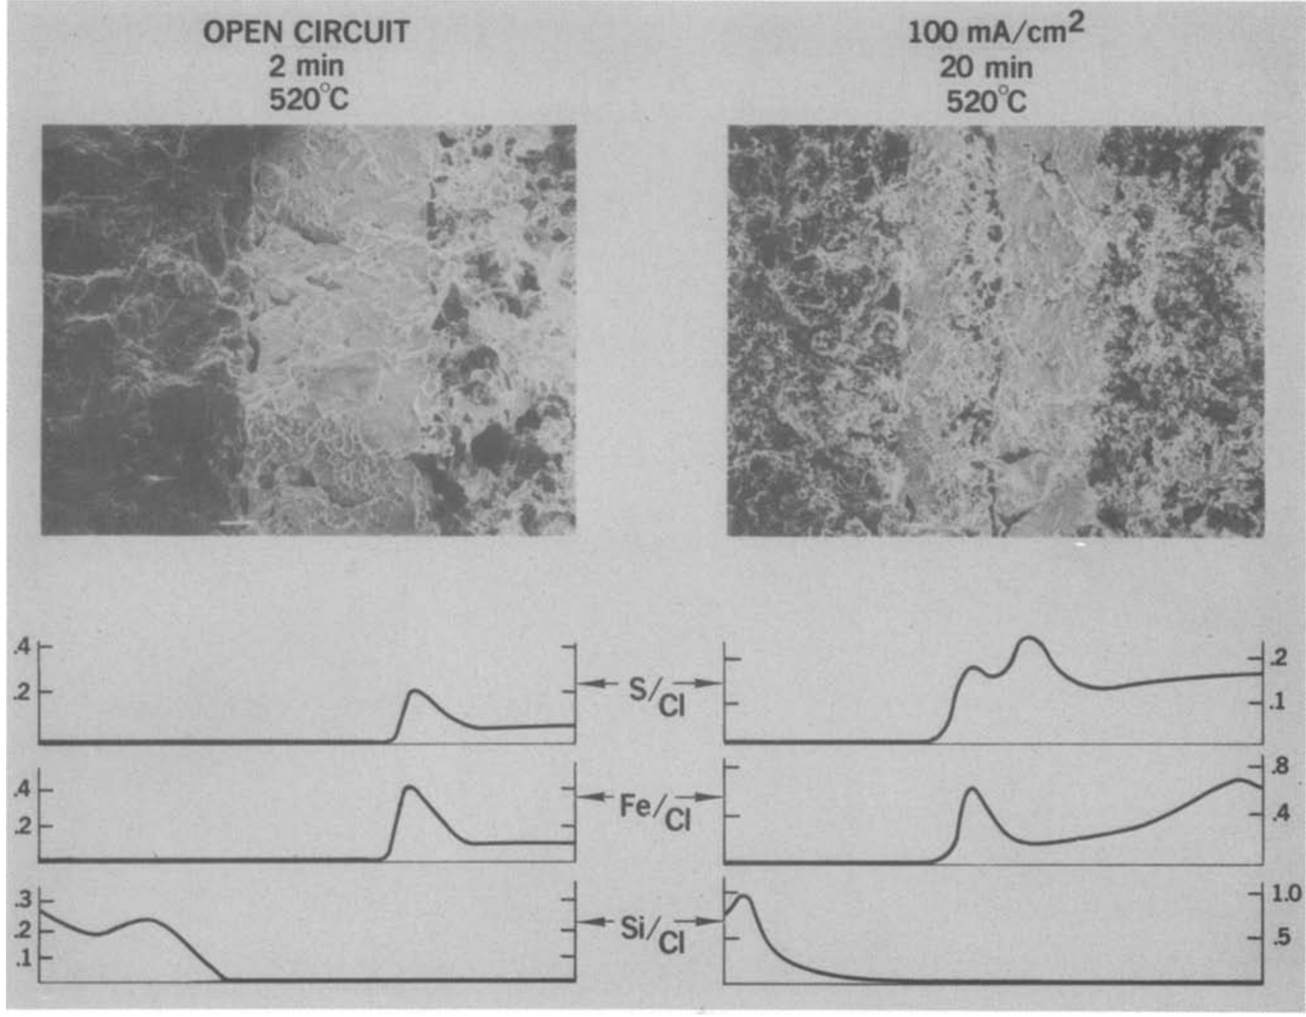

Fig. 4. Scanning electron micrographs and AES/line scans for the relative atomic ratios of sulfur, iron, and silicon in freshly fractured single cells which were (a) held at open circuit for 2 min at 520°C, and (b) discharged at 0.1A for 20 min at 520°C.

rine AES intensity as this intensity remained reasonably constant.

Figure 4a shows the Fe (LMM), S (LMM), and Si (LMM) line profiles for a cell heated to 520°C, but not discharged. There was some variation in the iron and sulfur relative atomic ratios in the cathode layer. Concentrations of iron and sulfur were also detected at the EB interface. It is worth noting that the relative atomic ratio for silicon at the anode/EB interface increases as a function of distance away from that interface. Since the Li/Cl ratio remained constant in this same region, we conclude that some depletion of silicon occurred at the anode/EB interface. The lowering of the silicon content was not due to wetting of the Li(Si) alloy by the LiCl/KCl eutectic. These results are corroborated by other surface analysis studies presented below. Figure 4b shows similar data for a single cell discharged at 520°C for 20 min at 1.0A. The line profiles for this cell clearly show the migration of both sulfur and iron away from the cathode/EB interface. This observation was made several times on different locations along the plane of the single cell, thus it is clearly not an artifact of the fracture procedure. These results confirm the presence of sulfur and of iron in the EB layer as seen by electron microprobe techniques. Figure 4b also confirms the depletion of silicon from the anode/EB interface. It is not yet clear whether this depletion is directly related to the morphological changes observed in the photomicrographs of the anodes which have been heavily discharged.

Surface analysis of individual anode and cathode components.—The discharge behavior of the lithium/silicon-iron disulfide primary batteries is obviously complicated by a variety of morphological and compositional changes. X-ray photoelectron spectroscopy (XPS) and AES, with ion-beam depth profiling, were conducted on the separate anode and cathode materials to help in the elucidation of these changes.

XPS/AES studies of the iron disulfide cathode materials.—The XPS data obtained for the powdered and single crystal iron sulfides and related standard materials are shown in Fig. 5 and 6. Of particular interest is the comparison of the surface compositions of the various FeS_2 materials. Figure 5 shows changes in the

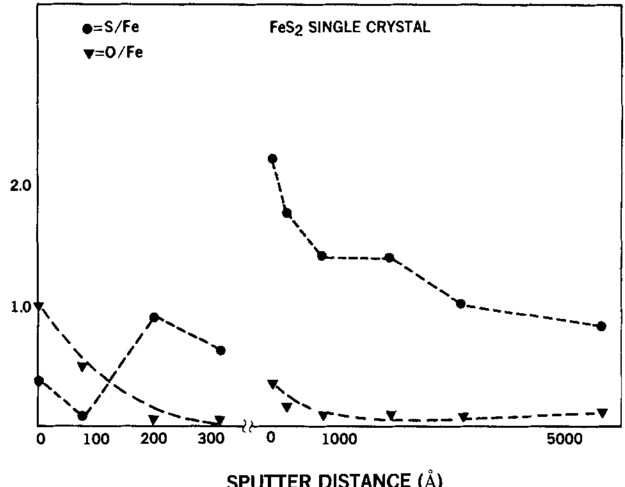

Fig. 6. AES/depth-profile plot of FeS_2 single crystal surface before and after electron beam annealing.

Fe(2p, 1/2, 3/2) peaks of a sample which was synthesized in our laboratory and a commercial FeS_2 sample. Larger amounts of oxygen are present on the surfaces of the commercial samples. Examination of the sulfur (2s) or (2p) peaks in Fig. 6 indicates that the sulfur exists in the form of SO_4^{2-} anions (perhaps SO_3^- anions) in addition to the sulfide form (8) on the commercial FeS_2. Further evidence of the different surface features of the two FeS_2 samples lies in the existence of energy-loss peaks of the Fe(2p) transitions of the commercial sample. These peaks indicate the probable presence of Fe(III) on the surface material (9). It is possible that oxygen is bonded directly to iron in both the FeO and Fe_2O_3 forms, as well as in iron sulfates on the commercial FeS_2. The presence of oxygen-rich materials in the cathode may lead to a positive voltage excursion in the initial stages of primary cell discharge (1, 26). This voltage excursion (as shown in Fig. 1) is minimized by using cathode materials that are oxygen-free, and by discharging in an oxygen-free atmosphere (22).

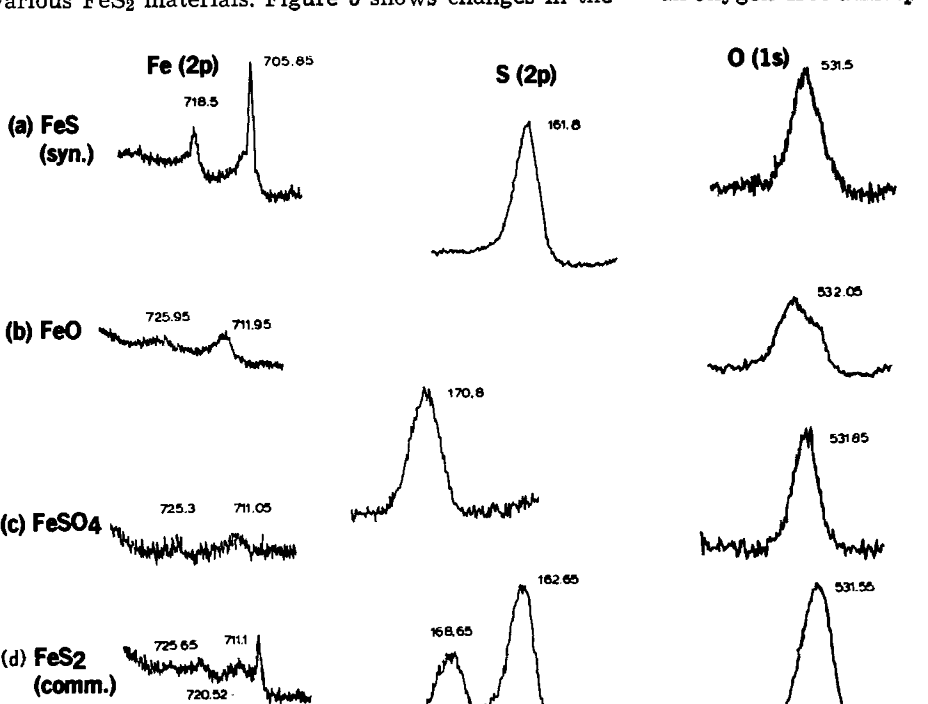

Fig. 5 ESCA spectra of FeS_2 cathode and standard materials, Fe(2p), S(2p), and O(1s) spectral regions. Spectra (a) FeS_2 prepared standard; spectra (b) FeO standard, specta (c) $FeSO_4$ standard, and spectra (d) FeS_2 commercial sample.

An AES study was performed on 1 mm slices of single crystals of natural FeS_2 (not polished) to obtain a comparison of surface composition with the XPS data, a depth profile of the crystal, and information on the movement of species through the lattice at the high operating temperatures normally found in the battery during discharge. Single crystal FeS_2 was selected for study as a matter of convenience. It is known that the discharge behavior of single cells using single crystal FeS_2 cathodes is very similar in its initial stages to the behavior observed using pelletized FeS_2 particles (6). The surface compositional changes observed at the FeS_2 single crystal surface can be extrapolated to those observed in the smaller particles.

The AES surface spectra of the FeS_2 surface showed adventitiously adsorbed carbon and oxygen and no other impurities. Brief ion sputtering removed these adsorbed materials and left a surface with an S/Fe ratio of 0.63. This number is corrected for ionization cross section, but does not reflect the true stoichiometry because of the uncertainties in such numbers for both the major sulfur and iron Auger transitions. An electron beam heater was used to thermally shock the FeS_2 samples while still in ultrahigh vacuum. Figure 6 shows the results of an AES/depth profile, before and after treatment of the FeS_2 surface with a 2W electron beam for 30 sec. Following the application of the thermal shock, a large increase in the S/Fe ratio ($\geqq 2.0$) was observed, consistent with the migration of sulfur away from the FeS_2 matrix. Following several thousand seconds of ion sputtering, the original surface composition was achieved.

SEM/EM analysis of the thermally shocked FeS_2 samples confirmed the morphological and chemical changes indicated by the AES studies. A distinct separation of phases was indicated following thermal shock. X-ray fluorescence point analysis indicated a sulfur-rich nonhomogeneous layer on the surface of the crystal (extending to depths of up to 1 μm), and a sulfur-deficient layer underlying. X-ray diffraction of the underlying layer showed it to be mainly $FeS_{0.9}$ (pyrrhotite). The formation of this phase by simple application of heat is discussed below with regard to compositional changes in the primary battery.

Further studies have shown that prolonged heating (greater than 1 min) under the conditions in Fig. 6 further increased the S/Fe ratio on the single crystal surface. Electron beam heating of the sample under conditions sufficient to cause desorption of sulfur from the surface while at about 10^{-9} Torr caused a decrease of the surface S/Fe ratio back to levels that were seen on the unheated surface. These experiments are described in more detail elsewhere (14).

XPS/AES studies of anode materials.—XPS spectra were obtained from 40 w/o Li(Si) alloy and 45 w/o Li(Si) alloy, and lithium/silicon alloys which had been exposed to atmosphere. The carbon (1s) spectra [as in Fig. 7(c)] indicated the presence of two forms of carbon on the surface of the Li(Si) alloy. This was the case for all lithium metal samples examined. The larger peak at lower binding energy [charge shift corrected to 284.4 eV (7)] was attributed to hydrocarbon contamination of the XPS vacuum system. Comparison of the C (1s) peaks of the alloy to the Li_2CO_3 standard indicated that the rest of the alloy surface carbon was probably present as the carbonate species. As discussed below, this contaminant was not observed in the AES experiments conducted in a cleaner vacuum. It does imply, however, that the carbonate will be a contaminant on samples exposed to normal battery assembly atmospheres.

In attempting to record XPS spectra of Li(Si) alloy samples which had been exposed to atmosphere for long times (10-24 hr) we discovered an interesting technique for examining a freshly exposed Li(Si) alloy surface. Spectra shown in Fig. 7(a) show the C(1s), Si(2s), and Li(1s) regions for surfaces which were atmospherically exposed for 10 hr, loaded into the XPS system, and then had the fresh Li/Si surface exposed just prior to analysis by physical removal of the passive layer which forms on these materials. Figure 7(b) spectra were obtained for the same spectral regions on a sample which had been fresh-fractured under argon and then atmospherically exposed for 1-5 min prior to loading in the spectrometer. Spectra illustrated in Fig. 7(c) are for a sample fractured and loaded in atmosphere. Comparison of Fig. 7(a), (b), and (c) indicated that carbonate buildup on the alloy surface is slow at 10^{-7} Torr, but still appreciable over the 24 hr required to achieve operating vacuum. It appears that the first few monolayers

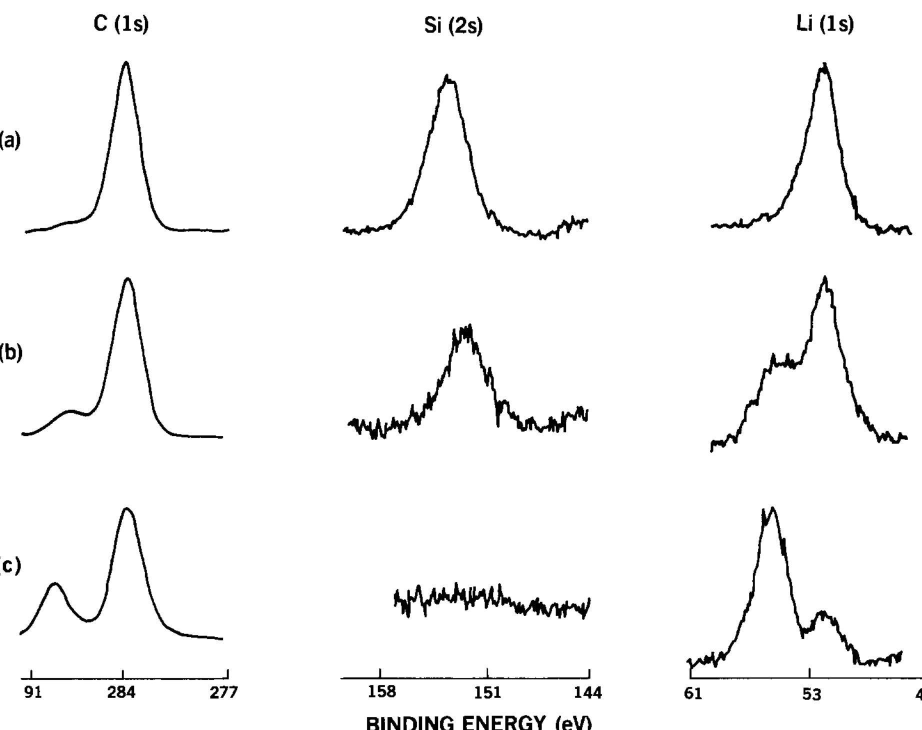

Fig. 7. XPS C(1s), Si(2s), and Li(1s) spectra of 40 w/o Li/Si alloys exposed to atmosphere for various times: (a) the C(1s), Si(2s), and Li(1s) spectra of freshly exposed Li/Si alloy; (b) the C(1s), Si(2s), and Li(1s) spectra of Li/Si alloy exposed momentarily to atmosphere; (c) the C(1s), Si(2s), and Li(1s) spectra of Li/Si alloy fractured and loaded under a normal atmosphere.

were added very quickly (less than a few minutes). Subsequent buildup probably follows an isotherm dependence as observed for other active metals.

The Si(2s) spectrum in Fig. 7(c) showed that no detectable silicon was present on the strongly passivated alloys. Since the escape depth of the Si(2s) electron is about 20-35Å in most solids, this lack of a silicon signal implies a silicon-depleted layer of at least 50-100Å (12, 27). The freshly exposed surfaces showed higher concentrations of silicon. Aging studies discussed below indicate the segregation of lithium and silicon during passivation of the surface.

The Li(1s) spectrum of the freshly exposed Li(Si) surface is shown in Fig. 7(a). The pristine nature of this surface was confirmed by the appearance of only one Li(1s) peak due to lithium metal (13). On those samples which have been partially passivated, two Li(1s) peaks are observed [Fig. 7(b) and (c)]. One might expect that only ionic lithium, with a higher Li(1s) binding energy, would be observed on these samples. Previous studies have shown the reduction of ionic lithium compounds to metallic lithium by the x-ray source (11). Two forms of lithium are always observed in an XPS spectrum of any lithium salt. Figures 7(b) and (c) show an ionic lithium whose concentration roughly correlates to the extent of passivation. Further studies of the kinetics of x-ray photoreduction of these compounds and the kinetics of surface passivation are underway (14).

In studies conducted thus far, no evidence of the formation of Li_3N on the Li(Si) surface has been observed. N(1s) signal intensities were below detectable limits. Although nitrogen will react with lithium at room temperature (15), the reaction is too slow to effectively compete with reactions of the metal with CO_2, H_2O, and O_2. Furthermore, Li_3N decomposes in the presence of H_2O to form Li_2O and NH_3 (16).

Figure 8 shows the AES spectrum of a typical Li/Si alloy (45 w/o). The surface of this material [Fig. 8(a)] showed only lithium, oxygen, and traces of carbon and silicon in the spectrum. The low levels of silicon are consistent with the XPS data; the absence of carbon is likely due to the fact that these materials were freshly fractured under high purity argon and loaded into the AES, UHV system directly. An expanded AES spectrum indicated that the precise energy position and intensity of the lithium Auger transitions are strongly dependent upon chemical form and matrix (17-21), but our data clearly indicate no metallic lithium on the surface (21). Lithium does not possess sufficient core electrons to undergo an intra-atomic, Auger ionization. The detected electron must be donated by neighboring atoms; thus, several Auger transitions are possible, depending on the energy levels of the electrons in the neighboring atoms (18). These AES spectra show transitions consistent with lithium in a fully oxidized form (17).

Following extensive ion sputtering, a larger silicon peak appeared [Si/Li = 0.26, Fig. 8(b)]. The alloy stoichiometry was still not achieved even after prolonged sputtering. We feel that the heating caused by the incident ion beam is also responsible for initiating migration of the lithium away from the bulk alloy (see below). The continued presence of oxygen on the extensively sputtered surface is puzzling. The bulk composition of the alloy does not indicate appreciable oxygen present (22). When the sample in Fig. 8 was exposed to laboratory atmosphere for about 10 min, and then reanalyzed, the spectrum in Fig. 8(c) was obtained. Note the disappearance of silicon in favor of increased lithium and oxygen intensities. This again demonstrates the effect of atmospheric passivation on these alloys.

To approximate the conditions seen by the freshly exposed anode surface in the high temperature battery environment, a series of experiments was conducted where an ion-sputtered alloy was subjected to thermal shock using an electron-bombardment heater. The alloy surface was ion sputtered until appreciable silicon was present [Si/Li = 0.14, similar to Fig. 8(c)]. The surface was then subjected to E-beam heating of 1W for 1 min and the silicon dropped to below detection limits. Clearly, heating of the sample caused migration of the lithium away from the silicon as was the case for atmospheric passivation. Diffusion of Li into p-type single crystals of silicon at high temperatures has been reported previously (23), supporting this hypothesis.

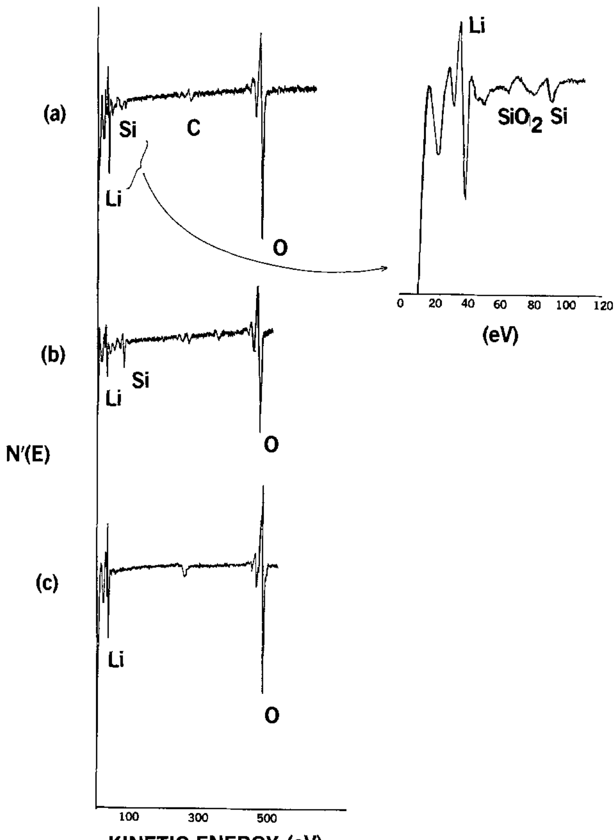

Fig. 8. Auger spectra and ion-beam depth profiling of 45 w/o Li(Si) alloy. (a) Surface scan; (b) surface scan after approximately 5000Å had been ion-beam sputtered, and (c) surface scan after exposure to the atmosphere for 10 min.

Discussion

The microscopic examination of the cathode and anode materials before and after discharge leads to the observations that (*i*) the FeS_2 particle undergoes a chemical and physical change at its surface which likely leads to the migration of a sulfur-rich layer into the EB region of the single-cell; and (*ii*) there is a color change and a morphological change in the Li(Si) anode during discharge which is likely due to a chemical compositional change. This compositional change is possibly due to the migration of lithium away from the anode bulk, as shown by AES studies. The AES/XPS experiments on the individual components show that (*i*) there is a significant concentration of oxygen-rich species on the surface on the FeS_2 cathode; (*ii*) that thermal shock of the cathode material leads to a migration of sulfur away from the bulk and leaves a substoichiometric iron sulfide behind; (*iii*) a passive oxide/carbonate film forms on the Li(Si) surface following exposure to atmosphere; and (*iv*) that atmospheric passivation and/or thermal shock of the anode material leave an anode surface that is rich in ionic lithium.

Oxide-rich forms of sulfur and iron on the cathode surface may be responsible for the initial voltage excursion seen in the cathode during single cell discharge. The voltage excursion correlates with the particle size used in the cathode pellet (6). Smaller cathode particles lead to a larger voltage excursion which is consistent with their higher oxide content. Depletion of the oxide-rich layer leads eventually to a more constant discharge voltage.

Thermal or electrochemical migration of sulfur away from the cathode material is not unexpected, especially at the operating temperature of the thermal battery system. Thermal loss of sulfur can cause serious problems in the poisoning of current collectors and unwanted reaction directly with the anode material. In the event that recharging is desired, this loss of volatile sulfur will result in lower charge/discharge capacity. The migration of sulfide from the cathode can be understood in terms of the migration of all anions toward that anode (24). Reasons for the migration of iron are less obvious and may be due to the formation of a nonstoichiometric iron, sulfur, potassium, lithium complex. An X-phase (Li_2FeS_2) and a J-phase ($LiK_6Fe_{24}S_{26}Cl$) have been identified in discharged Li/FeS_2 batteries following cooling (4). Countering the movement of sulfide is the precipitation of a lithium-sulfur salt in the EB layer. Any precipitation of this type means the removal of current carrying ions from the electrolyte and an addition to the internal cell resistance if the precipitate has low solubility at the operating temperature of the battery.

Movement of lithium at the anode surface can lead to increased resistance toward charge transfer when this migration occurs with the formation of a passive oxide or carbonate layer. Loss of lithium from the anode interface has also been observed through the reduction of the adjacent KCl to metallic potassium, which can volatilize to another part of the sealed battery (1). This type of lithium movement would result in decreased discharge capacity at the anode surface. The kinetics of migration processes at the anode/EB interface are currently under investigation (14).

Further experiments will study the significance of each of these complications in individual half-cells. At the high temperatures of cell operation, the resistance to current flow represented by the reactions noted above may not be restrictive to the near optimum performance of these batteries. If storage of the battery is required before use (especially in adverse environments), or if extended use is required, such as long discharge or several charge and discharge cycles, then these interfacial reactions will be important.

ABSTRACT

The covalent, metallic conductor, polymeric sulfur nitride, $(SN)_x$, has been used as an electrode material in aqueous media. Irreversible redox couples were used as kinetic probes to monitor changes in the $(SN)_x$ electrode surface/solution interface after chemical modification resulting from the strong interaction of $(SN)_x$ with metal cations and/or oxidation of the $(SN)_x$ surface. The iodate reduction and iodide oxidation reactions permitted the study of two different potential regions. Palladium(II) and silver(I) were chemically and/or electrochemically reduced at the $(SN)_x$ surface forming a metallic surface phase. Chromium(III) remained in a cationic form immobilized on parallel $(SN)_x$ surfaces in both potential regions.

Recently there has been a great deal of interest in the chemical modification of electrode surfaces in order to produce electrodes having selective analytical, synthetic, or catalytic properties (1). A few of the applications which have resulted from these chemically modified electrodes are: Electrocatalysis (2), enhancement of surface stability (2d, 2p, 3), spectral sensitization or improved light-electrical energy conversion (2c, 2p, 4), *in situ* analysis (5), reference electrodes for nonaqueous systems (6), or simulation of photosynthetic primary processes (7).

Organosilane chemistry is used extensively in the covalent attachment of different species to electrode materials, thereby introducing a σ-bonded system between the electrode and the electrochemically active group. This increases the electrical resistance and capacitance, making kinetic studies at these chemically modified electrodes more difficult. Direct attachment of metal ions to an electrode surface is less common (2b, k, q; 3b; 4e, g, h, j-m; 5b; 8b; 11) with several instances involving polymers or organic ligands attaching the metal to the electrode surface (2b, k; 4e, g, h; 8a-c). The inorganic metal, polymeric sulfur nitride or $(SN)_x$, provides functional groups for convenient chemical modification at the surface of this highly conducting material (9). Thus, it is not necessary to introduce insulating species between electrode and active groups. Consequently, systematic fundamental studies have been undertaken (10, 11) in order to determine the electrode characteristics of this unusual material in aqueous solutions.

In order to study the effects of chemical modification on the $(SN)_x$/solution interface, an electrochemical probe technique (12) was used in the present cyclic voltammetric study. This method employs redox couples which exhibit irreversible behavior at the electrode and, therefore, their electrochemical kinetics are strongly influenced by the nature of the electrode/solution interface. The iodate reduction and iodide oxidation were chosen for this study because these systems: (*i*) are irreversible, (*ii*) have been studied extensively with electrodes other than $(SN)_x$ (13), and (*iii*) provide two different potential regions for study. The qualitative results obtained were compared with the electrochemical behavior of these systems with metal electrodes.

Capacitance studies were not carried out as $(SN)_x$ electrode surfaces are very rough (11) and cannot be polished mechanically (for example, with sandpaper or a polishing powder) without causing considerable damage. In addition, background currents in supporting electrolytes alone exhibit a significant faradaic component (10).

Experimental

All chemicals were of reagent grade. As the redox couples employed in this study were kinetic probes of the nature of the $(SN)_x$/solution interface, all $(SN)_x$ electrodes did not necessarily yield the same peak potentials for a given couple because of variations in surface characteristics between different $(SN)_x$ electrodes. For example, Fig. 3A and 4A show iodate reduction peaks for two different $(SN)_x$ electrodes. The peak potentials and indeed, the general appearance of the peaks are significantly different for these electrodes. For this reason, comparison of the redox behavior of iodate (or iodide) before and after chemical modification was only meaningful if the same electrode was involved.

Electrodes were prepared as described elsewhere (9). The $(SN)_x$ fiber bundles were either parallel or perpendicular to the electrode/solution interface. Both surfaces exhibited similar electrochemical behavior with respect to the experiments reported here, with the exception of the experiment involving chromium(III).

All other experimental details have been outlined elsewhere (11).

Results and Discussion

Iodate reduction.—Iodate was chosen as one of the systems to probe the nature of $(SN)_x$ surfaces before and after modification for the reasons stated above. Figure 1 illustrates the reduction of 0.040M iodate in 0.5M acetate buffer ($pH = 4.75$) on platinum and a parallel $(SN)_x$ electrode. The behavior was similar for perpendicular surfaces. The iodate reduction peak re-

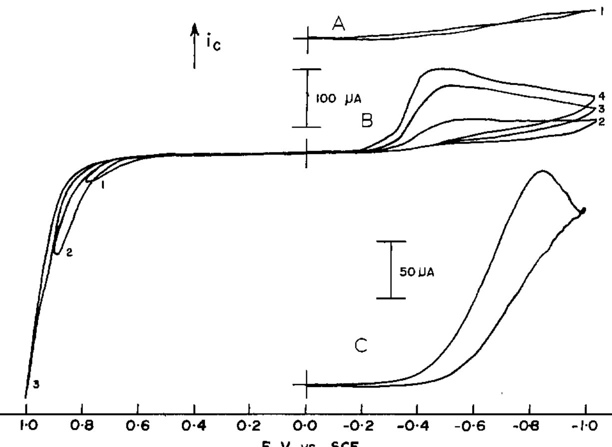

Fig. 1. Dependence of the reduction of 0.04M KIO_3 in 0.5M acetate buffer, pH 4.75 on positive reversal potential at a parallel $(SN)_x$ electrode. Scan rate 0.02 $Vsec^{-1}$. Numerals refer to scan number. Curves A and B, $(SN)_x$. Curve C, Pt.

corded with the platinum electrode was concomitant with hydrogen evolution which agreed with chronopotentiometric studies obtained by Anson (14) under similar conditions at platinum electrodes having no surface oxides. The first scan with an $(SN)_x$ electrode (Fig. 1A, curve 1) initiated from 0.0V to negative potentials showed no reduction peak for iodate at potentials similar to those on Pt (Fig. 1C). Only after the potential excursion reached values positive of approximately 0.5V, sufficient to cause oxidation of the surface of $(SN)_x$ (10), (Fig. 1B, curve 1) was the iodate reduction peak observed. The magnitude of the iodate reduction peak was a function of the extent of positive polarization on the preceding scan (Fig. 1B, curves 2-4). If, after obtaining an initial well-defined peak, the scan into positive potentials was reversed at 0.0V on all subsequent cycles, the peak gradually disappeared. Davis (15) has shown that the rate of reduction of iodate on the surface of platinum electrodes, at fixed potential, increases as the amount of platinum oxides on the surface increases. Anson (14) has demonstrated that the reduction of iodate at platinum electrodes having surface oxides present, occurs at potentials 200-600 mV more positive than at electrodes having no surface oxides. The decrease in overvoltage is thought to involve the simultaneous reduction of platinum oxide and the iodate (14). It must be noted that a large excess of iodate (10^3 times the equivalents of platinum oxide) can be reduced at these lower overvoltages (14). The behavior of iodate at $(SN)_x$ electrodes might be explained similarly, *i.e.*, iodates were reduced at relatively low overvoltages at oxidized $(SN)_x$ electrodes. After several scans without positive polarization there were no longer any oxidized surface functional groups and, hence, the iodate reduction no longer occurred at low overvoltages.

To investigate this possibility further, periodate ion was studied in voltammetric experiments with both $(SN)_x$ and platinum electrodes. The results indicate that the periodate ion chemically oxidized the platinum surface, resulting in a positive shift in the iodate reduction potential. The reduction of periodate to iodate precedes the reduction of iodate which takes place at −0.560V at the oxidized platinum electrode. These results are consistent with those previously reported (14). When this process was investigated at $(SN)_x$ electrodes, only one peak was observed at *ca.* −0.60V, in contrast to the behavior at the platinum electrode. Also, there was no need for prior positive polarization, as was required in the iodate experiments described above. Prior polarization to +0.70V had no effect on the peak current, and the current did not decrease in subsequent scans as was the case with iodate at $(SN)_x$. Periodate ion apparently oxidizes the $(SN)_x$ surface and the observed peak was simply the reduction of iodate at the oxidized electrode surface. The following CE mechanism may, therefore, be proposed

$$(SN)_{x\text{red}} + IO_4^- \rightarrow (SN)_{x\text{ox}} + IO_3^- \underset{\text{red}}{\rightarrow}$$

Such behavior is opposite to that observed with chromic acid preoxidized glassy carbon electrodes (16). These electrodes revealed a loss of reproducibility with respect to iodate reduction and a negative shift in peak potential after oxidation.

Iodate reduction also served as a kinetic probe in experiments involving modification of $(SN)_x$ electrodes with metal cations. Surface modification of $(SN)_x$ consisted of brief immersion (30-60 sec) in solutions containing one of the following ions: silver(I), palladium(II), chromium(III), or periodate. After pretreatment, the electrodes were thoroughly rinsed with distilled water before use. Cyclic voltammograms were recorded in iodate solution before and after pretreatment in order to determine if the nature of the surface had changed for the same $(SN)_x$ electrode under study.

The following study was carried out in the order stated, with the same $(SN)_x$ electrode. After pretreatment with 0.1M $AgNO_3$ solution (Fig. 2A), a well-defined iodate reduction peak was observed at *ca.* −0.67V, without the need for prior polarization at positive potentials. Subsequent cycling resulted in a decrease in the peak current if the positive reversal potential was 0.0V. If the electrode is polarized at +0.65V (Fig. 2B) for approximately 15 sec before initiating the negative scan, the iodate potential is shifted to *ca.* −0.48V; however, on subsequent scans, the peak shifted negatively to its original position with a simultaneous decrease in peak current. The electrode was then immersed in a 0.040M KIO_4 solution followed by negative scanning in iodate solution. The behavior was similar to that after immersion in silver(I) solution (Fig.

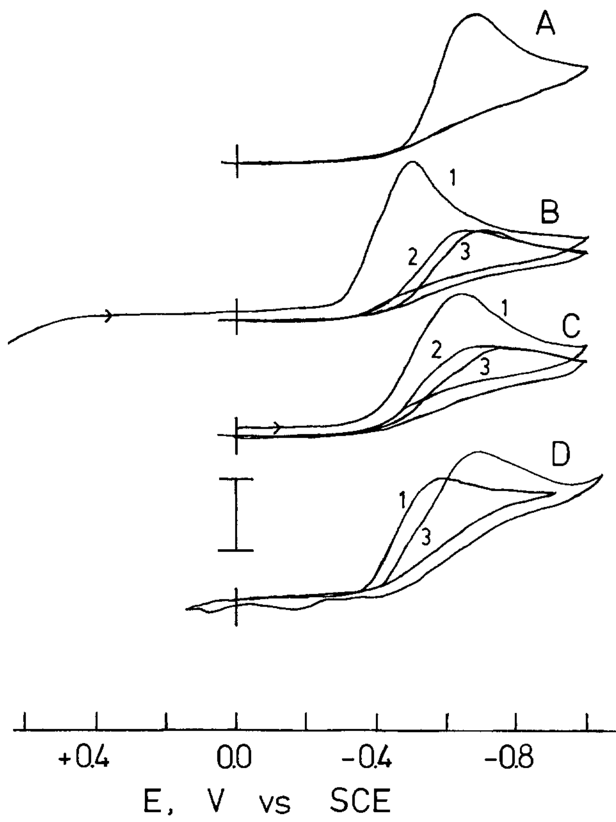

Fig. 2. Influence of (A) pretreatment with 0.1M $AgNO_3$, (B) polarization at +0.65, (C) pretreatment with 0.04M KIO_4 on $(SN)_x$ electrodes, (D) silver metal electrode. Scan rate: 0.02 $Vsec^{-1}$ (numerals refer to scan number).

2C). The first negative scan from 0.0V showed a positive shift of about 50 mV and a marked increase in current compared to the later scans after silver(I) immersion. However, once again the peak current decreased and there was a negative shift on subsequent scanning. One complete cycle was then made without interruption, beginning positively from 0.0V. The effect of this brief electrochemical oxidation was to produce a peak on the negative scan which was very similar with respect to peak current magnitude and peak potential, to the peak obtained when the electrode was immersed in periodate solution. Finally, the potential was held for 15 sec at +0.65V before scanning, which resulted in a 200 mV positive shift in peak potential from that at an unoxidized $(SN)_x$ electrode and an increase in the current as was observed earlier. Figure 2D (scan 1) shows the behavior of iodate on a silver electrode. The program for the second scan (not shown) was: 0.0 → +1.0 → − 1.0 → 0.0V. During this second scan a large split cathodic peak was observed for iodate reduction whose components had the same two peak potentials as those of scans 1 and 3, indicating a partial alteration of the surface. The third scan was initiated negatively from 0.0V without previous positive polarization and resulted in the shift of the cathodic peak potential to more negative values and a marked decrease in the cathodic peak current (when compared to scan 2).

Thus, the electrochemical behavior of iodate at silver electrodes is quite similar to that observed with silver ion pretreated $(SN)_x$ electrodes. Potentiostating at +0.65V, for approximately 15 sec, scanning positively into anodic current regions or periodate pretreatment resulted in the shifting of the iodate reduction peak potential to more positive values with a simultaneous increase in cathodic current. As silver(I) pretreatment is sufficient to yield a well-developed iodate peak without positive polarization and there is similarity between silver(I) pretreated $(SN)_x$ electrodes and silver electrodes with respect to iodate electrochemistry, it might be concluded that silver(I) chemically oxidizes the $(SN)_x$ surface while simultaneously producing metallic silver deposits. The presence of deposits has been verified by scanning electron microscopic investigations.

Iodate studies with $(SN)_x$ electrodes pretreated by brief immersion in 0.02M $PdCl_2$ or $Pd(NO_3)_2$ solutions yielded similar results as those with silver ion pretreated material (Fig. 3). Curve A (scans 1 and 2) resulted from an initial scan positively from 0.0V followed by a second complete cycle. When the scan into positive potential was reversed at 0.0V at the end of the second cycle, the diminished reduction peak (scan 3) was recorded. As observed previously, this resulted from the partial reduction of the electrode surface. After the electrode was pretreated with palladium(II), the voltammograms shown in Fig. 4B were obtained. As in the experiments with silver(I) or the periodate pretreatment, a well-defined iodate reduction peak was observed without scanning to positive potentials where a significant quantity of anodic current was passed. The reduction peak potential was shifted by approximately 300 mV to more positive values. As previously shown, there was a decrease in the current with scan number when the positive potential scan reversal was made before significant anodic current flow. When palladium(II) pretreated $(SN)_x$ electrodes are polarized negatively to −0.8V in 0.5M acetate buffer, hydrogen is evolved and there is no hysteresis in the current/potential curves. Untreated $(SN)_x$ electrodes exhibit a current hysteresis at negative breakdown potentials without the evolution of hydrogen (10). This is evidence for the presence of metallic palladium deposits on palladium(II) pretreated $(SN)_x$ electrodes. These deposits can be seen under high magnification.

As silver(I) and palladium(II) are highly oxidizing species and are reduced to metals by $(SN)_x$ in a chemical reaction, chromium(III) was also used to pretreat $(SN)_x$ electrodes. This metal cation was found to be electrochemically inactive at $(SN)_x$ electrodes although its presence in solution significantly decreases background currents caused by surface redox processes (11). It was thought that chromium(III) interacts strongly with $(SN)_x$ and thus, might affect iodate reduction at the surface. This was found to be the case for parallel $(SN)_x$ electrodes (Fig. 4). Iodate behavior on an untreated electrode was as observed previously (Fig. 4A). No reduction peak for iodate was observed on scanning to negative potentials until after scanning into the positive region. After brief pretreatment of this electrode in a 0.1M solution of $Cr(ClO_4)_3$, the voltammograms shown in Fig. 4B were obtained. The first scan was negative from 0.0V, and was followed by one positive scan and several negative scans with 0.0V as the potential of reversal. A positive shift in peak poten-

Fig. 3. Influence of (A) prior positive scanning and (B) pretreatment with 0.02M $Pd(NO_3)_2$ on cyclic voltammetric behavior of an $(SN)_x$ electrode in 0.04M KIO_3, 0.5M acetate buffer, pH 4.75. Scan rate: 0.02 $Vsec^{-1}$ (numerals refer to scan number).

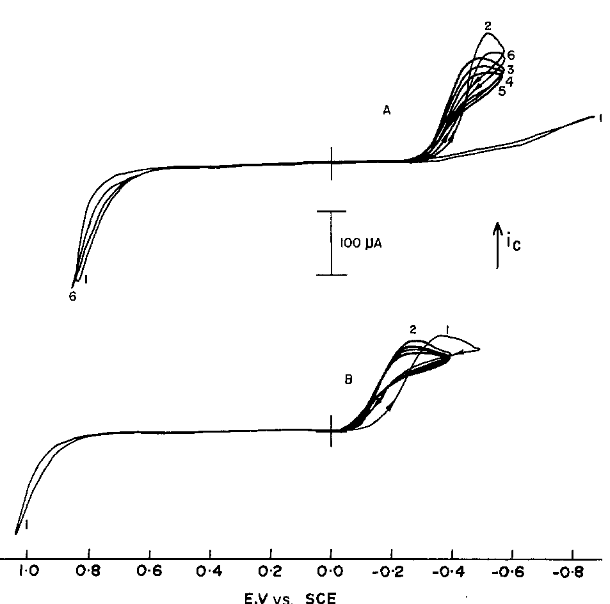

Fig. 4. Influence of (A) prior positive scanning and (B) pretreatment with 0.1M $Cr(ClO_4)_3$ on cyclic voltammetric behavior at a parallel $(SN)_x$ electrode in 0.04M KIO_3, 0.5M acetate buffer, pH 4.75. Scan rate: 0.02 $Vsec^{-1}$ (numerals refer to scan number).

tial of approximately 200 mV was observed (Fig. 4B), which is persistent even after multiple cathodic scans initiated at 0.0V. It appears from these data and previous studies (10) that a form of nonmetallic chromium is immobilized on the $(SN)_x$ surface. The valence state of the chromium is unknown at this time.

Iodide oxidation.—The iodine/iodide couple was also used as a probe system to study the surfaces of modified $(SN)_x$ electrodes. As iodide is oxidized at positive potentials at $(SN)_x$ electrodes, this couple offers a different potential region for study. For comparison purposes, cyclic voltammetric studies of iodide at palladium, silver, and hanging mercury drop electrodes were performed.

At low scan rates (0.01-0.05 $Vsec^{-1}$) the oxidation peak on untreated $(SN)_x$ electrodes was drawn out and not of a diffusion controlled character. Furthermore, on the reverse scan, the reduction peak was often comprised of two ill-defined peaks. The relative height of these two peaks was dependent on scan rate. The more positive peak decreased with a concomitant increase in the second peak with an increase in scan rate until, at 0.500 $Vsec^{-1}$, only the latter at $E_{pc} = +0.170V$ remained (Fig. 5D). Also the oxidation peak appeared to be diffusion controlled at this scan rate ($E_{pa} = +0.500V$ at 0.500 $Vsec^{-1}$). The separation between the anodic and cathodic peak potentials increased with increasing scan rate.

As with the iodate studies, $(SN)_x$ electrodes were pretreated by brief immersion in solutions containing cations which might undergo chemical reaction with the surface. Cyclic voltammograms were recorded in iodide solution at two scan rates for untreated, pretreated, and the appropriate metal electrode for comparison.

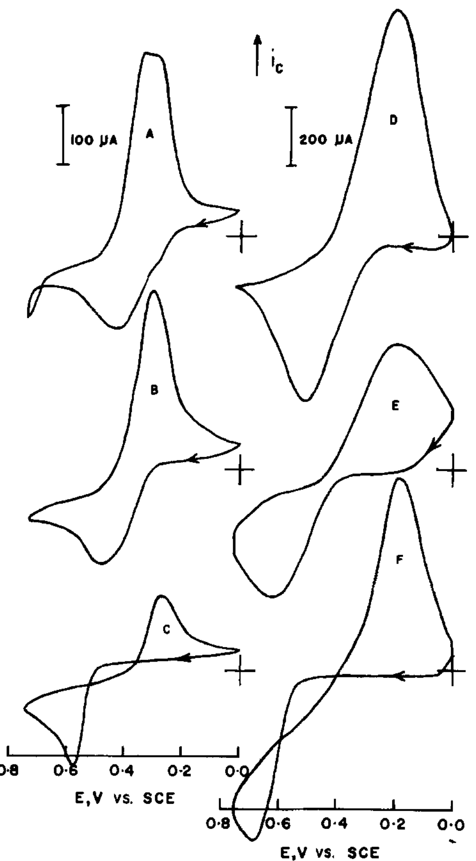

Fig. 5. Influence of palladium(II) pretreatment of $(SN)_x$ electrodes on cyclic voltammetric behavior in 0.05M KI and 0.5M $NaClO_4$: (A, D) untreated $(SN)_x$; (B, E) pretreated $(SN)_x$; (C, F) palladium metal electrode. Scan rate (A-C) 0.1 $Vsec^{-1}$, (D-F) 0.5 $Vsec^{-1}$ (numerals refer to scan number).

When an $(SN)_x$ electrode was pretreated with 0.02M $Pd(NO_3)_2$ voltammograms were obtained in iodide solution (Fig. 5B, E) which had characteristics intermediate between untreated $(SN)_x$ electrodes and a palladium wire electrode. The peak potential for the oxidation of iodide became increasingly positive as one went from untreated to palladium(II) pretreated to palladium metal electrodes for a given scan rate (*cf.* Fig. 5A, B, C or 5D, E, F). Furthermore, the palladium(II) pretreated $(SN)_x$ electrode exhibited only one (the more positive) of the two reduction peaks at slower scan rates (0.01-0.1 $Vsec^{-1}$). This may indicate that the palladium(II) pretreated $(SN)_x$ electrode surface consists of regions having palladium metal deposits and other areas of exposed $(SN)_x$. The electrode process is presumed to occur on both of these surfaces simultaneously.

The potential for the oxidation of electrodeposited palladium metal for an $(SN)_x$ electrode in 5 mM $PdCl_2$ (17) corresponds to the same potential (*ca.* +0.60V) for the oxidation of iodide at a palladium(II) pretreated $(SN)_x$ electrode at a scan rate of 0.500 $Vsec^{-1}$ (Fig. 5E). It is conceivable that metallic palladium present on the $(SN)_x$ surface could be undergoing simultaneous oxidation with iodide in a manner analogous to the reduction of iodates at oxidized metal or $(SN)_x$ surfaces as discussed earlier.

The voltammograms obtained with the palladium wire electrode exhibited a hysteresis of the current upon scan reversal at positive potentials (Fig. 5C, F). At higher scan rates (Fig. 5E) the palladium(II) pretreated electrode exhibited more of a tendency toward hysteresis than the untreated $(SN)_x$ (cf. Fig. 5D).

Qualitatively, the same type of behavior was observed when the $(SN)_x$ was pretreated with 0.1M $AgNO_3$. However, with silver(I) pretreated electrodes, voltammograms changed with scan number until they appeared to be identical with those obtained with untreated electrodes. Repetitive cycling appears to remove any deposited or immobilized silver. This also was found to be true for mercury in a series of similar experiments, but this was not the case with palladium pretreated $(SN)_x$ electrodes.

Finally, it should be noted that pretreatment of $(SN)_x$ electrodes with chromium(III), europium(III), iron(III), or iron(II) had no effect on I_2/I^- redox behavior. This may be due to electrostatic repulsion resulting in the removal of these cations from the surface in such positive potential regions.

In conclusion, pretreatment of parallel or perpendicular $(SN)_x$ electrodes with palladium(II) or silver(I) solutions results in the formation of a metallic phase on the surface. This is expected since they have redox potentials more positive than that of $(SN)_x$ (17). At positive potentials, the metallic palladium is bound more permanently to the $(SN)_x$ surface than silver, as is evidenced by the iodide studies. For a chromium(III) pretreated electrode, the chromium appears to be strongly bound to parallel $(SN)_x$ electrodes in an ionic form, which is logical on the basis of the redox potentials of chromium(III) and $(SN)_x$ (17). The latter modified surface catalyzes the electrochemical reduction of iodate. Periodate, with a redox potential which is more positive than that of $(SN)_x$, oxidizes the surface of $(SN)_x$ electrodes, thus shifting the potential of iodate reduction to more positive potentials (17).

Technical Notes

Electrodissolution Kinetics of Iron in Highly Acidic Chloride-Free Solutions

N. L. Nguyen* and Ken Nobe*

Department of Chemical Engineering, UCLA, Los Angeles, California 90024

One of the most important landmarks in the development of the modern science of corrosion has been Bonhoeffer and Heusler's hypothesis of the existence of univalent iron surface intermediates formed by reaction of solution components and iron during corrosion (1). Subsequently, the two classic papers by Bockris and co-workers (2, 3), which describe the kinetics and mechanism of iron corrosion, laid the foundation for electrochemical modeling of fundamental metallic corrosion processes.

Both groups reported that the rate of iron electrodissolution had a negative reaction order with respect to hydrogen ions. Kelly (4), subsequently, confirmed the negative first order result of Bockris and co-workers (2). More recently, McCafferty and Hackerman (5) reported a positive reaction order with respect to hydrogen ions for the rate of iron electrodissolution in concentrated acidic chloride solutions, in contrast to results obtained for iron in solutions of lower concentrations of hydrogen ions. This positive reaction order was later confirmed by Lorenz *et al.* (6) and Kuo (7). This note reports on studies of iron in concentrated acidic chloride-free solutions. Some preliminary data on this system had been reported previously by Kuo (7).

Experimental

The same rotating disk apparatus, instrumentation, and experimental procedure, as described previously (7), was used in this work. The electrolyte was $HClO_4$-$NaClO_4$ with the ionic strength maintained at 5M while H^+ concentrations were varied from 0.05 to 5M. The test electrodes were prepared from 1.27 cm diam Ferrovac E iron rod. The detailed preparation and pretreatment procedures of the iron electrodes have also been described previously (7). Electrode potentials were corrected for liquid junction potentials and the *IR* drop.

Results and Discussion

The dependence of the rest potential on hydrogen ion concentration

$$\left(\frac{\partial E_0}{\partial \log [H^+]}\right) = 0.06 \text{ V/dec}$$

is the same as reported for iron in chloride-free solutions of lower acidity. Figure 1 shows the anodic polarization behavior of iron in the $HClO_4$-$NaClO_4$ solutions within the active region. Linear and parallel anodic Tafel lines of slope 0.04 V/dec, over the entire range of H^+ concentrations (0.05-5M) examined, are obtained. The H^+ reaction order plot, as shown in Fig. 2, gives a negative slope of 1.1. This result shows that the rate of iron electrodissolution is negative first order at high as well as at low acid concentrations in chloride-free solutions. Negative first order kinetics and 0.04 V/dec Tafel slopes indicate that the Bockris mechanism of iron electrodissolution is also valid at high acid concentrations in the absence of chloride ions. On the other hand, in the presence of sufficient concentrations of chloride ions, different kinetic parameters are obtained indicating changes in the mechanism (5-7, 8, 9).

Figure 3 shows the cathodic polarization behavior (hydrogen evolution reaction) of iron in the $HClO_4$-

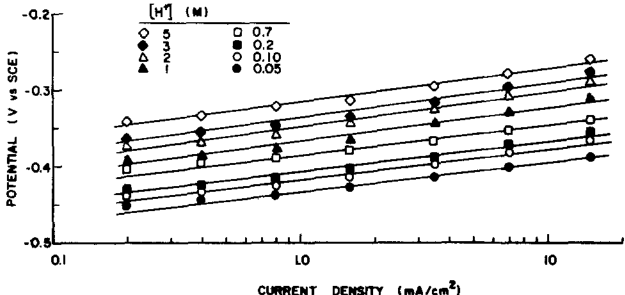

Fig. 1. Electrodissolution rate vs. potential at various H^+ concentrations. Iron in x $HClO_4$ — y $NaClO_4$ (x + y = 5M).

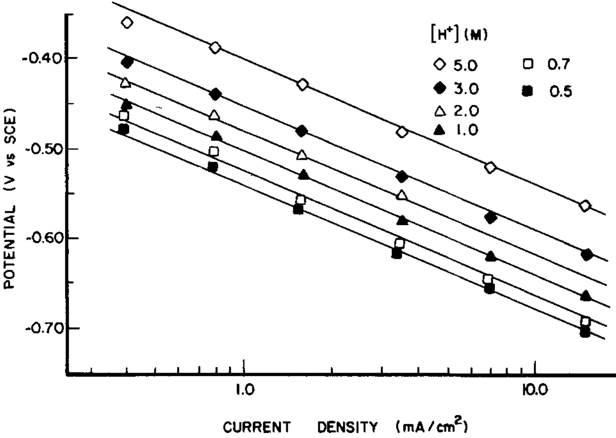

Fig. 3. Hydrogen evolution rate vs. potential at various H^+ concentrations. Iron in x $HClO_4$ — y $NaClO_4$ (x + y = 5M).

$NaClO_4$ solutions. Linear and parallel cathodic Tafel lines of 2 $RT/\mathbf{F}$ are obtained. The H^+ reaction order plot for the hydrogen evolution reaction (HER) is also shown in Fig. 2 and gives a slope of 0.9 indicating first order kinetics for the HER on iron in highly acidic perchlorate solutions. The same kinetic parameters were obtained for iron in highly acidic chloride solutions (10).

The dependence of the corrosion current on H^+ is

$$\frac{\partial \log i_{corr}}{\partial \log [H^+]} = 0.5$$

The kinetic parameters for the HER on iron (including $\partial E_o/\partial \log [H^+]$ and $\partial \log i_{corr}/\partial \log [H^+]$) are equivalent to corresponding values obtained by Kelly (4) for iron in sulfate solutions of substantially lower ionic strength and acidity.

The results of this work indicate that chloride ions significantly affect the mechanism of iron electrodissolution but not that of the HER on iron.

Procedure for Evaluation of Exchange Current Density and Coverage by an Intermediate at the Reversible Potential in a Process Such as Cl_2 Evolution

B. V. Tilak*

Hooker Chemical Corporation, Hooker Research Center, Grand Island, New York 14072

and D. M. Novak*,[1] and B. E. Conway*

Chemistry Department, University of Ottawa, Ottawa, Ontario K1N 9B4, Canada

The electrode kinetics of anodic Cl_2 evolution have, in recent years, become a topic of major interest especially in applications using RuO_2-based DSA®[2] electrodes (1-4) employed in the chlor-alkali industry. The kinetics of anodic Cl_2 evolution have also been extensively studied at Pt anodes from a more fundamental mechanistic point of view, commencing from the early work of Chang and Wick (5).

Mechanistic criteria such as reaction order, Tafel slope, and stoichiometric number values were applied to experimental results for Cl_2 evolution at Pt from aqueous Cl^- solutions, *e.g.*, by Yokoyama and Enyo (6) and by Tilak (7). Applications to Cl_2 evolution from molten chloride salts were made by Triaca, Solomons, and Bockris (8). From most of this work (6-10), it was concluded that the recombination of discharged (chemisorbed Cl· atoms was rate determining, giving rise to a Tafel slope of $RT/2\mathbf{F}$ (10) at low overpotentials and an approach to a limiting current at high overpotentials (6, 11, 12). While an approach to limiting current behavior was also observed by Yokoyama and Enyo (6), they concluded that the kinetics were determined by rate-controlling discharge of Cl^- ion, followed by equilibrium recombination/dissociation of Cl_2 ($Cl^- \rightarrow Cl\cdot + e$; $Cl\cdot \rightleftharpoons \frac{1}{2} Cl_2$). A new method for testing recombination-controlled kinetics

* Electrochemical Society Active Member.
[1] Present address: National Research Council, Division of Chemistry, Corrosion and Metal Oxidation Section, Ottawa, Ontario, Canada.
Key words: adsorbed intermediates, Cl_2 evolution, H_2 evolution, platinum, nonaqueous media.
[2] DSA® is a registered trade mark of Diamond Shamrock Technologies S.A.

was proposed by Conway and Novak (11, 12) and applied to the anodic Cl_2 evolution on Pt in trifluoroacetic acid and water as solvents in order to evaluate the role of the surface oxide monolayer at Pt anodes with regard to electrocatalysis of the Cl_2 evolution reaction. This method enabled the recombination kinetics to be tested over a wide range of coverages θ by the adsorbed $Cl^{\cdot}$ intermediate by means of a linear test plot (11, 12) over a wide range of $\theta_{Cl^{\cdot}}$ values from $\theta_{Cl^{\cdot}} \rightarrow 0$ to $\theta_{Cl^{\cdot}} \rightarrow 1$ as the limiting current is approached.

It was demonstrated that the experimental results for Cl_2 evolution from both aqueous and trifluoroacetic acid and water solutions of Cl^- ion gave excellent linear plots of the kind mentioned above except near the reversible potential where the back-reaction component must be taken into account.

It is the purpose of the present communication to show that the data obtained in Ref. (11) and (12) can be treated by a procedure which enables an estimate to be made of the coverage of the adsorbed intermediate in the reaction at the reversible potential. The method also enables the exchange current density to be obtained other than by the usual procedure of extrapolating a Tafel line. Thus, for recombination controlled reactions, *e.g.*, Cl_2 on Pt, this is not always feasible since the overpotential (η) — log [current-density (i)] plots are continuously curved under most conditions (5, 6, 8, 11, 12) for kinetic reasons rather than diffusion limitations. In the data to be treated below, absence of mass-transfer limitation effects in the observed approach to limiting currents was demonstrated by independence of the η *vs.* log i plots on rotation rate at a rotating disk electrode (11, 12).

The experimental conditions for which the data for Cl_2 evolution kinetics at Pt were obtained were fully described in Ref. (11) and (12). Here we shall make some further analysis of these results for anodic Cl_2 evolution kinetics in completely anhydrous trifluoroacetic acid as solvent with RbCl as electrolyte [where no oxide film exists on the electrode (11)] in comparison with the results for aqueous 1M KCl + 0.05M HCl solutions where a significant coverage by a surface oxide monolayer film, with co-adsorbed Cl^- ion, is present (12).

Basis of the Treatment

The following reaction equations [cf. Ref. (8)-(12)] are considered for a discharge/recombination controlled type of two-step reaction sequence such as is well known in the H_2 and Cl_2 evolution processes. The case of Cl_2 evolution will be exemplified here but the treatment will obviously apply to any similar reaction sequence. The steps are

$$Cl^- + M \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} M\,Cl_{ads}^{\cdot} + e \qquad [1]$$

$$2H\,Cl_{ads}^{\cdot} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} 2M + Cl_2 \qquad [2]$$

M are the surface sites on the metal (in the anhydrous solution case) or oxide $+Cl^-$-covered electrode in the aqueous solution case. k_1, k_{-1}, k_2, and k_{-2} are the rate constants for the steps [1] and [2] as indicated above With the recombination step [2] rate controlling, step [1] is assumed to be in quasi-equilibrium.

For brevity, C_{Cl^-} will represent the Cl^- ion concentration in solution and $RT/\mathbf{F}$ is represented by h^{-1}. The symmetry factor β in the discharge step is taken as 0.5. η is the overpotential defined as $V - V_{rev}$ where V is the metal-solution potential difference at finite net current density and V_{rev} that at zero net current density. Double-layer factors are absorbed in the k values and are considered constant for the purposes of the present analysis for constant concentration. θ will represent the $Cl^{\cdot}$ coverage at the overpotential η and θ_{rev} that at $\eta = 0$. A term θ_o is defined as $\theta_o = \theta_{rev}/1 - \theta_{rev}$.

The quasi-equilibrium assumption for step [1] gives

$$\frac{\theta}{1-\theta} = \frac{k_1}{k_{-1}} C_{Cl^-} \exp(hV) = \theta_o \exp(h\eta) \qquad [3]$$

Since $\theta_o = \frac{k_1}{k_{-1}} C_{Cl^-} \exp(hV_{rev})$, simple rearrangements result in

$$\theta = \frac{\theta_o \exp(h\eta)}{1 + \theta_o \exp(h\eta)} \qquad [4]$$

The current density i for the rate-determining $Cl^{\cdot}$ recombination is given by

$$i = 2\mathbf{F}[k_2\theta^2 - k_{-2}(1-\theta)^2] \qquad [5]$$

In terms of the exchange current density, i_o, and θ_o defined above through the coverage θ_{rev} at $\eta = 0$, the net current density i is given by

$$i = i_o \left[\frac{\theta^2}{\theta_{rev}^2} - \frac{(1-\theta)^2}{(1-\theta_{rev})^2} \right] \qquad [6]$$

where the two terms in the brackets correspond to forward and backward rate factors in the reaction velocity near the reversible potential.

Substituting θ in terms of θ_o from Eq. [4] gives

$$i = i_o \left[\frac{1}{\theta_{rev}^2} \left(\frac{\theta_o \exp(h\eta)}{1+\theta_o \exp(h\eta)} \right)^2 - \left(\frac{1}{1+\theta_o \exp(h\eta)} \right)^2 \frac{1}{(1-\theta_{rev})^2} \right] \qquad [7]$$

Rearrangement, following the definition of θ_o in terms of θ_{rev}, leads to

$$i \left(\frac{1+\theta_o \exp(h\eta)}{1+\theta_o} \right)^2 = i_o[\exp(2h\eta) - 1] \qquad [8]^3$$

By plotting the ln of each side of this function for various experimental i and corresponding η data, ln i_o will be obtained as the value of ln $[i[1 + \theta_o \exp(h\eta)]/(1 + \theta_o)^2]$ when ln $[\exp(2h\eta) - 1] = 0$. The required linearity of Eq. [8] will be achieved with the appropriate value of θ_o, hence giving θ_{rev}, all the other quantities being known. Evaluation of θ_o can be made either by regression analysis or by numerical evaluation using pairs of data points for η and i. Here we have evaluated θ_o as the value giving a best linear fit of the data to Eq. [8] in ln form.

Results

Figures 1 and 2 show log plots of the left-hand side and right-hand side of Eq. [8] for kinetic data for Cl_2 evolution at Pt in TFA and aqueous solutions of Cl^- ion. The various curves in Fig. 1 and 2 correspond to a range of selected θ_o values. The plotted graphs indicate that the linear relation expected for the mechanism [1], [2] is only approached as θ_o is quite near 0, $\theta_o \simeq 0.01$ for aq. solution, *i.e.*, $\theta_{rev} \doteqdot 0$. This is consistent, in the TFA solution case where no oxide film formation is detectable in cyclic voltammetry (11), with the absence of any reversible underpotential deposition of $Cl^{\cdot}$ species. The anodic current curve on the cyclic-voltammogram goes directly from a double-layer charging current into a continuing faradaic current curve for the Cl_2 evolution without any current

[3] For the "electrochemical desorption" case, which does not apply to the present experimental results, the equation equivalent to [8] is

$$i = i_o \left[\frac{(1+\theta_o)\exp[h\eta(1+\beta)]}{1+\theta_o \exp(h\eta)} \right] [1 - \exp(-2h\eta)] \qquad [8a]$$

Application of the procedure described above to recently discussed results of Khristalik (15) for Cl_2 evolution on RuO_2 electrodes also gives a θ_o value for $Cl^{\cdot}$ coverage near to zero. This is consistent with the requirements for Khristalik's mechanism for this electrode.

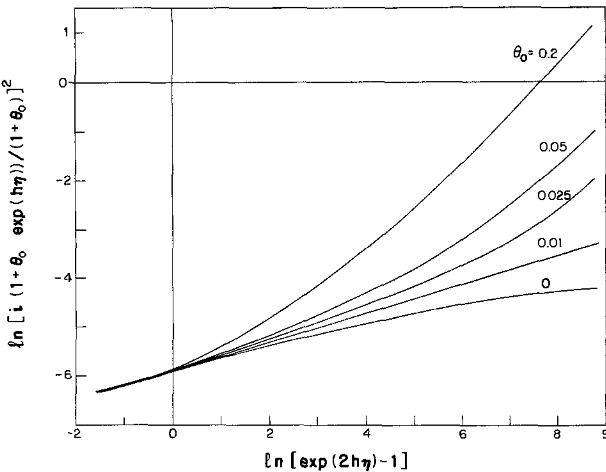

Fig. 1. Plot of $\ln[i(1 + \theta_0 \exp(h\eta))/(1 + \theta_0)]^2$ vs. $\ln[\exp(2h\eta) - 1]$ for the system Pt/0.5M aq. KCl + 0.05M aq. HCl during anodic polarization at room temperature.

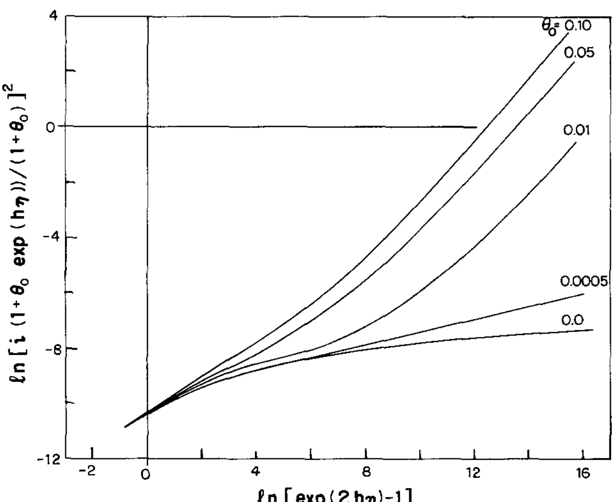

Fig. 2. Plot of $\ln[i(1 + \theta_0 \exp(h\eta))/(1 + \theta_0)]^2$ vs. $\ln[\exp(2h\eta) - 1]$ for the system Pt/100% CF_3COOH + 0.5M RbCl during anodic polarization at room temperature.

due to Cl• deposition prior to the Cl_2/Cl^- reversible potential (Fig. 3).

As Eq. [8] indicates, ln i_o values can be estimated from the plots of Fig. 1 and 2. The values are *ca.* e^{-10} ($=4.5 \times 10^{-5}$) and $e^{-6.2}$ ($=2.03 \times 10^{-3}$) A cm^{-2}, respectively, for TFA and 100% aqueous solutions of Cl^- ion at 0.1M Cl^-. These data are consistent with the differences of k_2 derived from the special linear test plots made in Ref. (11) and (12) for the recombination-controlled kinetics.

Interaction effects in the Cl• ad-layer.—Hitherto we have not mentioned [but cf. Ref. (11)] that there can be significant lateral interaction effects in the ad-layer of Cl•, especially when $\theta_{Cl^\bullet} \rightarrow 1$ as the limiting current is approached. When interaction effects are significant, Eq. [3] may take the form of a Frumkin isotherm (13) where k_1/k_{-1} is replaced by $k_1/k_{-1} \cdot (\exp - g\theta)$, g being the lateral interaction energy parameter (13, 14) characterizing 2-dimensional interactions in the monolayer.

If the "g" factor is included in the analysis, Eq. [8] becomes

$$i\left[\frac{1 + \theta_0 \exp(h\eta - g\theta)}{1 + \theta_0}\right]^2 = i_o\left[\exp(2h\eta) - \exp(-2g\theta)\right] \quad [9]$$

Then, of course, the evaluation of θ_0 becomes more

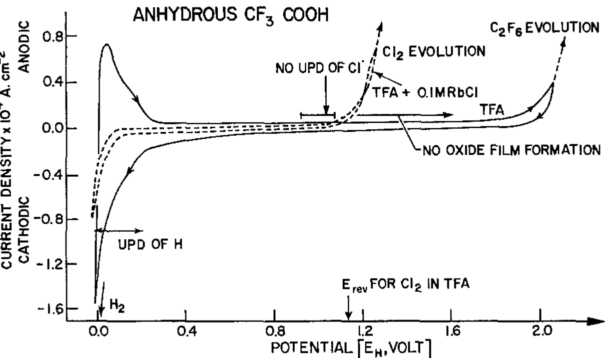

Fig. 3. Cyclic-voltammogram for Pt in 100% anhydrous CF_3COOH with 0.1M CF_3COOH or 0.1M RbCl, showing absence of Pt surface oxide formation or reduction currents, and no detectable upd of Cl atoms.

complex. However, some indication of whether a significant value of g is involved or not can be obtained from the shape of the experimental η *vs.* log i curves as the limiting current is approached [see Ref. (11) and (12)].

The equation for i at appreciable η takes the form

$$i = 2\mathbf{F}k_2\theta^2 \exp(2g\theta) \quad [10]$$

When $g > 0$, this gives (*i*) a limiting current greater than that for Langmuir adsorption ($g = 0$) and (*ii*) a slower approach of i to its limiting value as $\theta \rightarrow 1$. In fact it is seen that

$$\frac{d \ln i}{d \ln \theta} = 2(1 + g\theta) \quad [11]$$

which is the surface reaction order "in θ."

Comparison of theoretically calculated ln i *vs.* η curves for various small g values in the range of $0 < g < 10$ with the shapes of the experimental curves gives $g \sim 2.5$, near the value found in another way for CF_3COOH solutions in Ref. (11). This enables Eq. [9] to be used to evaluate θ_0. Small values of θ_0 near $0(<0.05)$ are again found.

An iterative method could also be employed by substituting θ_0 for the condition $g = 0$ (as above) and then using the equation $h\eta = \ln(\theta/1 - \theta) - \ln \theta_0 + g\theta$ to estimate g. A further estimate of θ_0 could then be made with the aid of Eq. [9]. In the light of the limited range of linearity of Fig. 1 and 2 for θ_0 near 0, we have found that the further step is unproductive of exact results for θ_0 for this system. Nevertheless, a low value of θ_0 is still indicated. It is pertinent to note here that Ludwig *et al.* (13) examined the kinetics of H_2 evolution on Pt in 6.1*N* HCl and observed linearity over 7 decades by plotting η *vs.* log $\{i(1 - \exp(2\mathbf{F}\eta/RT))^{-1}\}$. This indicates that $\theta_0 = 0$ since Eq. [8] degenerates to the above form (with appropriate sign for η) in the absence of coverage by the adsorbed intermediates on the electrode surface at the reversible potential. Hence, it appears that the mechanism of H_2 evolution on Pt from acid media involves slow recombination of weakly bound H_{ads}, whose coverage is zero near the reversible potential, even though the electrode is already covered with a monolayer of strongly bound adsorbed hydrogen (14).

Calcium Thionyl Chloride High-Rate Reserve Cell

E. Peled,* A. Meitav, and M. Brand

Department of Chemistry, Tel-Aviv University, Tel-Aviv, Israel

Recently, noteworthy progress has been made in the development of a high-rate reserve lithium thionyl chloride cell (1-3). At room temperature, discharge rates as high as 150 mA cm^{-2} were obtained with an average discharge voltage above 2.5V (2). At 65°C the rate capability of the cell is improved and a cell with a 0.05 mm thick cathode can deliver 400 mA cm^{-2} for a few seconds at a voltage above 2.0V (2).

One of the major obstacles to the development of a high-rate, pile-type (or multi-cell) lithium thionyl chloride battery is its well-known hazard during reversal or charging. Reversal of one or more cells, or the charging of one row of cells by another row connected in parallel, are each likely to happen during deep discharge. The metallic lithium, which deposits under these conditions on either the cathode or the anode, may have a large active surface area. At a high deposition rate, a powder-like lithium deposit can be formed. A mechanism for such a lithium deposition process was recently proposed (4). The presence of lithium powder deposit in a thionyl chloride cell may create a very hazardous condition. Another danger is the formation of an internal short circuit (sometimes accompanied by an internal spark), due to lithium dendrite growth. This will lead to rapid melting, or even evaporation, of the lithium dendrite, thereby initiating a cell explosion.

Replacement of lithium with calcium can solve these safety problems. This is due to the following facts: (*i*) the melting point of calcium is much higher (838°C); and (*ii*) the most important safety feature of the $Ca/Ca(AlCl_4)_2$-$SOCl_2$ system is the inability to practically deposit calcium on a metallic inert electrode (5), on a carbon cathode or even on calcium itself, as will be shown below.

Recently it was demonstrated (5-7) that calcium thionyl chloride cells can deliver, at low rates, a capacity comparable to lithium cells. The faradaic yield of a 0.5 mm thick calcium anode at 2.5 mA cm^{-2} was found to be 70-80% (7). The electrochemical behavior of calcium in thionyl chloride solutions was recently studied (5, 7). It was found that in thionyl chloride solutions calcium is covered by a passivating layer which acts as a solid electrolyte interphase (SEI). The resistivity of this SEI is (7) 10^8-10^{10} Ωcm, an order of magnitude or more higher than that of lithium in thionyl chloride solutions. The goal of this work was to assess the high-rate capability of a reserve type calcium-$Ca(AlCl_4)_2$ thionyl chloride cell and to exhibit its excellent safety features.

Hermetically sealed glass cells containing a flat 0.5 mm thick calcium (Roc/Ric) anode and a flat 1.1 mm thick Teflon-bonded carbon cathode were assembled inside a glove box. The carbon cathode had porosity of about 80% and consisted of 90 weight percent (w/o) Shawinigan black and 10 w/o Teflon binder. The electrode area was 5.6 cm^2. A nonwoven 0.18 mm thick glass separator paper was inserted between the cathode and the anode. The two electrodes were supported by two stainless steel plates held together with four bolts, which tightened at constant force. The cathode was isolated from this support plate by glass separator paper. An electrolyte reservoir was attached to the cell through a Teflon "Rotaflo" stopcock. The electrode compartment was evacuated before the discharge test. The cell was activated by opening the Teflon stopcock and letting the electrolyte fill the cell (about 30 ml) under atmospheric pressure. The cell was loaded as soon as its OCV reached 3.1V. This took 5-20 sec, depending on the temperature and on the composition of the electrolyte. Discharge at 60°C was carried out inside an oven. The cell with the attached electrolyte reservoir was stored at this temperature for 2 hr prior to the discharge test. The procedure for conductivity measurements is described in Ref. (8). Solutions were prepared by vacuum and glove box techniques. Fluke AR $AlCl_3$ was sublimed under vacuum, Merck AR

* Electrochemical Society Active Member.

Key words: electrodeposition, conductance, electrolysis.

$SOCl_2$ was twice distilled under vacuum, and Baker AR $CaCl_2$ was vacuum dried for 24 hr at 250°C.

It was recently found by Staniewicz (5) that the deposition process of calcium on nickel substrate is inefficient and only "little evidence" for calcium deposition was obtained. His experiment was carried out at a current density of 1.25 mA cm^{-2}. Our efforts to electrodeposit calcium on tungsten and Teflon-bonded carbon cathodes at current densities of 1-30 mA cm^{-2} all failed. On turning off the current after 15 min of electrolysis of a 0.95M $Ca(AlCl_4)_2$ solution at 1 mA cm^{-2}, using a tungsten cathode and calcium anode, the OCV of the tungsten reached 1V (*vs.* calcium reference electrode) within 1 sec while a few seconds later it rose to 2.5V. The same results were obtained after 1 min of electrolysis at 10 mA cm^{-2} or 3 min at 30 mA cm^{-2}. In the last two experiments, massive gas evolution (most likely SO_2) was observed on the tungsten cathode. The tungsten overpotential in these experiments rose to 20 and 35V, respectively. The open-circuit voltage of a cathode-limited cell which was overdischarged at 10 mA cm^{-2} for 2 hr rose to 2.5V within 1 sec after turning off the current. This cell contains 0.95M $Ca(AlCl_4)_2$ thionyl chloride solution. A massive evolution of gas was observed on the cathode during this reversal test. Plots (B) and (C) in Fig. 1 show cell voltage as a function of the current density during a galvanostatic reversal test of fully discharged cells. Cell (B) was galvanostatically discharged at 20 mA cm^{-2} to zero voltage prior to the reversal test. It can be seen that up to a reverse voltage of 15V the current density is rather small, a few mA cm^{-2} only. However, above 15V there is a steep increase in the current and a current density as high as 30 mA cm^{-2} was measured at a reverse voltage of 17.5V. Cell (C) was discharged at 1 mA cm^{-2} to zero voltage prior to the reversal test. This cell can stand a reverse voltage of 30V with no massive current flow. At reverse voltage above 30V the current steeply increases as in the previous case. These results can be explained in the following way. The cathode of a fully discharged cell is passivated by a film of $CaCl_2$. The thickness of such a passivating film is below 100Å (9). This film is a very poor electronic conductor so the reduction of thionyl chloride ceases and the working voltage of the cell is zero. The low current densities measured up to 15V under reversal condition indicates that the deposition process of calcium is also blocked. At a high cathodic overpotential a very strong electric field, of the order of 10^7 V cm^{-1}, is built up. This strong electric field causes an electrolytic breakdown of the $CaCl_2$ film, increasing its electronic conductivity and resulting in a massive reduction of the solvent. The electrolytic breakdown process observed for the cathode which was passivated at 1 mA cm^{-2}, took place at a much higher reverse voltage than that observed for the cathode which was passivated at 20 mA cm^{-2}. This indicates that the film which was formed at the low current density is thicker, more compact, and is a better electronic resistor.

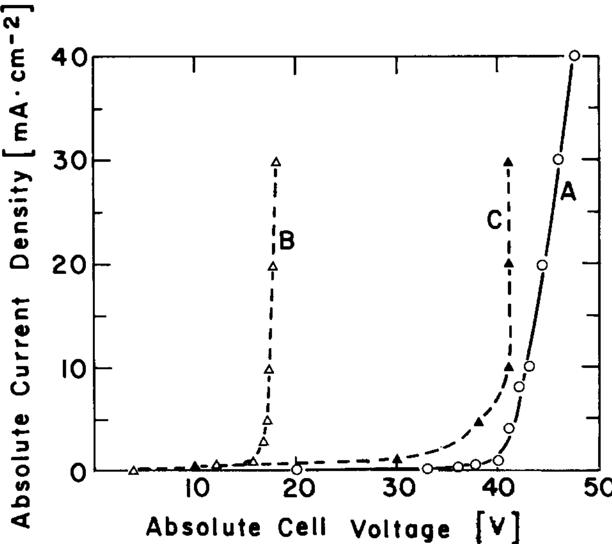

Fig. 1. Cell voltage as a function of the curent density during a galvanostatic charging experiment of a fresh cell (A) and during galvanostatic reversal tests of fully discharged cells (B) and (C). Prior to the reversal tests, cell B was discharged at 20 mA cm^{-2} and cell C at 1 mA cm^{-2}. All cells contained 0.95M $Ca(AlCl_4)_2$.

It can be seen (Fig. 1, curve A) that the charging current density of a fresh cell is smaller than 0.1 mA cm^{-2} up to 30V. At charging voltage above 40V the current steeply increases and massive gas evolution (most likely SO_2) is observed on the calcium. This test proves that it is practically impossible to "charge" a Ca-Ca $(AlCl_4)_2$ thionyl chloride cell. The main cathodic reaction taking place on reversal or on charging of a cell at current densities above 1 mA cm^{-2} is the reduction of the thionyl chloride and there is no indication of calcium deposition. Staniewicz (5) has proposed that the inefficiency of the calcium deposition process results from the fact that the $CaCl_2$-SEI is a pure anionic conductor ($t_- \simeq 1$), and so the deposition reaction requires the destruction of $CaCl_2$ at the SEI-metal interface and precipitation of it at SEI-solution interface. It seems that, as in the case of magnesium deposition from thionyl chloride solutions (9), (and in the case of cathodic polarization of passivated inert electrodes), some blocking of the ionic current leads to the development of a very high overpotential and electric field on the SEI. This electric field causes an electrolytic breakdown of the SEI and as a result, large electronic currents start to flow through it, leading to a massive reduction of thionyl chloride and evolution of SO_2.

The capacity, per square centimeter of cathode, of lithium thionyl chloride reserve cells was found to increase when acidic solutions (excess of $AlCl_3$) were used (1, 2), instead of neutral solutions. The maximum electrolytic conductivity of $LiAlCl_4$ thionyl chloride solutions at room temperature is about three times of that of $Ca(AlCl_4)_2$ solutions. As high-rate cells require the highest electrolytic conductivity, we studied the effect of temperature and excess of $AlCl_3$ on the electrolytic conductivity of $Ca(AlCl_4)_2$ solutions. The results are summarized in Fig. 2. The total concentration of $AlCl_3$ was kept constant at 2.2, 2.8, and 3.5M while the concentration of $CaCl_2$ [or $Ca(AlCl_4)_2$] was changed. In general, the conductivity increases with increase in the concentration of $CaCl_2$. At 20°C the highest conductivity was measured for 2.2M $AlCl_3$

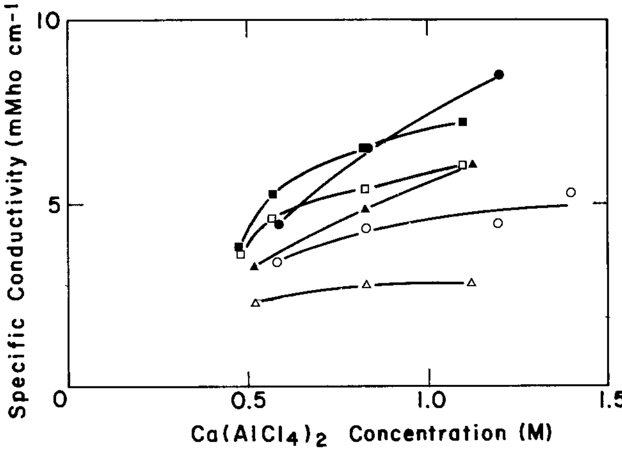

Fig. 2. The effect of $CaCl_2$ concentration on the specific conductivity of $AlCl_3$-$SOCl_2$ solution for 20°C (empty symbols) and 60°C (full symbols). Triangles, 3.5M $AlCl_3$; Circles, 2.8M $AlCl_3$; Squares, 2.2M $AlCl_3$.

solutions and this decreased as the concentration of $AlCl_3$ was increased. At 60°C for high concentrations of $CaCl_2$ the highest conductivity was measured for solutions containing 2.8M $AlCl_3$. It seems that one of the reasons for the decrease of the specific conductivity of the solution with the increase of the concentration of $AlCl_3$ is that solutions become more viscous.

The discharge curves of cells containing 0.85M $Ca(AlCl_4)_2$ + 0.4M $AlCl_3$ and 1.2M $Ca(AlCl_4)_2$ + 0.4M $AlCl_3$ at 23° and at 60°C are shown in Fig. 3. All cells were loaded on 8.2Ω resistor as soon as their OCV reached 3.1V. This took 5 sec (from filling the cell) for cell No. 3 and 15-20 sec for the rest of them. Cells No. 1, 2, and 3 exhibited a rather flat discharge curve up to 80% of the discharge time to a cutoff voltage of 1.5V. The discharge plateau at 60°C was about 2.2V while that at 23°C was about 2.0V (for cell No. 2). Higher capacities were obtained at 60°C than at 23°C. At 60°C, cell No. 3, which contained 2.8M $AlCl_3$(+1.2M $CaCl_2$), gave a higher capacity than cell No. 1 which contained 2.2M $AlCl_3$(+0.85M $CaCl_2$). This is due to the better electrolytic conductivity of the more concentrated solution (see Fig. 2). At 23°C the opposite is true. Cell No. 2, which contained only 2.2M $AlCl_3$ (+0.85M $CaCl_2$), had a much higher capacity than cell No. 4 which contained 2.8M $AlCl_3$(+1.2M $CaCl_2$). Here again the higher capacity was obtained for the cell which had higher electrolytic conductivity. The current density at 60°C was about 50 mA cm^{-2}. The maximum capacity at this rate was about 12 mA hr cm^{-2} (to a 1.5V cutoff voltage). At 23°C and at a current density of 45 mA cm^{-2} the capacity was about 7 mA hr cm^{-2} (for cell No. 2).

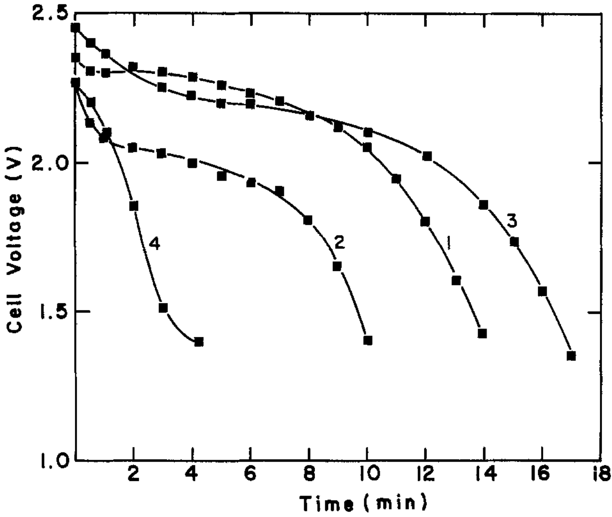

Fig. 3. The effect of temperature and electrolyte concentration on the discharge performance of calcium $Ca(AlCl_4)_2$ thionyl chloride reserve cell. Curves 1 and 2, 2.1M $AlCl_3$ + 0.85M $CaCl_2$ at 60° and 23°C, respectively; curves 3 and 4, 2.8M $AlCl_3$ + 1.2M $CaCl_2$ at 60° and 23°C, respectively.

The good discharge performance at a discharge time of 10-15 min, together with the excellent safety features of the Ca/$Ca(AlCl_4)_2$ thionyl chloride cell encourage further investigations of this system as a promising candidate for high-rate multi-cell reserved and nonreserved battery applications.

Investigation of Photoelectrochemical Corrosion of Semiconductors

III. Effects of Metal Layer on Stability of GaAs

K. W. Frese, Jr.,* M. J. Madou, and S. R. Morrison

SRI International, Menlo Park, California 94025

ABSTRACT

The effects of displacement plated metal layers on the photoelectrochemical corrosion of the (100) surface of n-GaAs were investigated using the rotating ring disk electrode (RRDE). A large beneficial effect on stability was demonstrated. Measurable improvements in stability were observed for less than a monolayer gold metal coverage. Capacitance/voltage data were consistent with Fermi level pinning caused by metallic deposits.

In view of the current interest in development of photoelectrochemical (PEC) solar cells, the stabilization of semiconductors in contact with electrolytes against photocorrosion is a highly relevant problem. We have been studying fast redox couples that can be effective stabilization agents, as well as the effects of defects (1, 2) on the corrosion process.

In addition to enhancing the stability by fast redox kinetics on the "clean" surface, it is of considerable interest to find other methods to enhance the corrosion stability of semiconductors. A possible way to increase the stability and the solar-electrical conversion efficiency of the semiconductor in a PEC cell is through an effective surface pretreatment. Indeed it has already been shown that pretreatment of n-GaAs electrodes (3) with various metal ions such as Ru^{3+} leads to enhanced solar cell efficiency. However, no quantitative data have been reported about the effect of deposited metals or metal ions on the stability against photoelectrochemical corrosion.

This paper reports some of our results of stabilization efficiency, *S*, and of capacitance/voltage measurements on (100) single crystal n-GaAs surfaces that have been pretreated with solutions containing metal ions. The technique of displacement deposition from solution is used to obtain the metal deposits. To our knowledge, this displacement technique has not been applied to stabilization of PEC solar cells.

Experimental

The GaAs (100) surfaces were chemomechanically polished with a 1% V/V chlorox (5.25% sodium hypochlorite) solution. The surface was then etched in a 0.05% chlorox solution for ~ 10 min at room temperature. The surface was rinsed successively with H_2O, 1M HCl, and H_2O, and then blown dry.

Solutions of various metal ions were prepared at ~ 0.01M concentrations. The solutions included acidic $RuCl_3$, $Pb(NO_3)_2$, $Cu(NO_3)_2$, $Fe(ClO_4)_2$, H_2PtCl_4, K_3IrCl_6, and $AuCl_3$. The surface to be treated was covered with a layer of the solution and then illuminated with a microscope lamp for 3-5 min. The surface was then rinsed with H_2O and blown dry. Finally, the samples were inserted into the rotating disk (RRDE) cell (1) and stabilization measurements were made.

This treatment is known (4, 5) to cause irreversible deposition of metallic gold, silver, copper, and mercury on GaAs and InSb. It was shown in this early work that these deposits could not be removed by successive washing with 1*N* HNO_3. We have previously used this plating technique to form gold-back contacts on p-GaAs for electrochemical measurements (6).

Capacitance/voltage curves were obtained using a lock-in amplifier technique with a 10 kHz, constant current a.c. signal of 1 μA. The ring disk apparatus included a two potentiostat, six electrode system so that the potentials of the ring and disk could be independently controlled. The RRDE consisted of a 5 mm diam GaAs disk, an epoxy insulator, and an amalgamated copper ring. The calculated collection efficiency was 0.36, whereas the experimental value was 0.344 determined (1) in the presence of a highly effective stabilizing agent such as Fe(II) EDTA. The rotation speed was about 1000 rpm. The results were independent of speed in this range. All measurements were done in aqueous solution.

Results and Discussion

The displacement deposition of metals on GaAs occurs by circulating currents where the anodic current corrodes the GaAs, and the cathodic current reduces the metal. Thus in analyzing the deposition process, we look to the energy levels involved in these two processes. Figure 1 shows a diagram of redox energy levels, $-(E_{NHE}^\circ + 4.48\ eV)$, for various metal ion/metal couples; these levels can be used to thermodynamically predict which metals can deposit on GaAs. On the left the redox energy levels of various couples, including those used in this work, are shown. On the right side the redox level for the anodic corrosion reaction of GaAs in acid solution is shown at −4.40 eV. The metal deposition on the single crystal is assumed

* Electrochemical Society Active Member.

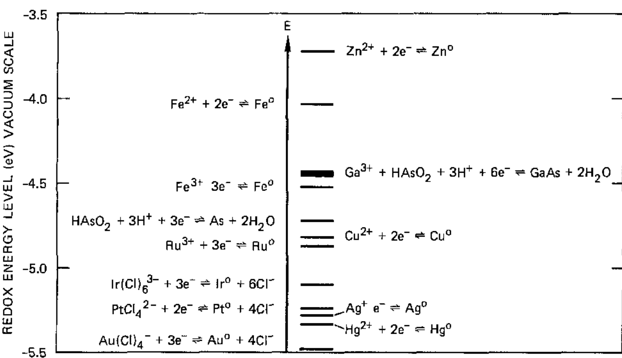

Fig. 1. Redox energy levels for various metal deposition couples and the GaAs corrosion couple in acidic solutions.

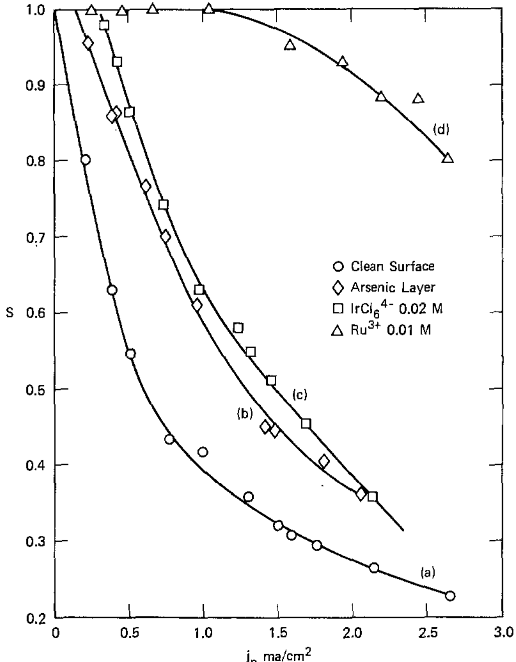

Fig. 2. Stabilization efficiency vs. disk photocurrent for 100-n-GaAs for various surface pretreatments. (a) Clean surface; (b) after 1000Å anodic oxidation (arsenic-rich surface); (c) 0.02M $IrCl_6^{3-}$; (d) Ru^{3+} 0.01M. Stabilization experiments in 0.02M Fe(II) in 0.1N Na_2 EDTA $pH = 6.7$.

to occur via local anodes and cathodes. The sites of corrosion behave as anodes and the sites of metal deposition are the cathodes. On an ideal single crystal surface, no site is preferred for anodic or cathodic current. However, if the n-type surface is illuminated (5), regions of relatively high light intensities become anodes (corrosion occurs) and the dark regions become cathodes (plating occurs). A similar local anode-cathode effect (plating effect) could be caused by surface defects in the absence of illumination.

The metal ion/metal couples shown on the right of Fig. 1 were investigated by Larrabee (4). In the case of Cu^{2+}, Ag^+, and Hg^{2+}, the metals were irreversibly deposited on GaAs, and Au^{3+} was similarly deposited on GaAs (5) and InSb (4). Importantly, Na^+ ($E° = -1.77$ eV below vacuum) and Zn^{++} did not deposit (4) irreversibly. Note that these two couples have redox energy levels above the corrosion redox level of GaAs. From the chemistry of these semiconductor-metal systems it can be seen that using metal couples with redox energy levels below the corrosion redox level will lead to deposited metal layers and using those above it will not.

We will assume that the above deposition process occurs in the pretreatments described here. Capacitance/voltage data and visual observation support this assumption.

In RRDE measurements, it is found that very low coverages of deposited metals strongly affect GaAs photocorrosion. We will compare results of measurements involving no deposited metal to those involving the various deposited layers.

In the RRDE measurement, the fraction of the photocurrent that leads to reaction with a redox species in solution (stabilizing agent) is found by measuring the current due to reduction of $[Fe(III)\ EDTA]^-$. This ratio is termed the stabilization efficiency, S. It is found (1) that S varies with disk photocurrent level, j_p, for a given stabilization agent concentration. Figure 2 shows results on the stabilization of (100) GaAs in aqueous 0.02M Fe(II)/0.1M Na_2 EDTA, $pH = 6.7$. The disk potential was 0.0V *vs.* SCE. Curve (a) refers to the well-etched clean surface. The stabilization decreases rapidly as j_p increases. We note that the level of stabilization presented here is very close to that already observed (1) for the same concentration of stabilizing agent but using the (111) As face. This observation may indicate a small dependence of corrosion rate on crystallographic face.

Curves (b) and (c) show typical S *vs.* j_p plots for "arsenic-treated" (see below) and iridium-treated surfaces, respectively. Modest but measurable increases in stabilizatiion are found. Curve (d) shows data for a ruthenium-treated surface. A threefold increase in stabilization efficiency is observed. The magnitude of the stability enhancement was similar for Ru and Au. Results with gold will be discussed in more detail later. The data in curve (a) for the "clean surface" could be reproduced after chemomechanical etching of the previously metallized surface. The coverage by the metals after this preparation is difficult to determine. In our more detailed examination of gold deposits, described below, attempts were made to correlate improvement in stabilization with coverage.

Several other metals were tried, each with much less effectiveness than Ru or Au. For comparison with the data in Fig. 2, the stabilization efficiency at 1 mA/cm^2 and 0.02M Fe(II) EDTA, $pH = 6.5$, was 0.54 for Pt, 0.59 for Cu, and 0.44 for Fe, whereas for the unmetallized "clean surface" it was 0.41. The value for iron is reasonable since the reduction of Fe^{2+} is thermodynamically unfavorable according to Fig. 1.

The observation that an "arsenic-treated" surface provides increased stability deserves further discussion. The GaAs was not treated with an arsenite solution as could have been assumed from Fig. 1, but the sample was covered with the residue remaining after growth and removal of an anodic oxide. We have good evidence from our work on passivation of GaAs (6, 7) that anodic oxidation of GaAs leads to unoxidized elemental arsenic in the oxide and, importantly, in the GaAs/oxide interfacial region. It was postulated that since semimetallic As may be present on the GaAs surface, growing an anodic oxide and dissolving it with HCl would leave a "semi-metallized" surface rich in elemental, insoluble arsenic. The arsenic surface was thus prepared by growth of a 1000Å oxide by a standard method (6) followed by its removal in HCl. The enhancement in stabilization found by such a treatment is consistent with the As layer model. Attempts to deposit arsenic from arsenite solutions are planned for the future.

Another redox couple was investigated to confirm that the stabilization enhancement was not unique to ferrous EDTA. Figure 3 shows plots of S *vs.* j_p for 0.1M hydroquinone, H_2Q, ($HQ^- \sim 0.01M$) (1), $pH = 9.0$. The lower curve shows data for a clean well-etched surface and the upper curve (b) shows data for the Au^{3+}-treated surface. In this case, a three to fourfold increase is observed in the stabilization efficiency.

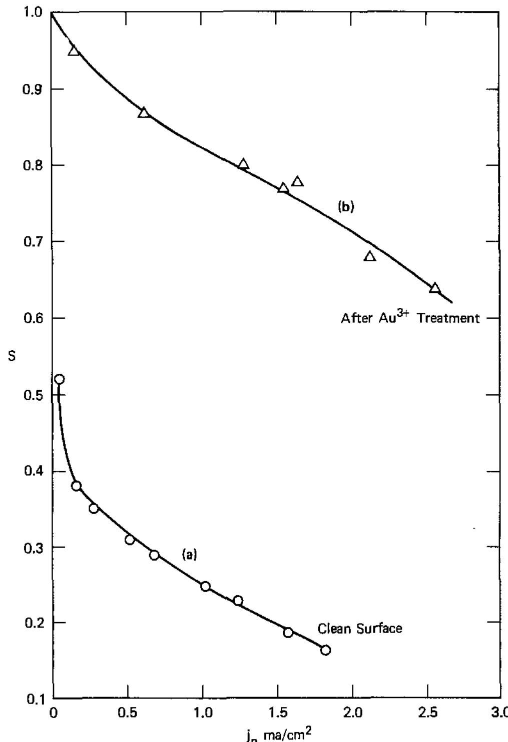

Fig. 3. Stabilization efficiency vs. disk photocurrent for 100-n-GaAs. Stabilization experiments in 0.1M hydroquinone 0.1M KCl pH = 9.0.

In Fig. 4, stabilization efficiency *vs.* photocurrent is shown for (100) GaAs with varying amounts of gold using 0.02M Fe(II) EDTA. In these studies using auric solutions, an upper limit could be calculated for the amount of gold on the surface. Solutions of $AuCl_3$/0.1*N* $HClO_4$ were prepared in the concentration range 2.3 $\times$ 10^{-6} to 1.15 $\times$ 10^{-3}M. By use of micropipettes, 10 μl drops containing as low as 2 $\times$ 10^{-11} mol of gold were placed over the whole area of the GaAs electrode. If one assumes a uniform layer of gold and an ideally smooth surface and that all the gold in the drop plates (surface illuminated), then the 2 $\times$ 10^{-11} mol of gold is equivalent to 0.1Å film thickness or 7 $\times$ 10^{13} atoms/cm². Thus a 2.3 $\times$ 10^{-6}M Au solution could ideally give less than a monolayer coverage whereas 1.2 $\times$ 10^{-3}M solution could give 60Å of gold. Thicknesses calculated in this manner are a convenient index to the maximal amount of Au on the surface. It should be mentioned that even if all the gold plated uniformly, the calculated thickness could still be 50% too large due to possible surface roughness. It cannot be proved from the stabilization data that gold film was uniform (although it appears uniform in Fig. 7 at 20,000$\times$). What can be shown is that the stabilization is increased even for a gold deposit equivalent to less than a monolayer.

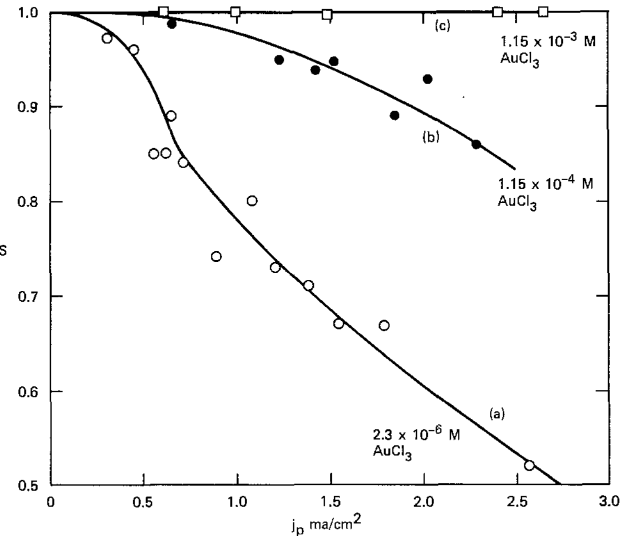

Fig. 4. Stabilization efficiency vs. disk photocurrent for 100-n-GaAs treated with various concentrations of $AuCl_3$/0.1*N* $HClO_4$. Treatment after 5 min under illumination, electrode area 0.195 cm². 10 μl samples of Au^{3+} solution. Stabilization experiments in 0.02M Fe(II) in 0.1M Na_2 EDTA *pH* = 6.3.

Curve (a) in Fig. 4 shows the stabilization efficiency *vs.* photocurrent for a case where the total amount of gold in the plating drop was 2.6 $\times$ 10^{-11} mol. As discussed above, this could only give less than a monolayer coverage if the gold were uniform. Nonetheless, significant increases in stabilization occurred as can be seen by comparing curve (a) in Fig. 2 with curve (a) in Fig. 4. The stabilizatiion efficiency is doubled at j_p of 1 mA/cm². Curve (b), Fig. 4, shows a further increase in stabilization where the ideal gold thickness was 6Å. Finally, the top of Fig. 4 shows points for a gold solution with an ideal film thickness of 60Å. With this surface treatment the stabilization efficiency was constant and close to unity over a period of at least 2 hr at a photocurrent of 2.5 mA/cm². During this extended RRDE experiment, neither the disk photocurrent nor the ring current decayed. If significant amounts of corrosion occurred, films of Ga_2O_3 would be expected to remain on the surface at *p*H = 6.5. This film would eventually lead to a degradation of the photocurrent that was not observed. It should be noted that in all these experiments only 0.02M Fe(II) EDTA was used. Diffusion limitation of the stabilizing agent could be avoided because of the high rotation speed. The low concentration was necessary to provide a test of the metal additive, for with high concentration of stabilizing agent a metal additive is not required for efficient stabilization. However, metal pretreatment may be needed to give the very high stability needed for practical PEC solar cells. Stabilization efficiencies approaching 100% for the "clean" single crystal surface could be obtained using 0.08-0.1M Fe(II) EDTA (1, 2).

It is desirable to obtain further evidence that metallic layers do indeed form on the surface. This can be done by observing changes in the space charge capacitance/voltage behavior after exposure of the GaAs to metal ions. Figures 5 and 6 show Mott-Schottky plots for clean surface and metal-deposited electrodes. Reasonably linear Mott-Schottky plots were obtained for the "clean" surface over a voltage range of about 1V. The experimental donor densities, 2 $\times$ 10^{18} cc^{-1}, were expected from the known electrical properties of the crystals.

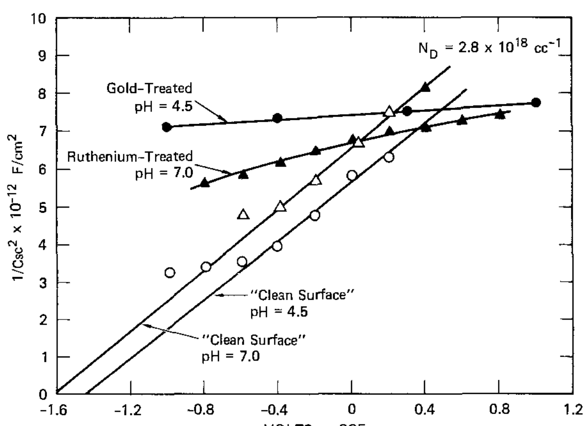

Fig. 5. Mott-Schottky plots for 100 n-GaAs before and after ruthenium and gold ion treatment. Electrolyte 0.1M Na_2 EDTA *pH* = 7.0 and 4.5, respectively.

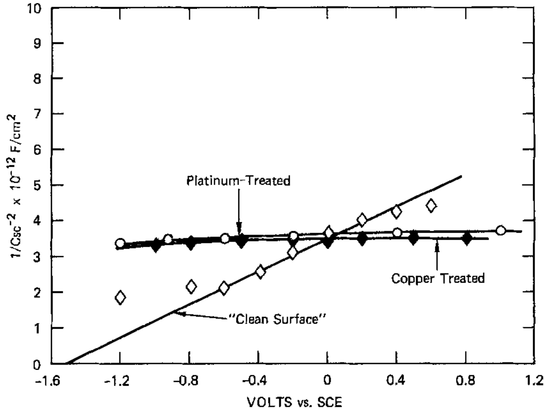

Fig. 6. Mott-Schottky plots for 100-n-GaAs before and after copper and platinum treatment. Electrolyte 0.1M Na_2 EDTA pH = 6.5.

The Mott-Schottky plots changed drastically after exposure of the electrode to the metal ion solution. As shown in Fig. 5 and 6, after treatment the space charge capacitance changes very slowly with electrode potential, indicating that most of the changes in applied potential appear outside the space charge region. Such changes in applied potential could be divided between the semiconductor/metal interfacial layer and the solution Helmholtz layer. Further work is needed to decide the distribution of potential outside the space charge region.

Finally, the oxidation state of the metal deposits is of interest. Our key conclusion from the Mott-Schottky plots is that metallic layers deposit on the surface. This conclusion is reached by analogy to well-known experiments (8) of evaporated metal layers on semiconductors. In such experiments it is concluded that a large density of interface states ($\sim 10^{14}$ cm^{-2} eV^{-1}) cause Fermi level pinning and built-in (space charge) barriers up to 1 eV on GaAs. Similar pinning with large surface barriers is observed here according to the C/V results in Fig. 5 and 6.

On the other hand, if the metal ions were not reduced to metal atoms, two cases could occur. A positive shift in the flatband voltage could occur for sorption of an inert positive ion. The Mott-Schottky plot would have the same slope as the "clean" surface. This effect is completely analogous to the role of protons in shifting the flatband potential of oxide semiconductors. This type of behavior is not observed.

The other case for the positive ion that could account for the pinning observed in that it may act as a surface state and change only its oxidation state to +3 or +2 but not zero. Such a case is rare in semiconductor electrochemistry and can be ruled out for gold and copper since thick, easily visualized metallic films can be grown.

Figure 7 shows a scanning electron micrograph of a 100 n-GaAs surface treated with Au^{3+} to give an ideal film thickness of 60Å. The light region is the gold film, while the dark track is the GaAs surface. The track, which is about 5000Å wide, shows a region where the gold film was scratched in handling. In the adjacent regions of the sample the film looked quite uniform at this magnification.

Conclusions

A very simple method has been demonstrated by which a thin metal layer can be deposited on semiconductors such as GaAs. The layer is formed by simply dipping the illuminated surface of the semiconductor into a dilute solution of the appropriate metal ion. In previous work with metal overlayers (9, 10) evaporated layers were used and gave only qualitative results concerning stability. In addition these authors used H_2O as the reducing agent whereas we are concerned with

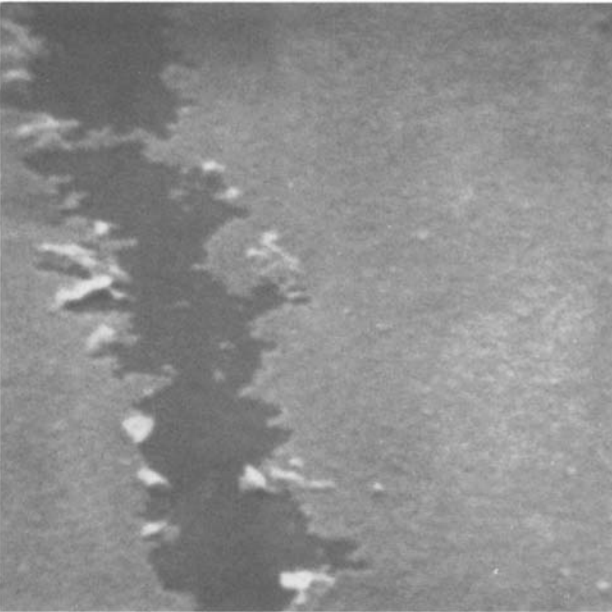

Fig. 7. Scanning electron micrograph of ~60Å of gold (light region) on (100) n-GaAs. The gold was deposited by a displacement plating technique. The scratch in the gold film is about 5000Å wide and was made during handling.

reducing agents that can effectively capture photogenerated holes. In the present case very substantial increases in the stability of the treated surface (discussed here) were observed with small amounts of metals such as gold or ruthenium.

Several models can be advanced to account for the stabilization results. It is not our purpose to discuss these models in detail, but some general comments are useful in indicating possible explanations.

First, the metal layer can block the electrolyte from contacting the semiconductor directly while still providing a conducting path for photogenerated holes. If the Ga^{n+} and As^{m+} ions formed cannot find OH^- or H_2O from the electrolyte, no corrosion product can form. For a sufficiently thick metal layer, field-aided diffusion (the normal mode of oxide growth) should be minimal because of the small zero field in the metal. Therefore, As° and Ga° atoms can be reformed by electrons from the metal, the stabilizing agent, or the GaAs conduction band (recombination). An auxiliary model that could help explain the results makes use of the concept of hot holes in metals. Holes generated at the valence bandedge would enter the metal as hot holes since they probably would be several tenths eV below the metal Fermi energy. At such low energies below the Fermi level, the mean-free path for holes can be quite large. For example, the attenuation length for holes in evaporated gold films was found to be 550Å (11) at 0.8 eV below the Fermi energy. This implies that the metal layers used in our experiments are completely transparent to holes.

It may be shown that in certain cases the presence of a metal layer can increase the overlap between filled levels in solution and the hot holes (hot relative to the metal Fermi energy) at the valence band energy because of the potential drop in the metal semiconductor interfacial layer. This model and implications for photoelectrochemical solar cells will be discussed in future publications.

A third mechanism for the increased stability is that the metal atoms (or crystallites) at the surface have a very large effective capture cross section for holes, and so even a fractional monolayer can act as a very effective stabilizing agent. A stabilizing agent must be present in solution to capture the holes from the metal, but

once the hole is captured by the metal it may be rendered ineffective in corroding the host GaAs.

These results with deliberately deposited metal layers seem to explain our previous puzzling results (2) concerning the increase in stabilization efficiency after several minutes of cathodic current passage. In these RRDE/stabilization experiments we used (111) n-GaAs in Fe(II) EDTA. The solutions contained soluble arsenic species and Ga^{3+} (from corrosion) and Fe^{2+} and Fe^{3+} as EDTA complexes. In the cathodic pretreatment one or more of these metals could have been electrodeposited on the GaAs and thus could have given some kind of corrosion protection as observed in the present work.

RF Sputtering of Yttria on Indium Tin Oxide Substrates

M. P. R. Panicker* and W. F. Essinger*

Sigmatron Nova, Thousand Oaks, California 91311

ABSTRACT

The blackening of indium-tin oxide and tin oxide thin film substrates during rf sputter deposition of yttrium oxide has been investigated to determine the precise conditions and mechanisms effecting this phenomenon. It was determined that at argon pressures below 4 microns and/or with the substrate films grounded, the yttria films deposited were oxygen deficient. The subsequent reduction of the substrate film by the more stable yttria resulted in the blackened appearance of the film. The problem was further compounded when these electrically conductive substrates were of optimum properties (sheet resistance below 20 Ω/sq and light transmission greater than 80%), as these properties can be simultaneously obtained only from a high oxygen deficiency. Based on these results, sputtering conditions are described which effectively deal with the problem.

Degenerate tin oxide (SnO_2:SbO_x) and indium oxide (In_2O_3:SnO_x) are materials commonly used for the electrically conductive (EC) coatings on glass substrates used to make electro-optic devices such as liquid crystal and electroluminescent displays and back-wall-type photovoltaic cells. Low sheet resistance and high optical transmission are two prerequisites for these applications. However, having fixed the dopant concentration and thus the electrical resistivity in an otherwise stoichiometric EC film, these properties are interdependent since lowering the sheet resistance can now be done only by increasing the film thickness resulting in decreased transmission. Under these conditions, the above properties can independently be varied only by reducing the degree of oxidation of the EC film.

In most of the above cited applications, the reduced degree of oxidation of the EC film is not a serious disadvantage either because of the absence of any chemically reactive layer adjacent to it or because of the fact that the electric fields these films encounter are small. However, such conditions do exist in light emitting thin film (LEF) displays and hence EC coatings with a high oxygen deficiency can present serious problems during the performance of the device.

This paper relates specifically to the problems encountered while sputtering yttria (Y_2O_3) on indium tin oxide and SnO_2 substrates. Yttria is used as the dielectric material in the electroluminescent thin film displays developed by Sigmatron Nova. These yttria films are deposited by radio frequency sputtering. It has been observed that during sputtering the EC coating frequently turned black as a result of the reduction of these films by oxygen-deficient yttria. This made the EC coatings highly unstable leading to display failure during operation, observed as blown holes at random or along the entire length of the conducting lines. Further, this occurred more frequently with ITO substrates than with SnO_2 substrates.

Sigmatron Electroluminescent Thin Film Display

Figure 1 illustrates the structure of the display made by Sigmatron (1). The substrate is ITO- or SnO_2-

coated glass on which desired patterns are developed through photolithography. On this a 2000Å thick yttria film is deposited by rf sputtering. This is followed by a one micron thick ZnS:Mn phosphor layer on which a light absorbing layer is deposited (2). The device is then completed by depositing another 2000Å thick yttria layer followed by the deposition of the counter-electrodes.

Experimental

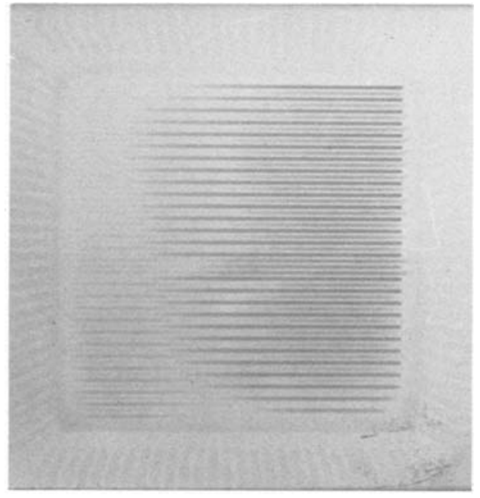
The yttria targets used for the study were obtained from Kema Corporation and were 99.99% pure and hot-pressed to suit the Sloan S-310 sputter gun. The substrates were either ITO-coated soda lime glass obtained from Optical Coating Laboratories, Incorporated, Santa Rosa, with a sheet resistance varying from 10 to 50 Ω per square or SnO_2-coat 7059 glass obtained from Corning, having resistivity in the range of 50-150 Ω/sq. Both types of glass had white light transmissions of 75-85%. The substrates used to make the devices had an effective area of 2.5 × 2.5 cm with a resolution of 22.4 lines per cm. These were cleaned under class-100 environment, degreased, and rinsed in deionized water prior to yttria deposition. Yttria was then rf sputter-deposited on these substrates using a Sloan 310 gun in an argon-oxygen gas mixture at chamber pressures varying from 1 to 10 microns. The oxygen content was varied from 0 to 50%. The substrate temperature was varied from room temperature to 300°C. The chamber was evacuated to about 3×10^{-6} Torr using a turbo-molecular vacuum system with a liquid nitrogen trap prior to sputtering.

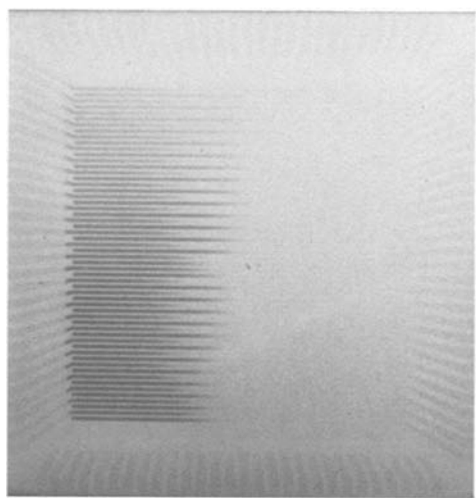
[1] LEF is a trademark of Sigmatron Nova.

The resistivity measurements on the EC coatings were done using a four-point probe. Yttria films were tested for their dielectric properties using a capacitance bridge. The annealing of the EC coatings was done in air using a muffle furnace.

Results and Discussion

The effect.—When yttria is rf sputtered on ITO- or SnO_2-coated glass substrates at temperatures above 200°C, often the conductive lines turn black. This indicates that the EC film has been reduced and now has a large oxygen vacancy concentration (3). It has been observed that the effect is not necessarily uniform over an area or along a line. Figure 2a and b are ITO on soda lime, while 2c is SnO_2 on 7059 glass. The net effect of this on the device performance is nonuniform





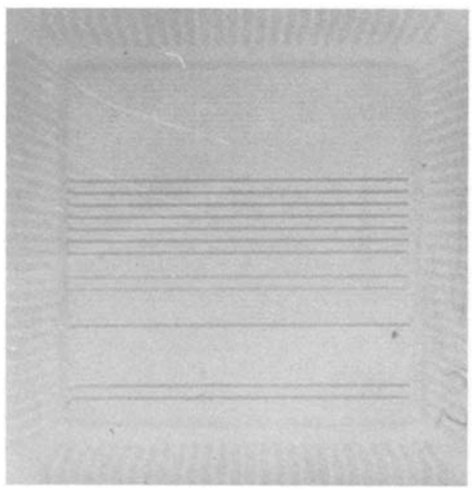


Fig. 2. Reduction of EC lines during yttria sputtering. (a, top left) ITO on soda-lime glass. Low chamber pressure leads to uneven oxygen distribution causing formation of nonstoichiometric Y_2O_3 regionally. (b, top right) ITO on soda-lime glass. Yttria was oxygen deficient on the left half. (c, bottom left) SnO_2 on 7059 glass. Reduction is only along "grounded" lines. Note that no adjacent lines are affected.

light output, and in extreme cases total failure where the active area is blown away as soon as the voltage is turned on. The latter could be either because these reduced lines, which are thinner and mostly metallic, melt away at the increased current densities ($|i^2R| > \Delta H_{fusion}$) or because the microcraters and pores that can result from the reduction create highly localized electric fields leading to the breakdown of the films. These black lines are very unstable and dissolve readily even in very dilute acids.

Figure 3a shows a panel where some dark lines were completely dissolved, while 3b shows one in which the dissolution was only partial. The difference is the result of varying degrees of reduction of the ITO because ITO films with varying degrees of oxidation are etched differently in HCl (3) or conversely, varying degrees of oxygen deficiency of the yttria films deposited in those regions. The degree of reduction of the conductive lines varies from line to line, from region to region, and sometimes from run to run.

Figure 4, like 2c, shows an interesting pattern in which the reaction made all alternate lines black. The panel has 56 lines, of which 28 lines originate at each side. Hence, this pattern indicates the reaction was electric field assisted as will be explained later.

Mechanism.—The EC coating turns black because it loses oxygen to the stronger, but oxygen-deficient yttria which is being deposited directly on top. This oxygen deficiency stems from the low oxygen partial pressure (7%) we use during sputtering to attain a reasonably high deposition rate. The presence of oxygen vacancy has been indicated by Tallan and Vest (4) and Tsutsumi (5). The substrate temperature during sputtering is about 225°C at which the standard free energies of formation for the three oxides under consideration are as shown below (6)

$$\frac{4}{3}\text{Y} + \text{O}_2 = \frac{2}{3}\text{Y}_2\text{O}_3, \quad \Delta G^\circ = -260\ \text{kcal} \quad [1]$$

$$\frac{4}{3}\text{In} + \text{O}_2 = \frac{2}{3}\text{In}_2\text{O}_3, \quad \Delta G^\circ = -122\ \text{kcal} \quad [2]$$

$$\text{Sn} + \text{O}_2 = \text{SnO}_2, \quad \Delta G^\circ = -114\ \text{kcal} \quad [3]$$

This shows that in order to replete an oxygen deficiency, yttria can reduce both ITO and SnO_2 at 225°C if the rate is adequate. The rate also seems adequate because oxygen-deficient yttria can pick up oxygen at temperatures as low as 100°C (4, 5). Also, we have observed in our experiments that ITO and SnO_2 increase their surface resistance 2-3 times over 6-8 hr of heating in air at 150°C and that their conductivity increases on annealing in vacuum at 150°C for a few hours.

The extent of reduction and consequently the degree of blackening of the lines depend on the oxygen deficiency in the yttria and ITO. This can be understood by writing the reduction reactions as follows

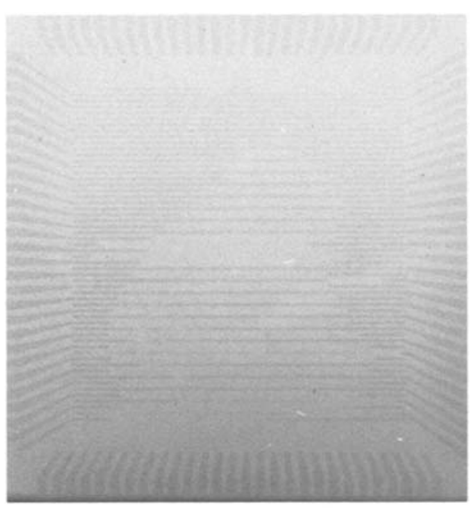
$$[\text{In}_2\text{O}_{3-x} + xV_\text{O}] + [\text{Y}_2\text{O}_{3-y} + yV_\text{O}] = \text{Y}_2\text{O}_3 + [\text{In}_2\text{O}_{[3-(x+y)]} + (x+y)V_\text{O}]^2 \quad [4]$$

If ITO has considerably high oxygen deficiency to begin with, even a small amount of oxygen deficiency can cause the ITO to turn black. Thus it is imperative that the ITO should have minimum possible oxygen deficiency.

Factors effecting the reduction.—It can be shown that the reaction is brought about by any or a combination of the following factors:

Chamber pressure.—It was shown earlier that in order to obtain the highest possible film resistivity the optimum oxygen partial pressure during sputtering is 7-10% (7). Hence, experiments were done in this range. Chamber pressure during sputtering is another

[2] V_o = *oxygen vacancy.*



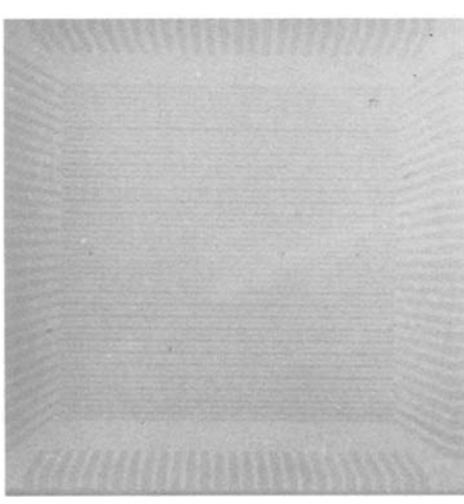


Fig. 3. Dissolution of reduced EC lines in 0.5N H_2SO_4. (a, top) Lines are totally dissolved in certain areas. (b, bottom) The light lines are affected.

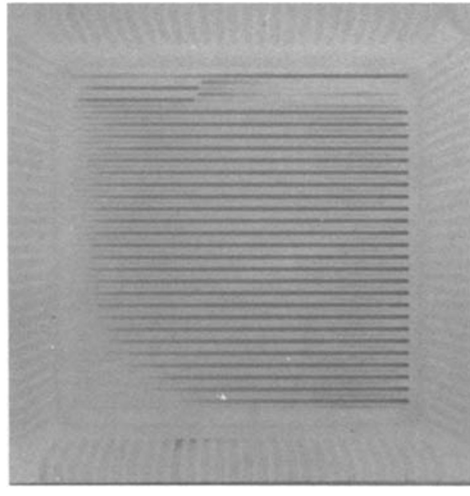

Fig. 4. Reduction of grounded lines. (Note the abrupt change about the discontinuity marked.)

important parameter. As the pressure goes up, the deposition rate falls. However, at very low chamber pressures it is extremely difficult to ensure an even distribution of oxygen over a large substrate area because the mean-free path of the gas molecules at these pressures is very large. The substrate target distance was about 10 cm. Under such circumstances the oxygen inlet design becomes critical. The gas should enter very close to the substrate, well within one mean-free path, less than 2 cm (8), from as many symmetrically placed inlets as possible. Average dissipation factor fell from 0.07 to 0.003 on bringing the gas inlet closer at 2 micron chamber pressure. A slight variation can result in an uneven distribution of oxygen over the substrate which eventually leads to the deposition of oxygen-deficient yttria, the degree of deficiency varying from point to point. Increasing the P_{O_2} did not help solve the problem. Such an oxygen-deficient yttria readily reduces the ITO beneath it, making it black. The result is shown in Fig. 2a where all the lines are black to the left half.

Resistivity of the EC coating.—The allowable electrical resistance along the conducting lines in the LEF display is determined by the driving wave form, the pulse width, and rise time. In order for the display to be efficient the line impedance should be low. High resistance would cause considerable voltage drop along these lines resulting in decreasing light output toward the end of the line. However, considering the dielectric strength of the thin film structure and hence the useful life of the display itself, a high resistance value is desired. Accordingly, the EC lines in our displays have impedances in the range of 400-800 Ω per cm.

The linewidth at 22.4 lines per cm resolution is 0.03 cm. If the starting ITO has a sheet resistance of 100 Ω/sq, the line impedance works out to be 3200 Ω per cm. Line impedance of below 800 Ω per cm can be achieved only if the EC coating has a resistance of less than 25 Ω/sq to start with. However, it was observed that with ITO of low sheet resistivity, such as 10-25 Ω/sq, the reduction effect became very pronounced. Subsequent experiments showed that annealing these low resistivity ITO films at 350°C in air for 4-6 hr prior to sputtering prevented or minimized the problem. Nevertheless, this heat-treatment raised the sheet resistivity of the films from 10 to 20 Ω/sq to 50-100, indicating that the low resistivity ITO was oxygen deficient and that a large part of its high electrical conductivity arose from the abundant oxygen vacancies rather than from the dopant.

Such an oxygen-lean ITO will get reduced further by giving up oxygen to sputter-deposited yttria which is inherently oxygen deficient due to the low P_{O_2} used during sputtering. Figure 5 shows the effect of annealing and the relevant mechanism. Up to point A,

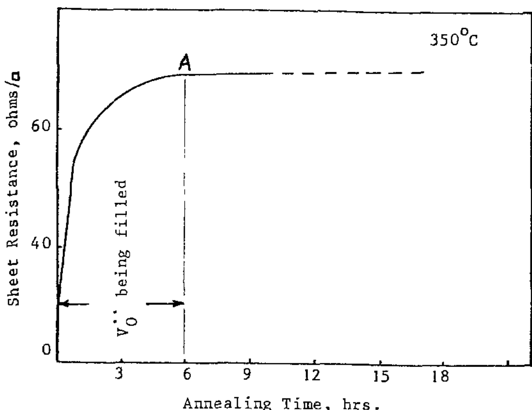

Fig. 5. Effect of air annealing on ITO films

the sheet resistance is a function of the dopant concentration $[D]$ and vacancy concentration $[V_O]$.[3] Beyond this point the resistance is essentially a function of $[D]$ and the EC film is fully oxidized.

It is thus imperative that while specifying low sheet resistance for the EC coating this property be achieved during deposition and not by subsequent vacuum annealing. This would mean a trade-off between percentage transmission and low sheet resistance, because once the dopant concentration has been fixed, as is the case with commercial glass, the sheet resistance can be brought down only by increasing the thickness of the coating.

The reduction pattern of oxygen-deficient, low resistivity ITO is similar to that from low chamber pressure. Figure 2b is an example of this. The effect would be all over the area and on all adjacent lines where the resistivity is low. If the entire surface of the glass shows a uniformly low resistance, the glass would be black all over.

Grounding the substrate.—It is necessary to provide a path from the top surface of the glass substrate to the ground during the sputtering (9) of a dielectric because the charge that builds up on the surface reduces the deposition rate, often to zero. However, care should be exercised to ensure that the glass alone is "grounded" and not the conducting lines. It was observed that grounding the conducting lines during sputtering enhanced the probability of the lines being reduced. In other words, grounding the EC lines leads to the deposition of oxygen-lean yttria along these lines. This effect is caused by the electric field. When the lines are grounded some of the O^- ions reaching the electrode surface pick up the necessary electrons from the ground (ITO) instead of combining the Y^{+++} according to the following equation

$$2Y^{+++} + 3\,O^{--} = Y_2O_3 \quad [5]$$

Effectively, two O^{--} ions pick up four electrons from the ground, along the ITO lines, and form a molecule of oxygen gas which gets pumped out of the chamber. Consequently, oxygen-deficient yttria is deposited along the grounded EC lines which reduces the lines. An example for such reduction is shown in Fig. 2c where the lines are black entirely along the length. Another interesting feature is that the two adjacent lines are not affected at all.[4] In Fig. 4, it can be observed that the blackening effect stops abruptly at a scratch across the lines. Up to this discontinuity the line is uniformly black, beyond which the line is no more connected to the ground and it is not affected at all, indicating that the effect indeed was an electric-field assisted one.

Thus, the characteristic features of reduction due to the grounded electrode are that it will be along the total length of the lines and that the adjacent lines need not be affected at all. However, if a discontinuity like a scratch exists across the line, the abrupt change described above will be observed. The alternate black lines mentioned in the section "The effect" were due to the fact that the lines from one side were grounded, while those from the other side were open.

Summary

When a strong oxide like yttria is sputter deposited on EC coatings like SnO_2 or ITO, under certain conditions these coatings can get reduced and turn black. Three factors contribute to this effect individually and collectively.

At low chamber pressures the concentration of oxygen over a large area is not uniform and this makes the yttria film oxygen deficient to varying degrees over the substrate. As a result, the EC lines get reduced,

[3] This excludes inherent initial $[V_o]$.
[4] This is because they originate on the opposite side and are not grounded.

manifested as patches of black lines. This problem can be eliminated by carefully designing the oxygen inlet. As a rule of thumb, below 4 microns chamber pressure, oxygen inlet should be as close to the substrate as possible and should ensure an even distribution of the gas over the substrate area.

Commercially available EC coatings with very low sheet resistance (below 20 Ω/sq) and high optical transmission (above 85%) are generally oxygen deficient. When some oxygen-deficient oxides are rf sputter deposited on such EC films, they get readily reduced by these oxides and turn black. Hence, it is necessary to stabilize such EC films prior to sputtering by annealing in air at 350°C for 6 hr.

Grounding the EC lines during rf sputtering leads to the deposition of oxygen-lean yttria along these lines which eventually reduces the conducting lines. Thus care should be taken not to ground these lines during sputtering.

ABSTRACT

Heteroepitaxial Ge films have been obtained by solid-phase crystallization of amorphous Ge deposited on single crystal <100>Si substrates. The Si substrates were chemically cleaned by conventional procedures without any attempt to achieve atomically clean surfaces. Epitaxial crystallization of the amorphous Ge films were accomplished by furnace annealing at temperatures of 500°-900°C. The as-crystallized Ge films contain dislocations and twins whose densities decrease with increasing annealing temperature. Significant reduction in twin density has been achieved by using an ion implantation and reannealing treatment. Epitaxial GaAs layers of good crystal quality have been grown by chemical vapor deposition on heteroepitaxial Ge films subjected to this treatment.

The growth of heteroepitaxial Ge films on crystalline Si substrates have been the subject of numerous investigations because of the many interesting electrical and optical properties of Ge-Si heterojunctions (1). Much work has been done by use of liquid-phase epitaxy such as solution growth techniques (2), as well as vapor phase epitaxy such as vacuum evaporation under UHV environment (3, 4) and chemical vapor deposition (5). Recently, considerable attention has been directed toward the preparation of epitaxial thin films by means of solid-phase crystallization of amorphous deposited layers. For example, epitaxial growth of amorphous Si films deposited on chemically cleaned <100>Si substrates has been achieved upon furnace annealing at 550°-750°C (6, 7). The solid-phase epitaxial Si layers were found to be comparable in crystal quality to the single crystal Si substrate underneath. The technique of solid-phase epitaxy

(SPE) is attractive because of the low processing temperatures required and the ability of using simple experimental apparatus.

In the present work, we investigated the formation of heteroepitaxial Ge films by solid-phase crystallization of amorphous Ge deposited on single crystal <100>Si substrates. The study was motivated by our recent development of efficient GaAs solar cells with conversion efficiencies exceeding 20% at AM1 that are fabricated on bulk single crystal substrates of Ge (8). It is expected such thin film cells could also be fabricated on crystalline Si substrates with a heteroepitaxial Ge overlayer so that the substrate cost can be markedly reduced. We found that heteroepitaxial Ge films on <100>Si can be accomplished by the SPE process. The crystal quality of the heteroepitaxial Ge films can further be improved by using an ion implantation and reannealing treatment. The preliminary results of this work have recently been reported (9). In this paper we present detailed results on the effects of preparation of Si substrate surfaces, annealing conditions, as well as Ge film thickness on the crystalline perfection of the SPE Ge films.

Experimental

Amorphous Ge films 1000-3000Å thick were deposited by electron beam evaporation of high purity Ge (99.999% pure) on single crystal <100>Si substrates. Prior to use the Si wafers were degreased in organic solvents, immersed in a 5 H_2O:NH_4OH:H_2O_2 solution for 10 min, rinsed in DI water, and then immersed in a 6 H_2O:HCl:H_2O_2 solution for 10 min. A final rinse in dilute HF (~10%) was employed immediately before loading in the liquid-nitrogen trapped oil-diffusion-pumped vacuum system. The background pressure was 3×10^{-7} Torr before evaporation and increased to 8×10^{-7} Torr during evaporation. The average deposition rate was about 8 Å/sec. The substrates were not intentionally heated or cooled during deposition.

The Ge/Si<100> samples were heat-treated in a quartz-tube furnace with flowing forming gas (Ar/H_2) ambient. In each experiment annealing was carried out for 20 min (including the heating period of ~2-3 min) at a constant temperature in the 400°-900°C range at a 100°C increment. Isothermal annealing was performed on a few samples at 400°C up to 120 min. The composition and structure of the annealed samples were analyzed by $^4He^+$ ion backscattering, Auger spectroscopy, x-ray diffraction, reflection high energy electron diffraction (RHEED), and transmission electron microscopy (TEM).

Results and Discussion

X-ray and electron diffraction measurements showed that the films annealed at temperatures at or above 500°C were single crystalline, while the films annealed at 400°C still contained amorphous materials at the film surfaces. Figure 1 is the (011) RHEED pattern of a typical SPE Ge film, 2000Å thick, annealed at 700°C; similar patterns were obtained for samples annealed at temperatures between 500° and 900°C. The pattern contains strong matrix spots streaked along the (011) azimuth direction, indicating that the film is epitaxial and has a rather smooth surface. Additional weak satellite spots are present due to {111} twinned regions of the crystal. Faint traces of polycrystalline rings were occasionally detected for the 3000Å thick Ge films, but most of the thinner films did not give polycrystalline reflections. For samples annealed at 400°C, RHEED measurements showed amorphous diffraction patterns over the entire surfaces of the Ge films.

The RHEED patterns were generated by diffraction from a region estimated to be a few hundred angstroms in depth. In contrast with the RHEED data, the x-ray patterns for the heat-treated samples were generated by diffraction from a mean depth of several

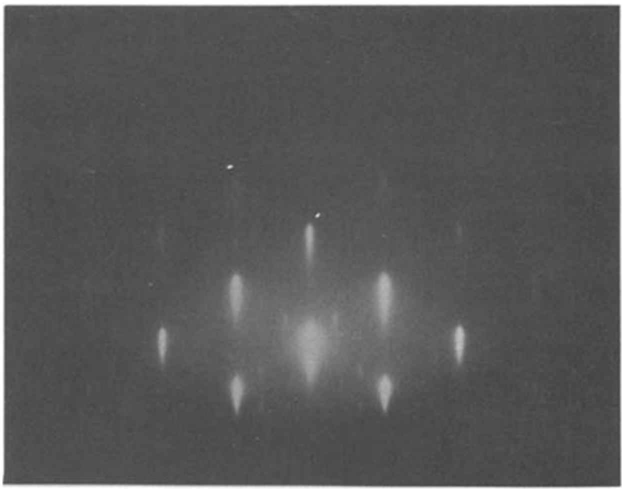

Fig. 1. RHEED pattern for a heteroepitaxial Ge film obtained by solid-phase crystallization of an amorphous Ge film deposited on a <100>Si single crystal substrate. The annealing was carried out at 700°C for 20 min in a quartz-tube furnace with a flowing Ar/H_2 ambient.

micrometers, so that these patterns contain peaks due to the Si substrate. The (400) diffraction peak intensities for the epitaxial Ge films and those for the single crystal Si substrates have been measured. Figure 2 shows a plot of the ratio of the measured (400) peak intensities for 1000Å thick SPE Ge films *vs.* annealing temperature. As can be seen in the figure, the ratio increases markedly as temperature increases from 400° to 500°C, which then increases gradually, reaching a maximum at 800°C and falls off at 900°C. The presence of Ge crystalline diffraction peaks for samples after annealing at 400°C for 20 min indicates that epitaxial crystallization already occurs at this temperature. However, the crystallization front advancing from the Ge-Si interface has not reached the film surface during the 20 min annealing period so that the film remains amorphous near surface regions as revealed by RHEED measurements. For samples annealed at 400°C for 30 min, a mixture of single crystalline and amorphous diffraction patterns was detected by RHEED measurements. Each pattern was found on different locations of the sample, indicating that the Ge film was partially crystallized in the form of localized epitaxial islands. Increasing the annealing time leads to successive lateral growth of the epitaxial islands and a uniform epitaxial Ge film is obtained after 60 min of annealing. This growth mechanism is

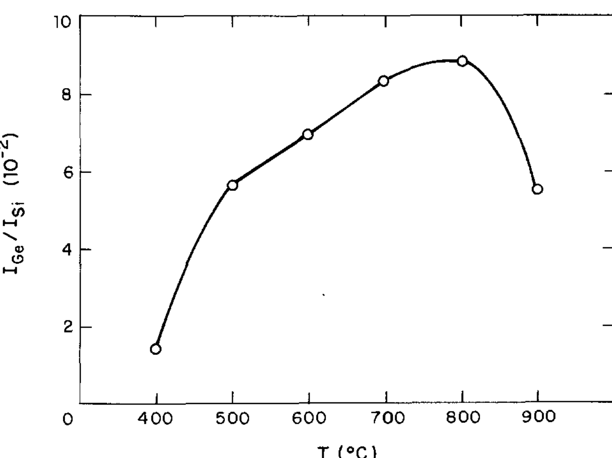

Fig. 2. Ratio of (400) diffraction peak intensities for heteroepitaxial Ge films and those for single crystal Si substrates as a function of annealing temperature.

similar to that recently observed in the epitaxial growth of amorphous Si films deposited on <100>Si (6).

The decrease in diffraction peak intensity for Ge films annealed at 900°C (Fig. 2) is intriguing. Examination of film surfaces under an optical microscope showed that the films annealed at or below 800°C were mirror smooth, while the films annealed at 900°C were somewhat milky, indicating surface oxidation or contamination during the annealing. Rutherford backscattering measurements showed a significant interdiffusion between Ge and Si for samples annealed at 900°C. Figure 3 is the 2 MeV $^4He^+$ ion backscattering spectrum of such a sample. The arrows marked in the figure are surface signals due to Ge (channel number ~ 290) and Si (channel number ~ 200). An appreciable amount of Si is observed near the surface region with a peak concentration of approximately 20 atomic percent (a/o) at the surface. Trace Ge, less than 0.4 a/o in concentration, is detected between channels 200 and 250, which is attributed to in-diffusion of Ge into the Si substrate. These results indicate that interdiffusion between Ge and Si is not symmetrical and the process is dominated by outdiffusion of Si toward the surface. Outdiffusion of Si through thin deposited metal overlayers at low temperatures has previously been observed (10). The reaction was attributed to grain-boundary diffusion of Si through the metal film as well as formation of Si oxides on the film surfaces especially in an annealing ambient containing water vapor (10). The solid-phase interdiffusion observed in the present case may be due to a similar cause since our Ar/H_2 annealing ambient may contain some water vapor or oxygen and fast outdiffusion of Si could take place via structural defects contained in the Ge layers. The observation that the Si concentration near the film surface is higher than that in the Ge film (Fig. 3) suggests such a reaction, otherwise a normal diffusion profile (such as an error function) will be expected. The interdiffusion between Ge and Si may explain (in part) the decrease of Ge (400) diffraction peak intensity for samples annealed at 900°C as shown in Fig. 2.

Samples annealed at temperatures between 400° and 800°C have also been examined by backscattering measurements. No broadening of Ge-Si interface was observed for those samples yet faint traces of Si signals were detected on the film surfaces for samples annealed at 700° and 800°C. Figure 4 shows the backscattering spectrum of a sample annealed at 700°C. As can be seen in the spectrum, the Si surface signals (near channel 200) are slightly above the noise level. Again, we attribute outdiffusion of Si (or accumulation of Si on the film surface) to formation of Si oxides on the surface. It should be noted that solid-phase interdiffusion between Ge and Si at this temperature (~700°C) is negligible because of the small diffusion coefficient (11). The outdiffusion of Si is, therefore, presumably defect enhanced and the most probable defects are twin boundaries because twins are the predominant defects observed in the SPE Ge films.

X-ray diffraction analyses have been carried out to obtain a quantitative estimate of the microtwin density. The experiments were carried out in a standard diffractometer with a motor-driven goniometer allowing sample rotation along three perpendicular axes. Details of experimental procedures have been described previously (12). Briefly, the (311) peak intensity for the epitaxial regions of the film was first measured and the sample was tilted by 20°C toward a {111} plane to maximize the (311) peak for the twinned regions. The ratio of the (311) peak intensities for the twinned and epitaxial regions, which we call the twin index (TI), is a measure of the microtwin density. Our detection limit for TI is about 2×10^{-4}, corresponding to a value of about 6×10^{-4} for the volume fraction of twins. In Fig. 5 the TI values for a

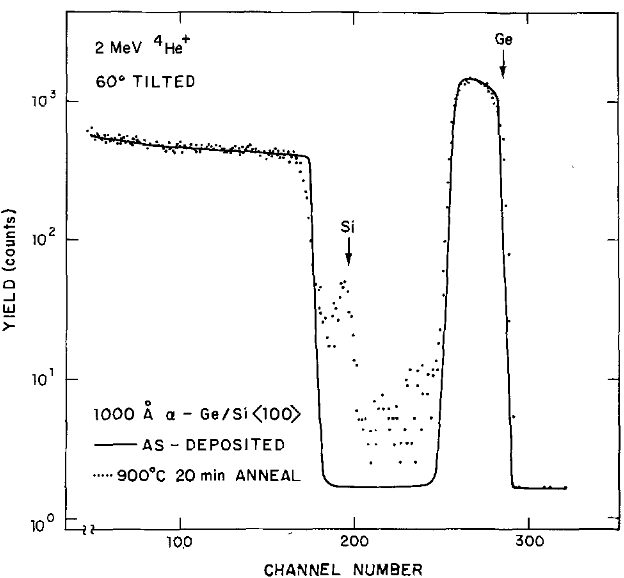

Fig. 3. $^4He^+$ ion backscattering spectra for a Ge/Si<100> sample before and after annealing at 900°C for 20 min. Significant interdiffusion between Ge and Si occurs during annealing.

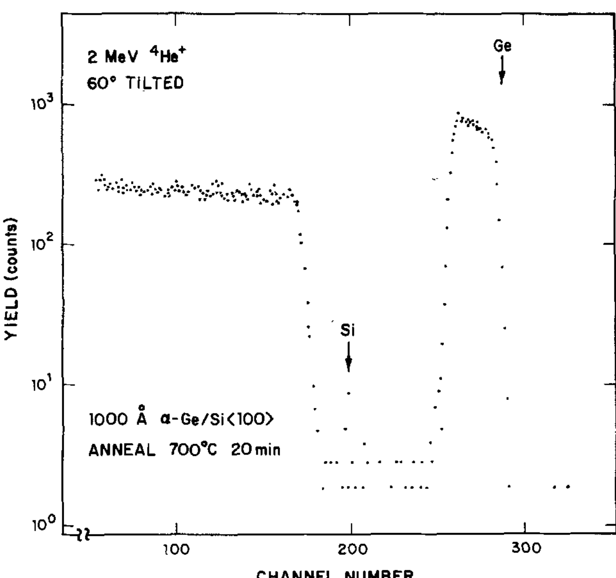

Fig. 4. $^4He^+$ ion backscattering spectrum for a Ge/Si<100> sample after annealing at 700°C for 20 min. Trace Si is detected on the surface of Ge film.

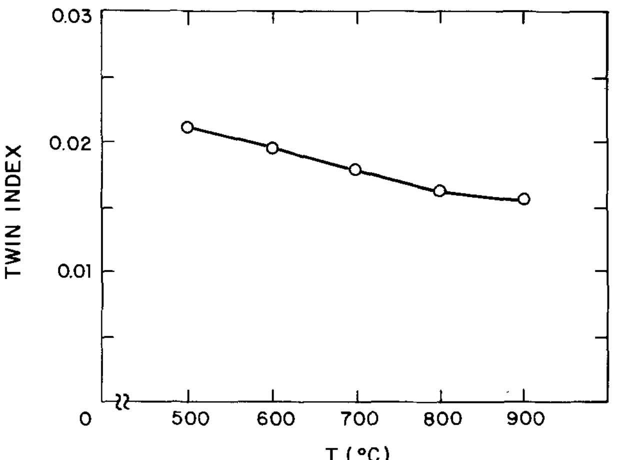

Fig. 5. Twin index (TI) for five SPE Ge films as a function of annealing temperature.

number of SPE Ge films are plotted against annealing temperature. The TI values decrease gradually with increasing temperature. This result is consistent with the gradual increase of (400) diffraction peak intensities with temperature (in the range of 500°-800°C) for epitaxial Ge films as shown in Fig. 2, except for samples annealed at 900°C where interdiffusion between Ge and Si results in a decrease of Ge (400) peak intensity.

Our results demonstrate that epitaxial growth of Ge on Si can be accomplished by solid-phase crystallization in spite of the large lattice mismatch (4%) between the two materials. Marked contamination either at the Ge-Si interface or within the Ge film would be expected to lead to random nucleation in the amorphous Ge films and therefore to extensive polycrystallinity (13). The success of epitaxial growth indicates that electron beam deposition of Ge did not introduce such contamination. This has been confirmed by Auger spectroscopic analysis of both as-deposited and annealed samples. Figure 6 shows the Auger electron spectra obtained from an annealed Ge film (at 700°C) before [Fig. 6(a)] and after [Fig. 6(b)] argon sputter etching. Oxygen and carbon are detected on the surface of annealed films [Fig. 6(a)]. Traces of Si signals due to the KLL transition near 1600 eV and LMM transition near 90 eV (which overlaps with the Ge MNN transition) are also detected. The Si signals were too weak for chemical state identification (*i.e.*, SiO_2 or pure Si). However, the presence of Si on the Ge film surface is consistent with the backscattering observations (Fig. 4) described above. After argon sputter etching, the Auger spectrum of Fig. 6(b) shows that the Si, O, and C signals are within the noise level, indicating their concentrations at or below ~0.1 a/o. Depth-profile measurements showed that the O and C signals were not detected at the original Ge-Si interface either.

The absence of oxygen signals at the Ge-Si interface in Auger spectroscopic analysis suggests that our surface preparations for Si have minimized the formation of native oxide which is known to occur readily in air.

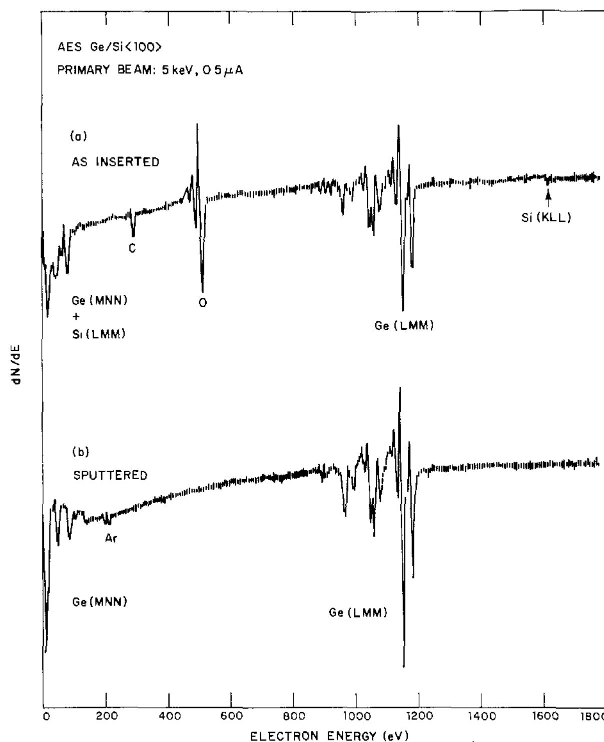

Fig. 6. Auger electron spectra for an SPE Ge film (annealed at 700°C) before (a) and after (b) argon sputter etching. Oxygen, carbon, and Si are detected on the surface of Ge film and they are absent within the detection limit after argon sputter etching.

To test the effects of native oxide on the formation of SPE Ge films, the following experiment has been carried out. After the last HF rinse, the Si substrates were deliberately exposed in air for 5-10 min before loading in the vacuum deposition system. The resulting SPE Ge films were found to contain either high densities of twins (with TI value ~ 5% or higher) or random polycrystallites. If the exposure time was increased to 30 min or more, complete polycrystallinity was obtained. Auger analysis indicated the presence of O and C at the Ge-Si interface with amounts just above the noise level for samples that underwent a 5-10 min air exposure and about 0.5-1 a/o for samples that underwent over 30 min air exposure.

As mentioned before, polycrystalline materials were occasionally observed near the surfaces of thick SPE Ge films. The formation of polycrystallites is attributed to either surface or impurity-induced random nucleation due to penetration of impurities into the Ge film from gas ambient (14). Increasing the film thickness increases the probability of polycrystalline formation since random nucleation may occur before ordered transformation is completed by the crystallization front advancing from the film-substrate interface.

We have significantly improved the crystal quality of SPE Ge films on Si substrates by employing a technique suggested by the fact that solid-phase homoepitaxy of Ge (15) and Si (7, 16) has been used to convert amorphous layers to high quality crystalline materials. Following the initial SPE anneal (700°C, 20 min), the Ge film was implanted at liquid nitrogen (LN_2) temperature with Ga^+ ions, using an ion energy and dose selected to produce an amorphous upper layer about 2/3 the total thickness of the film. For example, a layer about 1200Å thick was produced in a film 2000Å thick by implantation with a dose of 1×10^{14} cm^{-2} 180 keV Ga^+ ions in a nonchanneling direction (7° from normal incidence). The p-type Ga ions were used to ensure good ohmic contacts between Ge and GaAs because the presence of Ga is expected to overdope any As (an n-type dopant in Ge) that may diffuse into the Ge during subsequent growth of GaAs layers (8). The Ge/Si sample was then reannealed at 700°C for 15 min, causing the amorphous upper layer of the Ge film to recrystallize by solid-phase homoepitaxy, which was seeded by the lower region of the film that had not been damaged by ion implantation. After reannealing the film surface was as smooth as it had been after the initial annealing.

Figure 7 is the RHEED pattern obtained for an SPE Ge film after ion implantation and reannealing. In comparison with the pattern of Fig. 1 for another portion of the same film subjected only to the initial SPE

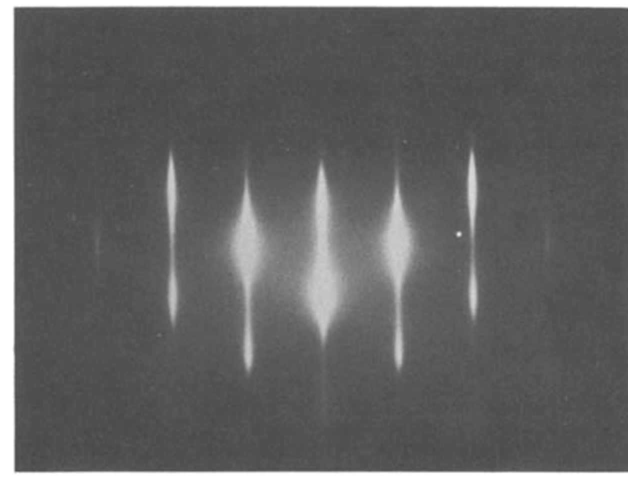

Fig. 7. RHEED pattern for an SPE Ge film after implantation with 180-keV 1×10^{14} cm^{-2} of Ga^+ ions and reannealing at 700°C for 15 min.

anneal, the principal diffraction spots are sharper and more elongated, the spots due to (111) twins have disappeared, and the Kikuchi lines are stronger. All these features are evidence for a marked improvement in crystal quality at the surface due to implantation-reannealing treatment. The improvement has been confirmed by TEM observations. Figure 8 shows the cross-sectional TEM micrograph for an SPE Ge film, 2000Å thick, before [Fig. 8(a)] and after [Fig. 8(b)] the implantation-reannealing treatment. {111} primary and secondary twins are present throughout the Ge film after the initial SPE annealing [Fig. 8(a)]. After the implantation-reannealing treatment, the twin density reduces markedly especially in the near-surface region of the film as shown in Fig. 8(b). The TI value for this sample was measured to be 0.004, about a factor of 4 smaller than that (0.016) of this sample before the treatment. Both micrographs show sharp Ge-Si interfaces as expected for the solid-phase crystallization process.

The improvement in crystal quality has also been confirmed by the results of channeling experiments with 1.0 MeV $^4He^+$ ions. Figure 9 shows the channeling spectra for a 2000Å thick Ge film on <100>Si after the initial SPE anneal [Fig. 9(a)] and after implantation and reannealing treatment [Fig. 9(b)]. Figure 9(b) also shows the spectrum for a polished <100>Ge single crystal wafer. The implantation-reannealing treatment results in a decrease of minimum surface yield for the SPE film from 18% in Fig. 9(a) to 4.5% in Fig. 9(b). After the treatment the spectrum for the near-surface region of the film is almost the same as that for the Ge single crystal wafer, indicating that this region of the film is comparable in crystal quality to the bulk crystal. Note that the aligned yield near the interfacial region is much higher than that of single crystal Ge because of the presence of twins and a high concentration of dislocations near this region. Figures 10(a) and 10(b) show the planar bright-field and

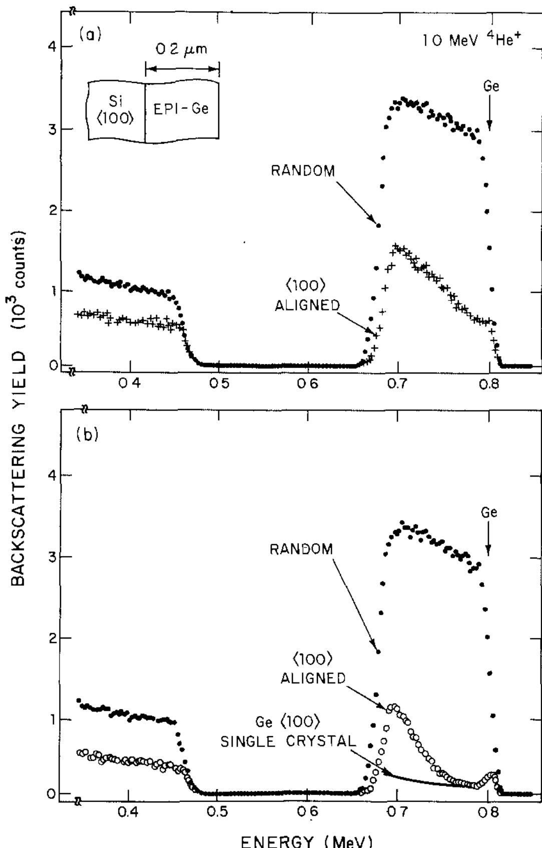

Fig. 9. $^4He^-$ ion channeling spectra for an SPE-Ge/Si<100> sample. (a) After initial annealing. (b) After subsequent implantation and reannealing treatment. The TEM micrographs of the sample are shown in Fig. 8a and b, respectively.

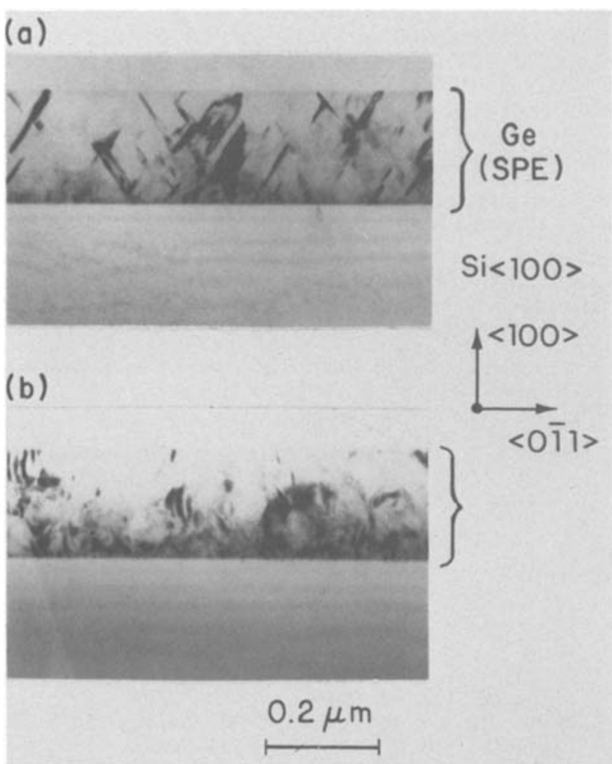

Fig. 8. Cross-sectional TEM micrographs for an SPE Ge film on <100>Si. (a) After initial annealing at 700°C for 20 min. (b) After subsequent implantation of Ga^+ ions and reannealing at 700°C for 15 min. Significant reduction in twin density in the surface region of Ge film is observed after the implantation-reannealing treatment.

weak-beam dark-field TEM micrographs, respectively, for such dislocations. Similar results were obtained for SPE Ge films without the implantation-reannealing treatment. The dislocations are presumably misfit type. They are formed during the growth of heteroepitaxial Ge films to release the interfacial misfit strain originating from the large lattice mismatch (~4%) between Ge and Si. The dislocation density is estimated to be of the order of 10^{10}-10^{11} cm^{-2} from Fig. 10. Extensive interactions between dislocations are observed, which result in climbing and propagation of dislocations toward the film surface as inclined dislocations. TEM observations on thinner portions (near-surface regions) of the Ge films indicated that the density of inclined dislocations was in the range of 10^8-10^9 cm^{-2}, about two to three orders of magnitude lower than that of misfit dislocations near the interface. No significant reduction in dislocation density was observed in Ge films after the implantation-reannealing treatment.

As an initial step in determining the usefulness of SPE Ge films as substrates for the growth of GaAs, undoped GaAs epitaxial layers about 2 μm thick were grown by chemical vapor deposition (CVD) on the SPE Ge films. Details of the deposition procedure, which employs the $AsCl_3$-GaAs-H_2 method, have been described elsewhere (8). The GaAs layers were found to be comparable, and in most cases superior, in crystal quality to the underlying Ge films. Figure 11 shows the 1.0 MeV $^4He^+$ channeling spectrum of a GaAs layer grown on a Ge film that had been subjected to the implantation-reannealing treatment. The minimum surface yield is only 4% indistinguishable within the experimental uncertainty from that of a polished GaAs single crystal. Separate surface peaks due to Ga and As can be distinguished in the aligned spectrum near 0.8 MeV, indicating good crystal quality. For GaAs layers grown on single-step annealed Ge films, the

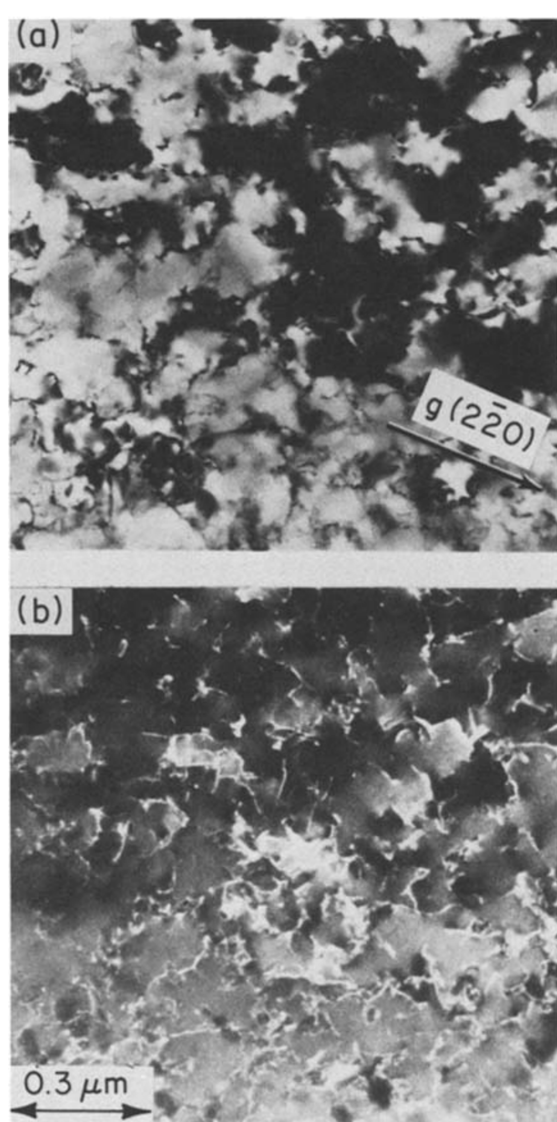

Fig. 10. TEM micrographs of (a) bright-field image and (b) dark-field image under a weak-beam ($g = 2\bar{2}0, 3g$) diffraction condition for an SPE Ge film showing the misfit dislocations near the interfacial region.

crystal quality was found to be inferior to that of layers grown on implanted and reannealed Ge films.

Summary

In conclusion, solid-phase epitaxial crystallization of amorphous Ge films deposited on <100>Si has been achieved upon thermal annealing at temperatures of 500°-900°C. The Si substrates were chemically cleaned by conventional procedures without any attempt to achieve atomically clean surfaces. By minimizing the exposure time of Si substrates after the predeposition chemical etching, the native oxides on the Si surfaces were reduced to a level so that epitaxial crystallization of the amorphous Ge can be achieved by low temperature annealing. Increasing the exposure time increases the probability of native oxide formation which leads to the formation of highly defected epilayers or polycrystalline films.

Structural characterization showed that the SPE Ge films contained dislocations and twins. Significant reduction in twin density has been achieved by implanting the SPE Ge film with 180-keV 1×10^{14} Ga^+ ions/cm^2 at LN_2 temperature to produce an amorphous Ge upper layer and then recrystallizing the layer by annealing at 700°C for 15 min. Epitaxial GaAs layers of good crystal quality have been grown by CVD on SPE films subjected to this treatment. On the basis of this result, it appears highly probable that GaAs layers suitable for the fabrication of high efficiency thin film solar cells can be grown on SPE-Ge/Si substrates.

Evaporation of High Quality In_2O_3 Films from In_2O_3/In Source—Evaporation Chemistry and Thermodynamics

C. A. Pan and T. P. Ma

Department of Engineering and Applied Science, Yale University, New Haven, Connecticut 06520

ABSTRACT

Highly transparent conductive In_2O_3 films can be easily deposited by simple thermal evaporation from an In_2O_3/In source in a low pressure O_2 environment. The important role of In in the evaporation process has been examined. From an analysis of the evaporation chemistry and the thermodynamics of the system, it has been concluded that the incorporation of In in the evaporation source not only significantly enhances the evaporation rate, but also gives rise to a higher concentration of conduction electrons. Many possible reactions in the source region and on the substrate have been considered, and only a few have been found to be of significance, which greatly simplifies the theory. Good qualitative agreement has been found between the theory and several key experimental observations. The theory has also been verified by quantitative comparisons with the experimentally measured film growth rate and the conduction electron concentration.

Optically transparent, electrically conducting films of In_2O_3 are useful in a variety of applications. The most commonly used preparation techniques include sputtering (1-6) and chemical spray deposition (7-9). In two recent publications (10, 11), we showed that high quality polycrystalline In_2O_3 films could be readily produced by a simple thermal evaporation technique. Resistivity of 2×10^{-4} Ω-cm and optical transmission of 90% in the visible range are typically observed.

The observed optical transparency arises from the relatively wide direct and indirect bandgaps of In_2O_3, which have been measured to be 3.56 and 2.69 eV, respectively (10). Its high conduction electron concentration ($\geq 4 \times 10^{20}/cm^3$) is believed to result from the interstitial In atoms (10, 12, 13) or oxygen vacancies (14) in the In_2O_3 structure, which act as shallow donor levels.

As we reported previously (10, 11) the key to the success of this simple evaporation process is the use of a combination In_2O_3/In (approximately 90%:10% by weight) as the source material. Other relevant processing parameters will be described in the next section. It has been found that the incorporation of the metallic In in the evaporation source results in two significant effects. These are (*i*) a substantial increase of the evaporation rate at the operating temperatures, and (*ii*) a significant improvement of the film conductivity.

In this paper, the role of In in the present evaporation process is examined. It will be shown that, based on simple evaporation chemistry and thermodynamics, our experimental results can be explained qualitatively as well as quantitatively.

Key words: evaporation rate, In_2O, electron concentration, excess In, vapor transport.

Evaporation Parameters

The evaporation is done in a diffusion-pump vacuum system with a resistance-heated source. As shown in Fig. 1, the evaporation boat consists of an alumina crucible heated by a tungsten heater. A pack of In_2O_3 powder on top of a pack of metallic In (approximately 90% In_2O_3:10% In by weight) is used as the source material. The substrate is a microscope cover glass slide, and a substrate heater maintains a temperature range from 320° to 350°C during evaporation.

Initially, the vacuum chamber is evacuated to a base pressure in the 10^{-6} Torr range. Pure O_2 is then admitted to the chamber. With the high vacuum remaining open a steady-state chamber pressure ranging from 5×10^{-5} Torr to 2×10^{-4} Torr is rapidly reached and regulated by adjusting the O_2 needle valve. The evaporation rate, monitored by a crystal oscillator, is primarily controlled by the source temperature. Typical source temperature ranges from 800° to 900°C, providing a deposition rate of 20-40 Å/min on the thickness monitor, which is 29 cm above the source. The sheet resistance of the film is also monitored continuously during the evaporation.

The temperatures of the crucible wall and the In_2O_3 powder can be measured by two separate thermocouples, which are used to establish the temperature dependence of the evaporation rate. In a normal run, however, the thermocouples are removed from the source region to minimize the possible contamination sources.

Evaporation Chemistry and Thermodynamics of the System

Figure 2 shows the sheet resistance as a function of thickness during the growth of the In_2O_3 film. It can

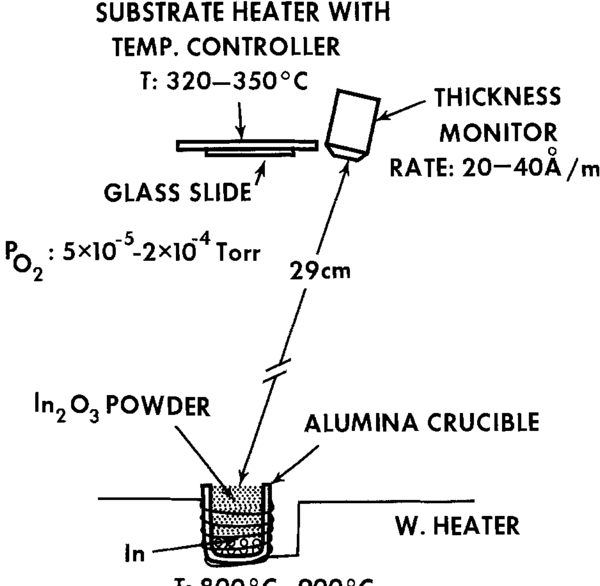

Fig. 1. Source, substrate, and thickness monitor arrangement in the evaporation chamber. Typical evaporation parameters are indicated.

be seen that a sheet resistance of 6.75 Ω/□ is reached at a film thickness of 2700Å, corresponding to an average resistivity of 1.8×10^{-4} Ω-cm. From the Hall effect measurement, an average free electron concentration of 4.69×10^{20} cm^{-3} and a Hall mobility of 74 cm/Vsec have been determined for this film.

Since no dopant impurity has been introduced into the film, the conduction electrons are believed to arise from the excess In atoms or oxygen vacancies in the structure which act as shallow donor levels (12-14). Assuming each excess In atom gives rise to one donor level, which in turn gives rise to one conduction electron at room temperature, one expects a concentration of 4.69×10^{20}/cm^3 for the excess In. Within the accuracy of the given assumption and the experimental uncertainty, a successful theory should therefore be able to predict this result. The enhancement of the evaporation rate due to the presence of In in the evaporation source is another important observation, which should also be contained in the theory.

In the subsequent analysis of the evaporation process, the relevant processing parameters for the film shown in Fig. 2 will be used, which are: (*i*) Film growth rate = 33 Å/min, (*ii*) O_2 pressure = 1×10^{-4} Torr, (*iii*) crucible temperature = 860°C (1133 K), and (*iv*) substrate temperature = 340°C (613 K).

Reactions in the source region.—At a source temperature of 1133 K, a number of reactions involving In_2O_3, In, and O_2 in the source region may be possible, which are listed below

$$\text{In (l)} \rightarrow \text{In (g)};\ \Delta G_1° = 29 \pm 0.5 \text{ kcal} \quad [1]$$

$$2\text{In (l)} + 1/2\, O_2 \text{ (g)} \rightarrow In_2O \text{ (g)};\quad \Delta G_2° = -22 \pm 1.4 \text{ kcal} \quad [2]$$

$$2\text{In (l)} + 3/2\, O_2 \text{ (g)} \rightarrow In_2O_3 \text{ (s)};\quad \Delta G_3° = -133 \pm 0.45 \text{ kcal} \quad [3]$$

$$\text{In (l)} + 1/2\, O_2 \text{ (g)} \rightarrow \text{InO (s)} \quad [4]$$

$$In_2O_3 \text{ (s)} \rightarrow In_2O \text{ (g)} + O_2 \text{ (g)};\ \Delta G_5° = 111 \pm 1.47 \text{ kcal} \quad [5]$$

$$4\text{In (l)} + In_2O_3 \text{ (s)} \rightarrow 3In_2O \text{ (g)};\quad \Delta G_6° = 67.3 \pm 4.2 \text{ kcal} \quad [6]$$

Because of the low melting point of In (430 K at 1 atm), and the low boiling point of In_2O (800 K at 1 atm), In does not exist in the solid phase in the crucible, and In_2O is in its vapor phase. It should also be noted that no gas phase of In_2O_3 has been found in the thermal decomposition experiment performed by Burns *et al.* (15), and the thermal evaporation of In_2O_3 involves gas phase transport of In_2O, In, and O_2.

The free energy changes, $\Delta G°$ in the above equations, have been calculated based on published data and laws of thermodynamics, which are summarized below

$$\Delta G_1° (T) = 58{,}840 + 3.2T \log T - 35.82T \pm 500 \text{ cal/mol} \quad \text{(Ref. 16, 17)} \quad [7]$$

$$\Delta G_2° (T) = -5000 - 15T \pm 1400 \text{ cal/mol} \quad \text{(Ref. 17, 18)} \quad [8]$$

$$\Delta G_3° (T) = -215{,}550 + 72.63T \pm 450 \text{ cal/mol} \quad \text{(Ref. 17, 18)} \quad [9]$$

$$\Delta G_5° (T) = \Delta G_2° - \Delta G_3° = 210{,}550 - 87.63T \pm 1950 \quad \text{(From Eq. [2], [3], [5])} \quad [10]$$

$$\Delta G_6° (T) = 3\Delta G_2° (T) - \Delta G_3° (T) \quad \text{(From Eq. [2], [3], [6])} \quad [11]$$

$$= 200{,}550 - 117.63T \pm 4.2 \text{ kcal}$$

The reactions [2]-[4] all involve the oxidation of In, and they can be neglected because of the very limited supply of O_2 in the crucible. The O_2 partial pressure in the chamber is rather low (1×10^{-4} Torr) to begin with, and it is expected to be even much lower near the opening of the crucible due to the rapid evaporation of In_2O (see subsequent discussions), which pumps the O_2 away from the source.

Reaction [5] is the thermal decomposition of In_2O_3. From the value of the free energy change associated with this reaction, $\Delta G_5° = 111$ kcal, the partial pressure of In_2O has been calculated to be below 10^{-9} Torr, suggesting that this reaction can also be neglected. It should be mentioned that Burns *et al.* (15) have measured the vapor species over In_2O_3 at elevated temperatures, and they reported a partial pressure of In_2O below 10^{-8} atm at 1200 K, a result consistent with our calculation. This explains why the evaporation rate from the In_2O_3 source (without the presence of In) is negligibly small at a source temperature of 860°C, as we have observed experimentally.

Therefore, only reactions [1] and [6] need to be considered in the source region for our experiment, which are rewritten as

$$\text{In (l)} \rightarrow \text{(g)};\ \Delta G_1° = 29 \text{ kcal} \quad [1]$$

$$4In\ (l) + In_2O_3\ (s) \rightarrow 3In_2O\ (g);\ \Delta G_6^\circ = 67.3\ \text{kcal} \quad [6]$$

From these two reactions, the equilibrium partial pressure of In and In_2O can be expressed as

$$P\ (In) = \exp\ [-\ \Delta G_1^\circ\ (T)/RT] \quad [12]$$

and

$$[P(In_2O)]^3 = \exp\ [-\ \Delta G_6^\circ\ (T)/RT] \quad [13]$$

At the operating temperature, the numerical values of the partial pressure are

$$P(In) = 2.2 \times 10^{-6}\ \text{atm} = 1.67 \times 10^{-3}\ \text{Torr} \quad [14]$$

and

$$P(In_2O) = 4.7 \times 10^{-5}\ \text{atm} = 3.6 \times 10^{-2}\ \text{Torr} \quad [15]$$

In summary, the only two significant vapor species evaporating from the source are In and In_2O, with their respective partial pressures given by [14] and [15]. Thus, the simple theory presented above suggests that the incorporation of the metallic In in the evaporation source should result in several orders of magnitude increase in the evaporation rate. Comparing [14] with [15], it is apparent that the dominating evaporating component is In_2O, and In vapor constitutes approximately 4.6% of the total.

Since our x-ray diffraction analysis indicates that the deposited films are polycrystalline In_2O_3 (10, 11) some chemical reactions must be taking place during the evaporation process, which convert In_2O into In_2O_3. This process is considered next.

Reactions on the substrate.—The chamber pressure is maintained at 1×10^{-4} Torr (primarily O_2) during evaporation, which corresponds to a mean-free path of 50 cm and is longer than the source-substrate distance. Therefore, reactions with O_2 in the vacuum chamber can be neglected except at the substrate, which is held at 340°C (610 K).

The possible reactions on the substrate are listed below

$$In_2O\ (l) + O_2\ (g) \rightarrow In_2O_3\ (s);\ \Delta G^\circ = -163.1\ \text{kcal} \quad [16]$$

$$4In\ (l) + O_2\ (g) \rightarrow 2In_2O\ (l);\ \Delta G^\circ = -15.7\ \text{kcal} \quad [17]$$

$$4In\ (l) + 3\ O_2\ (g) \rightarrow 2In_2O_3\ (s);\ \Delta G^\circ = -342\ \text{kcal} \quad [18]$$

$$2In\ (l) + O_2\ (g) \rightarrow 2InO\ (s);\ \Delta G^\circ = 64\ \text{kcal} \quad [19]$$

Note that both In and In_2O are in the liquid phase on the substrate due to their low melting points. Equations [7]-[11] have been used again to obtain the free energy changes in the above equations.

Reaction [16] is the dominant reaction because In_2O is the major evaporating species. Our x-ray diffraction data indicate that the film structure is polycrystalline In_2O_3, which is also consistent with the outcome of reaction [16].

Equations [17]-[19] all involve the reactions between In and O_2, which may be neglected based on probabilistic considerations. Because of the low evaporation rate of In, and the low In/In_2O_3 ratio arriving at the substrate, it is highly unlikely that two or more In atoms could be tightly distributed spatially to react with O_2 in a relatively short period of time.

Thus, the primary reaction taking place on the substrate is the conversion of In_2O into In_2O_3, according to [16]. The condensation of In_2O on the substrate in its liquid phase may be responsible for the formation of the crystalline phase of In_2O_3. A small amount of In atoms, however, is incorporated in the film during growth, which gives rise to the conduction electrons. The exact chemical state of the excess In is not clear at the present time. Whether the In atoms indeed occupy the interstitial sites, or form some complexes with the host In_2O_3, remains to be studied.

Comparison Between Theory and Experiment

In the previous section, we have shown that the theory is in qualitative agreement with our experimental observations. We shall now make a quantitative comparison based on two important experimental observables: (*i*) the film growth rate, and (*ii*) the conduction electron concentration.

Film growth rate.—The theoretical growth rate of the In_2O_3 can be calculated given the partial pressures of In_2O and In at the source and the known source-substrate distance. The calculation is as follows.

The average thermal velocity of In_2O at the source temperature ($T = 1133$ K) is

$$\overline{V} = \sqrt{\frac{8kT}{\pi m}} = 1.6\sqrt{\frac{kT}{m}} = 3.13 \times 10^4\ \text{cm/sec} \quad [20]$$

The rate of transported molecules across the effective source surface area A is [see Fig. 3(a)]

$$\frac{dQ}{dt} = A \int f(v)\ dv^3\ |\vec{n} \cdot \vec{v}| \quad [21]$$

where $f(v)$ is the molecular speed distribution function, $f(v)\ dv^3$ is the average number of molecules per unit volume that has a velocity between v and $v + dv$, and n is the outgoing unit vector normal to the surface A.

Evaluating the integral in the upper half of the velocity space

$$\frac{dQ}{dt} = A \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi/2} \int_{v=0}^{\infty} f(v) v^3 \cos\theta \sin\theta\ d\phi\ d\theta\ dv$$

$$= A\pi \int_0^\infty v^3 f(v) dv \quad [22]$$

On the other hand

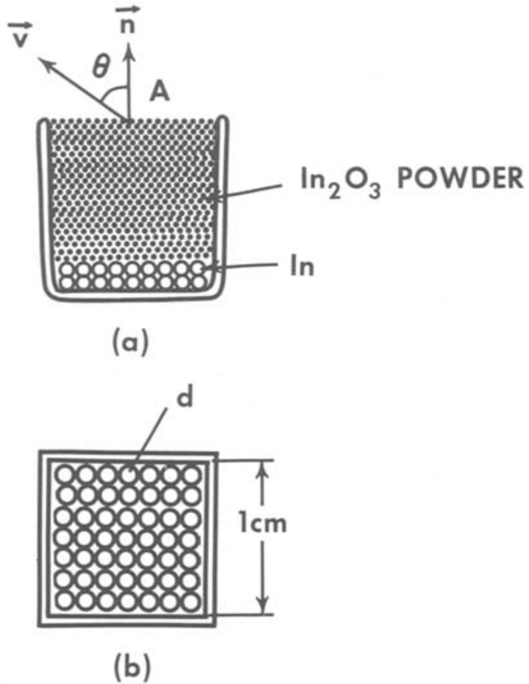

Fig. 3 (a) Schematic of the crucible showing the velocity vector of the vapor particle $\vec{v}$, surface normal vector $\vec{n}$, and the angle parameter θ. A is the effective area of the source surface for gas transport, which is the integrated cross-sectional gaps at the surface between the In_2O_3 particles. (b) Schematic top view of a box containing tightly packed spherical particles of diameter d. This is used to calculate the effective area for gas transport.

$$\bar{v} \equiv \frac{1}{N} \int v f(v) dv^3$$

$$= \frac{1}{N} \int_{\phi}^{\pi} \int_{0}^{2\pi} \sin\theta \, d\theta \, d\phi \int_{0}^{\infty} v^3 f(v) \, dv$$

$$= \frac{4\pi}{N} \int_{0}^{\infty} v^3 f(v) \, dv \quad [23]$$

where N is the total number of In_2O molecules per unit volume. From [22] and [23]

$$\frac{dQ}{dt} = \frac{AN}{4} \bar{v} \quad [24]$$

where $\bar{v} = 3.13 \times 10^4$ cm/sec as given in [20], and N can be calculated from the equation

$$P = NRT \quad [25]$$

At $T = 1133$ K and $P(In_2O) = 4.7 \times 10^{-5}$ atm, $N = 5.3 \times 10^{-10}$ mol/cm^3. Substituting the values of $\bar{v}$ and N into [24]

$$\frac{dQ}{dt} = A \times 4.15 \times 10^{-6} \text{ mol/cm}^2\text{-sec}$$

$$= A \times 1.02 \times 10^{-3} \text{ g/cm}^2\text{-sec} \quad [26]$$

The evaporation rate of In_2O from the source, therefore, can be obtained once the effective source area, A, is known.

The crucible has a cross-sectional area of 1 cm^2, but because of the tight packing of the In_2O_3 powder, the effective opening for the evaporating In_2O molecules is reduced [see Fig. 3(b)]. This effective area for the evaporation process can be estimated as follows.

Suppose the In_2O_3 powder is made of spherical particles of diameter d, each giving a cross-sectional area of $\pi d^2/4$. For a 1 cm^2 cross-sectional area of the crucible, the total area covered by the particles is then $1/(d)^2 \times \pi/4 \, d^2 = 0.79$ cm^2, which is independent of the individual diameter of the particles. The effective area for the evaporation process is therefore $A = 0.21$ cm^2. From the visual examination under a microscope, the particle size in the powder is of the order $d = 10$ μm, and the calculated effective area is in reasonable agreement with the observation.

Substituting $A = 0.21$ cm^2 into [26], the evaporation rate of In_2O from the source is

$$\frac{dQ}{dt} = 2.15 \times 10^{-4} \text{ g/sec} \quad [27]$$

Since the thickness monitor is at a distance 29 cm from the source, the theoretical deposition rate for In_2O on the crystal monitor is

$$2.15 \times 10^{-4}/2\pi (29)^2 = 4.06 \times 10^{-8} \text{ g/cm}^2\text{-sec}$$

$$= 34.4 \text{ Å/min (density of } In_2O$$

$$= 7 \text{ g/cm}^3) \quad [28]$$

Following the same procedure, the theoretical deposition rate for In is calculated to be 1.7 Å/min. Therefore, the total evaporation rate on the thickness monitor is

$$34.4 + 1.7 \text{ Å/min} = 36.1 \text{ Å/min} \quad [29]$$

The agreement between this value and the one recorded by the thickness monitor (33 Å/min) is better than we expected, especially when one considers the manner in which the effective area was estimated. The result, however, does suggest that the evaporation kinetics is consistent with the assertion that Eq. [6] is the principle reaction in the source region, and that the partial pressure of In_2O at the source is of the order given in Eq. [15].

Conduction electron concentration.—It has been reported that the conduction electrons in the crystalline In_2O_3 arise from the excess In atoms. The electron concentration is therefore expected to be proportional to the concentration of excess In in the crystalline In_2O_3 structure.

From the evaporation rates obtained previously, the molar ratio between In and In_2O in the deposited film is calculated to be 0.06. This suggests an excess In concentration in the In_2O_3 film of 9×10^{20}/cm^3. This value is within a factor of two of the experimentally determined free electron concentration, 4.69×10^{20}/cm^3.

Since the vapor pressure of In is very sensitive to the temperature (see Eq. [12]), a small error in the experimentally determined crucible temperature could account for the discrepancy. It is also possible that not every excess In atom contributes to a conduction electron. A direct measurement of the In concentration using the composition profiling techniques is necessary to resolve this question, which is unavailable to us at the present time.

Conclusions

From an analysis of the evaporation chemistry and thermodynamics of the system, it has been found that the incorporation of In in the In_2O_3 evaporation source gives rise to two important effects: (*i*) A great enhancement of the evaporation rate, and (*ii*) a significant increase in the conduction electrons.

In the source region, the most important reaction involves In and In_2O_3 to form In_2O, which is the dominant vapor species evaporating from the source. On the substrate, In_2O reacts with O_2 to form In_2O_3, which is the primary end product of this evaporation process. A small amount of In (approximately 6%) is also being evaporated, which is incorporated in the growing In_2O_3 film. These excess In atoms are believed to be the source of conduction electrons.

Deep Levels Study in Float Zone Si Used for Fabrication of CCD Imagers

Department of Material Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

The development of a better understanding of the origin of defects which affect device performance requires the characterization of deep levels in Si wafers at various stages of processing. This work reports the results of deep level measurements by standard DLTS (deep level transient spectroscopy) and the newly developed DSPS (derivative surface photovoltage spectroscopy) technique on float zone p-type (10 Ωcm) Si wafers used for the fabrication of CCD imagers. The DSPS measurements revealed the presence of deep centers (in the range of 10^{11}-10^{13} cm^{-3}) around the middle of the energy gap in the as-grown and the heat-treated wafers. The effect of these deep centers on the quantum efficiency and the fixed pattern noise in CCD imagers is discussed.

One of the most challenging problems in VLSI technology is the fabrication of large area defect-free devices. This is particularly true in the case of large area CCD imagers (1 cm^2 of area or more) for TV applications (in order of 10^5 elements) where any defect locally affecting the generation or recombination current will be visible in the displayed image. In addition to being defect-free, these devices require a long lifetime for minority carriers in order to achieve a good sensitivity and a low background dark current.

Two types of unacceptable cosmetic defects, *i.e.*, localized spots or lines and striation bands, are usually observed in CCD imagers. Most of the lines and spots are caused by electrically active crystallographic defects in the silicon substrate (1-5), while "striations" in the image are generated by inhomogeneities of resistivity and concentration of recombination centers (6). It should be pointed out that the ratio of crystallographic defects, which are electrically active, to the total amount of crystallographic defects as well as striation contrast in the displayed image depends on the heat-treatment involved in CCD imager fabrication (7). Deep levels usually act as recombination centers, therefore their detection after the various stages of processing could provide useful information about mechanisms involved in decoration of crystallographic defects, striation contrast enhancement by heat-treatments, as well as lifetime degradation during processing. Improvement in our understanding of the relationship between defects present in as grown crystals, process-induced defects, and the device performance requires characterization of deep levels in as grown silicon as well as processed wafers.

The characterization of deep levels in semiconductors is most often done with deep level transient spectroscopy (DLTS) (8). This technique relies on the measurement of capacitance changes caused by thermal emission of the trapped carriers from deep states. Another technique, the newly developed derivative surface photovoltage spectroscopy (9) (DSPS) is based on the measurement of photovoltage changes caused by the photoinjection of carriers from and to deep levels under subband illumination. It should be noted that the thermal activation energy measured by DLTS provides the energy level only for the simple trapping centers as defined within the Shockley-Read recombination model. In general, the ionization of defect centers may involve absorption (emission) of phonons, lattice relaxation, excited states, and/or configurational changes which can be disclosed easier by optical studies (due to strict momentum and energy conservation rules) rather than thermal emission.

The present work reports on the results of deep level measurements by DLTS and DSPS on high quality as-grown and oxidized float zone silicon wafers used for solid-state imager fabrication. The correlation between the deep centers measured by these techniques and other material parameters influencing imager performance will be given.

Experimental Approach

2 in. diam swirls and dislocation-free float zone silicon wafers 10 Ωcm p-type (boron-doped) used for the measurements were bought from Monsanto and Wacker. The wafers were cleaved in half. Schottky diodes were made on one-half of the wafer by Ti evaporation. The second half was oxidized at 900°C in steam + HCl for 2 hr (about 2000Å oxide thickness) and MOS structures were prepared by subsequent Ti or Au evaporation. For DLTS measurements the ohmic contacts were made by alloying gold-germanium, sintering aluminum or soldering indium or tin. For DSPS measurements a second contact was usually made with silver paint and kept in the dark during the experiments. By applying different geometries (*i.e.*, by changing the distance, which photogenerated carriers had to

* Electrochemical Society Active Member.
Key words: defects, DLTS, wafers.

diffuse to the back contact) it was established that it did not influence the measured photovoltage.

The DLTS experiments were performed with a typical system using lock-in detection (8) in the temperature range of 77-320 K and the frequency range of 3-200 Hz. From the slope of the plot of the reciprocal temperature, for which peak of capacitance changes occurs, as a function of the frequency, the position of the energy levels was obtained. The interpolation of this curve to zero frequency allowed the estimation of the capture cross sections. The concentration of the deep centers was estimated from the absolute values of capacitance changes.

The photovoltage experiments were performed in the temperature range 8-300 K using light in the spectral range of 0.5-2.5 eV. The photovoltage was measured with respect to a transparent reference gold electrode, evaporated directly on a semiconductor (MS-configuration) or on an oxide layer (MOS-configuration). The photovoltage transient measurements were performed using square pulses of the incident light (with a frequency adjustable between 0.1 and 500 Hz) and the signal averager. In derivative measurements the wavelength modulation of a constant incident light was provided by a vibrating slit of a double-prism monochromator. Typically $\Delta\lambda/\lambda_0$ was of the order of 10^{-3}. The frequency of wavelength modulation was selected between 1 and 25 Hz. In order to minimize a signal to noise ratio the photovoltage signal generated by wavelength modulation was measured with a lock-in detection. Precautions were taken to eliminate the interference of spurious signals (arising, *e.g.*, from light intensity modulation). The detailed description of the experimental arrangements and the procedure was given elsewhere (10). The procedure presently employed for determination of deep level parameters can be briefly summarized as follows.

1. The low temperature subbandgap photovoltage appears when transition from or to a localized level in the depletion region is taking place. The threshold photon energy corresponds to the difference between the energy level and the conduction or the valence band.

2. The amplitude of the corresponding, low signal steady-state photovoltage, ΔV, depends on the amount of generated carriers Δp

$$\Delta V = C\Delta p \quad [1]$$

where the proportionally constant, C, can be experimentally determined. The Δp can be expressed as

$$\Delta p = I\sigma_i N_t \tau \quad \text{and} \quad \tau = \frac{1}{K_p p v_t^p} \quad [2]$$

where I is the light intensity, N_t is the trap density, σ_i is the capture cross section for photoionization, τ is the characteristic relaxation time, K_p is the capture cross section for majority carriers, $p = p_o + \Delta p$ is the majority carrier concentration, and v_t^p is the thermal velocity of a hole.

3. The transient of photovoltage V_t for illumination "on" and "off" is given by expressions

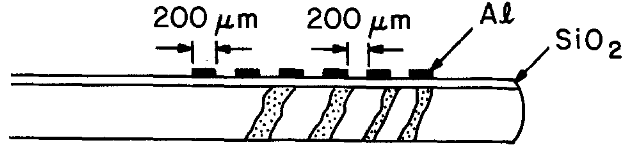
$$\Delta V_t/\text{on} = \Delta V(1 - e^{-t/\tau}) \quad \text{and} \quad \Delta V_t/\text{off} = \Delta V\, e^{-t/\tau} \quad [3]$$

where t is time.

As pointed out above, the spectral dependence of the subband photovoltage enables the determination of the energy levels of deep centers as the threshold energy for which increase in photovoltage takes place. The wavelength modulation measurements of photovoltage derivative allow the establishment of a precise location of the threshold energy and they also enhance a fine structure of photoionization transitions. The measurement of the photovoltage transient allows one to obtain τ and thus the capture cross section K_p. In order to determine the trap density, N_t, the constant C in Eq. [1] has to be estimated from the dependence of the photovoltage relaxation time on the illumination intensity. Thus, when the amount of generated carriers Δp in Eq. [2] becomes comparable with an equilibrium carrier concentration p_o, the relaxation time, τ, starts to decrease with increasing light intensity because p in Eq. [2] is no longer p_o but now $p = p_o + \Delta p$. Estimating the value of Δp in relation to p_o and utilizing Eq. [1] the value of C was determined from the measured steady-state photovoltage, ΔV, for high light intensity. This in turn allowed one to obtain a product $\sigma_i N_t$ from Eq. [1] and [2], knowing ΔV and τ.

To measure the microscopic distribution of the deep centers, a series of parallel and geometrically identical MOS structures were prepared by photolithographic definition of an Al layer evaporated on the oxide. The geometry, spacing, and position of the capacitors in respect to the wafer edge is given in Fig. 1. The photovoltage generated by a monochromatic incident light was measured between a given MOS structure and an electrical contact which was kept in the dark. It has been found that for a reliable assessment of the differences in photoresponse of individual MOS structures, it is necessary to position the structures perpendicularly to a monochromator slit. Positioning of MOS structures parallel to the slit resulted in generation of spurious photovoltage signals similar to that arising from the wavelength modulation of an incident light.

The information about recombination center concentration in the measured wafers was obtained from the measurements of diffusion length by the surface photovoltage technique (11). Nonuniformity in the distribution of recombination centers was obtained from the measurement of the collection efficiency variations of the electron beam induced current (EBIC) collected by the electron-transparent Schottky diodes (12). Under plasma generation condition the variations in the collection efficiency correspond to the recombination centers concentration fluctuations (13). The measurements were performed using beam voltages between 3 and 15 keV and a beam current between 10^{-8} to 10^{-10}A.



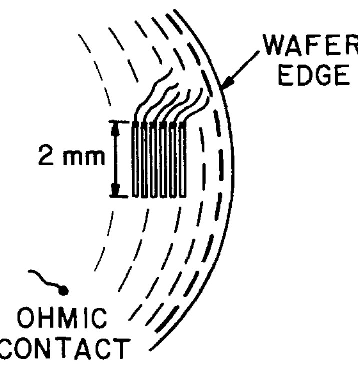


Fig. 1. Geometry of MOS capacitors used to measure microscopic distribution of deep centers.

Experimental Results and Discussion

Deep center parameters.—The typical subband photovoltage spectrum (normalized to light intensity) of MOS structures is shown in Fig. 2. This subband photovoltage is caused by two transitions between valence band and localized states. The photovoltage which is observed in the low energy end of the spectrum involves a center with an energy level of less than 0.5 eV (outside of the spectral range covered by the monochromator). The sharp increase of the photovoltage above 0.56 eV indicates that the additional transition to the state of energy about 0.56 eV above the valence band takes place. The occupation by electrons of any deep levels is rather unlikely in p-type silicon at low temperature; therefore, the photovoltage of Fig. 2 cannot be attributed to the optical transition from deep levels into the conduction band. The precise energy location of the deep level and additional information about its nature is obtained from the derivative surface photovoltage $dV/dh\nu$ spectrum, on Fig. 3b. In addition to the peak corresponding to the 0.56 eV energy level, a series of maxima is observed. These maxima

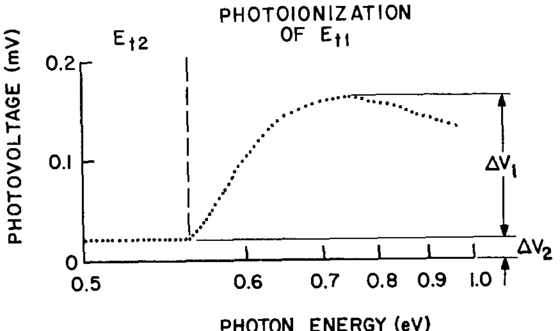

Fig. 2. Spectral dependence of steady-state, subbandgap photovoltage, and the contributions from photoionization of deep levels E_{t1} and E_{t2}. Spectrum was normalized to constant photon flux.

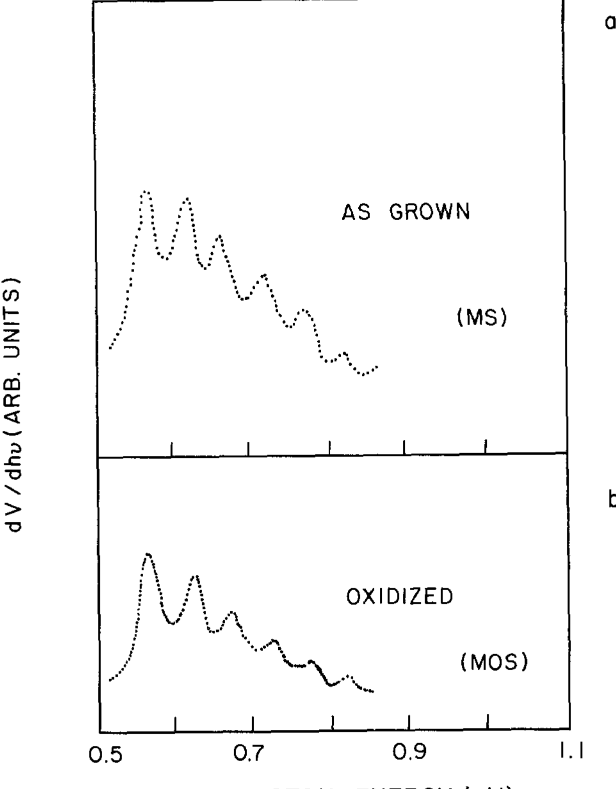

Fig. 3. Subbandgap first derivative photovoltage spectra at 10 K, (a) as grown wafer (MS), (b) oxidized wafer (MOS).

result from the fine structure in the photovoltage, which is not visible in Fig. 2. The separation of the maxima coincides with the energy of the optical phonon 55 meV (14); therefore, it seems to be justified to assume that they are caused by the phonon replica of the optical transitions to the deep level (10). The strong interaction of the deep state with phonons shows a strong coupling of the given state with the lattice, which is characteristic for a recombination center. The same photovoltage spectra (same energy levels) as for the MOS structures on the oxidized wafers were also obtained on the Schottky diodes made on as grown crystals (compare Fig. 3a and 3b). This indicates that the observed levels are not related to the interfacial states but to the states present in bulk of the as grown material and of the oxidized material. (However, note that the oxidation increases the concentration of deep levels, see below.)

The transient photovoltage measurements in the MOS structures for the 0.56 eV level at 12 K give the τ value of about 10 msec. The relaxation time, τ, was found to be independent of the light intensity up to 10^{14} photons per cm^2. However, above this value it decreased with the light intensity. For example, at 12 K and 2×10^{14} photons per cm^2 (or 0.8 eV) the relaxation time was reduced by about 10%. Accordingly, Δp had to be about 0.1 $p_o \approx 10^8$ cm^{-3} (p_o at this temperature was estimated to be about 10^9 cm^{-3}). From the value of Δp and the magnitude of photovoltage ΔV (Fig. 2) the factor C in Eq. [1] was estimated. The concentration of deep levels was determined from Eq. [2] (using the value of ΔV from Fig. 2). The required values of photoionization cross section σ_i were calculated using the quantum defect model (15) ($\sigma_i \simeq 2.5 \times 10^{-18}/E^2$, where E is the energy level). Utilizing the value of the measured time constant, τ, the capture cross section for holes was estimated from $K_p = 1/\tau p_o v_t^p$. The deep center parameters measured in the two typical MOS samples taken from the wafer center and the same wafer edge are given in Table I. The deep center concentration is about three times higher by the wafer edge than of the wafer center.

As pointed out above, the subbandgap photovoltage spectra similar to that shown in Fig. 2 and 3 were also obtained for Schottky diodes. However, for Schottky diodes the ratio of subbandgap to bandgap photovoltage was found to be about one order of magnitude lower than in MOS structures. This fact suggests that the deep level concentration in the as-grown material is about one order of magnitude below that observed in the oxidized samples (*i.e.*, on the level of 10^{12} cm^{-3}). Consistently, because of an order of magnitude lower concentration of deep levels in as-grown crystals no decrease in the relaxation time with increasing illumination intensity up to 2×10^{15} photons/cm^{-3} was observed for the Schottky diodes. Accordingly, the photovoltage transient analysis could not be used for more precise evaluation of N_t in the as-grown material.

The DLTS experiments showed the presence of two levels in the MOS samples (Fig. 4); the hole trap at energy 0.23 eV; hole capture cross sections of about

Table I. Comparison of deep centers parameters measured by DLTS and DSPS

Nr	DSPS	DLTS

Center	$E_1 = 0.56$ eV $N_1 = 9 \times 10^{12}$ cm^{-3} $\sigma_1 \sim 10^{-14}$ cm^2 $E_2 < 0.5$ eV $N_2 < 5 \times 10^{11}$ cm^{-3} $\sigma_2 > 2 \times 10^{-15}$ cm^2	$E_1 = 0.45$-0.65 eV $N_1 = 1.0 \times 10^{13}$ cm^{-3} σ_1—not determined $E_2 = 0.23$ eV $N_2 = 7 \times 10^{11}$ cm^{-3} $\sigma_2 \sim 10^{-14}$ cm^2

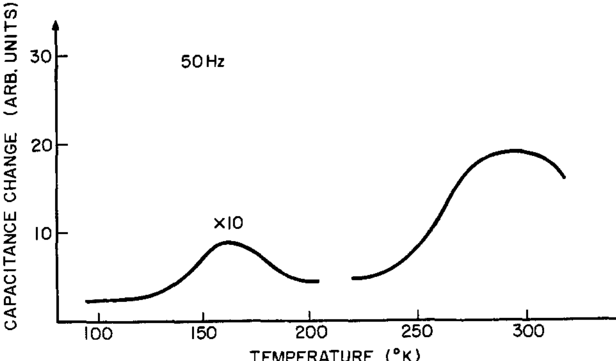

Fig. 4. DLTS spectrum obtained on MOS structure. The high temperature peak corresponds to concentration of about 10^{13} cm^{-3} of deep levels.

10^{-14} cm^2 and concentrations of about 7×10^{11} cm^{-3} and the second level close to the middle of the energy gap (0.45-0.65 eV range) with a concentration of about 10^{13} cm^{-3}. The capture cross section and precise position of the second level was difficult to determine because a broad band of capacitance changes was observed rather than a sharp peak. This could possibly be caused by the interaction of this level with minority carriers present at this temperature in silicon.

A comparison between DLTS results and the deep level parameters determined from DSPS is presented in Table I and suggests that in both instances we are dealing with the same set of two deep levels located at 0.23 and 0.56 eV above the valence band. DLTS measurements performed on Schottky barriers in as grown crystals showed the deep level concentration to be about one order of magnitude lower (Fig. 6) than in the oxidized wafers, which confirms the DSPS results.

Microscopic distribution of the deep centers.—The important material property affecting the CCD imager performance is distribution of the deep centers on the microscale. Studies on the deep center distribution were performed using a series of geometrically identical MOS capacitors (as shown in Fig. 1). First, uniformity of the MOS capacitors with respect to the photovoltage response was established from the room temperature photovoltage measurements in a region of intrinsic excitation. Under conditions of "back-side" illumination this photovoltage arises due to (*i*) almost homogeneous generation of electron-hole pairs ($h\nu \simeq E_g$) and (*ii*) due to "back-surface" excitation of excess carriers ($h\nu > E_g$) and subsequent diffusion of excess carriers across the specimen to the region of the MOS barrier. In case (*i*) the magnitude of photovoltage probes the lifetime of excess carriers and the value of the interface barrier height. In case (*ii*) it also probes the interface recombination velocity on the "back surface" in addition to the diffusion lengths of excess carriers. The present results of photovoltage measurements have shown only slight differences between various MOS structures. Typical results of photovoltage *vs.* incident photon energy are given in Fig. 5 (photovoltage measured between metal electrode of MOS structure and electrical contact to the sample) and it is seen that differences between various structures do not exceed 5%.

It can be concluded from the results of Fig. 5 that homogeneous excitation of excess carriers results in only minor differences between photovoltaic response of individual MOS structures, which can be treated as an indication of negligible differences in potential barrier heights of MOS structures (note that all other factors, *i.e.*, the lifetime, diffusion length, and surface recombinatioin velocity on the back surface are in the present configuration averaged over a relatively large area).

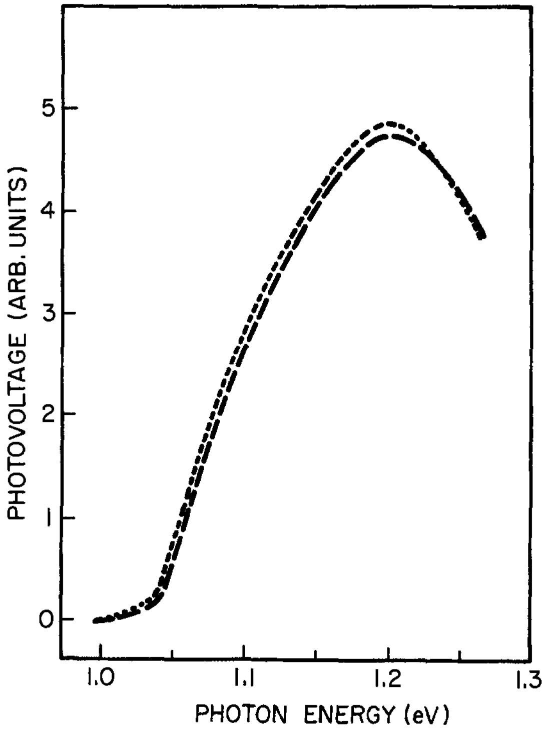

Fig. 5. Comparison of photovoltage generated by band to band transitions of the typical two MOS structures used to measure inhomogeneities in distribution of deep centers. Differences do not exceed 5%.

For a comparison between the concentration of deep levels in wafer regions corresponding to various MOS structures the subband photovoltage spectra were measured at low temperature with respect to a common contact to the sample. The typical results obtained at two temperatures (60 and 100 K) are summarized in Table II. It is seen from this table that the maximum relative difference between the subbandgap photovoltage of different structures is about 20%. These differences reflect primarily different concentrations of deep levels, N_t. As discussed above, the changes of surface barrier height were estimated as not exceeding 5%, *i.e.*, about four times lower than the observed changes in photovoltage due to photoionization of deep levels. Therefore, it can be concluded that deep center concentration variations of at least 20% at distance of a few hundred microns are present in silicon wafers.

Lifetime and inhomogeneity in the recombination center distribution.—The concentration of the deep centers was found to be directly correlated to the lifetime of minority carriers. Figure 6 presents lifetime in the as grown and oxidized silicon (measured by DLTS and DSPS, respectively) as a function of the reciprocal concentration of the deep centers (0.56 eV level) measured, as described earlier. It seems that dependence is linear, which could be described by the expression

$$\tau = \frac{1}{K_e \cdot V_t^e \cdot N_t}$$

where K_e is the capture cross section for electron (minority carriers) and V_t^e is the thermal velocity of an electron. From the slope of the line in Fig. 6, the value of K_e equals 5×10^{-15} cm^2 is obtained. It is not surprising that those centers act as recombination centers and control the lifetime of minority carriers in view of their strong interaction with the lattice demonstrated by the phonon replica in the derivative spectra (Fig. 3).

One of the problems in the CCD imagers used for TV applications is the appearance of a circular striation pattern in the background of the defected video image

Table II. Photovoltaic response of MOS structures at photon energy 0.8 eV
Photovoltage (μV)

Temperature (K)	Photovoltage (μV)							
							Maximum difference	
	Structure 1	Structure 2	Structure 3	Structure 4	Structure 5	Average value	Absolute	Relative (%)
100	8.5	7.5	8.1	8.8	8.9	8.36	1.5	18
60	21.2	18.4	20.1	22.4	22.7	21.0	4.3	20

(Fig. 7). It has been established that this pattern reflects nonuniform collection efficiency, caused by inhomogeneous distribution of recombination centers in the silicon substrate (6). The typical fluctuations in the recombination center concentration observed at the edge of the wafer (measured by EBIC under plasma generation conditions) are shown in Fig. 8a. Figure 8b shows the histogram of recombination center variations obtained by integrating variations presented in Fig. 8a. Figure 8c shows the variations in the concentration of deep centers in the same area, measured by DSPS where EBIC measurements presented in Fig. 8b were performed. Good correlation exists between the distribution of the deep levels measured by DSPS and the distribution of recombination centers measured by EBIC. Therefore, it can be concluded that inhomogeneous distribution of deep levels is responsible for appearance of a striation pattern in the CCD image.

It has to be pointed out that the inhomogeneity of the recombination center distribution can be affected by the heat-treatment. The upper plot in Fig. 9 represents the typical fluctuations in the recombination center concentration observed at the edge of as-grown wafers (measured by EBIC under plasma generation conditions). The lower plot of Fig. 9 represents the fluctuations (measured under the same conditions) in the recombination center concentration observed in the same place in the wafer after oxidation. The periodicity of oscillations is about a few hundred microns in both samples, and their amplitude in the as grown wafer is about 10-15% when in the oxidized wafer it increases to about 20-25%, which indicates that the oxi-

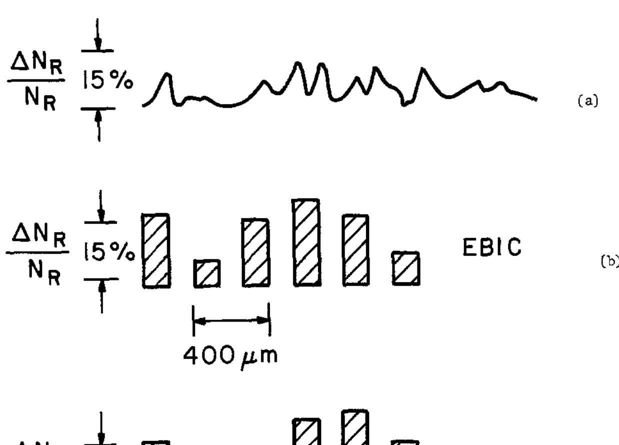

Fig. 8. (a) Distribution of recombination centers measured by EBIC; (b) histogram of recombination centers distribution (EBIC); (c) measured by DSPS histogram of deep centers distribution.

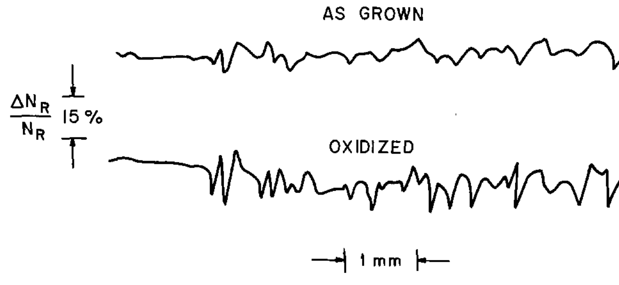

Fig. 9. Distribution of recombination centers measured by EBIC in the virgin wafer and in the same place after oxidation.

dation process enhances the inhomogeneity in recombination center concentration already present in as grown material. The degree of this enhancement for the same heat-treatment was found to differ significantly between the wafers. The observed increase in the inhomogeneity of deep centers during the heat-treatment accounts for the enhancement of striation contrast by processing.[1] The large differences between the striation contrast in the different CCD imagers processed in the same manner (7) can be explained by the observed significant differences in which the heat-treatment influences the inhomogeneity of deep centers in the different wafers.

The second important issue for device performance is the amount of electrically active crystallographic defects which will show up as spots or lines in the displayed image (1-5). Crystallographic defects usually become electrically active after decoration with recombination centers (16). Figure 10 shows observed relationships between the amount of electrically active edge dislocations observed in the image (ratio between the amount of edge dislocations giving white spots and lines and the total amount of edge dislocations observed in the imager area after etching) and the value of the average diffusion length in the silicon. When none of the dislocations were electrically active, the point was placed in the region "no correlation." From the presented plot it is evident that the probability of decoration of edge dislocation increases with the increase of total concentration of deep centers in the crystal (their relationship to lifetime is given in Fig. 6).

The nature and origin of these defects as well as the mechanism responsible for the increase of the deep center concentration and the enhancement of recombination center inhomogeneity after oxidation are not clear at present. Further extensive work is required which would allow one to establish the origin of deep centers and to provide the model describing their behavior during heat-treatment. It is likely that the deep centers are not associated directly with residual chemical impurities but are rather related to the point defect clusters or their complexes with impurities present in as grown float zone crystals. The inhomogeneous distribution of these defects in the crystals could be related to the effect of growth kinetics on the formation of point defects on the growing interface. The segregation of point defects during the growth process is affected by the nonequilibrium point defect trapping (17-19), which takes place at the growing interface during growth velocity acceleration (20). The additional explanation of the nonuniform distribution of these defects in the crystals could be the condensation of point defects in the regions with high carbon concentration. This mechanism has been proposed by Foll *et al.* (21) to account for swirls formation. The point defect complexes with impurities or their clusters are probably introduced to the as grown crystals in two different states during the growth process and the subsequent heat-treatment involved in the oxidation affects their concentration in a given state accounting for the increased concentration of deep centers.

[1] Inhomogeneities in the recombination centers concentration, responsible for striation pattern in the displayed image, are from 20 to 200% larger in the processed wafers (with final devices) than in as grown wafers.

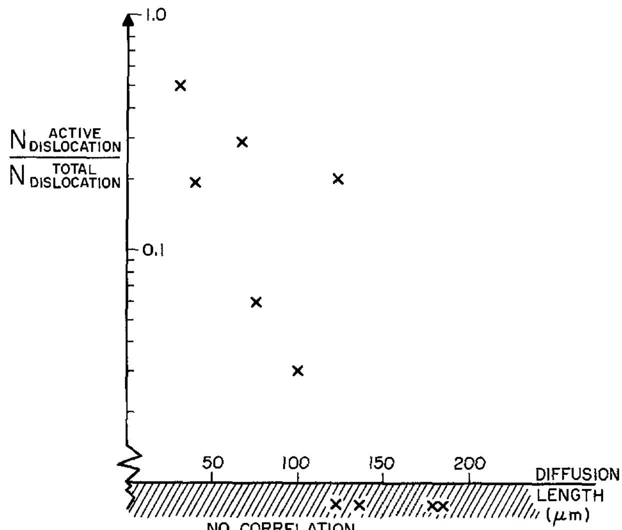

Fig. 10. Ratio of electrically active dislocations observed as white spots in the CCD imagers to total amount of dislocations revealed by etching in the imaging register as a function of diffusion length in silicon. When dislocations did not generate any white spots, the data point was placed in "no correlation" region.

Summary

Deep levels in high quality float zone slicion used for fabrication of CCD imagers have been measured by deep level transient spectroscopy and derivative surface photovoltage spectroscopy. These two different techniques revealed presence of two deep levels: 0.23 and 0.56 eV above the valence band in the as grown and oxidized wafers. Their concentration was found to be about 10^{11}-10^{12} cm^{-3} in the virgin crystal and was increased about one order of magnitude by oxidation. Large macroscopic and microscopic inhomogeneities in the deep level distribution across the wafers have been found.

It has been established that the deep level concentration controls the minority carrier lifetime, a parameter controlling quantum efficiency and dark current in CCD imagers. It was also observed that the probability of crystallographic defect decoration sharply increases with an increase of the average deep level concentration in silicon. It has been found that the nonuniform deep level distribution in the wafers is responsible for the appearance of a striation pattern in the displayed image.

Although the origin of the deep levels and their behaviors during heat-treatments are not fully understood at the present time, the authors believe that the deep levels are introduced by point defect complexes or their clusters with impurities rather than by heavy metals or other simple chemical impurities.

The Instabilities in the Al-Si Temperature Gradient Zone Melting

Mike F. Chang*

General Electric Company, Syracuse, New York 13221

ABSTRACT

By using the TGZM technique, a job that traditionally needs hundreds of hours of diffusion can be done in minutes. However, various instabilities may be encountered in the application of this new technique. Some of these instabilities and the methods of resolving them are discussed.

The basic physics of temperature gradient zone melting (TGZM) have been investigated by Pfann (1) and others (2-5) for its possible interest to semiconductor applications. For making p-n junctions, solid-state diffusion has been used by the semiconductor industry as a standard technique. Later, the TGZM technique became attractive after Anthony and Cline announced the results of their zone melting studies of KCl-H_2O systems (6). Recently, the Semiconductor Products Department of the General Electric Company started a program to explore TGZM techniques for device fabrication, mainly silicon products (7). Some of the results and analyses are presented in this paper.

The simplified mechanism of TGZM is shown in Fig. 1. In Fig. 1(a), a liquid droplet of Al-Si alloy is embedded in a solid silicon bulk, which has been subjected to a temperature gradient with the lower temperature above the Al-Si eutectic point. According to the phase diagram of the Al-Si system, the upper portion of the droplet, being hotter, will dissolve more silicon than the lower portion, as shown by the solid line in Fig. 1(b). A silicon concentration gradient will be created in the liquid droplet and the silicon atoms will diffuse toward the lower portion at a high liquid diffusion rate. This process, in turn, will create undersaturation and oversaturation conditions in the upper and lower portions of the droplet, respectively, as indicated by the dashed line in Fig. 1(b). Silicon atoms must be supplied by the bulk at the AB interface and deposited back to the bulk at the CD interface. Accordingly, the droplet moves up against the temperature gradient through the bulk. As the droplet moves, it leaves behind a trail of heavily doped p-type silicon whose doping concentration is determined by the solid solubility of aluminum in silicon at the operating temperature.

* Electrochemical Society Active Member.

Key words: semiconductor, process, defects, thermomigration.

As compared with the well-established solid-state diffusion process, the TGZM technique has only recently received much attention (7, 9-12). The TGZM technique offers many unique features not found in any other process, yet it still needs some improvement.

Experiments

Theoretically, any system that provides a controllable temperature gradient can be used for TGZM operation. The quartz lamp system shown in Fig. 2 was used in this study (13).

In this paper, we discuss only the Al-Si system, namely, aluminum pattern migrating through silicon. N-type silicon wafers and billets of (111) and (100) orientations were employed. Their resistivity ranges from 10 to 180 Ωcm. The aluminum patterns for migration included straight lines, curves, points, and lumped areas. Since the migration of various patterns are subjected to a common effect of instabilities, a grid-type

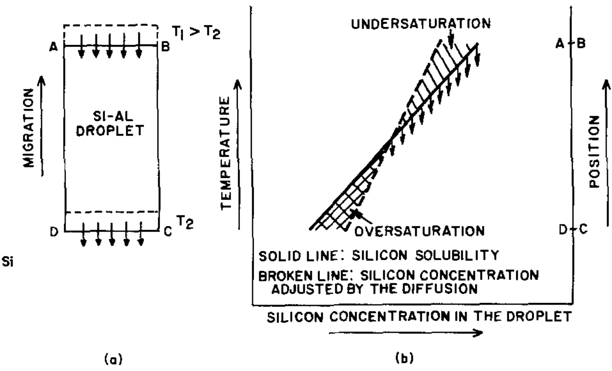

Fig. 1. Simplified mechanisms of an Al-Si droplet migrating in a solid silicon bulk.

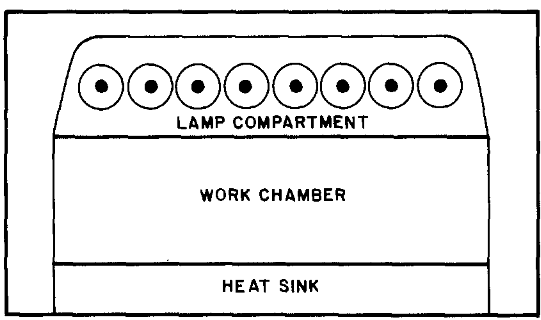

Fig. 2. A schematic diagram of a quartz lamp system for TGZM operations.

pattern is chosen to demonstrate and explain the instabilities of migration without losing generality. The detailed process and variations will be given in a paper to follow.

An aluminum pattern 1-10 μm thick was created on one side of the silicon wafer by evaporation and photolithography. The wafer was placed in the TGZM work chamber with the aluminum pattern facing the heat sink. Radiant energy from quartz lamps heated the wafer from 1000°C up to the melting point of silicon. The molten aluminum pattern reacted with silicon and formed an Al-Si alloy. This liquid alloy pattern migrated toward the hotter side of the silicon wafer and eventually passed through. Figure 3 shows a wafer before and after migration. The migration time depends on the thickness of the wafer and the operating conditions. For example, it took only 8 min to migrate through a 16 mil thick wafer at 1200°C with a temperature gradient around 50°C/cm. Heavily doped p-type trails with abrupt p-n junction borders were left inside the wafer. The doping concentration in the trail is about 1×10^{19} atoms/cm^3 and is constantly produced with a temperature range of 950°-1300°C as predicted by Trumbore's curves (8). The concentration profile across a typical TGZM doped trail is shown in Fig. 4.

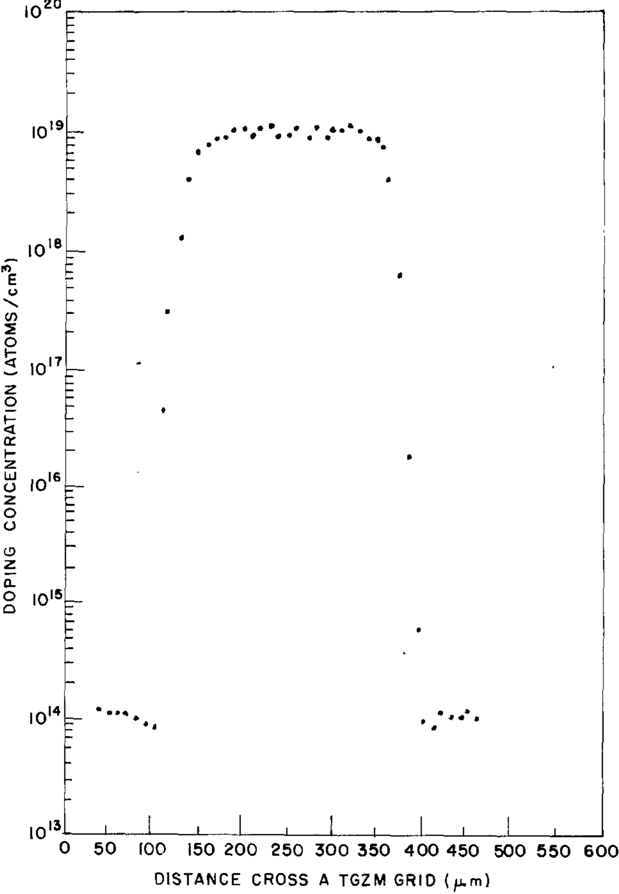

Fig. 4. Doping concentration measured across a TGZM trail

Results and Discussion

The migration rate of a water droplet in salt has been studied by Anthony and Cline (6). The physics was applied equally well to the Al-Si system (10). There are two opposite forces involved. The temperature gradient is the driving force for the migration of droplets. The surface tension is the retarding force. This retarding force is essential for the stability of migration. Since the surface tension increases as the size of the droplet decreases, the speed of migration will be reduced as the size of the droplet is reduced. By contrast, as the droplet size is increased, the possibility of disintegration or other instabilities of the droplet increases. Therefore, a speed limit is required in each system to ensure the safety of droplet migration. Fortunately, only a few of the instabilities present difficulties in the area of semiconductor device fabrication. They are discussed below.

Ball up.—In some cases, solid silicon balls (Fig. 5) may be left on the entrance surface of the wafer after migration, creating problems for subsequent photoresist processing. These balls may scratch the mask and damage the photoresist film. The wafer may also be cracked in the mask aligner by the local pressure

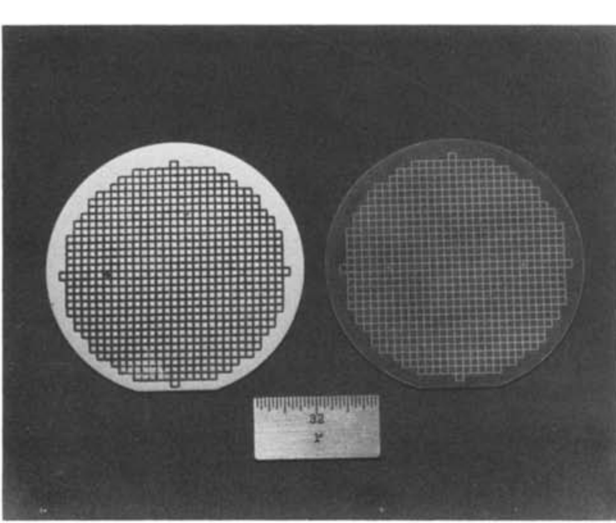

Fig. 3. Aluminum grids on silicon wafers before (right) and after (left) the migration.

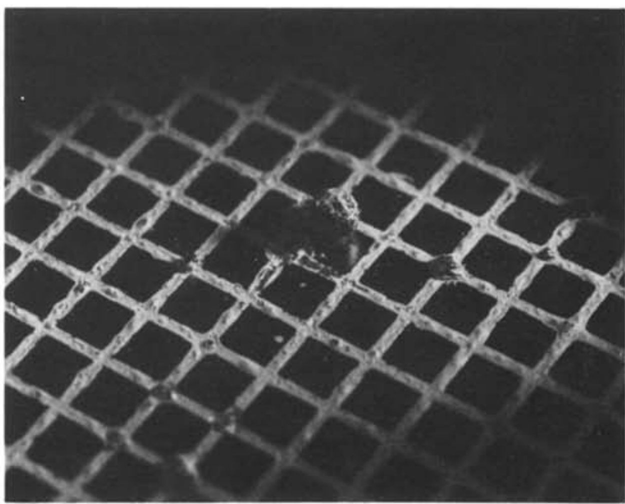

Fig. 5. A solid ball left on the entrance side of a silicon wafer after the migration.

developed from the point contact between the glass mask and balls. Two possible mechanisms of ball formation are considered here. First, the balls may be generated by an excessive operating temperature, *i.e.,* before the temperature gradient has a chance to drive the aluminum-silicon liquid into the silicon bulk, the liquid zone has already been balled up by surface tension. This liquid aluminum ball, in turn, absorbs silicon atoms from the wafer to form an equilibrium Al-Si solution. In this situation, with no parental crystal site or ledge available, the liquid Al-Si melt transforms into a solid silicon ball after the aluminum migrates away. Second, the ball may be induced by a fluctuation in temperature (14). The slope of the Al-Si phase diagram is quite flat at 1200°C. Therefore, the volume of liquid Al-Si droplet is very sensitive to the temperature variation. When the droplet is exposed to a temperature fluctuation, the vigorous change of the volume ejects the excess liquid to the surface to form a ball as depicted by Fig. 6. Thus, a proper and stable temperature is an important factor for a ball-free TGZM operation.

Rough surface.—In most cases, the aluminum pattern is deposited on the surface of the silicon wafer. In the initial stage of migration, the solidified silicon atoms have no crystal ledge to follow, instead they randomly precipitate out of the melt to form a polycrystalline silicon surface that preserves the contour of the former Al-Si liquid surface. Therefore, a flat surface should not be expected. As the droplet moves forward, the single crystal matrix, which originates from the peripheral edges of the droplet, grows wider as illustrated in Fig. 7. Finally, this single crystalline side band, around the polycrystalline cone, pinches off the polycrystal growth. After this point, all the newly solidified silicon atoms find their depositing ledges and become a part of the parent crystal. For example, KOH etches polycrystalline silicon faster than it etches single crystalline silicon. The etched surface of a (111) silicon wafer leaves a V-shape groove on the TGZM site as shown in Fig. 8. The roughness and the amount of polycrystal material produced are closely related to the temperature and the speed of migration.

Droplet break-up and freeze-in.—An oversized droplet may break into two or more subdroplets as shown in Fig. 9. Generally, this phénomenon of droplet disintegration is caused by the difference in thermal conductivity between the Al-Si droplet and its surrounding solid silicon. This difference generates a higher temperature gradient around the peripheral area of the Al-Si droplet. Thus, the outer portion of the droplet will migrate faster than the center portion. In some cases, the droplet may be torn apart by this nonsynchronized migration if the surface tension of the droplet is not strong enough to hold the droplet together. Figure 10 shows a split grid line. The two split branches migrated as two independent grid lines in parallel. In the KCl-H_2O system, Anthony and Cline reported a higher temperature gradient at the center of each droplet due to the relatively low thermal con-

ductivity of the brine droplet (6). Sometimes subdroplets caused by the droplet break-up may be too small to gain enough momentum to migrate any further and will be left inside the silicon wafer as freeze-in droplets. This droplet freeze-in phenomenon may also happen under two other conditions. In one case, when the TGZM pattern has different sizes of lines, the wider lines will migrate faster than the smaller ones. For a given operating time, the wider lines can migrate through the wafer, but the smaller ones may be only part way through the wafer. In the second case, when the migrating droplet hits a dislocation site, this droplet may be trapped in this energy well and frozen in. The volume of silicon increases when it is solidified from the liquid phase. These freeze-in droplets will generate huge stresses that may crack the wafer. Figure 11 shows a star-shaped crack resulting from a trapped droplet under the area of a registration key. This freeze-in effect makes it difficult for a droplet to migrate into a wafer to a predetermined depth and then to migrate backward out of the wafer. For this application, it is necessary to keep the droplet in the liquid phase for the entire operation period, thus a double heater set is required with one heater on each side of the wafer.

End expansion.—There is a potentially troublesome but interesting phenomenon in TGZM migration. The

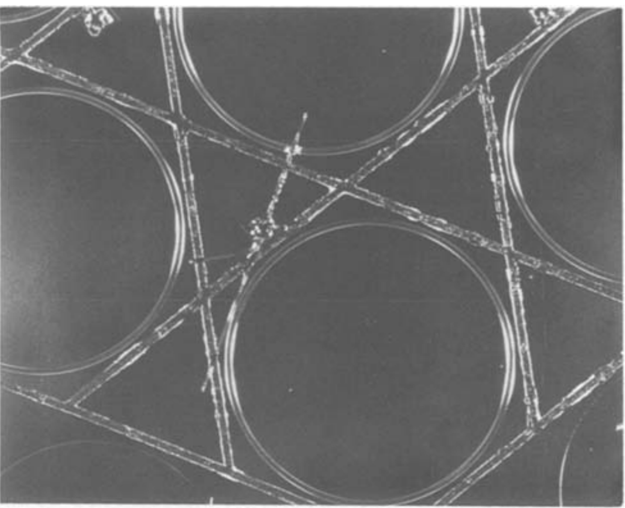

Fig. 11. A star shape crack on the site of an alignment key due to a frozen-in droplet.

stained cross-section picture shows that each migration trail has a cone shape expansion at the exit end as shown in Fig. 12. This phenomenon should be considered for the application of TGZM technique to a two-sided device. The mechanism of this end expansion can be explained by basic TGZM principles. When the droplet reaches the exit surface of the wafer, there are no more solid silicon atoms available at the front surface of the droplet, but the solidifying action at the back interface is still taking place. At this point, the droplet starts to dissolve the solid laterally from the front edges. The result is that the droplet keeps migrating forward by changing its shape, namely, becoming wider and thinner as depicted in Fig. 13. Finally, the droplet migrates out of

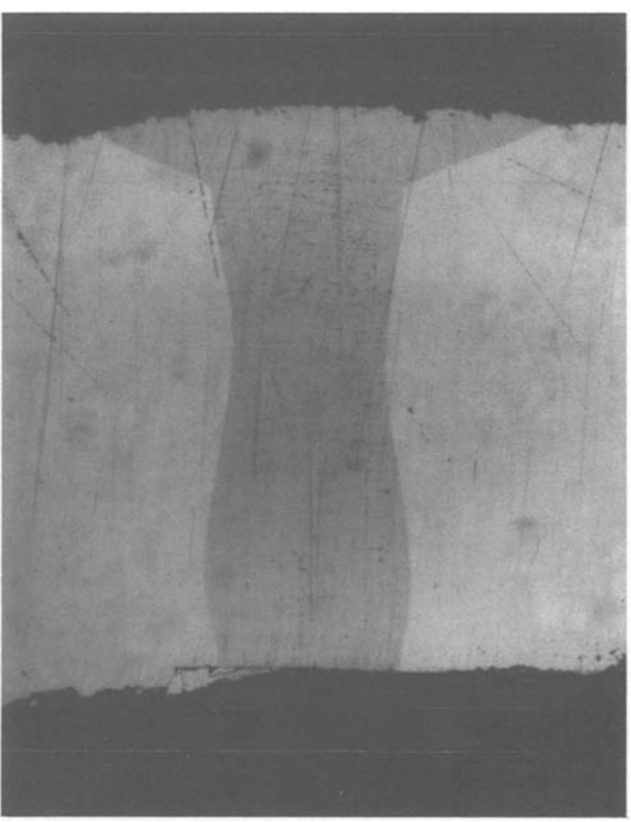

Fig. 12. Lapped and stained sample showing the effect of end expansion.

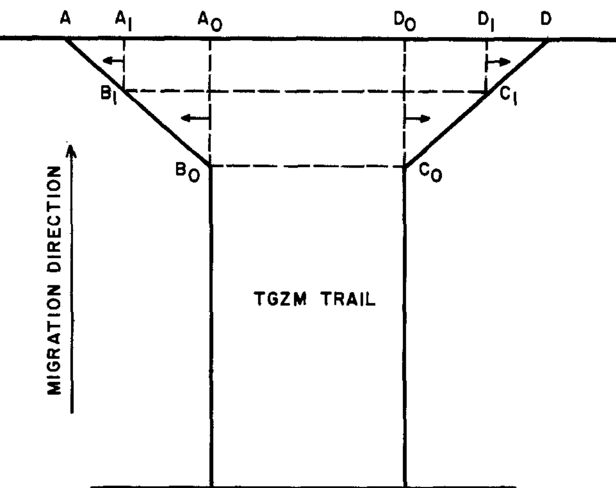

Fig. 13. A schematic diagram explaining the mechanism of end expansion.

the surface and leaves a cone-shaped trail behind. The height of the cone will be the original thickness of the droplet at the migration condition. For example, 10 μm thick aluminum produces droplet thickness of approximately 28 μm at 1200°C and the measured height of the cone is about 26 μm. One way to avoid this cone shape end expansion inside the silicon wafer is to supply more silicon to the droplet when it reaches the surface. The phenomenon of lateral surface spreading can also be explained by the above principles. The emerging liquid Al-Si alloy at the surface continues to stretch itself thinner and wider. In other words, the liquid spreads out from the center and eventually may cover the entire surface of a wafer if it is left in the high operating temperature environment long enough. Thus, a beneficial procedure would be to cool the wafers immediately after the liquid droplets reach the surface. Before the droplet has a chance to wet the silicon surface, the aluminum will be frozen out of the liquid as shown by the Al-Si phase diagram.

By avoiding or minimizing these instabilities, we have made several semiconductor devices with the TGZM technique. These devices have a current range from 1 to 600A and a blocking voltage over 2500V. Circular patterns have also been migrated through polysilicon wafers as shown in Fig. 14.

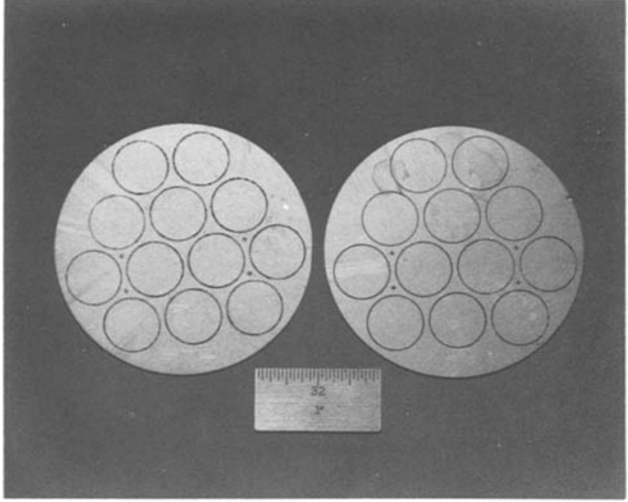

Fig. 14. A circular pattern migrated through polycrystalline silicon wafers. The right-hand side wafer is top side up and the left hand-side wafer is bottom side up.

Conclusion

The TGZM technology is a very powerful tool for the manufacture of semiconductors. It has opened a new dimension for device design and process engineers. We have observed various potential instabilities in TGZM operation. A qualitative interpretation of some of these instabilities has been presented for the first time. Through this understanding, TGZM doped structures, which are close to ideal abrupt p-n junctions, can be produced. The fabrication of some actual devices, using this technique, will be discussed in a later paper.

ABSTRACT

Auger electron spectroscopy was used to study the interface of vacuum-deposited tin oxide on GaAs substrates. The ratio of oxygen to tin in the tin oxide film, thermally evaporated from SnO_2 powder, was about 1.53. The films are likely a mixture of SnO and SnO_2. A transition region approximately 55Å in width exists between the tin oxide and GaAs substrate, possibly composed of oxides of GaAs and SnO, although the formation of a binary compound (GaSn) is possible. Heating in air further oxidized the tin oxide to SnO_2. Heating in air and vacuum resulted in a Ga-rich surface on the GaAs substrate. Metal-insulator-semiconductor solar cells using vacuum-evaporated tin oxide interfacial layers showed substantial improvement over cells made without the interfacial layer.

Metal-insulator-semiconductor (MIS) and heterojunction solar cells have received considerable interest in recent years. Cells have been developed with efficiencies approaching those of conventional homojunction cells and have the added advantage of ready adaptability to mass production (1-3). However, both types of cells have experienced problems with degradation of their electrical characteristics, leading to life expectancies less than those necessary for practical utilization (4, 5). The degradation of MIS and heterojunction solar cells is due partly to changes at the surface of the semiconductor and in the insulator or interfacial layer. The electrical characteristics of these devices are intimately related to the oxide-semiconductor interface. A study of the interfacial region could yield useful information toward improving solar cell performance as well as understanding degradation mechanisms.

We report the results of a study of tin oxide-GaAs interfaces using Auger electron spectroscopy (AES). Tin oxide was vacuum evaporated on GaAs substrates with electron beam and resistive heating techniques. Depth profiling by AES was employed to determine the composition of the tin oxide layer as well as the tin oxide-GaAs interface. The results show the ratio of oxygen to tin to be approximately 1.53 in the deposited films. Heating in air oxidized the film to SnO_2. Heating in vacuum had little effect on the tin oxide layer. In either case the transition region width was about 55Å. We also present the results of MIS solar cells made by the vacuum evaporation of tin oxide interfacial layers. Open-circuit voltages of 0.765V and efficiencies in excess of 7.0% (without antireflection coatings) were achieved and possible modes of improvement have been identified (6).

Sample Preparation

The substrates used in the study were n-type Te-doped single crystal <100> GaAs with carrier concentration of 5×10^{15} cm^{-3}, epitaxially grown by chemical vapor deposition on GaAs substrates with $N_d > 10^{17}$ cm^{-3}. After ultrasonic cleaning in trichloroethylene and methanol, the wafers were etched in a 50:1:1 solution of H_2O:H_2O_2 (30%):H_2SO_4 (96%). Fabrication was performed in an LN_2-trapped, oil-pumped vacuum system evacuated to a pressure of less than 3×10^{-6} Torr. The GaAs wafers were at ambient temperature during deposition. SnO_2 (99.9%) powder was evaporated using an electron beam gun and using a resistance-heated alumina-coated Mo boat at an average rate of 1 Å/sec. Vacuum pressure rose to 3×10^{-5} Torr during deposition and thickness was monitored *in situ* with a quartz crystal thickness monitor. Samples prepared for Auger electron spectroscopy (AES) were fabricated by both electron beam and boat evaporation of the tin oxide. Film thickness was 200Å and sample size was 1.0 cm^2.

MIS and heterojunction solar cells were fabricated in a similar manner. A back-contact was formed by successive evaporation of Sn and Ag layers and annealing in forming gas. A cell area of 0.07 cm^2 was delineated by evaporation through a stainless steel mask. The MIS cells were made by evaporation of a thin layer (30-50Å) of tin oxide followed by boat evaporation of 65Å of Au. In addition to the MIS cells, Au-GaAs cells were made with no tin oxide layer. A very thin native oxide present after etching precludes the formation of a true Schottky barrier cell, but does provide for a baseline cell for comparison purposes. Heterojunctions of SnO_2-GaAs were made by deposition of about 900Å of tin oxide and annealing in air at 300°C. Front contact to all types of cells was made with an Ag pad giving a cell active area of 0.06 cm^2.

Results

Current-voltage characteristics.—Illuminated current-voltage characteristics were taken under simulated AM1 sunlight using an ELH lamp calibrated with a NASA-Lewis silicon standard cell. Figure 1 is the illuminated *I-V* characteristics of a typical cell of each type—baseline, heterojunction, electron beam MIS, and boat MIS. Short-circuit current density was calculated using the cell active area. The open-circuit voltage enhancement and the consequential increase in efficiency due to the interfacial tin oxide layer in the MIS cells is evident.

The difference in short-circuit current between the two types of MIS cells is due to slight, unavoidable variations in Au-layer thickness between fabrication runs. Variations in GaAs substrate properties between wafers would also contribute to the difference in short-circuit current. The open-circuit voltage of electron beam MIS cells was lower than those of boat MIS cells due to damage caused by the electron beam source to

Key words: solar energy, heterojunctions, interfacial layer.

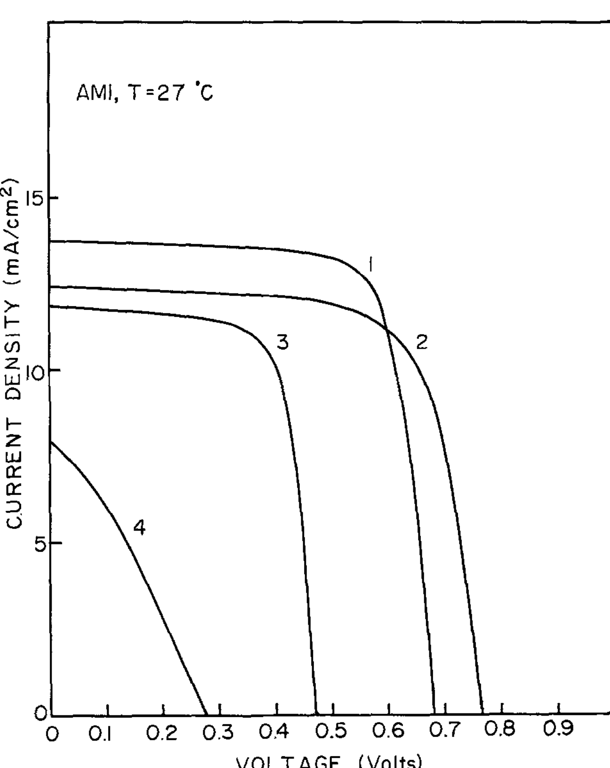

Fig. 1. The illuminated current-voltage curves of: curve 1, electron beam MIS; curve 2, boat MIS; curve 3, baseline; and curve 4, heterojunction solar cells.

the interfacial layer (6). Heterojunction solar cells had the lowest efficiencies and offer the least promise for useful devices fabricated by evaporation techniques.

Auger electron spectroscopy.—Films of electron beam- and boat-evaporated tin oxide on GaAs were depth profiled using Auger electron spectroscopy. A freshly etched GaAs wafer was also analyzed. The Auger depth profiles were obtained using a Physical Electronics thin film analyzer. In this study, the electron beam current was 15 μA at 5 KeV with a spot size of about 100 μm. The ion beam of 2 KeV Ar^+ was rastered over an area of several square millimeters to avoid loss of depth resolution due to crater edge effects and to maintain a slow sputtering rate of about 12 Å/min. The sputtering rate and therefore the depth were calibrated using the known tin oxide layer thickness (200Å) and the sputtering time necessary to completely penetrate this layer. Tin oxide layer thickness was monitored during deposition with a quartz crystal thickness monitor and checked with ellipsometry.

The AES depth profile of electron beam-evaporated tin oxide on GaAs is shown in Fig. 2. The tin and oxygen atomic concentrations were calibrated with an SnO_2 standard prepared by chemical vapor deposition from $SnCl_4 \cdot 5H_2O$. The atomic concentrations of arsenic and gallium were calibrated with the known stoichiometry of the GaAs substrate. The average error in atomic concentration is ±5%. The ratio of oxygen to tin in the tin oxide bulk is 1.53.

Figures 3 and 4 are the AES profiles of electron beam tin oxide samples annealed in air and vacuum, respectively. These samples were from the same specimen as the unannealed sample of Fig. 2. The air-annealed sample was heated at 300°C for 15 min in a small muffle furnace. The effect of the annealing can be seen in the increase in oxygen level throughout the profile. The vacuum-annealed sample was mounted on a stainless steel block heated by a cartridge heater. The temperature was ramped to 300°C, was held there for 15 min, and allowed to cool. Pressure during annealing was 2.2×10^{-6} Torr.

A freshly etched GaAs wafer was also examined to determine the composition and thickness of the resid-

ual native oxide layer. Results show a native oxide 17-19Å thick.

Discussion

The stoichiometry of the tin oxide deposited by thermal evaporation of SnO_2 is significantly different than that of the starting material. As seen in Fig. 2, the oxygen to tin ratio is 1.53 in the bulk of the tin oxide layer. Similar analysis of boat-evaporated tin oxide yields a ratio of 1.60. Two oxides of tin exist, stannous oxide (SnO) and stannic oxide (SnO_2); clearly, the deposited films are not composed solely of either of these two oxides. Stannic oxide sublimes upon heating in vacuum and evaporates via the reaction

$$SnO_2(s) = SnO(g) + 1/2\, O_2(g) \qquad [1]$$

above 1250 K (7, 8). The oxygen liberated during evaporation is consistent with the tenfold increase in vacuum system pressure. It has been demonstrated that SnO will oxidize to SnO_2 at temperatures as low as 513 K (9). It is likely that a portion of the gaseous SnO produced by the evaporation will reoxidize forming SnO_2, either before or during condensation on the substrate. The resulting film is a mixture of SnO_2 and SnO.

The transition region from the tin oxide to the GaAs substrate is marked by an increase in the concentration of gallium and arsenic. The width of the transition region is estimated to be approximately 55Å for both the electron beam- and boat-evaporated samples. As seen from Fig. 3 and 4, annealing in either air or under vacuum does not appreciably change the interfacial region width.

As previously mentioned, the etched GaAs wafer was covered with a native oxide about 17-19Å thick. If we assume that a percentage of the oxygen at the interface exists as GaAs oxide, then the ratio of oxygen to tin in the sample of Fig. 2 rapidly decreases from 1.53 to 1.0 as depth increases toward the GaAs substrate. This indicates that the tin oxide layer may change from a mixture of SnO and SnO_2, to predominantly SnO near the GaAs substrate. A reaction between SnO_2 and GaAs is thermodynamically possible with the reduction of SnO_2 to SnO and further oxidation of the substrate.

Heating in air at 300°C increased the oxygen/tin ratio in the sample of Fig. 3. Although the ratio is equal to 2.0 throughout the tin oxide, it again falls as the depth increases toward the interface. Again assuming that a portion of the oxygen is in the form of GaAs oxide, the oxygen/tin ratio falls to 1.0 as in the unannealed case. Electrical measurements show the annealed SnO_2 to be conductive and of high optical transparency, necessary conditions for efficient heterojunction cells, but SnO_2-GaAs heterojunction cells fabricated have high series resistance and low fill factor. A change in chemical composition of the interfacial layer or the electrical properties of the interface due to annealing could explain the poor performance of the heterojunction cells.

Another interesting feature of the air-annealed sample is the presence of a Ga-rich surface. This excess of gallium could be due to the outgassing of arsenic from stoichiometric GaAs. In the unannealed electron beam- and boat-evaporated samples as well as the freshly etched wafer, the ratio of As to Ga was unity from the surface through the oxide to the bulk. Because of the excess Ga at the surface of the substrate crystal, the formation of a binary compound of Ga and Sn is possible (10). The eutectic lies at 5 atomic percent Sn at 20°C. The formation of a Ga-Sn eutectic could explain the "shoulder" or flat part of the Sn concentration curve seen in all samples, annealed and unannealed, although such a layer would be quite thin. Formation of such a metallic compound could account for the poor performance of the heterojunction cells; the electrical characteristics would be dominated by a GaSn-GaAs interface rather than an SnO_2-GaAs interface.

The sample of Fig. 4 was heated to 300°C in a vacuum of 2.2×10^{-6} Torr. The oxygen/tin ratio remains essentially unchanged throughout. Again a Ga-rich surface is seen, possibly allowing the formation of a GaSn compound as in the air-annealed case. The width of the transition region did not change.

In conclusion, the results show that the films of tin oxide deposited by vacuum evaporation of SnO_2 are deficient in oxygen. The films appear to be a mixture of SnO_2 and SnO. Auger electron spectroscopy depth profiling shows that the transition region between the tin oxide and GaAs substrate is approximately 55Å in width. The transition region may be composed of oxides of GaAs and SnO, although the formation of a thin region of a binary compound (GaSn) is possible. Annealing of the films in air further oxidized the tin oxide to SnO_2, but did not significantly alter the transition region. Annealing in air and vacuum resulted in a Ga-rich surface. The constituents of the 30-50Å interfacial layer of the MIS solar cells was seen to be a mixture of SnO and SnO_2. The high series resistance and low fill factor of the heterojunction cells can be attributed to changes in the chemical composition or electrical properties of the interface due to annealing.

An Electron Microscope Investigation of the Effect of Phosphorous Doping on the Plasma Etching of Polycrystalline Silicon

E. A. Irene,* E. Tierney,* J. M. Blum,* C. F. Aliotta, A. C. Lamberti, and B. J. Ginsberg

IBM Thomas J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

The effects of excess phosphorous on plasma etching of polycrystalline silicon were studied by SEM and TEM. The phosphorous levels were altered by the time duration of $POCl_3$ deposition, by the presence or absence of a phosphosilicate glass layer during high temperature treatments, and by using either an N_2 or O_2 drive-in anneal thereby causing the snow plow effect of oxidation to locally increase the phosphorous levels. Wherever the phosphorous levels were highest (at the poly-Si free surface or at grain boundaries), the extent of plasma etching was greatest. This etching effect was found to cause poly-Si line edge roughening.

The use of dry etching techniques such as plasma etching for delineation of polycrystalline silicon (poly-Si) is becoming widespread in the microelectronics industry. Basically, the plasma etching technique utilizes a fluorine-containing gaseous plasma, to form volatile products that are easily pumped away. It has been our experience that for the plasma etching technique to be described, the presence of phosphorous in the poly-Si greatly enhances the etch rate of poly-Si.

The purpose of the present study is to show definitive scanning electron microscopy (SEM) and transmission electron microscopy (TEM) evidence of the effects of heavy phosphorous doping on the morphology of poly-Si that has been exposed to plasma etching. From the SEM and TEM studies of the various process variables, cause and effect relationships are identified which enable the selection of processing steps that yield high quality delineation of heavily phosphorous-doped poly-Si.

Experimental Procedures

Sample preparation.—Commercially available high quality single crystal silicon wafers were used in this study. All films studied were deposited on the polished side of the wafer. All the poly-Si films were deposited via the decomposition of 100% SiH_4 at 625°C at a total pressure of 4.6×10^{-4} atm and a total flow of 45 sccm onto 90 nm of thermally grown SiO_2. The phosphorous doping was accomplished by $POCl_3$ deposition at 870°C using N_2 bubbled through $POCl_3$ liquid and added to a mainstream carrier of 10% O_2 in N_2. The resultant phosphosilicate glass (PSG) film was removed chemically using buffered HF (BHF). The drive-in anneal was done at 1000°C for 10 min in either O_2 or N_2. Any resulting oxide was removed in BHF. For delineation, a 100 nm CVD SiO_2 film followed by photoresist was deposited on the poly-Si. The photoresist was then exposed through a mask, the resist was developed, and the oxide was chemically removed. Using the resist and/or oxide as the mask, the plasma conditions for etching the $POCl_3$-doped low pressure CVD (LPCVD) poly-Si were set at 35W, 0.3 Torr at room temperature (~23°C) in an ambient of CF_4 + 8% O_2. The etch rate of the doped polysilicon is 850-900 Å/min. The etching time was adjusted for a 10% overetch when poly-Si lines were to be delineated. For the present study when it was desired to view a partially etched surface, a 1 min etch was used which removed about 40% of the 2500Å polysilicon film.

Electron microscopy.—Scanning electron microscopy (SEM) was performed on samples coated with a thin gold layer. Transmission electron microscopy (TEM) samples were thinned using mixtures of HF and HNO_3.

Results and Discussions

The phosphorous doping of poly-Si is accomplished using a $POCl_3$ deposition followed by a P diffusion drive-in. The $POCl_3$ deposition results in a layer of phosphosilicate glass, PSG, on top of the poly-Si. Typically, the PSG is chemically removed prior to a phosphorous drive-in anneal. The drive-in is done in either O_2 or a relatively inert ambient such as N_2 or Ar. If the drive-in is done in O_2, SiO_2 will form. It is known that the formation of SiO_2 causes the pile-up of phosphorous at the Si-SiO_2 interface (1, 2) or the so-called "snow plow" effect. The drive-in anneal in N_2 permits excess phosphorous to escape from the poly-Si by evaporation. Therefore, the O_2 anneal will result in more free phosphorous at oxidized grain boundaries and on the oxidized surface of the poly-Si than will the N_2 process.

Figure 1(a) shows the morphology of the poly-Si surface after a 30 min $POCl_3$ deposition and PSG strip.

* Electrochemical Society Active Member.
Key words: etching, deposition, anneal.

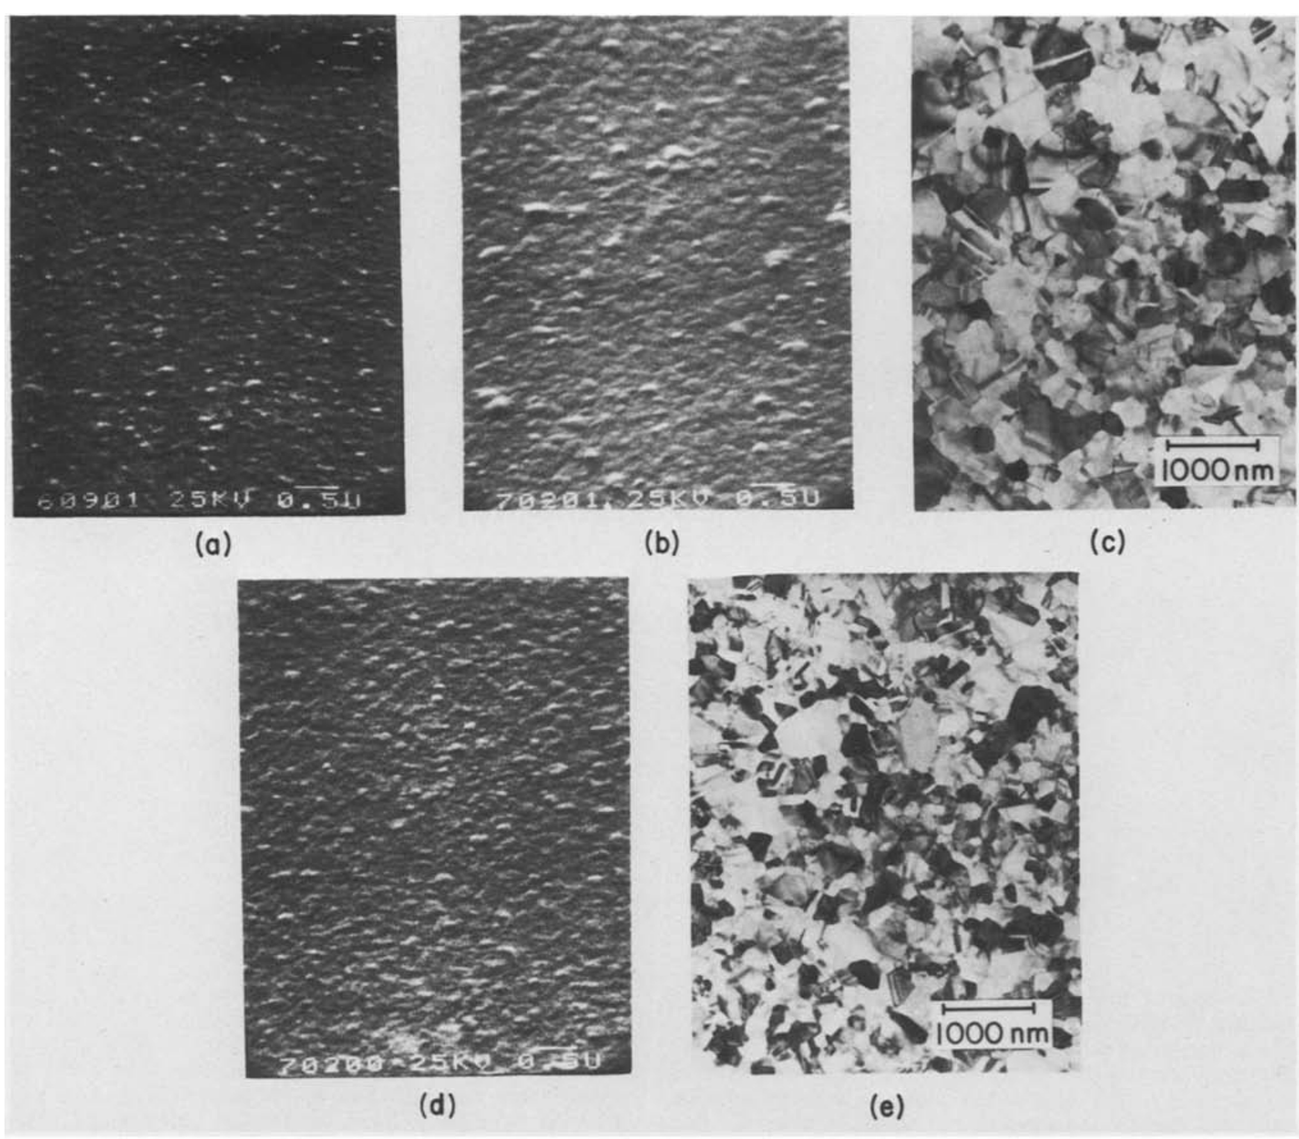

Fig. 1. (a) SEM of blanket poly-Si, 30 min $POCl_3$, PSG stripped; (b) SEM of sample in (a) plus O_2 drive-in and BHF strip; (c) TEM of sample in (a) plus O_2 drive-in and BHF strip; (d) SEM of sample in (a) plus N_2 drive-in and BHF strip; (e) TEM of sample in (a) plus N_2 drive-in and BHF strip.

The surface texture is due to the grain morphology (3). The remaining micrographs in Fig. 1 compare the O_2 and N_2 drive-in processes. It is seen that the samples are similar. However, closer examination reveals that the O_2 annealed sample has larger and more dramatically outlined grain boundaries. The larger sized grains are caused by the presence of more phosphorous which causes enhanced grain growth (3). The deeper grain outlines for the O_2 annealed poly-Si are due to the chemical etching (with BHF) of the oxide that formed intergranularly (3). Figure 2 shows the effect of partial plasma etching on the O_2 and N_2 annealed samples. The O_2 annealed sample shows both extensively roughened mid-grain regions and deeply etched grain boundaries. The etched grain boundaries are somewhat difficult to discern by SEM in Fig. 2(a) due to the rough surface texture but Fig. 2(b) using TEM clearly shows the thinned grain boundary regions. The intensity variation in Fig. 2(b) across individual grains is due to the surface roughness. The N_2 annealed, plasma-etched sample shown in Fig. 2(c) and (d) shows extensive grain boundary etching but the grain surfaces are smooth. Resistivity measurements of N_2 and O_2 annealed poly-Si samples show no differences in conduction behavior. Therefore, it is concluded that the drastic difference in etching behavior is related to excess electrically inactive phosphorous caused by the snow plow effect. The phosphorous accumulates in grain boundaries and at the grain-free surfaces and this effect is enhanced, since oxidation occurs at these surfaces and prevents escape of the excess phosphorous.

Based on these findings, it is likely that plasma etching will affect the quality of delineation of poly-Si into conducting lines. Therefore, in order to determine the extent of the line edge roughening, a series of experiments were performed using delineated poly-Si.

The effect of the total amount of phosphorous on line delineation is shown by comparing Fig. 3(a) and (b) with Fig. 4(a) and (b). The only processing difference between the two samples shown in these figures is that the sample in Fig. 3 received a 15 min $POCl_3$ deposition while that in Fig. 4 received a 30 min $POCl_3$ deposition. The resistivity of these films was 2.0×10^{-3} and 1.3×10^{-3} Ω-cm for the 15 and 30 min deposition conditions, respectively. The unmasked portion of both samples was extensively etched to exaggerate any etching effects. It is seen that the masked portion of the sample with 15 min $POCl_3$ has quite reasonable line edges; the unmasked portion appears somewhat jagged. The sample that received 30 min $POCl_3$ displays more jagged edges on both the masked and unmasked portions. The masked surface is rougher on the 30 min $POCl_3$ treated sample. This roughness is attributable to more extensive grain growth at the higher phosphorous levels

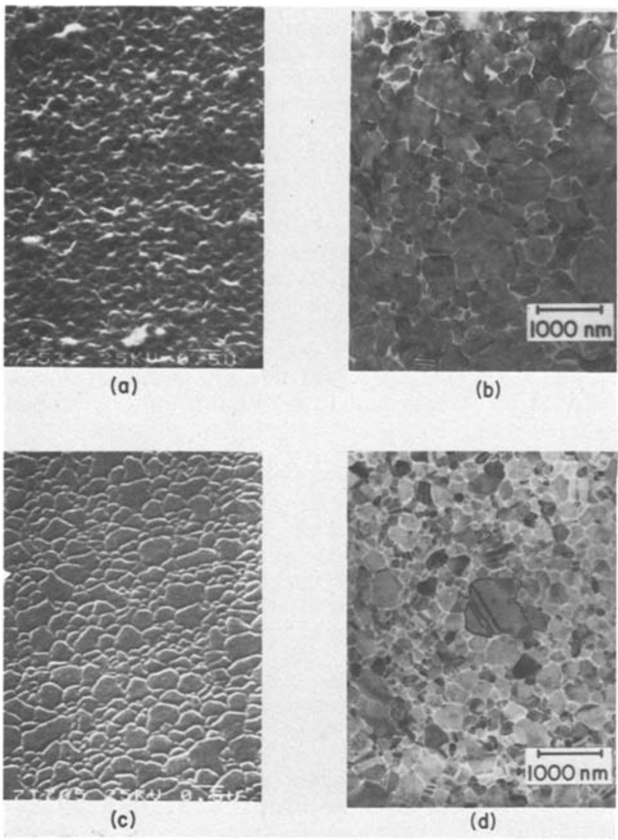

Fig. 2. (a) SEM of blanket poly-Si, 30 min $POCl_3$, PSG stripped, O_2 anneal, BHF strip, plasma etch; (b) TEM of (a); (c) SEM of sample same as (a) but N_2 anneal; (d) TEM of sample in (c).

while the unmasked side and the line edges of both sides are roughened by the plasma etching.

Although the PSG layer is usually removed after $POCl_3$ deposition, the presence of this film as both a capping layer and source of phosphorous is worth considering. Figure 5 compares 15 and 30 min $POCl_3$ doped samples processed with PSG in place. Both samples are considerably more roughened on masked and unmasked surfaces and at line edges. The masked areas of both samples show mound-like protrusions. These features are common but not always observed in this type sample and energy dispersive x-ray analysis (EDAX) shows no increased phosphorous associated with these features. TEM micrographs which follow (Fig. 6) display nothing relative to these features. Therefore, the protrusions are likely to be the result of extensive surface recrystallization where grains are tilted during growth. This explanation is consistent

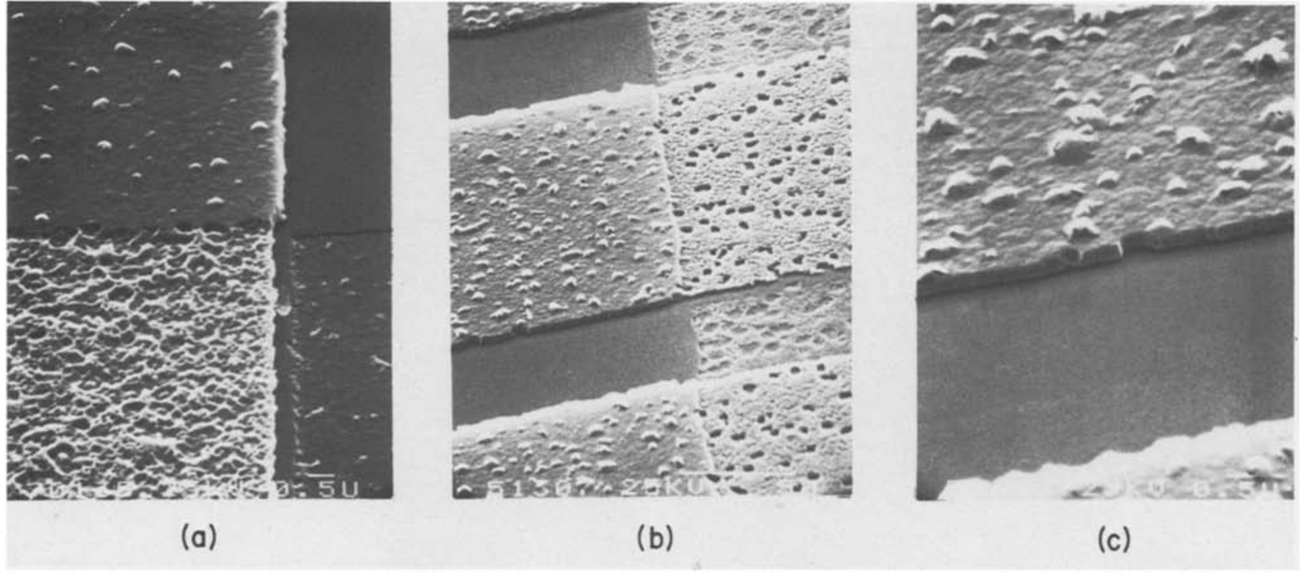

Fig. 5. (a) SEM of delineated poly-Si, 15 min $POCl_3$, PSG in place during O_2 anneal, BHF strip, CVD SiO_2 mask on one-half, plasma etch; (b) same as sample (a) but with 30 min $POCl_3$; (c) same as sample (b) higher magnification.

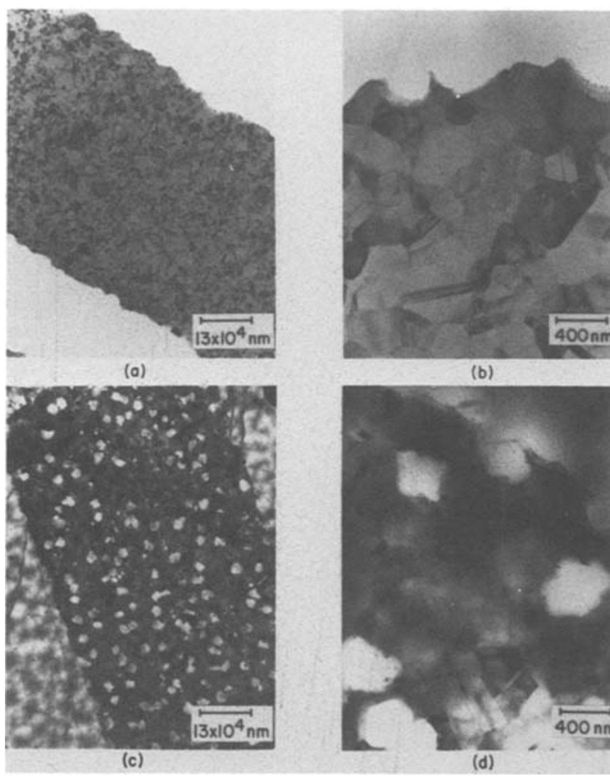

Fig. 6. TEM micrographs of 30 min $POCl_3$ doped poly-Si annealed with PSG in place of (a) masked, (b) the edge of (a), (c) unmasked, (d) the edge of (c).

with the observation that Si self-diffusion is enhanced in the presence of phosphorous (4). The appearance of jagged line edges and extensive etching of unmasked regions for both the 15 and 30 min $POCl_3$ doped samples processed with PSG in place demonstrates the importance of removing PSG prior to further processing. For the 30 min $POCl_3$ treated sample in Fig. 5(b), the shape of the line edge roughness seems to match the holes etched in unmasked midline areas. This suggests that entire grains or grain clusters are attacked by plasma etching.

In order to elucidate a possible relationship between the poly-Si grain structure and the edge roughness, TEM was used to observe these features for the 30 min $POCl_3$ samples treated with PSG in place. Figure 6(a) for the masked side shows the jagged line edges while the higher magnification of 6(b) shows that entire grains and groups of grains were removed from the line edge. Some grains at the line edges display curvature which develops during the plasma etching. Figures 6(c) and (d) show a similar sequence of micrographs for similarly etched lines after the mask was removed and the surface partially plasma etched. This treatment results in extensively etched areas within the poly-Si lines. From these micrographs, it is easily observed that the etched out areas both in the line and at the edge show the angularity associated with the etched out grain boundaries. The location of the removed grains appears to be random. At higher magnification it is also seen that the regions adjacent to the etched holes are thinned. Since the etch rate is quite strongly dependent on the amount of phosphorous present, and since there is likely a random distribution of excess phosphorous at grain boundaries, it is probable that the etching proceeds initially and most vigorously at these randomly distributed highly doped regions leaving a random distribution of holes.

Summary and Conclusions

It has been shown that the presence of excess phosphorous enhances the rate of plasma etching of poly-Si. In the present study, the phosphorous was altered in three ways: simply by the amount of time for the $POCl_3$ deposition, by the presence or absence of a PSG layer during high temperature anneals, and by drive-in anneals in either N_2, Ar, or O_2. The O_2 anneal causes oxidation and pile-up of phosphorous at oxidized surfaces. Whenever a processing step increased the local phosphorous levels at the poly-Si free surface and/or at grain boundaries, the extent of plasma etching was found to be greatest where the phosphorous levels were highest. These etching characteristics affected the poly-Si line edge quality and the quality could be enhanced by a proper choice of processing steps. In particular, those steps which prevented excessive phosphorous pile-up yielded superior poly-Si line edges.

Laser Damage Gettering and Its Application to Lifetime Improvement in Silicon

Y. Hayafuji, T. Yanada, and Y. Aoki

SONY Corporation Research Center, 174 Fujitsuka-cho, Hodogaya-ku, Yokohama 240, Japan

ABSTRACT

Lattice defects induced by laser irradiation and their thermal stability during subsequent oxidation were studied by transmission electron microscopy, x-ray topography, and preferential etching. High power laser pulses above 20 J/cm^2 produced dislocation lines and dislocation clusters. Laser pulses of about 15 J/cm^2 also generated dislocation clusters and pseudo-swirl defects in the irradiated region. All of these defects were thermally stable. However, thermally stable defects were not observed when laser pulses of less than 15 J/cm^2 were used, although unstable dislocations were generated. The suppression of defect formation by laser damage gettering was examined using Sirtl etching. It was found that thermally stable dislocations and pseudo-swirl defects acted as sinks for point defects and prevented the formation of precipitates during a subsequent oxidation. Laser damage gettering was used to improve generation lifetime in metal-oxide-semiconductor (MOS) capacitors with the result that generation lifetime in the gettered area was improved by two orders of magnitude over that in the ungettered area.

Much work has been reported on the effects of lattice defects on the electrical properties of silicon crystals and on the electrical characteristics of silicon devices. Precipitates, stacking faults, and dislocations induced during the manufacturing process act as generation-recombination centers for carriers (1-4) and degrade the electrical characteristics of p-n junctions (5-8). This degradation is especially noticeable in photosensitive mosaic devices such as CCD imagers where the defects produce generation sites responsible for bright spots and lines in video displays (9-13).

In recent years, one of the major aims of VLSI technology has been the fabrication of large area devices free of lattice defects. For this reason, efforts have been concentrated on the suppression of the formation of process-induced defects in silicon.

The effectiveness of back-side damage gettering in the reduction of process-induced defects has been reported (14-18). Back-side damage gettering uses lattice damage, which is capable of eliminating nuclei of defects and absorbing impurities during high temperature processing.

A number of methods of inducing dislocations for gettering have been proposed, for example, lapping, sand blasting, phosphorus diffusion, and ion implantation. The problem with these methods, however, is that very often the wafers are contaminated with abrasive particles or are subjected to thermal stress. To solve these problems, a method of gettering which we call laser damage gettering has been developed (19-22). Laser damage gettering utilizes laser irradiation damage to generate gettering sites where a variety of point defects, such as impurities and interstitials, gather. Technological advantages of this method are controllability and room temperature treatment for introducing gettering sites.

The purposes of the present work are: (*i*) to examine the lattice defects caused by laser irradiation and subsequent oxidation, (*ii*) to investigate the suppression by laser irradiation damage of defect formation, and (*iii*) to study the improvement of generation lifetime in silicon caused by laser damage gettering.

Experimental Procedure

Silicon wafers with (111) orientation, prepared from a p-type dislocation-free Czochralski-grown crystal with oxygen content of about 10^{18} cm^{-2}, were used. The doping impurity was boron and the resistivity range was 3-5 Ω-cm. Both surfaces of the wafer were mechanochemically polished. The wafers were about 300 μm thick and 50 mm in diameter.

Laser damage was induced on the rear surface of the wafer by Q-switched Nd:YAG laser pulses. The laser pulses were scanned in the [110] direction at a pitch of 500 μm and with a pulse spot overlap of about 65%. The laser had a CW output power of 5W in the TEM$_{00}$ mode ($\lambda = 1.06$ μm). The pulse repetition frequency was 10 kHz, the pulse duration time was 150 nsec, and the spot size of the pulses was about 40 μm. The amount of laser damage induced can be controlled in two ways: one, by varying the pitch of the scanning laser beam and the amount of overlap between spots; and two, by changing the energy density of the laser pulses. In this experiment, the latter method was applied with an energy density from 1630 to 5 J/cm^2. The energy density was set by moving the samples out of the focal plane and by using an attenuator with an analyzer and a polarizer. Wafers were irradiated on the back surface with laser pulses with an energy density over 30 J/cm^2 and on the front surface outside the active area with laser pulses with an energy density below 30 J/cm^2. After irradiation, some of the samples were oxidized in a dry oxygen ambient at 1200°C for 1 hr so that the thermal stability of the laser damage could be examined and so that the suppression of defect formation by laser damage could be studied.

In order to study the improvement of generation lifetime through laser damage gettering, metal-oxide-semiconductor (MOS) capacitors were fabricated as follows. Silicon wafers were irradiated by laser pulses of 1630 J/cm^2 on half of the back surface at a pitch of 500 μm. After irradiation, chemical vapor deposition of silicon-dioxide 8000Å thick was carried out at 420°C to make a diffusion mask. A channel-stop region was formed by boron diffusion in wet oxygen at 1000°C for 30 min. Gate oxidation was carried out in wet oxygen at 1000°C for 30 min, followed by annealing in dry nitrogen for 10 min. After aluminum deposition for electrodes, the capacitors were annealed in dry nitrogen at 400°C for 1 hr. MOS capacitors 1.5 mm in diameter with a silicon-dioxide layer 1500Å thick were then fabricated. In high temperature processes above 900°C, slow insertion and slow retraction of wafers

Key words: defects, capacitor, etching, semiconductor, topography.

into and out of furnaces were carried out to heat and to cool the wafers at a rate of about 3°C/sec to avoid dislocation propagation to the front surface.

The capacitance-time curve (transient response) of the MOS capacitors was measured by applying a step input of 15V to the gate electrode at 1 MHz. Generation lifetime t_g was determined from the transient response using the equations derived by Heiman (23).

Lattice defects caused by laser irradiation were examined by transmission electron microscopy (TEM), x-ray topography, and preferential etching. TEM samples about 1 μm thick were prepared by chemical thinning.

Results and Discussion

Lattice defects caused by laser irradiation.—TEM study of the as-irradiated samples established that lattice defects occurred in the samples irradiated by laser pulses with an energy density higher than about 8 J/cm^2 and that these defects could be classified into three types of configuration. We later found that these three types of configuration were indicative of the configuration of the dislocations they contained. Figures 1a, b, and c are transmission electron micrographs taken of samples exposed to laser pulses of 10, 15, and 22 J/cm^2, respectively, and show the three types of defect configurations produced by laser irradiation at these three different energy densities. In Fig. 1a, the defects were distributed generally over the periphery of the melted area. We compared the TEM images from different diffraction planes and found that the defects were small dislocations.

In addition to these dislocations, defects of a second type were generated in the samples irradiated by laser pulses of about 15 J/cm^2, as can be seen in Fig. 1b. This second type of defect grew in fanlike clusters and was also determined by TEM analysis to be dislocations. These fanlike clusters are termed "dislocation clusters." In every trace of a laser spot, dislocation clusters appeared only in the $[\bar{1}2\bar{1}]$ direction. Stereoscopic observation showed that dislocation clusters lay in the $(\bar{1}1\bar{1})$ plane. Contrast analysis of the TEM images revealed dislocation clusters composed of dislocations with a Burgers vector of **a**/2 [110], running close to the [011] direction, and dislocations with a Burgers vector of **a**/2 [101], running very close to the [110] direction, as can be seen in Fig. 2.

We might expect from these results that dislocation clusters could be generated on any {111} plane which approximately coincides with the melt front and we confirmed that the dislocation clusters were, in fact, formed on the $(\bar{1}1\bar{1})$, $(\bar{1}\bar{1}1)$, and $(1\bar{1}\bar{1})$ planes which lay in the $[\bar{1}2\bar{1}]$, $[\bar{1}\bar{1}2]$, and $[2\bar{1}\bar{1}]$ directions, respectively. Dislocation clusters did not appear on the $(\bar{1}\bar{1}1)$ and $(1\bar{1}\bar{1})$ planes in Fig. 2 because they were annihilated by the remelting caused by the following pulse.

A third type of defect was observed after irradiation at a pulse energy density of about 22 J/cm^2. Defects of this type were long dislocation lines running along the scan direction of the laser pulses, that is, the $[1\bar{1}0]$ direction and lying on the (111) plane parallel to the wafer surface. These defects had a Burgers vector either of **a**/2 [110] or of a **a**/2 [101]. At higher energy densities than 22 J/cm^2, most defects observed were dislocations of this third type, although laser grooves in excess of 1 μm depth were formed. Only a few of these dislocations were entangled.

TEM observations of the three types of defects after oxidation at 1200°C for 1 hr gave the following thermal stability results. Dislocations of the first type were found to be thermally unstable. After oxidation, there remained no trace of dislocations in the transmission electron micrographs taken of the samples irradiated by 10 J/cm^2 pulses, which suggests that dislocations of this type were completely annealed out of the surface.

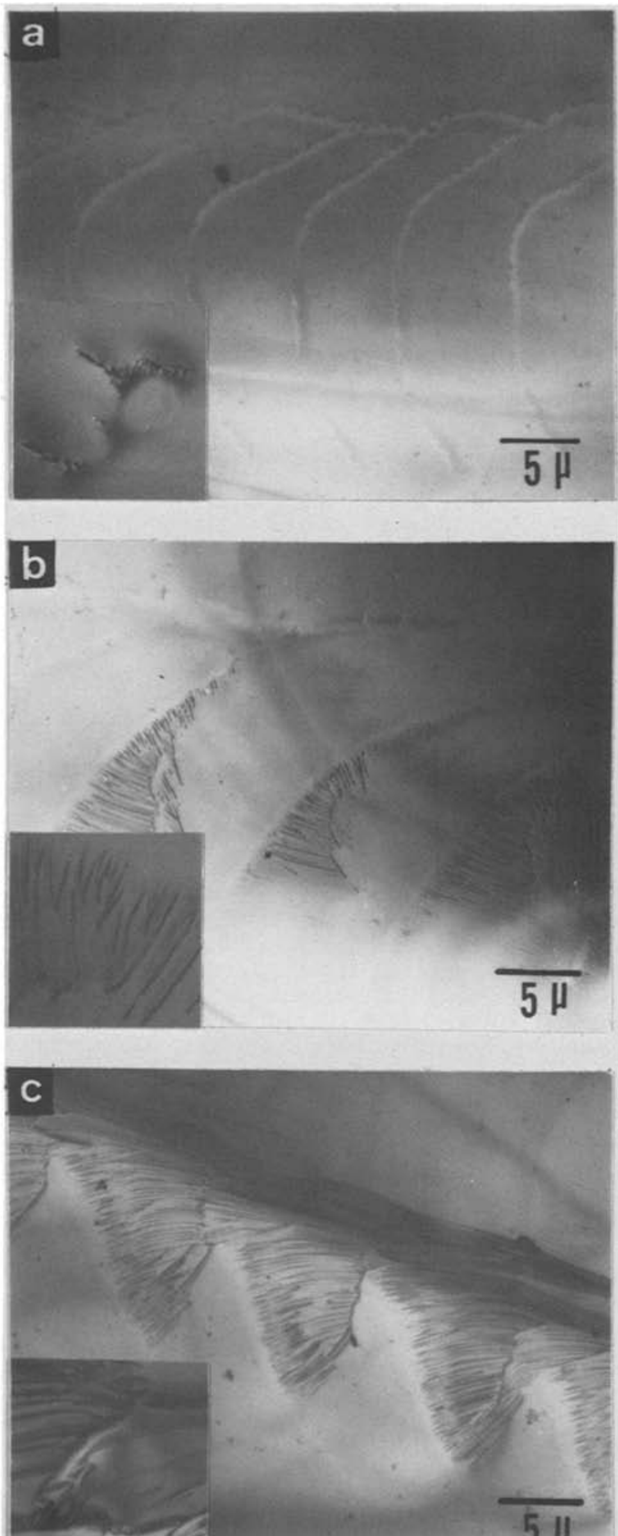

Fig. 1. Transmission electron micrographs showing dislocations induced at laser pulses with an energy density of: a, 10 J/cm^2; b, 15 J/cm^2; and c, 22 J/cm^2.

Some dislocations of the second type proved to be thermally stable because a small part of every dislocation cluster near the bottom of the melted region remained when the other part of the dislocation cluster closer to the surface had been annihilated, as can be seen in Fig. 3a. Figure 3a also shows that oxidation-induced precipitates were generated on dislocations and on other sites. Figures 3b and c are magnified views of the areas marked "d" and "s," respectively,

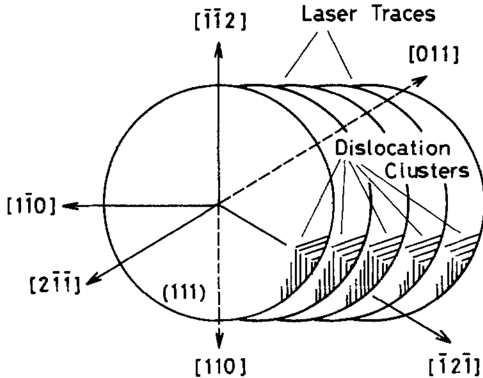

Fig. 2. Position of dislocation clusters

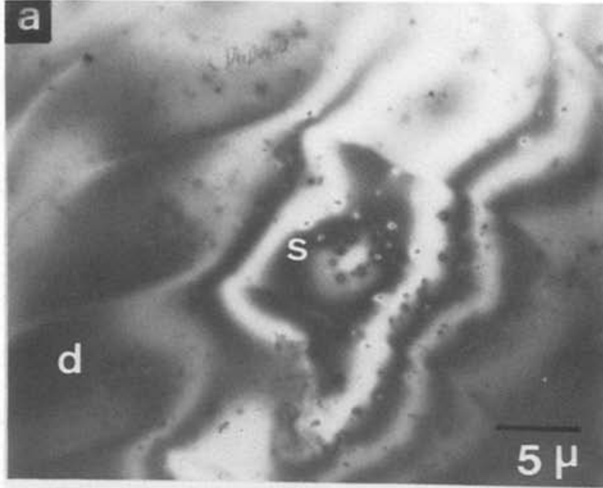
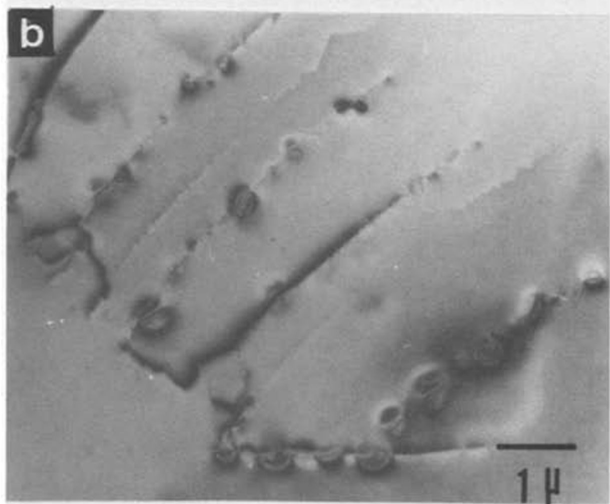
in Fig. 3a. Figure 3b shows that dislocations act as nucleation sites for the precipitates. In Fig. 3c, however, it is not clear what defect the nucleation sites of the precipitates are. These as yet undefined sites may be undetectable microdefects induced by laser irradiation. These microdefects may be clusters of self-interstitials generated during recrystallization after irradiation which are analogous to swirl defects in bulk silicon. For this reason we call these sites "pseudo-swirl defects."

Dislocations of the third type were also thermally stable. Some of these dislocations moved far from the laser grooves and formed networks during subsequent oxidation, as can be seen in the x-ray topographs of Fig. 4. Detailed study using the Secco etching technique showed in the cross section of the sample that dislocation propagation through the wafer toward the undamaged surface did not occur, but stopped two thirds of the way to the wafer surface. Dislocation movement caused by laser damage will be discussed in a separate paper.

Suppression of defect formation by laser damage gettering.—In the previous section, we noted that two types of thermally stable dislocations induced by laser irradiation exist, that is, dislocations which compose a dislocation cluster and dislocations parallel to the scan direction of the laser pulses. Pseudo-swirl defects were also thermally stable. We established that these thermally stable defects act as gettering sites for point defects and suppress the formation of oxidation-induced precipitates outside the irradiated region during subsequent oxidation by examining, using the Sirtl etching technique, the ability of laser damage to getter oxidation-induced precipitates. When low power laser pulses were used, the wafers were irradiated by laser pulses with 10 and 15 J/cm^2 energy density on the front surface and then oxidized at 1200°C for 1 hr in a dry oxygen ambient. An example of laser damage gettering is exhibited in Fig. 5. Many etch pits of oxidation-induced precipitates, of which composition and structure were not determined by TEM, appeared on the front surface of the wafer without irradiation, as can be seen in Fig. 5a. In Fig. 5b, it can be seen that etch pits also appear with traces of laser pulses of 10 J/cm^2 energy density and that there has been no gettering effect in this wafer. In Fig. 5c, however, it can be seen that there are no defects in the wafer irradiated with 15 J/cm^2 pulses, only traces of laser pulses. We can therefore say that laser damage caused by laser pulses with an energy density of 15 J/cm^2 or more is essential for laser damage gettering.

In another experiment very high power laser pulses were used. Pulses with an energy density of 1630 J/cm^2, for example, were scanned on half of the back surface at a pitch of 500 μm. The wafer was then oxidized at 1200°C for 1 hr. Figure 6 is a set of optical micrographs taken of the front and the back surfaces after Sirtl etching for 3 min. The optical micrograph





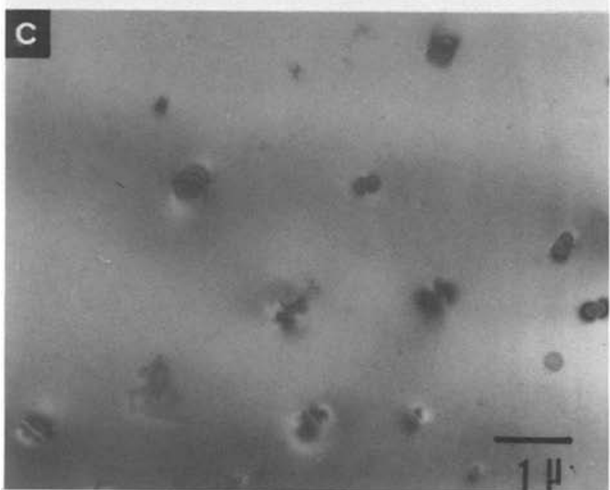


Fig. 3. Transmission electron micrographs of sample oxidized after irradiation by 15 J/cm^2 pulses. Fig. 3b and c are magnified views which correspond to d and s in Fig. 3a, respectively.

of the front surface shows that the two halves are different. The upper half corresponds to the nondamaged area of the back surface and appears bright because of the scattering of the light by irregularities on the surface. This brightness indicates the existence of oxidation-induced precipitates. The lower half is black, indicating that no lattice defects were formed. We confirmed that laser damage caused by 1630 J/cm^2 pulses on the back surface prevents defect formation near the front surface, as was the case with laser pulses of 15 J/cm^2 energy density.

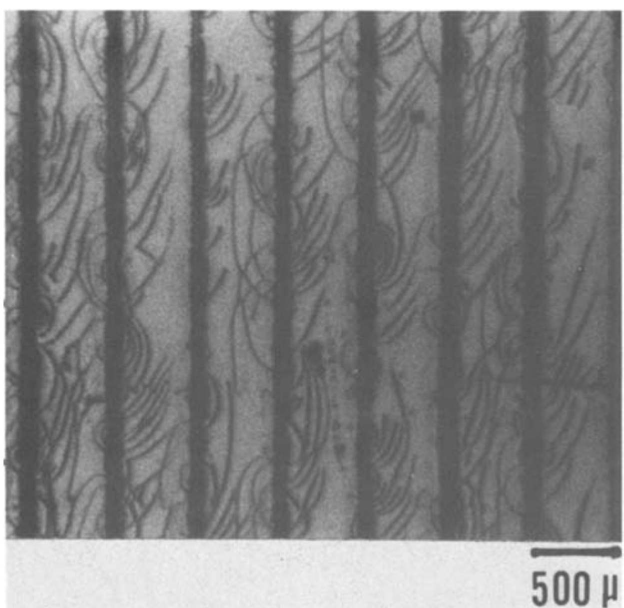

Fig. 4. X-ray topographs taken of oxidized wafer irradiated by 1630 J/cm^2, showing that dislocations moved far from the laser grooves and formed networks.

On the basis of these observations, the following gettering mechanisms are proposed. When a wafer is irradiated by low-power laser pulses, the near-surface region of the wafer melts. The melt front moves rapidly into the crystal. In the recrystallization of a melt caused by 15 J/cm^2 pulses, dislocations are generated to relieve thermal stress at glide planes so that maximum shear stress occurs. In addition, clusters of self-interstitials supersaturated in the cooling process grow to be pseudo-swirl defects. These dislocations and pseudo-swirl defects are thermally stable so these defects interact with point defects during subsequent oxidation and act as sinks for point defects. The effect of laser damage gettering at low energy is explained by this mechanism, which is illustrated in Fig. 7. In wafers irradiated by laser pulses less than 15 J/cm^2, the maximum depth of the melt front is shallow. In this case the wafers were not heated long enough to induce thermally stable defects, so gettering is not efficient.

When a wafer is irradiated by high-power laser pulses, thermally stable dislocations are generated around the laser grooves and propagate into the bulk during oxidation to relieve the stress induced by irradiation. These dislocations act as gettering sites for point defects to suppress defect formation. A schematic view of this mechanism is shown in Fig. 8.

Improvement of generation lifetime through laser damage gettering.—Although it is well known that controlled damage on the back surface of the wafer can improve generation lifetime by removal of point defects such as undesirable impurities, it has not been established that laser damage gettering specifically improves generation lifetime.

Results summarizing the effect of laser damage gettering on generation lifetime are plotted in Fig. 9. The generation lifetime in the gettered area was improved by about two orders of magnitude over that in the ungettered area. Generation lifetime in the gettered area tended to level off at about 10^3 μsec. The plots in the ungettered area, however, were spread between 1 and 100 μsec. To investigate the reason for the improvement of the lifetime, the surface of the wafer was preferentially etched using the Sirtl etching technique after removal of the MOS capacitors. It was found that lifetime improvement was caused by the

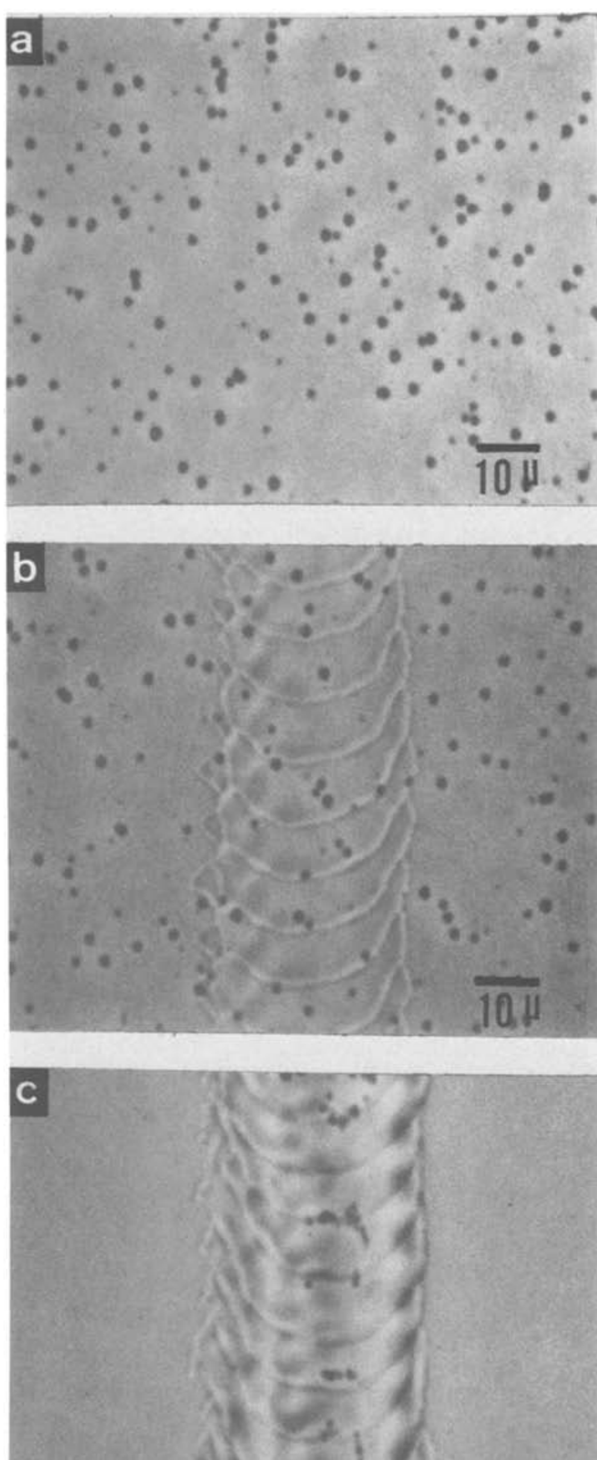

Fig. 5. Etch patterns of the oxidized samples: a, without irradiation, and b and c with irradiation by 10 and 15 J/cm^2, respectively.

suppression of defect formation by laser damage gettering.

To evaluate the electrical activity of the defects in the ungettered area, the reciprocal of generation lifetime $1/t_g$ was plotted against the density d of defects in Fig. 10. The graph shows that the value of $1/t_g$ is nearly proportional to defect density d. Therefore, $1/t_g$ can be expressed by

$$1/t_g = k \cdot d + 1/t_o$$

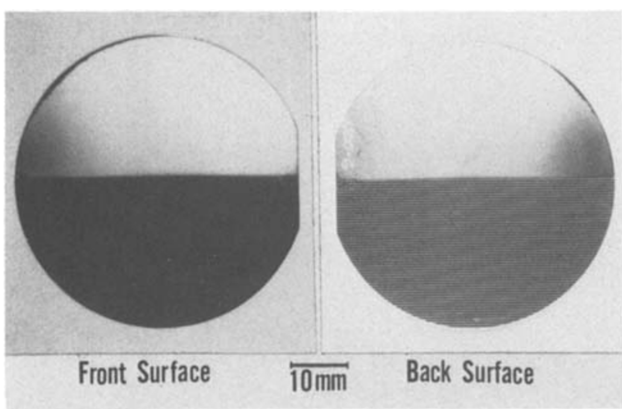

Fig. 6. Optical micrographs of wafer oxidized after irradiation by 1630 J/cm², showing laser damage gettering suppression of defect formation.

where k is the proportional constant which defines the electrical activity of defects expressed in $cm^2/\mu sec$ and t_0 is background generation lifetime expressed in μsec (24). The constant k had a value of 2×10^{-6} in Fig. 10.

Conclusion

A method of gettering, which we call laser damage gettering, has been developed to suppress the formation of lattice defects and to improve generation lifetime in silicon. This method utilizes laser irradiation damage as gettering sites for a variety of point defects, such as impurities and self-interstitials. Summarizing the data, the following conclusions can be drawn.

1. High-power laser pulses above 20 J/cm^2 produced thermally stable dislocation lines and dislocation clusters and low-power laser pulses of about 15 J/cm^2 also generated stable dislocation clusters and pseudo-swirl defects in the irradiated region. However, no generation of thermally stable defects was observed in the case of laser pulses of power lower than 10 J/cm^2.

2. Thermally stable lattice defects acted as sinks for point defects during subsequent oxidation. Laser damage gettering prevented the formation of oxida-

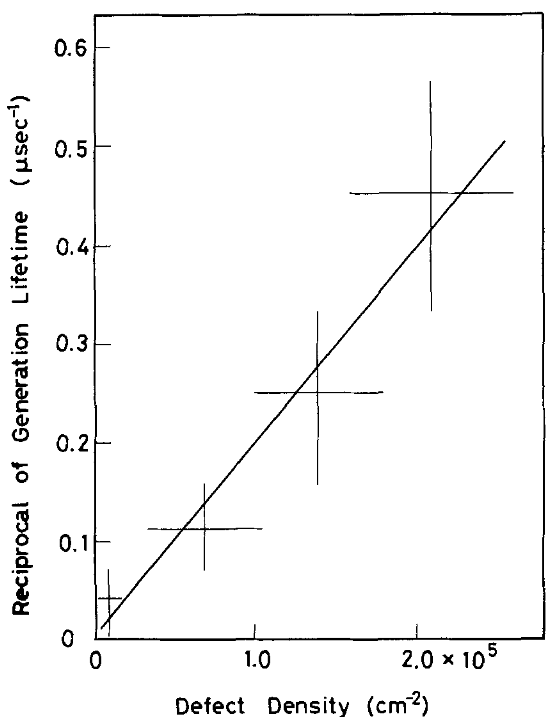

Fig. 10. $1/t_g$ vs. d curve. The tangent of this curve indicates the electrical activity of defects.

tion-induced precipitates. An energy density of at least 15 J/cm^2 was necessary to produce the laser damage which produced effective gettering.

3. Laser damage gettering improved generation lifetime in the gettered area by two orders of magnitude over generation lifetime in the ungettered area. This lifetime improvement was caused by the suppression of defect formation by laser damage gettering.

Single Crystal Silicon-on-Oxide by a Scanning CW Laser Induced Lateral Seeding Process

H. W. Lam, R. F. Pinizzotto,* and A. F. Tasch, Jr.*

Texas Instruments Incorporated, Central Research Laboratories, Dallas, Texas 75265

ABSTRACT

A 1 μm thick layer of silicon dioxide is grown on selected areas of a {100} silicon wafer such that the resulting silicon dioxide surface is coplanar with the surface of the silicon wafer. A 0.5 μm thick layer of polycrystalline silicon is deposited onto the silicon wafer using a low pressure CVD process. By scanning a focused CW argon laser beam onto the area where the polycrystalline silicon is deposited directly on the exposed silicon substrate, the polycrystalline silicon is converted into an epitaxial layer by a liquid phase process. By scanning the laser beam from the epitaxial region to the region where the polycrystalline silicon is deposited on the silicon dioxide layer, the polycrystalline silicon is converted into a single crystal through a zone melting process, where the previously formed epitaxial layer is used as the seed. This process is named "lateral seeding." It is found that the resulting area of the single crystal on the silicon dioxide layer is dependent on the temperature of the substrate and the crystallographic direction of the edges of the oxide layer. The best results are obtained with a high substrate temperature and with the edges of the oxide layers aligned along a <100> direction. Single crystal regions that extended as much as 80 μm from the epitaxial seed region onto the silicon dioxide region have been obtained. It is inferred from the experimental results that a line-shaped beam with a flat intensity profile is preferred for improved lateral seeding results.

Silicon on an insulating substrate (SOI) is an attractive material structure for high speed and high density integrated circuit application. An insulating substrate provides dielectric isolation between devices, so that they can be packed more closely together. The insulating substrate becomes increasingly important in CMOS by eliminating latch-up between devices. The insulating substrate further reduces the parasitic capacitances between devices and interconnecting metal or polycrystalline silicon lines, thus increasing the speed of the circuit. Since the active volume of silicon used in SOI is limited to that in the device islands, the susceptibility of the circuits to α-particles is greatly reduced. The most commonly used SOI material structure is silicon-on-sapphire (SOS) where the silicon epitaxial layer is grown on a sapphire substrate using conventional CVD techniques.

Recently, several laser recrystallization techniques for obtaining large grain SOI were demonstrated. Gat *et al.* (1) demonstrated that by scanning a focused laser beam on the surface of an LPCVD polycrystalline silicon (polysilicon) layer deposited on a thin silicon nitride (nitride) layer on a silicon substrate, very large grain crystallites, typically 2 $\times$ 20 μm, can be obtained. The orientation of the crystallites is random with a slight preference for {111} (2). Gibbons *et al.* (3) developed a technique for laser recrystallization of polysilicon islands on a nitride substrate. The polysilicon layer is deposited on the nitride using a standard LPCVD technique. The polysilicon islands are defined photolithographically and then formed by etching. For narrow (2 μm wide) islands, {100} single crystal has been obtained. Larger single crystal islands have been subsequently obtained with random orientations (4). Using a scanning laser beam induced graphoepitaxy technique, Geis *et al.* (5) obtained a uniformly oriented silicon film on a quartz substrate with a surface relief grating structure. Several reports of MOSFET devices fabricated in the laser recrystallized silicon-on-insulator material have demonstrated that the surface electron mobility measured in these devices is as good as or better than those obtainable in SOS (6-12).

Except for the graphoepitaxy approach, control of the resulting orientation of the recrystallized silicon film is not possible. The fact that the grains in the laser recrystallized film are randomly oriented can probably account for the variability in the characteristics observed in devices fabricated in the laser recrystallized SOI material (11).

A silicon bridging epitaxy technique using a Q-switched, pulsed ruby laser annealing (13) was demonstrated where lateral growth of single crystal silicon over silicon dioxide (oxide) was initiated from the single crystal substrate. However, the lateral growth was limited to 1.2 μm beyond the oxide edge. This limited extent of the growth stems from the inability to control the resolidification process with the pulsed laser. Since the lateral growth technique is equivalent to the zone melting process, the control of the melt zone and the melt/solid interface is of paramount importance.

We have developed a method for obtaining large area, controlled orientation, single crystal silicon on a one micron thick oxide substrate using a scanning CW laser induced lateral seeding process involving a microzone melting technique. In this technique, silicon dioxide is grown in selected areas of a silicon substrate and polysilicon is deposited onto the surface of the entire wafer. By scanning a focused CW laser beam onto the polysilicon-on-silicon region, epitaxial growth is induced in the polysilicon layer. When the laser beam is scanned from the epitaxial region to the polysilicon-on-oxide region, single crystal growth is induced in the polysilicon by a melting and recrystallization process, where the previously formed single crystal epitaxial layer provides the seed (Fig. 1). This process is called "lateral seeding."

Sample Preparation

Single crystal silicon wafers of {100} orientation were used as the substrate. A 140 nm thick layer of CVD silicon nitride was deposited onto the surface of the wafers. Photoresist was applied to the surface of

* Electrochemical Society Active Member.

Key words: silicon-on-insulator, zone melting, laser induced epitaxy.

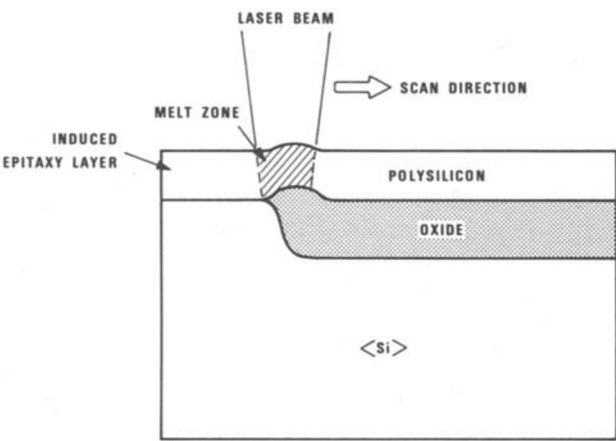

Fig. 1. Schematic representation of the lateral seeding process

the nitride layer and rectangular patterns of various sizes were defined photolithographically. After developing and baking the photoresist, the exposed nitride regions were removed by a plasma etching technique. A 0.55 μm thick layer of the then exposed silicon was removed by an anisotropic plasma etch. After removing the photoresist, the wafers were placed in an oxidation furnace set at 1000°C with a steam ambient, timed to grow a one micron thick layer of oxide, so that the oxide surface was almost coplanar with the original silicon surface. After etching the wafers in a 10% HF solution for 90 sec, the nitride layer was removed by etching in hot phosphoric acid. The wafers were then etched in a 10% HF solution for 30 sec, dried, and loaded immediately into a low pressure CVD reactor, where a 0.5 μm thick layer of polysilicon was deposited at 620°C. A thermal anneal in nitrogen at 1100°C for 1 hr completed the preparation. It was shown that the 1100°C anneal significantly reduces the "etching" (removing the polysilicon from the surface of the insulator) of the polysilicon during the laser recrystallization process (6). Without this thermal annealing step, the proper beam power window for the recrystallization of the polysilicon-on-oxide region is typically ±0.5W. Furthermore, the beam power for proper liquid phase regrowth of the polysilicon-on-silicon region is higher than the beam power for the recrystallization of the polysilicon-on-oxide region due to the higher thermal conductivity of the polysilicon-on-silicon region. Consequently, a beam power level chosen to induce epitaxial regrowth in the polysilicon-on-silicon region will be excessive for the recrystallization in the polysilicon-on-oxide region and will usually result in the removal of the polysilicon from the oxide surface. The thermal annealing widens the window of beam power for proper recrystallzation of the polysilicon-on-oxide area to ±3W. The exact mechanism is not presently understood. This thermal annealing step allows the utilization of a single beam power level to be used for both regions simultaneously.

The finished structure is shown in Fig. 2. A step-like oxide substrate was also produced by growing a layer of oxide on a silicon wafer, etching away part of the oxide, and depositing a layer of polysilicon, resulting in a structure shown in Fig. 3.

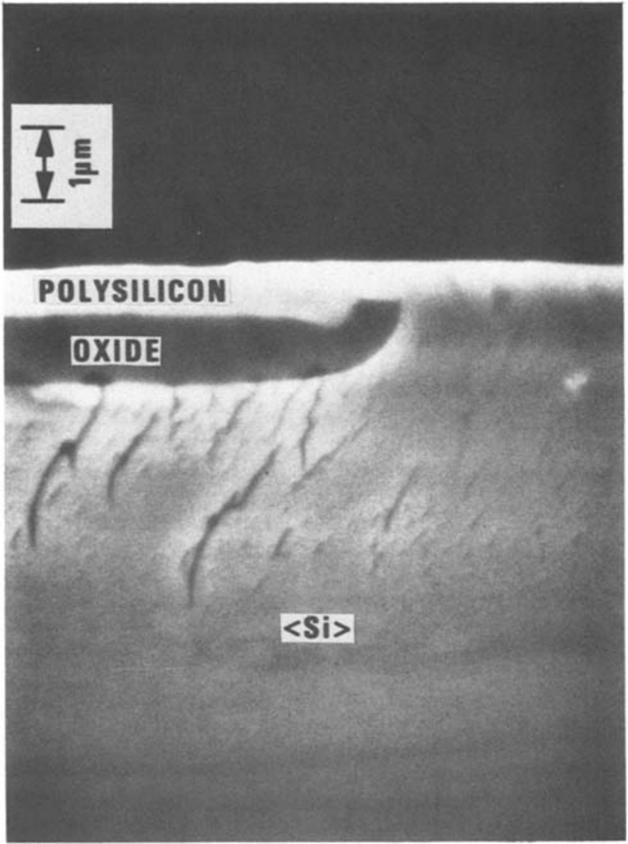

Fig. 2. Cross-sectional electron micrograph of the finished structure. The oxide layer is 0.96 μm thick. The polysilicon layer is 0.5 μm thick. The lines below the oxide region are artifacts of the sample preparation.

Laser Processing

The laser-induced recrystallization was performed with a CW argon ion laser system similar to the one described in Ref. (14). Two different lens systems, a single 190 mm focal length spherical lens and a combination of a 300 and a 100 mm focal length cylindrical lenses, were used. Most experiments discussed were performed with the spherical lens. The raster line scan speed was 10.4 cm per sec and the line-to-line step size varied from 5 to 20 μm. The wafers were mounted such that the lines were scanned parallel and perpendicular to the oxide and single crystal substrate interface. The wafers were held with a vacuum chuck and were heated to a temperature as high as 500°C.

The wafers were studied by optical microscopy, using a Secco etch (15) to decorate the grain boundaries and defects. We have compared the grain boundary patterns observed after Secco etching with TEM studies of the recrystallized SOI material and determined that the pattern obtained after Secco etching is a true representation of the grain structure. Electron channeling was used to study the crystallographic orientation of the laser recrystallized silicon-on-oxide material.

Results and Discussion

An optical interference contrast micrograph of a typical laterally seeded silicon-on-oxide area is shown in Fig. 4. The wafer was etched in a Secco etch for 10 sec to decorate the grain boundaries. It is generally observed that when the silicon-on-oxide area is small, such as the smaller squares at the bottom of the pic-

Fig. 5. Rutherford backscattering spectra of the arsenic-implanted polysilicon-on-silicon. The arrow in the figures indicates the polysilicon surface.

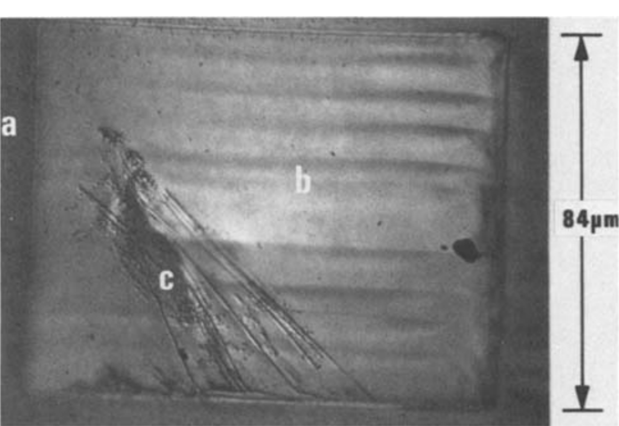
ture, no grain boundaries are observed, indicating that the silicon layer is a single crystal. For the silicon-on-oxide areas that are larger in size, large single crystal regions that are free of grain boundaries are obtained immediately adjacent to the epitaxial regions, but the entire silicon-on-oxide region is not of one orientation.

The laser scan lines are also evident in Fig. 4. It is interesting to note that the single crystal region extended over three successive scan lines, indicating that the single crystal silicon-on-oxide area formed during the first scan served as the seed for the growth during the subsequent scans. Therefore, the single crystal area indeed propagated laterally, using the previously formed single crystal as the seed.

It should also be noted that the smaller square oxide substrates had been displaced from their original position. The displacement is always in the direction of scan of the beam. This displacement is probably caused by the melting of the silicon substrate during the laser process. If the recrystallized layer were to be used for device application, the displacement would cause severe difficulties in placing the device in the SOI region. By measuring the redistribution of implanted dopant after the laser process, we have confirmed that the epitaxial growth in the polysilicon-on-silicon region was induced through the liquid phase. In one wafer, arsenic was implanted into the polysilicon layer at 90 keV to a dose of 5×10^{15} cm^{-2}. The wafer was laser-recrystallized at power levels ranging from 7 to 15W, using conditions similar to those described earlier. Rutherford backscattering spectroscopy was performed in the polysilicon-on-silicon region before and after the laser process and the results are shown in Fig. 5. A very strong segregation of the arsenic was observed at the surface of the laser-recrystallized epitaxial layer, indicating that melting had occurred. As the molten region regrew epitaxially, the implanted arsenic was segregated out at the surface by a process similar to zone refining (16). Furthermore, the arsenic could be detected as far as 2 μm into the substrate, indicating that melting occurred beyond the polysilicon-silicon interface and the epitaxial growth proceeded in the liquid phase. Since the thermal conductivity in the polysilicon-on-oxide region is lower than that in the polysilicon-on-silicon region and over 99% of the laser power is absorbed in the 0.5 μm thick polysilicon layer, the polysilicon on the oxide substrate is, therefore, also melted by the beam at these power levels.

Figure 4 shows a high etch pit density in the epitaxial region while the etch pits are only sparsely distributed in the single crystal on oxide area. This indicates that the beam power optimized for the silicon-on-oxide region is not optimized for the silicon-on-silicon region and results in damage in the epitaxial layer. Electron channeling experiments which have a resolution of about 2 μm were performed and a typical result is shown in Fig. 6a and b. By focusing and rocking a 40 keV electron beam in the laser-recrystallized polysilicon-on-silicon region, a distinct electron diffraction pattern is observed, indicating that the polysilicon has regrown epitaxially on the single crystal substrate. By moving the beam so that the single crystal silicon-on-oxide area was illuminated, a distinct electron diffraction pattern is again obtained. Furthermore, this diffraction pattern indicates that the single crystal silicon-on-oxide area has the same orientation as the substrate.

The behavior of the silicon crystal growth in the lateral seeding process can be understood with the aid of Fig. 7-9. Figure 7 shows a schematic representation



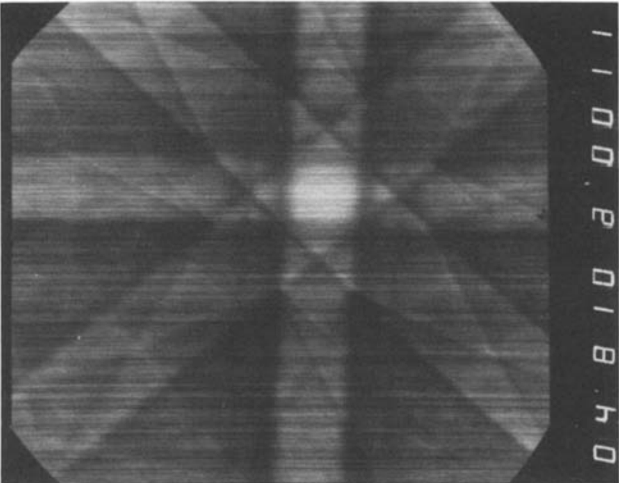


Fig. 6. (a, top) shows an optical interference contrast micrograph of a polysilicon-on-oxide region after the laser process. The electron diffraction pattern shown in b (bottom) is obtained when regions a and b in Fig. 6a are illuminated with the electron beam. Region a is the polysilicon-on-silicon epitaxial layer and region b is the polysilicon-on-oxide which has been converted to single crystal by the laser. The bulging region indicated by "c" is clustered with defects and no electron diffraction pattern is obtained at region c. The rectangular silicon-on-oxide region is 107 μm long × 84 μm wide.

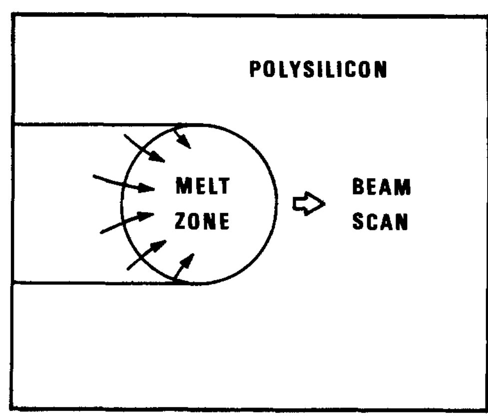

Fig. 7. Schematic representation of a top view of a laser beam scanning over a polysilicon-on-oxide region. The beam induces a zone of molten silicon, which travels as the beam is moved. The molten silicon cools and crystallizes at the trailing edge of the molten zone. The arrows in the diagram indicate the thermal gradient and therefore the directions along which the crystals will grow.

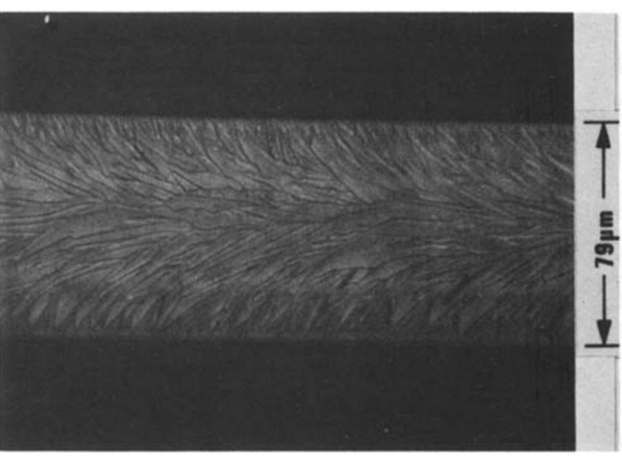

Fig. 8. An optical interference contrast micrograph of a polysilicon-on-oxide region after it is recrystallized by a single scan of the focused laser spot at 13W and then etched in a Secco etch for 10 sec. The laser beam scans from left to right. The chevron-shaped crystals are evident. The width of the recrystallized region is 79 μm.

of a laser beam scanning over a polysilicon-on-oxide region. The silicon region illuminated by the laser beam is melted, forming a small, localized molten zone of silicon on the oxide. As the beam is scanned, the silicon near the trailing edge of the beam cools rapidly. As the molten silicon recrystallizes, it is seeded from the silicon immediately adjacent to the molten zone. Furthermore, the grains grow in a direction normal to the isotherms, namely, in the direction of the thermal gradient which points toward the center of the beam. This is responsible for the chevron-shape grain structure observed (1) (Fig. 8).

The lateral seeding process is represented in Fig. 9. When a laser scan line represented by I is scanned parallel to an interface between a silicon substrate and an oxide layer, with more than 50% of the beam overlapping the oxide layer, the grain growth at the edge of the oxide layer will be seeded by the epitaxial layer. Because of the higher thermal conductivity in the polysilicon-on-silicon region, the epitaxial layer in the region solidifies earlier than the polysilicon-on-oxide region (13). Therefore, the molten silicon on the edge of the oxide layer is seeded with a single crystal epitaxial region and the single crystal propagates into the oxide region along the thermal gradient, as indicated in Fig. 9. The grain growth from the bottom half

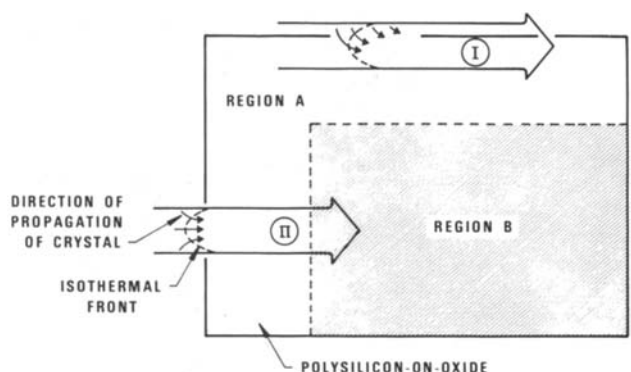

Fig. 9. Schematic representation of lateral seeding. The polysilicon-on-oxide region is surrounded by the polysilicon-on-silicon region. Beam I represents transverse seeding and beam II represents longitudinal seeding.

of the beam is seeded from the polysilicon. On subsequent scans and as long as the scan lines are overlapping by more than 50%, the grain growth from the top half of the molten silicon is seeded by the previously formed single crystal. The successive lateral

seeding process is evident in Fig. 4. Since the single crystal silicon region propagates over the oxide layer from the seed region in a direction transverse to the direction of the scan of the beam, this lateral seeding mode is called transverse seeding. In the case of a scan line represented by II, the crystals again grow normal to the thermal gradient as depicted in Fig. 9. Since the single crystal region propagates into the silicon-on-oxide region from the seed region in the direction of scan of the beam, we call this mode of seeding longitudinal seeding. On oxide layers with a large surface area, the polysilicon in region A is usually converted to single crystal while that in region B is converted to elongated polycrystalline grains.

It has consistently been observed that the transverse seeding mode yields larger single crystal silicon-on-oxide areas than the longitudinal mode, even after multiple scans. It is believed that the shape of the beam, the intensity distribution of the beam, and the isothermal surfaces induced in the silicon are responsible for this result. When the circular laser spot is scanned across the surface of the silicon, the motion of the laser spot induces an elliptically shaped isotherm in the thin silicon layer (17). It is known that thermal stress is induced by a nonplanar solid/melt interface because of the differential rate of contraction across the crystal (18). Furthermore, when a solid/melt interface has a small radius of curvature, point defects can be trapped more easily in the solid, and there is also an increased chance of spurious nucleation (19). In the transverse mode, the crystals are growing normal to an isotherm that has a larger radius of curvature than that of the longitudinal seeding case. Therefore, we would expect that the single crystal growth is more favored in the transverse mode than the longitudinal mode.

Defects are usually formed near the corner where the beam enters the oxide substrate region (Fig. 10). We believe that the clustering of defects, which subsequently leads to the formation of grain boundaries, is probably caused by the crystalline mismatch of the two single crystals propagating in the transverse and the longitudinal directions. In the micrograph shown in Fig. 6, there is significant bulging of the silicon layer where there is a high defect density. This bulging is probably caused by a "snow plow" effect in the laser process where some silicon is "pushed" ahead of the beam. This kind of matter transport is very common in the zone melting process (16) and is due to the expansion in volume in the silicon during solidification. This "snow plow" effect is only observed when the beam power is excessively high. At a power level just sufficiently high enough to induce lateral seeding, no bulging due to matter transport is observed.

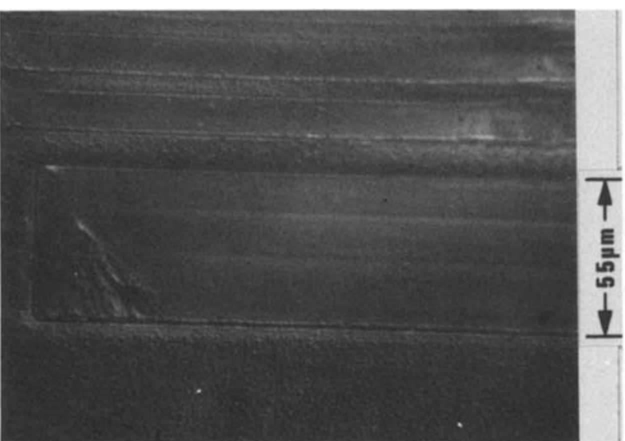

Fig. 10. An optical interference contrast micrograph of a lateral seeding sample after etching the sample in a Secco etch for 10 sec. The long polysilicon-on-oxide strip in the center of the micrograph is 194 μm long $\times$ 55 μm wide and is completely converted to single crystal except for a small region near the corner where the beam entered the oxide substrate region. The laser scanned from left to right and the lines stepped from top to bottom.

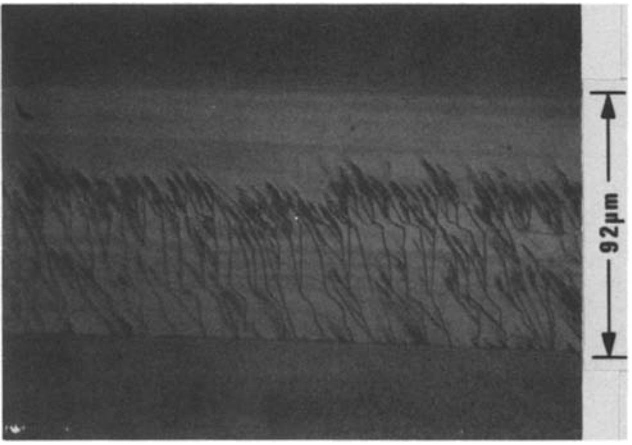

Fig. 11. An optical interference contrast micrograph of the lateral seeding sample after etching the sample in a Secco etch for 10 sec. The laser scanned from left to right and the lines stepped from top to bottom. The silicon-on-oxide strip in the middle of the picture is 92 μm wide. The feather-shaped defect clusters are evident. The defect clusters are formed in the silicon after the single crystal extended about 30 μm from the epitaxial seed region immediately above the silicon-on-oxide region.

Large areas of single crystal SOI have been obtained by using transverse lateral seeding. Figure 10 shows a typical result of a 55 $\times$ 194 μm^2 silicon-on-oxide region. Our best result to date is a lateral growth of approximately 80 μm (Fig. 6). Figure 11 demonstrates that a feather-shaped cluster of defects is commonly formed after the lateral growth has proceeded beyond some critical distance. This distance is found to be proportional to the substrate temperature. There are several possible explanations for this phenomenon. The defects may be caused by thermal stress. A higher substrate temperature reduces the thermal gradients and thus the stress due to these gradients. Alternatively, the higher substrate temperature may reduce the number of grown-in defects. If a critical dislocation density is needed to destroy crystallinity (20), a longer distance must be traversed before this occurs. A related explanation is that the rate of dislocation formation at the silicon-silicon dioxide interface is inversely proportional to the temperature. Once again, longer growth distances would be needed before grain boundary formation occurs. There is insufficient experimental evidence available to reach any conclusions.

When the nitride patterns are defined such that the resulting oxide layers have their edges along a <100> direction, the best lateral seeding results were obtained. When the edges of the oxide layers are along a <110> direction, the extent of the single crystal growth is typically 20-30 μm, while the growth is typically 50-80 μm in the <100> case. This result is believed to be a consequence of the fact that, in silicon, growth along the <100> directions has a higher rate.

We have also performed lateral seeding experiments where the oxide layer was grown on top of the silicon wafer so that there was a step at the edge of the oxide areas. The single crystal growth in those wafers is limited to about 20 μm, at best, and slip planes are usually observed. Wafers with {110} and {111} orientations were also used and the results were comparable to those obtained with {100} materials.

By using a combination of the two cylindrical lenses to obtain an elliptically shaped beam with its shorter axis along the direction of scan, we have been able to obtain improved results in the longitudinal seeding case. The single crystal typically grows longitudinally

into the oxide substrate region by as much as 50 μm. Since the radius of curvature of the isothermal surfaces is increased with an elliptically shaped beam, it is not surprising that the single crystal area extended further over the oxide layer.

It is apparent from the experimental results that the laser beam, with a Gaussian intensity profile and a trailing edge that is convex to the direction of scan, is not an ideal radiation source for the lateral seeding process. These two attributes of the laser beam promote radial cooling and, therefore, thermal stress in the material and spurious nucleation at the outermost and, therefore, the coolest portion of the scanned region. Therefore, if one can obtain a radiation source that has a trailing edge that is flat or concave to the direction of scan and a "top-hat" intensity profile, these problems can be overcome. This conclusion was also arrived at for traditional zone melting experiments (18). If this radiation source is available, the longitudinal mode of lateral seeding is preferred. From the throughput consideration, the argon laser beam, with a power output limited to about 20W for available commercial sources, is also undesirable since it is estimated that with the scan speed and line-to-line overlap used presently it will take about 30 min to complete a silicon wafer 3 in. in diameter. It is believed that a scanning stripe-shaped electron beam or a scanning focused spot of rod-shaped quartz lamp may be potential alternate sources for the laser.

Summary

We have developed the lateral seeding process to obtain single crystal silicon-on-oxide. This process is similar to the zone melting process, but is performed on a very small scale. Given the beam shape of the focused laser spot, two modes of lateral seeding, transverse and longitudinal, have been distinguished. The best results are obtained when the edges of the oxide substrates are aligned in the <100> directions in {100} oriented wafers, and with the laser scanning in the transverse mode. Furthermore, a higher substrate temperature results in a larger single crystal on oxide region. It has also been shown that the isothermal surfaces induced in the silicon and, therefore, the shape and intensity profile of the beam are the controlling parameters in determining the laterally seeded growth. From the experimental result, it is expected that the ideal radiation source for lateral seeding is one that has a trailing edge that is linear or concave toward the directions of scan and a flat or "top-hat" intensity distribution profile. If this kind of a beam shape and intensity profile can be obtained, probably by a stripe-shaped electrom beam or a focused spot of a line-shaped high intensity lamp, then improved lateral seeding results can be obtained by scanning in the longitudinal mode.

It is worth noting that although the single crystal area obtainable in the present experiments is relatively small, this area is large enough for the fabrication of active devices for VLSI applications. The single crystal substrate seed area can be placed adjacent to each of the active device areas in the circuit so that after the lateral seeding process, the active devices can then be fabricated in the single crystal silicon-on-oxide area. Hence, a truly single crystal silicon-on-oxide IC can be fabricated. Although the laterally seeded area is not free of defects, the etch pits obtained after a Secco etch are only sparsely distributed. A study of the microstructure of the laterally seeded material is underway, and the results will be reported in a later publication.

Open-Tube Diffusion

Mike Chang*

General Electric Company, Syracuse, New York 13221

ABSTRACT

In the power semiconductor industry, aluminum, the fastest diffusion p-type species in silicon, has been used for years but due to the active nature of the process, it was only performed in closed-tube systems. Now, however, aluminum diffusion has been achieved in an open ambient. The related properties of this diffusion technique, together with the characteristics of the devices made with this diffusion process, are described.

Aluminum is the fastest p-type diffusion species for silicon. The diffusion coefficient of aluminum is three times higher than that of gallium and five times higher than that of boron. In the power semiconductor industry, where deep junctions are required, aluminum diffusion has been used for years, but due to the active chemical nature of the process, it can only be achieved in closed-tube systems, as shown in Fig. 1. The resultant surface concentration of aluminum is very low ($\sim 10^{16}$ atoms/cm^3) and many researchers have spent considerable time and effort trying to understand this low surface concentration mechanism (1, 2). It is well accepted that aluminum vapor has a strong affinity to silicon dioxide. The presence of SiO_2 can retard the usable aluminum vapor generation. Based on a thermochemical analysis, Rai-Choudhury, Selim, and Takei (3) concluded that in an all-quartz closed-tube system, the surface concentration is low due to an effective reduction of aluminum partial pressure through interactions with SiO_2, SiO, residual moisture, and oxygen. By aluminizing the quartz tube wall, Kao (2) did obtain a higher surface concentration diffusion.

Nevertheless, the closed-tube diffusion is a tedious and expensive process, involving pump-down and seal-off and usually the quartz envelopes must be discarded after each use. It is highly desirable, then, to have an open-tube system for aluminum diffusion. A semi-open tube system was developed by Rosnowski (4), who performed aluminum diffusion in a regular diffusion tube under high vacuum, but strictly speaking, this is still a closed-tube system. Nevertheless, the diffusion tube can be reused many times.

After considerable experimentation, we have successfully performed aluminum diffusion in an open ambient.

Experimental Work

Various types of diffusion sources were used (Fig. 2). Among these, aluminum-coated silicon wafers, aluminum-doped silicon wafers, and elemental aluminum yielded the best results. When source wafers were used, they were loaded alternately with the target wafers, as for BN diffusion, such that every target wafer faces a source wafer; the ambient can be argon or nitrogen. Some hydrogen can also be added if desired. It is important to keep oxygen away from this system; a partial pressure of 0.5% oxygen can severely retard the aluminum diffusion and a partial pressure of 1% can completely shut off the diffusion process. Normally, the source and target wafers were loaded into a quartz boat. The boat and wafers were then placed in a 100 mm quartz tube for diffusion. The diffusion temperature ranged from 1100° to 1250°C. The resultant surface concentration is about 2×10^{18} atoms/cm^3 on the target wafers. The aluminum-coated source wafers (ACS) were made by coating 2000Å of pure aluminum onto high resistivity silicon. After diffusion, the surface concentration of the ACS wafers is about 1×10^{19} atoms/cm^3 which is in the range of the solid solubility of aluminum in silicon at the temperature range involved. The aluminum-doped silicon wafers (ADS) were made by pulling a silicon rod from a melt, a process that lends itself to tight control of the doping concentration of aluminum in silicon. Each doped silicon rod can be cut into hundreds of ADS wafers. In the case of the elemental aluminum source, a special sapphire plate and tubes were used. The elemental aluminum chunks were stored in the sapphire tube and this assembly was entered into the diffusion tube at the upper stream of the gas flow. The target wafers were loaded into a lad-

* Electrochemical Society Active Member.

Key words: aluminum diffusion, semiconductor, device.

der-type boat so that they were parallel to the gas flow, for better uniformity of diffusion. In most cases, the diffusion temperature was about 1200°C or less.

For some applications, a lower surface concentration and graded junction are required for higher reverse junction blocking capability. This type of diffusion profile can be achieved via a two-step process. Wafers were diffused at 1200°C for 2-4 hr to obtain a 15-20 μm deep aluminum diffusion; then a drive-in process without source wafers followed. The drive-in temperature can be higher than 1200°C and the diffusion time depends on the required depth of the device junction. In this case, the ambient can contain some oxygen. If a higher surface concentration is required for better ohmic contact and injection level, a thin layer of aluminum (<1000Å) can be deposited on the target wafers directly. After diffusion, the surface concentration may reach 1×10^{19} atoms/cm^3.

Results and Discussion

Figure 3 shows both the lap-and-stain and the spreading-resistance profile photos of a typical 20 hr open-tube aluminum diffusion with ACS source wafers at 1200°C. The diffusion results for a ACS source wafer (direct aluminum diffusion in this case) are shown in Fig. 4. The surface concentration of a direct aluminum diffusion is about five times higher than that from the cross-diffusion for target wafers.

The ACS wafers can be used repeatedly. As a matter of fact, it is better to precondition these source wafers before using them. Normally, we heat-treat the fresh ACS wafers at a higher temperature (~1250°C) for a long time so that the aluminum diffuses deep into the silicon bulk, thus extending their usable lifetime. After this prediffusion treatment, such ACS wafers can be used many times with consistent results; in one experiment, ACS wafers were reused 13 times (each time as a source for diffusion at 1200°C for 15 hr), and there was no noticeable decline of surface concentration of diffused target wafers (Fig. 5). Without pretreatment, ACS wafers tend to emit lumps of aluminum from their surfaces. Sometimes these lumps may reach target wafers, increasing the local surface concentration. Surface damage can also occur as a result of heavy local aluminum diffusion in target wafers.

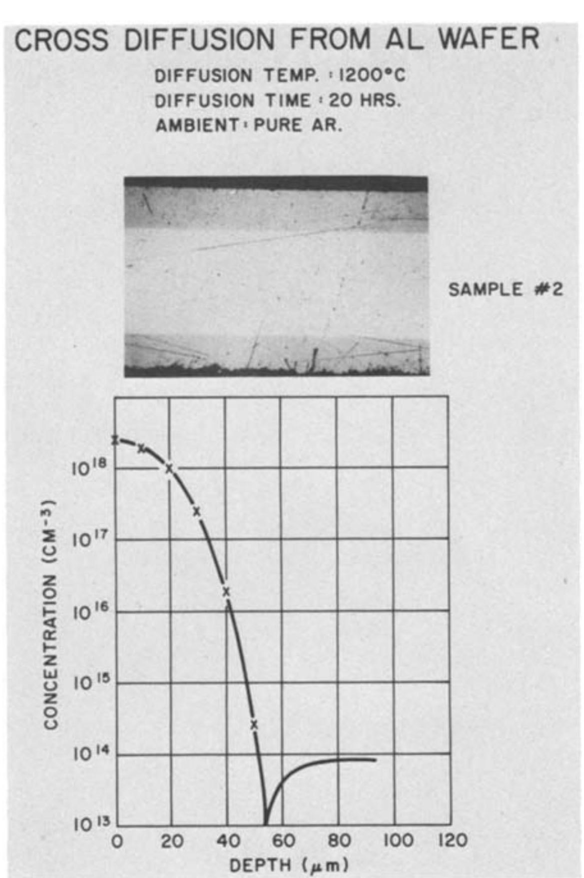

Fig. 3. The doping profile of a target silicon wafer obtained from an open-tube aluminum diffusion.

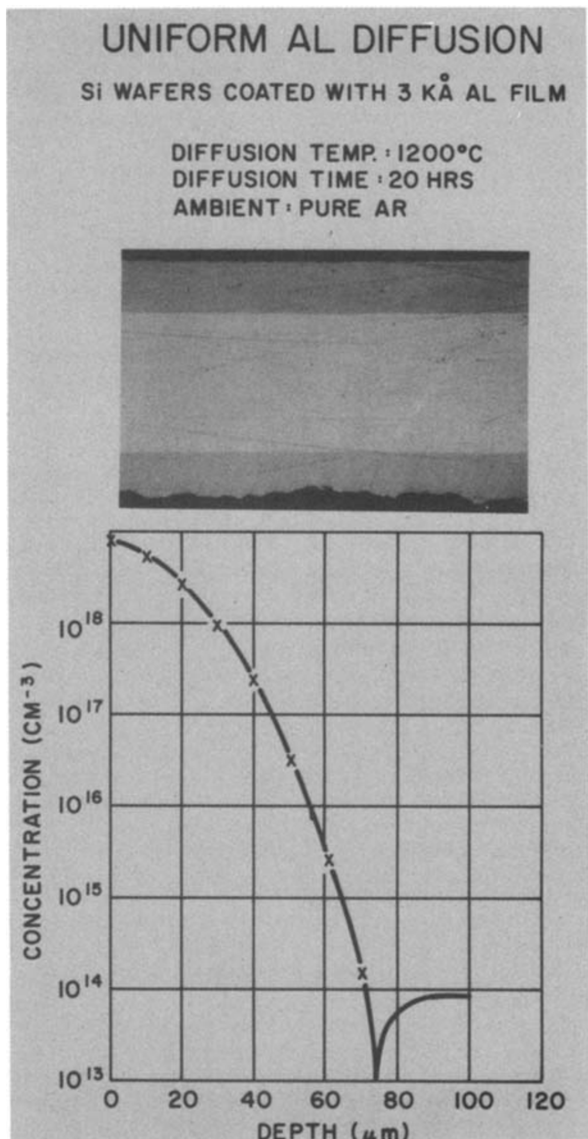

Fig. 4. The doping profile of an aluminum-coated silicon wafer obtained from an open-tube aluminum diffusion.

Diffusion under these conditions will normally have a consistent erfc profile with a surface concentration of about 2×10^{18} atoms/cm^3 at 1200°-1250°C. We found that the surface concentration is not sensitive in the upper diffusion temperature but drops drastically at lower temperatures (<1150°C), as shown in Fig. 6.

The surface concentration increases with diffusion time in the early stages of the process, as shown in Fig. 7. This feature has been utilized to create a diffusion profile of low surface concentration with deep penetration. In this case, a two-step process (predeposition and drive-in) was used to obtain the required profile. This type of process is consistent; for example, in one experiment, the same ACS wafers were used five times to diffuse target wafers. Each time, there was a 2 hr predeposition in argon at 1200°C followed by a 10 hr drive-in in oxygen. The variation in the diffusion results is less than 10% as shown in Fig. 8. This two-step technique has been used to make several diodes and SCR's.

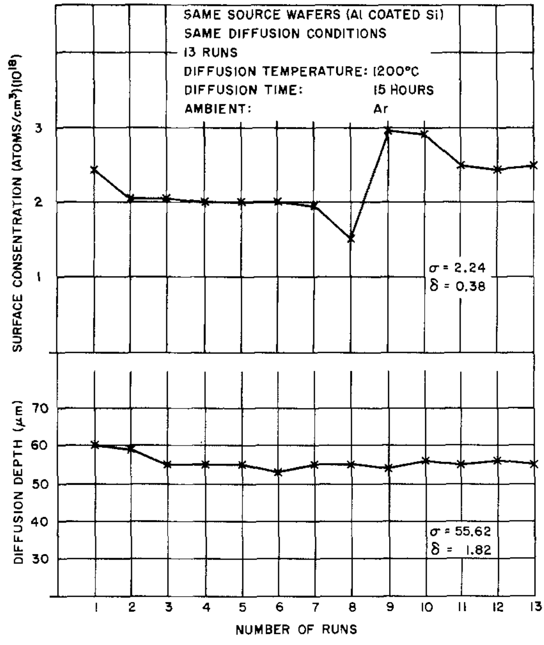

Fig. 5. Diffusion data for 13 runs, using the same source wafers to demonstrate reproducibility.

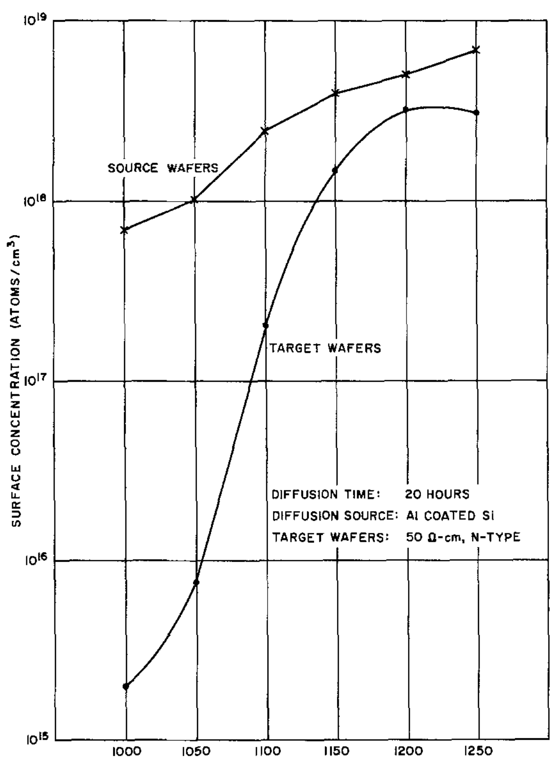

Fig. 6. Diffusion profile as a function of diffusion temperature

In order to compare this open-tube process with conventional boron diffusion, 9 mm diodes were made using the two processes with the resulting profile kept identical for both cases. The starting material was 50-70 Ω-cm, n-type single crystal silicon. It is interesting that the open-tube processed diodes can block up to 1500V, while the boron-diffusion diode can only block up to 1000V. This is due, possibly, to a more favorable lattice match for aluminum atoms in silicon, compared to boron in silicon (6). We also made a direct comparison of gallium diffusion and the open-tube aluminum diffusion. The C441 SCR (silicon control rectifier) was

chosen as a test vehicle. This device is a standard product rated at 1800V and the blocking junction is made via a gallium diffusion step.

Some C441 devices were made with an open-tube aluminum diffusion at 1200°C substituting for the standard 1250°C gallium diffusion. Aluminum has a higher diffusion coefficient at 1200°C than gallium has at 1250°C. Therefore, even at a reduced temperature, the diffusion time was shortened for the open-tube aluminum diffusion, to realize the same diffusion profile. It is well known that the higher the diffusion temperature, the worse the carrier lifetime. The characteristics of these open-tube aluminum C441 devices demonstrate this fact. The open-circuit decay measured carrier lifetime is around 50 μsec. This better lifetime directly reflects on device performance. The forward drop at 1500A is only 1.3V, in contrast to 1.5V for the standard gallium-diffused C441.

Ideally, ADS wafers should do equally as well as ACS wafers. In the case of ADS wafers, a silicon rod is pulled from a melt with precise control of the doping concentration. Each doped silicon rod can then be cut into hundreds of ADS wafers. There are three major advantages in using ADS wafers for the open-tube diffusion process: (*i*) They are cheaper than the ACS wafers, (*ii*) they are cleaner, and (*iii*) they lend themselves more easily to control of the doping concentration. Generally speaking, ADS wafers are also more

desirable for their consistency and reliability. However, at this moment, no silicon vendor can offer the required ADS wafers at a reasonable price. We managed to grow three silicon rods in a Cz puller. The diffusion profiles from these source wafers are good. Hopefully, with more demand, some silicon vendors will soon provide ADS wafers at reasonable prices.

In the case of elemental aluminum diffusion, the source was located in the upper stream and the target wafers were arranged so that they were parallel to the gas flow. In a typical run, 15 wafers were loaded into each row of a 3-row quartz boat. They were diffused at 1200°C for 20 hr. The sheet resistivity was uniform across each row, as shown in Fig. 9. The variation is less than ±5%. However, the two outermost wafers, due to the gas-flow pattern, have a very high resistivity (low diffusion concentration). In production, it would be wise to place two dummy wafers at the outermost position of each row.

The diffusion coefficient of aluminum in silicon has been calculated from many diffusion runs. From this study, it is clear that the diffusion coefficient is also dominated by the surface concentration. For the aluminum-coated source wafers, due to severe surface damage by the aluminum-silicon alloy and the resultant high surface concentration ($>10^{19}$), the diffusion coefficient is higher than for the target wafers, as indicated in Fig. 10. In general, the data in this study are quite close to previously published data (5) at higher temperature ranges (>1000°C). However, the diffusion coefficient has a pronounced different slope in the lower temperature ranges. There are no published data in this temperature range. We do not yet have a satisfactory explanation for this phenomenon.

It was also found that a strong interaction between aluminum vapor, quartz, and/or oxygen existed. As the oxygen content in the main flow stream rises to 1%, no cross-aluminum diffusion occurs. We have witnessed the effect of aluminum source depletion in the vicinity of quartz. For most of this study, quartz boats were used to hold the wafers for diffusion. It is also interesting that there was an n-type inversion layer in the spot of target silicon where it touched the slot of the quartz boat. This n-type inversion is clearly a result of the combined effect of aluminum, silicon, and oxygen. We are still studying the exact nature of this phenomenon. A small distance (≧30 mils) away from this spot, the n-type inversion disappears, but the effect of source depletion is still there to reduce the surface concentration of diffusion, as shown in Fig. 11. This source depletion and n-type inversion effect also occurs in other areas of silicon wafers if some silicon oxide is present. For example, a silicon dioxide mask was used in one

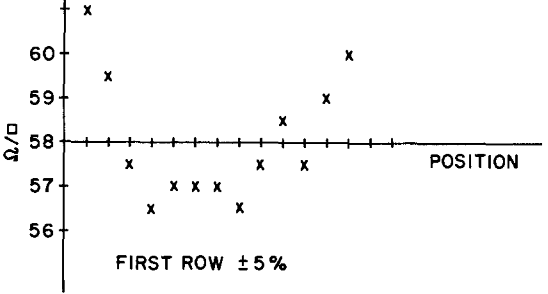

Fig. 9. Diffusion data across a row of silicon wafers using an elemental aluminum source.

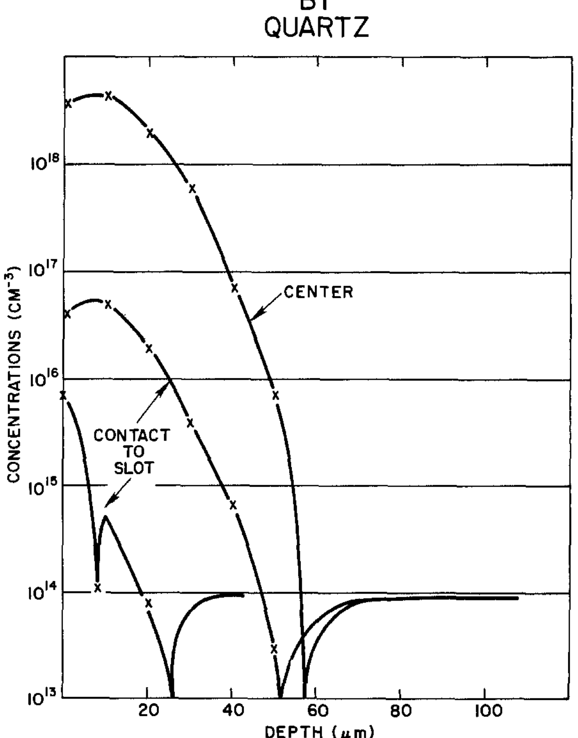

Fig. 11. The anomalous aluminum diffusion resulting from direct contact to a quartz boat.

experiment to mask the aluminum diffusion. While it was shown that silicon dioxide can mask the aluminum diffusion, the presence of the silicon dioxide caused an n-type inversion and a source depletion effect on each aluminum-diffused area where the oxide was removed, as shown in Fig. 12. Silicon tubes and boats have been used to avoid this source-retarding effect, but without success. We found that silicon particles can be evaporated from these silicon wares at temperatures higher than 1200°C under an inert ambient. These evaporated silicon fumes condensed at the end of the tube and formed white film, which proved to be silicon (by atomic emission and absorption analysis).

Another interesting phenomenon is that phosphorus diffusion can slow down aluminum diffusion (reduce the aluminum diffusion coefficient). In one experiment, a short $POCl_3$ diffusion was done at 1100°C, selectively, onto a silicon wafer, which was masked with an SiO_2 pattern. The oxide pattern was etched away completely after the $POCl_3$ deposition. These wafers were diffused with ACS wafers at 1200°C for 20 hr. It was clearly shown, by the lap-and-stain photo (Fig. 13), that the

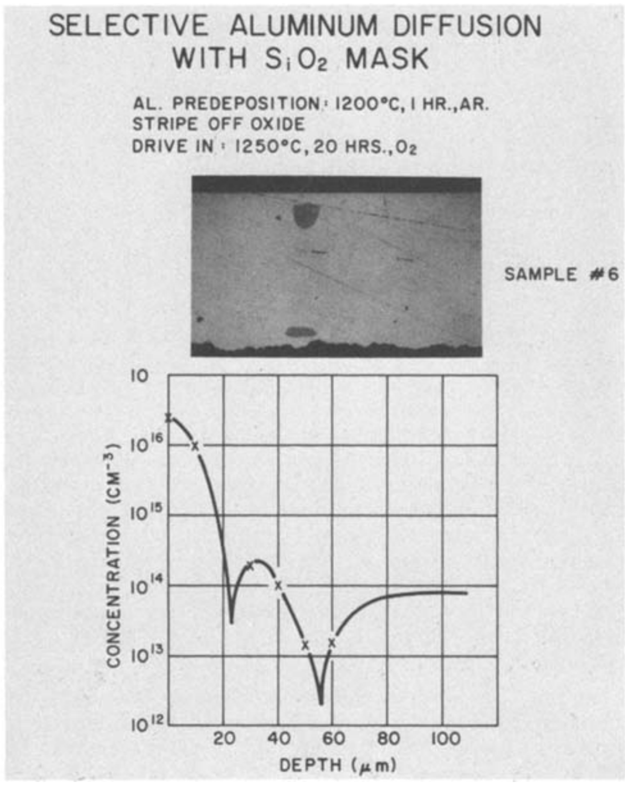

Fig. 12. An inversion layer in the aluminum diffusion due to the presence of silicon dioxide on the silicon surface.

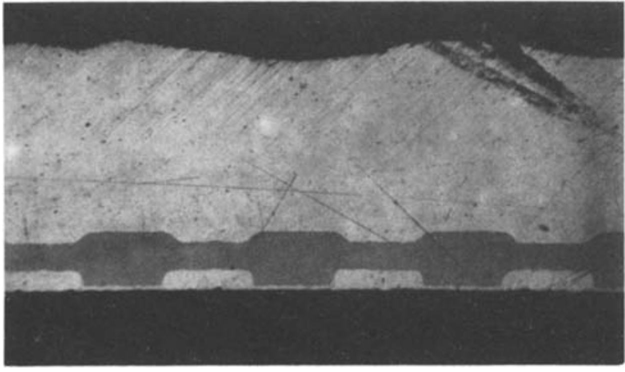

Fig. 13. The retardation effect on aluminum diffusion by a simultaneous phosphorus-aluminum diffusion.

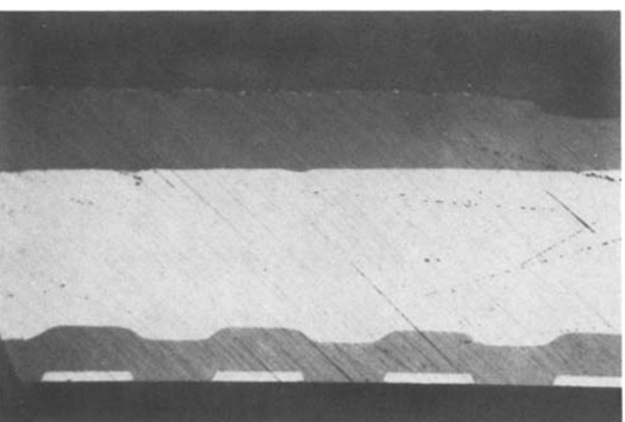

Fig. 14. The enhancement effect on aluminum diffusion by a simultaneous arsenic-aluminum diffusion.

aluminum diffusion was retarded in these areas under the phosphorus deposition. A similar effect also was observed on GaAs simultaneous diffusion.

A reverse effect was found for the aluminum-arsenic diffusion system. The presence of arsenic atoms can locally enhance the aluminum diffusion. In one experiment, arsenic atoms were implanted, selectively, into silicon wafers which were masked with a silicon dioxide pattern. The oxide pattern was etched away completely after the arsenic implantation. The same aluminum diffusion cycle was used on these wafers as in the Al-$POCl_3$ case. The lap-and-stain photo (Fig. 14) indicates that the aluminum diffusion was enhanced in the arsenic implanted areas. This enhancement effect is not likely due to the surface damage of ion implantation. The implanted surface damage is restricted to a few microns from the surface and should be annealed out completely at the diffusion temperature, which was 1200°C. These effects were not found in the Al-B system.

Conclusion

Open-tube aluminum diffusion was used to replace closed-tube aluminum diffusion. This new technology is not only easier and less expensive, but also offers more process freedom and control. The resultant surface concentration of aluminum diffusion can be selected from 1×10^{16} to 1×10^{19} atoms/cm^3. Several devices were made with this technique. The measured device characteristics were far better than those made with the conventional processes. Three types of aluminum diffusion sources were evaluated. The properties and results associated with these sources were discussed. Several new phenomena were discovered and presented in this study.

Techniques for Preparing and Grinding Hard and Brittle Diffusion Layers, Application to the Determination of the Nitrogen Diffusion Profile in α-Titanium Nitrided at 1350° and 1450°C

E. Etchessahar, J.-P. Bars, and J. Debuigne

Laboratoire de Métallurgie et Physico-Chimie des Matériaux, Institut National des Sciences Appliquées, 35043 Rennes Cedex, France

ABSTRACT

Grinding techniques and the corresponding metrology are often weak points of the whole process of diffusion measurements. Techniques for preparing and grinding hard and brittle diffusion layers are given in every detail. Application is made of this process to the determination of the diffusion profile of nitrogen in α-titanium and particularly in the vicinity of the α/ϵ interface.

The methods described here were developed for the study of nitrogen diffusion in α-Ti at 1450° and 1350°C (1, 2). The diffusion coefficients are calculated on the basis of concentration-distance curves, the nitrogen concentration being measured by use of nuclear microanalysis (3). The methods of preparation which we describe are very useful for sectioning brittle diffusion layers.

During nitriding of a parallelepipedic sample, the different phases are growing in layers, parallel to the prismatic faces of the sample. Figure 1 shows this configuration on a cross section after nitriding at a temperature above the transition point of titanium.

For the determination of a diffusion profile of nitrogen in the α-phase, we have to choose one of the two interfaces limiting the layer as the origin. The two methods used allow the determination of such a profile for α-layer thicknesses of 80 μm at least. Direct analysis of nitrogen is performed either on planes obtained by parallel sectioning, or on inclined plane crossing of the whole α-layer.

Technological Definitions of Operations

Several samples must be used to work the first method (parallel sectioning). Since hoping to obtain many identical and perfectly nitrided samples is unrealistic, their number was limited to four per temperature considered. Several analyses on each sample are then necessary in that case.

The second method necessitates only one sample, but a long one, in order to spread the concentration gradient as much as possible. The analytical spots must be rigorously located. If in the first method, the surface of the probe is of little importance, the use of the second method implies a probe as small as possible, for in this case the nitrogen distribution is not constant over all the inclined sectioning plane.

Parallel sectioning (first method).—Our parallelepipedic specimens (20 × 10 × 8 mm) have their two largest faces plane ground parallel to one another. Two symmetric samples were cut out of each specimen after nitriding; the cut is a symmetry plane and the sizes of both samples are 20 × 10 × 3.5 mm.

Three planes are metrologically defined (Fig. 2): (*i*) the "S" plane, for the largest nitrided face, (*ii*) the α/β interface, and (*iii*) the "R" plane of cut, ground parallel to one another. Plane "R" is the reference plane in each specimen.

In order to facilitate the control of the α/β interface, a lateral face of each sample is submitted to a metallographic polishing down to alumina; after that, the sample dimensions are 20 × 5 × 3.5 mm. Parallel grindings through the α-phase are performed by means of a special stage assembly using the "R" plane as reference. The corresponding nitrogen analyses were obtained with the probe always localized in the middle of each plane.

Inclined sectioning (second method).—We have to consider two types of inclined planes, (Fig. 3) for this type of grinding: (*i*) those which cross the whole

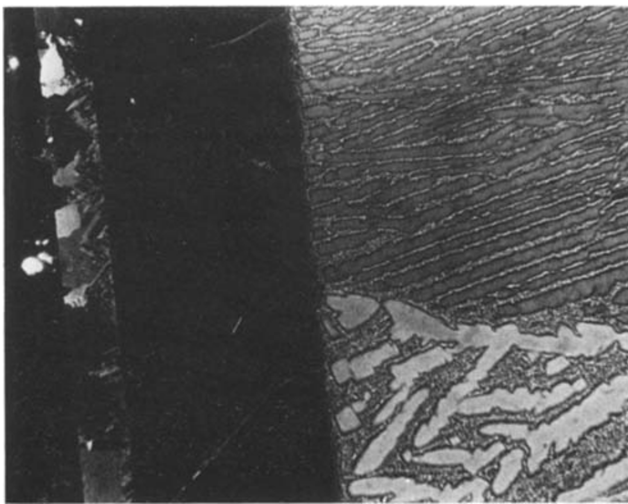

Fig. 1. Cross section after nitriding

Key words: diffusion solids.

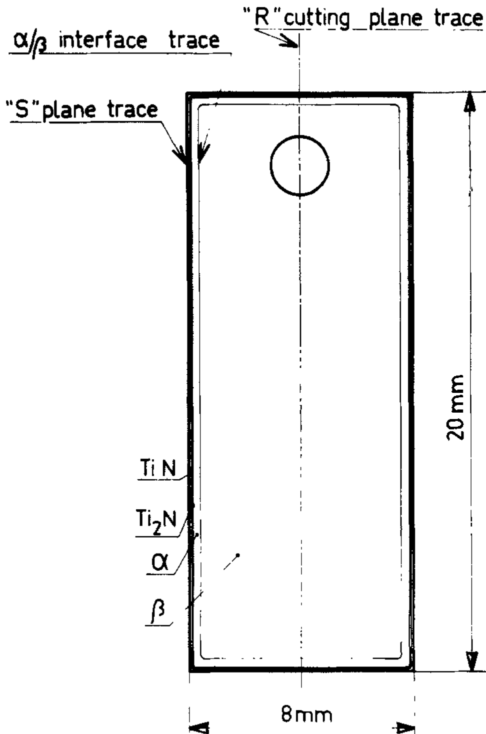

Fig. 2. Schematic representation of the symmetric samples

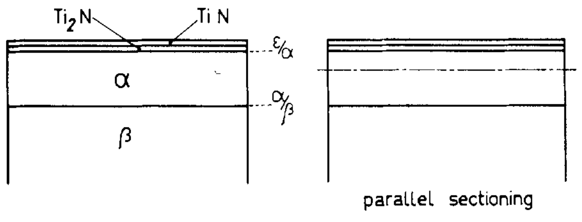
α-layer, called totally inclined sectioning planes; and (*ii*) those which reveal only a reduced part of the α-layer, called partially inclined sectioning planes.

The latter type is necessary for a good examination of the layers in the vicinity of the interfaces.

High slope inclined sectioning.—In the case of totally inclined sectioning planes, the special parallelepipedic sample (22 × 5 × 4 mm) is cut out of a nitrided specimen (35 × 10 × 4 mm) the largest faces of which were plane ground parallel to each other before nitriding. The "R_1" reference plane is one of these large planes which are in principle parallel to the α/β interface. All lappings and measurements are performed with reference to "R_1".

By grinding with a sin x value of 0.00625, metallographic observation on this plane shows from one end of the sample to the other: (*i*) a 4 mm wide zone, transformed from β; (*ii*) a 15 mm α-zone; (*iii*) a 2 mm ε-zone; and (*iv*) a 1 mm nitride zone. One and a half analysis steps are used on the whole α-zone.



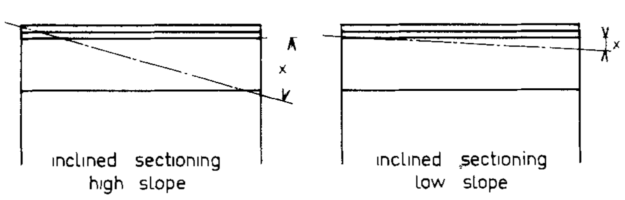


Fig. 3. Schematic representation of the sectioning planes

Low-slope inclined sectioning.—For the study in vicinity of an interface, partial sectioning is used. The samples are then identical to those for parallel sectioning but with grinding slopes corresponding to sin x values of 0.00138_4 or 0.0025 with reference to the "R" reference surface.

Technique and tool selection.—The technical problem of grinding as described above, presents a double aspect: (*i*) A macro-geometric one, that is, the precise positioning of the sectioning plane with reference to the reference surface. The machine used must be reliable and precise. (*ii*) A micro-geometric one corresponding to minimum rugosity of the grinding plane surface.

The grinding technique and tool must be adapted to the material studied. All of these technical requirements were finally satisfied by the choice of a plane rectifying machine equipped with a cubic-boron nitride wheel (wheel specification: CB: 126 Q BB-1.5; flattener: 2R 14 KF 7F; sharpening rod: 38 A; Norton specifications).

The surface profilometry on Fig. 4 shows the very good results obtained with pass depths of 3 μm under a very strong cooling fluid jet.

The use of this type of grinding wheel with resinoid binder is rather delicate. For good results, the centering must be very accurate and the ovality less than 0.01 mm. For a good shaping of the grinding wheel, the necessary flattening with a diamond flattener must be done with a maximum 5 μm penetration both backward and forward and with alternating the side of flattening rod penetration into the grinding wheel; the cooling liquid jet must be strong.

Flattening is necessarily followed by sharpening to give relief to the abrasive grains by eliminating part of the binder. The abrasive power of the cubic-boron nitride wheels depends on the quality of sharpening. This operation is performed with rods 38 A 150 HV BE (20 × 20 × 200 mm) (Norton specifications), the wheel rotating as in the normal working conditions, with a slow cooling-jet. Sharpening must be stopped as soon as the rod is consumed at great speed.

TiN and Ti_2N nitrides must be ground before reaching the α-phase; the high hardness of these three phases accounts for the geometric modification of the wheel in the course of work, giving then an alteration of the surface state of the samples. We must therefore control this evolution and then flatten the wheel with the diamond flattener. In our case, this operation is performed after each series of eight to ten abrasions.

Grinding stand and fittings.—For both methods of study (first method, parallel sectioning; second method, inclined sectioning), we have used the same steel stand and it is the way the stand is connected with the rectifying machine which differs. This stand is also used in the preparation of the specimens and for rectifying the "R" reference surfaces; it is shown in Fig. 5.

It shows three surfaces, A, B, and C. Faces A and B are parallel to each other (maximum deviation 0.5 μm). The C groove is parallel to these surfaces.

The specimens are glued to face A; face B is connected with the machine. This operation consists in applying the specimen on face A by using a screw

Fig. 4. Example of surface profilometry

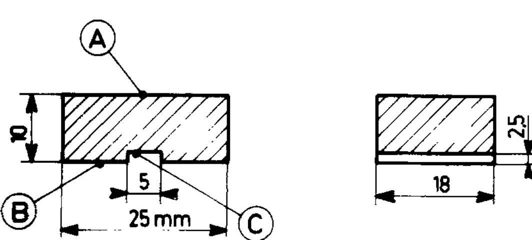

Fig. 5. Schematic representation of the steel stand

clamp with parallel holding jaws, tightened between the C groove and the surface to rectify (see Fig. 6).

The specimen is then stuck to the stand with a low temperature wax ($t_f \simeq 50°$-$60°C$). There is no wax between the specimen reference surface "R" and face "A" of the steel stand. This gluing has a good strength under cutting stress for 3 μm grinding passes.

For the first method, the specimen steel stand is connected to the rectifying machine table by means of a magnetic stage with faces ground in parallel with the table.

To perform inclined grindings, the slope of the grinding stand is given by a sinus table, as shown in Fig. 7.

Tests and Measurements

All tests and all thickness measurements are always comparative measurements carried out in a metrology room with the following equipment: meterologic surface-plate, a box of standard thickness gauges, a good comparator with a very sensitive dial giving 1 μm per division and a maximum amplitude of 200 μm.

"R" reference surface.—We test the parallelism of "R" compared to "S" and the parallelism of "R" as compared to the α/β interface on a Reichert metallographic bench with cross-carriage stage and occular micrometer.

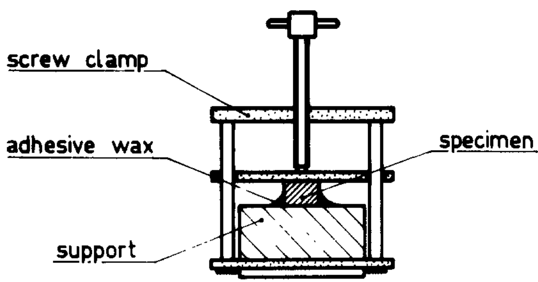

Fig. 6. Experimental setup used for glued-on specimens

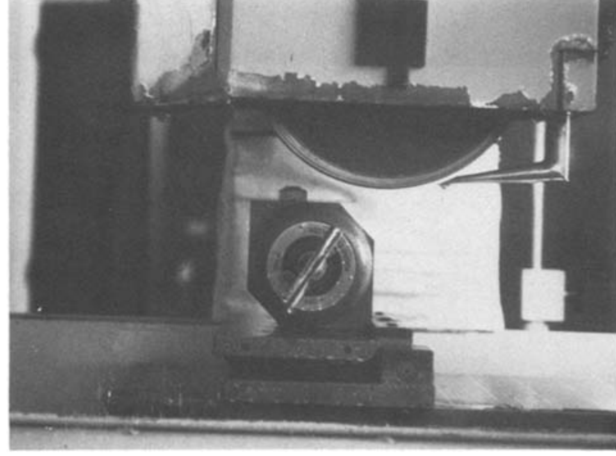

Fig. 7. Rectifying machine equipped with sinus table stage

Parallel grinding.—After grinding of each plane to be analyzed, three series of thickness measurements are performed on the sample: sample with grinding stand, sample alone, and sample alone with a hand precision micrometer in order to avoid gross human errors.

Prior to each thickness measurement, we test the parallelism between "R" and the plane to be analyzed; a surface profilometry is obtained. y_i being the height of ground plane "i" above "R" and $y_{\alpha\beta}$ the height of the α/β interface above "R", we have then

$$d_i = y_i - y_{\alpha\beta}$$

for the distance of the analyzed plane to the α/β interface.

After grinding of a plane close to the α/β interface, the height of this interface above "R" is measured on the metallographic microscope as seen above. The same measure is made also for the plane just ground. By comparing the y_i' obtained on a metallographic microscope and the y_i value for the same plane, obtained by mechanical metrology, we define a correction factor

$$K = \frac{y_i}{y_i'}$$

and we can then calculate

$$y_{\alpha\beta} = K y_{\alpha\beta}'$$

Inclined grindings.—The measurements are by far easier here. The height above the reference surface on each sample is measured along the ground plane and the value of the height of each interface is noted.

The positions of the probe on the sample being of great importance, a correct initial position of the sample in the reaction chamber is necessary. During the analytical process, the crossing of the interfaces constitutes interesting marks.

Practical example.—Our methodology gives for example Fig. 8, showing the diffusion profile of nitrogen, close to the α/ϵ interface, in the α-phase after nitriding at 1350°C. Very close to the α/ϵ interface, the experimental points correspond to analyses using partial inclined grinding. Over 15 μm from the α/ϵ interface, the analyses use parallel sectioning.

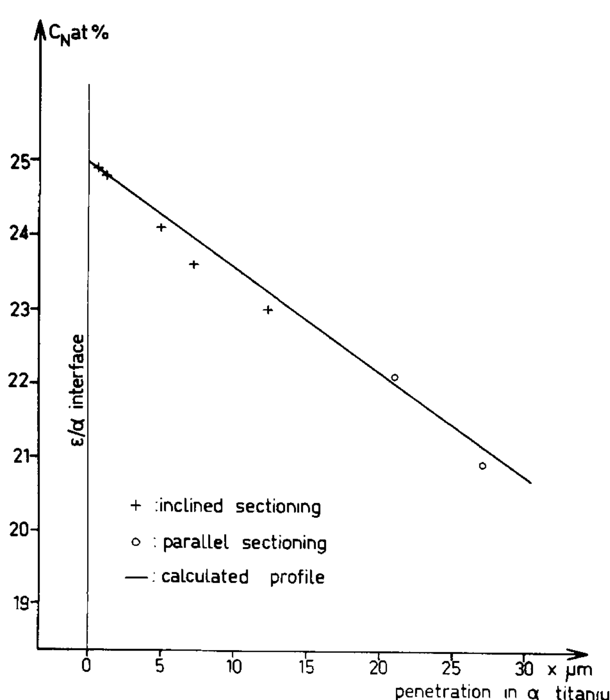

Fig. 8. Diffusion profile of nitrogen in α-titanium (1350°C, 7 hr)

With the hypothesis where only nitrogen diffuses and the diffusion coefficient is constant and independent from nitrogen concentration, we can optimize the adjustment of the experimental profile according to a single curve satisfying the equation

$$\frac{C_{(x_1)} - C_{(o)}}{C_{(x_2)} - C_{(o)}} = \frac{1 - \operatorname{erf}\dfrac{|x_1 + a|}{2\sqrt{DT}}}{1 - \operatorname{erf}\dfrac{|x_2 + a|}{2\sqrt{DT}}}$$

where $C_{(o)}$ = nitrogen initial concentration in the metal, $C_{(x_1)}$ and $C_{(x_2)}$ = nitrogen concentrations in planes at x_1 and x_2 beneath the α/ϵ solid solution interface, a = cumulated thickness of the preceding layers, corrected, taking into account the Pilling and Bedworth ratios, D = diffusion coefficient of nitrogen in α-Ti, and t = time of nitriding.

We note the good agreement between the experimental points and the theoretical profile calculated for the whole thickness (88 μm) of the solid solution Tiα/N and also the good complementarity of the two grinding techniques.

The advantage of this method is to avoid resorting to concentration values at interfaces deduced from the equilibrium diagrams.

Conclusions

The experimental determinations of diffusion profiles in solid-state materials often use nowadays very sophisticated techniques, but in some cases the weak points of the whole process are the preparation of the samples and the mechanical metrology used before the physical measurements which give values for drawing the diffusion profile. We have described in detail the preparation of samples of nitrided titanium (a particularly difficult case) before determining nitrogen concentration by observing a nuclear reaction. This method may be adapted to the grinding of numerous other brittle diffusion couples.

Growth of F Center in Zone II as a Function of Electron Injection in Some Potassium Halide Crystals

A. K. Maiti, K. Goswami, S. Choudhuri, and A. Choudhury

Department of Physics, Jadavpur University, Calcutta 700032 India

ABSTRACT

Single crystals of KCl and KBr have been colored by the process of electron injection at different temperatures and voltages. The coloration begins at the onset of zone II. The space charge limited (S.C.L.) injection current and the coloration are found to increase almost linearly in zone II. The efficiency of F-center formation in zone II is determined and is shown to be a function of S.C.L. current.

Mott and Gurney (1) have initiated the analysis of space charge limited injection into an insulator on the assumption that traps are absent in it. Later others (2, 3) put forward some theories for the better understanding of the space charge limited injection process in solid materials of not too high bandgap. Recently the electron injection process in alkali halide crystals found enormous scope although very limited results of the physical parameters are available.

When an electric field is applied to an alkali halide crystal placed between two electrodes and heated at an elevated temperature, a cloud of color centers originates from the pointed cathode and moves toward the flat anode (4). During the injection process the space charge limited (S.C.L.) current in the crystal reveals four distinct zones under suitable experimental conditions. The evolution of electrical current and the color center are intimately related to the applied voltage, temperature of the specimen, and the nature of the crystal (5). It is known (6, 7) that in the first zone (zone I) current remains nearly constant for some time and characteristically no coloration is produced. Experimental evidence (8-10) suggests that during zone I the process of electrolysis does occur, causing the accumulation of alkali metal at the cathode. Due to this accumulation of alkali metal a fresh ohmic contact at the cathode crystal interface is formed and the nature of zone I current has been attributed primarily to ionic transport (8-10). When the contact is formed, further accumulation of alkali metal ceases and the transport of electrons through the crystal starts (onset of zone II) showing a sharp rise in the electrical current with the formation of color centers. The zone II coloration continues until the color cloud reaches the anode and the entire crystal gets densely colored during which injection current remains practically constant, and this is known as the steady-state situation (zone III). Another zone, known as zone IV, does not participate to form color centers in any way (10).

Most of the current literature is concerned mainly with the growth of space charge limited current and its properties are related to transport processes in solid

Key words: solid electrolyte, injected carriers, color centers.

media under different ambient conditions. In the present experiment some results are reported regarding the growth of injection current at various stages of coloration in some alkali halide crystals under altered conditions of temperature and applied voltages. The efficiency of F-center production (*i.e.*, the energy required to form one F center) has been determined in the space charge region.

Experimental

Crystals of KBr (0.7 × 0.4 × 0.3 cm) and KCl (0.65 × 0.5 × 0.3 cm) obtained from the Department of Atomic Energy, Government of India, were cleaved from the single crystal blocks. An electrical furnace fitted with a flat platinum anode and pointed brass cathode could support a crystal block. The temperature of the furnace was controlled within ± 2°C. The electron injection was performed under a fixed voltage keeping the temperature of the specimen constant. The injection current flowing through the crystal was measured with a sensitive microammeter at a regular interval of time and at the same time the F absorption was recorded by shining F light normally on a small central part of the crystal. The intensity of the transmitted F light was measaured by an RCA IP 28 photomultiplier with conventional electronic circuits.

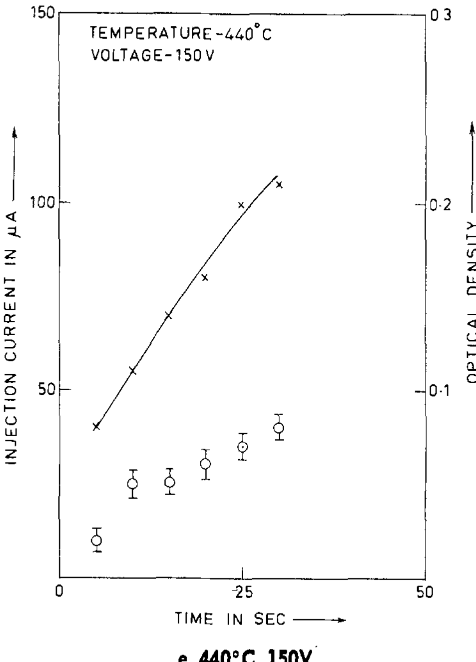
Fig. 1.



e. 440°C, 150V

Fig. 1. Electrical current (continuous line) and optical density (isolated points) *vs.* time during electrolytic coloration of KBr single crystal at temperature and voltage.

The injection procedure was limited within the third stage where current was found to record more or less a steady value. The coloration so produced in the crystal had been bleached by reversing the polarity of the electrodes under identical conditions. Thus the original transparency of the crystal was retained. The process of electron injection was carried out with a specimen for different temperatures and different voltages.

Results

Injection current and optical density are plotted against time for a particular temperature and voltage for KBr and KCl crystals. Five such sets of KBr and four such sets of KCl crystals for various temperatures and voltages are shown in Fig. 1 and 2, respectively. The error incurred in the measurement of optical density due to coloration is marked in each case (as shown in Fig. 1 and 2). The plots of optical density and injection current against time are almost linear in the second zone.

The energy necessary to create one F center, *i.e.*, the efficiency (η), is calculated in the following manner.

The number of electrons (N_e) per unit area participating in the formation of color centers is given by

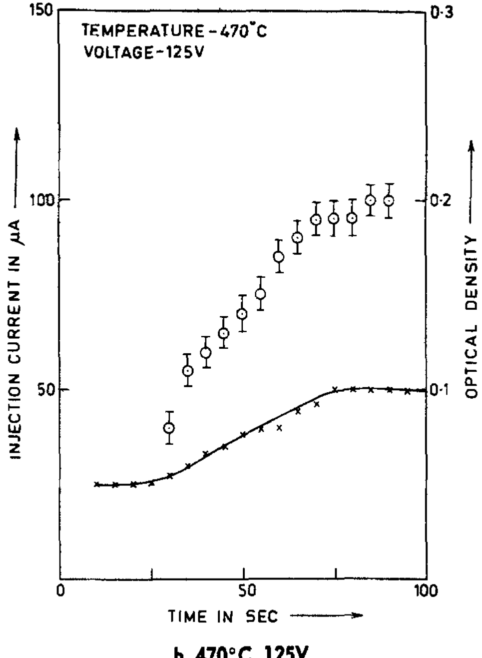
$$N_e = K \int i(t)dt \quad [1]$$

where the constant $K = 6.24 \times 10^{18}$.

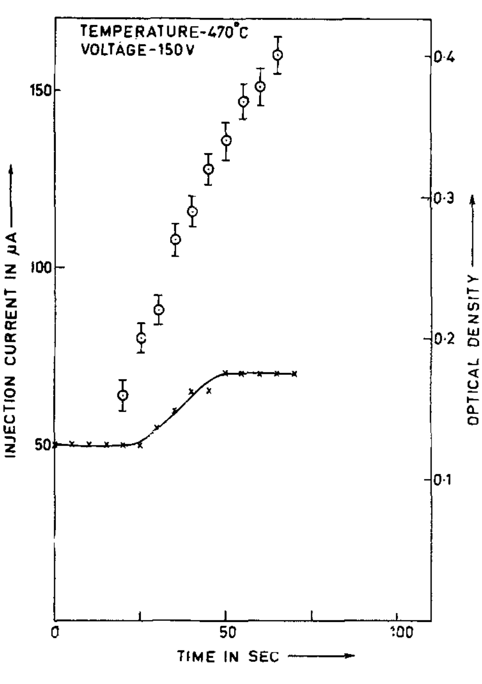
The number of color centers (N_F) per square centimeter is estimated using Smakula Dexter's equation (11) given by

$$N_F = 2.3036K'a \quad [2]$$

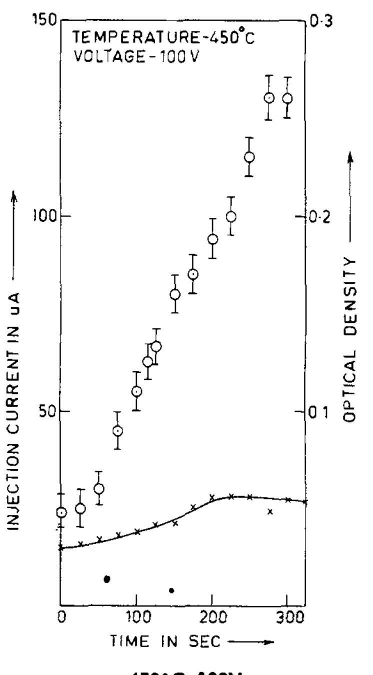
where a is the optical density, K' depends on the refractive index of the specimen, oscillator strength, and half-width ($W_{1/2}$) of the F band. The half-width involved in K' is computed from the equation (12) given by



b. 470°C, 125V

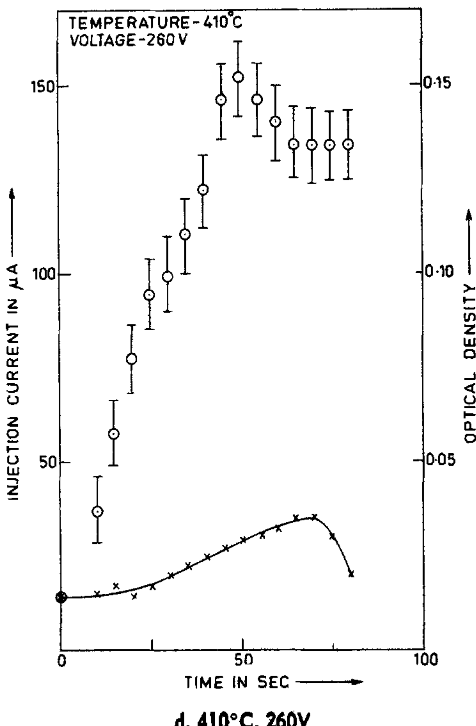


a. 470°C, 150V



c. 450°C, 100V

Fig. 2.



d. 410°C, 260V

Fig. 2. Electrical current (continuous line) and optical density (isolated points) vs. time during electrolytic coloration of KCl single crystal at temperature and voltage.

$$W_{1/2} = A\ [\coth\ (h\nu_g)/2KT]^{1/2} \quad [3]$$

Now defining efficiency (η) of F-center formation as

$$\text{Efficiency } (\eta) = \frac{\text{rate of flow of electrons per cm}^2}{\text{rate of F-center formation per cm}^2} \times \text{applied voltage per unit length}$$

i.e.

$$\eta = K''i(t) \quad [4]$$

where $K'' = 0.4341(K/K')\ (V/L)\ 1/da/dt$, K'' is a constant for a particular crystal at a fixed temperature and fixed applied voltage (V), and L is the distance between the two electrodes. Knowing the slope (da/dt) of optical density *vs.* time graph which is found to be nearly linear in zone II, the efficiency value (η) is calculated for each value of the injection current.

Discussion

The injection current *vs.* time graphs in Fig. 1 and 2 may be divided into three zones where the zone I contributes no F-center formation which corroborates some earlier work (5, 13). The beginning of coloration causes a sharp rise in zone II injection current and the current will continue to increase until a steady state (zone III) is reached. But the coloration in zone III is still increasing in a regular manner. These lead us to suggest: (*i*) that current following in zone I is not due to electronic transport, and (*ii*) that current flowing in zone II is affected by the space charge and this space charge will modify the existing field between the electrodes. The space charge decreases as the coloration as well as current growth during zone II increases with time. Consequently efficiency (η) becomes time dependent.

According to Hadley (14) the use of the pointed cathode facilitates the electron injection due to the high current density at the point tip and therefore to the high accumulation rate of alkali metal at the cathode. If the accumulation rate is faster than that of elimination, a new electrode is obtained and injection begins. From this point of view the start of electron injection into the crystal is controlled by the ionic current which is a function of temperature. To have appreciable ionic motion sufficient temperature is necessary. It is expected that there will be some lower limit of temperature for coloration.

The efficiency *vs.* space charge limited current [η — $i(t)$ is plotted for KBr and KCl crystals at different conditions of temperatures and voltages as shown in Fig. 3 and 4. It is evident from these figures that the value of the slope decreases with the increase in temperature. It indicates that by lowering the temperature of the crystal larger energy is necessary for the formation of the F center.

The generation of the color center under electron injection is quite different from other modes of coloration. Here the color centers migrate from the cathode toward the anode and the distribution of coloration is not uniform in the close vicinity of the cathode, due to which the optical density records have been made in a localized region of the crystal.

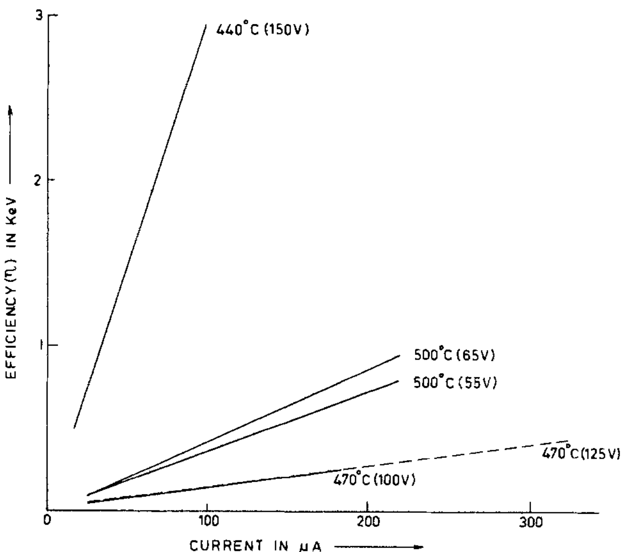


Fig. 3. Efficiency of F-center formation in zone II vs. injection current for KBr single crystal at various temperatures and voltages (dashed line is for 470°C and 125V).

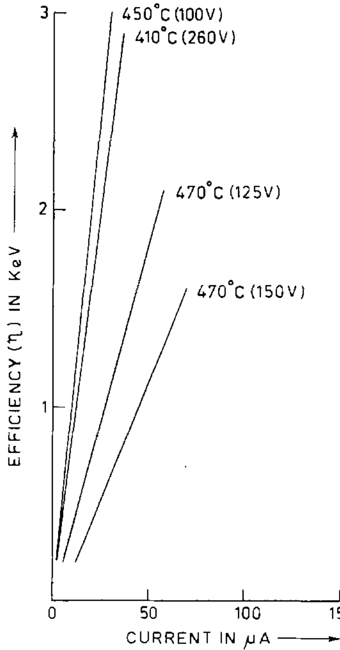

Fig. 4. Efficiency of F-center formation in zone II vs. injection current for KCl single crystal at various temperatures and voltages.

The currents in zone II and zone III are not sharply marked (see Fig. 2), while a theoretical analysis of Many and Rakavy (3) shows a sharp contrast between the two zones. The rounding of zone II and III current in our experiment is quite reasonable because the experimental electrodes are not of identical nature.

The Oxidation of Pure Zirconium in Steam from 1000° to 1416°C

R. E. Pawel* and J. J. Campbell

Oak Ridge National Laboratory, Metals and Ceramics Division, Oak Ridge, Tennessee 37830

ABSTRACT

The oxidation of pure, arc-melted crystal-bar zirconium in steam was studied over the temperature range 1000°-1416°C. The early stages of the reaction at all temperatures investigated above 1000°C were characterized by uniform parabolic growth of layers of zirconium oxide and oxygen-stabilized alpha zirconium. Parabolic rate constants were determined for the growth of each layer, and these served as a basis for the calculation of effective chemical diffusion coefficients for oxygen in the growing product phases. These calculations were made on the assumption that this system may be described as an ideal, multiphase, moving boundary diffusion problem. The results and their comparisons with similar data for the oxidation of Zircaloy-4 indicate that this diffusion model is accurate over the temperature range involved. At 1000°C, however, departures from ideal kinetics were observed that were attributed to structural changes in the oxide layer during the course of the reaction.

Recent investigations at this laboratory have examined the oxidation characteristics of Zircaloy-4[1] in steam at temperatures from 1000° to 1500°C. In particular we have studied oxidation kinetics (1), oxide morphology (2), the effect of steam pressure (3) on oxidation rates, oxygen diffusion in the oxide and oxygen-stabilized alpha layers and the applicability of ideal diffusion models (4-6), as well as the effect of the monoclinic-tetragonal transformation in the oxide on transient temperature oxidation behavior (6). Generally, this work has shown that, despite the complexities of the Zircaloy-oxygen system and the intricate structure of the growing oxide, the reaction proceeds by relatively ideal, diffusion-controlled growth of the product phases. Thus, we and others (7-13) have correlated the kinetic data in terms of the parabolic rate constants for the growth of the oxide and oxygen-stabilized alpha phases from the host beta Zircaloy. These data have been used mainly as a basis for developing models suitable for predicting oxidation behavior for a variety of experimental conditions.

Key words: zirconium, high temperature oxidation, oxygen diffusion, parabolic reaction kinetics.

[1] Nominal composition (w/o): Zr—1.60 Sn, 0.25 Fe, 0.12 Cr, 0.12 O, 0.009 C, 0.003 N, and 0.0025 H.

While a considerable amount of new information is available for the high temperature oxidation behavior of Zircaloy, few corresponding data for pure zirconium exist for a critical comparison. Previous experimental efforts here, like the earlier work with Zircaloy, concerned oxidation phenomena at temperatures below 1000°C. Good review articles (14-16) have been published that illustrate the complex nature of the reaction and the large scatter in experimental kinetic data and the different interpretations of the results. For oxidation above 1000°C, Debuigne (17), Pemsler (13), and Rosa and co-workers (14) have presented data and phenomenological descriptions of the oxidation process. Debuigne provided a detailed analysis of the oxidation process for temperatures from 1050° to 1200°C. Pemsler observed parabolic oxidation kinetics for growth of the oxide layer at temperatures from 1100° to 1300°C, but below 910°C (to as low as 750°C) found a complicated kinetic behavior. It was proposed that these complications were due to changing proportions of the monoclinic and tetragonal oxides. Later, Lightstone and Pemsler (19), observed both forms of the oxide growing at 920°C by an *in situ* x-ray examination. Rosa and co-workers (20), for temperatures between 875° and 1050°C, interpreted the growth of the oxide

as parabolic, but only after an initial period of faster growth.

It is clear that both similarities and differences exist when comparing the oxidation behavior of pure zirconium and Zircaloy-4. At the higher temperatures, above about 1100°C, both materials appear to exhibit virtually ideal parabolic growth kinetics. Thus, if measurable differences in the rates exist, they might serve as a basis for defining the mechanism by which the alloying elements in Zircaloy-4 affect oxidation. Our techniques for measuring the kinetics for Zircaloy-4 oxidation proved sufficiently sensitive and self-consistent to detect the small differences associated with different batches of specimen material and also with the presence of oxygen gas in the steam (1). In the present paper, we will report an extension of this work for oxidation of pure zirconium, with the aim of producing data suitable for testing oxidation models and for comparing with data available for Zircaloy-4.

Experimental Procedures

In order to make the comparisons of the oxidation behavior as straight-forward as possible, we utilized experimental techniques that were essentially identical to those reported earlier for the oxidation of Zircaloy-4 (1). Briefly, specimens of zirconium were machined from arc-melted crystal-bar stock[2] in the form of cylindrical tubes 3 cm long, 1.1 cm diam, and with a wall thickness of 0.075 cm. The outer surfaces were abraded and then chemically polished to remove the cold-worked surface layers. Each specimen was instrumented with three Pt *vs.* Pt-10% Rh thermocouples on its inner surface and installed between support tubes inside a larger concentric quartz tube that served as the reaction chamber. A slightly positive pressure of helium gas was maintained within the support tube, while steam at atmospheric pressure was allowed to flow in the annular region between the supports and the outer tube. Consequently, oxidation occurred only on the outer surface of the specimen.

A quad-elliptical radiant heating furnace surrounding the reaction chamber heated the specimen according to a programmed temperature cycle. One thermocouple served as a sensor for the programmer-controller-recorder system, while the other two thermocouples, located 180° apart, were connected to a computer-operated data acquisition system that furnished a precise record of the temperature excursions experienced by these points on the specimen. This record was used to normalize the reaction times for sets of experiments conducted at nominally the same reaction temperature. The normalization also included the effective times associated with heating and cooling of the specimen. Specimen heating rates of about 100 K/sec were employed, and the initial cooling rates from the reaction temperature were in this same range. The "isothermal" experiments thus consisted of a rapid heat-up to the desired temperature, a period of constant temperature (generally within ± 1°-2°C, followed by a rapid cooling.

The thickness of the oxide and oxygen-stabilized alpha layers at the two monitor thermocouple positions were determined for each oxidation experiment by standard metallographic methods. The mounted specimens were sectioned normal to their axes on a plane containing the thermocouple junctions. Layer thicknesses were measured with a filar micrometer eyepiece on a small bench metallograph. The details of the measurement procedures as well as other experimental items are discussed at length elsewhere (1).

Results and Discussion

The oxidation morphology and the kinetics of layer growth for pure zirconium reacting in steam were studied at 1000°, 1098°, 1200°, and 1416°C. With the possible exception of the data set at the lowest temperature, the early stages of oxidation conformed to ideal parabolic behavior. The layers of oxide and oxygen-stabilized alpha zirconium were uniform in thickness and, as will be documented below, little evidence of irregular alpha growth into the beta region (alpha "incursions") was observed even for extended oxidation. Consistent with our earlier results for Zircaloy-4, the tetragonal oxide phase is thought to be the product of isothermal oxidation under the conditions of our experiments, except, as noted above, for the data set at 1000°C. These data provided the basis of a diffusion-modeling analysis of the system. The calculated effective chemical diffusion coefficients for oxygen in the product phases were then incorporated into the MULTRAN computer program (5) to examine the influence of several system parameters on the model oxidation behavior.

Oxidation kinetics.—In anticipation of the sensitivity of the reaction kinetics to the oxygen concentration in the beta phase, as evidenced by our previous work with Zircaloy-4 (5), the maximum reaction time at each temperature for those experiments to be used in the determination of rate constants was purposely limited to assure that a semi-infinite geometry condition prevailed. By so doing, the layer growth exhibits wholly parabolic behavior, and a well-defined rate constant can be obtained. This constant is defined by the rate expression

$$\frac{dk}{dt} = \frac{\delta_k^2}{2k} \quad [1]$$

where k is one of the kinetic parameters [ϕ (oxide thickness), α (alpha thickness), or τ (oxygen consumption)] and $\delta_k^2/2$ is the parabolic rate constant. This constant is generally obtained from the slope of the k^2 *vs.* t plot. Depending upon the nature of the reaction and the experimental procedures, an intercept of 0, 0 may be observed, and this generally indicates that one is dealing with an "ideal" reaction in addition to well-defined experiments.

The squares of the oxide and alpha layer thicknesses, measured for zirconium oxidizing in steam at 1416°C, are plotted in Fig. 1. These data are accurately described by straight lines, and a least squares treatment was used to obtain the rate constant and its statistical uncertainty. The dashed lines in the figure indicate the

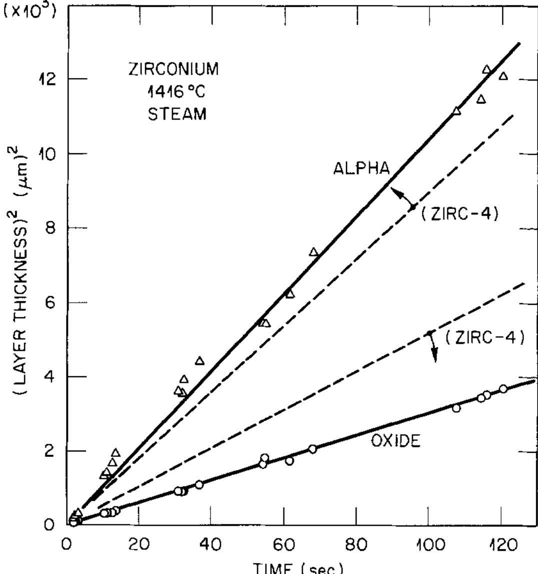

Fig. 1. Growth of zirconium oxide and oxygen-stabilized alpha zirconium layers on pure zirconium in flowing steam at 1416°C. The dashed lines compare the rates for Zircaloy-4 for the same conditions.

[2] Nominal composition (ppm by wt): Interstitial impurities—(O, C, H, N) to 30 ppm; metallic impurities—30 ppm Hf, other metals 0-10 ppm.

corresponding layer growth for Zircaloy-4. It is observed that the oxide layer on pure Zr grows more slowly than that on Zircaloy-4, while the reverse is true for alpha layer growth. Figure 2 shows a cross section of the product layers after oxidation for approximately 60 sec at 1416°C. While the uniformity of the layer thicknesses is apparent in this micrograph, the detail of the structure is less clear. SEM examination reveals that the oxide is comprised of a thin layer of fine, more-or-less equiaxed grains on its extreme outer surface, with the bulk of the layer consisting of thick (~20 μm) columnar grains each extending through a substantial fraction of the layer thickness. Careful polishing is necessary to discourage grains from popping out during normal specimen preparation; however, the artifacts furnish additional definition of the grain size and nature of the oxide. The alpha layer is also comprised of large columnar grains, and the tendency of this layer to exhibit cracking after cooling and specimen preparation is consistent with its suspected brittle nature. While the prior beta phase has transformed back to alpha upon cooling, it is clearly discernable from the alpha layer stabilized by oxygen at the reaction temperature.

Kinetic and morphological behavior similar to that observed at 1416°C was also found at 1200° and 1098°C. Figure 3 illustrates the excellent conformity of the layer growth to ideal parabolic kinetics at 1098°C. The dashed lines for layer growth on Zircaloy-4 indicate that the differences in growth rates for each layer are larger at the lower temperature.

The oxidation experiments at 1000°C, however, yielded complicated layer growth behavior that differed significantly from the simple behavior observed at the higher temperatures. These measurements are given in Fig. 4. While there is considerable scatter in the data, particularly the oxide thickness values, the dominant features of the first hour of reaction are the apparent changes in kinetics. At one stage, for example, it appears that the oxide layer may actually decrease in thickness as the reaction proceeds. In addition to the uncommon growth behavior for the oxide layer is the sigmoidal shape exhibited for alpha growth. If it is true, as we assume, that the oxidation of zirconium can be described as a multiphase diffusion process, the layer growths would be coupled in precisely this way.

The functional description of the layer growth at short times is not clear from the data in Fig. 4. For oxide growth, we have chosen somewhat arbitrarily to draw a curved line through the initial points, although a straight line segment (parabolic behavior) would seem equally acceptable. Thus, while reasonable estimates of "parabolic" rate constants can be obtained, we have omitted these values from the least squares analytical description of the variation in the rate constants with temperature. In any event, the general trend in the differences in layer growth kinetics between Zr and Zircaloy-4 is seen to persist, with complications, at this temperature.

We believe that the kinetic behavior observed during oxidation of Zr at 1000°C constitutes evidence that structural changes take place in the oxide layer during growth and that these changes may be responsible for

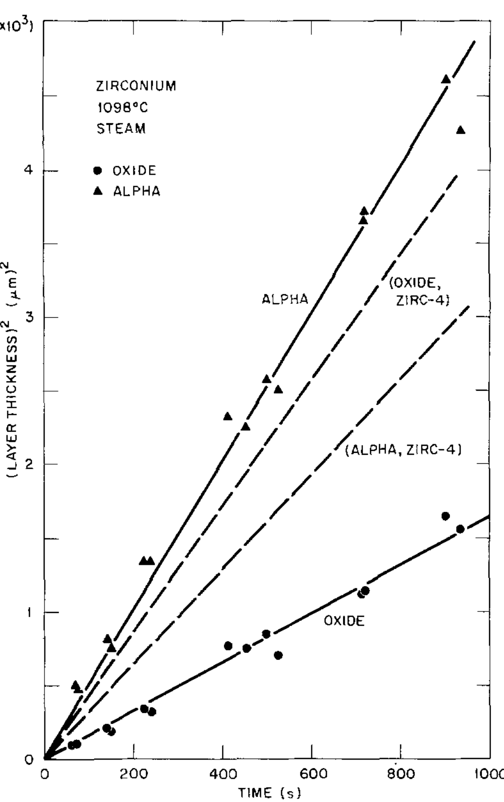

Fig. 3. Growth of zirconium oxide and alpha zirconium layers on zirconium in flowing steam at 1098°C. The dashed lines represent the product growth on Zircaloy-4 for comparable conditions.

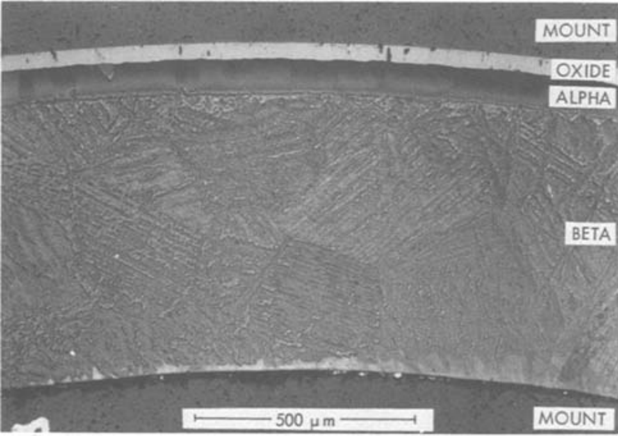

Fig. 2. Cross section of zirconium specimen oxidized in steam for 60 sec at 1416°C. Lightly etched in diluted Kroll's reagent followed by anodization to 20V in 1% KOH. Bright field micrograph.

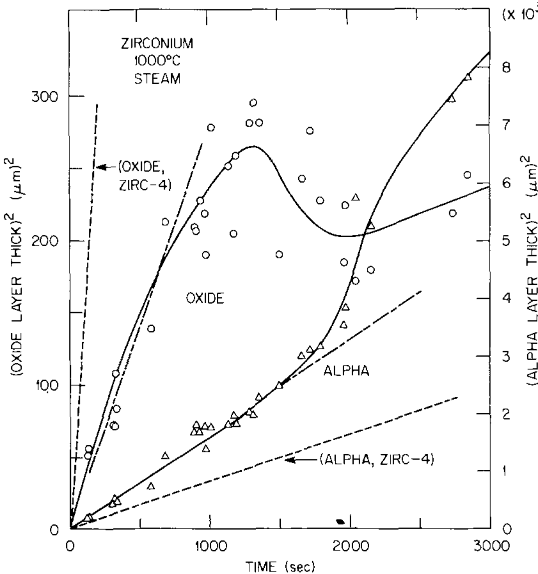

Fig. 4. Growth of zirconium oxide and alpha layers on zirconium in flowing steam at 1000°C showing variations in kinetics presumably due to structural changes within the oxide. Comparable parabolic rates for the early stage ($t < 1100$ sec) oxidation of Zircaloy-4 are given by the dashed lines.

many of the dramatic decreases in growth rates observed in this temperature range. As noted below, extrapolation of the high temperature kinetic parameters down to 1000°C suggests that in the very early stages of oxidation at this temperature, the oxide grows as the tetragonal form despite the fact that the monoclinic form is probably stable (at least for stoichiometric ZrO_2 (27). Pemsler (18) and others have noted that it may be possible to stabilize the tetragonal oxide at lower temperatures by the application of stress, high defect concentrations, or fine grain size. All of these factors are involved during the oxidation reaction.

Thus, a possible explanation for the change in the growth behavior of the oxide layer is the increasing proportion of the monoclinic oxide, which is characterized by a significantly lower oxygen diffusivity. The precise oxidation kinetics in the temperature range where the monoclinic-tetragonal transformation in the oxide is influenced by the metallurgical parameters in addition to its "normal" transformation hysteresis (27) might, therefore, be expected to depend sensitively upon experimental variables. In particular, heating rates, specimen shape, and temperature control would be important. As mentioned earlier, Pemsler (18) accounted for a continuously decreasing oxide growth rate on zirconium in the temperature range 750°-910°C by essentially this same hypothesis, and was later able to observe the existence of at least small amounts of the tetragonal oxide *in situ* at temperatures as low as 500°C (19). (The tetragonal oxide is not generally retained upon cooling to room temperature.) Rosa (20) also observed similar kinetic behavior at 875°-1050°C, but insufficient data were presented to describe the early stages of reaction in a detail sufficient for comparison with the present work.

The parabolic rate constants for layer growth determined in this investigation are given in Table I along with their statistical confidence limits. In addition, the rate constants for oxygen consumption, based on a modeling calculation in which the oxygen in each phase is accounted for consistent with the observed growth rates, are also given. Although, as previously noted, the oxidation does not exhibit precise parabolic kinetics at 1000°C, we nevertheless calculated "apparent rate constants" for the early stages of reaction at this temperature from the slopes of arbitrarily drawn straight lines through the origin of the rate curves using only the first few data points. The range of these values is also given in Table I. It was observed that the maximum value of the rate constant for oxide growth and the minimum value for alpha growth are approximately equal to the extrapolated values of these parameters based on the results of the higher temperature experiments. For the data obtained at the three temperatures above 1000°C, the measured rates conformed surprisingly well to simple Arrhenius behavior, as shown in Fig. 5.

Table I. Parabolic rate constants for oxidation of zirconium in steam[a]

Temperature (°C)	Oxide, $\frac{\delta_\phi^2}{2}$, cm²/sec	Dev. %[b]	Alpha, $\frac{\delta_\alpha^2}{2}$, cm²/sec	Dev. %[b]	Ox. cons., $\frac{\delta_\tau^2}{2}$, (g/cm²)²/sec[c]
1416	1.522×10^{-7}	1.6	5.193×10^{-7}	3.3	7.95×10^{-7}
1200	2.370×10^{-8}	2.8	6.464×10^{-8}	2.5	1.13×10^{-7}
1098	8.274×10^{-9}	8.4	2.503×10^{-8}	6.2	3.60×10^{-8}
1000	$1.1\text{-}2.2 \times 10^{-9}$	[d]	$6.7\text{-}8.2 \times 10^{-9}$	[d]	

[a] Rate constants calculated on basis of $\frac{\delta_k^2}{2} = k\ dk/dt$.
[b] Maximum uncertainty at 90% confidence level.
[c] Based on modeling calculations with MULTRAN program.
[d] Serious departures from parabolic behavior observed after short time at 1000°C.

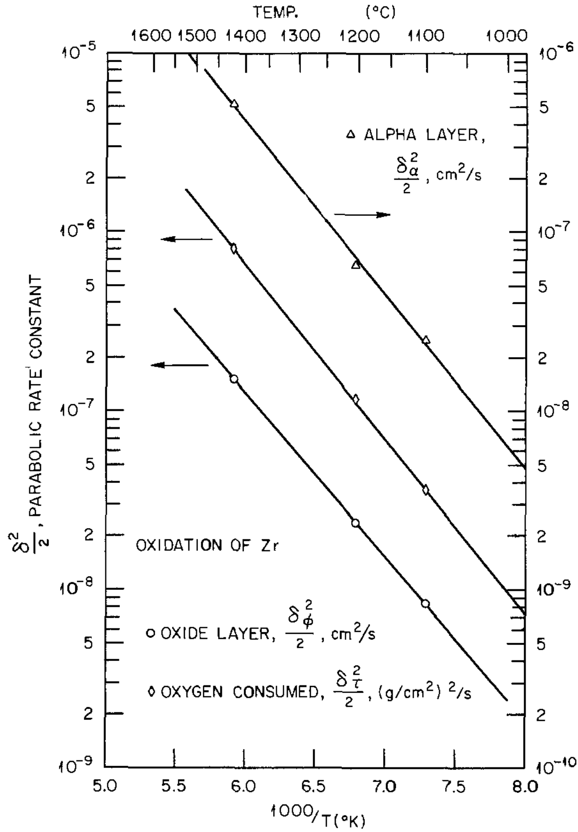

Fig. 5. Parabolic rate constants for oxide layer growth, alpha layer growth, and oxygen consumption. The rate constants for oxygen consumed were determined from a modeling analysis. Rate constants are based on the expression $\delta_k^2/2 = k\ dk/dt$.

The parabolic rate constants for oxide (ϕ) and alpha (α) growth, and for oxygen consumption (τ) are given by

$$\frac{\delta_\phi^2}{2} = 0.04361 \begin{bmatrix} +35\% \\ -26\% \end{bmatrix} \exp[-176{,}500(\pm 2.1\%)/RT] \text{ cm}^2/\text{sec} \quad [2]$$

$$\frac{\delta_\alpha^2}{2} = 0.2693 \begin{bmatrix} +1350\% \\ -93\% \end{bmatrix} \exp[-185{,}400(\pm 18\%)/RT] \text{ cm}^2/\text{sec} \quad [3]$$

$$\frac{\delta_\tau^2}{2} = 0.4948 \exp(-187{,}300/RT) \text{ (g/cm}^2)^2/\text{sec} \quad [4]$$

The activation energies are expressed in J/gmol, and R is 8.314 J/gmol · K. The small number of data points lead to the wide 90% confidence intervals on the individual terms of the Arrhenius expressions, especially for the rate constant for alpha layer growth. The joint confidence intervals, which estimate the statistical uncertainty on the rate constants themselves, are narrower. At the mean of the reciprocal temperature range involved, they are about ± 3% for oxide growth and about ± 25% for alpha growth. Confidence intervals are not given for oxygen consumption in Eq. [4] because this parameter was derived from a modeling analysis involving smoothed data rather than directly using experimental measurements. While these expressions are useful for a number of purposes, it should be remembered that each of these rate parameters is influenced by rate (diffusion) processes in more than one phase and, therefore, the kinetics would not be expected to be represented precisely by an Arrhenius expression with a single activation energy.

Oxygen diffusion.—Earlier (4), on the basis of an ideal model in which the oxidation of Zircaloy was considered to be a multiphase, moving boundary dif-

fusion problem, we derived expressions relating the effective chemical diffusion coefficients for oxygen in the oxide and alpha phases to the measured kinetic parameters. In the present work, we have applied these identical equations {essentially Eq. [11] and [18] of Ref. (4)} to the layer growth data for pure zirconium to arrive at diffusion coefficients relevant to this system. Aside from the kinetic data, it is necessary to have information on the Zr-O phase equilibria in order to solve uniquely for these diffusivity values. With the exception of the alpha-beta equilibrium, shown in Fig. 6, we have assumed that there are no significant differences between the zirconium-oxygen and the Zircaloy-oxygen phase diagrams over the temperature range of interest. The interfacial oxygen solubilities shown in Fig. 6 were drawn considering the data of Gebhardt *et al.* (21), Horz *et al.* (22), and Domagala *et al.* (23). The corresponding curves of the pseudobinary diagram for Zircaloy-4-oxygen are given as the dashed lines taken from the data of Chung *et al.* (24).

For the purpose of various calculations, it is convenient to express the equilibrium oxygen concentration at the various interfaces as functions of temperature. Using the terminology $C_{A/B}$ to represent the oxygen concentration in phase A in contact with phase B, the functions are

$$C_{\phi/gas} = 1.511 \text{ g/cm}^3 \text{ [3]}$$

$$C_{\phi/\alpha} = 1.517 - 7.5 \times 10^{-5}\,T(\text{K}) \text{ g/cm}^3 \quad \text{[Ref. (25)]}$$

$$C_{\alpha/\phi} = 0.4537 \text{ g/cm}^3 \quad \text{[Ref. (21), (23)]}$$

$$C_{\alpha/\beta} = -2.906 + 5.322 \times 10^{-3}\,T(\text{K}) - 3.170 \times 10^{-6}\,T^2(\text{K}) + 6.519 \times 10^{-10}\,T^3(\text{K}) \text{ g/cm}^3 \quad \text{[Ref. (21), (23)]}$$

$$C_{\beta/\alpha} = -0.11136 + 7.109 \times 10^{-5}\,T(\text{K}) + 2.271 \times 10^{-8}\,T^2(\text{K}) \text{ g/cm}^3 \quad \text{[Ref. (21), (22), (23)]}$$

The expressions are valid over the temperature range 1200-1760 K. In addition, the diffusivity of oxygen in beta zirconium, D_β, was taken as

$$D_\beta = 0.0263 \exp\,[-14{,}190/T(\text{K})] \text{ cm}^2\text{/sec} \quad \text{[Ref. (26)]}$$

[3] On the assumption that the oxide at the oxide-gas interface is stoichiometric ZrO_2 with a density of 5.82 g/cm³.

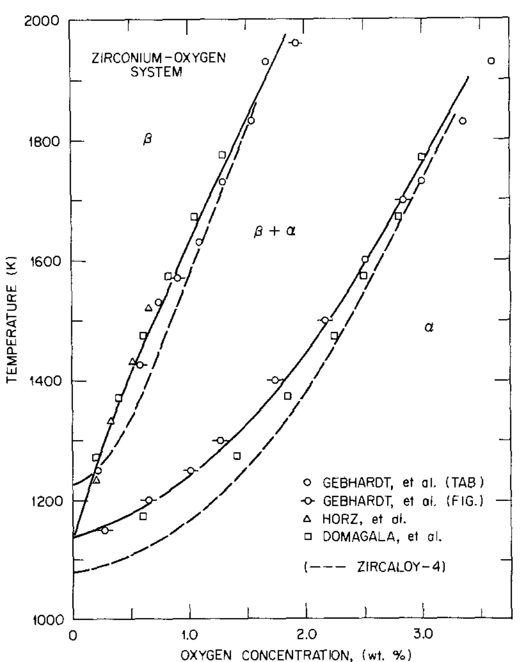

Fig. 6. Phase diagram for the Zr-O system showing the α-β equilibrium. Data are from Gebhardt *et al.* (21), Horz *et al.* (22), and Domagala *et al.* (23). Dashed lines are data for the Zircaloy-4 system from the data of Chung *et al.* (24).

Table II. Oxygen diffusion coefficients in oxide and alpha phases on zirconium during steam oxidation

Temperature (°C)	Oxygen diffusion coefficients, cm²/sec	
	Oxide, D_ϕ	Alpha, D_α
1416	2.90×10^{-6}	1.01×10^{-6}
1200	4.90×10^{-7}	1.01×10^{-7}
1098	1.80×10^{-7}	3.10×10^{-8}
1000[a]	$2.8\text{-}5.0 \times 10^{-8}$	$6.2\text{-}6.7 \times 10^{-9}$

[a] Calculated using range of "approximate parabolic rates" for the early stages of oxidation at 1000°C.

The effective chemical diffusion coefficients calculated for oxygen in the growing oxide and oxygen-stabilized alpha phases during reaction in steam are listed in Table II and plotted in Fig. 7. The three data points for each diffusivity at the higher temperatures exhibit classical Arrhenius behavior. The data points for 1000°C were calculated from the range of apparent "parabolic rates" assigned to our layer thickness measurements. While the alpha diffusivity is only slightly influenced, the variation of diffusivity indicated for the oxide is appreciably larger and, thus, we have chosen not to include either of these values in the analytical description of the diffusivities. For oxygen diffusion in the oxide phase, D_ϕ, the least squares Arrhenius expression is

$$D_\phi = 0.4684 \begin{bmatrix} +43\% \\ -30\% \end{bmatrix} \exp\,(-168{,}500\,[\pm 2.6\%]/RT) \text{ cm}^2\text{/sec}$$

For oxygen diffusion in the alpha phase, D_α, the three data points were judged to belong to the same set as that for Zircaloy-4 (4) and, thus, based on the more extensive latter data set

$$D_\alpha = 3.920 \begin{bmatrix} +27\% \\ -21\% \end{bmatrix} \exp\,(-213{,}400\,[\pm 1.4\%]/RT) \text{ cm}^2\text{/sec} \quad [6]$$

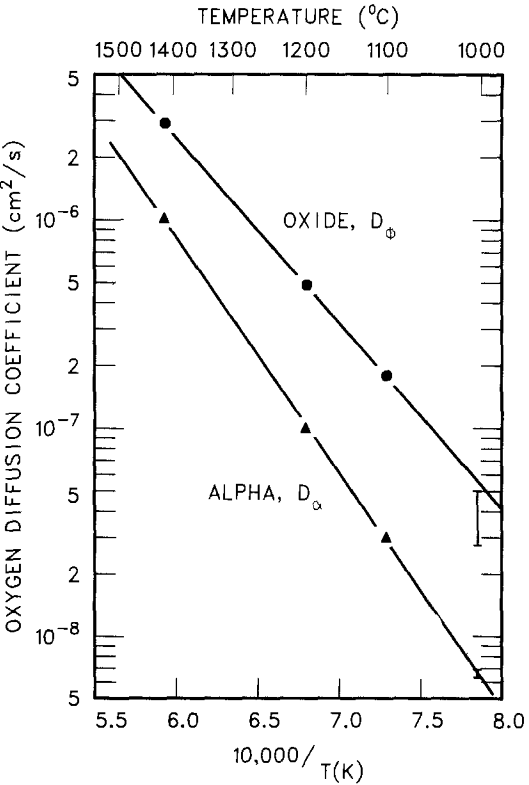

Fig. 7. Arrhenius plot showing temperature dependence of diffusion coefficients for oxygen in the growing oxide phase (D_ϕ), and in the alpha phase (D_α) on pure zirconium determined in the present investigation.

where, as before, the brackets refer to the 90% individual confidence limits. The joint confidence intervals for both diffusivities at the midpoint of the reciprocal temperature range are about ± 3.5 and ± 2.5%, respectively.

The experimental result that the calculated diffusion coefficient for oxygen in the alpha phase on zirconium is identical to that found for the alpha phase on Zircaloy-4 is particularly significant. Since one would not expect minor alloy additions to have a large influence on an interstitial diffusion rate, unless the impurities were highly reactive metals, this agreement tends to add confidence to the accuracy of the measurements and the data treatment. Thus, even though both layers grow at different rates on the two materials, all of the differences in the oxidation kinetics of the two systems can be attributed to a difference in the oxygen diffusivities in the oxide phases alone.

Modeling finite-geometry effects for zirconium.—In a recent paper (5), we reported the results of a modeling analysis that described the changes in layer growth kinetics that would be expected when specimens of Zircaloy-4 were oxidized for times sufficient to influence oxygen diffusion in the beta phase through its approach to saturation. The results of this analysis were generally consistent with experimental data, but a completely satisfactory comparison was not possible because irregularities in the alpha-beta interface developed at the longer oxidation times, resulting in a somewhat arbitrary measurement of the alpha layer growth.

In contrast to the behavior exhibited by Zircaloy-4, the oxidation of pure zirconium under similar conditions did not produce alpha "incursions," but uniform growth of both oxide and alpha layers were observed throughout the reaction to the point where virtually no beta phase remained in the specimen. For example, Fig. 8 and 9 show cross sections of zirconium specimens oxidized for approximately 260 and 1040 sec at 1416°C. These specimens show clearly the grain structure and characteristic brittleness of both the oxide and alpha layers. However, despite the fact that very thick layers are involved, and that the shrinking beta phase has become completely oxygen saturated, Fig. 9 shows very uniform layer thicknesses.

The ideal behavior observed here makes the oxidation of zirconium an excellent vehicle to test further this aspect of diffusion modeling. Thus, computer experiments were conducted using the MULTRAN code (5, 28) with diffusivity and equilibrium solubility input appropriate to the oxidation of zirconium in steam. For one-sided oxidation at 1416°C of specimens nominally 0.074 cm thick, the analysis predicts that significant departures from semi-infinite conditions for diffusion in the beta phase will exist by 120 sec and that the beta phase will become saturated at about 600 sec. Over this period of time, the original parabolic growth rates of the product phases increase to values consistent with those of growth into saturated beta. While only a second-order effect is found for growth of the oxide, the rate constant for alpha growth increases by more than a factor of two during this time.

The MULTRAN results for layer growth at 1416°C are shown by the solid curves in Fig. 10. The dashed lines are extrapolations of the short-time parabolic rates from Fig. 1. The comparison graphically illustrates the extent of the rate changes expected from the finite-geometry effect. The individual points are

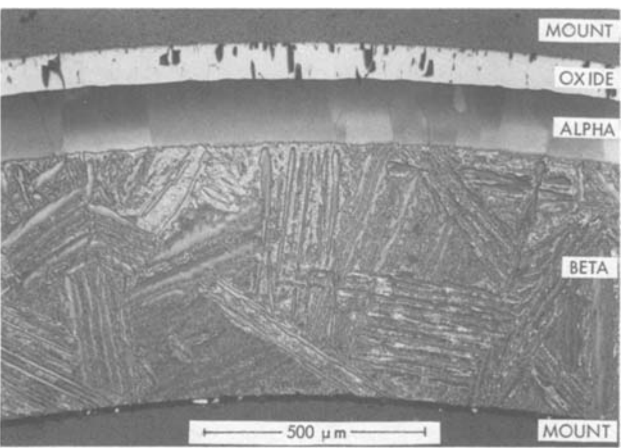

Fig. 9. Cross section of zirconium specimens oxidized in steam for 1040 sec at 1416°C. Growth has continued to be uniform although little beta phase remains. Note brittle response of the oxide and alpha layers to routine polishing.

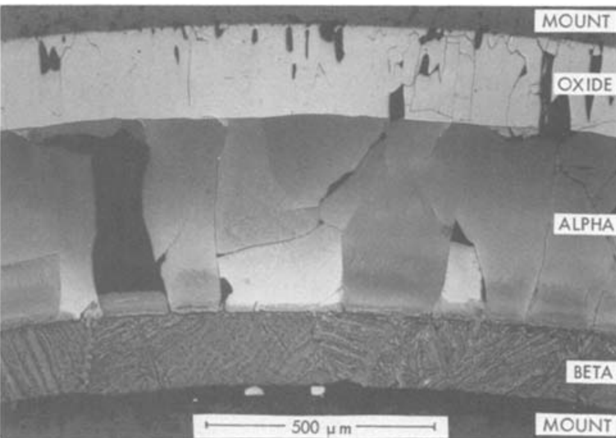

Fig. 8. Cross sections of zirconium specimen oxidized in steam for 260 sec at 1416°C. Coarse, columnar grains in both oxide and alpha layers are apparent.

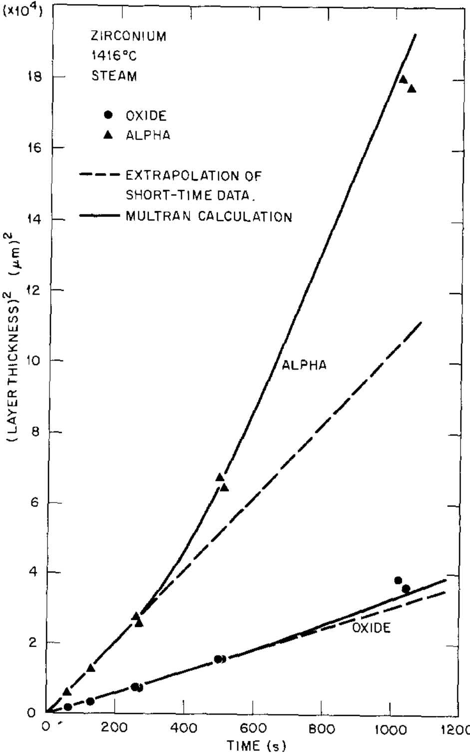

Fig. 10. Growth of oxide and alpha layers on zirconium in steam at 1416°C. The solid curves represent MULTRAN modeling results for a one-sided reaction of a specimen 0.074 cm thick. The dashed lines are extrapolations of the early stage parabolic rates (as in Fig. 1). The data points are experimental measurements.

the experimental data, and the excellent agreement between the predictions and the experimental observations gives additional credibility to the model ing technique. In addition, the extreme sensitivity of the alpha layer growth rate to the specimen thickness and extent of oxidation as well as to the original oxygen concentration points out yet another factor to be considered when evaluating and comparing oxidation behavior in this or a similar system.

Conclusions

1. At temperatures over the range 1098°-1416°C, the oxidation of pure zirconium in steam was characterized by ideal, diffusion-controlled growth of layers of oxide and oxygen-stabilized alpha zirconium.

2. From the parabolic rate constants determined for growth of both product layers, the effective chemical diffusion coefficient for oxygen in each of the phases was determined. These diffusivities exhibited classical Arrhenius behavior, and the alpha phase coefficient was statistically identical to that found earlier for diffusion in alpha Zircaloy-4.

3. A diffusion modeling analysis successfully predicted the changes in layer growth rates observed after "long" periods of oxidation of "thin" specimens. The effects of a finite specimen geometry as well as variation in the original oxygen content of the specimen were shown to be potentially large, particularly for growth of the alpha zirconium layer.

4. At 1000°C, the layer growth during oxidation exhibited complicated behavior. We proposed that this was due to changes in the relative proportions of the tetragonal and monoclinic oxides comprising the growing oxide film at this temperature.

ABSTRACT

The Gibbs energy of formation of beta alumina in equilibrium with alpha alumina has been measured over the temperature range 320°-800°C by two different equilibrium emf techniques. The results are well represented by the following equation

$$Na_2O + xAl_2O_3 = Na_2O \cdot xAl_2O_3 \ (\beta\text{-alumina})$$

$$\Delta G° = -22.0 \times 10^4 - 0.57T \pm 5.5 \times 10^3 J$$

Chronopotentiometric experiments were performed over the range 85°-140°C. If the observed plateaus are interpreted as representing the dissociation of Na_2O in the beta alumina, results are in agreement with the above equation.

Despite the great interest in the superionic conductor beta alumina in recent years, the thermodynamic stability of this compound still has not been well determined, particularly at lower temperatures. In the present study, the free energy of formation of beta alumina in equilibrium with alpha alumina was determined over the temperature range from 320° to 800°C by two different equilibrium emf techniques and over the temperature range 80°-140°C by chronopotentiometry. Normally, one cannot investigate a solid by this nonequilibrium technique due to the very high ohmic drop. However, the extremely high conductivity of the superionic conductor β-Al_2O_3 permits this method to be used for this material.

Equilibrium Techniques

Experimental.—In the equilibrium techniques, slipcast high density vacuum-tight beta alumina tubes from Polyceram Incorporated were used. The fabrication of these tubes has been described elsewhere (1). The tubes were approximately 6 cm long × 1 cm diam with a wall thickness of about 0.1 cm.

Approximately half of the tubes were made directly from commercial "Alcoa XB2" powder. Analysis by atomic absorption showed that these tubes had compositions varying from $Na_2O \cdot 9.3Al_2O_3$ to $Na_2O \cdot 9.9Al_2O_3$. Hence, according to the phase diagram (2), all the tubes were two-phase α-Al_2O_3/β-Al_2O_3 mixtures. This was confirmed by x-ray analysis of the tubes. For the other half of the tubes, about 25% α-Al_2O_3 powder was added during the grinding step so that these tubes had compositions even further within the two-phase region. No difference in the results obtained from the two sets of tubes was evident. Since Na_2O is the volatile component, slight volatilization losses from the surface of the tubes at high temperature will assure that there is even more of the α-phase at the surface than in the bulk.

Cell I.—Cell I is shown schematically in Fig. 1. This cell may be represented as

$$(\text{Chromel (W)}\ Na_{liq}|\beta\text{-}Al_2O_3|\ (NaNO_3 + NaNO_2)_{liq} \left| \begin{matrix} \alpha\text{-}Al_2O_3 \\ + \\ \beta\text{-}Al_2O_3 \end{matrix} \right| O_{2(0.21\ atm)}\ (\text{Pt})\ (\text{Chromel}) \quad [I]$$

The sodium electrode consisted of a beta alumina tube containing pure liquid Na. The cell was sealed with an alumina plug and "Cotronix 940"[1] ceramic cement. Contact was made via a tungsten wire which passed through a Pyrex metal/ceramic seal. The tube was sealed with a small amount of tungsten powder inside and the cement was then sintered at 900°C in order to give a gas-tight seal. Several grams of sodium were then titrated coulometrically into the electrode compartment from an $NaNO_3$-$NaNO_2$ bath. The oxygen electrode consisted of a two-phase α-Al_2O_3/β-Al_2O_3 tube cemented to an α-Al_2O_3 extension tube open to the air. Electrical contact was made via a platinum wire to the platinized inner surface of the tube. Contact between the two electrodes was via a molten $NaNO_3$-$NaNO_2$ bath. The use of the molten salt as an intermediary electrolyte eliminates the possibility of electronic transport between electrode compartments.

The overall cell reaction for cell I is

$$2Na_{liq} + \tfrac{1}{2} O_{2(0.21\ atm)} = Na_2O_{(in\ \beta\text{-}Al_2O_3)} \quad [1]$$

Hence, the emf of cell I is given by

$$\epsilon = -\frac{RT}{2\mathbf{F}} \ln \frac{a_{Na_2O}}{0.21^{1/2}} - \frac{1}{2\mathbf{F}} \Delta G°_{Na_2O} \quad [3]$$

where **F** is the Faraday, R is the gas constant, T is the temperature in Kelvin, a_{Na_2O} is the activity of Na_2O in β-Al_2O_3 in equilibrium with α-Al_2O_3, and $\Delta G°_{Na_2O}$ is the standard Gibbs energy of formation of Na_2O. Sub-

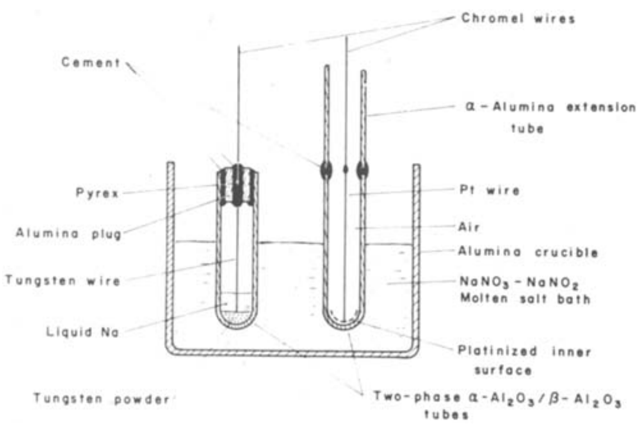

Fig. 1. Cell I

Key words: beta-alumina, thermodynamic properties, solid electrolytes.

stituting into Eq. [2] the value of $\Delta G°_{Na_2O} = -405{,}600 + 128.9T$ in joules obtained from the literature (3) we obtain

$$\log_{10} a_{Na_2O} = \frac{-10{,}080}{T}\epsilon + \frac{21{,}190}{T} - 7.08 \quad [3]$$

where ϵ is in volts.

Cell II. Cell II which is shown schematically in Fig. 2, may be represented as

$$(Pt)\, W_{(solid)}, WS_{2(solid)}, Na_2S_{(solid)} \left| \begin{array}{c} \alpha\text{-}Al_2O_3 \\ + \\ \beta\text{-}Al_2O_3 \end{array} \right| ZrO_2\text{-}Y_2O_3 \left| O_{2(0.21\ atm)}\ (Pt) \right. \quad [II]$$

A two-phase α-Al_2O_3/β-Al_2O_3 tube was filled with a mixture of W, WS_2, and Na_2S powders.[2] The compartment was sealed with a highly viscous Kovar glass. The tube rested inside a long ZrO_2-Y_2O_3 tube. Argon was passed inside the ZrO_2-Y_2O_3 tube in order to eliminate the possibility of oxygen traversing the Kovar seal. The exterior of the ZrO_2-Y_2O_3 tube was placed in an atmosphere of air. Electricol contact was made via a Pt electrode attached to the platinized surface. The $W/WS_2/Na_2S$ reference, which establishes a fixed activity of Na, was first used by Liang and Elliott (6). In order that the three-phase equilibrium be established, this reference electrode must be used at temperatures in excess of 550°C.

The overall cell reaction of cell II is

$$Na_2S_{(solid)} + \tfrac{1}{2} W_{(solid)} + \tfrac{1}{2} O_{2(0.21\ atm)} = Na_2O_{(in\ \beta\text{-}Al_2O_3)} + \tfrac{1}{2} WS_{2(solid)} \quad [4]$$

Hence the emf of cell II is given by

$$\epsilon = -\frac{RT}{2F}\ln\frac{a_{Na_2O}}{0.21^{1/2}} - \frac{1}{2F}\left(\frac{1}{2}\Delta G°_{WS_2} - \Delta G°_{Na_2S} + \Delta G°_{Na_2O}\right) \quad [5]$$

Substituting into Eq. [5] values for the standard Gibbs energies of formation of WS_2, Na_2S, and Na_2O from the literature (4, 5, 3) along with their estimated error limits, we obtain

$$\log_{10} a_{Na_2O} = -\frac{10{,}080}{T}\epsilon + \frac{7{,}210}{T} - 5.31 \pm 1.6 \quad [6]$$

where ϵ is in volts.

Results.—Values of $\log_{10} a_{Na_2O}$ calculated via Eq. [3] and [6] from the measured emf's of cells I and II are shown in Fig. 3. For both cells I and II the points

[2] Alfa Inorganics.

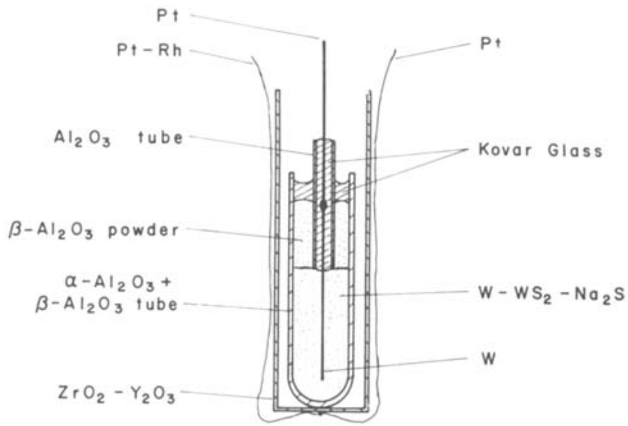

Fig. 2. Cell II

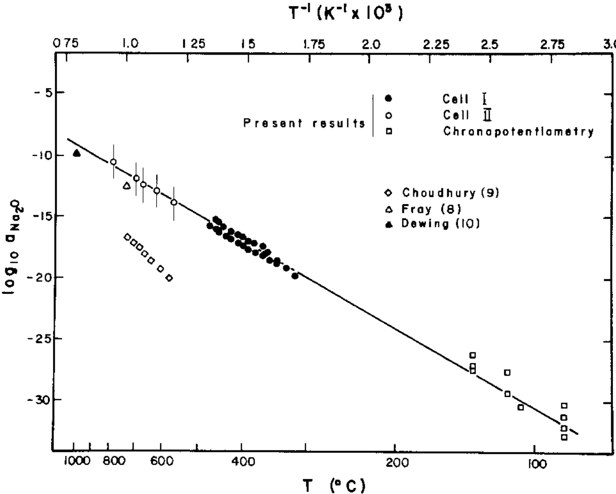

Fig. 3. Activity of Na_2 in β-Al_2O_3 in equilibrium with α-Al_2O_3

shown were obtained during both heating and cooling cycles. Measured emf's were very stable. If the cells were polarized, the emf quickly returned to within ±1 mV of its former value within 1 or 2 min. Overall reproducibility is estimated as ±5 mV. The error bars shown on Fig. 3 for cell II are those given in Eq. [6].

Chronopotentiometry

At lower temperatures, equilibrium techniques can no longer be applied because kinetic barriers to reactions involving the solid state become too great. Consequently, nonequilibrium techniques in which one attempts to force the decomposition of the beta alumina must be used. In these experiments it is assumed that the reaction involved is the decomposition of the sodium oxide in the two-phase α-Al_2O_3/β-Al_2O_3 mixture according to

$$Na_2O_{(in\ \beta\text{-}Al_2O_3)} = 2Na + \tfrac{1}{2} O_2 \quad [7]$$

As will be shown later, the final justification for this assumption is that the results agree well with those obtained by the equilibrium techniques discussed in the previous section.

The details of the cell for the chronopotentiometric experiments have been described by Foraison and Souquet (7). A two phase α-Al_2O_3/β-Al_2O_3 disk, 3.30 cm in diameter by 1.12 cm thick, was prepared by cold-pressing "Alcoa XB2" beta-alumina powder at 1 t/cm³ followed by sintering at 1600°C for 1 hr in a container packed with β-Al_2O_3 powder. Holes for the working, reference, and counterelectrode compartments were made with a diamond drill. The counterelectrode compartment was in the form of an annulus surrounding the working electrode. The reference and counterelectrode compartments were filled with Na-Hg amalgams containing approximately 0.3 weight percent Na. The working electrode compartment contained an amalgam with only a few ppm of sodium. Electrical contact was made via tungsten leads. The entire assembly was maintained under purified nitrogen in a Pyrex tube placed in a thermostated oil bath. A constant current of 1.0 μA was imposed between the working and counterelectrodes, the working electrode being the anode. The voltage between the working electrode and the reference electrode (which was never polarized) was measured as a function of time. A typical curve is shown in Fig. 4. In this figure, the ordinate is the overpotential η defined as

$$\eta = \epsilon - \epsilon_{(I=0)} \quad [8]$$

where ϵ is the measured voltage and $\epsilon_{(I=0)}$ is the voltage measured at open circuit (zero current).

The initial portion of the curve is presumed to correspond to the diffusion of sodium in the working electrode and the formation of a sodium-depleted boundary

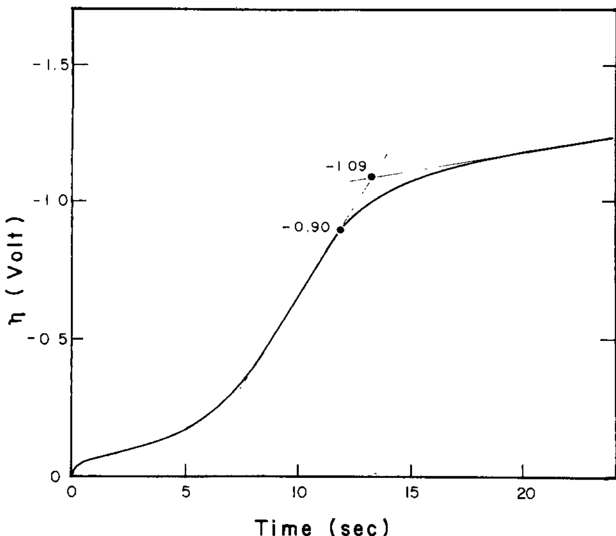

Fig. 4. Experimental chronopotentiometric curve. Conditions: $T = 115°C$, $\epsilon_{(I=0)} = 0.339V$, applied current = 1 μA.

layer. The plateau which begins between $\eta = -0.9V$ and $\eta = -1.09V$ is presumed to result from the decomposition of the β-Al_2O_3 according to Eq. [7]. The actual decomposition overpotential, η_{decomp}, was chosen in Fig. 4 as $\eta = -1.0 \pm 0.1$ which is the average of -0.9 and $-1.09V$. All the chronopotentiometric curves were interpreted in the same way. From Eq. [8]

$$\eta_{decomp} = \frac{RT}{\mathbf{F}}\left(\ln\frac{a_{Na(decomp)}}{a_{Na(ref)}} - \ln\frac{a_{Na(bulk)}}{a_{Na(ref)}}\right)$$

$$= -\frac{RT}{\mathbf{F}}\ln\frac{a_{Na(bulk)}}{a_{Na(decomp)}} \qquad [9]$$

where $a_{Na(ref)}$ is the activity of Na in the reference electrode, while $a_{Na(bulk)}$ and $a_{Na(decomp)}$ are the activities of Na in the bulk of the working electrode at the amalgam/β-Al_2O_3 interface at the moment when decomposition commences.

In order to calculate the activity of Na_2O in the β-Al_2O_3 it is necessary to know the activity of oxygen dissolved in the working electrode. It may be assumed that the system is saturated in oxygen. That is, the Na and O_2 dissolved in the bulk are in equilibrium with pure Na_2O. Hence

$$K = \frac{1}{a_{Na(bulk)}{}^2 P_{O_2}{}^{1/2}} = \frac{a_{Na_2O}}{a_{Na(decomp)}{}^2 P_{O_2}{}^{1/2}} \qquad [10]$$

where P_{O_2} is the partial pressure of oxygen dissolved the working electrode, a_{Na_2O} is the activity of Na_2O in the α-Al_2O_3/β-Al_2O_3 mixture, and K is the equilibrium constant for the formation of Na_2O from 2Na and ½ O_2. Substitution of Eq. [10] into Eq. [9] gives

$$\eta_{decomp} = \frac{RT}{2\mathbf{F}}\ln a_{Na_2O} \qquad [11]$$

Hence, ln a_{Na_2O} is given directly from measurement of η_{decomp}.

Results of several experiments between 85° and 140°C are shown in Fig. 3.

Discussion

It can be seen from Fig. 3 that the results from the two equilibrium measurements (cells I and II) fall on the same straight line. The equation of the line shown on Fig. 3, which was found by a least squares regression analysis of only the data obtained by the equilibrium measurements, is

$$\log_{10} a_{Na_2O} = -11.49 \times 10^3\, T^{-1} - 0.03 \pm 0.32 \qquad [12]$$

The root mean square deviation of the fit to $\log_{10} a_{Na_2O}$ was ± 0.32. The free energy of formation of β-Al_2O_3 in equilibrium with α-Al_2O_3 according to

$$Na_2O + xAl_2O_3 = Na_2O \cdot xAl_2O_3 \qquad [13]$$

is given from Eq. [12] as

$$\Delta G°_{[13]} = RT \ln a_{Na_2O} = -22.0 \times 10^4 - 0.57T \pm 5.5 \times 10^3 J \qquad [14]$$

When the line given by Eq. [12] is extrapolated to lower temperatures, it passes through the experimental points measured by chronopotentiometry as can be seen from Fig. 3. This supports the interpretation of these nonequilibrium measurements given in the previous section.

The present results are in close agreement with the measurement of Fray (8) at 725°C (see Fig. 3) whose cell consisted of a tube of β-Al_2O_3 containing a powdered mixture of α-Al_2O_3 and β-Al_2O_3 open to the air, immersed in pure sodium.

Choudhury (9) measured the activity of Na_2O in two-phase α-Al_2O_3/β-Al_2O_3. The sodium activity was fixed by a mixture of Ni, NiF_2, and NaF, while the oxygen potential was fixed by a Cu/Cu_2O mixture. All the components were in the solid state. Choudhury's results are also shown in Fig. 3.

Recent calculations and measurements by Dewing (10) (see Fig. 3) are in close agreement with the present study at the higher temperatures.

Conclusions

The free energy of formation of β-Al_2O_3 saturated with α-Al_2O_3 has been measured over the temperature range 320°-800°C by two different equilibrium emf techniques. The results are in good agreement with each other. In addition, measurements of the same quantity by chronopotentiometry over the temperature range 85°-140°C gave results which agree with the values extrapolated from the equilibrium measurements at higher temperatures. However, in view of the many assumptions required, the interpretation of the chronopotentiometric experiments should be regarded as only tentative.

ABSTRACT

Measurements have been performed on phosphorous-implanted polysilicon films and TEM investigation has given indications about the mean grain size and about its dependence on the temperature and duration of annealing. Results have also been obtained concerning the sheet resistivity of the films. A semiquantitative model has been derived which attempts to explain the variation in sheet resistivity as a function of the doping level. The observation of both grain size and sheet resistivity suggests that not only segregation to grain boundary and grain growth occur during annealing but that a third phenomenon (a crystallographic relaxation at grain boundary) should occur at a temperature of about 1000°C.

The electrical properties of polycrystalline silicon (polysilicon) have already been extensively investigated for solar cell applications as well as in integrated circuit technology.

The use of that material has given rise to structures such as self-aligned MOSFET's, FAMOS transistors, and charge-coupled devices (1-3). More recently, devices such as diodes, variable resistors, or MOS transistors have been built using polysilicon (4-6), but, until now, polysilicon has been mainly used in the fabrication of passive components such as interconnecting stripes, NMOS gates, or integrated resistors. The resistivity of a polysilicon film varies with the concentration of the dopant atoms in it; it can extend over several decades (from 8Ω per square up to 10^{10}Ω per square). Low resistance polysilicon stripes can be obtained by heavy doping, while small size resistors of high as well as low values can be made in less doped polysilicon.

The main parameters on which the resistivity of polysilicon depends are the temperature of deposition (below 580°C, the deposited silicon is amorphous; above that temperature, it is polycrystalline, with an average grain size increasing with increasing deposition temperature), the average grain size, the doping level, and the annealing cycles to which the material has been submitted.

It is well known that the resistivity of polysilicon varies with the dopant concentration in a way which is very different from that of single crystal silicon.

Several models have been proposed to explain the variation in resistivity of polysilicon, taking the dopant concentration as a parameter, but they all are qualitative models. The basic phenomena that presumably explain the difference between single crystal and polycrystalline silicon are the migration and inactivation of impurity atoms at grain boundaries (7, 8) and carrier trapping at grain boundaries (Seto's model) (9, 10). This last model has generally been found more acceptable.

Since all those models refer to the crystalline texture of the layers, it is important to notice that TEM and SEM investigations have shown that the polysilicon crystallites have a basaltic texture, *i.e.*, that the grains grow with a columnar shape from the substrate up to the top of the layer (11).

It has also generally been assumed that the variation of polysilicon resistivity as a function of the annealing temperature after doping (by implantation of phosphorous in this case) (12) is due to the competition of two phenomena: the segregation of dopant atoms to the grain boundaries below 1000°C and the grain growth above that temperature. One of the goals of this study is to demonstrate that a third phenomenon has to be taken into account: a solid-phase crystallographic relaxation at the grain boundary, at temperatures around 1000°C. Our second goal will be to provide a mathematical model of polysilicon resistivity as a function of the doping level that would give greater consideration to the physical characteristics of polysilicon than previous models (basaltic texture of the grains, film thickness, etc.).

Experimental Procedure and Experimental Results

Sheet resistivity and grain size as a function of annealing cycles.—Resistivity.—The samples were fabricated on <100> 10-20 Ωcm p-type silicon wafers. The wafers were thermally oxidized at 1000°C in dry oxy-

* Electrochemical Society Active Member.

Key words: semiconductor, annealing, diffusion, trapping.

gen, wet oxygen, and dry oxygen to obtain a good oxide surface, a thick oxide, and a good $Si\text{-}SiO_2$ interface, respectively. The oxide thickness was 3000Å to avoid leakage currents. A 5000Å thick polysilicon layer was deposited in a Tempress LPCVD reactor by pyrolysis of silane at 625°C, under a pressure of 180 mTorrs. The samples were implanted with phosphorous at an energy of 100 keV at different doses. The polysilicon was then capped with a 3000Å-thick SiO_2 layer deposited at 420°C to avoid dopant outdiffusion and the wafers were annealed at different temperatures, from 800°C up to 1100°C in nitrogen ambient. The annealing time was 30 min, 2 or 12 hr. The capping oxide was then removed and the sheet resistivity was measured by the four-point probe method. The variation in sheet resistivity with annealing temperature is illustrated graphically in Fig. 1.

The sheet resistivity curves show the same shape for various annealing times: a maximum in sheet resistivity is reached at a temperature T_i which decreases when annealing time increases, while the value of this maximum increases with annealing time. For a given higher annealing temperature ($T > T_i$), the longer the annealing time, the lower the sheet resistivity, while the opposite behavior is observed for $T < T_i$.

The dependence of sheet resistance on annealing time is illustrated in Fig. 2 in which one can see that the sheet resistance increases with annealing time for $T < 900°C$, while it decreases for $T > 900°C$ and is stable at 900°C.

Grain size.—The samples were annealed for 12 hr and prepared for TEM investigation: a photolithographic step was necessary to create small disks of polysilicon, 3 mm in diameter, which were removed from the wafers by dissolving the subjacent oxide in HF. The small polysilicon disks were observed with a TEM (the accelerating voltage was 100 keV and the magnification was 33,000 or 6,000). Wada's method (13) was used to determine the mean grain size in polysilicon.

It has been observed that the mean grain size is about 1400Å for annealings between 800° and 1000°C. For samples annealed at 1050° and 1100°C, the mean grain size is respectively 4400 and 4700Å (Fig. 3).

Resistivity as a function of the doping level.—The samples were prepared as described above. Phosphorous was implanted with an energy of 100 keV in order to obtain impurity concentrations of 2×10^{18}, 2.4×10^{18}, 2.7×10^{18}, 3.6×10^{18}, 5.5×10^{18}, 10^{19}, 5×10^{19}, and 10^{20} cm^{-3}.

The samples were then capped with a silox oxide and annealed for 30 min at 1000°C. The capping oxide was removed and the resistivity of the samples was measured by the four-point probe method, except for those with the highest resistance, which were measured by the Van der Pauw method. The results are reported in Fig. 9 and will be commented on in the following section under Resistivity of polysilicon.

A New Model for Polysilicon Resistivity

Several models have been proposed to explain the variation of polysilicon resistivity with dopant concentration. The models assuming a trapping of carriers at the grain boundary are generally more accurate than those based on the atom segregation assumption, although evidence of atom segregation to grain boundaries has been found (14). The model of carrier trapping has first been developed by Seto (9) and has been improved by Baccarini, Ricco, and Spadini (15) and by Martinez and Piqueras (16). The improvements of Seto's model these last studies have provided take into account the energy distribution of the trapping centers, but all these models remain qualitative. Furthermore, they take into account neither the real physical shape of the grains (a columnar shape) nor the effect of the film thickness. The present study starts from a columnar-shaped grain, taking into account the fact that a depletion region surrounds the whole grain and "spreads" from the grain boundary to the center of the grain. It also accounts for the effect of the film thickness on the carrier mobility.

The potential barrier.—Let us consider a cylindrical crystallite having a radius R and a height h (the cylindrical shape has been chosen for it is the simplest shape accounting for the basaltic texture of the grain, and it can describe in two dimensions the effect of a depletion region surrounding the crystallite). The grain is as-

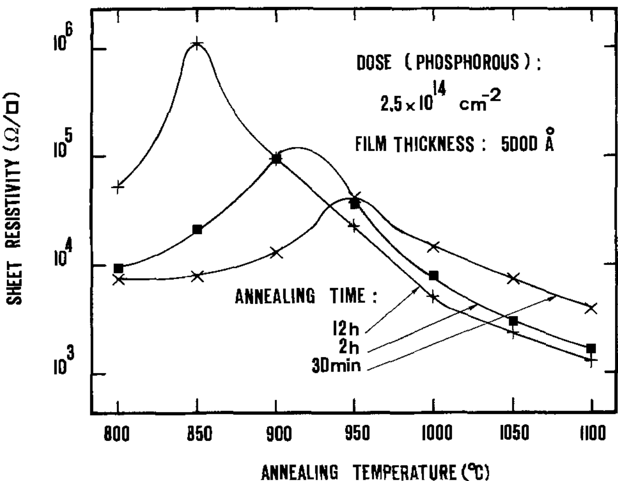

Fig. 1. Variation of sheet resistivity vs. annealing temperature

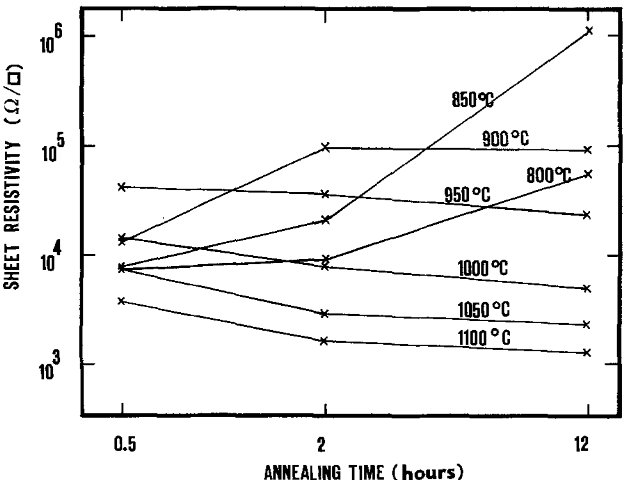

Fig. 2. Variation of sheet resistivity vs. annealing time

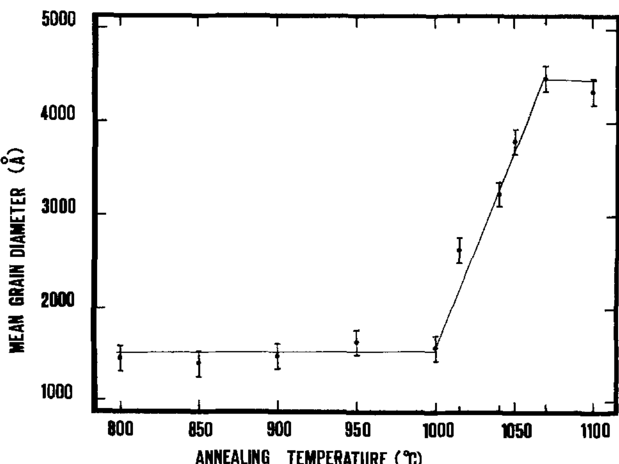

Fig. 3. Mean grain diameter vs. annealing temperature

sumed to be doped with a uniform impurity concentration N_d (cm^{-3}).

Let us also assume a concentration of traps N_t (cm^{-2}) located at the grain boundary (Fig. 4).

These traps are located in the bandgap and trap some carriers. The trapping of carriers gives rise to a depletion region spreading from the grain boundary to the core of the grain. This gives rise to a potential barrier between the grains. If the grain is not too small ($R > 2N_t/N_d$), there is a neutral region at the center of the cylinder; if this is not the case, the whole crystallite is depleted.

Solving Poisson's equation in cylindrical coordinates

$$\nabla^2\Phi = \frac{1}{r}\left[\frac{\partial}{\partial r}\left(r\frac{\partial\Phi}{\partial r}\right)\right] = -\frac{\rho}{\epsilon}$$

yields in the first case ($R > 2N_t/N_d$) a potential distribution

$$\Phi(r) = 0 \quad \text{if} \quad r < r_1$$

$$\Phi(r) = -\frac{qN_d}{4\epsilon}\left\{r^2 - r_1^2\left(1 + \ln\frac{r_2^2}{r_1^2}\right)\right\} \quad \text{if} \quad r > r_1 \qquad [1]$$

with r_1 being the radius of the neutral region.

Expressing the electrical neutrality of the set grain + grain boundary by

$$(R^2 - r_1^2)\,\pi h N_d = 2\pi R h N_t$$

we finally obtain the value of the potential barrier

$$V_b = \Phi(R) = -\frac{q}{4\epsilon}\{2N_tR + N_dR^2\,(1 - 2N_t/RN_d)\,\ln(1 - 2N_t/RN_d)\} \qquad [1a]$$

In the second case ($R < 2N_t/N_d$), the grain is "small" and one obtains

$$V_b = -\frac{qN_d}{4\epsilon}R^2 \qquad [1b]$$

One can see that the "smallness" of a grain is (strictly) relative: the importance of the grain size is directly related to the density of traps and to the doping level.

Similar expressions can obviously be derived for holes instead of electrons in the case of a p-type semiconductor.

Current flow through the potential barrier.—The current flowing from one crystallite to another has to overcome the potential barrier. For the sake of simplicity, we now consider a one-dimensional section, although the grains have been previously assumed to be cylindrical. Let $w = R - r_1$ and $dx = dr$ (see Fig. 5).

For a current flow which is assumed to be constant with respect to the x-direction, we have

$$J_n = qD_n\left\{-n(x)\frac{q}{kT}\frac{\partial\Phi}{\partial x} + \frac{\partial n}{\partial x}\right\}$$

Multiplying that equation by $\exp(-q\Phi(x)/kT)$ and integrating from 0 to w, we obtain

$$J_n\int_0^w \exp\left(-\frac{q\Phi(x)}{kT}\right)dx = qD_nn_0\left[\exp\left(\frac{qV_r}{kT}\right) - 1\right] \qquad [2]$$

where V_r is the voltage drop applied to the grain.

If one linearizes $\Phi(x)$ between 0 and w, one obtains (Fig. 6)

$$\Phi(x) = -\Phi_b + \left(\frac{x}{w}\right)(\Phi_b - V_r)$$

with Φ_b being the potential at grain boundary.

Under this assumption, Eq. [2] may be rewritten

$$J_n = \frac{q^2D_nn_0}{wkT}(\Phi_b - V_r)\,\exp\left(-\frac{q\Phi_b}{kT}\right)\frac{\exp\frac{qV_r}{kT} - 1}{1 - \exp\left(-\frac{q(\Phi_b - V_r)}{kT}\right)}$$

Now, if $V_r << \Phi_b$, $\Phi_b \simeq V_b$; V_r is equal to the voltage drop applied to the sample divided by the number of grains located between the two contacts. The assumption of $V_r << \Phi_b$ (and also $V_b << kT/q$) is valid if the grains are relatively small ($R < 1000$Å) as is the case in thermally annealed samples.

If V_b is small with respect to kT/q, we may estimate the resistivity near the grain boundary as being

$$\rho^{-1} = w\lim_{V_r\to 0}\frac{J_n}{V_r} = q\mu n_0\exp\left(-\frac{qV_b}{kT}\right) \qquad [3]$$

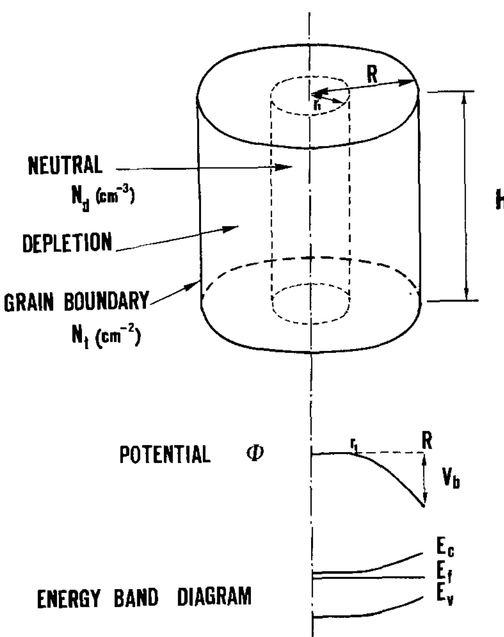

Fig. 4. Grain shape, potential, and energy band diagram in polysilicon.

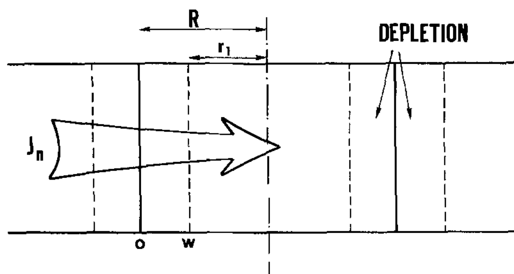

Fig. 5. Current flow through a grain boundary

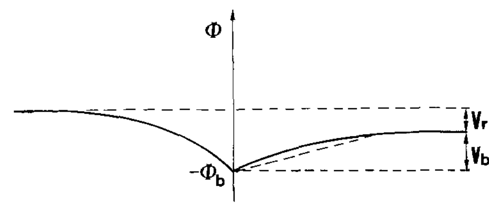

Fig. 6. Linearization of the potential near the grain boundary

Carrier mobility.—The last result allows us to define a "boundary mobility," μ_b. We have thus $\mu_b = \mu_0 \exp(-qV_b/kT)$ where μ_0 is the mobility in single crystal silicon. μ_0 has been found to vary as (17)

$$\mu_0 = 80 + 1570\{1 + (0.77 \times 10^{-17} N_d)^{0.91}\}^{-1} \text{ cm}^2/\text{Vsec}$$

If the crystallites are entirely depleted

$$\mu_{eff} = \mu_b \quad [4a]$$

If it is not the case, we must consider the neutral region and the barrier region as a serial association of resistors. A brief calculation shows that

$$\mu_{eff} = \mu_0 \frac{R \exp\left(-\frac{qV_b}{kT}\right)}{R - r_1\{1 - \exp(-qV_b/kT)\}} \quad [4b]$$

The mobility is also reduced by the effect of the film thickness; one can determine (18) that

$$\mu_{film} = \mu_{eff} \frac{3}{4}\left(\frac{t_f}{l_c}\right)\left\{0.423 + \ln\left(\frac{l_c}{t_f}\right)\right\} \quad [5]$$

where l_c is the mean free path of electrons (1.95 μm in silicon) and t_f is the film thickness.

Average carrier concentration.—We can estimate the average carrier concentration as follows: If $N_d > 2N_t/R$, the carrier concentration will be

$$\bar{n} = N_d - 2N_t/R \quad [6a]$$

$2N_t/R$ being the amount of carriers trapped at the grain boundary. If $N_d < 2N_t/R$, the carrier concentration can be calculated as follows

$$n(x) = N_c \exp\left(\frac{E_f - E_c + q\Phi(x)}{kT}\right)$$

$$\text{with} \quad \Phi(x) = \frac{-qN_d x^2}{4\epsilon}$$

the average carrier concentration is

$$\bar{n} = \frac{N_c}{\pi R^2}\exp\left(\frac{E_f - E_c}{kT}\right)\int_0^R 2\pi r \exp\left(\frac{-q^2 N_d r^2}{4\epsilon kT}\right) dr \quad [7]$$

If all the traps are located at the same energy level E_t, we have

$$\pi R^2 N_d = \frac{2\pi R N_t}{1 + 2\exp\{(E_t - E_f)/kT\}} \quad [8]$$

Equations [7] and [8] yield finally

$$\bar{n} = N_c \exp\left(\frac{E_t - E_c}{kT}\right) \frac{8kT\epsilon}{q^2\left(\frac{2N_t}{R} - N_d\right)}\left[1 - \exp\left(\frac{q^2 N_d R^2}{4\epsilon kT}\right)\right] \quad [6b]$$

A value of $E_c - E_t$ of 0.38 eV has been chosen in order to match the experimental data.

If the doping level is very low, all carriers are assumed to be trapped at the grain boundary, and the average carrier concentration is that of intrinsic silicon

$$\bar{n} = n_i = 1.45\ 10^{10} \quad [6c]$$

if $N_d < 10^{15}$.

The value of 10^{15} has been chosen because Eq. [6b] provides for n a value which is smaller than n_i for impurity concentrations lower than 10^{15} cm^{-3}.

Resistivity of polysilicon.—We have now all the necessary tools to calculate n, μ_{film}, and, thereafter, ρ by $\sigma = nq\mu$, where n is given by Eq. [6a], [6b], or [6c]; μ_{film} is given by Eq. [5] and [4a] or [4b]; and with V_b calculated by [1a] or [1b].

The model gives results in good agreement with the experimental data, although it predicts a too high resistivity for dopant concentration around $2N_t/R$ because of the exponential dependence of the resistivity on the potential barrier. However, Baccarini, Ricco, and Spadini (15) have demonstrated that the potential barrier does not reach values higher than 0.5 eV. This last result has been taken into account to obtain the curves of Fig. 7 and 9.

The numerical values we have chosen to match theoretical values with the experimental data (sheet resistivity, TEM measurements of grain size, and Hall mobility measurements) are (Fig. 7-9): $N_t = 3 \times 10^{12}$ cm^{-2}, $R = 600$Å, and $t_f = 5000$Å.

Discussion

The variation of sheet resistivity with annealing cycles is generally explained (12, 14) by a model in which the dopant atoms begin to diffuse and segregate to the grain boundaries, decreasing the active carrier concentration and thus increasing sheet resistivity. This happens at low annealing temperatures. For higher temperatures, the grain size is supposed to increase with increasing temperature. This diminishes the total grain boundary area and redistributes the dopant atoms to the bulk of the crystallites.

This model explains qualitatively the variation in sheet resistivity with annealing time. For low temperatures, ($T < 900$°C), phosphorous atoms become electrically inactive for they diffuse toward grain boundaries. This phenomenon causes the resistivity to increase with annealing time.

On the other hand, for higher temperatures ($T > 900$°C), the longer the annealing time, the lower the sheet resistance, for the grains grow and the boundary area is reduced with annealing time.

However, our measurements of grain size show that this model is not sufficient to explain accurately the decrease of ρ with annealing temperature. For instance, the maximum of resistivity in the case of a 12 hr an-

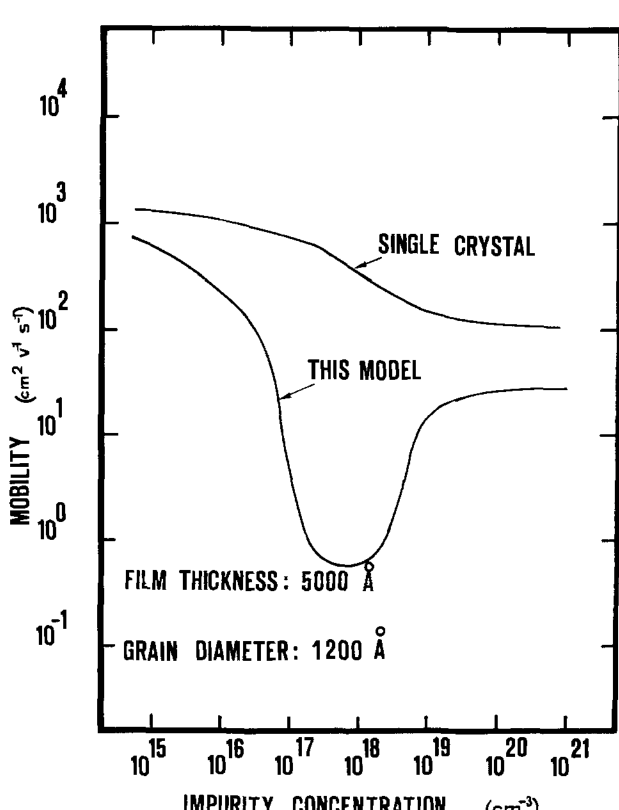

Fig. 7. Mobility vs. impurity concentration

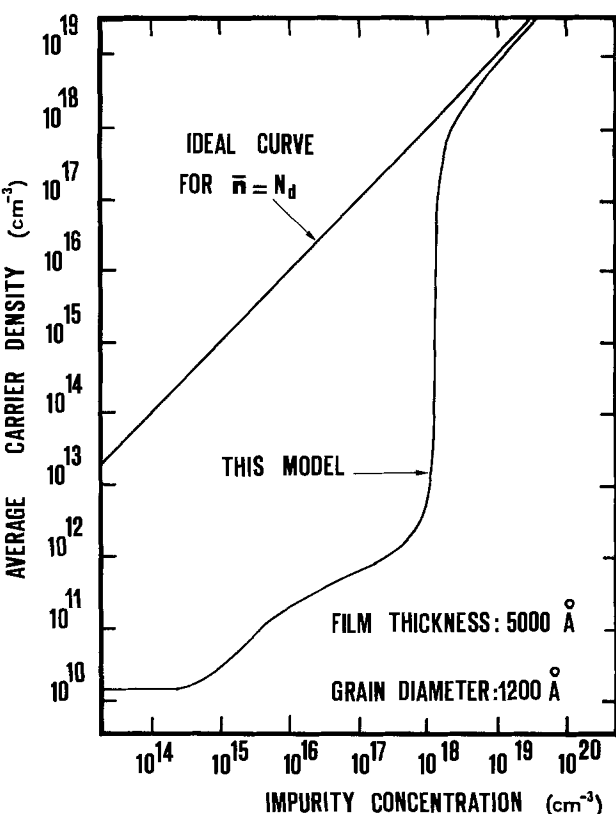

Fig. 8. Average carrier density vs. impurity concentration

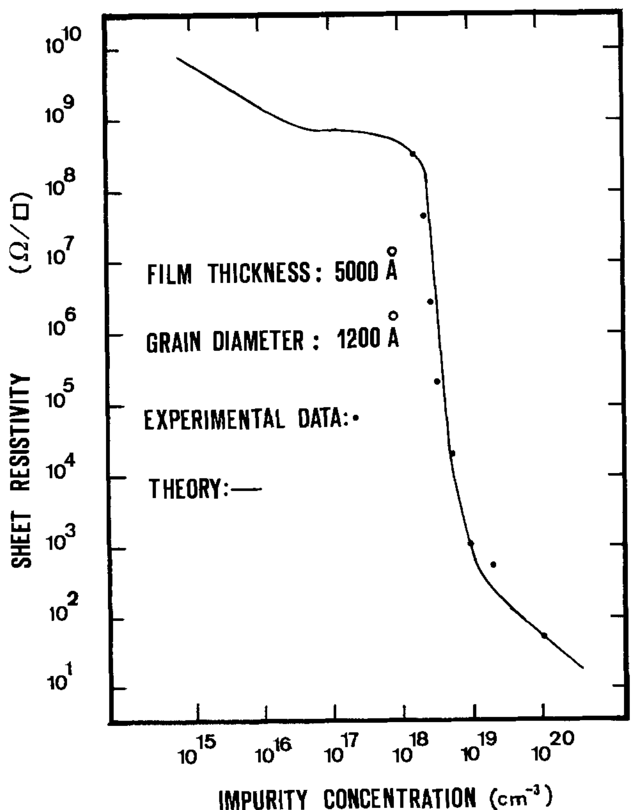

Fig. 9. Sheet resistivity vs. impurity concentration

nealing is reached at about 850°C, while the grain size is still quite unchanged at that temperature, and begins only to increase significantly at 1050°C.

With regard to the dependence of grain size on annealing temperature, our results appear comparable to those of Wada (13); a quantitative difference stems from the fact that we did not work at high doping levels [7.5 × 10^{20} cm^{-3} in Ref. (13) and 5 × 10^{18} cm^{-3} in our study] and our annealing times were different. Our results suggest that another phenomenon must be taken into account. One could assume that three phenomena are in fact competitive at annealing temperatures between 800° and 1100°C. The first one is the segregation of dopant atoms to grain boundaries. This phenomenon is prevalent below 900°C and makes resistivity increase with increasing annealing time.

Above 900°C and below 1050°C, a crystallographic relaxation seems to occur at the grain boundary, removing a part of the defects which trap the carriers. This causes an enhancement of free carriers in polysilicon and causes its resistivity to decrease before the appearance of the grain growth phenomenon. Above that temperature, the grains begin to grow; this reduces the total grain boundary area and further enhances the conductivity. This last phenomenon is increased by a long annealing time.

Summary

This paper reports the results of measurements which aim to explain the variation of resistivity and grain size of polysilicon as a function of annealing cycles and impurity concentration. It suggests a mechanism which would explain the variation of the sheet resistivity with annealing temperature and provides a semiquantitative model of the variation of the sheet resistivity with the doping level.

It also mentions the shortcomings of a previous model which assumed that the decrease in resistivity was directly related to the grain growth.

LIST OF SYMBOLS

D_n	diffusivity of electrons
E_t	energy level of the traps in the bandgap
h	grain height
J_n	electron current density
k	Boltzmann's constant
l_c	mean free path of electrons
μ_0	mobility of electrons in single crystal silicon
μ_{eff}	mobility in an infinitely thick layer
μ_{film}	mobility in a thin polysilicon film
$\bar{n}$	average carrier concentration
n_0	$N_c \exp\{(E_f - E_c)/kT\}$ = equilibrium electron concentration
N_d	impurity concentration
N_t	density of traps
$(-q)$	charge of an electron
R	grain radius
r_1	radius of the neutral region in the grain
T	absolute temperature
t_f	film thickness
V_b	height of the potential barrier
V_r	voltage drop applied to a grain = the voltage drop applied to the sample divided by the number of grains between the two current-injecting contacts
$\Phi(x)$	potential at any position x
Φ_b	$V_b + V_r$ = potential at grain boundary
w	width of the depletion region (= $R - r_1$)

Diffusion of Cd into InP at 680°C

B. V. Dutt,* A. K. Chin,* and W. A. Bonner

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Cadmium was diffused into undoped n-InP at 680°C using elemental mixtures of (Cd,In) and (Cd,P) as starting sources. The depths of the p-n junctions were determined as a function of the Cd-activity, a_{Cd}, of the (In,Cd) alloys, and as a function of the amount of P. The variation of the junction depth with phosphorus vapor pressure indicates the formation of Cd compounds which are the actual diffusion sources on the P-rich side. The diffusion of Cd in InP is interpreted based on the largely accepted interstitial-substitutional model. The charge states of the diffusing interstitial species and the substitutionally incorporated Cd appear to depend on the diffusion conditions. On the In-rich side, at $a_{Cd} < 0.4$, the diffusing interstitial is neutral and Cd is mostly present as a monovalent acceptor. At $a_{Cd} > 0.4$, the diffusing interstitital is doubly ionized and Cd is incorporated as a monovalent acceptor. On the P-rich side, the data suggest a doubly ionized Cd-interstitial as the diffusing species with the Cd largely present in a neutral form.

Diffusion of acceptor impurities such as Cd or Zn for formation of p-n junctions in n-type InP is of technological interest since devices for optical communications are based on the InP/(In, Ga) (As, P) materials system (1).

Tuck and co-workers (2-4) carried out extensive work on chemical and isoconcentration diffusion of Zn into InP. In order to explain the decreasing surface concentration of Zn, or the decreasing solid solubility of Zn with increasing phosphorus vapor pressure, a model was proposed in which Zn is largely present in the form of a complex ($V_PZn_{In}V_P$). The monovalent acceptor species Zn_{In}' is present in small concentrations and the fast diffusing species is a neutral interstitial Zn_i^x. From p-n junction depth measurements, Tien and Miller (5) suggested a similar model for Cd in InP, with most of the Cd present as a neutral complex.

Earlier work on diffusion of Zn into III-V compounds by several investigators has been extensively reviewed by Casey (6). Much of the work was interpreted on the basis of an interstitial-substitutional mechanism or dissociative diffusion originally proposed for Cu in Ge by Frank and Turnbull (7) and extended for Zn in GaAs by Longini (8). Tracer diffusion under chemical diffusion conditions showed concentration profiles that were anomalous and different from the error function behavior (6). Isoconcentration diffusion profiles exhibited error function behavior (6). Differences in the interpretation of the largely accepted interstitial-substitutional diffusion model generally pertained to the charge state of the fast-diffusing interstitial.

Key words: defects, transport properties, p-n junctions, cadmium phosphides, III-V compounds.

Recently, formation of $p^+p^-n^-$ junctions in nominally undoped n-type InP with $n = 4 \times 10^{16}$ cm^{-3} by a single step diffusion of Cd has been reported (9). Such junctions are suggested to result from the presence of an anomalous diffusion profile. The p^+p^- and p^-n^- junctions were spatially correlated by electron beam induced current (EBIC) profiling with the two diffusion fronts revealed by staining with A-B etch (10). In the present paper, the diffusion studies are extended to understand the diffusion mechanism of Cd in InP. The starting sources for diffusion are mixtures of elemental Cd with either excess In or P. The activity of Cd (the ratio of partial pressure of Cd in the alloy to that of pure Cd) is controlled by (In, Cd) alloys or by phosphides of Cd that appear to readily form at the diffusion temperature. The variations in junction depth with a_{Cd} are interpreted on the basis of an interstitial-substitutional model. On the In-rich side, at $a_{Cd} < 0.4$, the diffusing interstitial is neutral and Cd is mostly present as a monovalent accepter. At $a_{Cd} > 0.4$, the diffusing interstitial is doubly ionized and Cd is incorporated as a monovalent acceptor. On the P-rich side, the data suggest a doubly ionized Cd-interstitial as the diffusing species. Cd is largely present in a neutral form.

Experimental Conditions

The InP samples used in this study were of <100> orientation cut from boules grown by the liquid encapsulated Czochralski (LEC) technique (11, 12). One surface of the samples was polished using a 1% Br-methanol solution. Most of the diffusion work was done on undoped InP with an electron concentration of 4×10^{16} cm^{-3} with only a selected set of experiments

Diffusion of Cd into InP at 680°C

B. V. Dutt,* A. K. Chin,* and W. A. Bonner

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Cadmium was diffused into undoped n-InP at 680°C using elemental mixtures of (Cd,In) and (Cd,P) as starting sources. The depths of the p-n junctions were determined as a function of the Cd-activity, a_{Cd}, of the (In,Cd) alloys, and as a function of the amount of P. The variation of the junction depth with phosphorus vapor pressure indicates the formation of Cd compounds which are the actual diffusion sources on the P-rich side. The diffusion of Cd in InP is interpreted based on the largely accepted interstitial-substitutional model. The charge states of the diffusing interstitial species and the substitutionally incorporated Cd appear to depend on the diffusion conditions. On the In-rich side, at $a_{Cd} < 0.4$, the diffusing interstitial is neutral and Cd is mostly present as a monovalent acceptor. At $a_{Cd} > 0.4$, the diffusing interstitital is doubly ionized and Cd is incorporated as a monovalent acceptor. On the P-rich side, the data suggest a doubly ionized Cd-interstitial as the diffusing species with the Cd largely present in a neutral form.

Diffusion of acceptor impurities such as Cd or Zn for formation of p-n junctions in n-type InP is of technological interest since devices for optical communications are based on the InP/(In, Ga) (As, P) materials system (1).

Tuck and co-workers (2-4) carried out extensive work on chemical and isoconcentration diffusion of Zn into InP. In order to explain the decreasing surface concentration of Zn, or the decreasing solid solubility of Zn with increasing phosphorus vapor pressure, a model was proposed in which Zn is largely present in the form of a complex ($V_P Zn_{In} V_P$). The monovalent acceptor species Zn_{In}' is present in small concentrations and the fast diffusing species is a neutral interstitial Zn_i^x. From p-n junction depth measurements, Tien and Miller (5) suggested a similar model for Cd in InP, with most of the Cd present as a neutral complex.

Earlier work on diffusion of Zn into III-V compounds by several investigators has been extensively reviewed by Casey (6). Much of the work was interpreted on the basis of an interstitial-substitutional mechanism or dissociative diffusion originally proposed for Cu in Ge by Frank and Turnbull (7) and extended for Zn in GaAs by Longini (8). Tracer diffusion under chemical diffusion conditions showed concentration profiles that were anomalous and different from the error function behavior (6). Isoconcentration diffusion profiles exhibited error function behavior (6). Differences in the interpretation of the largely accepted interstitial-substitutional diffusion model generally pertained to the charge state of the fast-diffusing interstitial.

Key words: defects, transport properties, p-n junctions, cadmium phosphides, III-V compounds.

Recently, formation of $p^+p^-n^-$ junctions in nominally undoped n-type InP with $n = 4 \times 10^{16}$ cm^{-3} by a single step diffusion of Cd has been reported (9). Such junctions are suggested to result from the presence of an anomalous diffusion profile. The p^+p^- and p^-n^- junctions were spatially correlated by electron beam induced current (EBIC) profiling with the two diffusion fronts revealed by staining with A-B etch (10). In the present paper, the diffusion studies are extended to understand the diffusion mechanism of Cd in InP. The starting sources for diffusion are mixtures of elemental Cd with either excess In or P. The activity of Cd (the ratio of partial pressure of Cd in the alloy to that of pure Cd) is controlled by (In, Cd) alloys or by phosphides of Cd that appear to readily form at the diffusion temperature. The variations in junction depth with a_{Cd} are interpreted on the basis of an interstitial-substitutional model. On the In-rich side, at $a_{Cd} < 0.4$, the diffusing interstitial is neutral and Cd is mostly present as a monovalent accepter. At $a_{Cd} > 0.4$, the diffusing interstitial is doubly ionized and Cd is incorporated as a monovalent acceptor. On the P-rich side, the data suggest a doubly ionized Cd-interstitial as the diffusing species. Cd is largely present in a neutral form.

Experimental Conditions

The InP samples used in this study were of <100> orientation cut from boules grown by the liquid encapsulated Czochralski (LEC) technique (11, 12). One surface of the samples was polished using a 1% Br-methanol solution. Most of the diffusion work was done on undoped InP with an electron concentration of 4×10^{16} cm^{-3} with only a selected set of experiments

on samples doped with Sn to 1×10^{18} cm^{-3}. The diffusion anneals were carried out in sealed quartz ampuls for 4 hr at 680°C in a vertical furnace with the diffusion source located at the lower end of the ampul at 675°C in order to prevent condensation on the InP wafer. The sample was held above the diffusion source by a constriction in the ampul. The ampul volume and the amount of Cd were held constant at 5 cm^3 and 3.48 mg, respectively. The diffusion depth was varied by changing the Cd-activity of the (In, Cd) alloy or by varying the excess amount of P added to the ampul. The diffusion fronts were revealed by staining a cleaved edge with A-B etch at room temperature for 5 min (5, 10).

Figure 1(a) shows the typical stained edge of a sample with a doping level of $n = 1 \times 10^{18}$ cm^{-3} revealing only a single Cd diffusion front. Figure 1(b) shows the stained edge of a nominally undoped, n-type InP with $n = 4 \times 10^{16}$ cm^{-3} after Cd-diffusion. Two diffusion fronts are observed, whereas only one front defining the p-n junction was expected. The delineation of two diffusion fronts by etching has been previously reported (13). The two fronts could arise from either changes in doping density or dopant type since etching reveals both types of variations. Examination of the stained edge with a scanning electron microscope (SEM) showed that a step ~0.2 μm deep is delineated at the shallow diffusion front in 5 min of etching. No such step was observed at the deep front even after 30 min of etching.

An SEM image of a typical sample with two diffusion fronts is shown in Fig. 2. The positions of the shallow and deep diffusion fronts obtained from the optical micrograph are indicated by the dashed lines. An electron beam induced current (EBIC) profile is superimposed to demonstrate the nature of the junction. The EBIC signal reaches a peak at the shallow front, remains constant at the peak value for ~3 μm, and then decreases to a second inflection point at the position of the deep front. The EBIC profile thus reveals the presence of a depletion region bounded by the two fronts. The EBIC profile shown in Fig. 2 is characteristic of a p^+-p^--n^- junction (9, 14, 15).

In order to confirm that the two diffusion fronts are related to Cd diffusion, the region bounded by the two diffusion fronts was investigated by thermal probing and photoluminescence. Thermal probing showed that the surface of a Cd-diffused sample was strongly p-type. Low temperature photoluminescence measurements indicated a high Cd concentration as revealed by the strength of the Cd impurity line at 1.365 eV (16). Then using a 2% Br-methanol solution, a surface layer approximately equal to the depth of the deep front was removed. Thermal probing of the etched surface suggested a low doping level but the conductivity type could not be determined. Photoluminescence of the etched surface indicated a much weaker Cd line at 1.365 eV. It is estimated that the amount of Cd is lower by an order of magnitude. These experiments indicate that the two fronts observed are related to Cd diffusion.

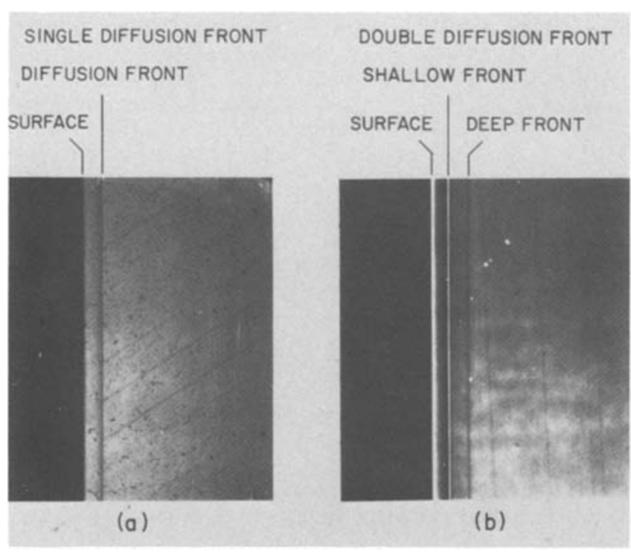

Fig. 1. Single and double diffusion fronts observed in InP. (a) InP:Sn with $n = 10^{18}$ cm^{-3}, (b) undoped n-InP with $n = 4 \times 10^{16}$ cm^{-3}.

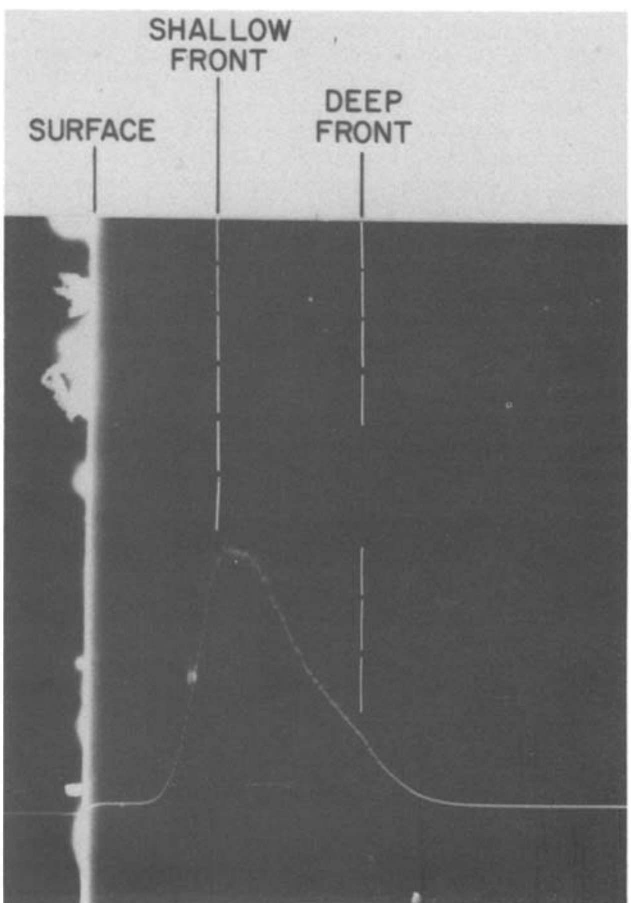

Fig. 2. EBIC profile obtained on a sample showing two diffusion fronts. The positions of the diffusion fronts are indicated by the dashed lines. The EBIC profile is superimposed.

Results

Experimental data.—Since the junction depth, x_j, is proportional to $(Dt)^{1/2}$ where D is the diffusion coefficient and t is the time of diffusion, the square of the junction depth is directly proportional to D_{Cd} for a constant t. Figure 3(a) shows the variation of the

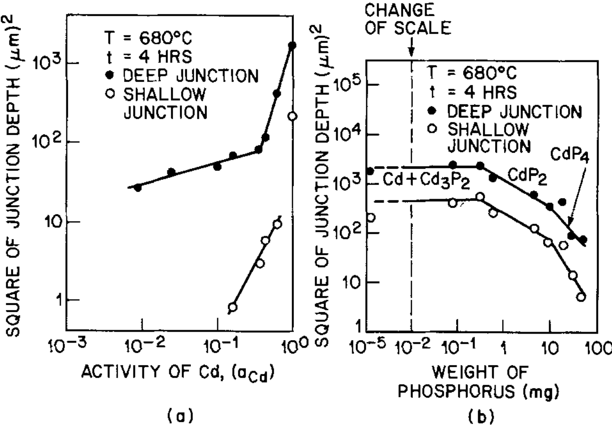

Fig. 3. Variation of diffusion coefficient with (a) a_{Cd} of (In-Cd) alloys and (b) weight of excess P, W_P(mg) in the ampul.

square of the junction depth with a_{Cd}, the Cd activity of the (In, Cd) alloys. The a_{Cd} of the (In, Cd) alloys is estimated from the data of Servis and Munir (17), assuming that the temperature dependence of the activities is weak. In Fig. 3(a), on the In-rich side, the diffusion coefficient for the deep front varies approximately as a_{Cd}^{α} with $1/3 < \alpha < 1/2$ for $a_{Cd} \lesssim 0.4$ and and as a_{Cd}^3 for $a_{Cd} \gtrsim 0.4$. The shallow front starts appearing at $a_{Cd} > 0.15$ and varies as a_{Cd}^2 or a_{Cd}^3.

On the P-rich side, the behavior is different as shown in Fig. 3(b). Here the square of the junction depth is simply plotted against W_P, the weight of phosphorus, for lack of precise knowledge of the phosphorus partial pressure. Both diffusion fronts are observed within the range of the experiments. The diffusion coefficients responsible for the two fronts are independent of the amount of P for $0 < W_P < 0.33$ mg, vary as $W_P^{-1/2}$ for $0.33 \text{ mg} < W_P < 10$ mg and as W_P^{-1} for $W_P > 10$ mg. Since the volume of the ampul, the amount of Cd, and the temperature were held constant, the vapor pressure of phosphorus would be expected to be a monotonic function of the amount of P. The variations in diffusion coefficient of Cd shown in Fig. 3(b) are thus either due to formation of Cd and P compounds or reflect changes in the diffusion process depending on the amount of P added to the ampul. In the following section, the In-P-Cd ternary phase diagram is qualitatively discussed in order to correlate the changes in diffusion coefficient of Fig. 3 with changes in phase equilibria (17-20).

Thermodynamic considerations.—Figure 4 shows the schematic of the In-P-Cd ternary phase diagram at 680°C based on the data reported in literature (17-20). The locus of our experimental diffusion sources is represented by a small region surrounding the solid InP. The solid lines indicate tie-lines connecting the indicated phases. Applying the phase rule, $f = C + 2 - \phi$, where ϕ = number of phases in equilibrium, C = number of components, to regions A through E, the various condensed phases in equilibrium besides the vapor phase and the degrees of freedom, f, are as follows:

Region A: Solid InP, (In, Cd) liquid alloy, $f = 2$

Region B: Solid InP, liquid Cd, and solid Cd_3P_2, $f = 1$

Region C: Solid InP, solid Cd_3P_2, and solid CdP_2, $f = 1$

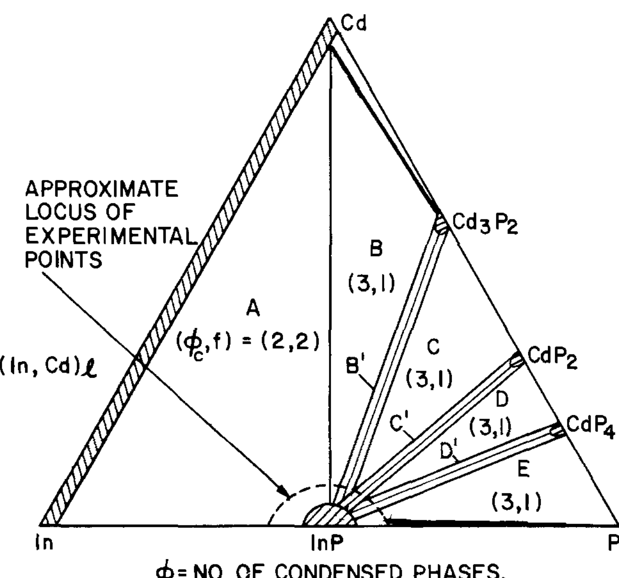

Fig. 4. Schematic of In-P-Cd ternary phase diagram at 680°C. The stability regions of the compounds are shown highly exaggerated. (See text).

Region D: Solid InP, solid CdP_2, and solid CdP_4, $f = 1$

Region E: Solid InP, solid CdP_4, and solid P, $f = 1$.

Regions B', C', and D': Solid InP is in equilibrium with solid Cd_3P_2, solid CdP_2, and solid CdP_4, respectively. The degrees of freedom in B', C', and D' are two. The widths of the regions B', C', and D' are shown exaggerated to suggest the pressure-temperature stability of the phosphides of Cd.

Considering the region A, the choice of temperature and the activity of Cd can be made independently. The vapor pressures of In and P will then be automatically fixed. In region B, there is only one degree of freedom and the choice of temperature automatically determines the activities of the three constituents. Regions C, D, and E are similar to B. However, in regions B', C', and D', where solid InP is in equilibrium with the phosphides Cd_3P_2, CdP_2, or CdP_4, respectively, both temperature and the vapor pressure of P can be independently chosen.

In the experiments described in "Experimental Conditions" the InP sample is at 680°C and the diffusion source is at 675°C. In such an arrangement, the InP sample initially loses P and the phosphorus vapor pressure in the ampul tends to approach the dissociation pressure of InP at 680°C. The vapor transports phosphorus towards the cooler end kept at 675°C, where the (In, Cd) alloy establishes the Cd and In activities proportional to their respective mole fractions. P-vapor reacts with the alloy forming InP and phosphides of Cd, provided the Cd activity is equal to or larger than the value corresponding to the evaporation of the compounds. For example, the sublimation of Cd_3P_2 occurs by congruent evaporation (19) according to

$$Cd_3P_2(s) = 3Cd(g) + 1/2P_4(g) \quad [1]$$

$$P_4(g) = 2P_2(g) \quad [2]$$

where (s) and (g) refer to the solid and gaseous phases, respectively. For congruent evaporation, the partial pressures (p) of Cd(g), P_4(g), and P_2(g) are related by

$$p(\text{Cd}) = 6p(\text{P}_4) + 3p(\text{P}_2) \quad [3]$$

The equilibrium constant for Eq. [1] is given (19) by

$$\log_{10}\left(\frac{K_p}{\text{atm}^{7/2}}\right) = -\frac{24{,}940 \pm 480}{T} + (23.70 \pm 0.39) \quad [4]$$

Using Eq. [4] and the estimated value of the equilibrium constant for Eq. [2] from Stull and Sinke (21), one can estimate K_p (at 680°C) $\approx 3.4 \times 10^{-3}$ atm$^{7/2}$ and a $p(\text{Cd}) = 0.25$ atm, which corresponds to an activity of 0.7, taking the value of the saturated vapor pressure of Cd (21) at 680°C as 0.36 atm. This indicates that at Cd activities higher than 0.7, the formation of Cd_3P_2 which will act as the diffusion source is to be expected.

Correlation of variation of diffusion coefficient with phase changes.—In this section, the variation of the diffusion coefficient is correlated with the different regions of the ternary phase diagram considered above. The diffusion data of Fig. 3(a), obtained by equilibrating InP with different (In, Cd) alloys correspond to region A of Fig. 4. Since the changes in composition of the alloy are continuous, the drastic change in the diffusion coefficient dependence on a_{Cd} shown in Fig. 3(a) is to be interpreted as a change in the diffusion or incorporation process. Alternatively, the system is not entirely in region A for the range of a_{Cd} investigated. In the previous section, we considered the possibility of (In, Cd) alloy with $a_{Cd} > 0.7$ reacting with the P escaping from InP to form Cd_3P_2 to coexist with InP and In-Cd. If this were to happen, there is only one degree of freedom, making temperature the only inde-

pendent variable. The activities of In, P, and Cd will be automatically fixed by the choice of temperature. In such a case the diffusion coefficient varying as the activities would be a constant. However, the diffusion coefficient as shown in Fig. 3(a) does not appear to remain constant at high a_{Cd} on the In-rich side. This rules out the possibility of Cd_3P_2 formation on the In-rich side and suggests that the changes in diffusion coefficient with a_{Cd} should be attributed to corresponding changes in the diffusion process or the incorporation of Cd.

On the P-rich side, D_{Cd} is independent of the amount of P for $W_P < 0.33$ mg. This suggests that the system is now in region B, where liquid Cd is in equilibrium with solids InP and Cd_3P_2. The partial pressure of Cd is a constant and is nearly equal to the saturated vapor pressure of Cd at 675°C. As the phosphorus content is increased D_{Cd} varies as $W_P^{-1/2}$ and W_P^{-1} or equivalently $p^{-1/2}(P_4)$ and $p^{-1}(P_4)$. We suggest that these two regions of Fig. 3(b) correspond to regions C′ and D′ of Fig. 4, respectively. In region C′, CdP_2 is in equilibrium with InP; the vapor pressure of Cd and phosphorus are related by the dissociation constant $K(CdP_2) = p(Cd)\ p^{1/2}(P_4)$. Thus, if D_{Cd} varies as $p^{-1/2}(P_4)$, this is equivalent to $D_{Cd} \sim p_{Cd} \sim a_{Cd}$. Similarly, in region D′, CdP_4 is in equilibrium with InP and a $p^{-1}(P_4)$ variation of D_{Cd} corresponds to $D_{Cd} \sim a_{Cd}$. Thus the D_{Cd} variations with W_P on the P-rich side can be grouped together into a linear dependence of D_{Cd} on a_{Cd}.

Discussion

Relation between diffusion coefficient and defect concentration.—It is well known that the diffusion coefficient, D_{Cd} of solute Cd in the present case, is a sum of the product of the microscopic diffusivities D_j of the various defect species and their respective concentrations [j]. Thus, neglecting correlation effects (6)

$$D_{Cd} = \Sigma_j D_j [j] \qquad [5]$$

At a constant temperature, D_j is a constant and variations of D_{Cd} represent corresponding changes in the concentration of the dominant defect species. The concentration of the defects, [j], in turn depends on the composition of the crystal, the component activities, the pressure, and the temperature.

Defect equilibria.—We shall assume that the system is in equilibrium when InP is heated at 680°C in the presence of Cd, P, or In vapor. Following the approach of Kröger and Vink (22) and also using their symbols for defects, the defect concentrations can be expressed as a function of $a_{Cd}^r\ p^s(P_4)$ or $a_{Cd}^l a_{In}^m$. This activity dependence of the defect species is useful in identifying the diffusion mechanism. Table I lists defect formation reactions of relevance here. Table II lists the values of the exponents l and m for various approximations of the neutrality condition and the Cd balance equation.

Based on Table II, defect isotherms portraying the variation of the defect concentrations as a function of a_{Cd} at a given a_{In} and temperature can be constructed using a log-log plot (22). One such set of isotherms is given in Fig. 5. On the extreme left, where the concentration of Cd in the sample is very low, InP behaves as an intrinsic semiconductor with $p = n = n_i$. In this range, $[Cd_{In}']$ and $[Cd_i^{\cdot\cdot}]$ vary linearly with a_{Cd}. This range ends when the concentration of $[Cd_{In}']$ increases to equal n_i, where the extrinsic behavior sets in. The neutrality is approximated by $[Cd_{In}'] = p$ and each of these vary as $a_{Cd}^{1/2}$. All the dissolved Cd concentration in the crystal is approximated by $[Cd_{In}']$. The neutral Cd-interstitial Cd_i^x and the neutral substitutional Cd_{In}^x vary as a_{Cd} in all the three ranges shown. Note that the doubly ionized Cd interstitial concentration rises as a_{Cd}^2 in range II. Eventually a range of self-compensation where $[Cd_{In}'] \approx 2[Cd_i^{\cdot\cdot}]$ may be reached. In this range both $[Cd_{In}']$ and $[Cd_i^{\cdot\cdot}]$ vary linearly with a_{Cd}. This range is hypothetical and has not been observed experimentally.

Table I. Defect formation reactions and the corresponding mass action relations

No.	Reaction	Mass action relation
1	$0 \rightarrow e' + h^{\cdot}$	$K_i = np$
2	$0 \rightarrow V_{In}^x + V_P^x$	$K_S = [V_{In}^x][V_P^x]$
3	$1/4P_4(g) \rightarrow P_P^x + V_{In}^x$	$K_V = [V_{In}^x]p(P_4)^{-1/4}$
4	$InP \rightarrow In(g) + 1/4P_4(g)$	$K_{InP} = p_{In}p(P_4)^{1/4}$
5	$Cd(In - Cd)$ alloy $\rightarrow Cd_{In}' + h^{\cdot} + V_P^x$	$K_{Cd} = \frac{[Cd_{In}']p[V_P^x]}{a(Cd)}$
6	$Cd(In - Cd)$ alloy $\rightarrow Cd_i^{\cdot\cdot} + 2e'$	$K_{Cd_i} = \frac{[Cd_i^{\cdot\cdot}]n^2}{a(Cd)}$
7	$Cd_mP_n \rightarrow mCd_{In}^x + nP_P^x + (m - n)\ V_P^x$	$K_{mn} = \frac{[Cd_{In}^x]^m[V_P^x]^{m-n}}{a(Cd_mP_n)}$
8	$Cd_mP_n \rightarrow mCd(g) + \frac{n}{4}P_4(g)$	$K_{Cd_mP_n} = p^m(Cd)p^{n/4}(P_4)$
9	$Cd_i^{\cdot\cdot} + V_{In}^x + 2e' \rightarrow Cd_{In}' + h^{\cdot}$	$K_{IS} = \frac{[Cd_{In}']p}{[Cd_i^{\cdot\cdot}][V_{In}^x]n^2}$
10	$n + [Cd_{In}'] = p + [Cd_i^{\cdot}] + 2[Cd_i^{\cdot\cdot}]$	
11	$[Cd]_{tot} = [Cd_{In}^x] + [Cd_{In}'] + [Cd_i^{\cdot}] + [Cd_i^{\cdot\cdot}]$	

Table II. Values of exponents l, m of $[j] \alpha a^l(Cd)a^m(In)$ for different approximations of the neutrality conditions

Neutrality approximation / Defect species	$p = n$		$[Cd_{In}'] = p$		$[Cd_{In}'] = 2[Cd_i^{\cdot\cdot}]$	
	l	m	l	m	l	m
Cd_{In}'	1	−1	1/2	−1/2	1	−2/3
$Cd_i^{\cdot\cdot}$	1	−1	2	−1	1	−2/3
p	0	0	1/2	−1/2	0	−1/3
n	0	0	−1/2	1/2	0	1/3
$[Cd_{In}^x]$	1	−1	1	−1	1	−1

Models for diffusion and incorporatioin of Cd.—Models for the diffusion and incorporation of Cd in InP should account for the following summary of experimental results from the junction depth measurements of the "Results" section.

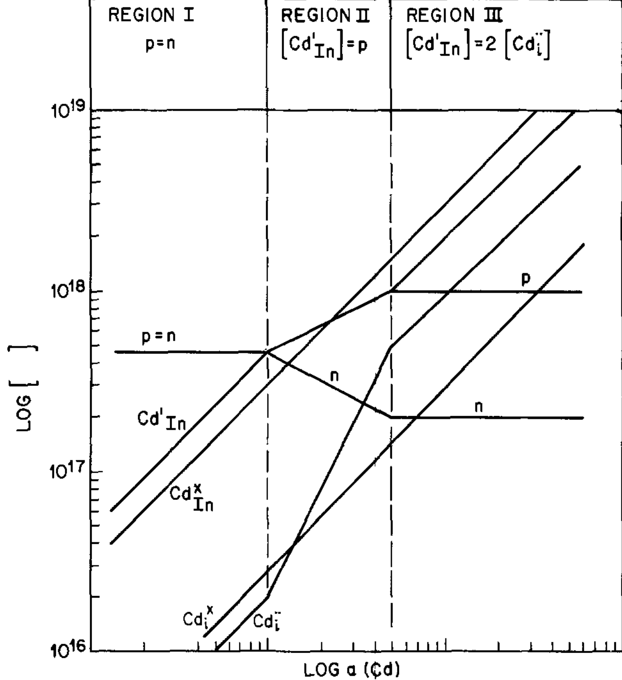

Fig. 5. Defect isotherm at 680°C showing the variation of concentrations of defects with a_{Cd} at a given a_{In}.

1. At low $a_{Cd} < 0.15$ only one diffusion front was observed.
2. The diffusion coefficient of the deep front varies as $\sim a_{Cd}^{1/2}$ for $a_{Cd} \lesssim 0.4$ and as $\sim a_{Cd}^3$ for $a_{Cd} \gtrsim 0.4$ on the In-rich side. The diffusion coefficient of the shallow front at higher a_{Cd} on the In-rich side varies as a_{Cd}^2 or a_{Cd}^3.
3. On the P-rich side, the diffusion coefficients for both the diffusion fronts are proportional to a_{Cd}.
4. When Cd is diffused into InP doped to 1×10^{18} cm^{-3}, only one diffusion front was observed under conditions where two fronts were observed in undoped InP.

Measurements based on p-n junction depth present several limitations in suggesting models for diffusion and incorporation of Cd in InP. First, the junction depth measurements give the position where the ionized acceptor concentration, in this case that of $[Cd_{In}']$, equals or exceeds n, the electron concentration of the InP sample. Secondly, the shallow p^+p^- junction arises due to a sudden change in the ionized Cd-acceptor concentration, presumably resulting from an anomalous profile. This reflects similar changes in the total impurity concentration, which leads us to believe that the Cd diffusion is concentration dependent similar to Zn in III-V compounds. Moreover, the Cd diffusion investigated here is chemical diffusion and whether equilibrium is reached under these conditions is uncertain. Lastly, as the sample is quenched from the diffusion temperature to room temperature, the junction depths measured at 300 K are expected to be different compared to the high temperature values as a result of the redistribution of electrons and holes. This difference is assumed to be negligible.

For a concentration dependent interstitial-substitutional diffusion mechanism, it has been shown (23) that the effective diffusion coefficient is given by

$$D_{eff} = D_i \frac{\partial C_i}{\partial C} \qquad [6]$$

where C_i = the concentration of the fast diffusing interstitial and C = total impurity concentration. Both C_i and C are functions of $a_{Cd}^l a_{In}^m$ or $a_{Cd}^r p^s(P_4)$ as discussed in the previous section. Since a_{Cd}, a_{In}, and $p(P_4)$ are interrelated to each other, Eq. [6] can be rearranged as

$$D_{eff} = D_i \frac{\partial C_i}{\partial a_{Cd}} \frac{\partial a_{Cd}}{\partial C} \qquad [7]$$

Case 1: Diffusion of Cd from (In, Cd) alloys.—We shall assume that $a_{In} = 1$ at low a_{Cd} because the amount of Cd in the ampul is considerably smaller than the sample size and the excess In added. This assumption does not hold as a_{Cd} approaches 1, when no In is added to the ampul.

At low Cd activities, under In-rich conditions, the surface concentration of Cd or the solubility of Cd is expected to be low. Assuming that the crystal is extrinsic with $[Cd_{In}'] = p$ and $[Cd]_{tot} = [Cd_{In}']$, the diffusion conditions correspond to column III of Table II which is displayed as range II of the defect isotherm given in Fig. 5. The singly ionized acceptor concentration, $[Cd_{In}']$ which is nearly equal to the total impurity concentration C varies as $a_{Cd}^{1/2}$ and the neutral interstitial concentration, Cd_i^x varies as a_{Cd}. Thus the factor $(\partial C_i/\partial a_{Cd})$ $(\partial a_{Cd}/\partial C)$ of Eq. [7] results in $D_{eff} \sim a_{Cd}^{1/2}$. It is therefore proposed that at low a_{Cd} on the In-rich side, Cd diffuses as a neutral interstitial Cd_i^x and dissolves as a monovalent acceptor Cd_{In}'.

At $a_{Cd} \geqq 0.4$, as shown in Fig. 3(a), there is an abrupt change in the dependence of D_{Cd} on a_{Cd}. Thus $D_{Cd} \sim a_{Cd}^{1/2}$ at $a_{Cd} < 0.4$ and changes to $D_{Cd} \sim a_{Cd}^3$ at $a_{Cd} > 0.4$. In addition, the shallow front appears at $a_{Cd} > 0.15$. A D_{Cd} variation of a_{Cd}^3 can be justified by the interstitial-substitutional model if the diffusing interstitial is doubly ionized. Longini (8) originally proposed a doubly ionized interstitial Zn as the diffusing species in GaAs. Later Weisberg and Blanc (26) and Chang and Pearson (23) showed that in the case of an interstitial-substitutional diffusion mechanism, the assumption of a doubly ionized interstitial with most of the impurity present as a monovalent acceptor, the diffusion coefficient varies as the third power of the impurity concentration. Thus in the present case, D_{Cd} would vary as $[Cd_{In}']^3$. From Table II and Fig. 5, it can be seen that $[Cd_{In}']$ varies as $a_{Cd}^{1/2} a_{In}^{-1/2}$. Thus $[Cd_{In}']^3 \sim a_{Cd}^{3/2} a_{In}^{-3/2}$. Since a_{In} is proportional to $(1 - x_{Cd})$ or $(1 - a_{Cd}/\gamma_{Cd})$, where γ_{Cd} = activity coefficient of Cd, it can be shown that

$$[Cd_{In}']^3 \sim \left(a_{Cd}^{3/2} + \frac{3}{2} \gamma_{Cd}^{-1/2} a_{Cd}^{5/2} + \frac{15}{8} \gamma_{Cd}^{-2} a_{Cd}^{7/2} \right)$$

This is in reasonable agreement with the observed $D_{Cd} \sim a_{Cd}^3$ behavior.

Case 2: $D_{Cd} \sim a_{Cd}$ on the P-rich side.—It has already been suggested that the D_{Cd} variations with the weight of phosphorus shown in Fig. 3(b) can be attributed to formation of phosphides of Cd. Under P-rich conditions, one would expect an increased solubility of Cd, if Cd is occupying the In-sublattice in an unassociated form. Approximating the total Cd concentration by $[Cd]_{tot} = C = [Cd_{In}^x]$, with $C_i = [Cd_i^{\cdot\cdot}] \sim a_{Cd}^2$ and $C = [Cd_{In}^x] \sim a_{Cd}$, Eq. [7] leads to $D_{eff} \sim a_{Cd}$, which is in agreement with the observed behavior.

Some of the Cd-diffused InP samples corresponding to the various regions of Fig. 3(a) and (b) have been examined by transmission electron microscopy (24). On the P-rich side, the samples showed precipitates identified to be Cd_3P_2 and Cd_7P_{10}. On the In-rich side the samples are free from precipitates. It is tentatively suggested that the observation of decreasing p-n junction depths with increasing phosphorus vapor pressure is due to the precipitation of Cd. This leaves in solid solution only a small fraction of Cd in an ionized acceptor form to cause the junction formation. However, if the solubility of Cd in InP is similar to Zn and decreases with increasing vapor pressure of phosphorus as observed by Tuck and Hooper (2), some sort of a neutral complex of Cd whose concentration roughly varies as a_{Cd} is to be invoked to explain the present measurements.

Origin of two diffusion fronts.—The origin of two diffusion fronts observed in the case of the undoped n-InP has been explained (9) assuming an anomalous diffusion profile as shown in Fig. 6. Curve A represents an error function profile, while curve B illustrates an anomalous profile with a sudden change in the concentration of the diffusant. The background doping level is indicated by the dashed line, marked n_B. Assuming that the profiles A and B correspond to ionized impurity species, for the profile A, one would expect a single junction, a p-n junction, to be revealed at a position where the impurity concentration equals the background level. For profile B, two possibilities arise. If the background doping level is above the concave section, again a single p-n junction will be observed. This corresponds to the case of Fig. 1(a) where Cd was diffused into an intentionally doped n-InP with $n \approx 1 \times 10^{18}$ cm^{-3}. However, when the substrate doping level is below the concave section, as shown by the dashed line, etching reveals two junctions: a deep p^-n^- junction and a shallow p^+p^- junction.

The question that remains to be answered is the origin of the anomalous profile itself in chemical diffusion experiments. It has been suggested (25) that this is due to breakdown of vacancy equilibrium in the interior of the sample, although such equilibrium is presumed to exist at the surface. However, the data of Fig. 3(a) and (b) cannot be satisfactorily interpreted using this explanation. If the vacancy equilibrium

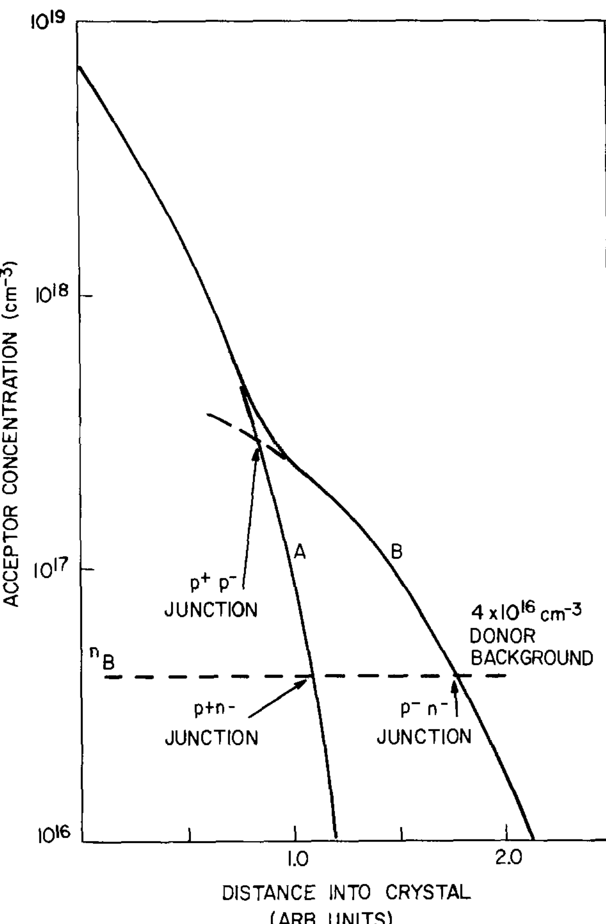

Fig. 6. Schematic of the normal error function diffusion profile (curve A) and the anomalous diffusion profile (curve B). For $n_B = 4 \times 10^{16}$ cm^{-3} substrate doping level, one junction (p^+n^-) is formed for normal profile A, whereas two junctions ($p^+ - p^-$) and ($p^- - n^-$) are formed for anomalous profile B.

breaks down in the interior, then the depth of the shallow junction nearer to the surface would be expected to be independent of the deeper junction. The results of Fig. 3 show that the two junctions move parallel to each other. This suggests that equilibrium is probably established in the interior at the same rate as the surface or that there may be cooperative phenomena such as the electric field dependent effects due to the presence of the p-n junction. Further work using tracer diffusion of Cd may throw some light on this problem.

Summary

Normal p-n junctions, as well as $p^+p^-n^-$ junctions could be formed by diffusion of Cd using starting sources of (Cd, In) and (Cd, P) at 680°C. The actual diffusion sources are (In, Cd) alloys and phosphides of cadmium. The linear variation of the diffusion coefficient with activity of Cd on the P-rich side is in good agreement with the generally accepted interstitial-substitutional model. The Cd-transporting species is a doubly ionized interstitial, $Cd_i^{\cdot\cdot}$, and cadmium is largely present as a neutral species. On the In-rich side, at higher Cd activities, the interstitial-substitutional model is valid with $Cd_i^{\cdot\cdot}$ as the diffusing species and most of the dissolved Cd in a singly ionized acceptor form. At low cadmium activities, the p-n junction depth measurements suggest that Cd is diffusing as a neutral interstitial and is incorporated largely as a singly charged acceptor.

Electrical Properties of Tin Oxide Ultrafine Particle Films

Hisahito Ogawa, Atsushi Abe, Masahiro Nishikawa, and Shigeru Hayakawa

Matsushita Electric Industrial Company Limited, Material Research Laboratory, 1006 Kadoma, Osaka, 571 Japan

ABSTRACT

The film structures and gas sensing properties of tin oxide ultrafine particle films deposited under oxygen pressures between 0.05 and 5 Torr have been studied. The ultrafine particle film having porous columnar structure is found to have high sensitivities in detecting humidity or combustible gases when operated at elevated temperatures. The films can be made selectively sensitive to these gases by choosing the film depositing conditions and the operating temperature.

Tin dioxide, SnO_2, in its pure form is an n-type metal oxide semiconductor. Its electrical conduction results from the existence of point defects (oxygen vacancies and interstitial tin atoms) which act as donors (1). Some unique properties of SnO_2 make the material useful for many applications such as resistor, NESA glass, and so on. Recently, SnO_2 has attracted special interest as a gas sensor material.

The properties of SnO_2 in the form of sintered polycrystals (2), thin films (3-5), or thick films (6) as gas sensors have been reported. Some of the gas sensors of above types have been put into practical applications for sensing combustible gases. However, the gas sensing mechanism, the change of electrical characteristics by means of gas adsorption, of these sensors has not been explained satisfactorily up to the present time.

Models which have been proposed to explain the conductance modulation in the senors by gas adsorption are:

1. Electron transfer between adsorbed gas molecules and SnO_2 materials, *i.e.*, change in surface conductance (7).
2. Change of SnO_2 composition, *i.e.*, change in bulk conductance (8).
3. Potential barrier height modulation at the grain boundary of polycrystalline samples (9).
4. Field effect transistor action at the neck parts of polycrystalline samples (10).

In any model, special attention must be paid to the surface quality (proportion of surface to volume) of the gas sensor materials, because the adsorption process responsible for the change in conductance takes place at the boundary between the gaseous and solid states.

We have developed a highly reproducible procedure for preparing the ultrafine particles of the metal oxide and the films (11). The ultrafine particles are grown by the evaporation of the metal in a low oxygen pressure atmosphere where ultrafine particles of metal oxide are deposited and form films having, for example, porous columnar structure on silica glass or silicon substrates covered with SiO_2 thin film. The SnO_2 typical ultrafine particle film fabricated by using this technology has the porous columnar structure constructed from the ultrafine particles having the median particle size of several tens of angstroms (in sintered polycrystalline materials, the particle size is more than several thousands of angstroms):

The unique characteristics of these SnO_2 ultrafine particle films are as follows.

1. Each ultrafine particle has a large specific surface area because of the smallness of its particle size. Therefore, the portion of the surface energy in the total energy of the particle becomes large and the surface activity against the adsorbed gases is expected to be increased.
2. The porous columnar structure of the ultrafine particle film makes it easy for gas molecules to enter into the film, so the conductance modulation by gas adsorption in the film is large.

Key words: ultrafine particle film structure, gas-evaporation technique, gas sensor, selective detection.

As mentioned above, when the effects of the surface of the materials become noticeable, the conductance modulation by gas adsorption is expected to have unique characteristics, such as gas sensitvity and gas selectivity, which have not been observed in sintered polycrystalline materials, thin films, and thick films.

In the present work, the electrical and gas sensing properties of tin oxide ultrafine particle films were studied in comparison with other reported gas sensors made of sintered polycrystals, thin films, or thick films.

Experiments

Sample preparation.—Two different substrate materials, silica glass (Corning No. 7059) and silicon covered with SiO_2 with the dimension of $2.0 \times 2.0 \times 0.2$ mm were used. There was no substantial difference between the sensors fabricated on these two different substrates. The sensing material, SnO_2 ultrafine particle film, was deposited between the two gold-plated interdigital electrodes (the gap of electrode is 0.02 mm and the total length of electrode is 11.6 mm) on one side of the substrate in the following procedures (11).

Evaporating materials such as Sn, SnO, and SnO_2, of purity higher than 99.99%, were placed in an evaporator boat. The chamber was pumped down to approximately 2×10^{-6} Torr and then oxygn (about 1 Torr) was introduced into the chamber. The glow discharge of the oxygen was produced by applying the rf power. Then the heating power was supplied to the boat and, after the growth rate of the tin oxide ultrafine particles in the glow discharge of oxygen reached a stable condition, the shutter was opened to deposit the ultrafine particles on the substrate. The deposition was allowed for a few minutes, depending on the thickness of the final ultrafine particle film.

Electrical contacts were made with 0.05 mm gold wires attached to the gold electrodes. The contact resistance between tin oxide ultrafine particle films and gold electrodes was measured at the operation temperature from 25° to 500°C, and was confirmed to be small enough compared with the resistance of the tin oxide ultrafine particle films themselves.

Analytical characterization of SnO_2 ultrafine particle films.—The quality of the ultrafine particles and the films was determined by the depositing condition, oxygen pressure, temperature of evaporator boat, and

others. The mean particle size and composition of the ultrafine particles were determined from x-ray diffraction analysis. The morphology and structure were observed by SEM and TEM. Figure 1 shows the curve of the mean particle sizes of SnO_2 ultrafine particles as a function of the oxygen pressure, and SEM photomicrographs showing three representative film structures at three different oxygen pressures. The mean particle size sublinearly increased as the oxygen pressure increased; the value of the slope was nearly ½. When the oxygen pressure was less than 0.05 Torr, the film grew along the direction perpendicular to the surface of the substrate, columnar structure. When the oxygen pressure was 0.5 Torr, derangement in the orientation of the film appeared. The structure was more or less aligned in the columnar direction, but became very much more porous. A structure like this was labeled as porous columnar. As the pressure was 5 Torr, the unidirectional growth of the film disappeared and the structure became spongy in appearance.

Results

Electrical characteristics and gas sensing properties of devices having SnO_2 ultrafine particle gas sensing films prepared by the above technique were studied. A closed stainless steel chamber (5 liters in volume) having a gas inlet port and a liquid (water or alcohol) evaporator was used for the measurement of the device characteristics. The gas in the chamber was circulated by means of a pump.

The circuit voltage (e_i) was applied across the device (the resistance of which is denoted as R_x) and a load resistor (R_L) connected in series. The load voltage (e_o) across the load resistor was measured.

R_x was calculated as follows

$$R_x = \left(\frac{e_i}{e_o} - 1\right) \times R_L$$

The internal impedance (60Ω) of circuit voltage source was negligible compared to R_x or R_L.

Electrical properties of SnO_2 ultrafine particle films.—In the present work, several kinds of SnO_2 ultrafine particle gas sensing film were prepared at oxygen pressure levels between 0.05 and 10 Torr. Films prepared at different oxygen pressures differed in their mean particle sizes and their film structures. In spite of these differences, most of the ultrafine particle films had a similar thermal hysteresis in conductance-temperature characteristics. A typical example is shown in Fig. 2.

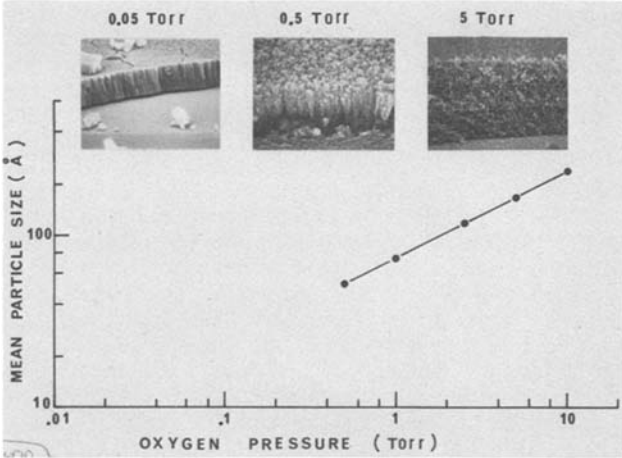

Fig. 1. Mean particle sizes of SnO_2 ultrafine particles and SEM photomicrographs showing the structure of the films deposited onto glass substrates. The structures of the films deposited in oxygen pressure at 0.05, 0.5, and 5 Torr are columnar, porous columnar, and spongy, respectively.

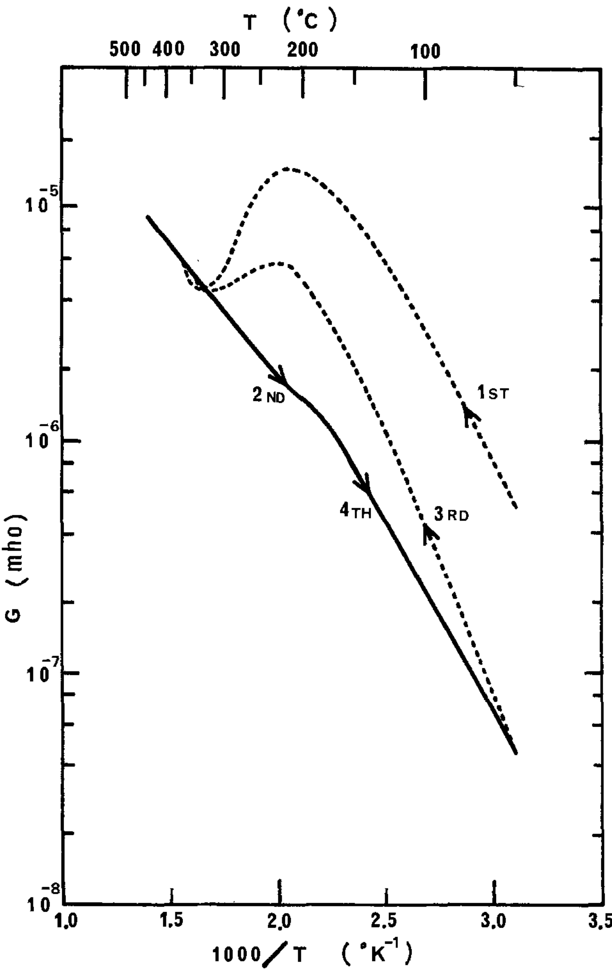

Fig. 2. A typical example of thermal hysteresis in conductance-temperature characteristics of tin oxide ultrafine particle film. The repeat measurements of the conductance done during cooling after the sample was heated to sufficiently high temperatures, agreed rather well.

When the conductance of the ultrafine particle film was measured during heating in air, the measured value depended greatly on preceding temperature-atmosphere history. On the other hand, when the measurement was done during cooling after the sample was heated to sufficiently high temperatures, repeated measurements agreed rather well. This kind of thermal hysteresis of conductance-temperature characteristics has been observed in SnO_2 thick films (6) and ZnO sintered polycrystalline materials (12), and it is considered to be an effect of adsorbed water. In the following measurements, conductance was measured while the sample was cooled down from an elevated temperature, thereby securing a good reproducibility in conductance-temperature characteristics.

When the circuit voltage e_i was varied from 0.01 to 100V (from 5 V/cm to 5 × 10^4 V/cm in ultrafine particle films), *I-V* characteristics of ultrafine particle films obeyed Ohm's law and never showed a nonlinearity which was often observed in the sintered polycrystalline materials. The high field *I-V* characteristics were determined by using a pulse technique with a pulse generator (H.P. Model 214A, pulse width 10 μsec, repeat time 1 msec).

Figure 3 shows the resistance R as a function of the film thickness t of the SnO_2 ultrafine particle films prepared with three oxygen gas pressures at 0.05, 0.5, and 5 Torr. The film thickness was determined from the SEM observation and the resistance was measured at the operating temperature of 300°C to avoid the effect of the surface adsorbed water. Without distinc-

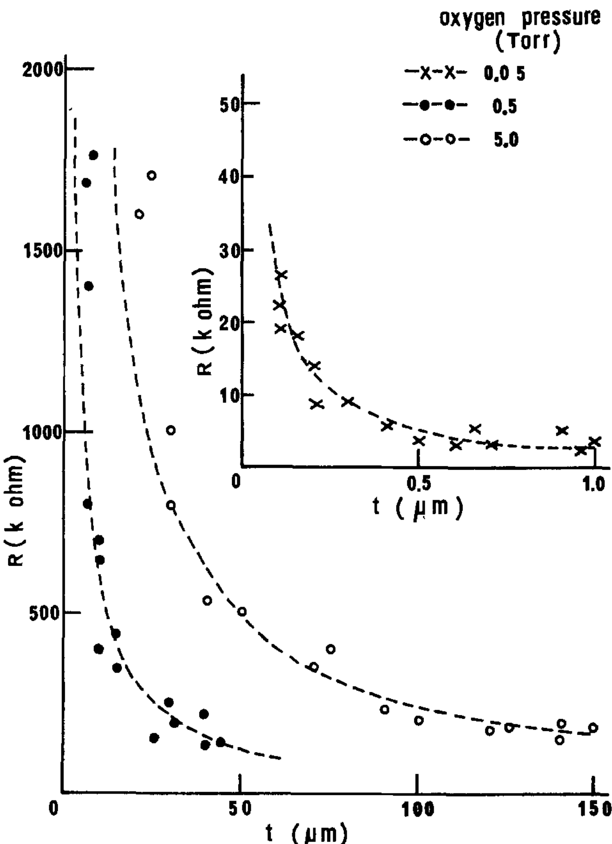

Fig. 3. The resistance R as a function of the film thickness t of the tin oxide ultrafine particle films prepared with three oxygen pressures at 0.05 Torr (—×—), 0.5 Torr (—●—), and 5 Torr (—○—). Most films showed the following relation: $R = k/t$ where k is the constant.

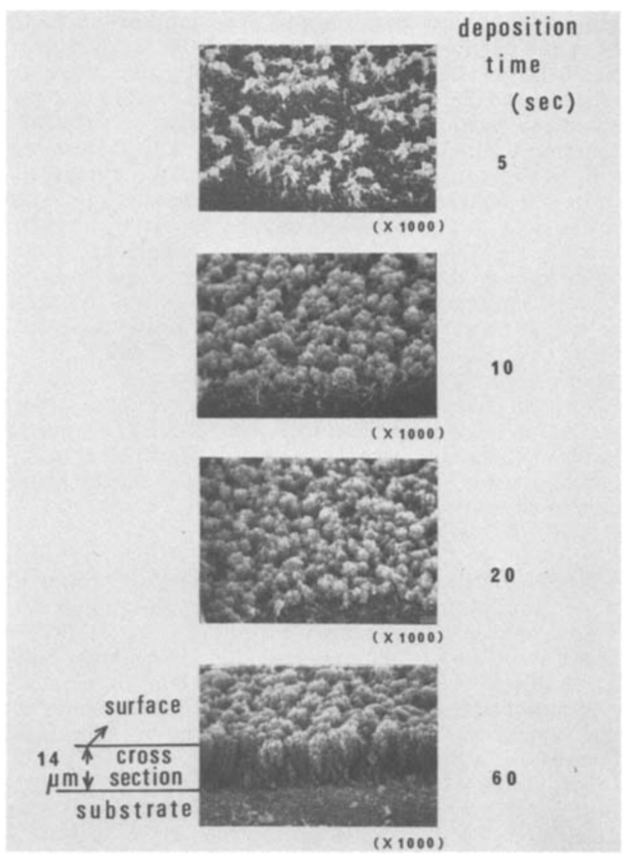

Fig. 4. Scanning electron microscopy examination of the growth of ultrafine particle films deposited in oxygen pressure at 0.5 Torr on glass substrates. Discontinuities in the film at the initial stage of the growth (when the depositing time is shorter than 20 sec) are observed.

tion of the preparation condition of SnO_2 ultrafine particle films, most films showed the following relation

$$R = \frac{\rho l}{tw} \quad [1]$$

where ρ is the resistivity, l is the gap between the electrodes, t is the film thickness, and w is the total length of the electrode. Only in the region of small t at each group, the observed R became larger than the value calculated in Eq. [1]. It is postulated that this was neither caused by a carrier reflection at the surface of the film nor a carrier dispersion at the grain boundary of the particle, but was due to discontinuities in ultrafine particle films at the initial stage of the growth on the substrate as shown in Fig. 4. The resistivity ρ of the ultrafine particle films was calculated from Eq. [1] using values of R shown in Fig. 3. Calculated values are: $\rho \doteq 60$ Ω-cm at oxygen gas pressure of 0.05 Torr, $\rho = 2 \times 10^5$ Ω-cm at 0.5 Torr, and $\rho = 6 \times 10^5$ Ω-cm at 5 Torr.

Gas sensing properties of SnO_2 ultrafine particle films.—Properties of SnO_2 ultrafine particle films operated as sensors at elevated temperatures and exposed to gases were measured.

Figure 5 shows the conductance of ultrafine particle films, deposited in the oxygen pressure at 0.05, 0.5, and 5 Torr, as a function of the reciprocal of the sensor operating temperature. Solid lines are for the sensor in room air [ambient temperature $T_a = 25°C$, relative humidity (RH) = 40%], broken lines are in wet atmosphere ($T_a = 25°C$, RH = 90%), dashed lines are in 100 ppm of ethyl alcohol, C_2H_5OH, in room air, and dotted lines are in 1000 ppm of isobutane, iso-C_4H_{10}, in room air. As the SnO_2 ultrafine particle film is an n-type semiconductor, the conductance in a reductive gas atmosphere, G, became larger than the conductance in room air, G_o. The gas sensitivity, S, is defined as the value of $(G - G_o)/G_o$. The sensitivity was strongly related to the operating temperature and the depositing condition of the ultrafine particle films, that is, the composition and mean particle size of ultrafine particles and to the structure of films. For example, the ultrafine particle films made under 0.05 Torr oxygen pressure having columnar structure like that in thin film was very sensitive to humidity, but not sensitive to iso-C_4H_{10} gas. In contrast with this, the ultrafine particle films made under 0.5 Torr oxygen pressure (porous columnar structure) exhibited an opposite property; high sensitivity to C_2H_5OH gas and iso-C_4H_{10} gas at operating temperatures higher than 200°C and low sensitivity to humidity at the same operating temperatures. The ultrafine particle films made under 5 Torr oxygen pressure (sponge-like structure) had characteristics similar to in nature but less sensitive than those of films made under 0.5 Torr oxygen pressure.

These properties were shown more clearly in Fig. 6 and 7. Figure 6 shows the sensitivity of the SnO_2 ultrafine particle film made under 0.5 Torr oxygen pressure (porous columnar structure) as a function of the sensor operating temperature. The sensor had high sensitivity to humidity at 50°C, to C_2H_5OH gas between 200° and 300°C, and to iso-C_4H_{10} gas between 350° and 450°C. Therefore, for example, selective detection of C_2H_5OH gas or iso-C_4H_{10} gas could be realized simply by operating the sensor at the temperature of 250° or 450°C, respectively.

Figure 7 shows the sensitivity as a function of oxygen pressure at the time of deposition of the ultrafine particle films. The sensor operating temperature was selected at the temperature where the sensor had the maximum sensitivity to each gas, that is, 50°C for H_2O,

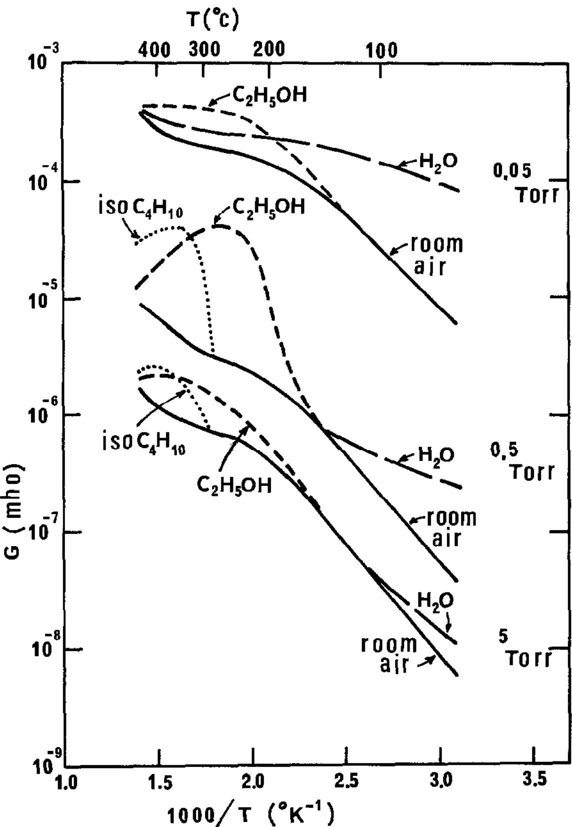

Fig. 5. The conductance of ultrafine particle films, deposited in the oxygen pressure at 0.05, 0.5, and 5 Torr, as a function of the reciprocal of the sensor operating temperature. These measurements were done in the atmosphere of room air (——), wet air (— —), 100 ppm of C_2H_5OH (- - -), and 1000 ppm of iso-C_4H_{10} (····).

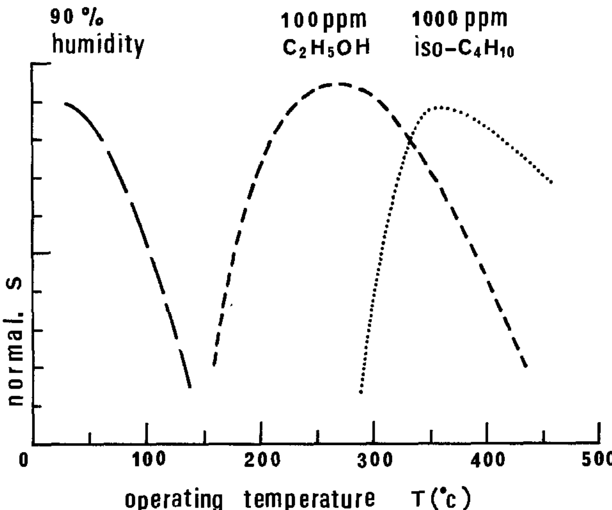

Fig. 6. The sensitivity of the tin oxide ultrafine particle film made under 0.5 Torr oxygen pressure (porous columnar structure) as a function of the sensor operating temperature.

250°C for C_2H_5OH gas, and 350°C for iso-C_4H_{10} gas. It was found that the SnO_2 ultrafine particle films made under the condition between 0.05 and 0.25 Torr were most sensitive to humidity, between 0.25 and 1 Torr to C_2H_5OH gas, and between 0.5 and 1.5 Torr to iso-C_4H_{10} gas.

As mentioned above, in the sensor having an ultrafine particle gas sensing film, the sensitivity to various gases could be separated not only by the sensor oper-

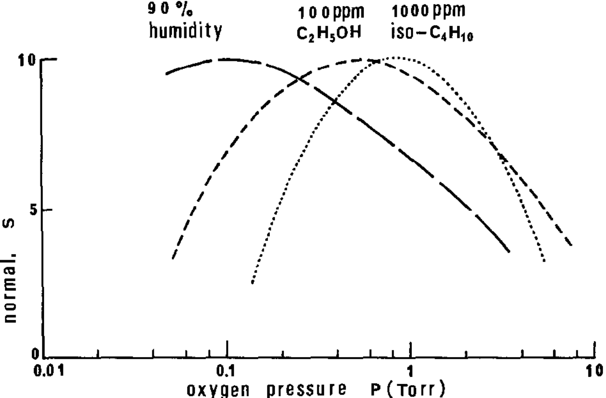

Fig. 7. The sensitivity as a function of oxygen pressure at the time of deposition of the ultrafine particle film. The sensor operating temperature was selected at 50°C for H_2O, 250°C for C_2H_5OH gas, and 350°C for iso-C_4H_{10} gas.

ating temperature, but also by the depositing conditions of the ultrafine particle films.

This gas-selectivity without using a catalyst is one of the unique characteristics of the ultrafine particle films.

Figure 8 shows the conductance, G, of the SnO_2 ultrafine particle gas sensor as a function of the concentration of C_2H_5OH. The film structure of the sensor was porous columnar deposited under oxygen pressure at 0.5 Torr and the sensor operating temperatures were 250° and 400°C. The conductance linearly increased as the C_2H_5OH concentration increased; the slope of the value of conductance was found to be unity at the temperature of 250°C, and nearly 0.5 at 400°C.

Reported values of the slope of conductance of SnO_2 as a function of C_2H_5OH concentration are 0.5 ~ 0.6 (13) for sintered polycrystalline materials having a crystal size of several thousands of angstroms, 0.5 (14)

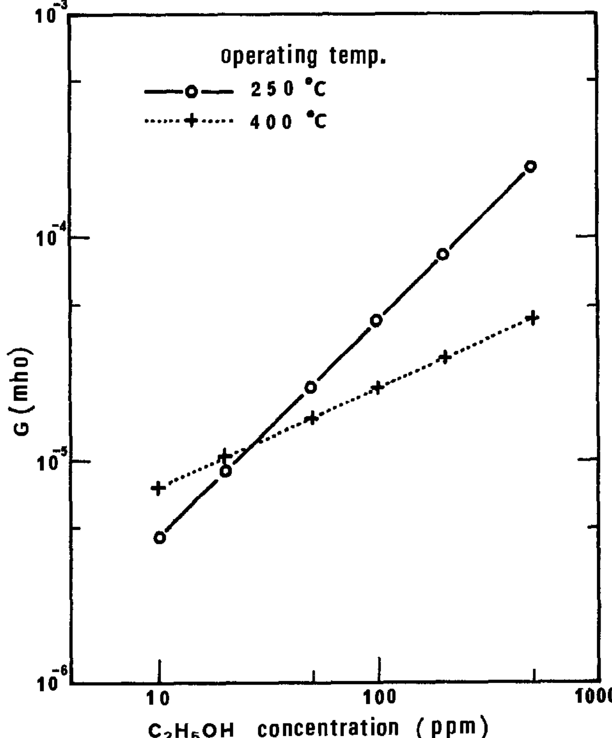

Fig. 8. The conductance, G, of the tin oxide ultrafine particle gas sensor as a function of the concentration of C_2H_5OH. The slope of the value of conductance is found to be unity at the temperature of 250°C, and nearly 0.5 at 400°C.

for thin films of several hundreds of angstroms in thickness prepared by the spraying technique, and 0.2 ~ 0.4 (15) for thin films of several thousands of angstroms in thickness prepared by the sputtering technique. Compared to these reported values, the value of the slope of conductance for SnO_2 ultrafine particle films having particle size of several tens of angstroms, at the optimum operating temperature, 250°C, is nearly twice as large, indicating higher sensitivity.

As shown in Fig. 8, the linear relationship extends down to 10 ppm of C_2H_5OH concentration, indicating a very low limit of detection.

It is considered that the high sensitivity of the ultrafine particle films is realized by the large surface area due to the smallness of the particles and to porosity in the film structure. The specific surface area of the ultrafine particle films is calculated to be several tens of times larger than that of the sintered polycrystalline materials.

Discussion

As it was shown in Fig. 3, the resistivity, $10^4 \sim 10^5$ Ω-cm, of the ultrafine particle films, where the structures were porous columnar or sponge-like, was extremely large compared with the value, $0.1 \sim 10^2$ Ω-cm, of single crystals, sintered polycrystalline materials, and thin films. Taking into consideration the results of the *I-V* characteristics and the particle size, several tens of angstroms, of ultrafine particles, the cause for the large resistivity was not a potential barrier of particle boundaries which prevent electrons from moving, but the pores constructed in the ultrafine particle film. That is, with the change of SnO_2 ultrafine particle film structure from columnar to spongy via porous columnar, the number of SnO_2 particles in a unit thickness of the film was decreased.

Figure 9 shows the result of optical transmittance measured with the SnO_2 ultrafine particle film of 175 μm in thickness having a spongy structure. In the case of SnO_2 thin films, it is known experimentally that the following relation between the film thickness (t μm) and the transmittance ($T\%$) is applicable (16)

$$\log T = \log (0.92) - 0.093t \qquad [2]$$

If $T = 0.86$, the transmittance in the wavelength beyond 0.45 μm, obtained from Fig. 9, is substituted into Eq. [2] then t is found to be equal to 0.3 μm. That is, the transmittance of SnO_2 ultrafine particle film of 175 μm in thickness is equivalent to the transmittance of SnO_2 thin film of 0.3 μm. This result clearly indicates that the ultrafine particle films have many pores. From the above result, we could estimate that the number of SnO_2 particles packed in ultrafine particle film was about 1/600 times in comparison with the value of SnO_2 thin film in the same thickness.

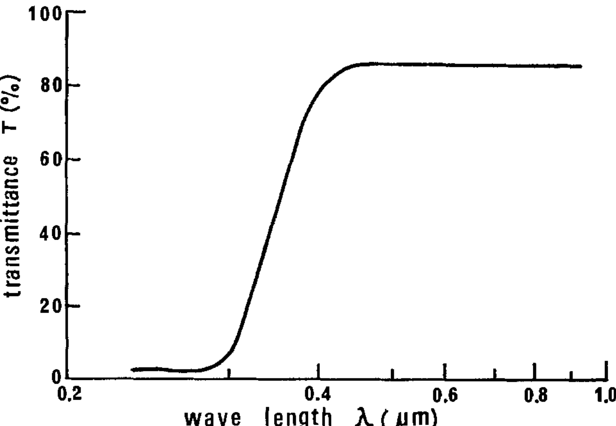

Fig. 9. Optical transmittance measured with tin oxide ultrafine particle film of 175 μm in thickness having spongy structure.

Figure 10 shows the curve of the sensitivity, S, to C_2H_5OH as a function of the thickness of ultrafine particle films deposited in the oxygen pressure at 0.05, 0.5, and 5.0 Torr. In the case of 0.05 Torr, the film structure was columnar and was similar to that of thin films.

With the increase of the film thickness, t, the sensitivity, S, decreases.

The reason is suggested to be as follows. Because of low porosity in the film, C_2H_5OH molecules cannot freely enter into the film. Adsorption of C_2H_5OH molecules, which contributes to lower the resistivity of film, is therefore restricted to the surface of the film.

With the increase of the film thickness, the effect of the surface to the resistivity, and to the sensitivity, of the film in total decreases. In the case of 0.5 and 5 Torr, the film structures are porous columnar and spongy, respectively, and the sensitivity, S is independent of the film thickness, t.

In these porous films, C_2H_5OH molecules enter into the film and are adsorbed not only to the surface of the film but also to SnO_2 particles inside the film. Consequently, as shown in Fig. 8, the sensitivity of the ultrafine particle films constructed from porous columnar structure, without addition of any catalyzers such as Pt or Pd, was quite large compared to the values of sintered polycrystalline materials and thin films.

Summary and Conclusion

Three distinct structures of SnO_2 ultrafine particles are observed, depending on the oxygen pressure at the time of deposition.

The characteristics of films having porous columnar or spongy structure are found to be different from those of reported gas sensing materials such as sintered polycrystals or thin films of SnO_2 in the following manner:

1. High gas sensitivity. The high sensitivity of the ultrafine particle film is considered to be caused by (*i*) a large specific surface area because of the smallness of its particle size, and (*ii*) the porous film structure which makes it easy for gas molecules to enter into the film and to be adsorbed at the surface of SnO_2 particles.
2. High gas selectivity. When the oxygen pressure at the time of deposition is varied from 0.05 to 0.5 and to 5 Torr, resulting in films of columnar, porous columnar, or spongy structure, respectively, the gas to which the ultrafine particle film is sensitive changes from humidity to C_2H_5OH and to iso-C_4H_{10}.

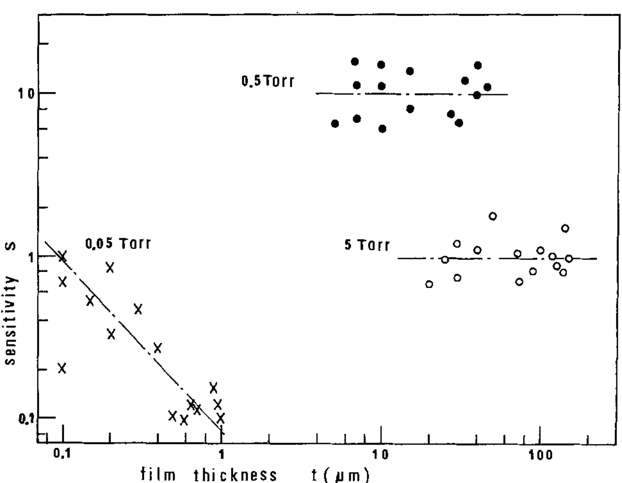

Fig. 10. The sensitivity, S, to C_2H_5OH as a function of the thickness, t, of ultrafine particle films deposited in the oxygen pressure at 0.05, 0.5, and 5 Torr. In the case of 0.5 Torr (porous columnar structure) and 5 Torr (spongy structure), S is independent of t.

That is, the optimum structure of the ultrafine particle film to detect each gas can be obtained by selecting the film deposition condition to be suitable. And, for example, the film having porous columnar structure has a high sensitivity to humidity at operating temperature of 50°C, to C_2H_5OH gas at the temperatures between 200° and 300°C, and to iso-C_4H_{10} gas between 350° and 400°C. Therefore, selective detection of these gases could be realized simply by sweeping the operating temperature of the sensor from 450° to 50°C.

3. The above-mentioned distinguishing characteristics of the ultrafine particle film are realized without addition of any catalyzers such as Pt or Pd.

Acknowledgments

We would like to express our hearty thanks to Dr. T. Nemoto, Dr. S. Sekido, and Dr. M. Mikoda for their deep interest throughout the progress of the work, and Professor R. Kiriyama, Dr. H. Hozumi, and Dr. L. Ozawa for many useful discussions.

Technical Notes

Properties of CdSe Thin Film Electrodes for Photoelectrochemical Cells

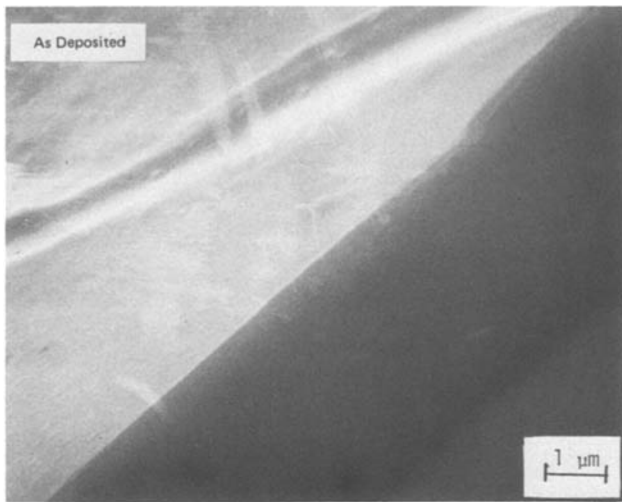
Joseph Reichman* and Michael A. Russak

Grumman Aerospace Corporation, Research Department, Bethpage, New York 11714

Recently, we reported results on n-CdSe thin film photoanodes for use in electrochemical photovoltaic cells (EPC) with aqueous sulfide-polysulfide containing electrolytes which pointed out the relationship between the basic material properties of the various thin film electrodes and their resultant *I-V* performance (1). This paper presents a summary of our more recent efforts on establishing the relationships among thin film processing parameters, electronic properties, and photoelectrochemical performance.

The electrodes under study were deposited onto titanium sheet (0.254 mm thick) and are intended for use in frontwall illuminated electrochemical photovoltaic cells, where the incoming radiation would pass through a transparent window, a thin layer of electrolyte, and then strike the semiconductor electrolyte junction. The CdSe thin films were produced by the simultaneous evaporation of Cd and Se from two independently controlled resistive heated boats. Each source is controlled by a Sloan MDC 9000 Thin Film Deposition Controller (Sloan Technology Incorporated, Santa Barbara, California). The substrates are clamped onto a copper plate into which cartridge-type heaters have been placed to provide substrate temperature control. The addition of the controllers to the co-evaporation system has improved the reproducibility of the deposition process over that obtained previously (1). The most important deposition parameters were found to be the Se to Cd molar ratio in the evaporant vapor streams, the substrate temperature, and to a lesser extent, CdSe condensation rate. The phase of the as-deposited films could be varied from crystalline to amorphous depending on deposition conditions. The films formed with Se/Cd ratios near one were crystalline (hexagonal) with a strong 001 growth texture at substrate temperature as high as 500°C. At Se/Cd ratios near three (represented as x in $CdSe_x$) the as-deposited films were amorphous at substrate temperatures up to 200°C above which temperature the films were not adherent to the substrates. These films, however, crystallized with a strong 001 texture upon heat-treatment. In this case, radical chemical, microstructural, and optical changes occurred with crystallization and loss of excess Se as shown in Fig. 1, 2, and 3. This contrasted with the results obtained for films deposited

* Electrochemical Society Active Member.
Key words: CdSe thin films, frontwall photoelectrochemical cells, photovoltaic energy conversion.



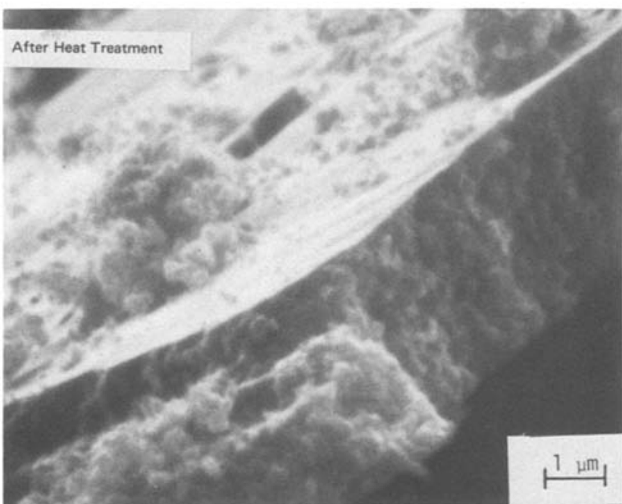


Fig. 1. Microstructural changes observed in a CdSe thin film with Se/Cd ratio of 3 with heat-treatment at 400°C, 15 min in air.

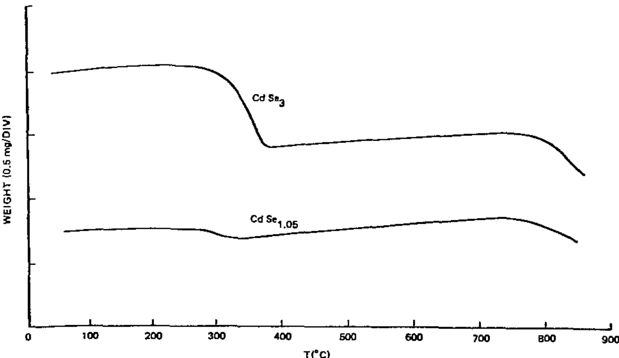

Fig. 2. TGA traces of two $CdSe_x$ as-deposited films in argon (heating rate 10°C/min).

at substrate temperature greater than 200°C, but with Se/Cd ratios near one, where no major microstructural or chemical changes were observed with heat treatment. In almost all cases, however, the photoelectrochemical performance of the as-deposited thin film electrodes was poor, with most films peeling from the substrate. The postdeposition heat-treatment employed was therefore critical to developing good film adherence as well as considerably improved *I-V* characteristics. Conventional photoelectrochemical testing procedures described previously were employed (1).

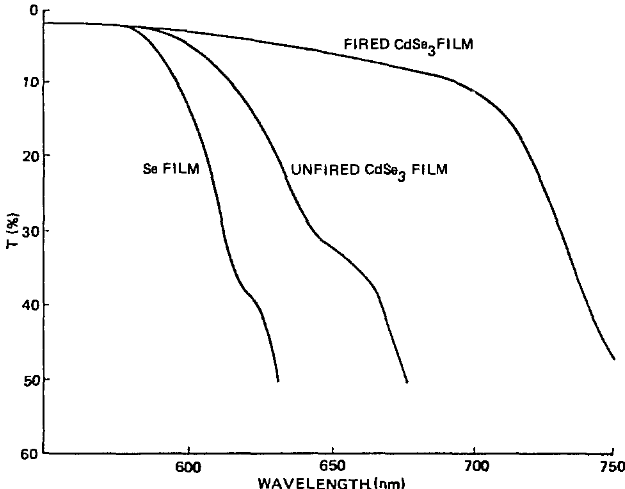

Fig. 3. Optical transmission curves for Se film (1), as-deposited $CdSe_3$ film, (2) and fired $CdSe_3$ film (3).

The most promising results to date with electrodes for use in frontwall cells have been obtained with CdSe films deposited at approximately 100°C with Se/Cd ratio of three and then heat-treated in the temperature range of 350°-400°C in air. These films usually had a very fine-grained microstructure after heat-treatment similar to that of Fig. 1 and the resultant electrodes had *I-V* characteristics with fill factors of 0.60 or greater and high current output. The overall power efficiency of these electrodes was limited by relatively low open-circuit voltages (~0.4V). Power conversion efficiencies at simulated AM2 conditions [W-I ELH lamp discussed in Ref. (2)] from 3 to 5% were obtained consistently with electrodes processed in this manner. Another type of film of interest was deposited on titanium but at substrate temperatures >400°C with a slight excess of Se. It can be seen in Fig. 4 that the microstructure of the films deposited under these conditions was quite different from that of the films produced at lower substrate temperatures and followed by heat-treatment. In particular, the average grain size was significantly larger and the film was columnar with grains that appeared to be continuous throughout the film. Even though these films were deposited at elevated temperatures a postdeposition heat-treatment was required to maximize their *I-V* performance, as was the case for MIS cells made with CdSe thin films

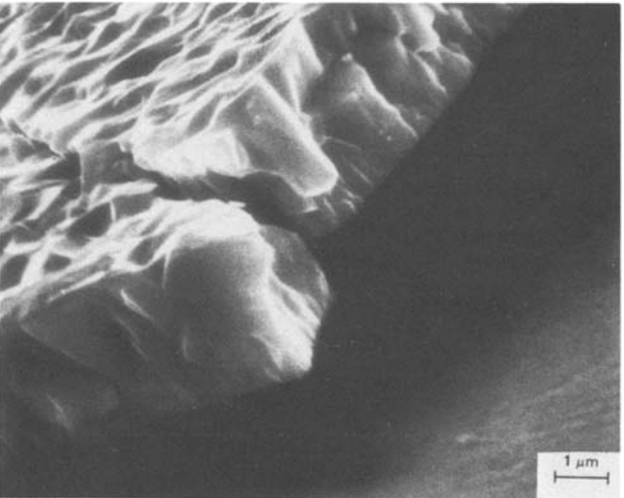

Fig. 4. SEM micrograph of CdSe film deposited at substrate temperature of 425°C.

of this type (3). The interesting feature of films produced in this manner was their higher open-circuit voltage, which was consistently in the range of 0.55 to 0.65V. However, the current output and fill factor were lower than those obtained with the films discussed previously. As a result, the power conversion efficiency of these electrodes was only in the range of 3-4% at 75 mW/cm^2, AM2 conditions.

Figure 5 compares the I-V performance of two thin film electrodes typical of the two types of processing. Curve A is representative of the high substrate temperature film and curve B typifies the film deposited at low substrate temperature and heat-treated. Table I summarizes the pertinent performance parameters for these electrodes. As can readily be seen the I-V characteristics of these two films are quite different. The high deposition temperature film, A, has a gradual decline in current with increasing voltage and a tail at the high voltage end. The low deposition temperature film, B, has a flat I-V characteristic at low voltages and a sharp drop in current at higher voltages. Some qualitative conclusions relating the resistivity values of these films to their I-V characteristics can immediately be made. The film with the higher resistivity, B, shows higher J_{sc} and lower V_{oc} values than those for film A, which had a lower resistivity by more than two orders of magnitude. If it is assumed the difference in the resistivities of the two films is due to changes in free carrier density, N_D, then the difference in the I-V characteristics can be explained in the following manner. Since the depletion width, W, is given by $W = (2\epsilon\epsilon_0(V_{FB} - V)/q\ N_D)^{1/2}$, a lower N_D value would result in a larger depletion width. This then would result in a higher short-circuit current since more carriers would be generated in the depletion layer rather than in the bulk where recombinations are more likely to occur. The initially flat I-V characteristic can also be explained as due to the high resistivity film depletion width being sufficiently large so that essentially all generation of electron hole pairs occurs in the space charge region. In contrast, the lower resistivity film's decline of J with V can be explained by narrowing of the depletion width with increasing voltage causing greater generation of holes in the bulk with subsequent recombinations. The differences in V_{oc} of the films is also consistent with their differences in resistivities. As the carrier density decreases, the Fermi level of the CdSe film is lowered. This then makes the flatband potential more positive and results in less band bending. Since the open-circuit voltage is slightly more positive of the flatband potential it decreases as the Fermi level of the film is lowered.

To obtain a more quantitative characterization of the effects of the film properties on the performance characteristics, the theoretical model we have developed (4) was used to analyze experimental I-V data. The I-V measurements on the two films were made using monochromatic light at a wavelength of 650 nm. The data were reduced to internal quantum efficiency by using measured values of reflectance, correcting for electrolyte absorption, and measuring the incident intensity. The net photocurrent was obtained by using the amplitude of the current resulting from a chopped monochromatic source. This was done to eliminate the effects of dark current on the I-V characteristics.

The model used to fit the experimental data was obtained by solving the diffusion equation for minority carriers using boundary conditions relevant to the semiconductor electrolyte junction, that is, the photocurrent is linearly related to the concentration of

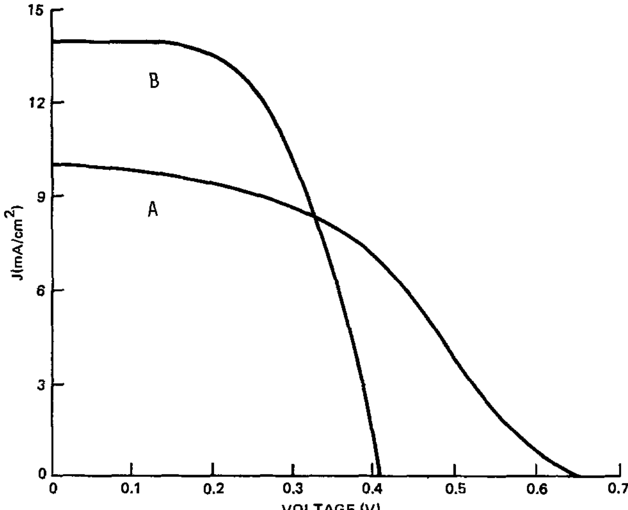

Fig. 5. Comparison of current-voltage curves for CdSe film electrodes discussed in text.

minority carriers at the interface (4). Using this boundary condition and assuming quasi-equilibrium conditions in the depletion region current-voltage relations are derived. The model takes into account losses in current due to recombinations in the depletion region and the bulk of the semiconductor.

The results of the comparison of the model calculations and the experimental I-V data are shown in Fig. 6 for the two films. The significant model parameters that were adjusted to fit the data were minority carrier diffusion length, L_p, carrier density, N_D, lifetime, τ, and charge transfer velocity, v_t. The other parameters such as absorption coefficient and flatband potential were obtained from experimental data. The diffusion length was obtained from the low voltage and reverse bias data (not shown) for the high temperature substrate film A. The results indicate that $L_p < 0.02$ μm, which is quite small. The value of N_D also obtained in this voltage region was 3.5×10^{15} cm^{-3}. Values between 10^{15} and 10^{16} have been determined experimentally for films of this type by a modified van de Pauw technique (5). Values of $\tau = 10^{-10}$ sec and $v_t = 5000$ cm/sec[1] were obtained from the data in the region where the current decreases more rapidly with voltage. These parameters characterize the losses due to recombinations in the depletion region. The short lifetime is consistent with the small diffusion length and inferred mobility from the measured resistivity and value for N_D. The fitted value of v_t of 5000 cm/sec is more than an order of magnitude greater than values we have obtained for the same electrolyte using a single crystal CdSe electrode (6). This higher charge transfer velocity for the thin films can explain the finding that the corrosion rate was lower for thin film than single crystal electrodes (7). Since the corrosion rate involves a competition between the decomposition reaction and the redox reaction a higher value of v_t would tend to favor the redox reaction.

The model fit to the low deposition temperature, high resistivity film, (B), data gave a carrier density

[1] This change transfer velocity, v_t, may appear somewhat high when compared to that predicted from theoretical expressions for metal electrodes. It should be noted, however, that values of v_t for metal electrodes refer to the charge transfer velocities of the redox ions, whereas v_t here refers to the holes of the semiconductor with an effective mass at least 5 orders of magnitudes less than the mass of typical redox ions.

Table I. Comparison of film characteristics for two frontwall electrodes (AM2 simulation)

Film	Thickness (μm)	Grain size (μm)	ρ (Ω-cm)	V_{oc} (V)	J_{sc} (ma/cm^2)	FF	η (%)
A	2.0	0.7	1.1×10^3	0.64	10	0.44	3.7
B	2.3	0.05	4.2×10^5	0.41	14	0.55	4.3

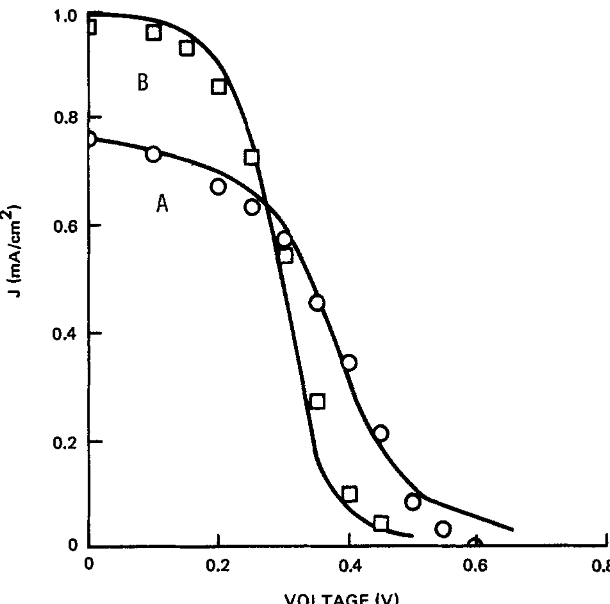

Fig. 6. Experimental monochromatic current-voltage curves (solid lines) and model calculations for electrodes A and B.

of 10^{13} cm^{-3}, in agreement with measured values of 10^{12}-10^{13} cm^{-3}. This low value indicates that the film is fully depleted, that is, the depletion width extends throughout the thickness of the film. The diffusion length therefore cannot be determined since no measure of absorption in the bulk is available. However, the value of 2×10^{-10} sec obtained for the lifetime and the resistivity measurement indicates a diffusion length comparable to that of the high temperature films.

Additional confirmation of the analysis of the CdSe thin film properties comes from the spectral response data as shown in Fig. 7. The figure shows that the internal quantum efficiency (ϕ) *vs.* wavelength characteristics of the two films are quite different. Film B has a measured response further out into the long wavelengths, at sub bandgap energies. This can be explained as being due to absorption from band tail states created by charged defects. The large depletion width of this film makes for efficient carrier collection despite the low absorption coefficients in the sub bandgap region. As the absorption coefficient gets larger, and bandgap absorption due to direct interband transitions takes place, the quantum efficiency reaches 100%. At shorter wavelengths the quantum efficiency decreases. This is attributed to photogenerated majority carrier diffusion to the interface where recombination with photogenerated holes takes place (8).

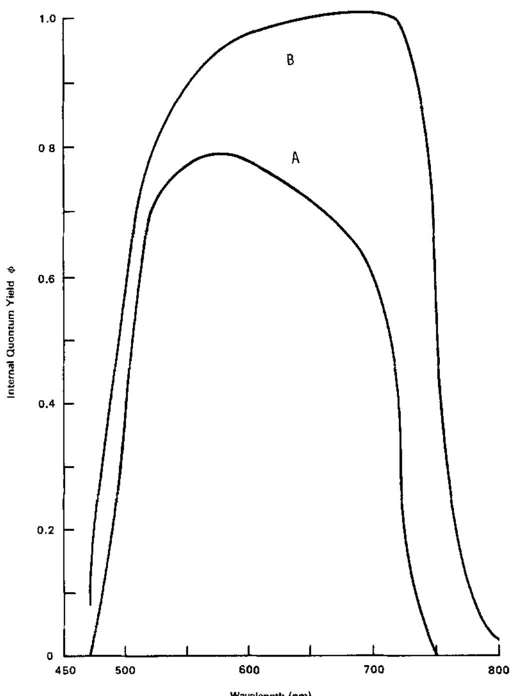

Fig. 7. Spectral response curves for electrodes A and B

Film A shows a lower quantum efficiency over the entire spectrum due to its smaller depletion width. The falloff in efficiency at short wavelengths, again, is attributed to diffusion of majority carriers to the interface. The peak in efficiency here, however, occurs at a shorter wavelength than for Film B. This is consistent with the higher carrier density of this film. A higher carrier density results in a greater electron field at the interface thereby making diffusion less likely. As a result losses due to diffusion start to occur for carriers generated closer to the interface, *i.e.,* at shorter wavelengths where the absorption coefficient is larger. At longer wavelengths the change in quantum efficiency with wavelength shows the same dependence predicted using the parameters obtained from the analysis of the monochromatic *I-V* data.

In summary, an analysis of the properties of the two CdSe thin film photoanodes using a theoretical model that describes the *I-V* characteristics leads to the following conclusions.

1. Both films appear to have poor diffusion lengths and carrier lifetimes. The larger grain size of the high temperature film does not improve these properties. It seems then that L_p and τ are not limited by grain boundary recombinations but rather by recombinations occurring at point defects or stacking faults within the grains (9).

2. The low substrate deposition temperature films are highly stoichiometric (or highly compensated) with carrier densities of the order of 10^{13} cm^{-3}. This is probably due to the postdeposition heat-treatment of the films that initially contain a high selenium to cadmium ratio. Since the films are fully depleted, high short-circuit currents result. The high substrate deposition temperature films have carrier densities of the order of 10^{15} with depletion widths of $\sim$0.4 μm. This results in films with lower short-circuit currents but higher open-circuit voltages than the higher resistivity films.

3. The charge transfer velocities of these films are quite high compared to the single crystal. This may be due to the larger surface area caused by highly irregular geometry of the polycrystalline material. As a result reasonably good efficiencies are obtained despite the poor carrier lifetime. The improved kinetics also provide an explanation for the reported higher corrosion resistance of the thin film than the single crystal material.

Thin Film CdSe Electrodes for Backwall Photoelectrochemical Cells

Michael A. Russak and Joseph Reichman*

Grumman Aerospace Corporation, Research Department, Bethpage, New York 11714

Considerable success has been achieved in converting light to electrical energy using single crystal electrodes in photoelectrochemical cells (PEC) with conversion efficiencies as high as 14% being reported (1). However, widespread application of these devices will most likely require the use of thin film polycrystalline or amorphous electrodes in order to minimize their cost. Figure 1 shows two basic thin film PEC designs. The difference between these cells is in the configuration of the semiconductor electrode. In Fig. 1a, defined here as a frontwall cell, the semiconductor film is deposited on an opaque conducting substrate and must be positioned in such a way that the incident radiation can reach the semiconductor electrolyte junction. In this case, a transparent window is necessary in front of the electrode and the light must pass through a layer of electrolyte before it strikes the junction. This can result in a significant reduction in the device conversion efficiency due to the highly absorbing nature of the chalcogenide containing electrolytes used to date in most PEC. In addition, it is necessary to have free flow of electrolyte from the photoactive electrode to the counterelectrode. In this configuration, however, semiconductor films of various thickness and a wide range of substrates can be used. Thin film polycrystalline electrodes for use in frontwall cells have been made with efficiencies in the range of 5-8% using CdSe, GaAs, and CdSe-CdTe solid solutions (2-4). Figure 1b, defined as a backwall cell, employs a semi-transparent photoactive electrode that allows irradiation of the junction through the semiconductor rather than through the electrolyte, thus eliminating electrolyte absorption. The cell design is also less complex. How-

ever, the number of substrate materials is limited due to the transparency requirement. Also, the combination of thin film properties necessary to optimize the performance of such a device is somewhat restricted. It is desirable to have the space charge region extend through the full thickness of the film to promote rapid carrier separation and obtain good collection efficiency (5). In addition, the film thickness should be such that all the incident light of greater than bandgap energy can be absorbed within the film. A calculation of this thickness for CdSe based on the measured values of the absorption coefficient, indicates that, at 500 nm, a film thickness of 0.680 μm is sufficient to absorb 99% of the light, whereas, at 700 nm, a thickness of 2.37 μm is required. This suggests a film thickness of 2-3 μm to provide an adequate amount of material for the absorption of sunlight. In order to have a space charge layer width of this order, a majority carrier doping density of less than 10^{14} cm^{-3} is necessary (assuming a voltage drop of 0.7V across the space charge layer).

The CdSe electrodes discussed here were deposited by the simultaneous vacuum evaporation of Cd and Se from two independently controlled resistive heated boats onto chemical-spray-deposited, halogen-doped, SnO_2-coated glass slides. The details of the deposition system employed have been given elsewhere (2, 6). The SnO_2-coated glass had resistivity in the range of 10 Ω/square and visible transmission of approximately 80%. Backwall electrode performance was tested in a cell specifically designed for this purpose, (see Fig. 2) which allows irradiation of the CdSe through the substrate glass and transparent conductor. This cell design eliminates the electrolyte absorption loss and allows reasonably quick sample change. A platinum counterelectrode and saturated calomel reference electrode were used in a standard potentiostatic arrangement. The light source was a W-I ELH lamp which simulates an AM2 spectral distribution (7). Narrow bandpass filters were used for monochromatic experiments. The electrolyte was aqueous 2.5m Na_2S, 1m S, 1m KOH.

CdSe films deposited with an Se/Cd atomic ratio of 3, subsequently heat-treated at 400°C in air, produced backwall electrodes with power conversion efficiencies greater than 4% at 75 mW/cm^2, AM2, as shown in Fig. 3. The short-circuit current density, J_{sc}, of 17 mA/cm^2 is almost at the theoretical limit for a material with E_g = 1.7 eV responding to an AM2 spectrum (8). The thickness of this film is 2.5 μm (see Fig. 4) so that all the impinging radiation is absorbed within the film. The open-circuit voltage of 0.45V, while far from the theoretical limit, is such that $V_{oc} \times J_{sc}$/intensity still results in a maximum efficiency of 10.3% at 75 mW/cm^2. It is the low fill factor of 0.42 that limits the efficiency of this electrode. The same type of film deposited on a titanium substrate generally has J_{sc} in the range of 12-14 mA/cm^2, fill factors from 0.55 to 0.65, and V_{oc} from 0.4-0.45 when tested with the same light source.

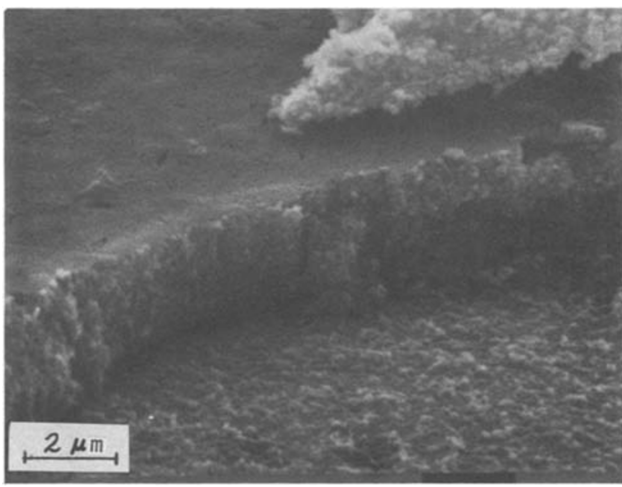

Fig. 4. Microstructure of CdSe film deposited on SnO_2-coated glass substrate.

Hall measurements and direct resistivity measurements on these films (9) indicate the donor densities, N_D, are in the range of 10^{12}-10^{13} cm^{-3}, majority carrier mobilities, μ, from 10-40 cm^2/Vsec, and resistivities, ρ, from 10^4 to 10^5 Ω-cm. These parameters indicate that the space charge region extends through the entire thickness of the films accounting for the high collection efficiency observed experimentally.

The spectral response and monochromatic *I-V* behavior of these backwall electrodes were also investigated. The *I-V* curve for this electrode at 650 nm is shown in Fig. 5. The power conversion efficiency is 9.5% and is limited by a fill factor of 0.52. The maximum $J_{sc} \times V_{oc}$ efficiency is 18.4%. The internal quantum efficiency at short-circuit conditions is 0.95.

The spectral response of another electrode of this type is shown in Fig. 6 (corrected for reflection losses). The response is quite flat and very near unity, with only a small falloff in the blue. This small decrease in quantum efficiency at short wavelengths is attributed to the electric field at the SnO_2-CdSe contact. Since the contact is ohmic, an accumulation layer exists in the CdSe film. The resultant electric field would therefore tend to oppose diffusion of holes to this interface and

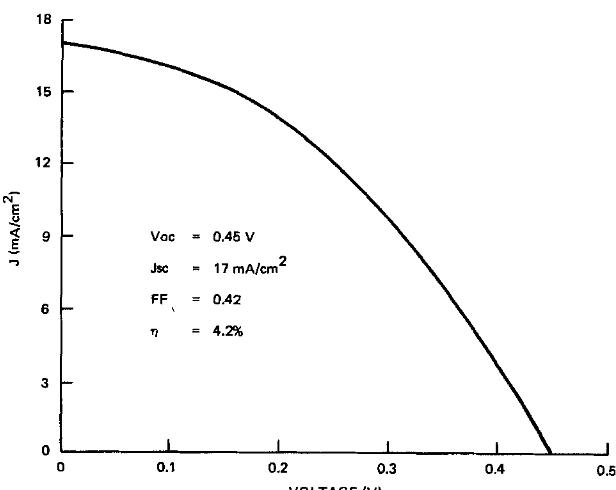

Fig. 3. Current-voltage curve for backwall electrode at 75 mW/cm^2, AM2 simulation (uncorrected for reflection).

thereby minimize recombination losses for those carriers generated by the short wavelength radiation.

Analysis of the *I-V* curves at different wavelengths revealed a significant variation in output power parameters, even though the quantum efficiency was fairly constant. These data are summarized in Table I. This variation is due to the difference in penetration depth of each wavelength radiation into the thin film. When the electrode is in forward bias, and the internal electric field reduced, it is less likely for holes generated closer to the ohmic contact by shorter wavelength light to reach the junction region before recombinations than for those holes generated by longer wavelength light nearer the semiconductor electrolyte interface. This effect is reflected in the observed reduction in fill factor in going to shorter wavelength radiation. This is also supported by the fact that increase in quantum efficiency with voltage in reverse bias is greater for the shorter wavelength curves than for the longer wavelength ones, indicating the additional bias is useful in preventing carrier recombination for radiation absorbed further away from the electrolyte junction.

The origin of the low fill factor of these electrodes, compared to the same film deposited on a metallic substrate, is not completely understood. It has been shown that a high series resistance can significantly reduce the fill factor of a solar cell *I-V* curve and also reduce the J_{sc} (5, 8). Also, series resistance losses have

been reported to give rise to a nonlinear J_{sc} *vs.* intensity plot for CdSe photoanodes on transparent conducting substrates (10). However, for the electrodes evaluated in this work, the J_{sc} was found to increase linearly to a value of 33.7 mA/cm² at 150 mW/cm² yet, the fill factor and therefore the efficiency increases with decreasing intensity as shown in Table II. The calculated voltage drop attributed to the SnO_2 layer under the collection area for this electrode (see Fig. 2 for electrode construction detail) at a current density of 20 mA/cm² is only 0.01V, indicating ohmic losses are not significant. However, this calculation does not take into account any losses that exist outside the collection area, such as those due to the spreading resistance of the SnO_2 or the wire contact resistance. At present, the low fill factor of these electrodes at AM2 conditions is attributed to the increased recombination of carriers generated by the short wavelength light as well as resistive losses due to the electrode configuration employed.

Recently, the fill factor of this type of film has been improved to 0.56 by minimizing the resistive loss outside the electrode active area and photoetching the electrode. As a result, power conversion efficiencies of 6% have been achieved.

Pulsed E-B Apparatus and Annealing of Ion-Implanted Silicon

T. Itoh,* H. Tamura, D. X. Rao, and Y. Ohkubo

School of Science and Engineering, Waseda University, Shinjuku-ku, Tokyo 160, Japan

The pulsed electron beam (PEB) has been recently used to anneal the disorders in ion-implanted semiconductors and to electrically activate the dopant species (1-4). Also, PEB has been applied to make a suitable metal-semiconductor contact (5). At present, there are few reports on the PEB apparatus. We have developed a single pulsed electron beam processing apparatus consisting of a high density electron source operated by means of pulsed He gas discharge and an accelerating diode. We have tried the annealing of arsenic ion-implanted silicon with $1 \times 10^{16}/cm^2$ at 50 keV to examine the ability of the apparatus.

The Rutherford backscattering (RBS) measurements with 350 keV $^4He^+$ were used to analyze the crystallinity and the impurity distribution in ion-implanted layers before and after the single PEB irradiation. Electrical properties of the PEB annealed silicon were evaluated by the carrier concentration and the mobility profiles which were obtained by Hall measurements with successive anodic oxidation and stripping.

Apparatus

The working characteristics of our apparatus are as follows: (*i*) The structure and operation are relatively simple compared with the scanning E-B annealing system (6, 7), (*ii*) the energy density of E-B can be controlled by the value of a main capacitor and its charging voltage, (*iii*) the magnitude of the charging voltage is low in contrast to other works (1), and (*iv*) E-B parameters can be chosen by a working pressure of He and an acceleration voltage.

Figure 1 shows the schematic diagram of the PEB apparatus. The column consists of two sections: an electron source (section A) and an electron accelerating diode (section B). These two sections are separated with a common mesh electrode that acts as an anode for the section A and a cathode for the section B. Carbon was chosen as the cathode electrode because of its thermal stability. To obtain a stable electron beam, a carbon mesh electrode laminated with aluminum was used for the reduction of its electrical resistivity.

The electron source is assembled as follows. A helical tungsten filament mounted on a metal-lid is used for the thermionic electron emitter. The metal-lid is fixed at the top end of a Pyrex tubing of 100 mm in diameter and 200 mm in length, and a metal flange with the mesh electrode is fixed at the bottom end of the tubing. Capacitor Cs (1.0 μF) connecting to the electron source is charged to 3-4 kV. The electron accelerating diode consists of the mesh electrode as a cathode and an aluminum pedestal as an anode. The metal flange is isolated from the ground potential by an insulator made of fluorocarbon polymers, and samples are set on the aluminum pedestal with a distance of 20 mm from the mesh electrode. Capacitors Ca (1.5 μF) which are composed of three low inductance type capacitors (0.5 μF), are charged to 4-15 kV. These three capacitors are arranged around the column, and connected in parallel with a cylindrical electrode to reduce the lead inductance as shown in Fig. 2.

The density of electrons emitted from the W-filament is multiplied by means of He gas discharged in the electron source. The high density electrons propagate into the electron accelerating diode through the distributed holes in the mesh electrode, so that these electrons are accelerated to sufficient energy for an-

nealing by the electric potential V_a of the capacitors Ca. A mechanical switch Q controls the discharge in the electron source and plays a role of triggering the discharge of the main capacitor.

Experimental and Results

The He pressure P_w and the acceleration voltage V_a are the significant parameters for annealing. Figure 3 shows the suitable working region in these parameters to anneal the arsenic ion-implanted silicon. Arsenic ions were implanted at 50 keV to a dose of $1 \times 10^{16}/cm^2$ at room temperature into (100) n-type silicon with a resistivity of 60 Ω-cm. This energy brings the arsenic atoms to a projected range of 322Å and this dose is sufficient to drive the silicon amorphous. After a single PEB irradiation with the parameters shown in Fig. 3 as open circles, the RHEED observations indicated that the implanted layers were singly recrystallized. It is considered that the sufficient energy density to anneal the ion-implanted layers was obtained by taking the parameters below the hatched line in the figure. In all cases, the pulse width determined from the current wave-form measurements was about 1 μsec (FWHM). The width of a pulse is governed mainly by the residual-inductance of the capacitors. The annealed area of 10-20 cm^2 was obtained. Mesa diodes were fabricated to examine the spatial uniformity of the annealed area. The substrates were p-type (100) silicon with a resistivity of 5-8 Ω-cm. Arsenic ions were implanted at 50 keV to a dose of $1 \times 10^{15}/cm^2$ into these substrates. Figure 4 shows the diode reverse current *vs.* the distance from E-B annealed edge. These data indicate that the annealed area is electrically uniform.

Figure 5 shows the energy spectra of 350 keV $^4He^+$ RBS measurements of as-implanted sample, PEB annealed sample with the parameters at point M shown in Fig. 3 and furnace annealed sample at 1000°C for 30 min. The E-B parameters used here were V_a of 8 kV and P_w of 1×10^{-5} Torr. The minimum yield of the PEB annealed sample was about 5.8%, and this value is slightly higher than that of the bulk silicon. The arsenic yield of the PEB annealed sample detected in

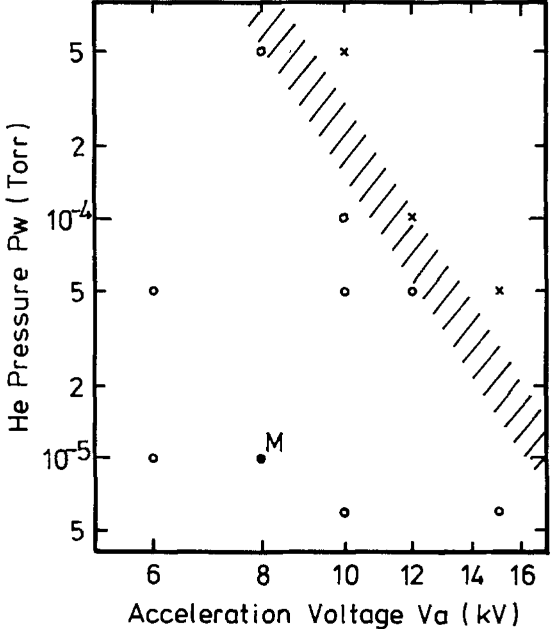

Fig. 3. Suitable working region for E-B parameters of P_w and V_a. Sufficient energy density to anneal ion-implanted silicon was obtained in the region below the hatched line. RHEED observations showed single crystalline pattern after a single PEB irradiation with the parameters shown as open circles (○). Point M (●) denotes the typical parameters of $V_a = 8$ kV and $P_w = 1 \times 10^{-5}$ Torr.

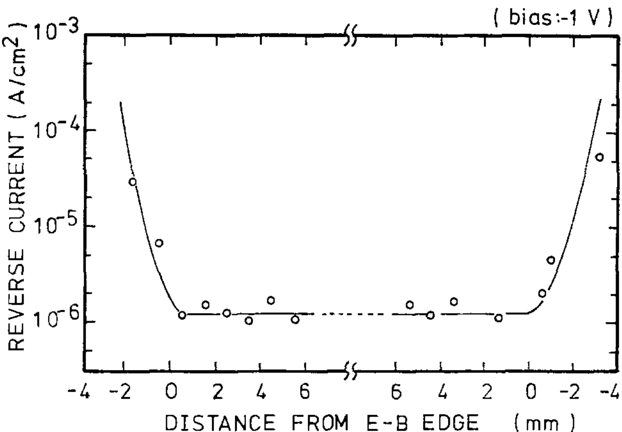

Fig. 4. Electrical uniformity of PEB annealed area. Diode reverse current vs. distance from E-B annealed edge.

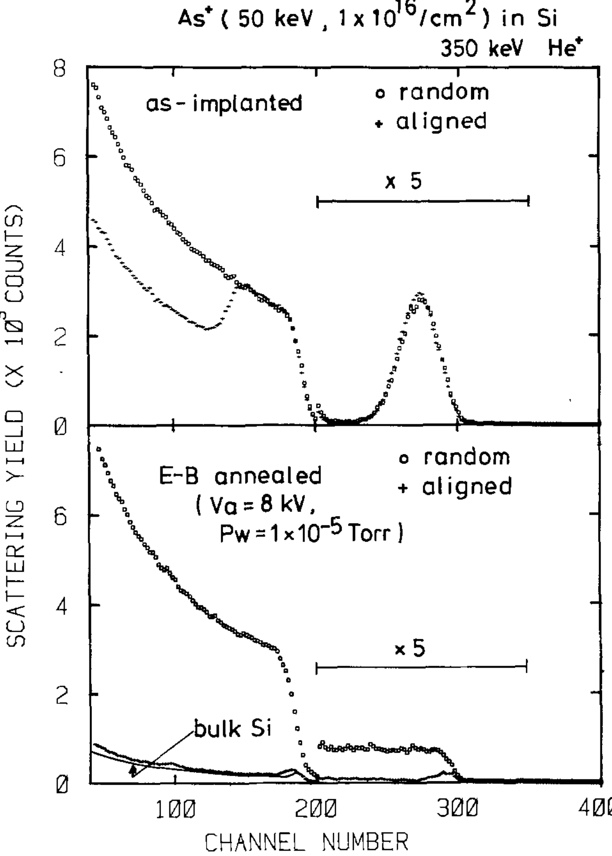

Fig. 5. RBS energy spectra of arsenic ion-implanted (100) silicon before and after PEB irradiation with the parameters at point M shown in Fig. 3. Arsenic ions were implanted at 50 keV to a dose of $1 \times 10^{16}/cm^2$ at room temperature.

a random direction shows a plateau, which indicates that significant diffusion of arsenic atoms took place. This type of diffusion is said to appear in liquid phase epitaxy (1-3, 8, 9). The arsenic yield ratio of <100> aligned to random spectra indicates that arsenic atoms more than 80% occupied substitutional lattice sites.

Figure 6 shows the depth profiles of the carrier concentration and the mobility. The profiles were obtained by the Hall measurements by the van der Pauw method with successive anodic oxidation and stripping. The anodic oxidation of silicon was done in a 0.04*N* solution of KNO_3 in N-methylacetamide (10). A uniform carrier concentration of $3 \times 10^{20}/cm^3$ was obtained from the surface to the depth of 2000Å. The surface carrier density calculated from this figure was $6.4 \times 10^{15}/cm^2$. This result indicates that 64% of im-

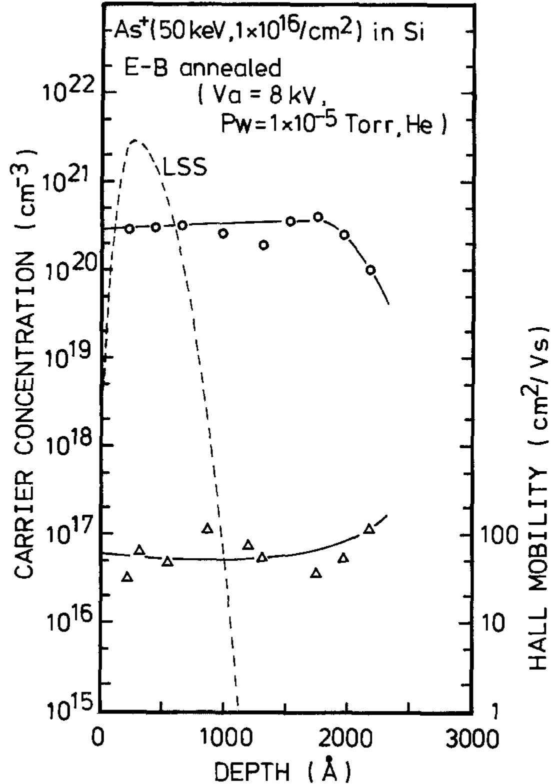

Fig. 6. Carrier concentration (○) and mobility (△) profiles of arsenic ion-implanted silicon after PEB irradiation with the parameters at point M shown in Fig. 3. As-implanted profile expected from LSS theory is also shown by dashed line.

planted arsenic atoms were electrically activated, and the mobility shows almost the same value as the bulk silicon. The carrier profile shows a redistribution by diffusion of arsenic atoms compared with the theoretical profile expected from the LSS theory (11). This carrier profile is in good agreement with the results of the RBS measurements.

Summary

A low voltage operating PEB apparatus has been developed. The energy density of the electron beam depended strongly on the He pressure and the electron accelerating voltage. Suitable parameters for annealing the ion-implanted silicon were presented. Under the typical condition of $V_a \doteq 8$ kV and P_w(He) = 1×10^{-5} Torr, we performed the annealing of silicon implanted with arsenic ions at $1 \times 10^{16}/cm^2$ at 50 keV. The ion-implanted layer was recrystallized by a single PEB irradiation, and the minimum yield of 5.8% was indicated from results of RBS measurements. The electrical activation efficiency of 64% was obtained by means of the Hall measurements. The mobility values were almost equivalent with that of the bulk silicon at the same carrier concentration. The redistribution by quick diffusion of arsenic atoms was observed by both measurements, and the redistribution profile suggests that liquid phase epitaxy is the dominant mechanism in these cases.

An Anomalous Effect in Angle Lapping and Staining Ion-Implanted Layers

P. Picco and M. L. Polignano

Divisione MOS, SGS-ATES, 20041 Agrate, Milano, Italy

Techniques for angle lapping and staining ion-implanted layers have recently been reviewed by Wu *et al.* (1).

The interest in these techniques is justified by their usefulness to control semiconductor device fabrication.

In their paper, Wu and co-authors extensively describe the experimental conditions to perform angle lap and stain operations. They claim the reliability of these operations for the determination both of the doping type of the different layers and of the exact positions of the junctions.

However, they do not mention the possibility of an anomalous effect due to partial compensation near the surface; the appearance of a p-n junction where one does not really exist.

The description of such an effect is the aim of this paper.

Boron-implanted layers were investigated, in view of their use as channel stoppers in MOS circuit technology. 40 KeV boron ions were implanted into 7-10.5

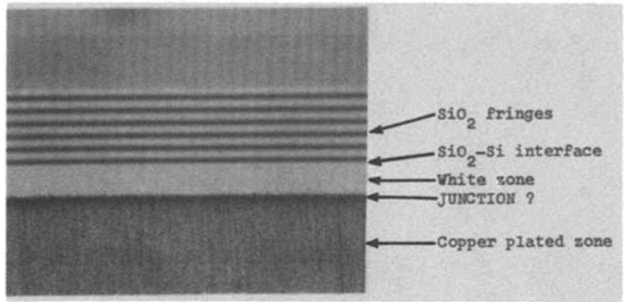

Fig. 1. An example of staining delineation obtained after the process described in the text. The picture has been taken in Na light (fringe distance $\simeq$ 2000Å). Implanted dose = 10^{13} cm^{-2}. All the implanted samples had this appearance.

Ω-cm, 100 oriented, phosphorus-doped silicon slices, through a 500Å thick SiO_2 layer (2).

After implantation, without removing the oxide, the slices were first annealed in an inert atmosphere (N_2) for 30 min at 920°C; then a diffusion was carried out in an oxidizing ambient at the same temperature. The furnaces (normally employed for gate oxidation and successive annealing in device production) were tested for contamination before the described operations.

The behavior of junction depth (x_j) and sheet-resistance (V/I) with respect to the dose was studied to characterize the process. Junction depths were determined following Wu and co-authors (1), using copper sulfate solution.

An example of the staining delineation is shown in Fig. 1 (it corresponds to one of the lowest implanted doses). All the stained samples had this appearance, where the width of the white zone (see Fig. 1) increased with increasing dose. V/I was determined with a four-point probe, at several different low currents (5-100 μA), in the dark (3, 4). It was found to be both uniform throughout the slice and independent of both direction and magnitude of the current.

Contradictory results were, however, observed: x_j monotonically raised with implanted dose, as expected, but V/I raised too (see Table I; the results of V/I are more widely discussed later).

These results can be explained as follows. The segregation of implanted boron into the growing oxide is so high that the remaining implanted boron in the silicon is not sufficient to completely compensate the substrate doping (such an effect is enhanced by phosphorus accumulation near the surface during oxidation). There is, however, a sufficient photovoltage due to the band bending under illumination, that the reaction

$$Cu^{++} + 2e^- \rightarrow Cu \quad [1]$$

can take place in the noncompensated region of the lapped area. The typical staining delineation of a p-n junction is then observed, as shown in Fig. 1, even if the whole silicon slice is still the same type as before.

The accuracy of this hypothesis is demonstrated by spreading resistance measurements on some samples, whose results are shown in Fig. 2. Our hypothesis is further supported by the behavior of V/I in a wider dose interval, shown in Fig. 3.

Table I. Sheet resistivity and junction depth values after diffusion in oxidizing ambient (final oxide thickness = 1.3 μm)

Dose (B atoms/cm²)	V/I (Ω)	x_j (μm) (determined by staining)
5 × 10^{12}	35 ± 2	0.26
10^{13}	150 ± 50	0.44
5 × 10^{13}	(2 ± 0.5) × 10^3	0.68

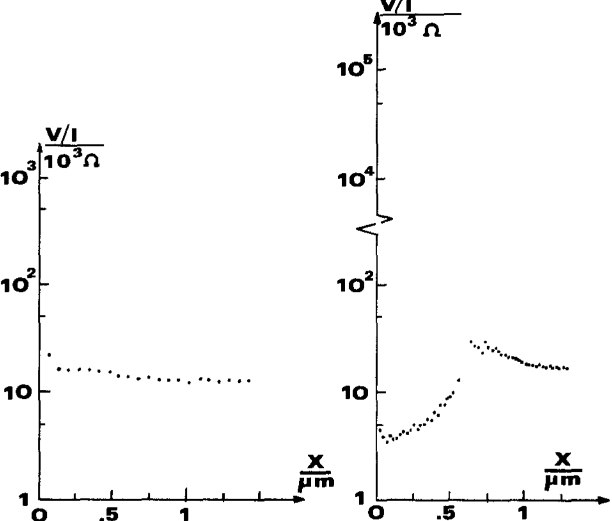

Fig. 2. Spreading-resistance measurements on samples implanted with different doses. (a) Q = 10^{13} cm^{-2} (the same sample as in Fig. 1); (b) Q = 10^{14} cm^{-2}.

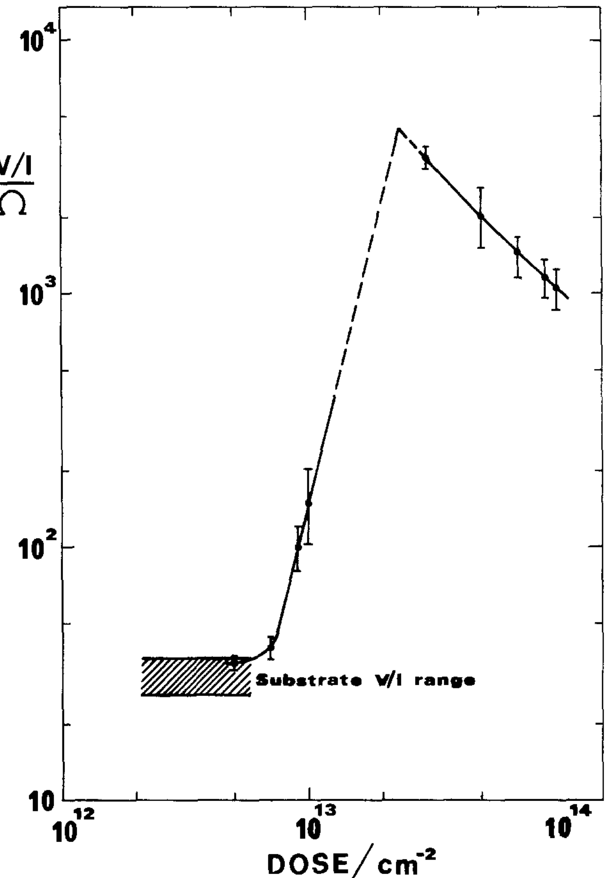

Fig. 3. V/I dependence on implanted dose after the process described in the text.

A critical implant dose $\overline{Q}$ exists; for $Q < \overline{Q}$, V/I increases from the unimplanted substrate value, while for $Q > \overline{Q}$ it regularly decreases. This increase is first of all due to carrier compensation. This effect increases in proportion to the dose $-V/I \propto Q$. Actually, $V/I \propto Q^{\alpha}$ ($\alpha \simeq 4$); this effect can be due to the screening effect of the compensated layer on the more conductive substrate. The decrease ($V/I \propto Q^{-1}$) is the usual one occurring when carriers are added to a conductive layer. In other words, for $Q < \overline{Q}$ the formation of the junction is only apparent, while for $Q > \overline{Q}$ the junction

truly exists. Our value for $\overline{Q}(\simeq 2 \times 10^{13}\ cm^{-2})$ is consistent with boron segregation and diffusion data given in the literature (6, 7).

The behavior shown in Fig. 3 can be found every time boron is implanted (in low dose) and diffused into an n-type substrate. When an n-species is implanted on a p-substrate, the described effect ought to occur at much lower doses, because of the opposite roles played by dopant segregation.

In conclusion, we have described an effect that may often occur when low dose boron implantations are made into an n-type substrate. We have described its appearance after angle lapping and staining operations, and its consequences from an electrical point of view. In this case an angle lap and stain operation, as described by Wu *et al.*, is not reliable to correctly identify the layers.

Generally speaking, then, if the doping type of the layer investigated by lapping and staining techniques is not *a priori* known, additional electrical tests must be performed to correctly identify the layers.

Phosphorus Silica Glass as Dopant Source

II. Validity of the Etch Rate Datum

M. L. Polignano, P. Picco, and G. F. Cerofolini

SGS-ATES, 20041 Agrate, Milano, Italy

In a previous paper (1) it was shown that simple profiles, such as Gauss or erfc, cannot be used to describe phosphorus diffusion from highly-doped phosphorus silica glass (PSG).
This conclusion was based on the difference between the amounts per unit area as computed from V/I and x_j data and the amounts Q^{Si} diffused from PSG as measured by etch rate. This difference was ascribed by us to a complex profile (plateau, kink, tail), though a referee pointed out that "it could equally be argued that the latter datum may be suspect".
To free this datum from any flaws, we have measured the amount diffused into silicon by two independent methods: neutron activation analysis followed by a measurement of β ray activity, and differential resistivity and Hall mobility.

For the analysis we choose the sample diffused at 940 °C for 2 h 15 min in N_2 atmosphere. The amount diffused is given by

$$Q_1^{Si} = (5.1 \pm 0.5) \quad 10^{15} \text{ cm}^{-2}$$

when evaluated at the Si-PSG interface, and

$$Q_2^{Si} = (5.8 \pm 0.6) \quad 10^{15} \text{ cm}^{-2}$$

when evaluated at the PSG surface.
Because of the etch-rate procedure, the datum Q_2^{Si} seems more reliable than the corresponding datum Q_1^{Si}.
Within the experimental error $Q_1^{Si} = Q_2^{Si}$ and this result is confirmed by other measurements on samples diffused at 1000 °C and 1050 °C.

The neutron activation analysis was carried out by M. Gallorini (CNR - Center for Radiochemistry and Activation Analysis, Pavia). The sample was irradiated in the central thimble facility of of the TRIGA Mark II Research Reactor of the University of Pavia for 10 h; in this position the nominal neutron flux is $9\ 10^{12}$ cm^{-2} s^{-1}. The subsequent β ray activity was monitored by a 2π Geiger counter previously calibrated with silicon samples with the same geometry implanted with several amounts of ^{31}P : $3\ 10^{15}$, $5\ 10^{15}$, $8\ 10^{15}$ cm^{-2}.
The analysis gave the following result:

$$Q_{NAA}^{Si} = (6.4 \pm 0.4) \quad 10^{15} \text{ cm}^{-2}$$

where the reported error is only due to the statistical fluctuations of the number of counts. This datum is an overestimate of Q^{Si} because of the phosphorus doping of the slice back due to P_2O_5 evaporated during the heat treatment.
Finally, an underestimate of Q^{Si} can be obtained by measuring the amount of electrically active phosphorus atoms diffused into silicon.
This measurement was carried out by M. Finetti and S. Solmi (CNR - Istituto LAMEL, Bologna) by determining differential resistivity and Hall mobility and gave the following result:

$$Q_{act}^{Si} = (5.1 \pm 0.5) \quad 10^{15} \text{ cm}^{-2}.$$

This value is an underestimate of Q^{Si} because phosphorus atoms may be electrically inactive in the form of interstitials, negatively charged E centers and SiP precipitates.

Keywords: diffusion, junction, resistivity

The situation is summarized in the following table that confirms the validity of the etch rate datum:

Method	Q^{Si} / 10^{15} cm^{-2}
Electrical	$\geq 5.1 \pm 0.5$
Etch rate 1	5.1 ± 0.5
Etch rate 2	5.8 ± 0.6
NAA	$\leq 6.4 \pm 0.4$

A last remark: reference (1) contains two typographical errors.
The first formula of scheme 1 reads

$$Q = C_o \sqrt{\pi D t} \quad ,$$

and eq. 3 reads

$$C_o = n_s \ (1 + 2.04 \ 10^{-41} \ n_s^2)$$

These errors did not affect the computations therein.

Direct Writing of Refractory Metal Thin Film Structures by Laser Photodeposition

D. J. Ehrlich,* R. M. Osgood, Jr., and T. F. Deutsch

Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts 02173

We have recently described a technique for high-resolution, one-step fabrication of thin-film structures using UV laser photodeposition (1,2). This technique, which makes use of near-ambient-temperature photochemical reactions, provides a means for maskless direct writing of thin-film structures for integrated optics and microelectronics. In this note, we describe results showing that micrometer-wide metal lines can be deposited directly by photodissociation of metal carbonyls, thus showing that the process can be used for deposition of such important refractory metals as Fe, Cr and W. One-step maskless deposition of these refractory metals is important in such diverse microfabrication processes as photolithographic-mask repair or direct writing of silicides and diffused integrated optical waveguides.

UV laser photodeposition requires that the carrier gas have a dissociative continuum extending into the range of available UV laser wavelengths. In the case of many metal carbonyls, molecular fragmentation begins to occur in the near UV at wavelengths greater than 300 nm, although, at least for the longer wavelengths, only one CO ligand is removed after single-photon absorption. As a result, at low laser powers and long laser wavelengths subsequent radiative or collisional events (3,4) are required to completely strip the remaining ligands and release metal atoms from gas-phase molecules.

During the course of our experiment, several laser wavelengths and carbonyl compounds were investigated. Both pulsed (10 nsec) excimer lasers at 248 and 193 nm and a cw, 257-nm, frequency-doubled, Ar-ion laser were used to successfully obtain deposition. The measurements described below were made using the 257-nm beam. Large-area cw photodeposition has also been reported using an ion laser at wavelengths near 350 nm (5).

Key words: Deposition, Lasers

*Electrochemical Society Active Member.

The photodeposition apparatus has been described in detail elsewhere (1,2). Photodeposited lines were "written" by translating a 1-cm-long gas cell, containing the substrate, in a plane perpendicular to the optical axis. The 257-nm beam was focused to a 2.5-μm spot size with a multi-element 3-cm-focal-length lens. The substrates used were Pyrex, fused silica and Si.

Three metal carbonyls $Fe(CO)_5$, $W(CO)_6$ and $Cr(CO)_6$ were investigated; the gas pressure of $Fe(CO)_5$ was adjusted to ~ 0.5 Torr so that the optical absorption length at 257 nm was ~ 7 cm. The pressures of $W(CO)_6$ and $Cr(CO)_6$ were fixed at the room-temperature vapor pressures by simply placing a several-milligram carbonyl crystal in the sample cell. No attempt was made to obtain higher pressures for the latter two compounds by heating the cell, although this would have increased the deposition rates.

Micrometer-scale resolution was obtained in photodeposits from all three gases. Figure 1 shows a series of 2.5-μm-wide

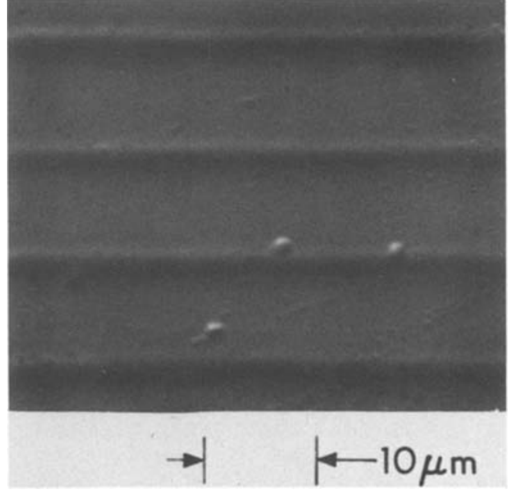

Figure 1. Optical micrograph of tungsten lines on Pyrex produced by single 0.9 μm/sec scans at a 257-nm power of 0.9 kW/cm^2.

tungsten features which were made on a quartz substrate. The line width is determined by the laser spot size at the surface and, based on experience with the alkyls, tighter focusing will undoubtably yield smaller line widths. With $Fe(CO)_5$, a particulate background, which extended many beam widths away from the central deposit, was sometimes produced. As is shown in Fig. 2, this material consisted of small crystallites; it apparently arises from a gas-phase reaction followed by homogeneous nucleation of the photoproducts occurring at many beam diameters away from the substrate surface. It was found that the amount of this particulate could be reduced to levels undetectable under the optical microscope by reducing the carbonyl dissociation rate per unit volume. This reduction can be accomplished through lowering the laser intensity or $Fe(CO)_5$ gas pressure; background deposits can also be reduced by the addition of an inert buffer gas such as He or Ar. In the case of $Cr(CO)_6$ and $W(CO)_6$, background deposits were never a serious problem.

The relative metal deposition rate was determined by measuring the rate of change in the attenuation of the UV deposition beam. Film thicknesses were estimated from the measured attenuation via the known optical constants of the metals, a procedure shown to be accurate within a factor two in studies of Cd and Zn deposition. Fig. 3 displays the variation of deposition rate versus laser intensity for $Fe(CO)_5$ and $W(CO)_6$. Both compounds show a linear dependence of deposition rate on laser intensity at laser intensities less than 200 W/cm^2. This linearity indicates that the rate limiting step in the deposition is a single-photon-initiated photochemical reaction. In this low-power linear regime the relative Fe and W deposition rates are approximately in the ratio of the vapor-phase carbonyl absorption strengths at 257 nm. Above 200 W/cm^2 the $Fe(CO)_5$ rate exhibits a sharp nonlinear increase or "runaway". In this intensity regime the amount of particulate deposit is large and the $Fe(CO)_5$ gas-depletion rate is rapid. We believe that above the threshold intensity a gas-phase chain reaction is initiated. Evidence of such a reaction has also been seen in the case of pulsed deposition. As suggested above, the onset of this reaction can be controlled by a variation in $Fe(CO)_5$ and buffer-gas pressure, and UV-laser intensity. However, particulate formation presently limits the Fe deposition rate.

The direct writing of high resolution structures by laser photochemical techniques is of particular importance as a potential means to correct faults or otherwise alter microcircuitry without the use of photolithography. Specifically the photodeposition of refractory metals discussed here provides a means for one-step fabrication of doping (6) and alloying (7) patterns. For example, tungsten-silicide conductors can be written by the technique of Ref. 6. Similarly, photodeposition of Ni and Fe followed by subsequent thermally-activated diffusion into the substrate can enable one to write an optical-waveguide doping pattern directly in $LiNbO_3$. Relatively slow rates of deposition are useful for these applications since they require small amounts of atomic

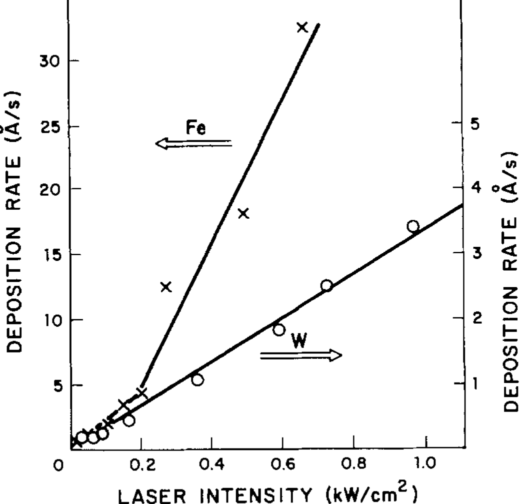

Figure 3. Deposition rate versus laser intensity for $Fe(CO)_5$ at 0.5 Torr and $W(CO)_6$ at 0.2 Torr. The substrate is SiO_2.

dopants. Our results show, however, that an improvement in rate is necessary for applications involving rapid deposition of thick metallic films. Such accelerated rates can be obtained with the use of higher carbonyl pressures in combination with gas diluents, or by the use of a shorter wavelength cw laser.

We would like to acknowledge the important technical contributions of D. Sullivan and B. Duquette to this project.

Semiconductor Electrodes

XXXIX. Techniques for Stabilization of n-Silicon Electrodes in Aqueous Solution Photoelectrochemical Cells

Fu-Ren F. Fan,* Bob L. Wheeler,* and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

and Rommel N. Noufi*

Solar Energy Research Institute, Photo Voltaic Division, Golden, Colorado 80401

A number of different approaches have been used in the stabilization of small band gap n-type semiconductors against photocorrosion in photoelectrochemical (PEC) cells. Such stabilization is necessary in the design of practical cells for conversion of solar energy to electricity, and is of critical importance in photoelectrosynthetic systems where the photogenerated holes produce species (e.g. O_2, Cl_2) at quite positive potentials at the semiconductor surface. 1) One approach involves the utilization of thin films of metals (1) or semiconductors (2) to protect the surface. For example, n-GaAs electrodes can be stabilized in a solution of Fe(II) EDTA by a thin (≤ 60 Å) film of gold (3). 2) Use of nonaqueous solvents (4) in PEC cells has been shown to aid in the stabilization of the semiconductor electrode by decreasing the extent of solvation of the oxidation products. A similar approach involves the use of concentrated electrolytes in aqueous solutions. Wrighton and co-workers (5) have recently demonstrated that n-$MoSe_2$ and n-MoS_2 electrodes are stable in concentrated LiCl solutions even in the presence of chlorine evolution. 3) The deposition of polymer layers on the semiconductor surface can also decrease photocorrosion. Noufi and co-workers (6) have described the stabilization of n-GaAs and n-Si by the electrodeposition of polypyrrole films on the surface.

We demonstrate here that by combining these approaches even better stabilization can be accomplished and describe the photo-oxidation of Fe^{2+} at n-Si electrodes covered by thin gold and thicker polypyrrole film and immersed in a concentrated electrolyte aqueous solution.

Electrodes were fabricated from n-Si single crystals (0.4 to 0.6 Ω cm) donated by Texas Instruments. Ohmic contacts were made with In-Ga alloy. They were connected to a copper wire with silver epoxy cement. The crystals were mounted in a glass tube with all sides insulated with 5 min epoxy and covered by silicone rubber sealant leaving an area of 0.2-0.5 cm^2 exposed. The surfaces of some crystals were polished with sand paper (600 grit), followed by etching in conc. HF for 15-20 sec. This pretreatment gave no improvement, compared with these unpolished electrodes, in the adhesion of the polypyrrole films and in the stability of the polypyrrole-covered n-Si electrodes. Immediately prior to electrodeposition of polypyrrole or Au, the electrodes were etched, if not otherwise mentioned, with an etchant containing HNO_3:HF:acetic acid (3:3:1) and bromine (one drop of Br_2 per 100 ml of solution) for 10-15 sec and then with conc. HF for 15-20 sec. This etching procedure produced more efficient etching than that simply with conc. HF. The electrodes were then rinsed thoroughly with water, methanol and acetonitrile.

The electroplating of Au on n-Si was carried out at -1.6 V vs. SCE from a gold plating solution that was prepared by mixing 30 ml of VIGOR fine gold plating solution (Vigor Co. New York, NY) with 20 ml of 2.5 M NaCN solution. The polypyrrole films were synthesized potentiostatically (0.75 V vs. SCE) with the electrode surface simultaneously illuminated with the red light (> 590 nm, 100-150 mW/cm^2) from a 450 W Xe lamp. The solutions used in this electrodeposition, CH_3CN/0.1 M tetra-n-butylammonium BF_4^-, were prepared as reported by Noufi et. al. The thicknesses of the polypyrrole and the Au films were estimated from the charge measured during electrodeposition, as discussed by Noufi et. al. (6).

The PEC behavior of naked or modified n-Si electrodes were compared in three different redox solutions: (A) 0.5 M $FeSO_4$ and 0.15 M $Fe_2(SO_4)_3$ in 0.5 M H_2SO_4; (B) 0.15 M $FeSO_4$ and 0.15 M $Fe_2(SO_4)_3$ in 0.1 M Na_2SO_4 at pH 1; (C) 0.5 M $FeCl_2$, 0.15 M $FeCl_3$ and 1 M HCl in 11 M LiCl.

For comparison, the light source used in all experiments, if not otherwise mentioned, was a sunlamp, which was separated from the PEC cell by a water IR filter of path length ~14 cm. The light intensity impinging on the window of the PEC cell was 41 mW/cm^2. The stability of the photoelectrodes was tested here based on two criteria: (A) constant

*Electrochemical Society Active Member. Key words: photoelectricity, solar energy, polymer.

steady-state photocurrent vs. time of illumination at a load resistance of 10 Ω and (B) constant fill factor (f.f.) and onset photopotential (V_{on}) (or invariant shape of the photovoltammetric curve) with time of illumination.

The photocurrents of naked n-Si photoelectrodes under the illumination with a light intensity of 41 mW/cm^2 decayed to small values (< 20 $\mu A/cm^2$) within three potential scan cycles between -0.2 and 0.7 V vs. SCE at 100 mV/sec in solution (A), (B), or (C). The attachment of polypyrrole film (∿ 3500 Å) on n-Si electrodes did, as reported by Noufi et. al. (6b), decrease the rate of photodegradation of n-Si electrodes in both electrolyte solutions (A) and (B). As shown in Fig. 1(A), the photoelectrodes still showed fairly ideal photovoltammetric curves even after ten potential scan cycles between -0.2 and 0.7 V vs. SCE. However, the V_{on} shifted in a positive direction with scanning. The photocurrent (through a load resistance of 10 Ω) produced by a PEC cell, composed of a polypyrrole coated single crystal n-Si photoelectrode and a Pt counter electrode in solution (A) or (B), decayed continuously with time, indicating the occurrence of slow passivation of the electrode even under these conditions. (See also curve a in Fig. 2.)

By the addition of 11 M LiCl to the redox solution (solution C) the suppression of the anodic photodegradation of the photoelectrodes was further improved. As shown in curve b of Fig. 2, the photocurrent decayed initially and then reached a steady state value (2.1 mA/cm^2) after 2-3 hrs upon continuous illumination with a light intensity of 41 mW/cm^2. Parallel to this behavior, the photovoltammetric curves changed continuously during the first 2-3 hrs of illumination and then reached a steady state. (See Fig. 1(B).) The drawn-out character of the steady state photovoltammetric curves shown in curve d of Fig. 1(B) suggests that an insulating layer was formed on the n-Si surface or that the polypyrrole film was photodegraded during the first 2-3 hrs of illumination. The results shown in the following experiments involving a gold underlayer favor the first possibility.

The third type of photoelectrode was prepared by electroplating 10-20 Å of Au on n-Si and then overlaying ∿ 3300 Å of polypyrrole on the Au photoelectrochemically. This type of electrode has been tested in solution (C). Very stable photocurrent and photovoltammetric curves were obtained with extended time of illumination. As shown in Fig. 1(D), the fill factor and the onset photopotential were only slightly changed after illumination with 41 mW/cm^2, giving a steady state photocurrent density of 3.1 mA/cm^2 at a load resistance of 10 Ω for more than 48 hrs. Only a slight decay of the photocurrent was observed, even in the first 2-3 hrs of illumination (see wave c in Fig. 2), indicating that the 10-20 Å of Au underlayer together with the polypyrrole coating suppresses the photodegradation of the n-Si electrodes quite effectively. However, the 10-20 Å of Au layer alone could not stabilize the n-Si electrode even in solution (C).

Under a light intensity of 41 mW/cm^2, a PEC cell composed of one of the third type of photoelectrodes and one Pt counter electrode in solution (C) gave a short-circuit photocurrent density of 3.5 mA/cm^2, a fill factor of 0.65 and an open-circuit photovoltage of 0.40 V, corresponding to a power conversion efficiency of 2.3%. Under illumination with a stronger light intensity (150 mW/cm^2 from a tungsten-halogen lamp), the photocurrent at a load resistance of 10 Ω decayed very slowly with time (∿ 10% decrease of the initial photocurrent, 12 mA/cm^2, after the first 8-hr illumination and 5% more decrease after the second 8-hr illumination). The decay rate of the photocurrent increased with an increasing temperature of the PEC cell.

In conclusion, polypyrrole films on a metal underlayer on n-Si photoelectrodes substantially improves their stability against photodegradation in an aqueous electrolyte containing Fe^{2+}/Fe^{3+} couple. The addition of 11 M LiCl to the solution further improves the suppression of the anodic photodegradation. The increased stability can be attributed to the following: 1) The highly concentrated LiCl solution substantially decreases the activity of H_2O thus decreasing its reactivity with the electrode surface (5). 2) Li^+ and/or Cl^- may also diffuse into the interstitial regions of the polypyrrole film and decrease penetration of water. 3) Both the gold and polypyrrole serve to remove photogenerated holes rapidly from the silicon surface before degradation occurs. In this way, they are analogous to stabilizing solution redox species (e.g. Se^{2-}) which are rapidly oxidized preferentially. 4) The gold layer improves the adhesion of the polypyrrole to the Si surface and blocks pinholes in the film.

Since the polypyrrole film is highly colored, it blocks some of the light impinging on the electrode surface and thus decreases the efficiency. Improvements should be possible by optimizing the metal and polymer layer thicknesses and by investigating electrolytes other than the Fe^{3+}/Fe^{2+} - LiCl systems to improve both the solar energy conversion efficiency and the stability.

Electrocatalytic Properties of Photodeposited Platinum on TiO_2

S. K. Vidyarthi* and N. R. Bharucha*

Noranda Research Centre, Pointe Claire, Québec H9R 1G5, Canada

INTRODUCTION

Recent demonstrations of metallic deposition on TiO_2 powders has created a new variety of catalysts which may find wide applications (1). Many such applications have been studied but await much further development prior to commercial application (2-5). We have found a new application of photodeposited platinum on TiO_2 which may be useful in existing commercial electrolysers.

Conventional electrolysis appears to be gaining popularity in the production of commercial hydrogen. The energy efficiency of such a process is low primarily as a result of high hydrogen overvoltage on cathodes. The overvoltage can be decreased by additives to the electrolyte, notably platinum in a suitable form. Chloroplatinic acid was used in the past to decrease the operating cell voltage (6) but the electrolytic effect had a short life due to sintering and poisoning of the very active platinum particles deposited on the cathode. We have shown that dispersion of platinum by photodeposition on TiO_2 powder creates a more stable electrocatalyst for the hydrogen producing electrolysis cell.

EXPERIMENTAL

The photodeposition of metallic platinum on TiO_2 powder (MCB, anatase, 99.99% pure and $<1\mu$ particle size) was performed by photolysing the suspension of a known amount of the powder in a 10-25% deaerated aqueous solution of H_2PtCl_6 with a reductant such as acetic acid or dimethyl formamide. The platinized TiO_2 solid was filtered and dried in an oven at 100°C. The detailed procedure has been described by other workers (1). Weighed amount of the final grey powder was added to hydrogen producing electrolysis cells and the performance was compared with chloroplatinic acid. All cells contained 300 ml of 28% KOH electrolyte, nickel-plated steel anodes and mild steel cathodes in a single compartment. Active cathode surface area was 25 cm^2. The operating cell voltage ranged from 1.90 to 2.30V at a current density of 51 mA/cm^2. The cells were operated at room temperature and the electrolyte was continuously stirred with a magnetic bar.

RESULTS AND DISCUSSION

The electrocatalytic activity of the photoplatinized TiO_2 was studied by following its effect upon the operating cell voltage with time. The results are shown in Figure 1. After 170 hours of operation without any additives, 100 mg of TiO_2 with 4% photodeposited Pt equivalent to a concentration of 14 mgpl of the electrolyte, was added to Cell A causing a 230 mV decrease in the cell voltage. The total platinum concentration can be expressed as 0.16 mg cm^{-2} of the cathode surface. To compare this performance with that of platinum in another form, a molar equivalent amount of chloroplatinic acid was added to Cell B at 190 hrs. It is evident that the photodeposition of platinum on TiO_2 increases the duration of the electrocatalytic effect from approximately 10 hours for platinic acid to over 250 hours for the Pt/TiO_2 powder. Furthermore, direct addition of chloroplatinic acid causes an anomalous increase in the cell voltage following the treatment compared to the behaviour of the control Cell C (note the increase in Cell B voltage after 220 hours). This was further substantiated by chloroplatinic acid treatment on the control Cell C yielding the similar short-lived electrocatalytic effect followed by a slow rise parallel to that of Cell B. This effect is not usually observed in commercial electrolysis when treated with H_2PtCl_6 (7). A highly resistive film may have formed on the cathode under the conditions of the electrolytic cell.

Key words: hydrogen evolution, platinum electrocatalyst

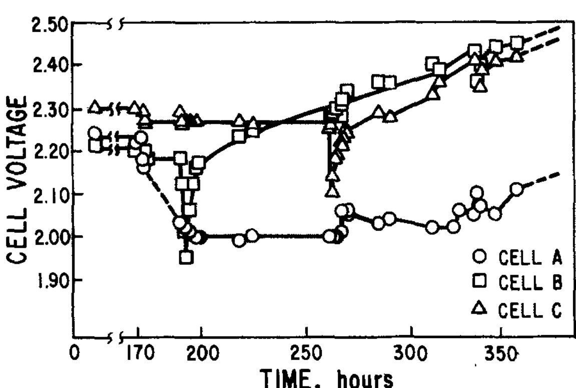

Fig. 1. The electrocatalytic effect of 0.16 mg/cm^2 of platinum as 4% Pt/TiO_2 (added at 170 hours) on the operating cell voltage of a hydrogen producing electrolysis cell 'A' compared with similar cell 'B' treated with molar equivalent amount of H_2PtCl_6 and a control cell 'C' without any additive. At 260 hours, the control cell 'C' was also treated with H_2PtCl_6 to confirm its short electrocatalytic life as compared to that of photodeposited Pt/TiO_2.

The mechanism of the electrocatalytic effect observed here may be the migration of charged Pt/TiO_2 particles towards the cathode followed by deposition. This creates a large number of sites for the electrolytic process. The electrostatic nature of the bond between the cathode and the catalyst particles was indicated by a noticeable increase in the cell voltage when the current was interrupted and the electrodes were physically disturbed (at 266 hours, Fig. 1, Cell A). The catalytic activity was recovered in 10 to 15 hours.

Dunn et al. (8) in a recent publication discuss the apparent negatively charged TiO_2 particles produced during the photolysis of a slurry. Interruption of the light source drastically reduces the cathodic current. We believe that this mechanism is not operative in our system. Fully platinised TiO_2 presumably acts as positively charged platinum particles. When partially platinised TiO_2 powder was used, the observed drop in cell voltage was minimal. We believe that TiO_2 acts as an efficient carrier for active platinum and that the potential differences caused by the semiconducting nature of TiO_2 is likely to be minimal in this highly ionic media.

Manuscript submitted Feb. 9, 1981; revised manuscript received ca. May 4, 1981.
Publication costs of this article were assisted by the Noranda Research Centre.

The electrocatalytic effect was enhanced by successive addition of Pt/TiO_2 to the cell as shown in Fig. 2. The decrease in cell voltage reached a plateau after approximately 220 mg of Pt/TiO_2 (4.5% Pt by weight) had been added to the 300 ml electrolyte; further addition of the catalyst had no effect. This indicates a saturation effect caused by a complete coating of the active electrode surface at an approximate platinum coverage of 0.40 mg/cm^2 of the cathode area.

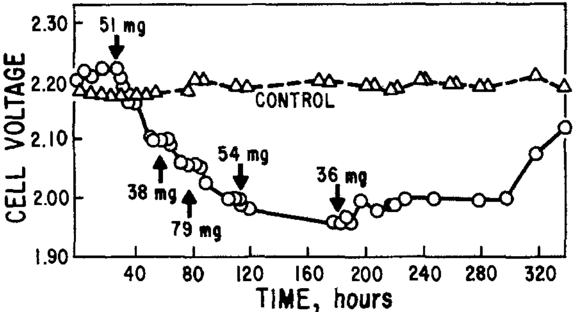

Fig. 2. Dependence of the electrocatalytic activity upon the amount of Pt/TiO_2 added to the cell. Time and amount of catalyst added are indicated by arrows and indicate a saturation of the effect when approximately 220 mg of the catalyst has been added to 300 ml of electrolyte. The active surface area of the cathode was 25 cm^2.

SUMMARY

In conclusion, the electrocatalytic effect of photodeposited platinum on TiO_2 was demonstrated. The Pt/TiO_2 species appears to be the more suitable form of platinum for the exploitation of its hydrogen overvoltage reduction property. Further optimisation of both the catalyst preparation and electrolysis conditions is required prior to a commercial application of this catalyst.

SEPTEMBER 1981

Reports on Electrochemical Society Summer Fellowship Awards

During the summer of 1980 the following graduate students received $1,350, $1,350, and $1,800, respectively, representing the three Summer Fellowship Awards of The Electrochemical Society.

Mr. Gregory L. McIntire, The University of Delaware, Newark, Delaware, was awarded the Edward Weston Fellowship.

Mr. Robert S. Glass, University of Illinois, Urbana, Illinois, was designated as the recipient of the Colin Garfield Fink Fellowship.

Mr. Richard M. Cohen, The University of Utah, Salt Lake City, Utah, received the Joseph W. Richards Fellowship.

The Summer Fellowship Awards are made "without regard to sex, citizenship, race or financial need, to a fellow or teaching assistant pursuing work between the degrees of B.S. and Ph.D. on a subject in a field of interest to The Electrochemical Society." They are intended to cover a period during which the recipient has no financial support for the continuance of his or her work.

The Edward Weston Summer Fellowship Report

Mr. McIntire's report is given below.

The Effects of Altered Counterions and Counterion Concentrations on the Reductive Electrochemistry of Nitrobenzene in Dodecylsulfate Micelles

Micelles impart a measure of order to systems such that normally insoluble molecules can be solubilized within the micellar aggregate (1). The ability of micelles to solubilize these normally water insoluble species in an essentially aqueous medium as well as the short-range order afforded to the reaction environment by micelles has given rise to the increasing use of these microstructures in a variety of studies including biological (2), synthetic (3), and energy transfer applications (4). Studies in these laboratories have addressed the effects of micelle solubilization on the redox properties (formal potentials) of solubilized substrates (5, 6). In addition, the effects of the micelle solution on the kinetic demeanor of the monoelectronic oxidation and reduction products (radical ions) arising from solubilized substrates have been examined in these systems (5, 6). An earlier report concerned the oxidation of sodium dodecylsulfate (SDS) solubilized 10-methylphenothiazine (MPTH) (5). Voltammetric examination of the oxidation of MPTH in SDS micelles showed that the product of the monoelectronic oxidation, the cation radical, associates with the anionic surfactant (5, 6). The interaction between the cation radical and the anionic dodecylsulfate suggested that negatively charged species arising from the reduction of solubilized neutral substrates might preferentially interact with cationic micelles (7). In contrast to predicted results, reduction of nitrobenzene (NB) to the corresponding anion radical ($NB^{\cdot-}$) in cationic, nonionic, and anionic micelle solutions indicates that the anion radical is more persistent in the anionic micelle system than in either isotropic aqueous solution or cationic micelles (6, 8). Electron spin resonance (ESR) spectroscopy has confirmed the formation of $NB^{\cdot-}$ in both anionic SDS and nonionic Brij-35 micelles while the existence of $NB^{\cdot-}$ in cationic micelles during the reduction of NB could not be demonstrated by this sensitive technique. In addition, ESR results suggest that $NB^{\cdot-}$ is resident within the Stern layer of SDS micelles (6, 8). In order to probe the effect of altered Stern layer character on the stability of $NB^{\cdot-}$, the reduction of NB has been examined in the presence of various counterions as well as varying counterion concentrations in dodecylsulfate micelles. The results are explained in terms of the kinetic demeanor of $NB^{\cdot-}$.

Experimental Section

Materials.—Sodium dodecylsulfate (SDS, Aldrich) was washed repeatedly with ether, then thrice recrystallized from 95% ethanol. Nitrobenzene (Baker) was passed through a column of activated alumina (400°C, 48 hr) before use. All other reagents were reagent grade or equivalent. All solutions were prepared with deionized distilled water.

Dodecylsulfate surfactants containing various counterions were synthesized as follows. To a stirred solution of 100 ml of ether at 5°C was added 10 ml (0.15 mol) of chlorosulfonic acid (Aldrich) and 28.0g (0.15 mol) of 1-dodecanol (Aldrich). The solution volume was then doubled with ethanol and a sufficient amount of the requisite hydroxide (*e.g.*, LiOH to yield lithium dodecylsulfate) added to ensure complete neutralization. The white, heterogeneous mixture was stirred at room temperature for 1 hr, then filtered and washed repeatedly with ether. Lithium dodecylsulfate (LDS), potassium dodecylsulfate (KDS), tetramethylammonium dodecylsulfate (TMADS), and ammonium dodecylsulfate (ADS) were all synthesized by the above procedure (9). LDS, KDS, TMADS, and ADS were further purified by recrystallization from isopropanol and dried *in vacuo* overnight at room temperature.

Apparatus and technique.—Cyclic voltammetry was performed with a three-electrode potentiostat equipped with circuitry for the compensation of solution resistance (10). Hanging mercury drop electrodes (HMDE's) were produced with a Metrohm E410 drop extruder using triply distilled mercury. Measurements of solution *p*H were made using a glass electrode, a saturated calomel reference electrode, and a Perkin-Elmer Metrion IV *p*H meter. All solutions for reductive electrochemistry were oxygen purged prior to use. All electrode potentials are reported relative to the aqueous saturated calomel electrode (SCE).

Results and Discussion

The reduction of NB in anionic SDS micelles at an HMDE is shown in Fig. 1. The two well-resolved processes have been shown to correspond to formation of the anion radical ($NB^{\bar{\cdot}}$) followed by reduction of $NB^{\bar{\cdot}}$ to the dianion which then undergoes protonation and further reduction to phenylhydroxylamine (6, 8). When the potential scan is reversed after only the first wave, that process is seen to be chemically reversible on the 5 sec time scale of the experiment (Fig. 1B). Alteration of the nature of the counterion did not produce a significant effect on the observed peak potential for the formation of $NB^{\bar{\cdot}}$ (Table I). The overall voltammetry of NB in KDS, LDS, and TMADS micelles consists of two well-resolved processes as was observed in SDS micelles (6, 8). KDS micelles cause the second reductive process to occur at more negative potentials than observed in SDS micelles. In ADS micelles, the reduction of NB proceeds as a single chemically irreversible process at potentials anodic of those observed in either isotropic aqueous solution or cationic micelles (6, 8). In the presence of increased counterion concentrations, the peak potential corresponding to formation of $NB^{\bar{\cdot}}$ is shifted to slightly more positive potentials. Addition of 0.7M NaCl to an SDS micellar solution of NB causes the first wave to shift 8 mV (Table II) while the second wave is shifted more than 100 mV in the positive direction (Table II).

Investigations of the effects of micelles on the redox properties of solubilized substrates must consider the thermodynamic and kinetic effects of these media on both substrates and the products of the electron transfer processes. In particular, the kinetic demeanor of the products of the electron transfer processes can affect the observed redox properties of the original substrates (11). Both the anion radical and dianion (second wave) of NB are susceptible to kinetic processes.

Table I. Effect of altered counterion on voltammetric peak potentials for the reduction of nitrobenzene in the presence of dodecylsulfate micelles[a]

Counterion[b]	$E_{p_{c_1}}$	$E_{p_{c_2}}$
Li^+	−779 (±3)	−1155 (±3)
Na^+	−766 (±2)	−1157 (±5)
K^+[c]	−755 (±6)	−1304 (±6)
TMA^+	−774 (±2)	−1136 (±2)
NH_4^+	−490 (±10)	d
NH_4^+	−325 (±5)[e]	d

[a] pH of bulk solution adjusted to 7.0 (±0.1) with corresponding hydroxides, peak potentials mV *vs.* SCE.
[b] All solutions 60 mM in respective surfactant, 0.5 mM NB.
[c] Cyclic voltammetry acquired at 40°C. All others at 25°C.
[d] No second wave evident.
[e] pH = 5.10.

Table II. Linear sweep voltammetric peak potentials for the reduction of nitrobenzene in 60 mM SDS with added NaCl[a,b]

[NaCl] M	$E_{p_{c_1}}$	$E_{p_{c_2}}$
0[c]	−772 (±1)	−1188 (±4)
0.047	−769 (±2)	−1137 (±4)
0.107	−766 (±4)	−1118 (±3)
0.314	−764 (±3)	−1088 (±3)
0.700	−764 (±3)	−1065 (±3)

[a] All at 50 mV/sec, HMDE radius = 4.6 × 10^{-2} cm, peak potentials mV *vs.* SCE.
[b] [NB] = 0.001M.
[c] No NaCl added, 60 mM SDS.

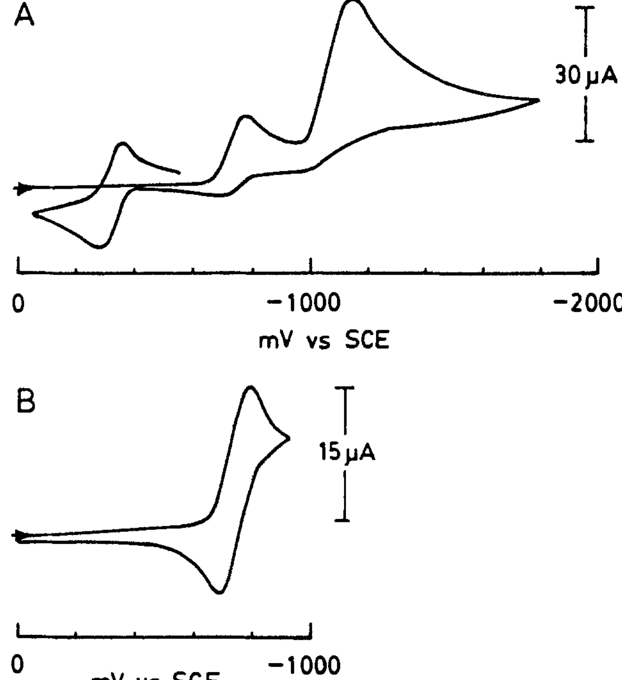

Fig. 1. Cyclic voltammetry of 0.5 mM NB in 50 mM LiCl/50 mM SDS. HMDE radius = 4.6 × 10^{-2} cm, sweep rate = 50 mV/sec. Arrow indicates initial potential and direction of sweep.

The second voltammetric process (dianion) is composed of a number of electron transfer and chemical reaction steps as shown below (12)

$NB + e^- \rightleftharpoons NB^{\bar{\cdot}}$ (1) first wave

$NB^{\bar{\cdot}} + e^- \rightleftharpoons NB^{=}$ (2)

$NB^{=} + H^+ \longrightarrow$ $C_6H_5N(O^-)(OH)$ (3)

$C_6H_5N(O^-)(OH) \xrightarrow{-(OH)^-} C_6H_5N{=}O$ (4)

$C_6H_5N{=}O \underset{2H^+}{\overset{2e^-}{\rightleftharpoons}} C_6H_5N(H)(OH)$ (5)

second wave

An increase in the rate of the reaction consuming the product of the electron transfer (the dianion) will cause the observed peak potential to shift to more positive potentials (11). In the above reaction sequence, reaction [3] has been reported to be the rate-determining step (12). Alterations of the hydrogen ion concentration will affect the rate of that process and therefore the observed peak potential for reduction of $NB^{\bar{\cdot}}$ to the dianion and ultimately phenylhydroxylamine. In addition, the anion radical of NB is rapidly protonated in aqueous media. The protonated form undergoes disproportionation followed by dehydration to nitrosobenzene which is readily reduced at less negative potentials to phenylhydroxylamine (13) as shown below

$$NB + e^- \rightleftharpoons NB^{\cdot-} \quad (1)$$

$$NB^{\cdot-} + H^+ \rightleftharpoons NBH\cdot \quad (6)$$

$$2NBH\cdot \rightleftharpoons NB + C_6H_5N(OH)_2 \text{ (I)} \quad (7)$$

$$\text{I} \rightarrow C_6H_5NO + H_2O \quad (8)$$

$$C_6H_5NO \underset{2H^+}{\overset{2e^-}{\rightleftharpoons}} C_6H_5NHOH \quad (5)$$

It is clear that the products of the reduction of NB are susceptible to kinetic processes that may be responsible for the observed voltammetry of NB in these systems.

Additionally, both $NB^{\cdot-}$ and the dianion of NB have been reported to undergo ion pairing with alkali metal cations (14, 15). The observed electrochemistry of NB in these media may reflect these stabilizing interactions and/or the kinetic processes discussed above. Specifically, if ion pairing of $NB^{\cdot-}$ with micelle counterions is favored over that between the dianion and the micelle counterions, then the formation of $NB^{\cdot-}$ should become more facile (positive shift of observed voltammetric peak potential) while reduction of NB (to the dianion) would become more difficult (negative shift in observed voltammetric peak potential). Conversely, if ion pairing of the dianion of NB is favored over that of $NB^{\cdot-}$, then the observed voltammetric peak potential for the reduction of $NB^{\cdot-}$ to the dianion would shift in a positive direction (16). The small shift in voltammetric peak potential observed for the $NB/NB^{\cdot-}$ redox couple together with the relatively large changes observed for the anion radical/dianion redox couple in the presence of weakly pairing cations (K^+, TMA^+) (13, 14) indicates that ion pairing is not a major factor in these systems.

The reduction of NB in LDS, SDS, KDS, TMADS, and ADS micelles gives rise to phenylhydroxylamine in all cases indicating that protonation of the dianion occurs rapidly in dodecylsulfate micelles (12). The small changes in the observed peak potential for the reduction of NB to $NB^{\cdot-}$ with altered counterion indicate that ion pairing is not the primary stabilizing interaction in these systems. Rather, the observed voltammetry of NB in these systems is dependent on the kinetic properties of $NB^{\cdot-}$ and the dianion in these media. Interaction of $NB^{\cdot-}$ and the dianion with the dodecylsulfate micelles results in retardation of the rate of protonation of these species (12, 13). In the case of $NB^{\cdot-}$, the stability provided by the micelle renders the observed reduction of NB to $NB^{\cdot-}$ chemically reversible on the cyclic voltammetric time scale. Kinetic stabilization is consistent with observation of $NB^{\cdot-}$ in nonionic micelles where counterion pairing with $NB^{\cdot-}$ is impossible (6). The dianion is sufficiently reactive that reduction of $NB^{\cdot-}$ to the dianion is chemically irreversible in all dodecylsulfate micelles examined. The nature of the interactions of NB and $NB^{\cdot-}$ with dodecylsulfate micelles is the subject of further study in these laboratories (8).

Acknowledgments

The support of The Electrochemical Society through the Edward Weston Fellowship is gratefully acknowledged. In addition, the assistance of D. M. Chiappardi and the continued support and encouragement of Dr. H. N. Blount were essential to this work.

The Colin Garfield Fink Summer Fellowship Report

Mr. Glass's report is given below.

Evidence for S-Route Behavior in Electrogenerated Chemiluminescence from the Tris(2,2'-bipyridine)ruthenium(II) System

For several years, workers in the area of electrogenerated chemiluminescence (ECL) have labored to explain the mechanisms of light production in high-energy electron-transfer reactions. It has, in particular, been difficult to find systems which adhere to expectations based upon light production via the "S-route." In these systems, the electron-transfer reaction is energetically sufficient to leave a product in the observed emitting state, and does so directly in the redox event. In systems where the electron-transfer reaction is insufficiently energetic to directly yield an emitting product, the mechanism of light production is assumed to proceed via the T-route. Here triplet intermediates are produced in the electron-transfer event, and triplet-triplet annihilation is invoked to account for production of emitting states. These schemes have been extensively reviewed (1-7).

In mechanistic investigations, the sequential step technique for producing light transients has been widely used (3, 5, 6, 8-11). Results of studies using this technique have, however, not generally been consistent with the above scenarios (6, 12-17).

In the sequential step experimental method, one generates the oxidant and reductant from precursors at a small planar electrode in quiescent solution. In the first step (of duration t_f), the first reagent is produced and diffuses into the solution. At $t = t_f$, the potential of the electrode is switched to a value where the second reagent is produced. It then diffuses into the solution, where it reacts with the first reagent at a total rate (N, moles/sec) that declines with time as the first species is consumed. The reaction rate can be predicted from the laws of diffusion (8, 11). A light transient results from the time dependence of the redox reaction rate N and the kinetics of light-producing processes.

The short-time region of the light transient has been stressed for kinetic evaluation (4, 6, 10, 11, 16), and it has been shown that in this region the light intensity should be linear with $(t_r/t_f)^{-1/2}$, where t_r is time measured into the second step from its start (11). Recently, Kawai *et al.* (18) have reported single transients adhering to this prediction in the anthrylamine charge-transfer systems, but they did not attempt to verify the predicted variations in the slopes and intercepts of the linear plots with step time, nor did they test for the expected invariance in behavior with the sequence of reactant generation.

In the absence of a paradigm showing predictable behavior with respect to all experimental variables, one cannot be sure whether the deviations from nonideality manifest defects in the experimental approach, significant misconceptions about the fundamental chemistry, or both. Our goal in this work and in a companion study done by Luttmer and Bard (19) is to establish the reaction between $Ru(bpy)_3^{+1}$ and $Ru(bpy)_3^{+3}$ (where bpy is 2,2'-bipyridine) as a reasonably well-behaved S-route case under certain conditions. This reaction is simple in comparison to energy-sufficient ion annihilations of aromatics, which can have parallel S and T pathways to emission. Emission arises by phosphorescence from a d-π^* metal-ligand charge-transfer triplet of $Ru(bpy)_3^{+2}$, which is the only excited state with an appreciable lifetime (20, 21). Early studies by Bard and co-workers (22, 23) postulated the direct production of the emitting state of this system in the electron-transfer event. Later work (24, 25) showed that at temperatures below $-30°C$, the ECL emission yield (photons emitted per redox event) approached the photoluminescence quantum efficiency, which implies 100% efficiency for production of the d-π^* triplet in electron transfer.

Even though the key state in this system is a triplet, the description of the kinetics as "S-route" is accurate as this is the emitting state and will be shown to be directly produced in the electron-transfer event. The results from this study are briefly summarized below. More complete details can be found elsewhere (26).

Experimental

Chemicals.—$Ru(bpy)_3Cl_2 \cdot 6H_2O$ was supplied by G. F. Smith Chemical Company. $Ru(bpy)_3(ClO_4)_2$ was prepared from it by metathesis with excess $NaClO_4$ in H_2O. It was then recrystallized three times from an H_2O-EtOH mixture (4:1), and then dried for 48 hr at 60°C under vacuum.

Tetra-n-butylammonium fluoborate ($TBABF_4$) was used as the supporting electrolyte. It was obtained from Southwestern Analytical Chemicals (Electrometric grade), recrystallized three times from a mixture of ethyl acetate-pentane (5:1), then dried at 95° under vacuum for 48 hr. The electrolyte was stored in a desiccator over $CaSO_4$.

N,N-dimethylformamide (DMF), 99% was obtained from Aldrich. The procedure for removal of amine decomposition products and H_2O has been described in detail (14).

Electrochemical cell and sample preparation.—The cell consists of a platinum disk working electrode (3.09 mm²) and a platinum wire quasi-reference electrode (QRE). The tip of the QRE is placed close (2-3 mm) to the working electrode to minimize uncompensated resistance. A platinum wire was also used as the counterelectrode. All other details of the cell and sample preparation are similar to those described previously (26).

Instrumentation.—Details of the computer interface and instrumentation have been reported elsewhere (26).

The triple-step mode of reactant generation was utilized in this study. The initial potential was always 0V *vs.* QRE, where $Ru(bpy)_3^{2+}$ was not electroactive. Two sequential steps of equal duration, t_f, were then used to generate the reacting species. At the end of the second step, the potential of the working electrode was returned to 0V *vs.* QRE. Uncompensated resistance was compensated for by positive feedback at the 80% level.

Results and Discussion

Electrochemistry and experimental design.—Initial work was performed in acetonitrile. However, both cyclic voltammetry and chronocoulometry revealed severe problems with filming of the electrode. We therefore changed to DMF in hopes of alleviating this obvious solubility problem. Also, in order to suppress the large anodic background seen in DMF at room temperature, the experimental work was performed near $-25°C$, where the anodic region is fairly clean.

Figure 1 is a cyclic voltammogram of $Ru(bpy)_3^{2+}$ in DMF at $-25°$. There are three reduction peaks situated at -1.33, -1.49, and $-1.74V$ *vs.* QRE, which are associated with the production of $Ru(bpy)_3^{+1}$, $Ru(bpy)_3^0$, and $Ru(bpy)_3^{-1}$, respectively. A fourth reduction peak, associated with irreversible ligand loss, is at $-2.5V$. Good reversible behavior is observed for the first three reductions, the splitting between the anodic and cathodic peaks in each case being 60-70 mV. One oxidation peak appears at 1.31V *vs.* QRE. It shows quasi-reversible behavior, with a peak separation of ~150 mV. At room temperature this oxidation exhibits more reversible character. No problems with deposition onto the electrode surface were noticeable in DMF, and the solubility of the chelate species generally appeared to be much greater in DMF than in acetonitrile.

In the quantitative model developed (11) for analysis of the early portions of ECL light transients, it was

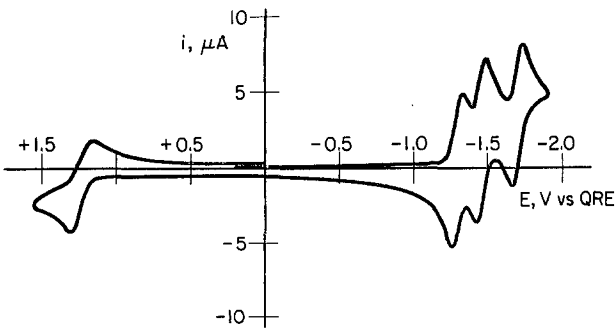

Fig. 1. Cyclic voltammogram of 1 mM $Ru(bpy)_3^{2+}$ in DMF at $-25°$. The supporting electrolyte was 0.1M $TBABF_4$. Scan begins at 0.0V and first moves negatively.

assumed that diffusion-controlled conditions for generation of the reactants was enforced. However, as seen in Fig. 1, the first and second reduction peaks are closely spaced, and potential oversteps of 200-250 mV past E_p for production of $Ru(bpy)_3^{+1}$, which are normally used to establish diffusion-controlled conditions for electroreduction, cannot be employed without simultaneous generation of $Ru(bpy)_3^0$. In such a case, the model relating the light intensity to the redox reaction rate, N, as discussed in the next section will be uninterpretable.

In a different approach to the problem, we employed a triple step program featuring the production of the $Ru(bpy)_3^{-1}$ species at the electrode in the forward step, and $Ru(bpy)_3^{+3}$ in the reverse step (27). No control problems were expected in this case because the fourth reduction is so widely separated from the third. During the forward step, $Ru(bpy)_3^{-1}$ diffuses outward from the electrode and encounters a flux of +2 species, hence the following reactions occur

$$R(-1) + R(+2) \rightarrow R(0) + R(+1) \quad [1]$$

$$R(-1) + R(+1) \rightarrow R(0) + R(0) \quad [2]$$

$$R(0) + R(+2) \rightarrow R(+1) + R(+1) \quad [3]$$

where the species are designated by the charges on the complexes. The net result is that virtually all of the electrons injected by reduction go to produce $R(+1)$ in the diffusion layer (except very near the electrode surface). When the second step begins, and $R(+3)$ is electrogenerated, the ECL reaction is then the usual one

$$R(+3) + R(+1) \xrightarrow{\phi_s} R(+2)^* + R(+2)$$
$$\hookrightarrow R(+2) + R(+2) \quad [4]$$

where ϕ_s is the branching ratio for producing the $d - \pi^*$ triplet $R(+2)^*$. Only in the earliest moments of the second step, when the homogeneous reaction takes place near the electrode, would $R(+3)$ be able to react with $R(-1)$ or $R(0)$.

Theoretical considerations.—For an S-route system, the total light intensity (I, einsteins/sec) is very simply related to N as

$$I = \phi_{ECL} N \quad [5]$$

where ϕ_{ECL} is the ECL efficiency (photons emitted per redox ion annihilation) and should be independent of time (16). The intensity should therefore be proportional to N.

For the case at hand, an analytical expression has been developed (26) which yields the redox reaction rate in a linearized form. In dimensionless terms, it is given as

$$\omega_n = a(t_r/t_f)^{-1/2} + b \quad [6]$$

where $\omega_n = N t_f^{1/2}/AD^{1/2}C_p^*$, $a = 2.15$, and $b = -1.96$.

This result applies only to the early part of the light decay ($t_r/t_f \leq 0.2$).

Assumptions which are made in deriving the above results are detailed elsewhere (26). In this reference, data are also presented which verify that our basic model of diffusional processes is correct. This verification consists of an examination of faradaic current flow during the second step (11, 16).

The problem was also treated by digital simulation (26). The results for ω_n agreed rather well with the theoretical expression over the time domain of interest ($t_r/t_f \leq 0.2$).

S-route behavior in these experiments would therefore require light transients that show linear plots of intensity *vs.* $(t_r/t_f)^{-1/2}$ with intercept-to-slope ratios $b/a = -0.91$, regardless of t_f.

Decay curves.—Shown in Fig. 2 are plots of I *vs.* $(t_r/t_f)^{-1/2}$ for experiments in DMF at −25° with t_f = 0.1-10 sec. It is seen that the plots show good linearity in all cases. The least-squares intercept-to-slope ratios are −1.18, −1.37, −1.36, and −1.62 for t_f = 0.1, 1, 5, and 10 sec, respectively. These values are significantly higher in magnitude than the theoretical value of $b/a = -0.91$.

By rearrangement of Eq. [5] and [6], one finds that both the slopes and intercepts of the lines in Fig. 2 should display direct proportionality with $t_f^{-1/2}$, and the plots in Fig. 3 show that the prediction is borne out. The ratio of the slope of line 1 in Fig. 3 to that of line 2 should be $-b/a = 0.91$. In reality, the ratio is 1.15.

The good linearities shown in Fig. 2 and 3 for single transients and among families of transients is concordant with an S-route mechanism of light production. The only remaining discrepancy from the behavior predicted by theory is the consistent tendency of the observed intercept-to-slope ratio $(-b/a)_{obs}$ to be high. This effect has also been seen by Kawai *et al.* (18) in the ECL of anthrylamine systems, and by Luttmer and Bard (19) in the system of interest here despite a totally different experimental attack.

More ideal values of the intercept-to-slope ratios were observed with shorter t_f and with lower temperatures. For example, from ratios of slopes of plots

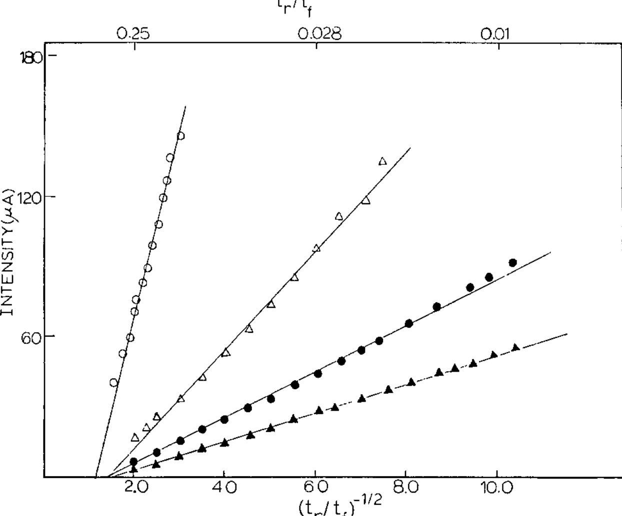

Fig. 2. Plots of I vs. $(t_r/t_f)^{-1/2}$ for experiments with 1 mM $R(+2)$ in DMF with 0.1M $TBABF_4$ at −27°. Values of t_f are: Open circles are 0.1 sec; open triangles are 1.0 sec; filled circles are 5.0 sec; filled triangles are 10 sec.

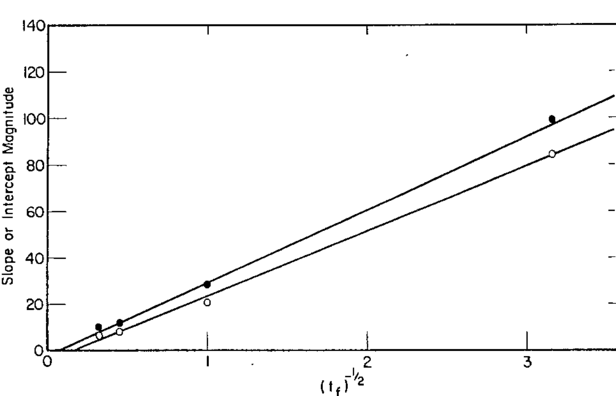

Fig. 3. Slopes (open circles) and intercepts (filled circles) of plots in Fig. 2 vs. $t_f^{-1/2}$.

equivalent to those of Fig. 3, the following trend was observed

T, °C	$(-b/a)_{obs}$
Ambient	1.58
−25	1.09
−35	0.96

These data were obtained with 0.2M $TBABF_4$, which was twice the value used in experiments described by Fig. 2 and 3. No effect of electrolyte concentration was discerned.

The high values of $(-b/a)_{obs}$ may be due to side reactions, perhaps with the electrolytic products of the faradaic process occurring in parallel with the oxidation of $R(+2)$. However, the generality of the behavior suggests that there may be a fundamental defect in experimental conformity to the theoretical model. One possibility is the existence of edge diffusion or convective lateral dispersion of the diffusion layer, resulting in losses of the first reactant which would tend to depress the intercepts further and raise $-b/a$ (26).

Conclusions

The following criteria are proposed for S-route behavior.

1. Linearity of plots of I vs. $(t_r/t_f)^{-1/2}$ for $t_r/t_f \leq 0.2$.
2. Plots of the intercepts and slopes of the individual linearized transients that are linear with $t_f^{-1/2}$ and pass through the origin.
3. A ratio of the slopes of the plots in 2 giving $(-b/a)_{obs}$ near the theoretical value.
4. Quantitatively equivalent behavior upon reversal of the order of reactant generation.

With these criteria the essentials of S-route behavior are captured in experimentally realistic terms. It is not felt that strict quantitative observation of the theoretical $(-b/a)$ value should be overstressed, as the observed value may be perturbed by a number of fairly minor experimental defects. It is highly unlikely that a system with a large T-route component would be able to fulfill these criteria (26).

From the data presented here, and in the companion work by Luttmer and Bard (19), the system at hand has fulfilled all of the above criteria and seems reliable as an S-route model.

Acknowledgments

The support of The Electrochemical Society through the receipt of the Colin Garfield Fink Summer Fellowship is gratefully acknowledged. I would also like to thank Professor Larry R. Faulkner for continued support and guidance. Also, I would like to express my appreciation to Drs. A. J. Bard, K. Itaya, and J. D. Luttmer for reports on their data in preliminary form.

27. Our experimental attack did not permit a reversal in the order of reactant generation. Producing $R(-1)$ second leads to extremely short-lived transients because the charge-consuming capacity of that species is so great.

The Joseph W. Richards Summer Fellowship Report

Mr. Cohen's report is given below.

Direct Measure of the Esin-Markov Coefficient in Mixed Solutions

The objective of this summer research was to demonstrate the feasibility of using an ion-sensitive field effect transistor (ISFET) to directly measure the Esin-Markov coefficient of ions which specifically adsorb to a polarized gate metal. Gold was chosen as the gate material since it has been studied as a polarized electrode (1-5). For solid materials, the standard technique for finding the Esin-Markov coefficient

$$\left(\frac{\partial E}{\partial \ln a}\right)_{q^m} = -RT\left(\frac{\partial \Gamma}{\partial q^m}\right)_a \quad [1]$$

requires measurement of a capacitance-voltage curve in an appropriate base solution to find the potential at the point of zero charge (pzc). One may then integrate the area under the curve to find the charge on the electrode at other potentials. Upon addition of a specifically adsorbing ionic species to the solution, the C-V curve will change; recalculating the potential of the pzc (or any other charge condition on the electrode) allows one to measure the shift in electrode potential as a function of ion activity in solution for a constant charge condition on the metal electrode, yielding the Esin-Markov coefficient.

Experimental

The theory, operation, and construction of ISFET's have been reviewed in detail elsewhere (6). As shown in Fig. 1, a gold gate ISFET is immersed into solution. An external circuit senses the drain current, compares it to a preset value, and adjusts the reference electrode potential to keep the drain current at the preset

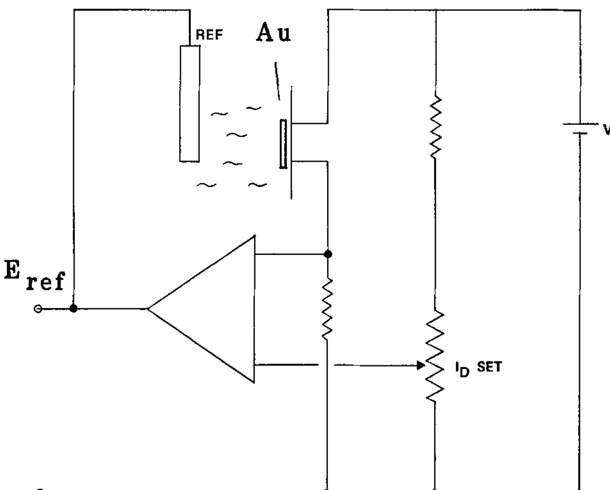

Fig. 1. Circuit for operation of ISFET with constant charge on gold gate.

value. The gold gate is electrically floating so that it makes electrical contact only with the solution.

As long as there are no charge leakage paths to the gold gate, the constant charge condition for measuring the Esin-Markov coefficient is satisfied. If an adsorbing anion is added to solution, positive countercharge must appear at the surface of the gold facing solution. Since this requires a change in charge density on the side of the gold facing the ISFET's conducting channel, the drain current begins to drop. The external circuit senses this change and increases the reference electrode potential sufficiently to maintain constant drain current, and, equivalently, constant potential (and charge density everywhere) on the gold gate. Thus, the change in potential of the reference electrode appears entirely across the gold-double layer region, and directly measures the Esin-Markov coefficient.

The gold gate is a thin film of gold with an area of about 10^{-4} cm^2. Gold is initially rf sputtered during chip manufacture on top of 200Å of titanium (to bond the gold to the silicon nitride) to form a gate with a thickness of about 0.2 μm. Some experiments were performed on this amorphous gold gate, while others were performed on a polycrystalline gold gate of several microns thick which was formed by using a Bell Laboratories electroplating technique (7) which gives gold of five nines purity.

Deionized, 18 MΩ-cm resistivity, water was passed through a quartz double distillation unit for our use in these experiments. Chemicals used were either Mallinckrodt Reagent grade or Merck Suprapur grade.

The reference electrode used was a double junction type with the compartments separated by porous glass plugs. The upper junction was composed of Ag|AgCl|sat. AgCl in 4M KCl. The lower junction contained electrolyte of the same composition as the base solution under test.

A thermostatted closed test cell at 25°C containing a base solution of 0.9M NaF in water was deaerated by bubbling humid N_2 through the 25 ml of solution for more than an hour before starting any measurements. Gas leaving the cell was passed through a water trap to avoid backflow of oxygen into the system. The ISFET's were entirely encapsulated, except for the gold gates, with EPON epoxy as described elsewhere (6).

For the summer project, iodide was chosen as the specifically adsorbing ion to study. A calibrated, Gilmont 250 μl syringe was used to add NaI to the solution over a concentration range of 10^{-6}-10^{-3}M.

Devices were cleaned for 10 min or longer in an argon plasma with a background pressure of about 0.3 Torr with 5W of power used to keep the plasma ignited. After plasma cleaning, the device was removed from the plasma chamber and immediately placed in a container of clean water, moved to the test cell, and placed in the test solution to avoid the possibility of surface contamination. Aqua regia made from electronic grade acids was used to clean other devices. These devices were dipped in the acid for 2-3 sec, plunged immediately into clean water for a minute, and then into the test solution.

Results

After equilibrating a device in solution for an hour to minimize drift and deaerate the solution, the experiment was begun. Nearly all of the 20 devices studied gave a slope of 40-50 mV/decade for both amorphous sputtered gold and polycrystalline plated gold gates (see Fig. 2). Ultrapure chemicals gave the same result as reagent grade chemicals; however, reagent grade chemicals led to a background drift of 5-10 mV/hr. There was no clear difference between cleaning devices in a low power argon plasma and aqua regia.

It is worth noting that these devices hold charge on the gates for days when in air. Early devices held charge only for minutes in air; upon examination of the transistor with ESCA, it was found that a few tens of ppm of titanium on the silicon nitride surface acted as a shunting resistor to drain charge off of the gate. This problem was solved by cleaning the wafer with EDTA solution in ultrasound.

It is desirable to demonstrate the operation of the devices at various charge conditions on the gold. This was done by turning off the feedback circuit, grounding the reference electrode, and applying a potential to the gate to set a known charge density there. This was done either by touching the gold gate with a gold wire set at a desired potential or by applying a potential to a lead which was connected directly to the gold gate when the device was constructed. This applied charge would not stay on the gate for a long enough period of time to make a measure of the Esin-Markov coefficient. The time constant for the charge leakage was about 10 min. Thus, all measurements were made after the charge on the gold gate stabilized. This potential is probably at or near the pzc, and the charge leakage is currently under investigation.

Discussion

Surface cleanliness was clearly an important factor in getting reasonable results; however, the crystallinity of the surface probably also made an important difference. For example, a single crystal face of gold has a well-defined pzc potential, whereas a polycrystalline gold surface has several crystalline faces in contact with solution, each of which has different pzc potentials. Thus, even if a gold gate has zero net charge on its surface, some crystal faces can be expected to have

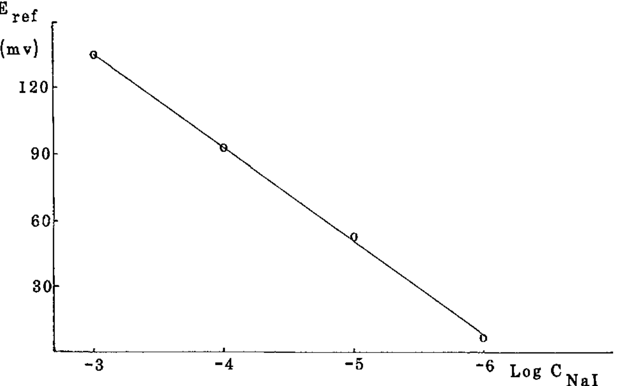

Fig. 2. Result of a direct measure of the Esin-Markov coefficient obtained by adding NaI to a background solution of aqueous 0.9M NaF at 25°C.

a positive surface charge density and others a negative surface charge density. This implies that an adsorbing species will adsorb with different surface concentrations on the various crystalline faces (3, 8) and any measured Esin-Markov coefficient will be a composite of several adsorption isotherms and ought to yield less than 59 mV/decade, particularly at low concentrations of adsorbate.

Due to the existence of a small, but nonzero exchange current density, these floating gate devices could be operated only in the neighborhood of the (averaged) pzc potential. The results demonstrate the feasibility of directly measuring the Esin-Markov coefficient with an ISFET. Extending its use to various surface charge densities is presently under investigation, and the results will be subsequently communicated.

Acknowledgments

Support for this work from The Electrochemical Society's award of the Joseph W. Richards fellowship is gratefully acknowledged. The author wishes to thank Professor Jiri Janata for his guidance and helpful suggestions, as well as Dr. Scott Collins, Gary Blackburn, and Rosemary Smith for their aid in the laboratory.

Conductivity of KOH Electrolyte Supersaturated with Zincate

Ming-Biann Liu,* Brian R. Faulds,[1] G. M. Cook,* and N. P. Yao*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

The specific conductivity of 7.32*N* KOH electrolyte with zincate concentrations ranging from 0 to 1.5M has been measured. The electrolyte conductivity was found to decrease with increasing zincate concentration. This finding is consistent with predictions based on the mixture rule. The equivalent conductance of 7.32*N* potassium zincate of 7 ± 5 mho · cm/equiv. may indicate the formation of neutral associated ion pairs from potassium and zincate ions in the electrolyte. Further calculations indicated that the mixture rule yields predictions of conductivities for the KF-KOH and K_2CO_3-KOH systems that are in good agreement with experimental data in the literature.

The primary purpose of this study was to obtain specific conductivity data for 7*N* KOH electrolyte supersaturated with zincate. These fundamental data are needed for engineering analysis of zinc porous electrodes used in alkaline batteries under development for near-term use in electric vehicles. These data also provide a baseline for the evaluation of modifications of battery electrolyte.

The electrolyte in Ni/Zn batteries is initially about 31% KOH (7*N*) saturated with ZnO. During cell discharge, the concentration of zincate has been observed to rise by three to four times the chemical solubility of ZnO in KOH solution (1-3). Furthermore, the conductivity of the electrolyte at a given concentration and temperature has been found to decrease linearly with an increasing amount of dissolved ZnO up to saturation concentration (4-6). We have determined the conductivity of the KOH electrolyte with zincate concentrations up to twice chemical saturation.

During the discharge of zinc/nickel oxide cells, the reactions for the zinc electrode may be written as follows

$$Zn + 4\,OH^- \rightarrow Zn(OH)_4^{2-} + 2e^- \qquad [1]$$

The zincate species may also precipitate to form zinc oxide according to the reaction

$$Zn(OH)_4^{2-} \rightarrow ZnO + H_2O + 2\,OH^- \qquad [2]$$

For the nickel oxide electrode, the reaction is

$$NiOOH(s) + H_2O + e^- \rightarrow Ni(OH)_2(s) + OH^- \qquad [3]$$

Thus, the net reaction of the cell system may be written as

$$Zn + 2NiOOH(s) + (2 - y)\,H_2O + (2 - 2y)\,OH^- \rightarrow (1 - y)\,Zn(OH)_4^{2-} + 2Ni(OH)_2(s) + y\,ZnO(s) \qquad [4]$$

where y is the molar fraction of zincate species precipitating to form ZnO. Reaction [4] suggests that the electrolyte is a ternary system consisting of potassium hydroxide, potassium zincate, and water.

Ternary electrolyte theory developed from the principle of irreversible thermodynamics has been described by Miller (7) and Sunu and Bennion (8). To predict the transport properties of a ternary electrolyte system by using the theory, one has to estimate the values of six solvent-fixed ionic transport coefficients. Miller (7) found empirically that, for seven ternary alkali halide mixtures at total concentrations ranging from 0.5 to 3*N*, the ionic transport coefficients (l_{ij}) can be closely approximated using l_{ij} data from appropriate binary systems. These estimated values of ternary l_{ij} yield good estimates of transference numbers, conductances, and solvent-fixed thermodynamic diffusion coefficients. In our system, sufficient conductivity data for potassium zincate are lacking. Therefore, this theory cannot be used to analyze our conductivity data. However, the conductance, Λ_{123}, of the seven alkali halide mixtures can also be predicted at low concentrations by the solution mixture rule (7), which states that

$$\Lambda_{123} = X_2\Lambda_{12} + X_3\Lambda_{13} \qquad [5]$$

where Λ_{1i} ($i = 2, 3$) is the conductance of the binary electrolyte at the same total equivalent concentration, N, of the mixture and where the equivalent fractions, X_i, are given by

$$X_i = \frac{N_i}{N_2 + N_3} \quad i = 1, 2, 3 \qquad [6]$$

$$X_1 = X_2 + X_3 = 1 \qquad [7]$$

Substituting Eq. [7] into Eq. [5], one obtains

$$\Lambda_{123} = \Lambda_{13} - (\Lambda_{13} - \Lambda_{12})X_2 \qquad [8]$$

In this study, we found that our conductivity data for the KOH-$K_2Zn(OH)_4$ system and the data for the KOH-KF system (9) and the KOH-K_2CO_3 system (10) are consistent with the solution mixture rule.

Experimental

Figure 1 shows the schematic diagram of the experimental apparatus, which consists of (*i*) zincate generation cell, (*ii*) electrolyte pump, (*iii*) power supply, and (*iv*) electrolyte reservoir. The Lucite zincate generation cell was at room temperature (22°C). The volume of the cell was about 125 ml. The working electrode was an array of four zinc sticks with dimensions of 0.7 × 0.7 × 10.5 cm; these sticks were manufactured by J. T. Baker Chemical Company (Phillipsburg, New Jersey), and had a purity of 99.6%. To prevent the removal of zincate from the electrolyte, a nickel oxide counterelectrode, obtained from Yardney Electric Company (Pawcatuck, Connecticut), was used. A polypropylene separator, purchased from Spectrum Medical Industries, Incorporated (Los Angeles, California), was placed between the two electrodes to prevent electrical shorting. An Hg/HgO reference electrode was used to monitor the electrode potentials. An oxygen-free nitrogen stream was introduced into the cell to eliminate CO_2 from air. The electrolyte reservoir was a 500 ml Pyrex three-necked round-bottomed flask which was kept in a constant temperature water bath at 25°C. The electrolyte was 7.32*N* KOH (reagent grade) in doubly distilled water which was initially saturated with zinc oxide (0.64M) (analytical reagent quality). No further purification of these materials was attempted. The electrolyte was prepared with doubly distilled water.

At the beginning of the experiment, the cell and the reservoir were filled with the electrolyte. During the discharge of the cell, the electrolyte was continuously pumped by a polypropylene bellow pump, manufactured by Gorman-Rupp Industries (Bellville, Ohio), from the reservoir to the bottom of the cell and then allowed to overflow from the top of the cell back to the reservoir. The flow rate was adjusted so that no gas bubbles were trapped in the overflow stream.

The electrical circuit for the experiment is illustrated in Fig. 1. To maintain a constant current level ranging from 0.6 to 1.2A (about 10-20 mA/cm² on Zn electrode), a dummy resistor was placed between the working electrode (WE) connector and the reference electrode (RE) connector of the Wenking HP72 potentiostat made by G. Bank Electronik (West Germany). The potential of the cell as well as that of the nickel oxide electrode with respect to the Hg/HgO reference electrode were recorded on a strip-chart recorder (Hewlett-Packard 7100 BM). When the recorder indicated that the potential of the nickel oxide electrode had dropped to 0.2V *vs.* the Hg/HgO electrode, cell discharge and electrolyte circulation were stopped. The nickel oxide electrode was then removed and recharged in fresh electrolyte in a cell using a nickel plate as a counterelectrode. Subsequently, the charged nickel oxide electrode was returned to the zincate generation cell and the zincate generation process continued. This procedure was repeated several times until the desired level of zincate concentration was obtained.

After completion of each discharge, time was allowed for the electrolyte in the reservoir to return to 25°C. Next, 1 ml aliquots of this electrolyte were pipetted for the determination of zincate concentration by titration with 0.1M EDTA (ethylenediaminetetraacetic acid) with Erichrome Black T as an indicator. The specific conductivity of the electrolyte in the reservoir was measured at different zincate concentrations (0-1.52M), using two conductivity cells in conjunction with an a-c conductivity bridge operated at a frequency of 1 kHz. The conductivity cells were Models G50 and G100 Beckman Instruments, Incorporated (Cedar Grove, New Jersey); the conductivity bridge was Model 31, Yellow Springs Instrument Company, Incorporated (Yellow Springs, Ohio). The cell constants were calibrated using 0.1*N* KCl (specific conductivity 0.11134 mho/cm) (11) and found to be 50.899 cm^{-1} for the Model G50 and 99.857 cm^{-1} for the Model G100. To make the conductivity measurement, the electrolyte was sucked into the conductivity cell and a conductance reading completed within 30 sec. In this manner the change in temperature is minimal.

When the concentration of zincate was above 1.3M, white precipitate was observed in the electrolyte. Therefore, several hours were allowed for the precipitate to settle to the bottom of the reservoir. Portions of clear electrolyte were taken for the determination of specific conductivity and zincate concentration; there were at least two measurements made for each determination. For one determination, electrolyte taken from the reservoir was vacuum filtered through 0.2 μm filter paper. The result of this measurement was in agreement with those obtained using clear unfiltered electrolyte. The average uncertainty for all the measurements was 1.5%.

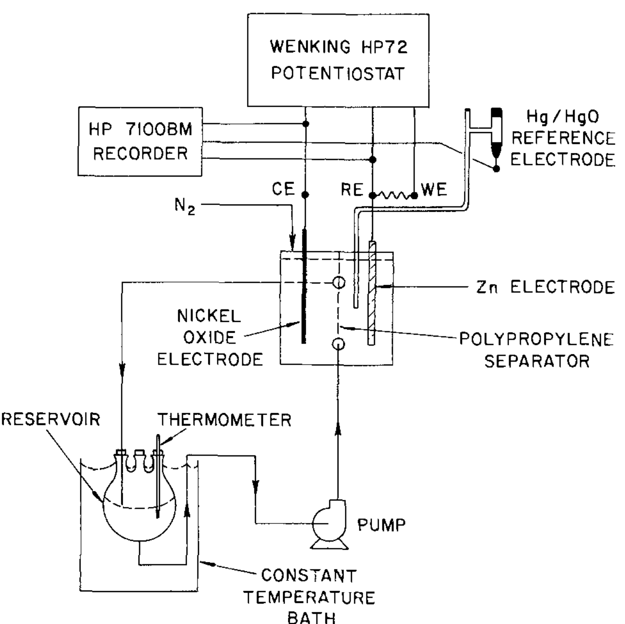

Fig. 1. Experimental apparatus

Results and Discussion

The specific conductivity data along with data obtained from other studies (5, 6, 9) under similar conditions are presented in graphical form in Fig. 2. This figure shows that a least squares fit of our specific conductivity data is in agreement with those of the

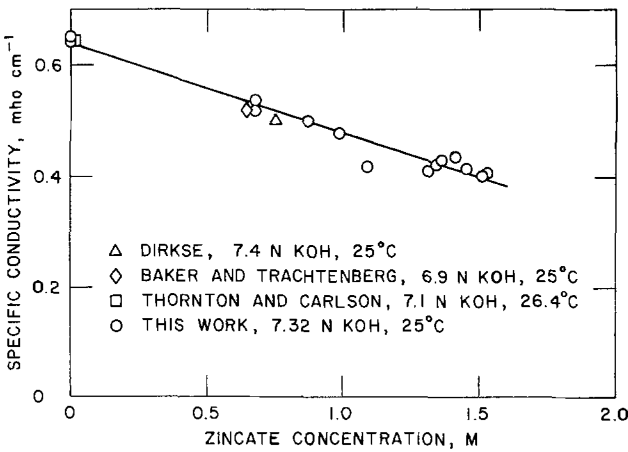

Fig. 2. Specific conductivity of KOH electrolytes as a function of zincate concentration.

other workers. This figure also indicates that the conductance of the electrolyte may be linearly correlated with zincate concentration. A linear relationship for conductivity *vs.* weight percent of ZnO was also observed by Dyson et *al.* (4) up to chemical saturation of ZnO in more concentrated KOH electrolyte (namely, 35-46% by weight or 8.3-11.6*N*). The linear relationship shown in Fig. 2, between the specific conductivity, *k*, and the molar concentration of zincate, $C_{Zn(II)}$, can be expressed by the equation

$$k = (0.637 \pm 0.011) - (0.159 \pm 0.009) C_{Zn(II)} \text{ mho/cm} \quad [9]$$

The slope of 0.16 for this equation is higher than the slopes estimated from the data at 25°C given by Dyson *et al.* (4) (slope of 0.13 for 35% KOH, 0.11 for 40% KOH, 0.095 for 46% KOH). These values indicated that the specific zincate conductance decreases with increasing KOH concentration. We also found that the specific conductivity of KOH decreases with increasing KOH concentration (k — 0.64 mho/cm at 31% KOH, 0.58 mho/cm at 40% KOH, and 0.45 mho/cm at 46% KOH) (4).

The zincate species in the solution of ZnO in KOH is $Zn(OH)_4^{2-}$ as evidenced by nuclear magnetic resonance (NMR), Raman, and infrared reflection spectroscopic studies (12-14). In the supersaturated solution, Dirkse (12) indicated that the zincate species is also $Zn(OH)_4^{2-}$. However, Briggs *et al.* (1) concluded from their spectroscopic study that the zincate species in the supersaturated state is initially $Zn(OH)_4^{2-}$ and sequentially becomes $[Zn(OH)_3(H_2O)]^-$ and $[Zn(OH)_2(H_2O)_2]$ as the degree of supersaturation increases. If there were any species other than $Zn(OH)_4^{2-}$ in our experiment, a change in the slope of the plot in Fig. 1 would have been detected as was shown in the plots of emf *vs.* $\log_{10}\{[Zn(II)]/[OH^-]^4\}$ given by Briggs *et al.* (1). We find no such evidence in Fig. 1. Therefore, we conclude that the zincate species in the supersaturated solution is the same as that in the solution of ZnO in KOH. Therefore, Eq. [1] is the electrode reaction.

According to Eq. [6]-[8], the concentration of potassium ions is required to apply the mixture rule to our data. The initial concentration of potassium ions was 7.32*N*. This value may be changed in the dissolution of ZnO and Zn due to possible change in the electrolyte volume and take-up/release of potassium ions by the nickel oxide electrode. We investigated these two possible ways for changing the K^+ concentration and found the change to be negligibly small. In the chemical dissolution of ZnO and anodic dissolution of Zn, the change in the electrolyte volume is small. This is justified by the fact that the additive rule predicts values within 1% of the density data given by Dirkse (5) for the solution of ZnO in KOH electrolytes and values within 3% of the density data given by Eisenberg *et al.* (15) for supersaturated zincate solutions. Experimental evidences (16, 17) indicate that potassium ions are taken up by nickel oxide electrodes during the charge cycle, and released during the discharge cycle. A recent study by Barnard *et al.* (17), indicates that the take-up/release of potassium ions depends on the crystal structure of the nickel oxide electrode: 0.102 mol per $2e^-$ for β-NiOOH and 0.47 mol per $2e^-$ for γ-NiOOH. Harivel *et al.* (18) indicated that the formation of β- and γ-NiOOH depends upon the charging rate, the state of charge, and the electrolyte concentration. In our study, the nickel oxide electrode was charged at 6 mA/cm^2 up to 20% of theoretical capacity (3 A-hr) in a cell with fresh electrolyte and then discharged in the zincate generating cell. Under such conditions, only β-phase materials are expected to be formed. Therefore, we estimate that 0.102 mol of potassium ions per $2e^-$ were taken up from the charging cell and released in the zincate generating cell. For our maximum zincate concentration of 1.53M, the concentration of potassium ions is estimated to increase by a maximum of 0.15*N* or 2% of its original value. Therefore, we may assume that the concentration of potassium ions in the electrolyte throughout the experiment did not change. When divided by the total equivalent concentration (7.32*N*), Eq. [9] is transformed to

$$\Lambda_{123} = (87 \pm 2) - (80 \pm 5)\, X_2 \text{ mho} \cdot \text{cm}^2\text{/equiv.} \quad [10]$$

where subscripts 1, 2, and 3 designate potassium, zincate, and hydroxide ions, respectively. Thus, from Eq. [8], it can be concluded that $\Lambda_{13} = 87 \pm 2$ mho · cm²/equiv. and $\Lambda_{13} - \Lambda_{12} = 80 \pm 5$ mho · cm²/equiv. In other words, the apparent equivalent conductances are 87 ± 2 mho · cm²/equiv. for potassium hydroxide and 7 ± 5 mho · cm²/equiv. for potassium zincate in the electrolyte. When the mixture rule is applied to the data given by Dyson *et al.* (4), values of about zero are also obtained for the conductance of potassium zincate. This low value of equivalent conductance for potassium zincate indicates that potassium ions and zincate ions are likely to form neutral associated ion pairs in the electrolyte.

If the mixture rule is a valid approximation for concentrated solutions, then it can be used to estimate the conductance of ternary electrolyte systems from the available conductance data of binary electrolyte systems (19). Conductivity data of the KOH-KF system (9) (7.13 ± 0.16*N*), the $KOH\text{-}K_2CO_3$ system (10) (8.35 ± 0.23*N*), and our $KOH\text{-}K_2Zn(OH)_4$ system (7.32*N*) are plotted in Fig. 3 as a function of equivalent fraction. It should be noted that there was a problem with Ref. (10). The data in Ref. (10) were given in both graphical and tabular forms, which was not consistent. It was decided to select that set of data for which the KOH values were consistent with those calculated from the table given in Ref. (19). Results of least squares analyses of these data are shown in Fig. 3 and Table I. As can be deduced for each electrolyte system in Table I, the conductance data of the binary system are in good agreement with those for the ternary system; the maximum difference between the experimental data and the ternary system data (obtained from analyses of binary data using mixture rule) shown in Fig. 3 is six equivalent conductance units for the KOH-KF system and five equivalent conductance units for the $KOH\text{-}K_2CO_3$ system.

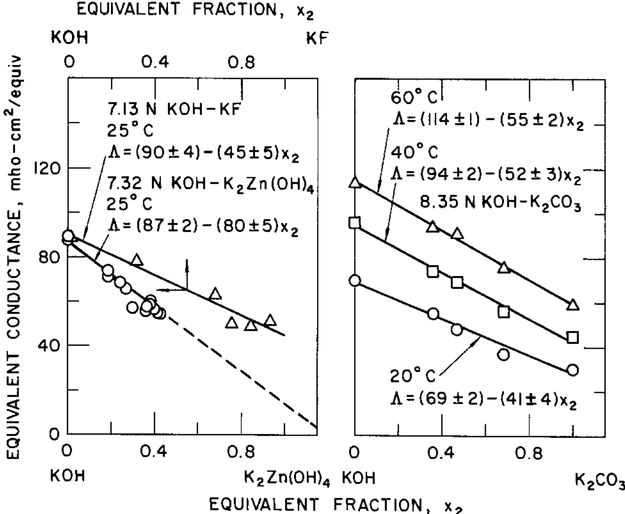

Fig. 3. Equivalent conductances of $KOH\text{-}K_2Zn(OH)_4$ system, KOH-KF system, and $KOH\text{-}K_2CO_3$ system as a function of equivalent fraction.

Table I. Values of Λ_{13} and $\Lambda_{13} - \Lambda_{12}$ obtained from binary system data and least squares analyses of ternary system data using the mixture rule (Eq. [8])

Electrolyte	Concentration, N	Temperature, °C	Binary system data,[a] mho · cm²/equiv.			Ternary system data,[b] mho · cm²/equiv.	
			Λ_{12}	Λ_{13}	$\Lambda_{13} - \Lambda_{12}$	Λ_{13}	$\Lambda_{13} - \Lambda_{12}$
KF-KOH	7.13	25	43	89	46	90 ± 4	45 ± 5
K_2CO_3-KOH	8.35	20	30	70	40	69 ± 2	41 ± 4
K_2CO_3-KOH	8.35	40	44	96	52	94 ± 2	52 ± 3
K_2CO_3-KOH	8.35	60	59	113	54	114 ± 1	55 ± 2
$K_2Zn(OH)_4$-KOH	7.32	25	—	88	—	87 ± 2	80 ± 5

[a] Obtained from Ref. (9) and (10) and this work except for the value of Λ_{12} for KF, which was calculated from the table given in Ref. (12).
[b] Calculated from our data and those from Ref. (9) and (10) [see text for a discussion of the data from Ref. (10)].

Summary

1. The specific conductivity of 7.32N KOH electrolyte at different zincate concentrations was measured. The conductivity of the electrolyte was found to decrease linearly with increasing zincate concentration. This is consistent with predictions based on the solution mixture rule (7).

2. A least squares analysis of our data by using the mixture rule indicates that the equivalent conductances of potassium hydroxide and potassium zincate (7.32N) at 25°C are 87 ± 2 and 7 ± 5 mho · cm²/equiv., respectively. This low value of equivalent conductance for potassium zincate indicates that the potassium and zincate ions are likely to form neutral associated ion pairs in the electrolyte.

Lithium Incorporation by V_6O_{13} and Related Vanadium (+4, +5) Oxide Cathode Materials

D. W. Murphy,* P. A. Christian,[1] F. J. DiSalvo, J. N. Carides, and J. V. Waszczak

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The known vanadium oxides VO_{2+y} ($0 \leq y < 0.5$) have been examined as cathode materials in ambient temperature nonaqueous secondary lithium cells. The discharge products have also been chemically prepared and characterized by x-ray diffraction, thermal analysis, and magnetic susceptibility. The best cathode materials are V_6O_{13} and a slightly oxygen-rich V_6O_{13+y}. Electrochemical and chemical preparations afford $Li_xV_6O_{13+y}$ ($x \leq 8$). The $Li_xV_6O_{13}$ is described as an insertion compound of V_6O_{13}.

A wide variety of inorganic compounds with either two-dimensional van der Waal's bonded layer structures or three-dimensional framework tunnel structures undergo topotactic reactions with lithium (1). Such reactions are often readily reversed, making these materials attractive candidates for the positive electrode in secondary lithium cells (2-5). Most previous work has centered on two-dimensional metal chalcogenides as potential lithium cathode materials, although transition metal oxides with framework structures such as many of the rutiles (6), vanadium oxides (6-10), molybdenum oxides (11), and tungsten oxides (12) have been shown to undergo reversible lithium incorporation both chemically and electrochemical cells. Herein we describe in detail incorporation of lithium by vanadium oxides with stoichiometries between $VO_{2.0}$ and $VO_{2.5}$. In addition to describing the preparation and characterization of the parent vanadium oxides, some of the chemical, thermal, magnetic, spectral, electrical, and electrochemical properties of their chemically derived lithium bronzes are reported.

Experimental

Reagent grade ammonium metavanadate, NH_4VO_3, (Alfa) was used without further purification. Vanadium pentoxide was prepared by thermal decomposition of NH_4VO_3 (13). Vanadium metal powder (325 mesh, 99.5% pure) was obtained from Cerac and stored under Ar. A solution of $\sim$2.4*N* n-butyllithium in hexane was obtained from Alfa-Ventron and was diluted to $\sim$1.3*N* with hexane. All reactions with n-butyllithium were carried out in an He atmosphere in a Vacuum/Atmosphere glove box. All solvents were reagent grade and were distilled under Ar from the appropriate drying agents.

V_6O_{13}.—Stoichiometric amounts of V_2O_5 and vanadium metal powder were intimately mixed and heated to 600°C in an evacuated quartz tube. After 1 day the temperature was increased to 680°C for 1-3 days. The resulting microcrystalline product was deep purple in color and exhibited a metallic luster. The vanadium-oxygen stoichiometry was verified by TGA in an oxygen atmosphere. The x-ray powder diffraction pattern of the product was obtained using CuKα radiation and is identical to that reported for V_6O_{13} (14).

V_6O_{13+y}.—Ball milled (1-5 μm), vacuum dried, NH_4VO_3 was thermally decomposed under an Ar stream. In a typical preparation, 38.0-40.0g of NH_4VO_3 was placed in a porcelain boat inside a quartz tube and heated in an Ar stream (140-150 cm³/min) from ambient to 500°C at a rate of $\sim$4 to 4.5°/min. After 1 hr at 500°C the temperature was increased to 550°C for 1 hr. The product was slowly cooled to room temperature in an Ar atmosphere. The powder obtained varied in color from blue-gray to navy blue. The stoichiometries of the products were determined by oxidizing the samples to V_2O_5 using TGA and range between $V_6O_{13.5}$ and $V_6O_{13.16}$. The powder x-ray diffraction patterns are similar to that of V_6O_{13}.

$VO_2(B)$.—The procedure of Theobald and co-workers (15, 16) was modified as follows. Finely ground V_2O_5 was reduced in a stream of H_2 ($\sim$200 cm³/min) at 320°C for 4 days. The resulting black powder was dried at 300°C under Ar for 3 days to remove residual water. The overall stoichiometries of the products prepared in this manner were determined by TGA to range from $VO_{1.99}$ to $VO_{2.11}$. The x-ray diffraction powder pattern of the product is consistent with that reported for $VO_2(B)$ (16).

V_4O_9.—Finely ground V_2O_5 was slowly reduced in a stream of anhydrous SO_2 ($\sim$200 cm³/min) at 430°C (17). The progress of the reduction was monitored by x-ray powder diffraction. Several intermediate regrindings of the sample were necessary to ensure homogeneity. After 2-3 days' time, the x-ray diffraction pattern was consistent with that reported for V_4O_9 (17).

V_3O_7.—A mixture of finely ground V_2O_5 (10 mmol) and the required amount of freshly reduced V_2O_3 (2 mmol) was pressed into pellets and heated for 11 days at 550°C in an evacuated quartz tube (18). The x-ray diffraction pattern of the dark blue-gray product is consistent with that reported by Thomas *et al.* (19) with only a trace of unreacted V_2O_5 present.

Lithiation of VO_y with n-butyllithium/hexane.—As described previously (20), a 100-250 mg sample of the oxide was treated with a known volume of standardized dilute ($\sim$1.3*N*) n-BuLi in hexane. X-ray powder diffraction patterns were measured for lithiated samples mounted in an evacuable holder fitted with a beryllium window.

Delithiation of Li_xVO_y with iodine/acetonitrile (21).—A known volume of $\sim$0.07M I_2 in degassed, dry acetonitrile solution was added dropwise to a 100-200 mg sample of the lithium bronze under Ar. The resulting mixture was stirred at room temperature for 10-12 hr. The vanadium oxide was collected by suction filtration and washed with acetonitrile. Titration of the filtrate and washings with a standard 0.1*N* $Na_2S_2O_3$ solution gave the amount of unreacted I_2 and allowed calculation of the residual lithium content. In some cases a solution of DDQ (dichlorodicyanoquinone) was

* Electrochemical Society Active Member.
[1] Present address: Western Electric, Engineering Research Center, Princeton, New Jersey 08540.
Key words: battery, lithium, insertion compound.

added to verify that all of the lithium had been removed.

Electrochemical cells.—Test cells were constructed as previously described (21). Cathodes were powders of the pure vanadium oxide or the oxide mixed with graphite. The electrolyte was generally 1*M* $LiAsF_6$ in propylene carbonate. Cells were cycled at constant current between preset voltage cutoffs, generally 3.1V on charge and 1.5V on discharge. Cells typically contained 10-20 mg of the active cathode material.

Results and Discussion

Vanadium oxides with octahedral or distorted octahedral coordination are known for all oxidation states between V^{5+} and V^{2+}. Furthermore, the energy differences between these different oxidation states are not very great and numerous examples of mixed valence and metallic compounds exist. V_6O_{13}, for example, is metallic with the formal oxidation state assignment: $V_4{}^{4+}$ $V_2{}^{5+}$. The possibility for easy redox chemistry with structures suitable for lithium ion insertion prompted our investigation of lithium insertion chemistry and galvanic cell behavior.

The structures of the vanadium oxides V_2O_5, V_6O_{13}, and VO_2(B) can be viewed as shear structures derived from that of ReO_3 (22, 23). A single shear (Fig. 1) is accomplished by removing every second (200) plane of oxygen atoms and closing the structure up along the shear vector 1/2[101] to give the V_2O_5 structure. The actual structure of V_2O_5 (24) is distorted toward five coordinate V by displacement of V out of the center of each octahedron. A V=O bond is formed which gives a strong *IR* stretch at 1000 cm^{-1}. Shearing the idealized V_2O_5 lattice by removing every third (020) plane of oxygen atoms and closing the structure along the shear vector 1/2[110] gives the V_6O_{13} structure. Similarly, removing every second (020) plane of oxygen from V_2O_5 and closing along 1/2[110] gives the VO_2(B) structure. The V_6O_{13} structure (14) contains only slightly distorted VO_6 octahedra joined by edge sharing into single and double zig-zag chains parallel to [010] and linked together by additional edge sharing into single and double sheets of octahedra parallel to the (100) plane. These sheets are interleaved so that single and double sheets alternate. The stacked sheets are interconnected by corner sharing into a three-dimensional framework. The VO_2(B) structure can be described similarly except that only double sheets of octahedra are present (15). The structures reported for both V_4O_9 (25) and V_3O_7 (18) are very open and cannot be derived by a simple shear mechanism from ReO_3. The structure of V_3O_7 contains both single and double chains of VO_6 octahedra, like V_6O_{13}, as well as some edge-shared zig-zag chains of VO_5 trigonal bipyramids, as in the V_2O_5 structure. Thus, V_3O_7 appears to have an intermediate structure between that of V_6O_{13} and V_2O_5.

The vanadium oxides V_2O_5, V_3O_7, V_4O_9, and VO_2(B) used in this study were prepared essentially by previously reported methods with slight modifications. Typical reaction conditions are summarized in Fig. 2. Stoichiometric V_6O_{13} is readily prepared by the solid-state reaction of V_2O_5 and the appropriate amount of V metal in a sealed quartz ampul. A vanadium oxide with a range of stoichiometries approximating V_6O_{13}, an x-ray powder diffraction pattern similar to that of V_6O_{13}, and a transition in magnetic susceptibility at the same temperature as V_6O_{13} can be prepared by several procedures. Based on reports that "reduced" phases with stoichiometries close to V_6O_{13} could be obtained by thermal decomposition of $[(NH_4)_2V_6O_{16}]$ *in vacuo* (26), by reducing V_2O_5 with NH_3 at 325°-350°C (27) or by thermally decomposing NH_4VO_3 *in vacuo* at 500°C (22), a procedure involving the thermal decomposition of NH_4VO_3 in a controlled stream of argon was developed. This procedure was utilized to produce slightly nonstoichiometric V_6O_{13+y}. The stoichiometries of the products are typically $\leq$1.5% oxygen-rich, although under more reducing conditions oxygen-deficient products can be generated. If more extensive reduction is desired, additional NH_3 or H_2 can be added to the inert sweep gas. Although the materials prepared in this manner have x-ray powder diffraction patterns very similar to that of V_6O_{13} there is significant variation in the relative intensities of several of the diffraction peaks as well as a slight shifting of peaks to lower angles. It appears that previously reported V_6O_{13}-related "reduced phases" can be rationalized in terms of nonstoichiometric $V_6O_{13\pm y}$ compositions. The "D" phase reported

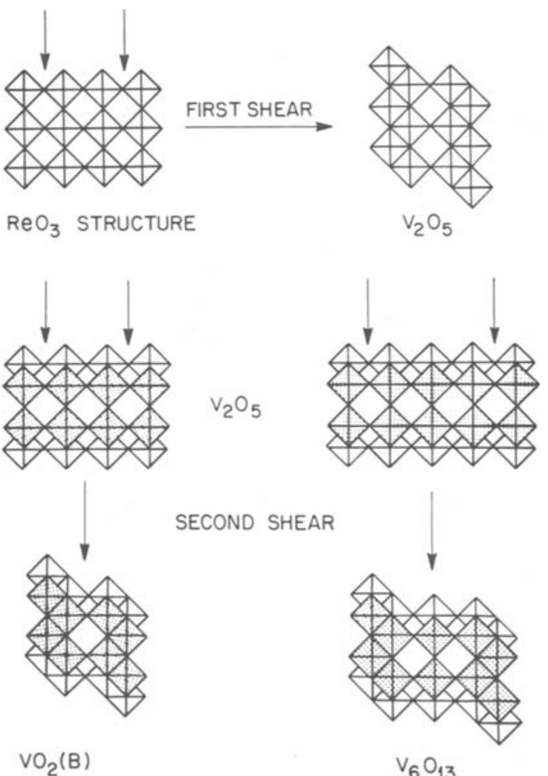

Fig. 1. The idealized V_2O_5 lattice is derived by a shear of the ReO_3 lattice along the planes indicated by arrows. The VO_2(B) and V_6O_{13} lattices are derived by a shear of the V_2O_5 lattice as indicated.

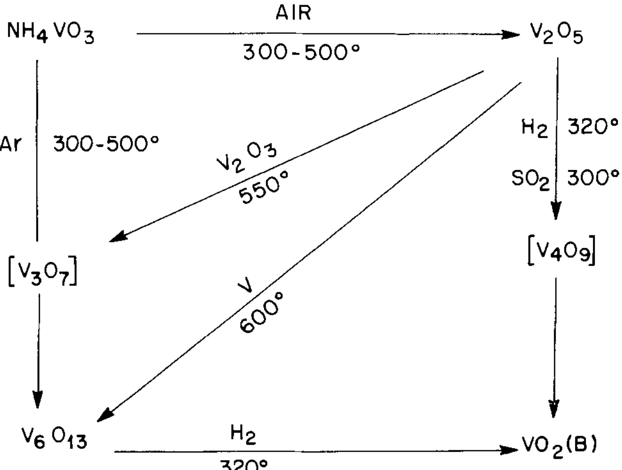

Fig. 2. The reactions used to prepare vanadium oxides are summarized. The reactions of V_2O_5 with V_2O_3 and V are stoichiometric in sealed ampuls. All others use flowing gas.

by Théobald and co-workers (26) exhibits a diffraction pattern with peak intensities comparable to those observed for samples of oxygen-rich V_6O_{13+y}. However, the powder diffraction pattern of the "C" phase reported by the same workers corresponds to that of a sample of oxygen-deficient V_6O_{13-y} prepared in this work below 300°C using H_2 to augment reduction. In this latter sample, the 001 diffraction peaks are greatly diminished in intensity or absent altogether. Differences in x-ray intensities are also sensitive to the maximum temperature reached during the preparation. Heat-treatment at 500°C of samples with weak 001 peaks results in an increase in the intensity of these peaks. Typically the ratio of the intensity of the 002 to the 110 peaks for V_6O_{13+y} discussed below which has been annealed at 550°C is about half that observed for stoichiometric V_6O_{13}. The unit cell parameters determined by a least squares analysis for several samples of V_6O_{13+y} are given in Table I.

The most interesting of the vanadium oxides for secondary cathode materials (vide infra) is the slightly oxygen-rich V_6O_{13+y} ($y \lesssim 0.2$) prepared by the thermal decomposition of NH_4VO_3 in an inert gas stream. The chemical and physical properties of V_6O_{13+y} differ perceptibly from those of stoichiometric V_6O_{13}. The nonstoichiometric V_6O_{13+y} is nearly single phase. Thermal analysis by DSC indicates the presence of ~1-2% VO_2 (endothermic transition at 69°C). Dilute acid or base wash under conditions which would dissolve all higher vanadium oxides does not affect V_6O_{13+y}. The magnetic susceptibility of V_6O_{13+y} is compared to that of V_6O_{13} in Fig. 3. The sharp break in susceptibility at the metal-insulator transition (149 K) characteristic of V_6O_{13} (28, 29) is appreciably broadened in V_6O_{13+y}. Because of the close structural relationship between V_6O_{13}, VO_2(B), and V_2O_5, a potential lattice defect might involve a stacking disorder in which extra single or double sheets are present. The presence of extra single sheets would correspond to a microregion of V_2O_5 in the structure and result in an oxygen-rich stoichiometry. Similarly, the presence of extra double sheets would correspond to a microregion of VO_2(B) and result in an oxygen-deficient stoichiometry. Such stacking disorders are not uncommon and have been previously observed in related materials. Colpaert and co-workers (30), in their study of the effects of low energy electron bombardment of V_2O_5, observed the nucleation of V_6O_{13} on the V_2O_5 (010) surface and the presence of shear planes at the boundaries between the V_2O_5 and the V_6O_{13} nuclei. Horiuchi and co-workers (31) have observed regions of VO_2(B) and its twin in areas surrounding small cavities in the V_6O_{13} structure by TEM. Crystallographic shear planes were also observed in the walls of these cavities and substantial stacking faults were present in the regions immediately surrounding the cavities. The relatively small number of extra single or double sheets (<1.5%) required to change the overall stoichiometry of V_6O_{13} would not be expected to significantly alter the bulk powder x-ray diffraction pattern. The presence of stacking faults is also consistent with observed broadening of the metal insulator transition since magnetic susceptibility is highly sensitive to structural disorder as well as the presence of interstitial impurities.

Table I. Crystallographic parameters for V_6O_{13+y}

Lithium bronzes of V_6O_{13} and V_6O_{13+y}.—Treatment of both solid V_6O_{13} and V_6O_{13+y} with dilute solution of n-butyllithium in hexane at room temperature affords bronzes with the nominal compositions $Li_xV_6O_{13}$ ($0 < x < 4.5$) and $Li_xV_6O_{13+y}$ ($0 < x \lesssim 8$), respectively. The extent and apparent rate of lithium incorporation by V_6O_{13+y} are significantly greater than for V_6O_{13}. At room temperature the stoichiometric material incorporates a maximum of ~0.75Li/V to give a bronze with the composition $Li_{4.5}V_6O_{13}$. Increasing the temperature of the reactants to ~50°C (in a sealed tube) affords a ~30% increase in the maximum lithium stoichiometry to $Li_{5.8}V_6O_{13}$. However, the reaction of an equivalent amount of $V_6O_{13.16}$ with a similar volume of n-butyllithium solution at room temperature is so vigorous that the hexane solvent boils. Even with a more dilute n-butyllithium solution, $V_6O_{13.16}$ incorporates as much as 1.3Li/V to give a bronze with the limiting composition $Li_{7.9}V_6O_{13.16}$. Typically, values of 1.25Li/V are obtained at room temperature with oxygen-rich V_6O_{13+y} compositions. Above room temperature, treatment of V_6O_{13+y} with dilute n-butyllithium solution results in some decomposition. Heat-treatment of V_6O_{13+y} at 650°C *in vacuo* reduces its lithium capacity to approximately that of V_6O_{13}.

Treatment of $V_6O_{13.16}$ with an acetonitrile solution of lithium iodide results in a small amount of lithium incorporation ($Li_{0.35}V_6O_{13+y}$) corresponding to less than 5% of the limiting amount of lithium incorporated by treatment with n-butyllithium. However, treatment of V_6O_{13} with LiI solution at and above room temperature results in negligible (<0.01Li/V) lithium incorporation.

The x-ray powder diffraction data for the lithium bronzes with the compositions $Li_{4.1}V_6O_{13.05}$, $Li_{5.5}V_6O_{13.5}$, and $Li_{7.6}V_6O_{13.16}$ are summarized in Table II. A comparison of the monoclinic unit cell parameters of these bronzes with those of the parent $V_6O_{13.05}$ and $V_6O_{13.16}$ appears in Table III. The detailed structure of the lithium bronzes $Li_xV_6O_{13+y}$, including the nature of the Li sites, is presently unknown. It has been postulated (6, 10) that the lithium ions occupy sites within the tricapped cube-octahedral cavity generated from the vacant perovskite cavity of ReO_3 in the double shearing process. For both $V_6O_{13.05}$ and $V_6O_{13.16}$ the incorporation of up to 1Li/V results in a 6% or less increase in unit cell volume. The incorporation of more than 1Li/V results in a 15% increase in unit cell volume compared to V_6O_{13}. Diffraction data for $Li_xV_6O_{13+y}$ ($0 < x < 8$) indicate the presence of a nonstoichiometric single phase region for $3.5 < x < 5.5$ in which

an increase in lithium content results in elongation of the unit cell in the b direction, contraction in the a direction, and virtually no change in the c direction. In addition to the unit cell parameters, other properties of these bronzes including thermal stability, electronic conductivity, magnetic susceptibility, electrochemical potential (OCV), and hydrolytic stability also vary with lithium content. The bronzes $Li_xV_6O_{13}$ and $Li_xV_6O_{13+y}$ are likely metastable relative to disproportionation or irreversible structural transformations. The thermal behavior of the $Li_xV_6O_{13+y}$ bronzes, as determined by DSC, is quite complex. Multiple endothermic and exothermic processes occur during the thermal decomposition of these bronzes. A major irreversible, exothermic structural transformation, which is nearly independent of the lithium content, occurs between 230° and 265°C. Another irreversible transformation observed by DSC at 100°-150°C is more strongly affected by changes in lithium content. At low lithium contents ($x \leq 3$) the transformation is endothermic and occurs at 140°-150°C while at higher lithium contents ($x \geq 4$) it is exothermic and occurs at about 120°-130°C. No change is observed by x-ray diffraction after annealing at 150°C.

The characteristic metal-insulator transition of V_6O_{13} (~140 K) as observed by magnetic susceptibility is influenced by the presence of lithium. This transition is significantly broadened at lithium contents as low as 0.01Li/V (Fig. 4). At lithium contents greater than 0.03Li/V the transition is further broadened and only a smooth increase in slope results. Finally, at lithium contents greater than 0.25Li/V, the susceptibility curve can be fit by a modified Curie-Weiss law. The lack of a transition at 0.03Li/V shows that the Li is homogeneous throughout the material.

Preliminary measurement of the electrical resistivities for pressed powder samples of various $Li_xV_6O_{13}$ suggests that resistivity increases dramatically with increasing lithium content. The resistivity of a fully lithiated material is nearly 10^3 greater than that for unlithiated material ($P \approx 10^{-2}$ Ω cm). However, more accurate measurements are required in order to determine the nature of the dependence of the resistivity on lithium content.

The bronzes $Li_xV_6O_{13}$ and $Li_xV_6O_{13+y}$ are stable to oxidation at room temperature in dry air for extended periods of time. Samples stored for more than one year over $CaSO_4$ exhibit no degradation of their thermal, structural, chemical, or electrochemical properties. These materials can be handled even in humid air for at least several hours without decomposition. Oxidative

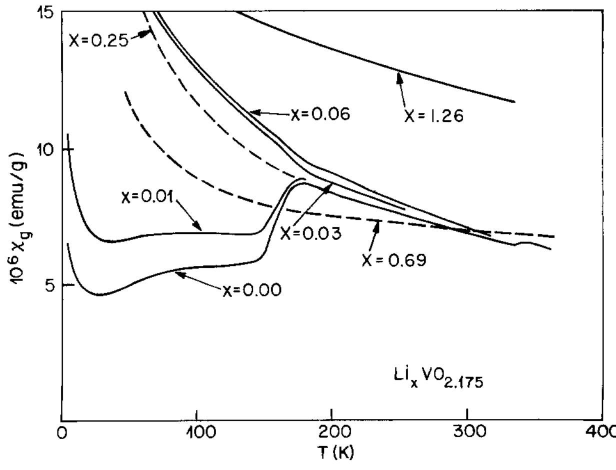

Fig. 4. The magnetic susceptibility of $Li_xVO_{2.175}$ as a function of x.

delithiation of $Li_xV_6O_{13}$ and $Li_xV_6O_{13+y}$ with an acetonitrile solution of I_2 removes most of the lithium (80-90%) as soluble lithium iodide. In order to remove the remaining lithium, a stronger oxidizing agent such as dichlorodicyanoquinone (DDQ) must be used (10). Virtually all of the lithium may be removed from $Li_xV_6O_{33}$ or $Li_xV_6O_{13+y}$ by DDQ to recover the host oxide unchanged. This is demonstrated by the reappearance of the metal-insulator transition in the magnetic susceptibility.

V_6O_{13} and V_6O_{13+y} cathodes.—Both V_6O_{13} and V_6O_{13+y} have been evaluated as active cathode materials for use in nonaqueous secondary lithium cells (9). The capacities of cells containing stoichiometric V_6O_{13} typically range up to 0.6Li/V for the first charge/discharge cycle, then decay slightly on subsequent cycles (Fig. 5). Blending stoichiometric V_6O_{13} with 50% graphite (by weight) does not appreciably increase the initial cell capacity, but such cells retain their capacity longer (Fig. 6). Cells with V_6O_{13+y} and graphite exhibit initial capacities of ≈1.0Li/V (Fig. 7). Without graphite capacities for V_6O_{13+y} cells may be diminished by as much as 50%. This is consistent with the reduced electronic conductivity at high Li concentrations.

Open-circuit potentials (OCV) of Li/LiAsF$_6$, PC/V_6O_{13+y} and Li/LiAsF$_6$, PC/V_6O_{13} cells were measured

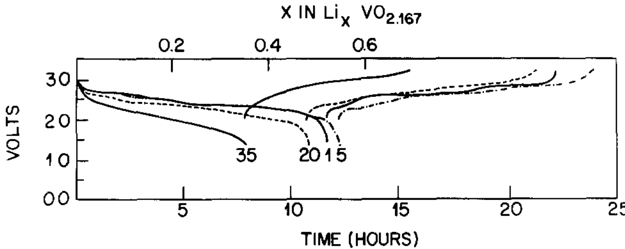

Fig. 5. Voltage vs. time and stoichiometry for a Li/LiAsF$_6$, PC/V_6O_{13} cell containing 14.4 mg V_6O_{13} cycled at 0.2 mA between voltage limits of 3.1 and 1.5. No conductive diluents were added. Cycle numbers are indicated.

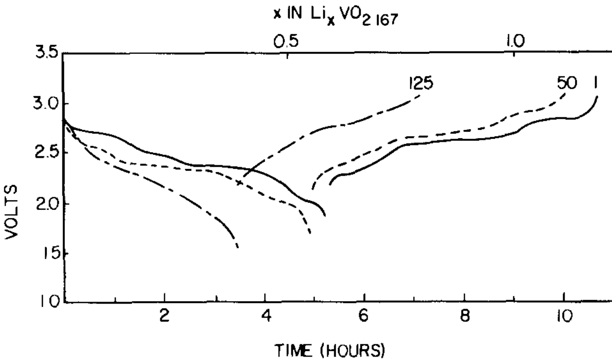

Fig. 6. Cycle data for a Li/LiAsF$_6$, PC/V_6O_{13}, C cell containing 5.8 mg V_6O_{13} and 5.8 mg graphite cycled at 0.2 mA.

as a function of state of charge. Cells were charged or discharged ~0.05Li/V between measurements. The OCV was taken after the measured value was unchanged for several hours. These results are shown in Fig. 8. The OCV curves are similar to the dynamic discharge curves for these materials.

Several distinct regions are present in these OCV curves. Results of x-ray powder diffraction also indicate the presence of at least three two-phase regions in Li_xVO_y ($0 < x < 1.2$). As x increases diffusion appears to slow down resulting in difficulty in reaching equilibrium at $x > 1.0$ for $y = 2.194$ and $x < 0.5$ for $y = 2.17$. This is also consistent with increased lithiation at elevated temperatures.

Cells containing V_6O_{13} without graphite can be discharged to zero volts briefly (<2 hr) with no apparent degradation of performance, whereas cells containing V_6O_{13+y} rapidly fail after such a discharge. Some protection from low voltage damage is afforded by heat-treating the V_6O_{13+y} at temperatures between 575° and 675°C *in vacuo*. At these temperatures, limited sintering of the particles occurs. Although the heat-treated V_6O_{13+y} appears to result in less degradation at low voltages, cells containing this material have only 25-45% of the capacity of the untreated material.

In addition to electrolyte and/or cathode decomposition at low voltages, cells containing 1M $LiClO_4$/propylene carbonate electrolyte are also susceptible to irreversible oxidation by V_6O_{13} above 3.0V during charging. This process appears to be catalytic and once initiated continues as long as current is passed through the cell. This electrolyte oxidation by V_6O_{13} is alleviated by using LiAsF$_6$ in PC.

The capacities of V_6O_{13} and V_6O_{13+y} cells were found to be strongly dependent on the operating temperature. A cell containing V_6O_{13} was cycled at −16°, 0°, 45°, and 70°C (Fig. 9). After five cycles at room temperature the cell capacity had stabilized at ~0.7Li/V. When the cell was cooled to −16° the capacity dropped to <25% of the room temperature value. At 0° the capacity was nearly 75% of the room temperature value. At 45° the capacity was almost 20% greater than the value at room temperature. Although the cell capacity at 70° was considerably greater than at room temperature, only limited cycling data could be collected since the rate of electrolyte decomposition was also greatly accelerated. At higher temperatures the discharge data of V_6O_{13} resembles that of V_6O_{13+y} at room temperature.

$VO_2(B)$.—The VO_2(B) prepared by the procedure of Theobald and co-workers (15, 16) exhibited an

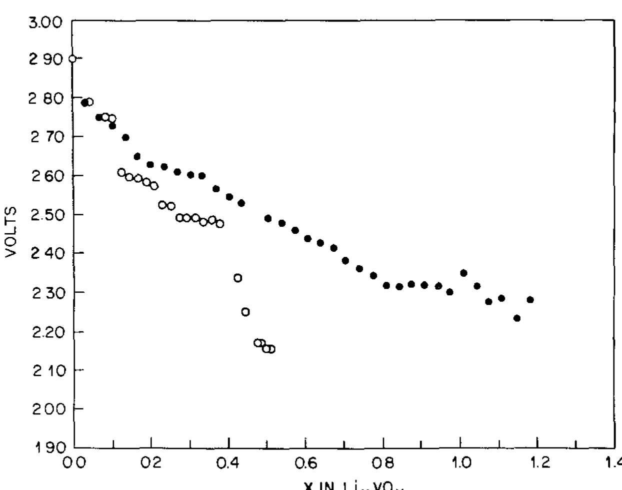

Fig. 8. Open-circuit voltages (OCV) for $VO_{2.167}$ (open circles) and $VO_{2.175}$ (closed circles) cells as a function of lithium stoichiometry.

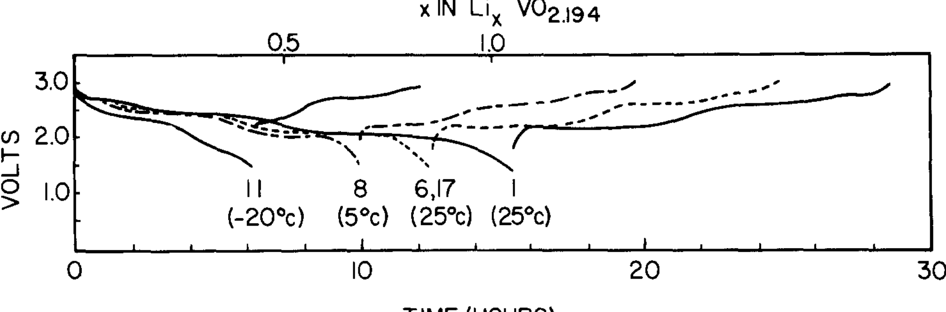

Fig. 9. Cycle data for a Li/ $LiAsF_6$, PC/$VO_{2.167}$, C cell as a function of temperature.

x-ray diffraction powder pattern which was consistent with that of the oxide B prepared by Sato and Ito (32) and the $VO_2 \cdot yH_2O$ described by Deschanvres *et al.* (33). The compressed powder resistivity of $VO_2(B)$ at room temperature is of the same order of magnitude as that of V_6O_{13} in contrast to the measurements reported by Sato and Ito (32). Also, the magnetic susceptibility of $VO_2(B)$ exhibits a broad peak at ~250 K as previously reported (32). However, the precise mechanism responsible for producing the peak is not known. Assuming a localized spin ($g = 2$, $S = 1/2$) for the d^1V^{+4} ions, the susceptibility for $VO_2(B)$ calculated from the Curie law of $+15.1 \times 10^{-6}$ emu/g is close to the observed value of $+14.2 \times 10^{-6}$ emu/g at 300 K and is nearly twice that of rutile VO_2 ($+7.6 \times 10^{-6}$ emu/g). As previously reported (15) $VO_2(B)$ was observed by DSC to undergo a transformation to the more stable rutile structure when heated in an inert atmosphere above 450°. This transformation has an onset temperature of 440° ± 20° and is exothermic with a heat of −200 ± 25 cal/mol. DSC analysis of samples of $VO_2(B)$ annealed at 500°C revealed the presence of an endotherm at ~69°C characteristic of the metal/insulator transition of rutile VO_2. The x-ray diffraction patterns of these samples are consistent with that of rutile VO_2. Very weak lines assignable to V_6O_{13} were also present. However, it is not certain whether V_6O_{13} was produced in the transformation or if it was present as an impurity in the $VO_2(B)$ since some of the lines of $VO_2(B)$ overlap with those of V_6O_{13}.

Lithium bronzes of $VO_2(B)$.—Treatment of solid $VO_2(B)$ with a dilute hexane solution of n-butyllithium at room temperature affords lithium bronzes $Li_xVO_2(B)$ for $0.5 < x < 0.85$. Treatment of $VO_2(B)$ with a solution of LiI in acetonitrile results in some lithium incorporation (~0.12Li/V) at room temperature. Conversely, most of the incorporated lithium (~80%) can be removed from $Li_xVO_2(B)$ by oxidation with a solution of iodine in acetonitrile.

The x-ray powder diffraction data obtained for several $Li_xVO_2(B)$ bronzes are given in Table IV and the calculated monoclinic unit cell parameters in Table V. The powder patterns of these $Li_xVO_2(B)$ bronzes closely resemble that of the parent $VO_2(B)$ as well as $Na_{0.2}TiO_2$ (34).

The thermal stability of $Li_xVO_2(B)$ bronzes as measured by DSC is somewhat improved over $Li_xV_6O_{13}$. The $Li_xVO_2(B)$ bronzes are thermally stable up to ~400° in an inert atmosphere. Thus, $Li_xVO_2(B)$ is nearly as thermally stable as the parent $VO_2(B)$. This stabilization may arise from the presence of lithium in the cavities. Andersson and Wadsley (34) suggested that the isomorphous $Na_{0.2}TiO_2$ is stabilized by the presence of the sodium ions. The analogous alkali-free $TiO_2(B)$ and $Li_xTiO_2(B)$ ($x < 0.85$) have recently been reported (35).

Other vanadium oxides.—Of the other vanadium oxides evaluated, $VO_2(B)$ appears to be the most promising candidate, after V_6O_{13} and V_6O_{13+y}, for use as a battery cathode material. Nonaqueous lithium cells with cathodes containing $VO_2(B)$ exhibit lower average voltages, less capacity, and poorer rechargeability than cells containing V_6O_{13}. With a charging voltage limit of 3.1V and a discharging voltage limit of 1.0V, $Li/LiClO_4$, $PC/VO_2(B)$ test cells gave initial capacities near 0.5Li/V which decayed slowly with cycling (Fig. 10). After 15 discharge/charge cycles the capacity decreased to ~65% of its value on the initial discharge. Similar performance was observed for cells using a 1.0M $LiAsF_6$/PC electrolyte. As observed for V_6O_{13}, the addition of graphite to the $VO_2(B)$ cathodes failed to increase the capacity. The capacity can be increased by heating the cell above room temperature. At ~60°C a cell containing $VO_2(B)$ and $LiAsF_6$/PC electrolyte exhibited a 65% increase in capacity. However, prolonged cycling at elevated temperature quickly results in cell failure presumably due to electrolyte decomposition.

The other vanadium oxides evaluated in this study, V_4O_9 and V_3O_7, were prepared by several methods. Kawashima and co-workers reported that the thermal decomposition of NH_4VO_3 at 500°C *in vacuo* affords V_3O_7 by TGA (22). In this work, the rapid thermal decomposition of NH_4VO_3 in an inert gas stream gave mixtures of V_3O_7 and V_6O_{13}. It has also been reported that V_3O_7 was prepared by reducing V_2O_5 with SO_2 under mild conditions (36). However, we detected no V_3O_7 in the reaction products for such a reduction. We were most successful in preparing pure V_3O_7 from finely divided V_2O_5 and freshly reduced V_2O_3 by standard solid-state techniques (18, 19). V_4O_9 was prepared by the reduction of V_2O_5 in a stream of anhydrous SO_2 at 400°C. This product exhibits a powder x-ray diffraction pattern which is consistent with that reported by Théobald and co-workers (17) for phase E, Sato and Ito (32) for oxide A, and Kawashima and co-workers (22) for V_4O_9.

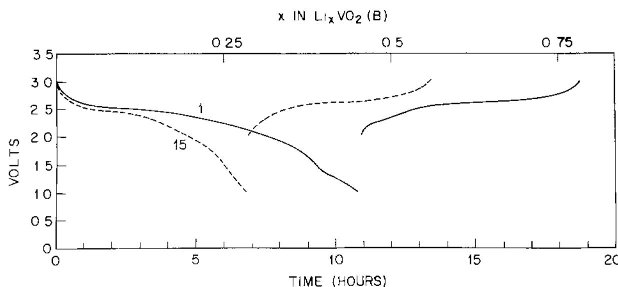

Fig. 10. Cycle data for a $Li/LiClO_4$, $PC/VO_2(B)$, C cell containing 14.8 mg $VO_2(B)$, 14.8 mg graphite, and cycled at 0.2 mA.

Treatment of V_3O_7 and V_4O_9 with dilute solutions of n-butyllithium in hexane at room temperature results in the consumption of ~1.2Li/V by V_3O_7 and ~1Li/V by V_4O_9. However, less than one-half of this lithium can be removed by oxidation with I_2. Furthermore, the lithiated materials appear to be amorphous to x-rays. Thus it appears that these oxides do not maintain their basic structural integrity on reaction with lithium.

V_3O_7 and V_4O_9 cathodes.—The capacities of cells containing V_3O_7 or V_4O_9 are considerably less than those typically observed for cells containing V_6O_{13}. A cell containing V_3O_7 blended with 50% graphite (by weight) exhibited an initial discharge capacity of ~0.9Li/V which decreased to ~0.3Li/V after 15 cycles (Fig. 11). This capacity was maintained for over 20 cycles. The initial irreversibility is not unexpected on the basis of the chemical lithiation-delithiation results. Also, the overall shape of the latter discharge curves is distinct from that of the initial curve and resembles that of cells containing heat-treated V_6O_{13+y}. It appears likely that the initial lithiation of V_3O_7 during the first discharge of the cell converted a substantial amount of the vanadium oxide framework to the V_6O_{13+y} structure. Cells made using V_4O_9 deteriorated even more rapidly and no stabilization of capacity was observed.

Conclusion

Of the vanadium oxides evaluated in the course of this work, only cells containing V_6O_{13} and V_6O_{13+y} consistently exhibited substantial capacities, good rechargeability, and high average potentials. Because of their exceptional overall performance, both V_6O_{13} and V_6O_{13+y} are outstanding candidates for use as active cathode materials in nonaqueous lithium secondary batteries.

Anodic Corrosion of Fiber Reinforced Lead Composites for Use in Large Lead-Acid Batteries

C. M. Dacres,* S. M. Reamer, R. A. Sutula,* and I. A. Angres

Naval Surface Weapons Center, Materials Division, Silver Spring, Maryland 20910

ABSTRACT

The corrosion resistance of lightweight, high strength lead metal matrix composites under conditions that simulate their use as grid materials in large lead-acid batteries has been studied. Constant potential testing provides an effective means for holding constant the oxidizing power of a metal-electrolyte system. Data are presented on corrosion currents, effect of exposure time on corrosion rates, dependence of the rate of corrosion on temperature, and the current flow that is proportional to the rate of corrosion.

Corrosion of the positive plate support grids is a major cause of failure in lead-acid secondary batteries. This corrosion problem limits the service lifetime of large lead-acid batteries. These batteries are maintained for most of the time in a fully charged condition. When battery power is needed, they must perform reliably in high rate, deep discharges.

The development of lightweight grid materials made of pure lead reinforced with strong nonmetallic fibers provides a possible solution to the corrosion problem. Pure lead is resistant to corrosion in sulfuric acid electrolyte, but grids made of pure lead lack adequate mechanical strength and the ability to resist deformation. Improved strength has been achieved by employing metal matrix composites technology to fabricate new experimental grid materials of fiber reinforced lead.

The main purposes of this study are to assess the corrosion resistance of new lead metal matrix composite battery grid materials in sulfuric acid electrolyte and to provide a basis for predicting grid corrosion rates from accelerated corrosion rate data at elevated temperatures obtained in the laboratory.

* Electrochemical Society Active Member.
Key words: corrosion, lead-acid batteries, power.

The shortening of the time for corrosion testing of grid materials used in lead-acid batteries at high temperatures was demonstrated by Willihnganz (1) in his work with cells on float service. However, the anodic corrosion of pure lead was first studied in detail by Lander (2-4). He combined thermodynamic thought with a kinetic approach to relate the mechanism of the positive plate reactions to the actual conditions in battery service. It was demonstrated earlier by Haring and Thomas (5) that the Pb/Ca alloy corroded much slower than Pb/Sb and at a rate comparable to that of pure Pb. Major work was conducted by Weininger and Morelock (6) in which conducting carbon fibers were introduced into the positive grid. An extensive study of lead alloys at high anodic potentials was done by Weininger and Siwek (7) in which Pb/Sb, Pb/Ca, and Pb/Ca/Sn alloys were maintained at constant high float charge, then examined metallographically.

We are reporting here initial corrosion studies. The materials studied were four experimental lead metal matrix composite grid materials, two conventional lead-based alloy grid materials, and pure lead.

Experimental Procedure

Materials.—Samples of five different materials used in this study were obtained from commercial sources in the form of long, thin rods with lengths between 10 and 25 cm, and cross-sectional areas between 0.25 and 0.1 cm^2. Descriptive information provided by the suppliers is given in Table I. Samples designated in this report as X1, X2, and X3 were three lead-alumina fiber composite materials (Pb/FP) prepared by three different methods. Samples designated Y were lead-carbon fiber composites. The lead alloy and pure lead samples designated A, B, and L were included in the study for comparison purposes.

Electrochemical corrosion testing.—Corrosion studies were performed in a 1.285 specific gravity sulfuric acid electrolyte at 70°, 60°, and 50°C. The materials were tested in a static constant potential mode. The anode to mercury-mercurous sulfate reference potential was maintained potentiostatically to approximate float service conditions of the battery. A schematic of the experimental arrangement is shown in Fig. 1. The test cells were housed in 10 liter Pyrex glass chromatography jars. The temperature was maintained by immersing the jars in a large constant temperature water bath.

The counterelectrodes were lead grid sheets which lined the walls of the chromatography jars. The working electrodes were those listed in Table I. They were fitted through rubber stoppers which were placed through the Teflon covers of the jar. These electrodes were suspended in the electrolyte towards the center of the cell. Each type of electrode was placed in a separate chromatography jar.

Electrical contacts were made through gold-plated battery clips. A constant potential of 1.226V anodic to the mercury-mercurous sulfate reference electrode was maintained using a DH Model potentiostat (8). The current flowing between the working electrode and the counterelectrode was recorded as a direct measure of the instantaneous corrosion rate.

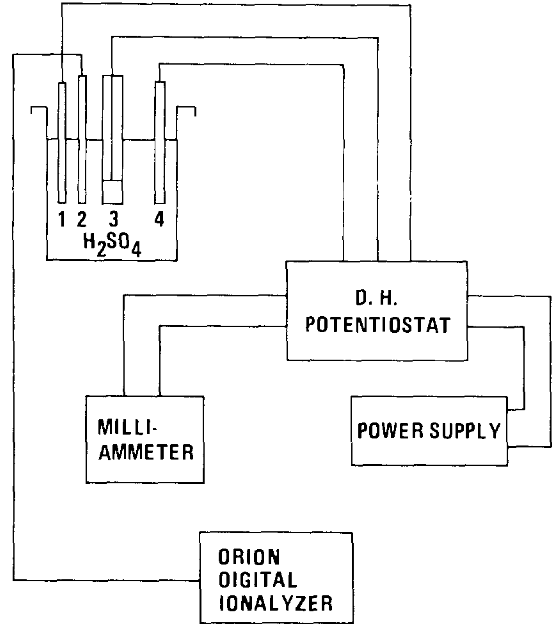

Fig. 1. Diagram of apparatus for investigating the anodic corrosion of metal matrix materials.

Test samples were mechanically cleaned and rinsed with distilled water and acetone. They were dried overnight in a desiccator, then measured and weighed before immersion in the sulfuric acid. After the corrosion period, the test samples were washed and dried with acetone and reweighed. The adhering corrosion products were removed by stripping in a hot hydrazine sulfate-mannitol-hydroxide solution. The samples were studied using the electron microscope.

Results and Discussion

Comparison of corrosion currents vs. time.—A comparison of the current densities of the various samples is shown in Fig. 2 for accelerated testing conditions at 70°C. Most of the corrosion currents were initially high except for pure Pb and Pb/FP-X2. The high corrosion currents declined sharply as the anodic (oxide) layer covered the specimens. At times a sharp rise in current is observed which indicates a rapid breakdown of this

Table I. Composition of grid material samples

Designation	Material	Preparation method	Composition: Volume percent Al_2O_3	Volume percent C	Weight percent Ca	Weight percent Sn
Experimental materials						
X1	Lead-alumina fiber composite	Liquid lead infiltration Fiber bonding method—unknown HF mold release agent	25			
X2	Lead-alumina fiber composite	Liquid lead infiltration Fiber bonding method—unknown Mold release method—unknown	7.5

Conventional and standard materials						
A	Lead-calcium alloy	Cast			0.07	
B	Lead-calcium-tin alloy	Cast			0.065	0.66
L	Pure lead	Cast				

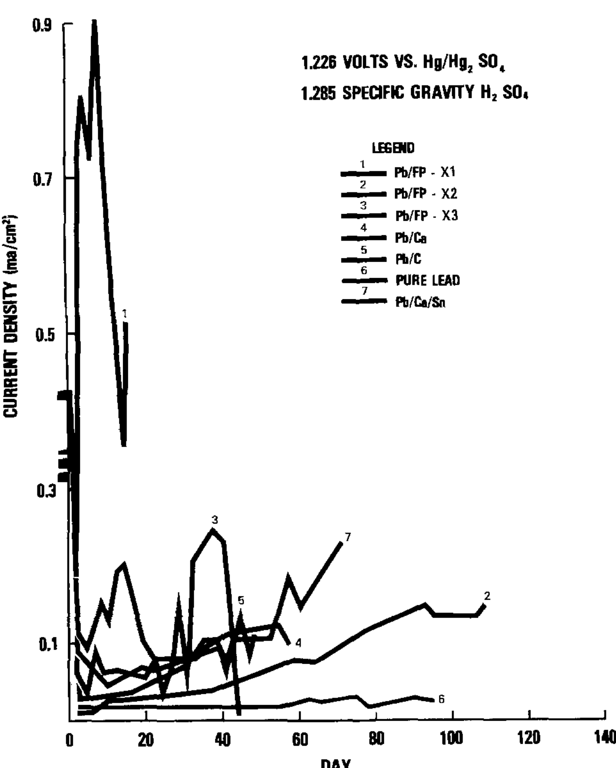

Fig. 2. Measured current densities vs. time at 70°C

oxide film. Corrosion currents for the fiber reinforced materials fell to very low values toward the end of the testing period when the samples physically fell apart and appeared to be no longer capable of conducting any appreciable current. However, the corrosion currents for the alloys increased with time.

The Pb/FP samples frayed at the lower end (Fig. 3) where the electrolyte infiltrated the fibers. The SEM for sample X1 (Fig. 4) shows that the fibers were completely separated from the lead by corrosion products. This indicates insufficient bonding at the lead-fiber interface which allowed electrolyte to diffuse into the interface, thus corroding the lead.

Distortion was peculiar to the graphitic samples (Fig. 5). Also, pitting along the seams where the fibers became exposed was observed. The distortion is attributed to intergranular corrosion whereby the products accumulate along the grain boundaries creating the forces which distort the sample.

Pb/Ca alloy is a conventional grid material for lead-acid batteries and was included in this study for comparison purposes. The surface of these samples was severely etched and stress corrosion cracks developed (Fig. 6). The cracks weakened the sample making it physically incapable of supporting a load.

Accelerated studies on X2 show that the samples were less severely corroded than X1. The reason is believed to be improved bonding of lead to the fibers as seen in Fig. 7. Also, X1 has 25% volume fiber loading as opposed to 7.5% in X2. This suggests that there is some relationship between the fact that the higher the volume of fibers incorporated in the lead structure, the more susceptible the structure is to corrosion.

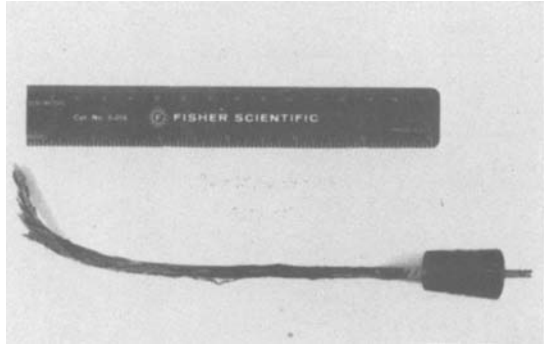

Fig. 3. X1 specimen after corrosion

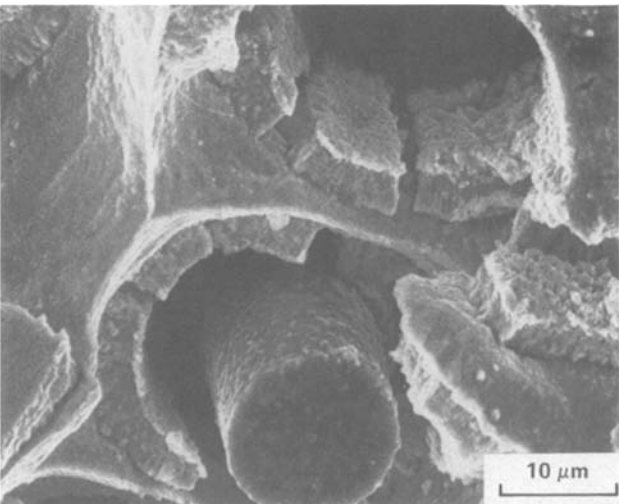

Fig. 4. Micrograph showing a buildup of corrosion products around the fibers in the X1 sample.

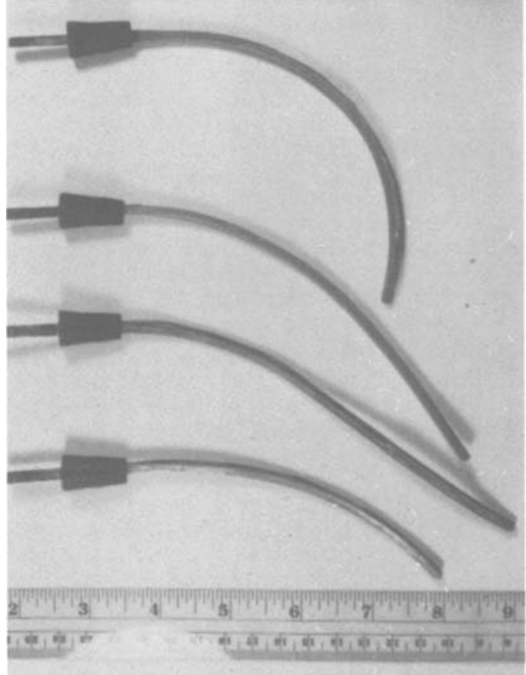

Fig. 5. Y samples after corrosion at 70°C

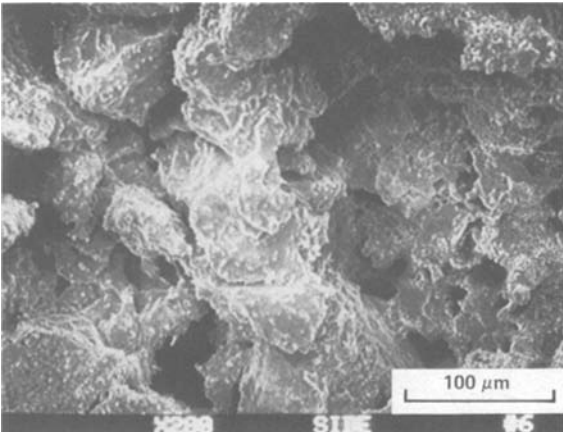

Fig. 6. Corroded surface of sample A

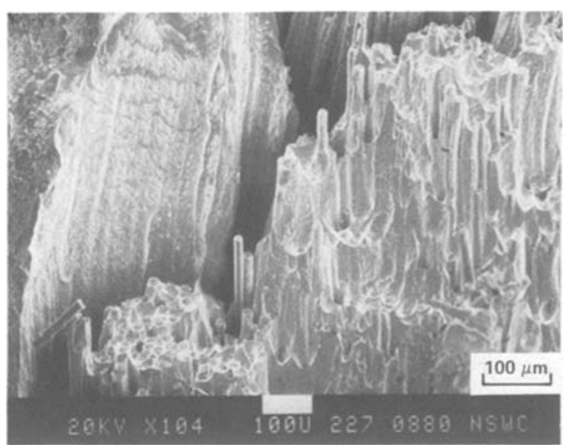

Fig. 7. X2 sample showing improved bonding

Comparison of corrosion rates.—The corrosion rate was determined electrochemically, where the resulting corrosion current densities are converted to corrosion rates through Faraday's law (9)

$$\text{Corrosion rate (mpy)} = 0.1288I\ (\mu\text{A/cm}^2)\ \frac{\text{eq. wt. (g)}}{\rho(\text{g/cm}^3)}$$

where I = current density, ρ = specimen density, and eq. wt. = specimen equivalent wt.

The calculation was based on the assumption that the anodic corrosion of lead occurs through the reaction (2)

$$Pb + 2H_2O \rightarrow PbO_2 + 4H^+ + 4e^- \quad [1]$$

Figure 8 contains a summary of average corrosion rates in units of mils per year (mpy) of various types of battery grid materials.

Effect of exposure time on corrosion rates.—The effect of exposure time on the corrosion rates of various samples is represented in Fig. 9. The curves A(Pb/Ca) and B(Pb/Ca/Sn) show an increase in corrosion

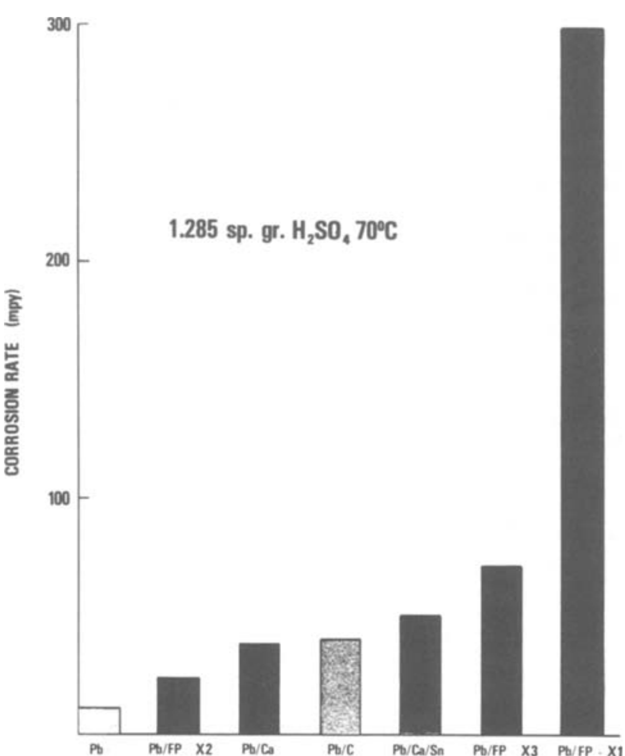

Fig. 8. Relative corrosion rates of lead samples

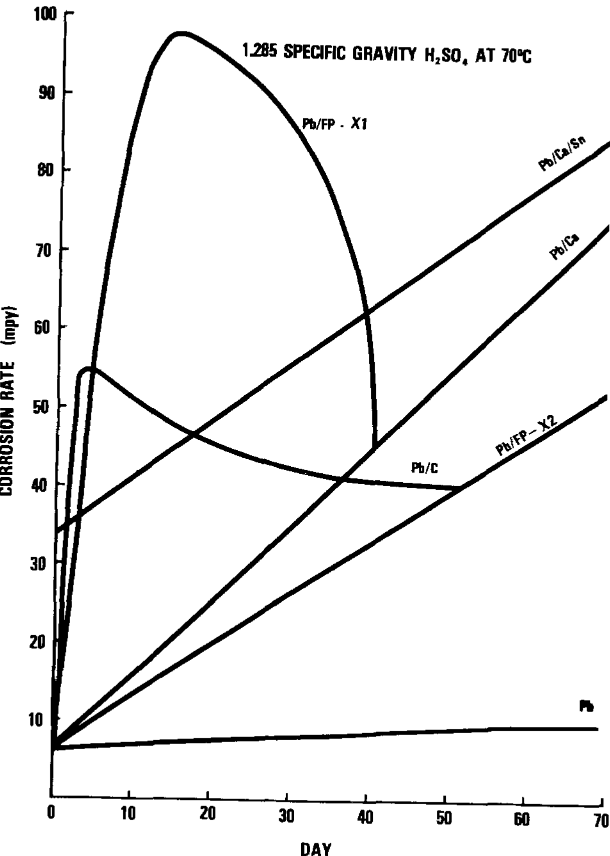

Fig. 9. Effect of exposure time on the corrosion rates of various lead samples.

rate due to acceleration of attack. This can be attributed to the relatively high solubility of the corrosion products in the acidic environment which inhibits the formation of a protective layer.

The corrosion rate/time curves for X1(Pb/FP) and Y(Pb/C) show an initial increase due to the acceleration of attack by the alumina and graphitic residue produced initially. This is followed by a decrease in rate as the residue becomes plugged with insoluble corrosion product and carbonaceous debris.

The X2 samples display a corrosion rate/time curve unlike those of other fiber reinforced materials. Its curve appears to be similar to those of lead alloys.

Prediction of corrosion rates.—Corrosion studies have been done on Y and B at 50° and 60°C, and the ratio of corrosion rates has been compared with those at 70°C. Figures 10 and 11 show that at lower temperatures the corrosion of the Y samples is considerably less and the distortions are also less than the distortions seen in Fig. 5. The bonding between the lead and the graphitic fibers remains good even during the corrosion period.

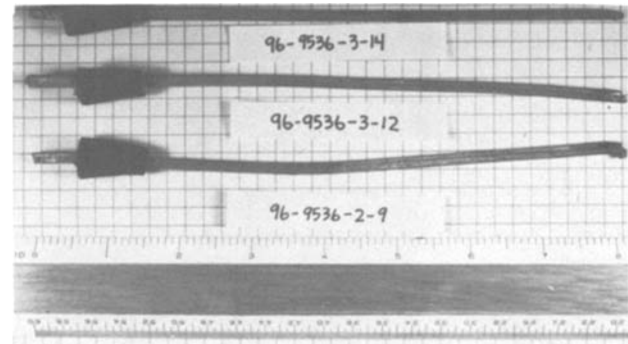

Fig. 10. Photograph showing little distortion of sample Y at 50°C

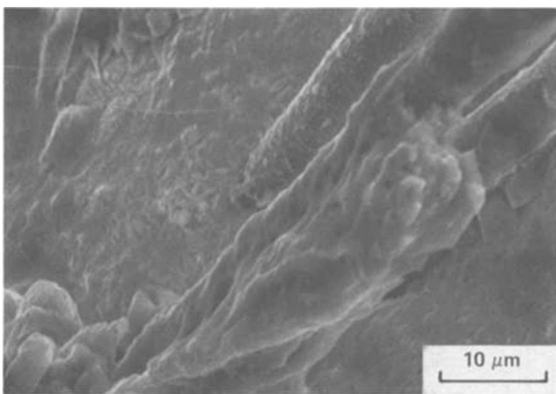

Fig. 11. Micrograph of sample Y after corrosion at 50°C

The corrosion rate data were linear for specimens Y and B. Figure 12 consists of plots of the log of the corrosion rates *vs.* the reciprocal of Kelvin temperature. These plots were extrapolated to room temperature permitting a prediction of the corrosion rates.

Weight-loss measurements.—The Pourbaix diagrams of reactions in the lead-sulfuric acid system (10) indicate that at the potential used in these studies (1.226V *vs.* the Hg/Hg_2SO_4 reference) both the oxidation of lead to PbO_2 by reaction [1] and the oxidation of water by the reaction

$$2H_2O \rightarrow 4H^+ + O_2 + 4e^- \quad [2]$$

can occur. The observation of gassing at the surface of the samples strongly supports at least the second of these two reactions. Because some of the current is being used up through reaction [2] it is difficult to make a direct correlation at this time between measured weight changes in the sample and weight changes according to Faraday's law. However, even though the mass loss of the samples may not be directly proportional to the current, a high current will indicate a high rate of corrosion.

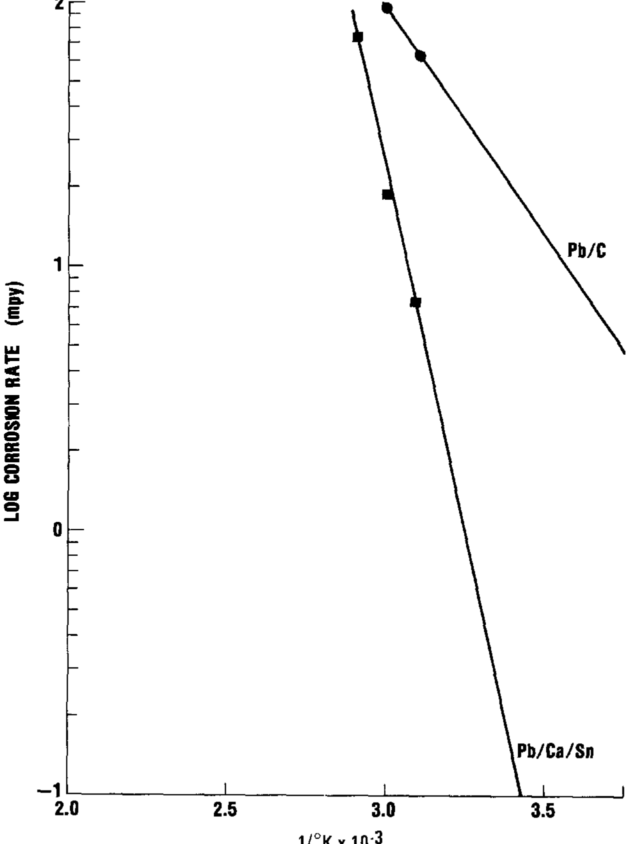

Fig. 12. Log of corrosion rates *vs.* temperature

Conclusions

On the basis of corrosion studies described in this article, it may be concluded that the equipment and methods employed are suitable for comparing the relative corrosion resistance of candidate grid materials. The major findings of this study in terms of the relative corrosion behavior of the samples studied are:

1. An important need in the selection of corrosion-resistant materials for battery grids is the correlation of laboratory studies with actual grid corrosion performance in battery service. The effects of temperature, float potential, and time on corrosion rates are not yet well enough understood to permit such correlations.

2. All of the samples were severely damaged, deformed, elongated, and weakened by corrosive oxidation in the sulfuric acid electrolyte except X2 and, of course, pure Pb.

3. The extremely severe and rigid corrosion of X1 was apparently a direct result of poor bonding between the lead and the alumina fibers.

4. The greatly improved behavior of X2 confirms the expectation that in fiber reinforced materials the wetting process between the fiber and the metal is extremely critical in the control of corrosion processes.

5. The Pb/Ca alloy, which is representative of a conventional grid material for lead-acid batteries, was severely weakened by etching and stress corrosion cracking.

6. The relationship between volume percentages, weight percentages, and corresponding corrosion rates emphasizes the fact that the ratio of lead to the amount of fiber used in strengthening the lead cannot be ignored in utilizing metal matrix materials.

Effect of Sulfide Ions on Caustic Cracking of Mild Steel

Douglas Singbeil and Desmond Tromans*

Metallurgical Engineering Department, University of British Columbia, Vancouver, B.C., Canada V6T 1W5

ABSTRACT

Potentiostatically controlled slow strain rate ($\dot{\epsilon} = 3.3 \times 10^{-6}$/sec) tensile tests were conducted on AISI 1018 mild steel in hot (92°C) caustic solutions of 3.35M NaOH and 2.5M NaOH + 0.423M Na_2S in a chemically inert cell. Reduction of area was used as a measure of susceptibility to stress corrosion cracking (SCC). The presence of sulfide ions raised the active-passive transition potential to more noble values, and maximum susceptibility to SCC occurred at potentials near the active-passive transition in each environment. Cracking at these potentials was further confirmed by conducting tests on prefatigue cracked double cantilever beam specimens at a known stress intensity, and crack fractography was studied by scanning electron microscopy. Crack liquid pH measurements were obtained with pH indicator paper using a freezing technique. A hydrogen embrittlement mechanism of SCC was eliminated from consideration in both environments on thermodynamic grounds. All observations were reasonably consistent with a dissolution mechanism of SCC involving film rupture events.

Several studies have shown that the caustic stress corrosion cracking (SCC) of mild steels exposed to hot, highly alkaline, aqueous NaOH solutions is associated with a small range of potentials near the active-passive transition potential (1-5). More recently, anodic polarization studies in hot alkaline and alkaline sulfide solutions showed that the presence of sulfide ions raised the active-passive transition potential to more noble potentials relative to the sulfide-free solutions (6, 7). This led to the suggestion (6) that there should be a corresponding change in the potential range for SCC due to the presence of sulfide. Confirmation of this prediction has both fundamental significance with regard to the understanding of SCC and practical consequences for prediction of SCC in hot, industrial alkaline sulfide solutions (white liquors) employed in the Kraft process for producing pulp from wood chips. In fact, some of the results from the present study have already been applied to SCC considerations in the pulp and paper industry (8).

The current program was designed to evaluate the effect of sulfide on the potential regime of SCC susceptibility of mild steel by conducting comparative tests in hot aqueous solutions of NaOH and NaOH + Na_2S, similar to those compositions employed previously (6). Slow strain rate tensile testing techniques (9, 10), conducted under potentiostatic control, were used for the initial evaluation of the potential regimes of SCC susceptibility. Confirmation of SCC in the susceptible regimes was obtained via the techniques of fracture mechanics, whereby potentiostatically controlled SCC propagation tests were conducted on prefatigue cracked double cantilever beam (DCB) specimens at a known stress intensity (K_I). In addition, fractographic studies were conducted on specimens subjected to SCC in the presence and absence of sulfide, and attempts were made to determine the pH of the solution within the stress corrosion crack.

Experimental

Tests were conducted on two batches of AISI 1018 mild steel. One batch was received as cold drawn cylindrical rod of 9.5 mm diam and the second batch was received as cold drawn bar with a square cross section, 31.8 $\times$ 31.8 mm. Chemical analyses of the two batches are shown in Table I.

Tensile test pieces for slow strain rate tests, machined from the rod, were 254 mm long with threaded ends for grips and a reduced gage section 25.4 mm long and 5 mm in diameter. The gage section was mechanically polished with 320 grit paper, degreased in chlorethane, cleaned in 10 volume percent (v/o) HCl, rinsed in water and alcohol, and dried. Subsequently, each specimen was annealed under vacuum at 920°C for 0.75 hr, air cooled, electropolished for 60 sec at 30V in a solution containing 135 ml CH_3COOH + 0.025 kg Cr_2O_3 + 7 ml H_2O, rinsed in water and alcohol, dried, and tested. The yield stress of the annealed specimens at 92°C was 297 MPa.

Double cantilever beam specimens (DCB) for fracture mechanics SCC testing were prepared from the bar by machining to the configuration shown in Fig. 1. The specimens were crack-line loaded single-edge crack specimens. Beam height (H) was 11.6 mm, specimen length from the loading line (W) was 66.7 mm, and specimen thickness (B) was 25.4 mm. Initial length of machined precrack from the loading line (a) was 25.4 mm. The beams were threaded to receive grips for application of load (P). Brown and Srawley (11) have shown that the stress intensity (K_I) calibration for the DCB specimen is given by Eq. [1] for a/W values up to 0.6, provided $W/H \geqq 5$

$$K_I = \frac{P \cdot a}{BH^{3/2}} \left(3.45 + 2.415 \frac{H}{a}\right) \qquad [1]$$

Final preparation involved mechanically polishing the faces to 600 grit, followed by washing in ethanol. The machined pre-crack was sharpened and extended a further ~2 mm by fatigue cracking at a K_I level of 12 ± 11 MPa · $m^{1/2}$. All DCB specimens were subjected to SCC in the as-received, cold-worked condition. The yield strength at 92°C was 523 MPa.

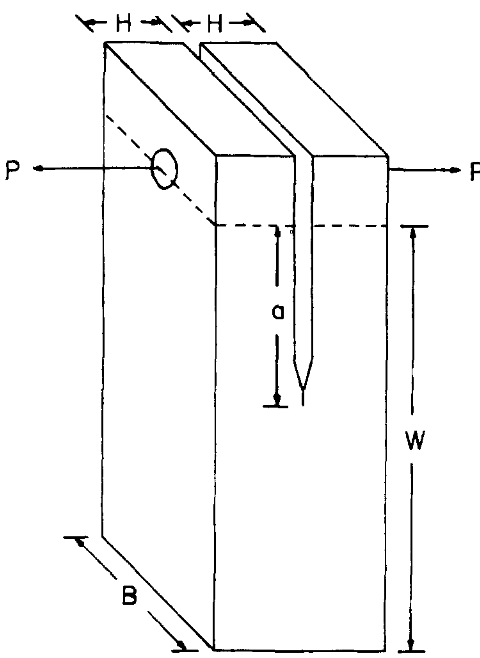

Fig. 1. Specimen geometry of double cantilever beam (DCB) specimen.

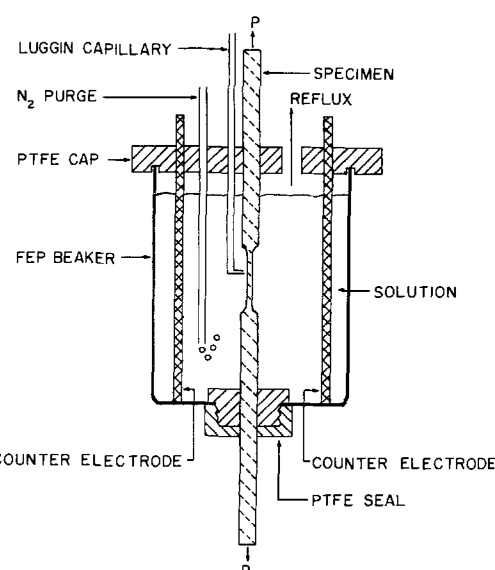

Fig. 2. Schematic diagram of test cell for slow strain rate testing, where *P* represents load applied by tensile machine.

Two test solutions, containing (*i*) 3.35M NaOH and (ii) 2.5M NaOH + 0.423M Na_2S, were prepared from reagent grade NaOH and $Na_2S.9H_2O$, using distilled water. Total Na^+ molality in each was 3.35M.[1] Nitrogen purging was employed during preparation and testing to prevent oxidation of sulfide. Calculations (6) showed that the pH of both solutions was near 14 at room temperature and near ~12 at test temperature (92°C).

Potentiostatic control was obtained via a Princeton Applied Research potentiostat (Model 173), equipped with an electrometer probe (Model 178), logarithmic converter (Model 376), and universal programmer (Model 175). Potentials were measured with respect to a room temperature saturated calomel reference electrode connected via a saturated KCl salt bridge to the Luggin capillary, which terminated ~1 mm from the specimen surface. Potential and current were recorded on a Houston Omnigraphic X-Y recorder (Model 2000). All potentials are reported with respect to the standard hydrogen electrode (SHE). No attempt was made to correct for negligibly small potential differences arising from concentration and thermal gradient effects in the salt bridge. All tests were conducted at 92° ± 1°C, corresponding to that usually found in industrial white liquor storage vessels and clarifiers.

Slow strain rate tests, using an Instron tensile machine, were conducted in 550 ml of solution contained within a Teflon cell (PTFE or FEP polymers), as shown in Fig. 2, which contained two graphite counterelectrodes, plus an FEP coated thermistor probe for temperature control. The specimen surface above and below the gage section was protected with PTFE tape. A potential of $-1.01V_{SHE}$ (~120 mV below the corrosion potential, E_{CORR}) was impressed upon the specimen for 120 sec. Thereafter, the potential was raised at 1 mV/sec until the desired test potential was reached. The specimen was then tested to fracture at a strain rate ($\dot{\epsilon}$) of 3.33×10^{-6} sec^{-1}. The percentage reduction in area at final fracture was determined by microscopy and plotted as a function of potential. The potential region of maximum SCC susceptibility was designated by those potentials giving rise to the smallest reduction in area (9, 10). Separate anodic polarization tests were conducted on unstrained specimens in fresh solutions at scan rates of 1 mV/sec.

Potentiostatically controlled SCC tests were conducted on the DCB specimens in a cell (Fig. 3) of similar size and materials to the slow strain rate cell. The solution was stirred via a Teflon coated magnetic stirrer. The specimen was wrapped in Teflon tape, except for the crack tip region, to minimize total current requirements and changes in solution composition during potentiostatic control. The whole assembly was placed in a horizontally mounted Hounsfield Tensometer tensile machine.

The specimen potential was raised to the preselected value and an initial load (*P*) applied to the specimen to produce a known stress intensity (K_I) value. The SCC test was allowed to run for ~400 hr. During this time the elastic compliance of the test assembly was such that a small change in K_I occurred as a result of crack growth. Aliquots of the sulfide solution were analyzed periodically for sulfide concentration and additions of $Na_2S \cdot 9H_2O$ were made to maintain the desired concentration. At the termination of the test, the solution was replaced with liquid nitrogen and the specimen broken by increasing the load (P). The fracture surfaces were examined under a travelling microscope, where SCC was clearly distinguishable from the fatigue precrack and brittle (cleavage) overload failure in liquid nitrogen. An average propagation

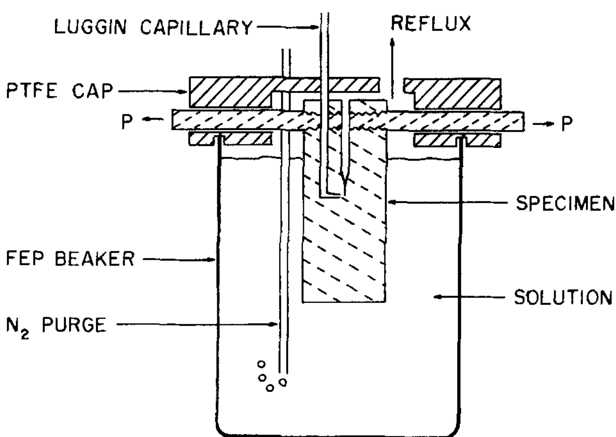

Fig. 3. Schematic diagram of test cell for testing of double cantilever beam (DCB) specimens. The load *P* was applied by means of a horizontally mounted tensile machine.

[1]Concentration, M, is moles of solute per kg of H_2O.

rate (v) was obtained by dividing the SCC growth increment by the test time.

The *p*H of the frozen solution remaining near the stress corrosion crack tip of the DCB specimens was determined using the technique of Brown *et al* (12). Commercial *p*H indicator paper (Hydrion Paper), with colorimetric intervals of 0.5 *p*H units, was employed.

The stress corrosion crack fractography of the DCB specimens was studied by scanning electron microscopy (SEM). The crack surfaces contained iron corrosion products (6) which were first removed by ultrasonic cleaning in an inhibited solution of 3 ml conc. HCl + 4 ml 35% 2 Butyne-1, 4-diol + 4 ml H_2O that produces no artifacts (13, 14). Following cleaning, the specimens were washed in water and ethanol, dried, and examined in an ETEC Autoscan, using secondary electron imaging mode and 20 keV excitation.

After cleaning, some DCB specimens were sectioned longitudinally normal to the stress corrosion fracture plane, mechanically polished to 1 μm diamond finish, etched in 2 v/o HNO_3 in ethanol to reveal grain boundaries and pearlite, and then examined by SEM. In this manner, the relationship between grain boundaries and SCC was more easily determined.

Results

Slow strain rate studies.—The effect of potential upon reduction in area is shown for the NaOH solution in Fig. 4 and for the NaOH + Na_2S solution in Fig. 5. These data have been superimposed upon the corresponding anodic polarization curves, the general characteristics of which are similar to those described previously (6).

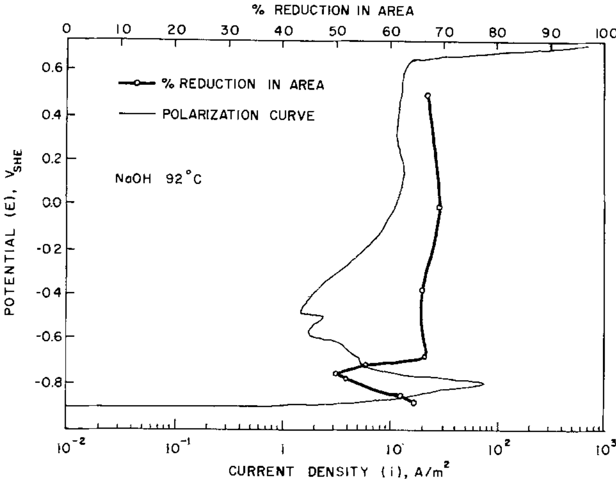

Fig. 4. Effect of potential upon reduction in area at $\dot{\epsilon} = 3.33 \times 10^{-6}$ sec^{-1}, and superimposed anodic polarization diagram, for mild steel in aqueous 3.35M NaOH.

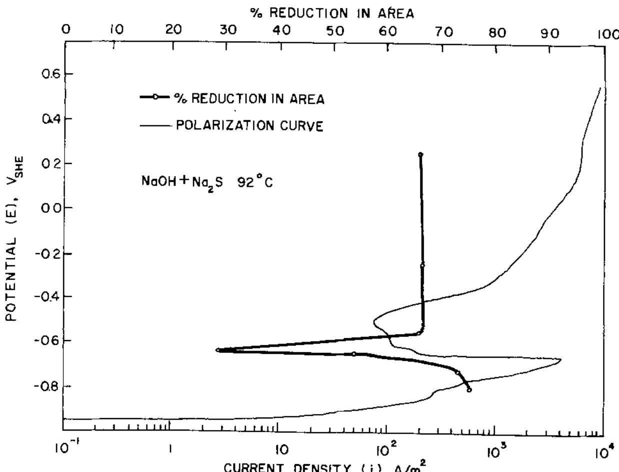

Fig. 5. Effect of potential upon reduction in area at $\dot{\epsilon} = 3.33 \times 10^{-6}$ sec^{-1}, and superimposed anodic polarization diagram, for mild steel in aqueous 2.5M NaOH + 0.423M Na_2S.

Clearly, Fig. 4 and 5 showed that the minimum reduction in area was associated with a potential close to, and slightly above, the active-passive transition potential in each solution. The minimum percentage reduction in area occurred at $-0.76V_{SHE}$ in NaOH and $-0.64V_{SHE}$ in NaOH + Na_2S.

Specimens which were fractured in the potential region giving rise to minimum reduction in area always exhibited numerous secondary surface cracks, as described elsewhere (8), whereas those fractured outside this region did not exhibit surface cracking. Consistent with these observations, the minimum reduction in area must have been associated with environment induced cracking, *i.e.*, SCC. Hence, the variation in reduction of area with potential, as shown in Fig. 4 and 5, was a measure of relative SCC susceptibility.

DCB tests.—Stress corrosion cracking tests were conducted on the DCB specimens at K_I levels near 50 MPa · m$^{1/2}$ and at potentials near the active-passive transition, which the slow strain rate tests had indicated to be the most severe. These were $-0.76V_{SHE}$ in NaOH and $-0.64V_{SHE}$ in NaOH + Na_2S. Cracking occurred in both solutions at average rates of the order of $\sim 1 \times 10^{-9}$ m/sec, the relative rate in NaOH being higher by a factor of two. The results are summarized in Table II, together with the slight variation in K_I which occurred during each test.

pH measurements.—Measurements of *p*H obtained from the crack liquid near room temperature gave a value of $\sim$14 in both solutions. This was the same value as that observed in the bulk solutions at room temperature. Hence, the measurements indicated no significant changes in *p*H within the crack during SCC.

Fractography.—The stress corrosion cracks in the DCB specimens remained in the initial crack plane with no tendency toward macroscopic crack branching. Longitudinally sectioned and etched specimens showed that the cracks followed a predominantly intergranular path along pearlite/ferrite boundaries and ferrite/ferrite boundaries. Occasionally, transgranular cracks through ferrite and pearlite were observed, the tendency being more noticeable in the NaOH solution. Figures 6a and b illustrate the general features of crack path.

Topographical characteristics of the stress corrosion cracks are shown in the SEM fractographs of Fig. 7a and b. The fractographs were obtained from near the crack tip, where dissolution and etching artifacts due to exposure of crack surfaces to the hot caustic environments were minimized. Intergranular crack topography and secondary microcracks were evident in both environments. In addition, a greater tendency for transgranular crack topography was observed in the NaOH solution, as evidenced in Fig. 7a.

Discussion

General.—The slow strain rate tests have shown that susceptibility to SCC is most pronounced in the passive region at potentials near the active-passive transition for the particular metal/environment combination concerned. The addition of sulfide ions to the NaOH solution raised the active-passive transition potential

Table II. Stress corrosion crack propagation rates (v) at 92°C

Solution (molality)	Potential (V_{SHE})	K_I (MPa · m$^{1/2}$)	v (m/sec)	
3.35 NaOH	−0.76	48-53	2.9×10^{-9}	2.4×10^{-9}
3.35 NaOH	−0.76	49-50	1.9×10^{-9}	
2.5 NaOH + 0.423 Na_2S	−0.64	47-50	1.5×10^{-9}	1.2×10^{-9}
2.5 NaOH + 0.423 Na_2S	−0.64	46-51	8.8×10^{-10}	

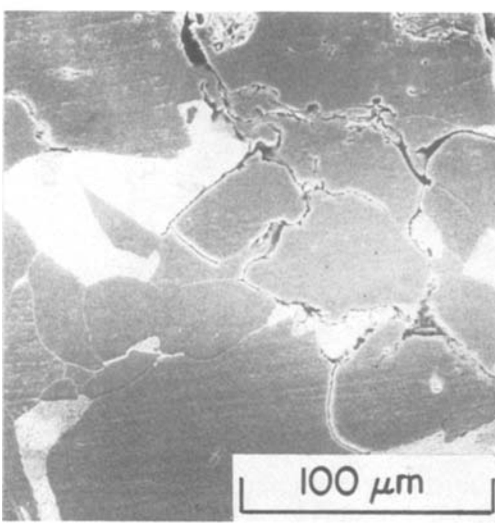

Fig. 6. SEM micrographs of sectioned and etched DCB specimens showing stress corrosion crack path at 92°C. Magnifications as shown in (b). (a, top) 3.35M NaOH, $K_I \approx 50$ MPa · m$^{1/2}$, $E = -0.76V_{SHE}$. (b, bottom) 2.5M NaOH + 0.423M Na_2S, $K_I \approx 50$ MPa · m$^{1/2}$, $E = -0.64V_{SHE}$.

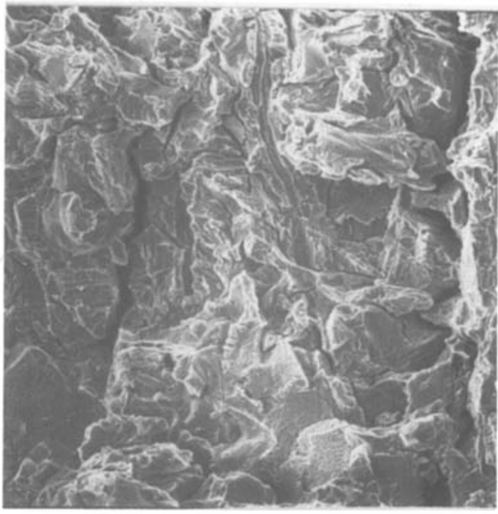

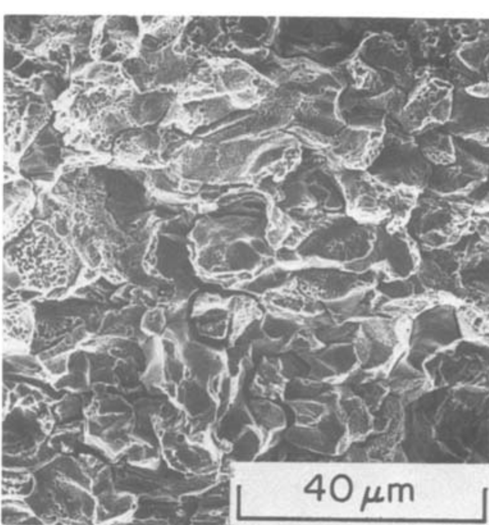

Fig. 7. SEM fractographs of DCB specimens showing stress corrosion crack topography at 92°C. Crack propagation from left to right and magnifications as shown in (b). (a, top) 3.35M NaOH, $K_I \approx 53$ MPa · m$^{1/2}$, $E = -0.76V_{SHE}$. (b, bottom) 2.5M NaOH + 0.423M Na_2S, $K_I \approx 51$ MPa · m$^{1/2}$, $E = -0.64V_{SHE}$.

to a more noble value and produced a corresponding rise in the potential for maximum susceptibility to SCC. Furthermore, the DCB tests confirmed that SCC at these potentials was not a peculiarity of the slow strain rate testing technique. This latter point is important because it has been noted previously by Parkins (15) that it is very difficult to obtain laboratory SCC of carbon steels in hot NaOH solutions, unless slow strain rate testing techniques are employed.

The results of the DCB tests were considered to be representative of plane strain testing conditions, because the K_I levels did not exceed the plane strain limit of ~60 MPa · m$^{1/2}$, as defined by the thickness criterion of Brown and Srawley (11) and ASTM (16) testing recommendations, *i.e.*, $B \geq 2.5\ (K_I/\sigma_y)^2$, where σ_y is the tensile yield stress. Under these conditions, and K_I levels of ~50 MPa · m$^{1/2}$, the results showed that there was a relatively insignificant difference in stress corrosion crack propagation rate between the NaOH and NaOH + Na_2S solutions when tests were conducted at the most susceptible potential for each environment (see Table II).

At the present time, it is not clear whether or not the influence of potential upon SCC susceptibility in NaOH and NaOH + Na_2S solutions, evident from the slow strain rate studies, is exerted primarily on the crack initiation period, the critical stress intensity (K_{ISCC}) for crack propagation, or upon the crack propagation rate itself. This requires further studies utilizing DCB specimens tested over a wider range of K_I levels and electrochemical potentials.

Mechanistic considerations.—The possibility of a hydrogen embrittlement mechanism of SCC in the present studies may be shown to be invalid on a thermodynamic basis. Such a mechanism requires the generation of hydrogen near the crack tip by electrochemical processes during SCC. The work of Biernat and Robins (17) has shown that the thermodynamically reversible potential for hydrogen evolution via reduction of hydrogen ions at 100°C and 1 atm pressure is given by Eq. [2]

$$E_{H^+/H_2} = 0.057 - 0.074\ pH,\ V_{SHE} \qquad [2]$$

The equation may be considered valid for the test temperature of 92°C without any significant error. The pH of the NaOH and NaOH + Na_2S solutions at 92°C was shown previously to be ~12 (6). The crack liquid pH measurements in the current study did not reveal any detectable difference from that of the bulk solution. Hence, the appropriate value of pH to be inserted in Eq. [2] for both the slow strain rate and DCB tests was 12. This showed that the corresponding reversible value of E_{H^+/H_2} was $-0.83V_{SHE}$. The potential of max-

imum susceptibility to SCC during slow strain rate testing was $-0.76V_{SHE}$ in NaOH and $-0.64V_{SHE}$ in NaOH + Na_2S, and SCC occurred at these potentials in the DCB tests. Both potentials were higher (more noble) than the thermodynamically reversible potential for hydrogen evolution. Hence, a hydrogen related mechanism must be dismissed from consideration.

An electrochemical dissolution mechanism of SCC may be considered possible if it can be shown that the maximum anodic dissolution current densities, i_a, occurring at the tip of the propagating cracks were either equal to, or larger than that required to account for the observed crack rates. This approach was first given credence by Parkins (5, 18, 19) and required that the crack rate, v, be equated to the rate of advance of a surface undergoing faradaic dissolution, as shown in Eq. [3]

$$v = \frac{i_a \cdot W}{\mathbf{F} \cdot d} \quad [3]$$

where W = equivalent weight of Fe (27.9×10^{-3} kg), $\mathbf{F}$ = Faraday (9.65×10^4 A · sec), and d = density of Fe (7.86×10^3 kg · m^{-3}).

The maximum value of i_a was assumed to correspond to that associated with the peak anodic current density, i_p, observed at the nose of the anodic polarization curve prior to passivation. This followed from the fact that maximum susceptibility to SCC occurred near the active-passive transition potential and rupture of passive films at the tip of the propagating crack would expose fresh metal to initial (momentary) current densities at least as large as i_p. Accordingly, with reference to Fig. 4 and 5, i_p was ~72 A/m^2 in NaOH and 3.84×10^3 A/m^2 in NaOH + Na_2S. Thus, with the assumption of a constant current density (i_p) at the crack tip, substitution of these values for i_a in Eq. [3] gave predicted maximum crack propagation rates of 2.6×10^{-9} m/sec in NaOH and 1.4×10^{-7} in NaOH + Na_2S. These rates were equal to or larger than those observed in the DCB tests (Table II).

In reality, once the passive film at the crack tip is ruptured, the exposed metal will tend to repassivate and the crack tip current density will decrease until the newly formed film undergoes further rupture in the presence of the plastic strain gradient at the crack tip. Thus, there will be alternating cycles of dissolution, repassivation, and film rupture, where the overall crack propagation rate will be dictated by the time spent in the dissolution stage, together with the time-dependent transient current density operating in this stage. This is the essence of the film rupture dissolution models detailed by Vermilyea (20, 21) and Scully (22).

The most susceptible potentials for SCC in a film rupture-dissolution model are anticipated to be in the passive region near the active-passive transition, as observed, because these conditions represent borderline stability of passive films. Consequently, at these potentials, repassivation kinetics at freshly exposed surfaces at the crack tip will be relatively slow, thereby allowing a larger increment of metal dissolution (crack advance). Changes in solution composition will affect the repassivation kinetics, alter the length of the dissolution stage, and cause differences in observed crack propagation rates. Also, the current density in the passive region will be important as this gives an indication of the amount of general dissolution in the presence of the passive film. Higher passive current densities (*e.g.*, in sulfide solutions, *c.f.* Fig. 4 and 5) will promote more general dissolution in the repassivation stage and partially blunt the crack. This would lower the local stress concentration, decrease the crack tip strain rate, retard the film rupture process, and decrease the time spent in the crack advance dissolution stage. The conjoint effects of repassivation kinetics and general dissolution may explain why the sulfide solution did not produce higher crack rates than the sulfide free solution (Table II) despite its larger i_p value.

In principle, the model does not specify an intergranular or transgranular crack path. Intergranular cracking may tend to be favored because of the lattice inhomogeneity represented by the grain boundary, which may affect local film rupture and repassivation events. However, rupture of the film by slip step emergence can occur elsewhere to promote transgranular cracking. In the present studies, intergranular cracking tended to predominate and transgranular cracking was also observed.

Parkins (15) and Scully (23) have argued that the success of the slow strain rate testing technique for studying SCC lies in the fact that the critical plastic strain increment (creep) necessary to promote film rupture and sustain crack propagation is precisely controlled. Constant load tests on smooth specimens may be unsuccessful because critical local strain rates cannot be maintained. Consistent with this, we were not able to obtain constant load SCC of smooth cylindrical tensile specimens in the current program, even at stresses approaching the ultimate tensile strength. The success of the DCB tests may then be attributed to the fact that the local plastic strain (creep) effects at the tip of the prefatigue crack, at the K_I levels employed, were sufficient to promote and sustain the film rupture events necessary for crack propagation.

Overall, the discussion has shown that many facets of the present study were reasonably consistent with the elements of a film rupture-dissolution mechanism of SCC. At this point in time, it does not appear necessary to deviate significantly from this model in order to understand SCC behavior of mild steel in the caustic environments employed.

Conclusions

Potentiostatically controlled caustic cracking studies of AISI 1018 mild steel in aqueous 3.35M NaOH and 2.5M NaOH + 0.423M Na_2S solutions at 92°C were consistent with the following conclusions.

1. The potential regime of maximum susceptibility to SCC occurred at potentials near the active-passive transition in each environment. Maximum susceptibility occurred at $-0.76V_{SHE}$ in NaOH and $-0.64V_{SHE}$ in NaOH + Na_2S.
2. Crack propagation rates were of the order of 1×10^{-9} m/sec at the most susceptible potentials and K_I levels of ~50 MPa · $m^{1/2}$.
3. Cracking generally followed a predominantly intergranular path, with a more noticeable tendency for some transgranular cracking in the absence of sulfide.
4. No detectable change in pH occurred in the liquid contained within the cracks.
5. A hydrogen embrittlement mechanism of SCC was discounted on thermodynamic grounds.
6. The overall studies were reasonably consistent with a mechanism of cracking involving anodic dissolution and film rupture processes.

Electrochemistry and Reactions of Transition Metal and Oxygen Ions in Dimethyl Sulfoxide

Fred C. Frederick and Keith E. Johnson*

Department of Chemistry, University of Regina, Regina, Canada S4S 0A2

ABSTRACT

Electrochemical studies of oxygen and transition metal ions in dimethyl sulfoxide solution indicate that the O_2/O_2^-, Cu^{2+}/Cu^+, and Fe^{3+}/Fe^{2+} couples are reversible while the Fe^{2+}/Fe, Co^{2+}/Co, Ni^{2+}/Ni, Cu^+/Cu, and Mn^{2+}/Mn couples are irreversible. The Cr^{3+}/Cr^{2+} and Mn^{3+}/Mn^{2+} systems are difficult to characterize and O_2^{2-} formed from O_2^- undergoes slow degradation. As predicted from the electrode potentials, Cu^{2+} and Fe^{3+} are able to oxidize O_2^- to oxygen. However, the reactions stop with the formation of mixed oxidation state superoxide complexes in solution. Cr^{3+} does not react with O_2^- but forms an insoluble compound with O_2^{2-}.

Dimethyl sulfoxide (DMSO) complexes of transition metal ions may be prepared with tolerable purity, *i.e.*, excess DMSO and perchloric acid can be kept below 5% in most cases (1). When solutions are made up in DMSO, only the perchloric acid impurity is significant, so that electrochemical studies of the Cu(II), Mn(II), Cr(III), Co(II), Ni(II), and Fe(III) complexes should be worthwhile. Previous investigators have employed polarography to study these complexes (2-5), but thorough studies by cyclic voltammetry and coulometry appear to be lacking. In addition to pursuing such studies we have investigated the reactions of several of these compounds and their redox products with electrogenerated superoxide and peroxide ion (6-9).

Experimental

The preparation and analysis of the complexes $M(DMSO)_x(ClO_4)_y$ is described elsewhere (1). Tetraethylammonium perchlorate (TEAP, Eastman Kodak) was recrystallized twice from water and dried *in vacuo*. All solutions for electrochemistry were 0.1M in TEAP and were purged with O_2-free N_2 (Cu at 300°).

Electrochemical measurements were carried out with a Princeton Applied Research Model 170 Electrochemistry System with Pt or Au working electrode, Pt counterelectrode, and an aqueous SCE reference electrode, the counter and reference electrodes being isolated in fitted glass compartments.

Results and Discussion

Cyclic voltammograms of DMSO solutions of the complexes of Cr(III), Mn(III), Fe(III), Co(II), Ni(II), and Cu(II) appear as Fig. 1-6. Figure 7 is the voltammogram of oxygen in DMSO. The last traces of oxygen were difficult to remove from the solutions, [*cf.* (10)] and the voltammogram of O_2 was superimposed on all of the metal voltammograms. For purposes of clarity, all peaks due to O_2 have been omitted from Fig. 1, 3, 4, 5, and 6. In Fig. 2 the combined waves for Mn ions and O_2 are shown for comparable (~ mM) concentrations. Removal of most of the O_2 leads to current-voltage curves approximated by the inner voltammogram which can be synthesized by subtraction of the

simple O_2 waves. The scan rate for all voltammograms was 200 mV/sec.

Table I lists the peak potentials. In Table II are presented the results of coulometry applied to the oxygen, Fe(III), and Cu(II) solutions.

Of the electrode processes identified, only the O_2/O_2^-, Fe^{3+}/Fe^{2+}, and Cu^{2+}/Cu^+ couples are reversible (ΔE = difference between reduction and oxidation peak potentials = 60 mV). It should be noted (Fig. 6) that while the $Cu^{2+} \rightarrow Cu^+ \rightarrow Cu^{2+}$ sequence is reversible on platinum, the coating of the electrode with copper changes its redox characteristics. The Cr^{3+}/Cr^{2+} peaks are partially masked by the O_2/O_2^- system but were discerned by varying the chromium concentration. The Mn^{3+}/Mn^{2+} peaks are close to the solvent limit. All the metal ion/metal couples are irreversible. Of special note are the reduction of superoxide to peroxide but

Table II. Coulometry of dimethyl sulfoxide solutions

Solute	Peak potential (V)	n (Faradays/mol)	Number of trials
O_2	−0.71	1.12 ± 0.05	5
	−2.13	2.36 ± 0.16	5
Fe^{3+}	+0.21	1.02 ± 0.03	3
Cu^{2+}	−0.10	0.87 ± 0.08	3

the oxidation of hydroxide ion formed by reaction of peroxide with TEAP and DMSO (11).

Agreement with the polarographic data is good in most instances. However, Burrus (2) probably mistook the O_2/O_2^- wave for the Fe^{3+}/Fe^{2+} reduction and there are discrepancies between the half-wave potentials and reduction peaks for metal ion/metal couples; differences of 0.1-0.2V would be reasonable.

From the electrode potentials one would anticipate the following reactions might take place

$$Fe^{3+} + O_2^- \rightarrow Fe^{2+} + O_2 \quad [I]$$

$$Cu^{2+} + O_2^- \rightarrow Cu^+ + O_2 \quad [II]$$

$$Cu^+ + O_2^- \rightarrow Cu + O_2 \quad [III]$$

$$Mn^{3+} + O_2^- \rightarrow Mn_2^+ + O_2 \quad [IV]$$

$$Cr^{3+} + O_2^- \leftrightarrows Cr^{2+} + O_2 \quad [V]$$

Mixing of electrogenerated superoxide solutions with those of the appropriate metal ion led to oxygen evolution in the case of Fe^{3+} and Cu^{2+}, and stabilization of the Mn^{3+}, presumably by neutralization of perchloric acid impurity. No copper metal was formed with Cu^+ and no change whatever occurred for Cr^{3+}. However, the solution derived from Fe^{3+} and O_2^- (or O_2^{2-}) was dark brown and that derived from Cu^{2+} and O_2^- green, compared to the yellow Fe^{3+}, pale-blue coulometrically generated Fe^{2+} (ν_{max} = 7.46 kk, ϵ_{max} = 1.41, ν'_{max} = 9.61 kk, ϵ_{max} = 1.93; an appropriate spectrum for high-spin d^6 in octahedral coordination), and blue Cu^{2+} ions in DMSO solution. The u.v. and visible-near *IR* spectra of the dark brown solution and the component spectra appear as Fig. 8 and 9. It is clear that a new species is formed involving both ferrous and ferric iron in combination with unoxidized superoxide, *i.e.*, reaction (I) is followed by

$$Fe^{2+} + O_2^- + Fe^{3+} \rightarrow \text{dark brown product} \quad [VI]$$

Efforts to reach the same equilibrium mixture from Fe^{2+} and O_2 or to drive reaction (I) to completion by bubbling nitrogen gas through the mixture were unsuccessful. A similar situation is believed to occur with reaction (II).

The mixing of DMSO solutions of $Cr(DMSO)_6(ClO_4)_3$ and electrogenerated peroxide (O_2^{2-}) led to the im-

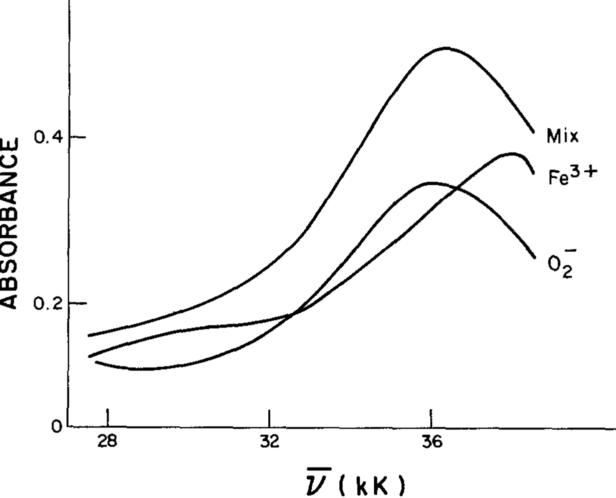

Fig. 8. U.V. spectrum of Fe^{3+}/O_2^- reaction mixture in DMSO solution.

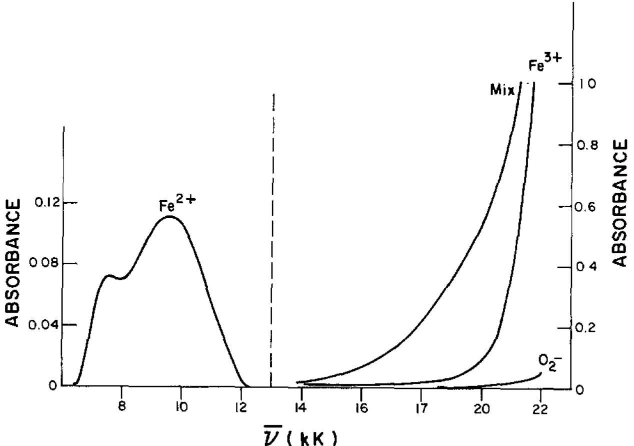

Fig. 9. Visible near *IR* spectra of Fe^{3+}/O_2^- reaction mixture, Fe^{3+}, O_2^-, and Fe^{2+} in DMSO solution.

mediate formation of a dark green precipitate. The material was very hygroscopic, evolved oxygen on treatment with aqueous permanganate and analyzed for Cr at 6.0 weight percent (w/o) and ClO_4 at 9.0 w/o (mole ratio ClO_4:Cr ≈ 0.8). When a DMSO solution of $Cr(DMSO)_6(ClO_4)_3$ was mixed with one of tetraethylammonium hydroxide, a green precipitate formed over a period of hours but this compound did not react with aqueous permanganate. Since some of the immediate reduction product of superoxide can be reoxidized on reversing the direction of scanning the electrode polarization, we conclude that the degradation of peroxide in DMSO solutions of TEAP to form OH^-, TEA^+, C_2H_4, $(C_2H_5)_3N$, and $DMSO_2$ (11) is not so fast that the peroxide chemistry is necessarily obscured. Thus we suggest that a complex perchlorate of Cr^{3+} and O_2^{2-} is formed; whether or not it contains a variety of other species, besides the coordinating solvent DMSO, remains to be determined. One can speculate that the bonding is of bidentate O_2^{2-} as in CrO_5 or of monodentate O_2H^-.

These findings indicate that a wealth of coordination and redox chemistry of oxygen ions may be waiting to be uncovered by careful studies in nonaqueous solvents.

Potentiodynamic Investigation of Cu in Alkaline Phosphate Solutions Containing Added Anions

F. M. Al-Kharafi and Y. A. El-Tantawy

Department of Chemistry, Faculty of Science, Kuwait University, Kuwait City, Kuwait

ABSTRACT

The effect of SO_4^{2-}, Cl^-, and I^- on the intensity of anodic peak currents for the successive processes that occur on Cu in alkaline phosphate media has been studied. At the same sweep rate repeated excursions resulted in a significant anodic current increase for the process corresponding to Cu(I) oxide formation; the anodic peak current of Cu(II) remained unaffected. Also Cu(I) and Cu(II) processes exhibited significant differences in their response to cycling at increasing scan rate. The increase of the anodic current for Cu(I) formation with increasing [Cl^-] showed a definite tendency to level off. Cu(II) anodic currents exhibited a continuous increase with increasing [Cl^-]. At relatively high [Cl^-] current oscillations were observed which have been explained. A mechanism of Cl^- attack involving adsorption, interaction with a soluble intermediate, and peptization of the passivating products is discussed. The effect of the Cl^- ion revealed that passivating Cu(II) products were formed, most probably, via a diffusion-controlled pathway.

Studies on the nature and kinetics of the electrodissolution of Cu are of considerable importance in corrosion, electropolishing, and electrochemical machining. The role of Cl^- on Cu dissolution has received special attention (1-8). It is noted that these investigations were performed in nearly neutral (1, 4, 5, 9) or acidic (3, 6-8) solutions and in flowing (5, 7) or static solutions. There is agreement (3, 5-7) that Cu dissolves as $CuCl_2^-$ and $CuCl_3^-$, and the dissolution process was reported to be diffusion controlled. In HCl media, it has been reported that a cuprous chloride layer may grow to considerable thickness by a solid-state mechanism (7).

In alkaline media (1) the effect of Cl^- in the electrochemical dissolution of Cu has been investigated by the observation of changes in the overpotential occurring during constant current polarization and after the current was interrupted. Thirsk *et al.* (1) observed "sharp unpredictable fluctuation" in the overpotential curves. They ascribed these variations to "mechanical breakdown" in the otherwise continuous area of the deposit.

The object of the present study is to reveal the nature of the role of the anions SO_4^{2-}, Cl^-, and I^- in the stability of passive films on anodized Cu in alkaline phosphate media. This investigation is also intended to emphasize the role played by these anions during the anodic formation of the passivating salt.

Key words: mechanism, passivity, anion influence, electrode.

Experimental

Chemicals.—The best, commercially available, BDH grade was used. Triply distilled water was employed throughout. Electrodes were of Specpure Johnson Matthey Cu rods with an exposed area of 3.29 cm².

Equipment.—*E-i* and *E-t* traces were obtained with the aid of a Model 350 Princeton Applied Research Set, Model 9700 cell complete with calomel, reference, and auxiliary electrodes and a Model 1201A HP recorder.

Experimental technique.—The value of the anodic current at the first peak (most negative potential) was observed to be significantly and systematically dependent on electrode cycling at the same rate. There fore, under the same set of conditions the electrode was cycled at least four times. In searching for a trend comparison between scans with the same cycle number is made. Electrodes were cleaned both mechanically and electrochemically (precathodization treatment). The surface treatment of the electrode involved successive polishing with 0,00 and 000 emery paper, degreasing with acetone, washing with triply distilled water, and carefully drying with filter paper. Each half-cycle covered the potential range from −1 to +0.60V. For the same scan rate, the time interval between successive cycles was roughly constant. Electrolytic solutions were deoxygenated by a fine stream of nitrogen gas, purified by passing through two towers containing

acidic vanadous aqueous solutions followed by two towers filled with triply distilled water. Deoxygenation took place before and during the precathodization treatment. All experiments were conducted in a temperature-controlled laboratory at 24° ± 1°C. However, during a run temperature tolerance was not more than ± 0.5°C. All potential values were recorded *vs.* SCE.

Results

Figure 1a shows a typical potentiokinetic trace for Cu in alkaline phosphate solution of *p*H value adjusted at 12.50. Three anodic and two cathodic processes are consistently observed. When compared with the behavior in NaOH in the same range of *p*H, the presence of phosphate ions has practically no effect on peak I but significantly inhibits peak II (10).

Very recent studies employing x-ray photoelectron spectroscopic (XPS) technique have focused attention on the nature and oxidation states of the anodically formed passivating copper oxide (or hydroxide) film (10-12) in alkaline media. These studies (10-12) agree that only Cu(I) and Cu(II) oxide species are formed. However, there is some disagreement on the nature of the Cu(II) species (10-12). Strehblow and Titze (11) stated that in weak alkaline phosphate buffer (*p*H = 8.0) the anodically formed film was composed for the most part of Cu_2O and $Cu(OH)_2$. McIntyre *et al.* (12), employing a medium of 1*M* KOH, reported that the film was composed of a layer of Cu_2O followed by a mixture of cupric oxide and cupric hydroxide. They (12) added that the hydroxide form predominated. Employing a medium of 1*M* NaOH, El-Tantawy *et al.* (10) reported that only Cu_2O and CuO were formed. In alkaline phosphate media possible formation of insoluble copper phosphate species was excluded on the basis of XPS (11) as well as electrochemical measurements (10, 13). A detailed discussion of the nature of the passivating products and the role of phosphate ion has been given by the authors elsewhere (10).

In the light of the above discussion, processes I, II, and III most probably correspond, respectively, to a solid formation of Cu_2O, CuO, and most probably $Cu(OH)_2$. The two cathodic peaks represent stepwise reduction of Cu^{2+} (irrespective of its nature) to Cu^+ and Cu^+ to Cu. By comparison with Fig. 1a traces b, c, and d illustrates the effect of mixing Na_2SO_4, NaCl, and NaI with the passivating phosphate solution. Peak I is the most affected. In terms of the current intensity for the various processes, the addition of I^- gave the largest relative increase of i_p for process I. Chloride ion comes next. The lowest effect is that of SO_4^{2-}. Addition of sulfate resulted in an initial decrease of $(i_p)_I$. Process III is observed to be significantly suppressed by sulfate and I^-.

Effect of cycling at the same sweep rate.—Table I contains the values of i_p for the anodic and cathodic processes at four consecutive cycles. A number of interesting observations may be noted.

1. i_p values for process I consistently increase on cycling. The magnitude of the increase is dependent on the type of added anion. Also, the mode of increase of i_p for process I is observed to be anion-dependent. While the addition of I^- resulted in the highest initial (cycle I) increase, the rate of increase of $(i_p)_I$ with cycling is seen to be the largest with Cl^-.

2. Cycling is noted to have practically no effect on i_p values for process II. It seems that while process I is very dependent on the changes that may occur on the surface as a result of cycling, process II is not controlled by such changes.

3. In general, peaks IV and V seem to vary very little on cycling. It was consistently noted that the area under peak V was always bigger than that of peak IV.

Cycling is expected to increase surface roughness. In the present case, the increase in surface area is believed to be due to two causes: (*i*) electrochemical dissolution from preferred sites and (*ii*) constant attack of selective surface sites by the aggressive anion: the latter occurring even in the absence of an imposed electric field. The dependence of the magnitude of the increase of i_p for process I, Δi_p^I (last column of Table I), on the type of anion reveals the order $Cl^- > I^- > SO_4^{2-}$.

Effect of increasing anion concentration.—The dependence of the values of (i_p) for peaks I, II, IV, and V on increasing additions of the different anions is given in Table II for the first and second cycles. A close look at Table II reveals two interesting features, especially with Cl^-.

1. The i_p values for peaks I and II generally increase with increasing amounts of the added anion. While the increase of $(i_p)_I$ tends to level off, $(i_p)_{II}$ shows a continuous rise.

2. It is observed that the charge accumulated at peak IV and V increases significantly with increasing $[Cl^-]$. It seems that considerable thickening of the passivating film takes place as the $[Cl^-]$ is increased.

Figure 2 depicts a redrawn potentiodynamic trace recorded in the presence of an added 1*M* Cl^- (compare Fig. 1c with 2). Except for the expected increase of the current intensity for the anodic peaks, the form of the potentiodynamic trace shown in Fig. 1c, was always

observed up to 0.5M Cl^-. At an added $[Cl^-]$ of 1M, peaks I and II remained practically unaffected (*viz.* their shape). In the potential region of III (0.0-0.7V, SCE) irregular current oscillations were observed. Current oscillations may indicate that the passivating species in a quasi-equilibrium state with the electrode surface do not permanently persist (2).

In presence of both OH^- and Cl^-, the deposition of the electrochemically dissolving Cu^{2+} as an insoluble hydroxide is thermodynamically favored (14). Nevertheless, from a kinetic viewpoint dissolving Cu^{2+} may, through random collisions, interact with Cl^- ions to form a soluble chlorospecies which may then diffuse away into the bulk of solution. Further, due to the probable absorption of Cl^- on the electrode surface, Cu^{2+} would have the chance to dissolve as a chlorospecies. It is probable that Cl^- ions react with the soluble intermediate species (*e.g.*, $Cu(OH)_n{}^{1-n}$ or $Cu(OH)_y{}^{2-y}$) to form, the more soluble chlorospecies (see Eq. [2]). This would result in a decrease of the concentration of the Cu-hydroxy species, a saturated (or supersaturated) layer of which is necessary to

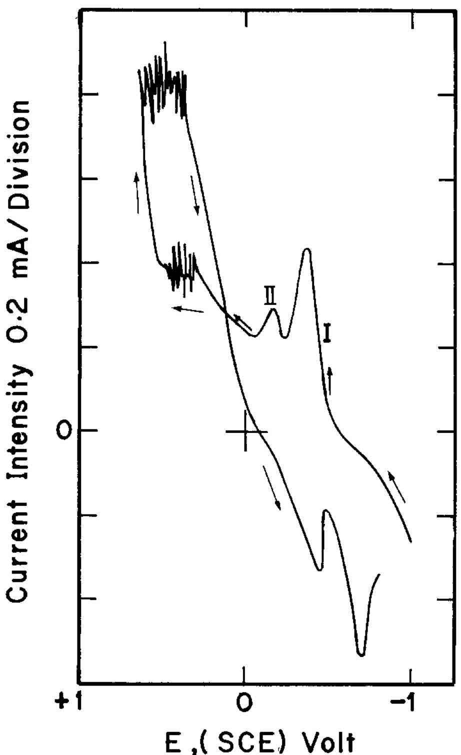

Fig. 2. First cycle redrawn potentiodynamic curve in 0.1M Na_3PO_4 + 1M NaCl; current oscillations appear in the potential region of process III; no oscillations were observed at lower [NaCl].

initiate the deposition of the passivating film. This leads to passivation delay.

In presence of added 1M Cl^-, a heavy gelatinous light-bluish precipitate was observed on the electrode surface near the end of the potential region of oscillation. The formation of such a gelatinous deposit is believed to be caused by spontaneous dispersion of the precipitated passivating film to form a colloid as a result of heavy adsorption of Cl^-. This peptization process presumably leads to exposure of the surface of the electrode and the anodic current increases. Therefore, the oscillations observed in Fig. 2 are a result of active ⇌ passive transitions on the electrode surface.

In the light of the above picture for the role of Cl^-, the increase in i_p values for the cathodic processes IV and V in Table II with increasing $[Cl^-]$ could result from the formation of thick anodic film deposits that may sustain aggressive attack.

Effect of sweep rate.—Figure 3 illustrates plots of i_p against $v^{1/2}$; v being in mV sec^{-1}. It is true that neither of the curves in Fig. 3 is strictly linear as demanded by purely diffusion-controlled processes (15). At least the deviation from linearity with increase sweep rate for peak II is definitely not as large as that for process I. This difference in behavior toward increasing scan rate is possibly due to a different mechanism for the two processes. Similar behavior at different additions of SO_4^{2-}, I^-, and Cl^- has been observed.

Open-circuit measurements.—In order to gain further insight on the nature of the interaction of halide ions with the various oxides that form along the anodic scan, the cleaned Cu electrode was anodically oxidized at selected constant potential values for long enough to allow the deposition of a film of a particular structure. The electrode was then rapidly transferred, under an inert atmosphere to a solution of only aqueous I^- on Cl^-. For comparison, the potential time behavior of a clean electrode is included in Fig. 4. In aqueous I^- media, irrespective of the past history, the electrode potential values rapidly drift in the direction of the value for a clean electrode, Fig. 4a. It seems that due to an I^- interaction the passivating film is rapidly ruptured. Because of the rapid nature of this interaction, assisted by the strong affinity of copper ions for I^- complexation (16) to form soluble species, it is believed that the potential drift is due to chemical dissolution of the surface film. In aqueous Cl^- media, the electrode potential values for the films precipitated at 0.5 and 0.05V slowly decay toward the open-circuit value. Stripping of the passive films through peptization is expected to occur slowly. Further, Fig. 4b shows

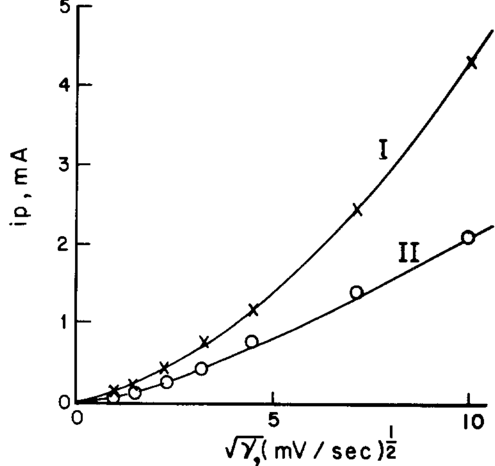

Fig. 3. Mode of response of the current intensities of anodic peaks I and II to increasing sweep rate in the range 1-100 mV sec^{-1}.

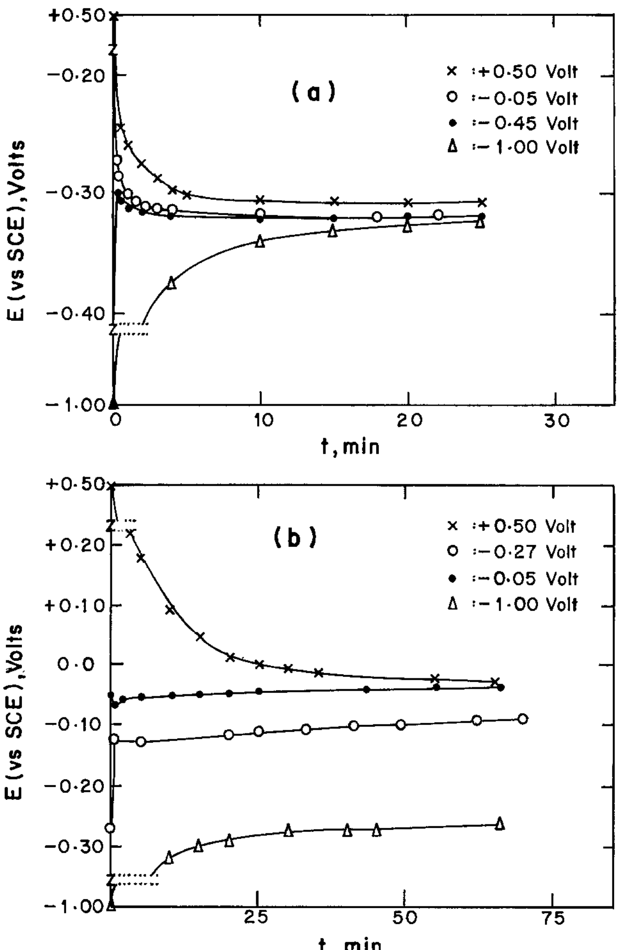

Fig. 4. Mode of potential decay in aqueous (a) 0.2M I^- and (b) 0.5M Cl^-.

that the open-circuit potential value of a clean electrode falls well below that of the oxidized surfaces.

Mechanism and Conclusion

A probable mechanism for the effect of Cl^- ions on the anodic passivation of Cu should conform with the tendency of $(i_p)_I$ to level off with increasing $[Cl^-]$, as opposed to the observed continual increase of $(i_p)_{II}$. An interesting feature to be accounted for, is the lack of dependence of $(i_p)_{II}$ on voltage cycling, contrary to the significant dependence (increase) of the intensity of the peak current for process I, Table I. Further, the $(i_p)_{II}$-$v^{1/2}$ plot deviates from linear behavior only slightly compared with that of $(i_p)_I$. For full discussion on the mechanism of the film formation in absence of Cl^-, refer to Ref. (10).

Peak I.—The presence of bulk Cl^- ions furnishes favorable conditions for competitive adsorption of Cl^- with OH^- (or H_2O dipoles) (17) on the Cu surface, in a dynamic step

$$Cu + Cl^- \rightleftharpoons CuCl^-_{ads} \quad [1]$$

i.e., increasing $[Cl^-]$ in the solution bulk favors the electrochemical dissolution of Cu in the form of chlorospecies. Also, increasing $[Cl^-]$ is expected to necessarily result in the dilution of an intermediate species, the supersaturation of which is needed for crystallization into solid Cu_2O (18, 19)

$$Cu(OH)_n{}^{1-n}(aq) + xCl^- \rightleftharpoons Cu(OH)_{n-x}(Cl^-)_x{}^{1-n}(aq) + xOH^- \quad [2]$$

Equilibria [1] and [2] should lead to leveling off of $(i_p)_I$ with increasing $[Cl^-]$. $Cu(OH)_n{}^{1-n}$ represents the intermediate soluble species of Cu(I) that crystallizes into the passivating products. The occurrence of equilibrium [1] should lead eventually to an increase in electrode surface roughness and consequently to the increase in $(i_p)_I$ observed on cycling. Cl^- ions are adsorbed on preferential sites. On starting an anodic excursion, Cl^- adsorbed sites represent potential electrochemical dissolution spots. Preferential site dissolution necessarily results in an increase in the surface roughness and consequently $(i_p)_I$ on cycling. However, after the Cu_2O has deposited it seems that the nature of Cl^- ion attack becomes different. Cl^- attack on the deposited solid was observed to be slow, see Fig. 4. It seems that Cl^- ions attack the precipitated oxide through initial preferential site adsorption which results in local peptization in a colloidal sense. Such a mode of attack may lead to creation of weak spots or perforations in the film structure.

Peak II.—The pronounced difference of $(i_p)_{II}$ form $(i_p)_I$ toward increasing the sweep rate, supported by the complete independence of $(i_p)_{II}$ of cycling (increase of surface area), is consistent with a model controlled mainly by diffusion for process II. At the completion of process I, the surface is nearly covered (19, 20) by Cu_2O and possible partially blocked with phosphate ions. The only chance for electrochemical generated cupric ions to precipitate is to diffuse through the Cu_2O film to the Cu_2O/solution interphase. This model is further supported by a recently published study (11) where XPS and ISS techniques were employed. There (11), it is reported that in weakly alkaline phosphate buffer of pH 7.0 and 8.0, the passivation of Cu resulted in the formation of Cu(II)-species on top of a Cu(I)-oxide layer. Therefore, the formation of Cu(II) passivating species is believed to be controlled by the rate of passage of soluble Cu^{2+} across the Cu(I) oxide barrier. This rate of ion transport is expected to increase with increasing $[Cl^-]$, due to the irreversible attack on selective sites as explained in the previous paragraph. Such a model explains the observed continuous increase of $(i_p)_{II}$ with increasing Cl^-.

The increase in $(i_p)_I$ caused by I^- ions is believed to be essentially due to chemical dissolution of the precipitated oxide. This speculation is based on the observations that: (*i*) the oxidized Cu surface rapidly attains the potential of the clean electrode in aqueous I^- media, (*ii*) compared with Cl^- or $SO_4{}^{2-}$, the increase of $(i_p)_I$ due to I^- addition is usually large for the first cycle, and (*iii*) surface oxidation of Cu in aqueous I^- medium (nearly neutral) yielded only one anodic peak which did not persist to exhibit a corresponding cathodic process. On reverse half-cycle, the anodic process appeared again. However, the I^- effect needs a detailed study.

Acknowledgments

The authors are gratefully indebted to one of the reviewers for a critical reading of the manuscript, to Mr. Z. Al-Fahd for assistance in the experimental part, and to Kuwait University for financial support under project number SCO12. Particular thanks are due to Dr. D. W. Shoesmith of Atomic Energy of Canada Limited, Pinawa, for his kindness in making available to us manuscripts to be published.

Manuscript submitted Feb. 13, 1981; revised manuscript received April 27, 1981.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1982 JOURNAL. All discussions for the June 1982 Discussion Section should be submitted by Feb. 1, 1982.

Publication costs of this article were assisted by Kuwait University.

Theoretical Treatment of the Transport Equations for Electrons and Ions in a Mixed Conductor

I. Riess

Department of Physics, Technion-Israel Institute of Technology, Haifa, Israel

ABSTRACT

The transport equations for the ions and electrons in a mixed conductor are considered. An exact solution of these equations in the steady state is given for a fixed ion concentration. Explicit analytic expressions are derived for the variation of electron concentration with position and applied voltage. From this, the electron chemical potential variations within the mixed conductor can be obtained. Explicit analytic expressions are also derived for the dependence of the current on the external voltage. The power output and energy conversion efficiency are then calculated for a fuel cell based on a mixed conductor. An example is discussed quantitatively. It is a high temperature fuel cell based on doped ceria and operating at 800°C.

The transport equations for ions and electrons in a mixed conductor were evaluated in parametric form by Choudhury and Patterson (1) and by Tannhauser (2). These calculations resulted in implicit equations for the dependence of the electron concentration and current density on the external parameters. For a fuel cell based on a mixed conductor the power output and efficiency could be calculated numerically.

It is the purpose of this paper to present a solution of the transport equations which yields explicit expressions for the variation of the electron concentration, n, with position and for the dependence of n, of the electric current and of the total current, on the external parameters. We then derive explicit expressions for the power output and the energy conversion efficiency as well as for the maximum power output and maximum efficiency in a fuel cell.

A high temperature fuel cell based on a solid mixed conductor is discussed to demonstrate the results and for comparison with calculations done before (2). Solid electrolytes used in fuel cells are doped oxides which conduct oxygen ions (3). Electronic conductance sets in due to reduction of the oxide on the fuel side. The degree of reduction depends on the oxide used. ZrO_2-10 mol percent (m/o) Y_2O_3 stays "pure" ionic to very low oxygen pressure, P_{O_2}. Its ionic transference number $\bar{t}_i$ is estimated to be 0.5 for $P_{O_2} = 10^{-31}$ atm at 1000°C (4). For CeO_2-10 m/o Gd_2O_3, $\bar{t}_i = 0.5$ for $P_{O_2} = 10^{-16}$ atm at 800°C (5). Doped ceria is therefore a mixed conductor due to the low oxygen pressures which prevail on the fuel side of a fuel cell, while doped zirconia can be considered as a "pure" ionic conductor under these conditions. On the other hand, the ionic conductivity of doped ceria is about three times higher than that of doped zirconia at the same temperature and the power density which can be obtained with doped ceria may be higher.

While the discussion is quite general, we shall use the notation relevant to a high temperature fuel cell, namely, the ions will be charged oxygen vacancies and the driving force will be due to a difference in oxygen pressures on both sides of the electrolyte.

Key words: fuel cell, energy conversion, solid electrolyte, cerium dioxide.

Ionic Current vs. Total Current in a Mixed Conductor

Figure 1 shows a mixed conductor solid electrolyte fuel cell (MSEFC) connected to an external voltage V. In general, V can be positive (as shown in Fig. 1) or negative. For normal fuel cell use, the external source, B, is replaced by a load resistance R and $V = IR$, where I is the total current through the mixed conductor solid electrolyte (MSE) and the load. The electrodes A_1, A_2 located at two different oxygen atmospheres are assumed to be nonblocking and reversible, so that there is no voltage drop on the electrodes.

The ionic current through the MSE consists of oxygen vacancies, $V_O^{\cdot\cdot}$, which have an effective double positive charge relative to the perfect solid. The ionic current density is

$$j_i = -\frac{\sigma_i}{2q}\nabla\tilde{\mu}_i, \quad \sigma_i = 2q\nu_i N \quad [1]$$

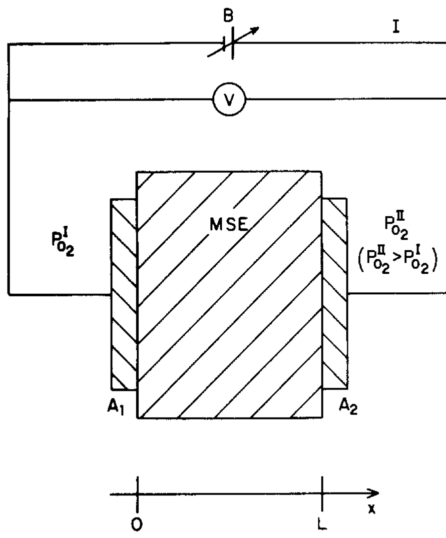

Fig. 1. Schematic representation of a mixed conductor solid electrolyte fuel cell connected to a variable external source *B* of voltage *V*.

and the electronic current density of quasi free electrons is

$$j_e = \frac{\sigma_e}{q} \nabla \tilde{\mu}_e, \quad \sigma_e = q\nu_e n \qquad [2]$$

where σ denotes conductivity, $\tilde{\mu}$, electrochemical potential, ν mobility, q is the electronic charge, N, n are the concentration of ions and electrons, respectively. ν_e, ν_i are assumed to be constant throughout the MSE, thus independent of concentration.

In the steady state j_i, j_e do not depend on position, x, and Eq. [1], [2] can readily be integrated

$$\tilde{\mu}_i(A_2) - \tilde{\mu}_i(A_1) = -2qj_i \int_0^L \frac{dx}{\sigma_i} \equiv -2qI_iR_i \qquad [3]$$

where R_i is the resistance of the MSE to ionic current I_i. In general R_i may be a function of V. L is the length of the MSE, S its cross section, and $I_i = Sj_i$. Similarly

$$\tilde{\mu}_e(A_2) - \tilde{\mu}_e(A_1) = qj_e \int_0^L \frac{dx}{\sigma_e} \equiv qI_eR_e \qquad [4]$$

where R_e is the resistance of the MSE to an electronic current, I_e. R_e depends on V. $I_e = Sj_e$.

The reaction

$$\tfrac{1}{2}\, O_2 + V_O^{\cdot\cdot} + 2e' = 0 \qquad [5]$$

takes place at electrodes A_1, A_2. The differences between the oxygen chemical potential μ_{O_2} and $\tilde{\mu}_i$, $\tilde{\mu}_e$ at A_1, A_2 are related by

$$\tfrac{1}{2}\,[\mu_{O_2}(A_2) - \mu_{O_2}(A_1)] + [\tilde{\mu}_i(A_2) - \tilde{\mu}_i(A_1)] + 2[\tilde{\mu}_e(A_2) - \tilde{\mu}_e(A_1)] = 0 \qquad [6]$$

where

$$\mu_{O_2}(A_2) - \mu_{O_2}(A_1) = kT \ln(P_{O_2}{}^{II}/P_{O_2}{}^{I}) = 4qV_{th} \qquad [7]$$

The voltage V is

$$-qV = \tilde{\mu}_e(A_2) - \tilde{\mu}_e(A_1) \qquad [8]$$

Substituting Eq. [6], [7], [8] into Eq. [3] and [4] yields

$$V_{th} - V = I_iR_i \qquad [9]$$

$$V = -I_eR_e \qquad [10]$$

Hence

$$I = I_i + I_e = \frac{V_{th} - V}{R_i} - \frac{V}{R_e} \qquad [11]$$

The following limits are immediately obtained

a) $V = V_{th} \leftrightarrow I_i = 0, \quad I_e = -V_{th}/R_e(V_{th})$

b) $V = 0 \leftrightarrow I_e = 0, \quad I_i = V_{th}/R_i(0)$

c) For $I = I_i + I_e = 0$ the open-circuit voltage is

$$V_{o.c.} = \frac{R_e(V_{o.c.})}{R_i(V_{o.c.}) + R_e(V_{o.c.})} V_{th} \equiv \bar{t}_i V_{th} \qquad [12]$$

$\bar{t}_i$ is identified as the average ionic transference number (4). For the MSE, the ratio I_i/I depends on V. From Eq. [9]-[11]

$$\begin{aligned} -\infty \leq I_i/I \leq 0 \quad &\text{if} \quad V_{o.c.} \leq V \leq V_{th} \\ 0 < I_i/I \leq 1 \quad &\text{if} \quad 0 \geq V, \quad V \geq V_{th} \\ 1 \leq I_i/I \leq \infty \quad &\text{if} \quad 0 \leq V \leq V_{o.c.} \end{aligned} \qquad [13]$$

since R_e, R_i are positive by definition. For normal fuel operation $0 < V < V_{o.c.}$ and I is seen to be smaller than I_i. The total current approaches the ionic one, I_i, only for small values of V.

Exact Solution of the Transport Equations

Solutions of the transport Eq. [1] and [2] were given in an implicit parametric form by Choudhury and Patterson (1) and by Tannhauser (2). Choudhury and Patterson, using Wagner's approach (6), assume that N, the concentration of ions, is uniform throughout the MSE. This assumption is valid for many electrolytes and will be used also here. For doped ceria, for example, the doping fixes the concentration of the ionic charge carrier (V_o'') and the variation in concentration, δN, due to extra vacancies created by reduction of the oxide, can be neglected. Tannhauser assumed local neutrality and showed that it was consistent with his results. The two assumptions yield similar results when $\delta N << N$. Local neutrality means: $2[V_o''] = [Gd_{Ge}'] + n$ for $0 \leq x \leq L$, in which case: $2\delta N = n$. Seemingly, Tannhauser's assumption is less restrictive than that used by Choudhury and Patterson. If the ionic current density is rewritten as

$$j_i = -kT\nu_i \frac{dN}{dx} - 2qN\frac{d\phi}{dx} \qquad [14]$$

where ϕ is the electrical field, then it is seen that $N(x) =$ const. leads to $d^2\phi/dx^2 = 0$. On the other hand, the assumption of local neutrality leads, using Eq. [7], to $d\phi/dx =$ const. and to δN which may vary exponentially with x. However, under fuel cell operation conditions, the concentration of quasi free electrons is low, $n << N$, also for a mixed conductor. Since $\delta N \sim \tfrac{1}{2}n$, hence, $\delta N << N$ and Tannhauser's assumption reduces to that of Choudhury and Patterson.

We present now a derivation of the solution of the transport equations for an MSE different from that in [1] and [2], which yields explicit expressions for the dependence of the current densities j_e, j_i, j on the fuel cell voltage V, as well as expressions for the local electron concentration and conductivity as a function of V and x. Then the power generated and the energy conversion efficiency are calculated and compared with that of a "pure" ionic solid electrolyte.

Equations [1] and [2] can be rewritten as

$$j_i = 2q\nu_i\epsilon N \qquad [15]$$

$$j_e = kT\nu_e\frac{dn}{dx} + q\nu_e\epsilon n \qquad [16]$$

where use was made of the relations: $\mu_e =$ const. $+ kT \ln n$, $\tilde{\mu}_e = \mu_e - q\phi$; T is the temperature, k the Boltzmann constant, and ϵ is the constant field $-d\phi/dx$. Equation [16] is an inhomogeneous linear differential equation of the first order and can readily be integrated. The boundary values of n at $x = 0$ (n_o) and

$x = L$ (n_L) are determined from the oxygen pressure $P_{O_2}{}^{I}$, $P_{O_2}{}^{II}$ at electrodes A_1, A_2 and from the mass action law $Nn^2P_{O_2}{}^{1/2} = K_o(T)$, where $K_o(T)$ is the constant of the reaction in Eq. [5] and N is a known concentration. Hence

$$n_o = \sqrt{\frac{K_o}{N}}\,(P_{O_2}{}^{I})^{-1/4} \quad [17]$$

$$n_L = \sqrt{\frac{K_o}{N}}\,(P_{O_2}{}^{II})^{-1/4} \quad [18]$$

and (cf. Eq. [7])

$$\frac{n_L}{n_o} = e^{-\beta qV_{th}}, \quad \beta \equiv 1/kT \quad [19]$$

The integration of Eq. [16] yields

$$n(x) = B_o e^{-q\beta\epsilon x} + \frac{J_e}{q\nu_e\epsilon} \quad [20]$$

where B_o and J_e are constants fixed by the boundary conditions n_o, n_L for given ϵ, T, and ν_e.

$$B_o = n_o - \frac{J_e}{q\nu_e\epsilon} \quad [21]$$

and

$$j_e = -q\epsilon\nu_e\frac{n_o e^{-\beta q\epsilon L} - n_L}{1 - e^{-\beta q\epsilon L}} \quad [22]$$

From Eq. [6], [7], [8] and $\nabla\mu_i = 0$, one can express ϵ in terms of the experimental quantities V_{th}, V

$$\epsilon L = V_{th} - V \quad [23]$$

The relation between the cell current density $j = j_i + j_e$ and the cell voltage, readily follows from Eq. [15], [19], [22], [23]

$$j = \frac{V_{th} - V}{L}\sigma_i\left[1 - \frac{\sigma_e{}^L}{\sigma_i}\,\frac{e^{\beta qV} - 1}{1 - e^{-\beta q(V_{th}-V)}}\right] \quad [24]$$

where $\sigma_e{}^L = q\nu_e n_L$.

$n(x)$ and $\sigma_e(x)$

The variation of the electron concentration with x ($0 \leq x \leq L$), determined from Eq. [19]-[23] is

$$n(x) = n_L e^{\beta qV_{th}}\left[1 - (1 - e^{-\beta qV_{th}})\,\frac{1 - e^{-\beta q(V_{th}-V)x/L}}{1 - e^{-\beta q(V_{th}-V)}}\right] \quad [25]$$

Since $\sigma_e = q\nu_e n$ and $\mu_e = \text{const.} + kT \ln n$ the dependence of σ_e and μ_e on x and V is readily obtained. For a fixed n_L, $n(x)$ increases with V_{th} due to reduction of the MSE. For $V_{th} \neq 0$ an increase in the applied voltage, V, has a similar effect on the MSE and $n(x)$ increases with V for $0 < x < L$. This is shown in Fig. 2.

Ionic Transference Number

The average ionic transference number $\bar{t}_i$, as well as the ionic transference number $t_i{}^{\circ}$ at the low pressure electrode (A_1), can be determined from the open-circuit voltage $V_{o.c.}$. $\bar{t}_i$ is defined as

$$\bar{t}_i \equiv V_{o.c.}/V_{th} \quad [26]$$

$V_{o.c.}$ is given by Eq. [24] for $j = 0$

$$V_{o.c.} = V_{th} + \frac{kT}{q}\ln\frac{\sigma_e{}^L + \sigma_i}{\sigma_e{}^{\circ} + \sigma_i} \quad [27]$$

where $\sigma_e{}^{\circ} \equiv q\nu_e n_o$, and we have used also Eq. [19]. At the high pressure side near A_2, the conductivity is assumed to be mainly ionic, i.e., $\sigma_e{}^L << \sigma_i$, hence

$$t_i{}^{\circ} \equiv \frac{\sigma_i}{\sigma_e{}^{\circ} - \sigma_i} = e^{-\beta q(V_{th}-V_{o.c.})} \quad [28]$$

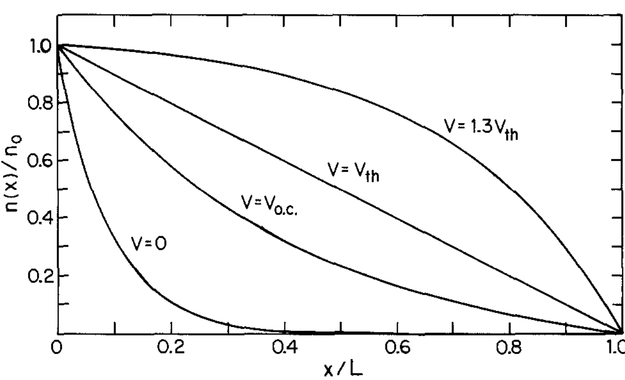

Fig. 2. $n(x)/n_o$ vs. x for various values of V, under the conditions: $V_{th} = 1.03V$, $T = 1073$ K ($n_L/n_o = 1.5 \times 10^{-5}$).

Equations [26] and [28] can be combined to relate $\bar{t}_i$ and $t_i{}^{\circ}$

$$\bar{t}_i = 1 + \frac{kT}{qV_{th}}\ln t_i{}^{\circ} \quad [29]$$

This was obtained also by Tannhauser (2) and is implicitly contained in the work of Schmalzried (8). As the oxide is reduced on the fuel side $t_i{}^{\circ}$ may be quite small. $\bar{t}_i$, however, decreases slowly with $t_i{}^{\circ}$. We shall repeatedly consider the following example which can represent a MSEFC made of doped CeO_2 (2, 5)

$$T = 800°C$$
$$V_{th} = 1.03 \text{ eV } (P_{O_2}{}^{I} = 10^{-20} \text{ atm},\ P_{O_2}{}^{II} = 0.21 \text{ atm})$$
$$t_i{}^{\circ} = 0.1 \quad [30]$$

For this example, $\bar{t}_i = 0.8$. It should be noticed that a small $t_i{}^{\circ}$ is possible though the electron concentration is smaller than the ion concentration since $\nu_e/\nu_i >> 1$ (2).

Comparison Between a MSEFC and a PSEFC

We compare now the power generated by a fuel cell based on a MSE with the power generated by a pure solid electrolyte fuel cell (PSEFC). To make the comparison meaningful we assume that, except for a difference in the electronic conductivities, all other parameters are the same, namely, σ_i, T, $P_{O_2}{}^{I}$, $P_{O_2}{}^{II}$, L, S, and the rate of fuel consumption (i.e., j_i is the same in both cells). Equations [15] and [23] show that j_i is the same in the two cells if operating with the same voltage V. Hence, the ratio r of the power generated by the MSEFC: VI, to that generated by the PSEFC: VI_i, is

$$r = \frac{I}{I_i} \quad [31]$$

From Eq. [15], [23], and [24]

$$r = 1 - \frac{\sigma_e{}^L}{\sigma_i}\,\frac{e^{\beta qV} - 1}{1 - e^{-\beta q(V_{th}-V)}} \quad [32]$$

where we have used $I = Sj$. r can be expressed in terms of the measurable quantities $\bar{t}_i$, V_{th}, and V using Eq. [19], [28], [29]

$$r = 1 - (e^{\beta q(1-\bar{t}_i)V_{th}} - 1)\,\frac{1 - e^{-\beta qV}}{e^{\beta q(V_{th}-V)} - 1} \quad [33]$$

For the normal use of a fuel cell $0 < V < V_{o.c.}$ Table I shows the values of r vs. V/V_{th} and $j_i/j_{i,max}$ for the example given in Eq. [30]. $j_{i,max}$ is the maximum ionic current through the cell obtained under short-circuit conditions ($V = 0$). It is seen that for $V/V_{th} \lesssim 0.6$, $r \gtrsim 0.9$, thus under these conditions the power generated by an MSEFC is only a few percent lower than

Table I. (T = 1073 K, V_{th} = 1.03V, t_i° = 0.1)

V/V_{th}	$j_i/j_{i,max}$	r	η	R_iP/V_{th}^2
0	1	1.00	0.00	0
0.1	0.9	1.00	0.10	0.09
0.2	0.8	1.00	0.20	0.16
0.3	0.7	1.00	0.30	0.21
0.4	0.6	0.99	0.40	0.24
0.5	0.5	0.97	0.48	0.24
0.5	0.4	0.89	0.54	0.21
0.7	0.3	0.67	0.47	0.14
0.787 ($V = V_{o.c.}$)	0.213	0	0	0

that generated by the comparable PSEFC. The decrease in r with V is due to an increase in the electronic component of the current and a decrease in the ionic one. This is shown in Fig. 3.

Efficiency

The efficiency η is defined as

$$\eta = \frac{VI}{V_{th}I_i} \quad [34]$$

and gives that fraction of the change in the oxygen-free energy ΔG which is turned into useful energy. From Eq. [31]

$$\eta = \frac{V}{V_{th}} r \quad [35]$$

Table I shows the calculated values of η. The maximum efficiency η_{max} occurs at $V/V_{th} = 0.6$, where $r = 0.89$. An analytic expression for η_{max} can be obtained. Inserting Eq. [33] into [35] yields

$$\eta = \frac{V}{V_{th}}\left(1 - \alpha \frac{1 - e^{-\beta q V}}{e^{\beta q (V_{th} - V)} - 1}\right) \quad [36]$$

where $\alpha \equiv [\exp\{\beta q (1 - \bar{t}_i) V_{th}\} - 1]$. In the neighborhood of η_{max}, $V \sim 0.5 V_{th}$. If $\beta q V_{th} >> 1$ then

$$\eta = \frac{V}{V_{th}} (1 - \alpha e^{-\beta q (V_{th} - V)}) \quad [37]$$

From $d\eta/dV = 0$, one finds $V_{m,\eta}$, the value of V for which $\eta = \eta_{max}$

$$V_{m,\eta} = V_{th} - \frac{kT}{q} \ln\{\alpha(1 + \beta q V_{m,\eta})\} \quad [38]$$

This implicit equation for $V_{m,\eta}$ can be solved by successive approximations. For $\beta q V_{th} >> 1$ and $\alpha \lesssim 10$, as for a high temperature fuel cell with conditions similar to those in Eq. [30], two iterations are sufficient to calculate $V_{m,\eta}$ to a very good approximation

$$V_{m,\eta} = V_{th} - \frac{kT}{q} \ln\left\{\alpha\left(1 + \beta q\left[V_{th} - \frac{kT}{q} \ln\{\alpha(1 + \beta q V_{th})\}\right]\right)\right\} \quad [39]$$

This yields $V_{m,\eta}/V_{th} = 0.64$ and $\eta_{max} = 0.54$ for the example in Eq. [30].

Maximum Power

The power output of the cell, $P = VI$, is shown in Table I. The maximum in P occurs at $V_{m,P} \sim 0.5 V_{th}$. To calculate $V_{m,P}$ we write P explicitly using Eq. [24]

$$P = \frac{S\sigma_i}{L}(V_{th} - V) r = \frac{S\sigma_i}{L}(V_{th} - V) V[1 - \alpha e^{-\beta q (V_{th} - V)}] \quad [40]$$

where we have limited V to values near $V_{m,P} \sim \frac{1}{2} V_{th}$ and have used $\beta q V$, $\beta q (V_{th} - V) >> 1$ to obtain an approximation for P. $dP/dV = 0$ yields

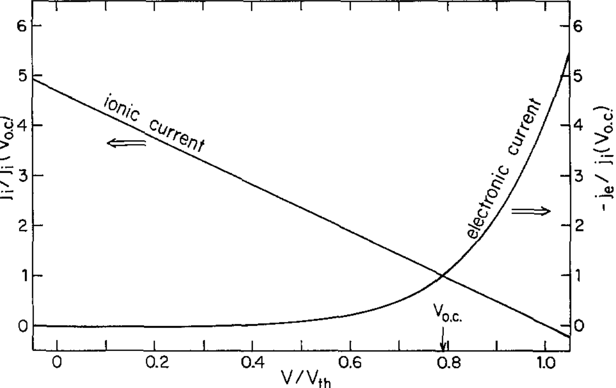

Fig. 3. $j_i/j_i(V_{o.c.})$ and $-j_e/j_i(V_{o.c.})$ vs. V/V_{th} for V_{th} = 1.03V, T = 1073 K.

$$V_{m,P} = \frac{1}{2} V_{th} - \frac{1}{2} \alpha e^{-\beta q (V_{th} - V)} [V_{th} - 2V_{m,P} + \beta q V_{m,P} (V_{th} - V_{m,P})] \quad [41]$$

This equation can be solved by successive approximations. At the lowest approximation $V_{m,P} = \frac{1}{2} V_{th}$ and the next approximation is

$$V_{m,P} = \frac{1}{2} V_{th} - \frac{1}{8} \alpha e^{-\frac{1}{2}\beta q V_{th}} \beta q V_{th}^2 \quad [42]$$

Equation [42] yields $V_{m,P}/V_{th} = 0.466$ for the example in Eq. [30]. Further iterations in Eq. [41] yield the exact solution $V_{m,P}/V_{th} = 0.480$. The maximum power is $P_{max} = 0.97 \times (0.25 V_{th}^2/R_i)$, where $R_i = L/S\sigma_i$ and the efficiency at $V_{m,P}$ is $\eta = 0.46$. These values referring to the MSEFC are only somewhat lower than the corresponding ones for the comparable PSEFC where $P_{max} = 0.25 V_{th}^2/R_i$ and $\eta = 0.50$. The differences are small since the electronic current is small, compared to the ionic one, for $V \sim \frac{1}{2} V_{th}$ (see Fig. 3).

Conclusions

We have expressed $n(x)$, j_e, J'', P, η, P_{max}, and η_{max} explicitly in terms of the parameters of the system, namely, V_{th}, V, T, σ_i, R, L, S, and $\bar{t}_i$. The characteristics of an MSE are σ_i and the value of $\bar{t}_i$ for given values of $P_{O_2}^{I}$, $P_{O_2}^{II}$, and T. If σ_i and $\bar{t}_i$ are measured, then the expected distribution of electrons in the MSE, as well as the properties of a fuel cell based on the MSE, can be calculated as a function of the remaining parameters. The quantitative example of a fuel cell based on the MSE CeO_2-10 m/o Gd_2O_3 shows that the maximum power output is only 3% lower than if $\bar{t}_i = 1$, the power output density increases almost linearly with the ionic conductivity of the MSE, and the maximum efficiency is 54%. This is consistent with results obtained before (2).

LIST OF SYMBOLS

I, j	current and current density
I_e, j_e	electronic current and current density
I_i, j_i	ionic current and current density
k	Boltzmann constant
L	length of MSE

MSE	mixed conductor solid electrolyte
MSEFC	mixed conductor solid electrolyte fuel cell
n	quasi free electron concentration
n_o, n_L	n at $x = 0$, $x = L$, respectively
N	ionic (V_o'') concentration
P	electrical power
P_{max}	maximum P
P_{O_2}	oxygen partial pressure
$P_{O_2}{}^{I}$, $P_{O_2}{}^{II}$	P_{O_2} near the anode and cathode of the fuel cell, respectively
q	absolute value of electronic charge
R	load resistance
r	I/I_i
S	cross-section area of MSE
$\bar{t}_i$	average transference number
t_i°	transference number at $x = 0$
T	temperature
V	voltage of fuel cell under load
$V_{m,p}$, $V_{m,\eta}$	V at maximum power output and maximum efficiency, respectively
V_{th}	$kT/4q \ln P_{O_2}{}^{II}/P_{O_2}{}^{I}$
x	position inside the MSE ($0 \leq x \leq L$)
ϵ	electrical field ($- d\phi/dx$)
σ_e	electronic conductivity
σ_e°, σ_e^{L}	σ_e at $x = 0$ and $x = L$
σ_i	ionic conductivity
η	energy conversion efficiency
η_{max}	maximum η
μ_e, μ_i, μ_{O_2}	chemical potential of quasi free electrons, ionic charge carriers, and oxygen, respectively
$\bar{\mu}_e$, $\bar{\mu}_i$	electrochemical potential of quasi free electrons and ionic charge carriers, respectively
ν_e, ν_i	electronic and ionic mobilities
ϕ	electrical potential

ABSTRACT

Corrosion resistant Zn-Co alloys were electrodeposited on the steel sheet cathode from an acid galvanizing bath containing a small amount of cobalt sulfate. Under most of the plating conditions studied, the anomalous codeposition and, hence, the preferential deposition of electrochemically less noble Zn occurred. The electrodeposition process of the alloy including the Zn hydroxide formation resulting from the rise in pH in the vicinity of the cathode was estimated by electrochemical and spectroscopic studies.

Since the standard electrode potential of Zn is more negative than that of Fe, Zn has been widely used as an electrochemically protective coating material for steel under ordinary atmospheric conditions. The corrosion resistance of pure Zn coatings is, however, not satisfactory under more corrosive circumstances, particularly in a very humid atmosphere. Recently, a composite electrogalvanizing bath containing a small amount of additive elements has been developed and it was indicated that the addition of Co, Co-Cr, or Co-In considerably increases not only the corrosion resistance but also the subsequent chromating characteristics of galvanized steel (1). The addition of these elements was so effective in the improvement of the surface properties of Zn coatings that these composite baths were employed in commercial galvanized steel production (2).

However, the mechanism which permits the improvement of the surface properties of galvanized steel is not yet available. This led to a serious drawback for the development of Zn coatings having further superior surface properties. In order to elucidate this mechanism, it is necessary to make clear the electrodeposition processes of the additive elements. In this paper, Co which markedly improved the corrosion resistance of galvanized steel was selected as the additive element and the mechanism of Co codeposition was estimated.

[1] Present address: Technical Research Center, Nippon Kokan K.K., Kawasaki 210, Japan.

Key words: electrodeposition, surface pH, film resistance, XPS measurement.

Experimental

Electrodeposition.—Deposits were obtained on the low carbon steel sheet cathode of 4 × 5 cm^2 area under coulostatic and galvanostatic conditions (80 kcm^{-2}). The standard plating conditions were similar to those commonly employed in ordinary electrogalvanizing (1, 2) and are shown in Table I. The deposited metals were weighed and dissolved from the cathode with dilute HCl solution. Co was determined colorimetrically by using the color development between the Co ion and β-nitroso-α-naphtol (3), and the composition of alloys was calculated.

Table I. Standard plating conditions

Bath composition		Operating condition
$ZnSO_4 \cdot 7H_2O$	1.739 kmol m^{-3} (114g $liter^{-1}$ as Zn)	Current density 3 kA m^{-2} Temp 50°C
$CoSO_4 \cdot 7H_2O$	0.170 kmol m^{-3} (10g $liter^{-1}$ as Co)	
Na_2SO_4	0.352 kmol m^{-3}	
$CH_3COONa \cdot 3H_2O$	0.110 kmol m^{-3}	
Metal—% of Co in bath = 8, pH 4.2		

Measurement of the pH in cathode layer.—The measurement of pH in the vicinity of the cathode during the electrodeposition of Zn-Co alloys was carried out by means of the antimony microelectrode method (4, 5). The experimental setup is shown in Fig. 1. The design of the apparatus permitted the antimony microelectrode of 1 mm diam and reference Ag/AgCl electrode to be placed in position exactly 10 μm from the steel sheet cathode of 4 × 5 cm^2 area. Figure 2 shows the pH dependence of the antimony microelectrode potential when the pH of the bath used in this work was varied. There existed a linear relationship between the pH and the potential of the antimony microelectrode, indicating the validity of the adoption of this method. Figure 2 was also used as the pH calibration curve.

Solubility measurement of the metal hydroxides.—Two types of solutions were prepared in which Zn or Co ion was removed from the standard bath composition and the pH was raised to various values with NaOH solution. The concentration of metal ion still remaining in each solution at 50°C was determined polarographically for Zn and colorimetrically for Co, and the solubilities of Zn and Co hydroxides at various pH's in the bath used were estimated.

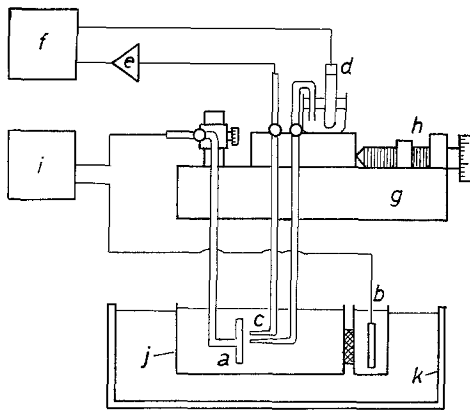

Fig. 1. Experimental setup for the measurement of the pH in the vicinity of the cathode during the electrodeposition of the alloys. a, Cathode; b, anode; c, antimony microelectrode; d, reference Ag/AgCl electrode; e, impedance transducer (10^7 MΩ); f, potential recorder; g, micrometer; h, micrometer screw; i, d-c constant current power supply; j, cell for electrolysis; k, thermostat.

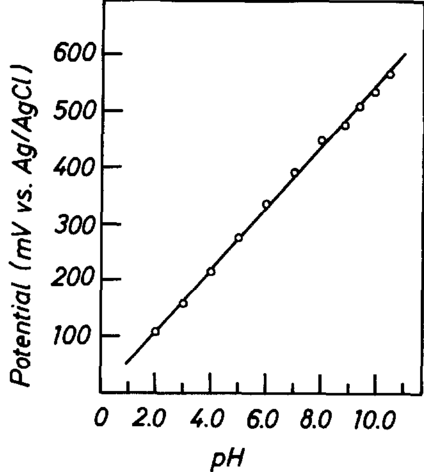

Fig. 2. Relationship between the potential of antimony microelectrode and pH of the solution at 50°C.

Evaluation of the surface film resistance.—In order to confirm the metal hydroxide film formation on the cathode during the electrodeposition of the alloys, the resistance across the cathode surface (steel sheet of 4 × 5 cm^2 area) and the tip of the capillary bridge of the reference NHE was measured by the interrupter method (6).

A constant current pulse of repetition frequency 18.3 msec, of duty factor 96.42%, and of various current densities was applied to the electrodes, and the cathode potential-relaxation waveform was observed on the oscilloscope, from which the resistance overvoltage was read off. The quotient of the resistance overvoltage by the applied current yields the resistance which consists of the film resistance and the resistance due to the solution between the cathode and the capillary tip of the reference electrode. The solution resistance between the cathode and the capillary tip in this electrode arrangement was also determined by applying the single current pulse of short duration (17.6 msec) where the pH rise in the cathode layer, and hence the formation of metal hydroxide, may be negligibly small. The measurement was carried out for each freshly prepared cathode at various current densities. When neglecting the change in solution resistance during the electrolysis, the change in the gap between the observed resistance and the solution resistance will be anticipated to give the information on the surface film formation.

Measurement of the x-ray photoelectron spectra of the electrodeposited alloys.—Experiments were performed in a Dupont 605 electron spectrometer using MgKα radiation (1253.6 eV), scanning at 0.05 eV sec^{-1}. The binding energies of the elements were referred to the vacuum-deposited gold on copper. The binding energies of Au $4f_{7/2}$ and Cu $2p_{3/2}$ lines were taken to be 84.0 and 932.0 eV, respectively. The C 1s binding energy, 285.0 eV, of contamination carbon was used as calibration to compensate for possible charging effects. Ion bombardment of the surface of mechanically polished samples, previously pressed to pellet if in powder form, was carried out for 3 min using prepurified argon prior to the spectra measurement.

Co metal, cobaltous (Co^{2+}), and cobaltic (Co^{3+}) compounds were used as reference material. The binding energies of Co $2p_{3/2}$ level in the reference materials examined are listed in Table II and are in good agreement with those reported earlier (7, 8). As is evident from Table II, the chemical shift generally used to distinguish the oxidation states of the element is very small between the cobaltous and the cobaltic compounds. Therefore, it is difficult to clarify the oxidation state of Co in these compounds. However, the chemical shift relative to the binding energy in metallic state is large enough to distinguish the metallic state from the oxidation state of Co.

Table II. Binding energies of Co $2p_{3/2}$ in different cobalt compounds

Compound	Binding energy (eV)
Co_2O_3	780.2
Co_3O_4	780.3
CoO	780.7
$Co(OH)_2$	780.6
Co metal	778.4

Results and Discussion

Deposition behavior of the alloys.—Electrodeposition of Zn-Co alloys is classified into anomalous codeposition by Brenner (9) and is characterized by the anomaly that the less noble metal deposits preferentially.

The effect of the metal percentage of Co in the bath on the Co content of the deposits is shown in Fig. 3. The broken line in the figure indicates the composition reference line (hereinafter simply referred to as CRL) which shows that the weight percentage composition of the alloy just equals the metal percentage of the bath. Figure 3 shows that the Co content of the deposits increased linearly with an increasing metal percentage of Co in the bath. And in all cases studied, the Co content of the deposit lay below the CRL, which indicated the preferential deposition of Zn, although the equilibrium potential of Zn is several tenths of a volt less noble than that of Co.

Figure 4 shows the relationship between the Co content of the deposits and the current density. In the low current density region, the deposit had a larger content of the noble metal Co than the metal percentage of Co in the bath. This indicaates that the codeposition appears to be of the normal type. With increasing current density, the deposit rapidly decreased in Co content and above the transition current density contained much more Zn than the metal percentage of Zn in the bath. This transition of the deposition behavior of Co from a normal to an anomalous type occurred in a rather small range of the current density. Further increase in the current density resulted in little change in alloy composition, followed by the trend of Co content slightly upward at still higher current density. Thus, with increasing current density, the Co content of the deposits either decreased, remained constant, or increased, which was the same trend as reported by Brenner (10).

Consequently, the electrodeposition study revealed that the deposition of each metal from the baths used in this work exhibited the characteristics of an anomalous codeposition.

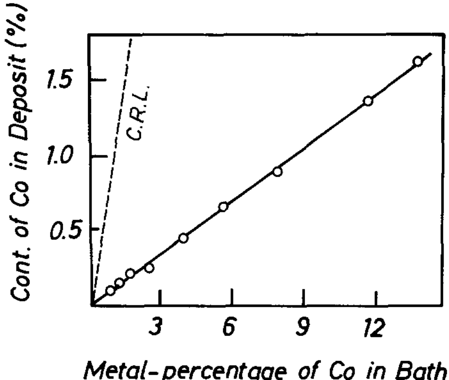

Fig. 3. Effect of metal percentage of Co in the bath on the composition of electrodeposited Zn-Co alloys. Metal percentage of Co = [wt Co/total wt (Co + Zn)] × 100.

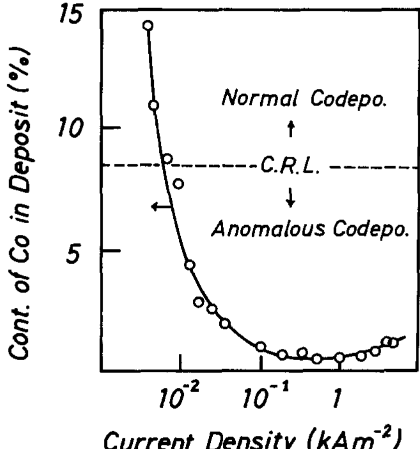

Fig. 4. Effect of current density on the composition of electrodeposited Zn-Co alloys.

Formation of Zn hydroxide film during the electrodeposition of the alloys.—There is, as yet, no theoretical explanation which satisfactorily describes the mechanism of the anomalous codeposition. Many hypothesis have been proposed so far (11-13) and one of the most plausible mechanisms included the assumption that the pH in the vicinity of the cathode was raised to permit the precipitation of metal hydroxide on the cathode (14-16).

Figure 5 shows the pH dependence of the solubility of Zn or Co hydroxide in the bath used. From Fig. 5, the critical pH values for the precipitation of Zn and Co hydroxides were 5.1 and 6.8, respectively.

Then, the alloys of various composition were electrodeposited at various current densities under the standard plating conditions shown in Table I, and the relationship between the Co content in the deposits and the pH in the cathode layer measured by the antimony microelectrode method was examined. The result is shown in Fig. 6 which also includes the critical pH's for each metal hydroxide precipitation, the pH of the bulk solution, and the CRL. Figure 6 showed that the critical pH for Zn hydroxide precipitation was not achieved in the normal codeposition region although the rise in pH of the cathode layer was observed in all cases. On the other hand, the abrupt rise in the pH was recognized from a value below to a value above the critical pH for Zn hydroxide precipitation when the transition of codeposition from the normal to the anomalous type occurred. In the anomalous codeposition region, the pH of the cathode layer remained in the pH range well below the critical one for Co hydroxide precipitation, probably by the buffering effect due to the Zn hydroxide formation. This indicates that the pH rise in the cathode layer and subsequent Zn hydroxide formation should be closely related to the mechanism of the anomalous codeposition.

Empirical confirmation of the formation of Zn hydroxide film during the electrodeposition of the alloys was also tried under the standard plating conditions by estimating the surface film resistance. Figure 7 shows the change in the resistance obtained by means of interrupter method (6) with the current density. The solution resistance between the cathode surface and the tip of the capillary bridge of the reference electrode was also included in Fig. 7. The resistance

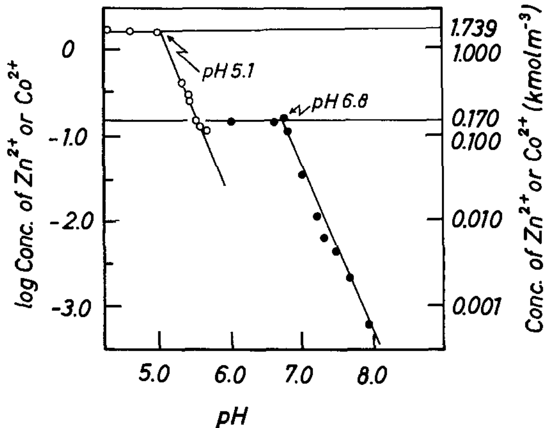

Fig. 5. pH dependence of the solubilities of Zn and Co hydroxides. ○ = Zn^{2+}; ● = Co^{2+}.

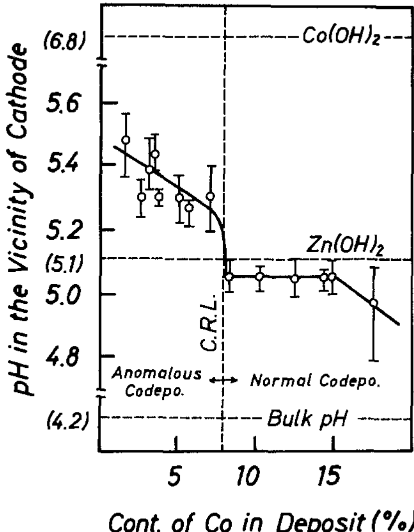

Fig. 6. Relationship between the composition of alloys and the pH in the vicinity of the cathode during the electrodeposition of Zn-Co alloys at various current densities under galvanostatic conditions.

during electrolysis was initially increased and then remained constant with the increased current density. And, at the low current densities where the codeposition of the normal type occurred, the smaller resistance mainly due to the solution was observed. With the increased current density to permit the anomalous codeposition, the larger resistance was observed. These indicate that the resistive component was formed on the cathode with an increase in the current density.

Estimation of the anomalous codeposition process and the confirmation of this mechanism by x-ray photoelectron spectroscopy.—From the results presented above, it becomes possible to propose a mechanism which provides a reasonable explanation for the following features of anomalous codeposition: the preferential deposition of Zn under most conditions of plating although Zn is considerably less noble than Co, the existence of a normal codeposition behavior at low current densities, and the abrupt transition of codeposition from a normal to an anomalous type as the current density is raised.

During anomalous codeposition of Zn with Co, the electrodeposition of Zn proceeds with preceding Zn hydroxide formation on the cathode, which results from a rise in pH in the vicinity of the cathode. On the other hand, since the critical pH for Co hydroxide precipitation is not attained in the cathode layer, Co deposition occurs by the direct discharge of Co^{2+} ions through the Zn hydroxide film, which makes the Co deposition difficult. Consequently, the superiority of Co over Zn in nobility is canceled out by the film resistance of Zn hydroxide, resulting in the preferential deposition of Zn in anomalous codeposition.

Comparison of Fig. 4 with Fig. 7 seems to support the above process of the alloy deposition. In the low current density range, the normal codeposition occurs reflecting the nobility of each metal, since Zn hydroxide neither quite precipitates nor precipitates to such an extent that the Zn hydroxide film exhibits enough resistance to prevent the Co deposition. At about the transition current density, the film resistance increases rapidly to compensate the superiority of Co in nobility, resulting in the abrupt transition of codeposition from a normal to an anomalous type. With further increase in the current density, the alloy composition remains almost constant because the formation rate of Zn hydroxide is balanced by the consumption rate of it due to the electroreduction, which makes the film resistance constant. Thus, the depositing behavior of Co agreed well with the change in the resistance during the electrodeposition of the alloys.

Assuming the alloy deposition occurs in accordance with the above mechanism, Co should be in a metallic state in the deposit. Figure 8 shows the x-ray photoelectron spectra of the deposit obtained under the standard plating conditions shown in Table I. In Fig. 8, spectrum (a) provided no definite peak probably because of the low Co content of approximately 0.9% in the deposit. However, spectrum (b) obtained by integrating 128 times the single scanned intensity using the multichannel analyzer indicated the well-defined peak at the binding energy of 778.2 eV, which is in good agreement with that of metallic state of Co in Table II.

Summary

Zn-Co alloys were electrodeposited from an acid electrogalvanizing bath containing a small amount of cobalt sulfate. In a wide range of plating conditions, the deposition behavior of each metal showed the main features of anomalous codeposition. Electrochemical and spectroscopic studies revealed the following mechanism of anomalous codeposition of Co with Zn. The electrodeposition of Zn proceeds with preceding Zn hydroxide formation through which the discharge of Co^{2+} ions occurs. Consequently, the superiority of Co over Zn in nobility is canceled out by the film resistance of Zn hydroxide, resulting in anomalous codeposition.

Electrogenerated Chemiluminescence of *trans*-Stilbene Derivatives

James R. Wilson, Su-Moon Park,* and Guido H. Daub

Department of Chemistry, University of New Mexico, Albuquerque, New Mexico 87131

ABSTRACT

Fluorescence maxima, fluorescence quantum yields, electrode potentials, and electrogenerated chemiluminescence (ecl) of 16 *t*-stilbene derivatives such as substituted indenes and dihydronaphthalenes (DHNP) are reported. Both indenes and DHNP's were found to have greatly enhanced fluorescence quantum yields in comparison to *t*-stilbene. Twelve single systems of 16 compounds gave ecl mostly attributed to the singlet excited state. With tri-p-tolylamine (TPTA) added as a source of cation radical, most of the systems produced ecl having shorter wavelength emission corresponding to the singlet excited state of the *t*-stilbene derivatives and longer wavelength emission attributed to the exciplex. The ecl intensities with respect to the possible applications are discussed.

Electrogenerated chemiluminescence (ecl) is a process where the electrochemically generated radical species, usually cation and anion radicals, annihilate to give an excited state molecule, which subsequently emits light (1, 2). Due to its uniqueness in exciting molecules, several possible applications have been suggested and discussed (3-9). In our continuing effort (10, 11) to discover more efficient ecl, we performed ecl studies on a series of laser dyes structurally related to *trans*-stilbene (*t*-St). Structures of these compounds are shown in Fig. 1. These compounds have been synthesized in one of our laboratories (GHD) as laser dyes (12, 13) and the lasing action of these dyes has been tested (14). As shown in Fig. 1, these dyes are of modified forms of the *t*-stilbene chromophore.

Electron transfer chemiluminescence of *t*-stilbene was first reported by Weller and Zachariasse (15, 16). The mixed system containing tri-p-tolylamine (TPTA)(+)/*t*-St(−) was chemiluminescent in THF with the longer wavelength emission attributed to the exciplex (16), while the one containing N,N,N′,N′-tetramethyl-p-phenylenediamine (TMPD)(+)/*t*-St(−) was nonchemiluminescent (15). Later, Keszthelyi and Bard (17) reported electrogenerated chemiluminescence in the THF solution for the TPTA(+)/*t*-St(−) system, where only exciplex emission was identified as in the chemiluminescence experiment.

In the present report, fluorescence, ecl, and electrochemical potentials of rigid *t*-stilbene analogs, having

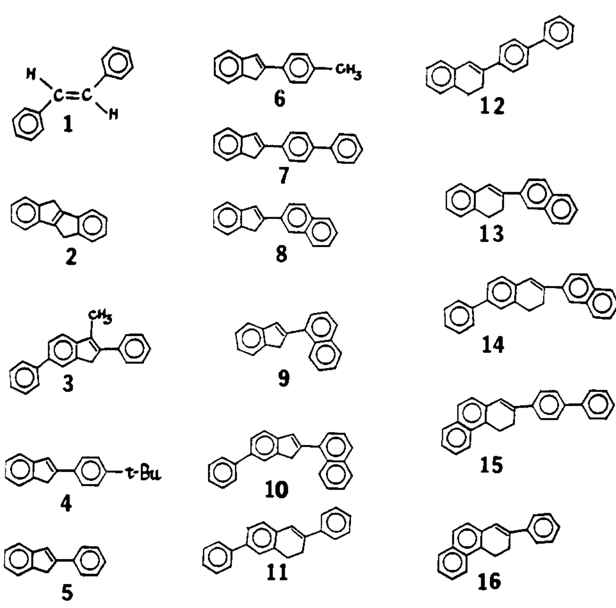

Fig. 1. Structures of compounds used in this study (see Table I for the nomenclature).

either indene or dihydronaphthalene structures (Fig. 1), have been studied, and the results are reported. In these compounds, the flexibility of the double bond is reduced. Fluorescence studies have shown that a rigid molecular structure reduces the excitation energy loss due to the vibrational and rotational energy loss of the excited molecule, enhancing the fluorescence emission quantum efficiencies (18). The effect of substitution on the fluorescence and ecl has been studied and discussed in this report.

Experimental

Spectrograde acetonitrile (ACN, Eastman Organic), spectrograde benzene (Bz, Aldrich), and polarographic grade *tetra*-n-butylammonium perchlorate (TBAP, Eastman Organic) were purified and dried as described previously (11) and used as solvents and supporting electrolyte, respectively. Spectrograde cyclohexane [Matheson, Coleman, and Bell (MCB)] was distilled under partial vacuum with the middle 30 ~ 40% collected and used as a solvent for the fluorescence measurement. Laboratory quinine sulfate (Fischer Scientific) and scintillation grade *t*-stilbene (MCB) were used as received. TPTA was kindly provided by Professor R. N. Adams of the University of Kansas and used as received. Compounds 2-16 were synthesized and purified in one of our laboratories (GHD) and procedures of syntheses and purifications have been published elsewhere (12, 13).

Solutions for ecl experiments have been prepared in a three-electrode configuration cell as described previously (11). Electrochemical measurements were also made employing a three-electrode cell with a platinum disk working electrode (area $\simeq$ 0.021 cm^2). At the conclusion of the electrochemical measurements, the electrode potentials were referenced to a saturated calomel electrode (SCE), which was inserted while the cell was flushed gently with helium.

A Princeton Applied Research (PAR) Electrochemistry Model 173 potentiostat-galvanostat with a PAR Model 175 universal programmer and a PAR Model 176 *I/E* converter were used for cyclic voltammetric measurements and ecl experiments. Ecl and fluorescence spectra were detected by an Aminco-Bowman spectrophotofluorometer with a Hammamatsu TV R446 photomultiplier tube and recorded on a Plotomatic 815 X-Y recorder. A Cary-14 spectrophotometer was used for the absorption spectrum measurements.

Results and Discussion

Fluorescence maxima, fluorescence quantum yields, electrode potentials, and ecl data for *t*-stilbene derivatives are summarized in Tables I and II. Ecl results for the TPTA/*t*-stilbene derivative mixed systems are listed in Table III. Typical results for selected compounds have been shown in Fig. 2-4. More detailed description of the results follows.

Fluorescence studies.—Fluorescence maxima and fluorescence quantum yields for 15 *t*-stilbene derivatives in cyclohexane solutions are listed in Table I. These quantities were measured with a spectral band pass of 5.5 nm for both excitation and emission and a fluorescer concentration of $1.0 \times 10^{-5}M$ at room temperature. The fluorescence maxima of these compounds were not dependent on the solvent used, indicating that dipole moments of the excited and ground state molecules may not be significantly different. The fluorescence quantum yields were measured by comparison with a reference compound [*i.e.*, quinine sulfate according to the well-known procedure (18)] and corrected for the refractive index of the solvent used (19). The fluorescence quantum yield for *t*-stilbene has been reported to be 0.04 ~ 0.08 at room temperature in nonviscous solvents, depending on experimental conditions (20-23). The results in Table I show that the

stilbene derivatives have generally lower transition energies and enhanced fluorescence quantum yields than *t*-stilbene. These results are consistent with the expectation discussed below. Excitation of *t*-stilbene reduces the double bond character of the ethylene bridge, which subsequently allows the two benzene rings to rotate around the single bond (24). The loss of excitation energy due to the rotation of the benzene rings will be reduced or minimized by substitutions, varying with the size and location of the substituent. When the double bond is made rigid, preventing the rotation of phenyl groups around it after excitation, the energy of the electronic transition is expected to decrease (red shift) and the fluorescence quantum yield should increase (20, 24). Although compound 2 may appear to be planar, it was shown to be the most nonplanar of the compounds when examined by the molecular model. This nonplanarity reduces the resonance between the two phenyl rings, resulting in a relatively high transition energy and a low fluorescence quantum yield in comparison with other compounds. Inspection of Table I and Fig. 1 reveals that compounds having a 6-membered ring around the double bond (3,4-dihydronaphthalene derivatives = DHNP) have generally low transition energies and higher fluorescence quantum yields than the corresponding 5-membered compounds (indene derivatives). This illustrates that the 6-membered ring around the *t*-stilbene double bond is more planar than the 5-membered ring, resulting in higher resonance and conjugation between the two phenyl groups on both sides of the double bond.

Electrode potentials.—Oxidation and reduction potentials of these compounds were measured at a platinum disk electrode using a saturated calomel electrode (SCE) as a reference electrode. The results obtained in ACN and ACN-Bz are reported in Table II.

Inspection of Table II reveals that indene derivatives are generally more difficult to reduce and easier to oxidize than *t*-stilbene. When more aromatic rings are incorporated as in compounds 7, 8, 9, and 10, the reduction is made easier, as expected. Dihydronaphthalenes are generally easier to reduce and oxidize, indicating that phenyl groups on both sides of the double bond communicate better through the six-membered ring configuration, which is consistent with the fluorescence results.

[c] Relative intensities with respect to that of 1.0 mmol 9,10-diphenylamine (DPA).
[d] Numbers in parentheses indicate second and third oxidation potentials.

While the reduction of *t*-stilbene was fairly reversible, the reduction of indenes showed little or no reversal current (Fig. 2). This is probably because radical anions of these compounds cannot obtain a planar structure unless the 5-membered ring is broken. The reduction of DHNP compounds, however, was generally reversible. Here both neutral and reduced molecules may have planar structures through the 6-membered ring structure, leading to lower reduction potentials and higher stability of the radical anion formed.

None of the oxidation processes were reversible with the exception of compound 3 as shown in Fig. 2. This illustrates that the steric effect may be more important than the inductive effect. We see from Fig. 1 that compounds 2 and 3 differ from the rest in that all hydrogens on the olefinic double bond are substituted. The reversibility observed for compound 3 may therefore illustrate the importance of the inductive effects of the methyl group, whose electron-donating property would stabilize the oxidation product, *i.e.*, the radical cation. The oxidation of compound 2 was not reversible, however; the reason may be that the steric effect is more important in making the radical cation stable, since compounds 2 and 3 are practically the same except that the double bond in 2 is tied up by two 5-membered rings around it. Electronic transition energies and the fluorescence quantum yields listed in Table I also demonstrate the importance of the steric effect. As mentioned previously, the molecular model built for compound 2 illustrates that the double bond bridging the two phenyl rings is out of plane, which reduces the resonance and conjugation through the double bond.

ECL of single systems.—The ecl was obtained by applying potential pulses such that a fluorescer is oxidized and reduced to give the cation radical and the radical anion alternately. The ecl results obtained from the single systems in (1:1) acetonitrile-benzene mixed solvents are summarized in Table II. Fluorescence and ecl spectra are shown for compound 3 in Fig. 3. Several compounds did not produce any ecl, probably a result of the ill-behaved electrochemistry.

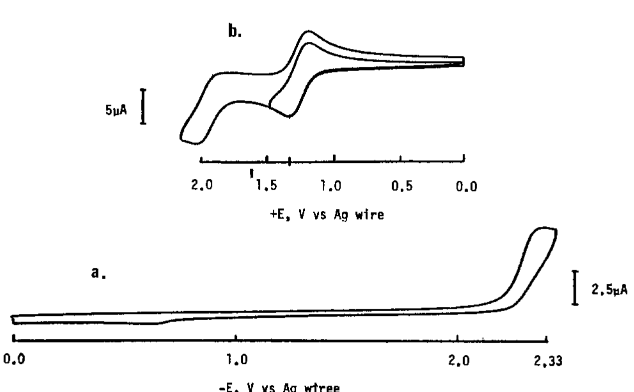

Fig. 2. (a) Cyclic voltammogram for the reduction of compound 3. (b) For the oxidation of compound 3 (C = 0.38 mmol). Both were recorded in (1:1) ACN-Bz mixed solvent with 0.1M TBAP as a supporting electrolyte. Scan rate was 100 mV/sec.

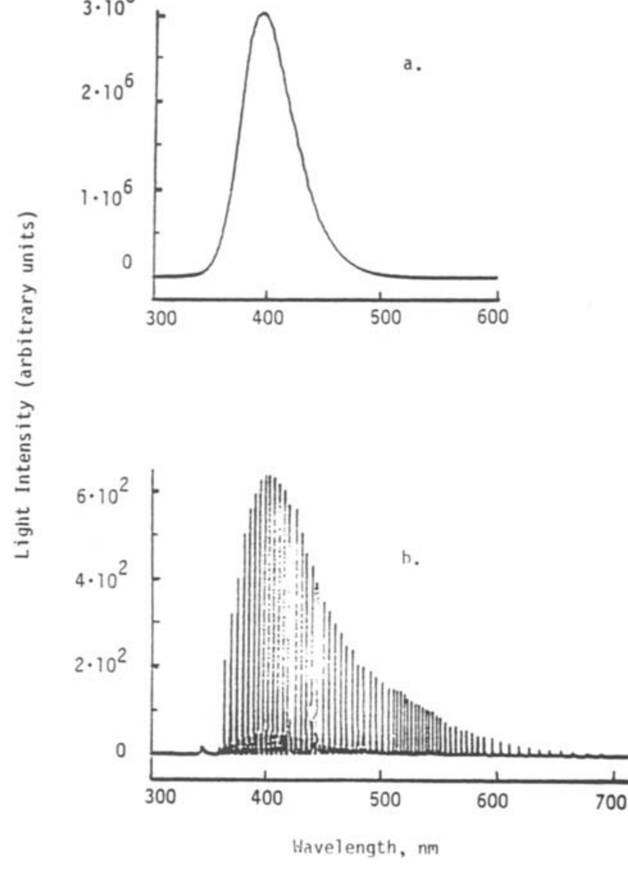

Fig. 3. (a) Fluorescence spectrum of compound 3 (0.67 mmol) in the (1:1) ACN-Bz mixed solvent. Excited at 320 nm. (b) ECL spectrum recorded from the single system of the above solution. Pulse duration was 1 sec.

It is interesting to note that the majority of DHNP's produce ecl corresponding to the fluorescence of the parent compound indicating that the singlet excited molecules are the emitting species. Many of the indene derivatives have ecl emissions which do not correspond to the fluorescence of the compounds studied. Their ecl emissions are at longer wavelengths by approximately 60 ~ 70 nm. The origin of the longer wavelength emission is somewhat unclear. We have carried out routine experiments to rule out the emission from a decomposition product, *i.e.*, fluorescence measurements before and after ecl experiment, frequency dependency of ecl spectra, and detection of impurity current in the cyclic voltammogram recorded before and after ecl experiments, but we have not performed a detailed study such as product analysis. These emissions might have been originated from the eximer, but it is very diffcult to rule out emissions from the electrolysis products, since radical species were not stable.

The reaction enthalpies listed for the single systems in Table II indicate that these ecl systems are energy sufficient. Thus, the emitting singlet excited states of DHNP's might have been produced directly from the ionic recombination reaction.

ECL of mixed systems.—Since most of the compounds studied here produced unstable cation radicals upon oxidation, TPTA was added as a source of the stable cation radical. When the cation radical of TPTA and the radical anion of the compounds studied were generated by the double potential step electrolysis, ecl was observed from all systems as summarized in Table III.

The ecl obtained from the TPTA(+)/*t*-St(−) system has only one emission attributable to the exciplex in agreement with the results observed in tetrahydrofuran (THF) by Keszthelyi and Bard (17). Although they were not able to observe it in a polar medium such as ACN or propylene carbonate, in our study ecl was observed in both ACN and ACN-Bz mixed solvent. The emission maximum listed in Table III for the TPTA(+)/*t*-St(−) is red-shifted by 40 ~ 50 nm from that of Keszthelyi *et al.*'s results This is probably due to a polarity effect of the solvent. A spectral shift of as much as 60 nm, due to the polarity of the solvent used during the ecl experiment (25, 26), has previously been reported for the exciplex emission. Exciplexes between *t*-stilbene and a tertiary amine have also been observed by photoexcitation methods (27).

For many of the systems two emission peaks were observed: a short wavelength emission originating from the singlet excited state of the compound studied and a long wavelength emission attributable to the exciplex. Typical ecl spectra of the mixed system are shown for compound 8 in Fig. 4. In order to establish that the longer wavelength emission originated from the exciplex, the same experiments described above were carried out. Results from these experiments and the stability of the radical species along with several observations described below support that longer wavelength emissions observed from the mixed systems are attributed to the exciplex.

As mentioned earlier in the TPTA(+)/*t*-St(−) system, the effect of the solvent polarity was remarkable for most of the systems studied. An example is shown in Fig. 4. Note in Fig. 4(a) and (b) that the ecl spectral shape changes greatly when the solvent polarity is changed. There are three main points to be noticed in Fig. 4(a) and (b), when the medium of the ecl experiment is changed from the more polar solvent (ACN) to the less polar one (ACN-Bz mixture). First, the overall ecl intensity went down by changing the solvent from the less polar to the more polar one by at least one order of magnitude. Second, the ratio of the monomer emission peak to that of the exciplex also changed. Finally, the emission energy of the exciplex is lower in a more polar medium (red-shifted). These observations were general for the systems studied with the exception of several systems containing indene derivatives. For systems containing indenes, the radical anions were frequently unstable and it was difficult to record good, stable ecl. For most of the DHNP's, the radical anions were stable as can be evidenced by the reversal currents observed in the cyclic

(b) ECL spectrum obtained from the TPTA(+)/2-(2′-naphthylyl)indene(−) system in the (1:1) ACN-BZ mixed solvent. Pulse duration was 1 sec. The solution was 2.2 mmols in TPTA and 0.96 mmol in 2-(2′-naphthylyl)-indene. (c) ECL spectrum obtained from the same system in the ACN solution. Pulse duration = 1 sec. TPTA = 1.2 mmols, 2-(2′-naphthylyl)indene = 1.2 mmols.

voltammogram. The observations summarized above may be understood with the following equilibrium reaction

$$A^- + D^+ \underset{\text{polar}}{\overset{\text{nonpolar}}{\rightleftarrows}} (A^-D^+)^* \underset{\text{polar}}{\overset{\text{nonpolar}}{\rightleftarrows}} {}^3A^* + D$$

where A represents *t*-stilbene derivatives and D, TPTA.

Inspection of Table III indicates that most of the mixed systems are energy deficient with respect to the singlet emitters. While the thermal excitation from the energy potential well of the exciplex to that of the lowest singlet excited state is not impossible (15, 16, 28), it may not be probable. In some cases the energy gap between the two potential surfaces is too large compared with that of kT to allow the thermal crossover. More likely is the dissociation of the exciplex to a triplet excited state of the acceptor, followed by the triplet-triplet annihilation (TTA) to produce the emitting singlet excited state. This process may not occur for *t*-St and several other related compounds due to the short triplet lifetime as pointed out by previous investigators (15-17). Although information about the triplet excited state of most compounds studied here is not available from which to draw any concrete conclusion (with the exception of compounds 1 and 2), the process may be summarized within the framework of our observations as follows

$$A^- + D^+ \rightleftarrows (A^-D^+)^* \rightleftarrows {}^3A^* + D$$

$${}^3A^* + {}^3A^* \rightarrow {}^1A^* + A$$

$${}^1A^* \rightarrow A + h\nu$$

$$(A^-D^+)^* \rightarrow A + D + h\nu$$

The lowest triplet energy level for compounds 1 and 2 are 2.14 and 2.06 eV, respectively (29). Similar or lower triplet energy levels are expected for other compounds.

We would finally like to comment on the intensity of these ecl systems. Approximate relative ecl intensities with respect to that of 9,10-diphenylanthracene (DPA) are listed in Tables II and III for the single and mixed systems, respectively. Although the compounds studied here have high fluorescence quantum yields and most of them lased (14), ecl intensities are orders of magnitude lower than that of DPA. The ecl of single systems was unstable and weak. By mixing with TPTA, ecl intensities were improved somewhat, but not enough to warrant any practical applications. It appears that those systems having two aromatic rings which are connected through a double bond, as in our present study, give unsatisfactory ecl behavior, compared to the polycyclic aromatic compounds such as benzo[a]pyrene derivatives (30).

ABSTRACT

The high temperature $Na/Na_5ErSi_4O_{12}/TiS_2$ cell has been constructed and its electrochemical properties have been investigated. At 125°C, the open-circuit voltage of this cell is 2.10V. Primary discharge studies indicate that the minimum Na^+ conductivity of the $Na_5ErSi_4O_{12}$ is 0.002 Ω^{-1} cm^{-1} at this temperature, so that the rate of charge transport within the cell appears to be controlled by the rate of Na^+ diffusion within the TiS_2. A mathematical model has been developed which predicts the current-time behavior for this kind of cell operating under alkali metal ion diffusion control within the positive plate material. This model predicts that the cell current is given by

$$i(t) = \frac{nFAD^{1/2}\Delta C}{\pi^{1/2}t^{1/2}} \sum_{k=-\infty}^{k=\infty} (-1)^k \exp(-k^2l^2/Dt)$$

where ΔC represents the difference between the surface and initial bulk concentration of alkali metal ion within the TiS_2 and l is the average grain boundary distance for this material. The observed charge-discharge characteristics of this Na/TiS_2 cell have been examined and interpreted on the basis of this model.

Advanced design secondary batteries are presently under development which employ an alkali metal as the negative electrode, a solid electrolyte as the separator material (1), and a solid solution material as the positive electrode (2, 3). Common to the separator and the positive plate material is a high ionic conductivity of the alkali metal employed in the cell, even though this ionic conductivity is generally higher in separator material than it is in the electrode material. While the electrode must exhibit high electronic conductivity, the electronic conductivity of the separator must be low.

Sodium erbium silicate ($Na_5ErSi_4O_{12}$) has been synthesized and identified as a solid electrolyte which has high Na^+ conductivity but low electronic conductivity (4) so that it is suitable as a separator material in a sodium cell. This compound is isotypic with $Na_5GdSi_4O_{12}$ which has a reported ionic conductivity of 0.3 Ω^{-1} cm^{-1} at 300°C (5); this high conductivity is apparently due to the framework structure of the compound in which almost half of the sodium ions are mobile (6). The erbium analog is easily prepared by high temperature synthesis. It may be pressed into pellets and is readily sintered. Because it is relatively stable when exposed to the atmosphere (no observable reaction over a period of several weeks), $Na_5ErSi_4O_{12}$ was judged to be ideally suited as a solid Na^+ conductor for a bench study of this type.

Titanium disulfide (TiS_2) is a well-studied (2, 7, 8) positive plate material that is known to intercalate alkali metal ions; it exhibits high electronic conductivity. Recent studies with chemically prepared Na_xTiS_2 samples indicate that TiS_2 conducts Li^+ much better than it conducts Na^+ (9). Nevertheless, the Na/TiS_2 cell has been under recent study (10), and TiS_2 has been found capable of intercalating Na^+. Thus, TiS_2 is quite acceptable for use in conjunction with a sodium conductor such as $Na_5ErSi_4O_{12}$ for the charge transport studies described below.

These studies, then, were initially undertaken to investigate the properties of $Na_5ErSi_4O_{12}$ as a solid electrolyte separator material and the properties of TiS_2 as a solid solution electrode material in a functional, high temperature, Na/TiS_2 cell. The $Na/Na_5ErSi_4O_{12}/TiS_2$ cell was prepared and subjected to primary and secondary cell testing. As a result of these investigations, it became evident that the charge transport behavior of this cell, both during discharge and during charge, appears to be controlled by the rate of Na^+ diffusion within the electrode material. Based on this observation, a mathematical model was developed which predicts the current-time behavior of the cell under the influence of solid-state diffusion control within the electrode material. The basis for this development, the development of the model itself, and a critique of the model in comparison with the available experimental data constitute the remainder of this report.

Primary Cell Characteristics

The disassembled Na/TiS_2 cell which was used in these studies is shown in Fig. 1. After this cell had been assembled and sodium had been placed in the cup formed by the quartz cylinder and the solid elec-

Key words: electrolyte electrode, current, diffusion.

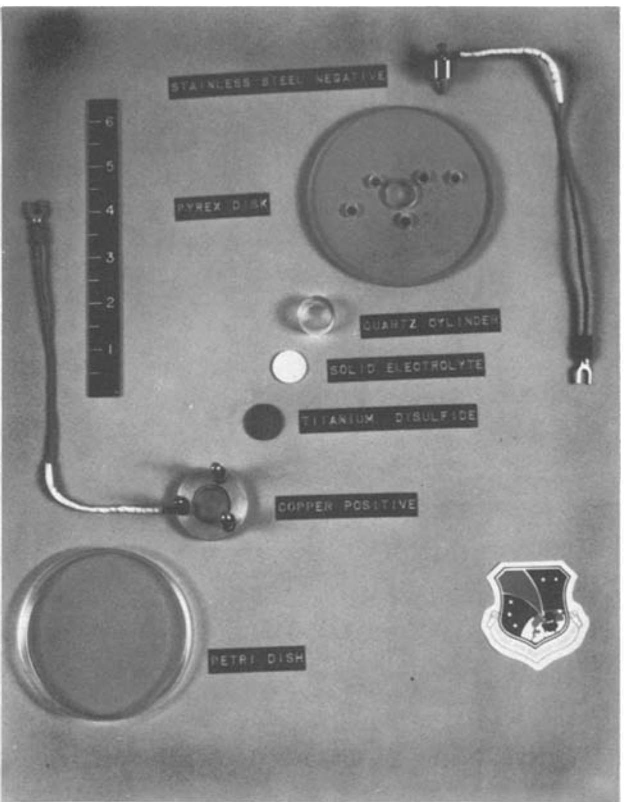

Fig. 1. The dissembled $Na/Na_5ErSi_4O_{12}/TiS_2$ test cell. After assembly, molten sodium was contained within the quartz cylinder which was spring-loaded against pressed pellets of $Na_5ErSi_4O_{12}$ and TiS_2. The assembly was operated under an atmosphere of dry helium. The scale shown is in inches.

trolyte, it was then heated in a glove box under an atmosphere of dry helium; contacts to the stainless steel negative collector and the copper positive collector were made with insulated wires passing through the walls of the glove box to external electronics. After the cell had been heated just beyond the melting point of sodium, it was discharged across a 10 kΩ load, and the initial discharge curve was recorded.

This primary discharge curve at 398 K is shown in Fig. 2. The cell voltage fell immediately to 83% of its open-circuit value during discharge and remained constant during the initial hour of operation; since the load was 10 kΩ this voltage level indicated a maximum

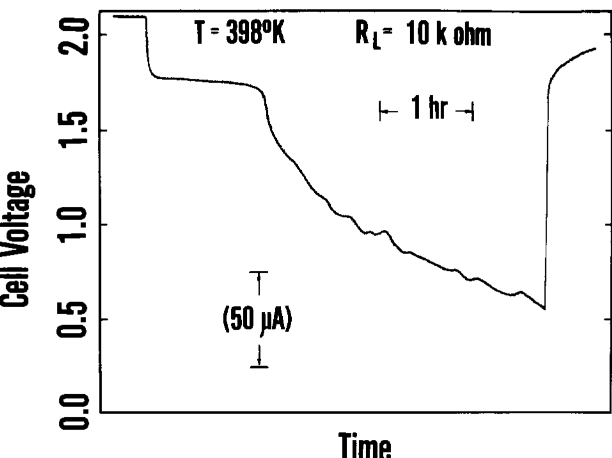

Fig. 2. The Na/TiS_2 primary cell behavior. The open-circuit voltage at the indicated temperature was 2.10V. During discharge this fell to 1.75V and remained constant for more than 1 hr. Thereafter, the cell voltage never exhibited this consistency, even following charge.

initial internal resistance of 2 kΩ. The $Na_5ErSi_4O_{12}$ pellet used in this experiment was 0.100 in. thick; this implies that the minimum conductivity of this material must be at least 0.002 Ω^{-1} cm^{-1}, even at this low temperature. (This approximation is based on the assumption that all internal cell resistance is across the electrolyte; contributions of polarization or interfacial resistances, if measured, would only serve to raise this estimate of Na^+ conductivity within the $Na_5ErSi_4O_{12}$.) Clearly, this material is more than satisfactory as an electrolyte material.

During spontaneous operation, the reaction

$$Na \rightarrow Na^+ + e \quad [1]$$

takes place at the negative ($Na/Na_5ErSi_4O_{12}$) electrode; the reaction which takes place at the positive ($Na_5ErSi_4O_{12}/TiS_2$) electrode is

$$Na^+ + TiS_2 + e \rightarrow NaTiS_2 \quad [2]$$

Secondary Cell Characteristics

After the initial hour of constant current discharge as a primary cell, the cell never again exhibited this constancy of voltage during discharge. Thereafter, the discharge voltage gradually fell off with time as shown in Fig. 2, even when different load resistors and different temperatures were employed. During a final primary discharge of 14 hr over a 100Ω load at 418 K in which the available TiS_2 was less than 2% utilized, the cell voltage fell to 0.5V and primary operation was ceased. The cell was then subjected to charge-discharge studies for various times at different temperatures.

Typical results of these secondary cell studies are shown in Fig. 3 at three different temperatures. In these studies, the cell was subjected to 20 min charge-discharge cycles separated by periods of relaxation that were sufficient to obtain constant open-circuit voltage. The net charge-discharge reaction for this secondary cell may be written

$$Na + TiS_2 \underset{\text{charge}}{\overset{\text{discharge}}{\rightleftarrows}} NaTiS_2 \quad [3]$$

Because the cell was prepared initially from pure TiS_2 and then subjected only to shallow discharges result-

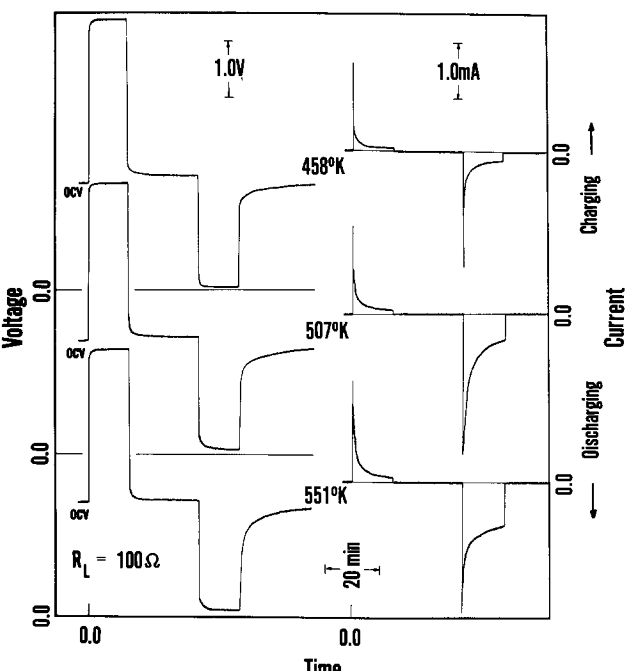

Fig. 3. Secondary cell characteristics at different temperatures. Cell voltages during a 20 min discharge (over a 100Ω load) are shown at the left, along with voltage transients between charge-discharge periods. Corresponding currents are shown at the right.

ing in minimal Na^+ intercalation, relatively high charging voltages were required to bring about the reversal of Eq. [2]; in each of the curves shown in Fig. 3, 5.0V (2.9V overvoltage) were applied to the cell to bring about charging. Discharge was allowed to take place over a 100Ω load. Uniform increases in both the charging current and the discharging current are observed with increasing temperature.

The open-circuit voltage transients which were recorded between periods of charge and discharge in experiments such as these were subjected to data analysis. The result of one such analysis is shown in Fig. 4 which relates the open-circuit relaxation voltage to the inverse square root of the relaxation time at four different temperatures. The fact that good linear behavior is obtained, following both periods of charge and periods of discharge, indicates that the relaxation to constant open-circuit voltage is a diffusion-controlled process. Other investigators (11) have used data analysis of this sort to evaluate solid-state diffusion coefficients, but this evaluation requires a knowledge of the Na^+ concentration (that is, evaluation of stoichiometric parameter x in Na_xTiS_2 as a function of position) within the TiS_2 which was unavailable at this point in the experiment. The relatively steeper slopes that are observed in this figure following periods of discharge are probably due to the relatively greater differences in bulk and surface Na^+ concentration within the TiS_2 phase that would be obtained following discharge.

Subsequent secondary cell experiments were carried out at 555 K to investigate the effect of the applied charging voltage on the rate of charge. As evidenced in Fig. 3, much more current passes during a given interval of discharge than is passed during that same interval of charging at 5.0V applied. Therefore, in an effort to maintain a constant average composition of Na_xTiS_2 in the positive plate material it was decided that the time of charge at a given charging voltage should be varied so that the same amount of Na^+ that was injected during discharge would be removed from the electrode during charge. The results of three such experiments for 100 sec discharges through a 100Ω load are shown in Fig. 5. Only in the vicinity of 15V applied was the average rate of charge equivalent to the rate of discharge. No apparent decomposition of electrolyte materials occurred even at these high charging voltages; subsequent discharge curves were quite reproducible as is indicated by the superimposition of the three curves in this figure. The refined data that are presented below confirm the fact that there is no evidence of irreproducibility in the discharge curves that would indicate solid electrolyte material decomposition on the application of charging voltages up to 15V.

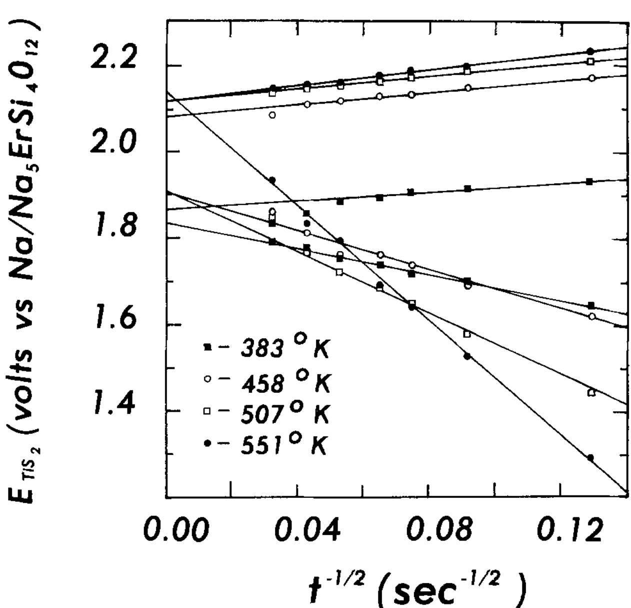

Fig. 4. The open-circuit potential of the TiS_2 electrode as a function of the time of relaxation following charge or discharge. Lines describing behavior following a period of discharge have negative slopes.

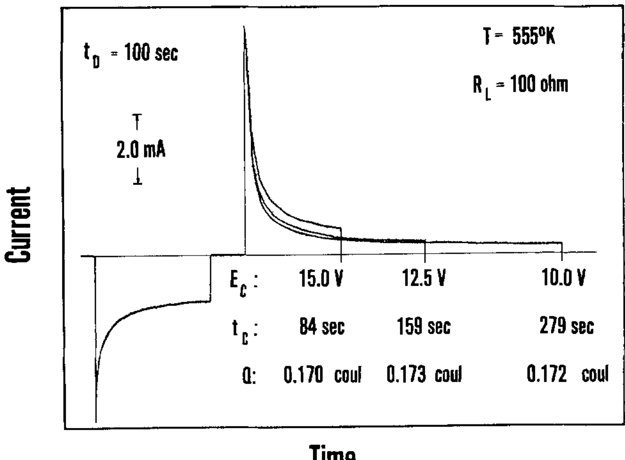

Fig. 5. The effect of charging voltage on the time of charge. Indicated charges passed during the 100 sec discharge. E_c represents the applied charging voltage and t_c represents the time required at that voltage to pass a charge equivalent to the discharge. The discharge curves are superimposed.

Three facts about the $Na/Na_5ErSi_4O_{12}/TiS_2$ cell emerge as a result of this preliminary experimentation:

1. Extremely low utilization of the available TiS_2 is achieved during the initial constant current discharge; thereafter, even after recharge, the current during discharge decreases with increasing time so that extremely long times would be required to achieve utilization in excess of 2% of the available TiS_2.

2. Cell potential relaxation studies following periods of charge and discharge indicate that charge transport is a diffusion-controlled process in this cell; since Na^+ diffusion in TiS_2 is known to be very slow (12) and the Na^+ conductivity of the $Na_5ErSi_4O_{12}$ is high, it is reasonable to assume that the rate-limiting step in this cell is the Na^+ diffusion within the TiS_2. This hypothesis is supported by the fact that the currents observed in this cell are not independent of time, as would be the case if these currents were limited by the ionic conductivity of the electrolyte.

3. Unusually high charging voltages are required to charge this cell at a rate comparable with the discharge rate; this indication of apparent kinetic irreversibility requires interpretation.

With these facts in mind, then, a model was developed to describe the charge transport processes taking place in this cell. This model was applied to interpret the refined data obtained during the course of the work described above.

Experimental

Reagents.—Metallic sodium (99.95%) was supplied by Gallard Schlesinger Chemicals and used as received. The solid electrolyte $Na_5ErSi_4O_{12}$ was synthesized at 1000°C from stoichiometric amounts of Na_2CO_3, Er_2O_3, and SiO_2. The original mixture was heated at the reaction temperature for approximately 20 hr; the resulting product was then ground in a ball mill and subjected to additional heating. This cycle was repeated until the product achieved a constant weight, usually after three or four cycles. The $Na_5ErSi_4O_{12}$ synthesized in this manner was pressed at 10 kpsi into 0.10 in. pellets of 1.5 cm diam and sintered at 1050°C to produce a rigid separator. Electrochemical grade TiS_2 was prepared by a variation of the method of Holleck (7). Stoichiometric amounts of the elements were placed in the

ends of an evacuated quartz tube and the tube was placed in a two-zone furnace. As the temperature of the sulfur zone was gradually raised from 350° to 500°C, the temperature of the titanium zone was maintained at 700°C. The resulting reaction of the sulfur vapor with the solid titanium produced the stoichiometric amount of gold-green TiS_2 after 16 hr of heating. This material was also pressed into a pellet at 10 kpsi, but the pellet was not sintered. X-ray powder diffraction data for the $Na_5ErSi_4O_{12}$ and the TiS_2 prepared by these methods are given in Table I.

Apparatus.—The unassembled cell used in these experiments has been shown in Fig. 1. Pressed pellets of TiS_2 and $Na_5ErSi_4O_{12}$ as prepared above were spring-loaded against the copper collector by means of a drilled Pyrex disk; the solid electrolyte was held against the TiS_2 with a quartz cylinder which also served as a container for the molten sodium negative electrode. Contact with the sodium metal was maintained with a stainless steel collector which passed through the central hole in the drilled Pyrex disk. The entire assembly was placed in a petri dish so that it could be heated under inert atmosphere.

Equipment.—During experimentation, the cell was placed in a Vacuum Atmospheres Corporation glove box equipped with a Model HE 193-2 Dri-Train and a Model HE-533 vacuum oven. This system routinely maintained the atmospheric water content at less than 2 ppm and the oxygen content at less than 2 ppm. Electrical contact was made through the walls of the glove box to a Trygon Electronics Model HR 20-1.5 d-c power supply used for cell charging. Currents and voltages were measured using precision resistors in conjunction with either a Mosley 7100B strip chart recorder, a Hewlett Packard 2401C integrating digital voltmeter, or a Non-Linear Systems Services X-3 digital voltmeter.

Theory

A schematic representation of the Na/TiS_2 cell used in these experiments is shown in Fig. 6. Superimposed upon this representation of the cell is a resistance diagram of the components (discussed below). Beneath the diagram is a hypothetical set of concentration profiles that depict the concentration of intercalated sodium at various stages of cell operation. Evidence has been presented above which indicates that the charge transport process is diffusion controlled. Since the TiS_2 is a good electronic conductor (the resistance of the pellet used in these studies was less than 5Ω), true

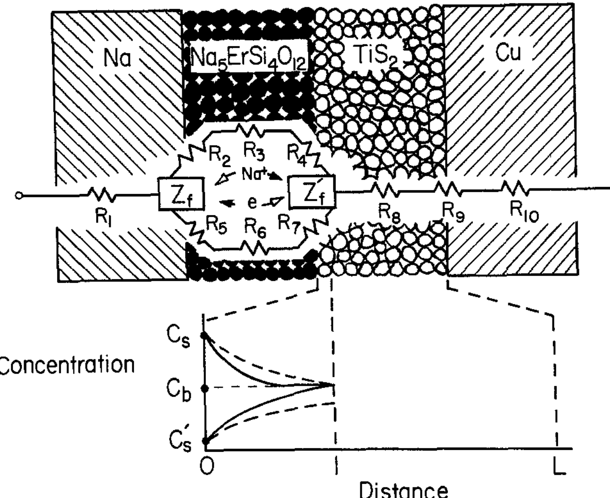

Fig. 6. A schematic representation of the Na/TiS_2 cell. A discussion of the various resistances and impedances appears in the text. Hypothetical concentration profiles for Na^+ are shown within the first average grain boundary layer (l) of the TiS_2. C_b represents the initial bulk concentration while C_s and C_s' represent the constant surface concentrations during discharge and charge, respectively. Dashed-line profiles would be obtained after the corresponding solid-line profile. The total thickness of the TiS_2 pellet is represented by L.

sodium ion diffusion could take place within the TiS_2 because the electronic conductivity would maintain local electroneutrality in much the same manner as supporting electrolyte minimizes migration effects in liquid solutions. Thus, sodium ion diffusion within the TiS_2 could provide the mechanism for charge transport control. However, only low utilization of the available TiS_2 is ever achieved; this implies that sodium ion diffusion is confined within a small fraction of the available TiS_2 volume. This confinement could be attributed either to a very slow diffusion process through a continuous solid solution, or to a more rapid diffusion process within a discontinuous medium. Since the former mass transport control mechanism is readily incorporated within a theoretical treatment of the latter, we have elected to base our model on the assumption that solid-state diffusion of the alkali metal ion within the TiS_2 is confined to the average grain boundary distance of the particles that are adjacent to the $Na_5ErSi_4O_{12}$. That is, the cell behaves as a solid-state thin layer cell in which charge transport across the grain boundary is controlled by local ionic conductivity. Thus the ionic concentration profiles shown in Fig. 6 are confined within a thin layer cell having the thickness of the average grain boundary distance, l. Minimal Na^+ transport is assumed to take place into the bulk of the TiS_2 pellet (thickness L).

To treat this model theoretically, one must solve the boundary value problem associated with Fick's second law of diffusion

$$\frac{\partial}{\partial t} C(x, t) = D \frac{\partial^2}{\partial x^2} C(x, t) \quad [4]$$

for the conditions required by this model. Initially, the concentration of Na^+ would be constant throughout the grain boundary layer

$$C(x, 0) = C_b \quad 0 \leq x \leq l \quad [5]$$

During cell operation, the concentration of Na^+ at the interior surface of the solid phase would be maintained a constant, C_s, at the applied potential

$$C(0, t) = C_s \quad t \neq 0 \quad [6]$$

At the grain boundary, the concentration profile would have zero slope as the boundary layer fills with (discharge) or empties of (charge) Na^+

$$\frac{\partial}{\partial x} C(x,t)|_{x=l} = 0 \quad t \neq 0 \qquad [7]$$

This boundary value problem may be solved by the Laplace transformation to obtain an expression for the transformed concentration

$$c(x,s) = \frac{C_b}{s} + \frac{(C_s - C_b)}{s(\exp(2l\sqrt{s/D}) + 1)} [\exp((2l - x)\sqrt{s/D}) + \exp(x\sqrt{s/D})] \qquad [8]$$

This allows the transform of the current function to be evaluated as

$$i(s) = nFAD \frac{\partial}{\partial x} c(x,s)|_{x=0}$$

$$= nFAD^{1/2} (C_b - C_s)\, s^{-1/2} \tanh(l\sqrt{s/D}) \qquad [9]$$

The inverse of this transform may be found in at least one compilation of Laplace transforms (13) and the resulting expression for $i(t)$ may be rearranged to give

$$i(t) = \frac{nFACD^{1/2}(C_s - C_b)}{\pi^{1/2} t^{1/2}} \sum_{k=\infty}^{k=\infty} (-1)^k e^{-k^2 l^2/Dt} \qquad [10]$$

This result is identical (after minor rearrangement) to that obtained by Oglesby *et al.* (14) for the liquid thin layer cell with $C_b = 0$.

This equation predicts that at short times, when the series factor is essentially equal to 1.0, Cottrell behavior will be obtained

$$i(t) = nFAD^{1/2} (C_s - C_b)/\pi^{1/2} t^{1/2} \qquad [11]$$

At longer times, when the series factor becomes significantly less than 1.0, deviation from Cottrell behavior will be obtained. The time at which this occurs corresponds to that time at which the system is no longer controlled by semi-infinite linear diffusion of Na^+ within the TiS_2, that is, when the first appreciable amount of Na^+ (during discharge) reaches the grain boundary and the solid state thin layer cell begins to fill; this reduces the flux of Na^+ into the TiS_2 and causes a corresponding decrease in current. This is illustrated in Fig. 7, which depicts the dimensionless current-time behavior that is predicted by Eq. [10] in the limits as $t \to 0$ (curve a) and as $t \to \infty$ (curve b).

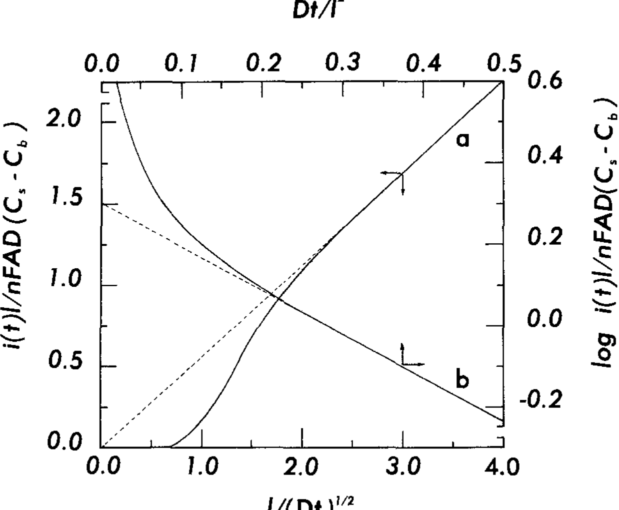

Fig. 7. Theoretical current-time behavior predicted by the solid-state thin layer cell model. Curve a (left and lower axes) shows the Cottrell behavior predicted at short times. Curve b (right and upper axes) shows the linearity obtained at long times. Equation [10] was used to construct both curves.

From curve a in this figure, it is clear that Cottrell behavior will be obtained at times less than 0.25 l^2/D. At times greater than this, the current falls off so rapidly that linear log $i(t)$ *vs.* t behavior is obtained. The equation of the straight line portion of curve b is given by

$$\log \frac{i(t)\, l}{nFAD\,(C_s - C_b)} = 0.301 - 1.0717\,(Dt/l^2) \qquad [12]$$

This limiting equation is numerically equivalent to a solution reported by Weppner and Huggins (15) and obtained for this boundary value problem by Ramanarayanan and Jose (16) in the long time limit, namely

$$\frac{i(t)\, l}{nFAD\,(C_s - C_b)} = 2 \exp(-\pi^2 Dt/4l^2) \qquad [13]$$

However, in their treatment of this problem Ramanarayanan and Jose assumed that solid-state diffusion takes place throughout the entire pellet of solid material (in their investigation, Cu_2S); thus, while Eq. [12] is mathematically equivalent to Eq. [13], it is conceptually different in the definition of l. Obviously, this definition will have implication in the determination of diffusion coefficients by the application of any of these models to physical systems. The implication of selecting the pellet thickness as the distance parameter in diffusion studies of this sort is discussed below.

This proposed thin layer model for mass transport control during electrointercalation, then, predicts the linear $i(t)$ *vs.* $t^{-1/2}$ behavior during the early stages of both charge and discharge. The magnitude of the observed current will depend on the effective electrode area, the diffusion coefficient (a function of temperature), the average grain boundary distance (a characteristic of pellet preparation procedures), and $\Delta C = (C_s - C_b)$, the difference between the surface and initial bulk concentration of Na^+ within the TiS_2; ΔC will depend on the applied potential. Each of those variables also affects the time at which deviation from Cottrell behavior will be observed. Only after this critical time is it predicted that linear log $i(t)$ *vs.* t behavior will be obtained. This model may be used in a variety of ways to determine D to whatever degree of accuracy that either one of the necessary spatial parameters (l or A) may be measured. Even in the absence of the information necessary to determine D, however, the model provides a way to investigate the surface concentration of Na^+ as a function of applied charging voltage. This is quite useful in the rationalization of the unusually high voltages necessary to charge the cell in the experimentation described above.

Results

Short time current-time behavior for the $Na/Na_5ErSi_4O_{12}/TiS_2$ cell at three different temperatures is displayed in Fig. 8 according to the theoretical model developed above. Excellent agreement with the model is exhibited by the data for all three charging curves (open symbols), and by two of the three discharge curves (filled symbols), namely, that linear $i(t)$ *vs.* $t^{-1/2}$ behavior which passes through origin is obtained. With the exception of the highest temperature discharge curve, the slope of these Cottrell plots all exhibit the trend that might be expected as the solid-state diffusion coefficient increases with increasing temperature. Since the extent of discharge was never very great during these experiments, $(C_s - C_b)$ would be expected to have a greater absolute value during charge than during discharge at all temperatures. Only the highest temperature discharge curve deviates from the short time behavior predicted by the model; in this case, even though linear $i(t)$ *vs.* $t^{-1/2}$ behavior is obtained, the current intercept is nonzero ($\sim$ 0.8 mA).

This nonzero current intercept is observed in the discharge curves shown in Fig. 9, also. It is quite reproducible. While the model predicts that deviations from

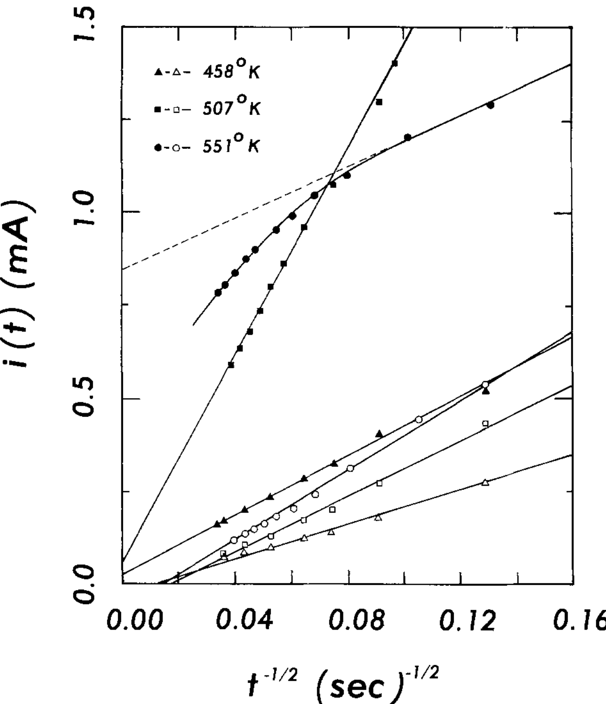

Fig. 8. Experimental current-time behavior for the Na/TiS_2 cell at different temperatures. Charging currents (open symbols) were measured at 5.0V applied. Discharges (filled symbols) were allowed to take place over a 100Ω load. Currents are plotted without regard to electrochemical sign convention.

Cottrell behavior will be obtained at longer times, only negative deviations are predicted on the basis of grain boundary layer saturation with Na^+. Thus, this experimental observation is unexplained by the model. However, it must be noted that the nonzero current intercept was obtained only after the cell had been heated to 551 K, and the cell had been subjected to several charge-discharge cycles. Na_xTiS_2 is known to exist in several phases (9), with differing charge transport properties (17). It is not altogether unlikely that a high temperature phase transition could result in the

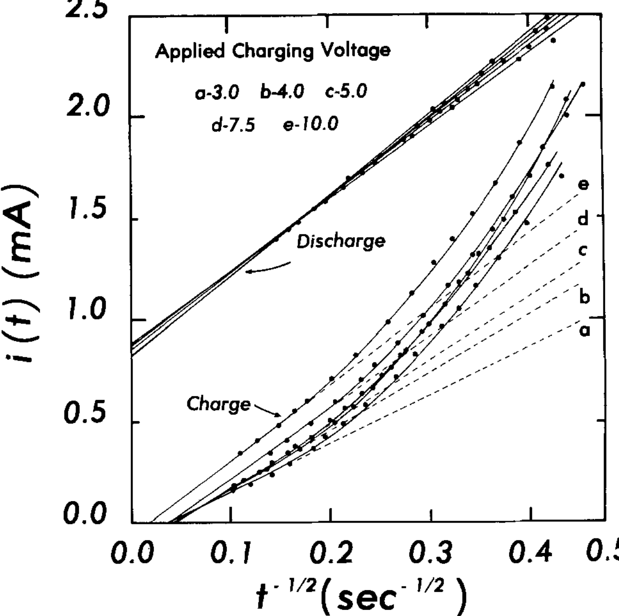

Fig. 9. The Cottrell behavior of the Na/TiS_2 cell at different charging voltages. All runs were made at 550 K. In the manner shown in Fig. 5, the extent of each charge was limited to the extent of the previous discharge.

formation of a surface layer of a different form of Na_xTiS_2 that might react directly with Na^+ from the solid electrolyte in a manner that would not be controlled by the rate of Na^+ diffusion within the TiS_2. The current due to a direct surface reaction of this sort would be observed as a background current (the nonzero intercept) on the diffusion-controlled electro-intercalation process. This explanation is made plausible by the fact that some phases of Na_xTiS_2 have been found to be electrochemically irreversible (9); thus, the observed background current is observed only during discharge.

Figure 9 also shows the effect of charging voltage on the rate of charge. Even though nonlinear behavior is obtained during the early states of each charge, good linearity is obtained at times between 25 and 100 sec, the range of Fig. 8. The slope of these linear portions increases, as anticipated, with increasing charging voltage (curves a-e). As the charging voltage is increased, the surface concentration of (Na^+) is lowered to the point where ΔC during charge is equal in magnitude to ΔC during discharge. When this occurs, the instantaneous rate of charge equals the rate of discharge and the slope of the discharge curve equals the slope on charging. This occurs over the 25 to 100 sec range at an applied charging voltage between 4.0 and 5.0V. This result is significantly different from the conclusion which would have been drawn on the basis of the coulometry times shown in Fig. 5. Clearly, this method of comparing the relative rates of charge transport appears to give more reasonable results.

Discussion

The experimental results presented above agree favorably with the theoretical model developed herein. The fact that negative deviation from Cottrell behavior is not observed indicates that Na^+ diffusion does not penetrate the TiS_2 to the average grain boundary distance. Thus, the current-time relationship of Eq. [10] is approximated by the Cottrell behavior of Eq. [11] for this system and not by Eq. [13] as might have been inferred from a previous treatment (16). Even if the average grain boundary distance is quite large because of the pressed nature of the TiS_2 pellet (thereby causing $l \rightarrow L$), the validity of the previously suggested approximation of the current-time relationship as expressed by Eq. [13] is not supported by the experimental data for the Na/TiS_2 cell. This is not to say, of course, that Eq. [13] is invalid for all systems; indeed, the data of Ramanarayanan and Jose support its validity for their system. However, this work demonstrates that the exponential approximation is valid only at times greater than those at which Cottrell behavior is obtained, that is, after the diffusing species reaches the interior wall of the thin layer cell represented by the distance l. This distance may be taken as the pellet thickness, L, instead of the average grain boundary distance as in this work, but a necessary consequence of this choice is that a detectable increase in the amount of the diffusing species reaching the pellet-collector interface must take place if the assumptions that $l = L$ and the applicability of Eq. [13] are to be simultaneously valid; this can be verified experimentally. Any overestimation of the size of l will result in an overestimation of the magnitude of D. Ramanarayanan and Jose have determined D for Cu^+ in Cu_2S to be up to 7.3×10^{-3} cm^2/sec at 400°C by assuming that l was the pellet thickness (0.8-2 cm).

In addition to utilizing Eq. [13] to estimate D, the time at which the transition from Cottrell behavior takes place may be used to estimate D, provided that l is known. While this was not possible in this work because the necessary transition to exponential behavior was not observed for this system, concurrent studies of lithium-TiS_2 electrointercalation reactions in liquid electrolyte that have been carried out in these labora-

tories indicate the feasibility of this method. These will be the subject of future communications.

The model developed herein may also be used to investigate the potential dependence of the surface concentration of Na^+ within the TiS_2 (that is, the interfacial stoichiometry of Na_xTiS_2). This arises from the fact that this slope is given by

$$m = nFAD^{1/2} (C_s - C_b)/\pi^{1/2} \quad [14]$$

over the range where Cottrell behavior is obtained so that the ratio of the slope of the Cottrell plot on charge to that on discharge is given by

$$(- m_c/m_d) = (C_s' - C_b)/(C_s - C_b) \quad [15]$$

where C_s' C_s, and C_b are defined in Fig. 6. Because these experiments were conducted in such a manner that the same state of charge was restored at each charging voltage, C_b may be regarded as a constant. Thus, the slope ratio is equal to one when the surface concentration on charge is lower than C_b by the same amount that it is above C_b on discharge. As shown in Fig. 10, this occurs at an applied voltage of 4.3V. The slope ratio ranges from 0.0 at an applied charging voltage equal to the cell potential (an overpotential of 0.0V) to 1.4 in the limit of high charging voltage. Since these two extremes correspond to the $C_s' = C_b$ and $C_s' = 0$ limits, respectively, it is possible to construct the concentration ratio axis shown on the right in Fig. 10. This allows the determination of the apparent overpotential that is necessary to achieve any relative surface concentration of Na^+ within the TiS_2 at the state of charge represented by C_b. Information of this sort is useful in assessing the reversibility of the kinetics of the electrointercalation reaction. In this case, since very high voltages must be applied to remove the Na^+ injected into the TiS_2 during discharge at the same rate as the discharge process, this reaction appears to exhibit highly irreversible electrode kinetics.

The fact that such high charging voltages can even be employed in this cell with no apparent degradation of the cell components is intriguing. (For example, this characteristic might imply that this cell could be subjected to high voltage charging for rapid recovery applications.) A possible rationalization of this behavior is provided by a consideration of the cell resistance network shown in Fig. 6. In this diagram R_1, R_6, R_8, and R_{10} represent the electronic resistances of the components of the cell; because $Na_5ErSi_4O_{12}$ is a good separator material, R_6 is quite large. The faradaic impedances associated with Eq. [1] and Eq. [2] are represented by Z_f and Z_f', respectively; each of these impedances is associated with the redox process and not with the transport of charge across the interface. This interfacial resistance is represented by R_5, R_7, and R_9 insofar as electronic transport is concerned and by R_2 and R_4 for ionic transport. Electronic conduction across the given interfaces would be quite facile; interfacial ionic conductivity would occur with much more difficulty. The resistance to ionic conduction within the solid electrolyte is represented by R_3. When the cell is charged, the charging voltage is applied over this network. Since the electronic resistance of the solid electrolyte (R_6) is quite high, the charging current is required to pass primarily through the ionic branch. The actual voltage drop across the solid electrolyte, then, is highly dependent on both the faradaic impedances and the interfacial resistances to ionic conduction (R_2 and R_4). Since these would be quite high, especially at a solid-solid junction like that at the $Na_5ErSi_4O_{12}/TiS_2$ interface under the influence of concentration polarization, most of the applied voltage would be used to overcome interfacial resistance. Thus, the overpotentials given in Fig. 9 may be regarded as only apparent; each may be in error by an amount proportional to the interfacial resistance. If this is the case, the magnitude of the apparent kinetic irreversibility would be diminished.

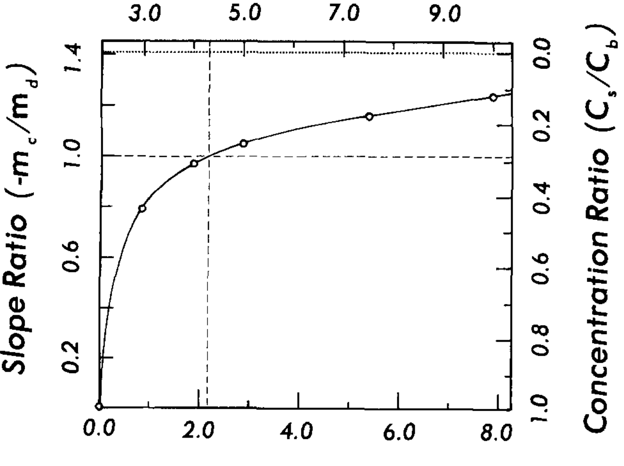

Fig. 10. The charge to discharge slope ratio for the Cottrell plots shown previously as a function of charging voltage.

Conclusions

A solid electrolyte material has been synthesized and tested in the Na/TiS_2 cell. These experimental results have been compared with a theoretical model which predicts the current-time behavior for a thin layer electrointercalation cell operating under the control of solid-state diffusion; to the extent of experimental feasibility, good agreement has been obtained. The model developed herein is applicable to other electrointercalation reactions, namely, that of lithium from liquid solution. The comparison of this model with experimental results for these systems will be the topic of subsequent publications.

On the Electrolysis of Coal Slurries

G. Okada,[1] V. Guruswamy, and J. O'M. Bockris*

Department of Chemistry, Texas A&M University, College Station, Texas 77843

ABSTRACT

Slurries of anthracite and lignite were used in suspension in 4.15M H_2SO_4. Gas chromatography was used to measure H_2 and CO_2; absorption spectroscopy was used to measure dissolved Fe. Voltammograms were taken of the system solution slurry. Hydrogen was evolved at cell potentials more negative than 0.6V. The limiting current density of this evolution was initially around 5-10 mA/cm^2 at 80°C. However, when the coal was filtered off from the solution, the current density was around the same. Atomic absorption spectra showed iron dissolved in solution. If coal was sufficiently washed in solution, the limiting current for hydrogen evolution at low potential dropped to around 0.1 mA/cm^2. The evolution of hydrogen was near 100% in faradaic efficiency. Anode gases were only $\sim$ 10% CO_2 in current efficiency. Results with pure carbon were radically different. Limiting current was low, but anode gases approached 80% CO_2. The essential facts of Coughlin and Farooque's work are confirmed; details are counter-indicated. Coal slurry electrolysis as a method for cheap hydrogen evolution is not in good prospect, because of the low current density available after the removal of Fe. It may be possible to obtain commercially interesting products from the anodic reactions.

The liquefaction and gasification of coal (1-4) are much needed processes for the replacement of gaseous and liquid fossil fuels. However, coal forms grit, which reaches the atmosphere; it contains sulfur, which is expensive to remove to a satisfactory degree. A greater difficulty in realizing liquid or gaseous fuels from coal is that the present processes are high temperature ones. If a low temperature process (5) could be found which would give rise to products of coal liquefaction without the materials problems of high temperature methods, while eliminating the sulfur and grit difficulty, it might become a powerful rival to the classical coal gasification.

A major contribution in this direction was claimed by the work of Coughlin and Farooque (6, 7) who reported that coal slurries could be electrolyzed, giving hydrogen at potentials around 1/3 those necessary for water electrolysis. Little detail was given by Coughlin and Farooque (7) concerning the anodic reactions. The three objectives of the present paper are to:

1. Report a re-examination of the facts of coal slurry electrolysis, bringing out the degree of verification, and bearing any differences between the present work and that of Coughlin and Farooque.
2. Begin work which could lead to the anodic liquefaction of coal.[2]
3. Investigate the removal of impurities in coal by electrolysis.

Key words: electrolysis, coal, hydrogen, current efficiency, slurry.

[2] As anthracite is approximately CH, and gaseous or liquid fuels can be represented as CH_n, where n is 2-4, one thinks first of a cathodic liquefaction of coal, the path of most past endeavors which, however, have had a limited success.

Experimental

Suspended coals in sulfuric acid (1M and 4.15M) solution were used as slurry electrolytes. Anthracite and lignite were ground into small particles (−100 mesh) by using a ball mill sieve. Pure carbon (−325 mesh) was also used.

The cells used are shown in Fig. 1(A) (a replica of the cell of Coughlin *et al.*) and 1(B). Cell A was employed for measurements of current as a function of potential. The anode compartment was 600 ml in volume. A Pt plate (3.55 cm^2) was the anode, and Pt gauze the cathode. The cathode compartment was separated by a fritted glass disk to prevent coal particles reaching the cathode. The anolyte was agitated, to avoid the settling out of coal particles and to increase the limiting current, by means of a magnetic stirrer. A calomel electrode was used as a reference.

Cell B was employed for analysis of the evolved gases and for long-time electrolysis. The anode was made of Pt foil, rolled into a cylindrical form, 1.25 cm long and about 1.6 cm in diameter (14 cm^2). The cathode was a square plate of 1.25 cm/side. The anode compartment had a volume of 28 ml. The electrolyte temperature in these cells was roughly controlled in the range 25°-80°C by a Corning Hot Plate, PC-101.

The electrolysis of coal was carried out under potentiostatic conditions by using a Stonehart Potentiostat, BC 1200. Voltametry was performed to measure the current/voltage curves by using a Princeton Universal Programmer, Model 175.

Evolved gases were analyzed by an Antec Gas Chromatograph, Model 461-LP. Iron in the coal electrolyte slurry was analyzed, using a Perkin Elmer atomic absorption spectroscopy, Model 306.

Results

Current/potential relations.—A typical current/potential curve from anthracite slurries (0.136 g/ml, 1M H_2SO_4 solution) is shown in Fig. 2. On the anodic side, the current rises sharply at 0.6 V/NHE, and reaches a limiting value at around 0.8 V/NHE. A limiting current density of 5 mA/cm² at 75°C is observed in the middle region. There is O_2 gas evolution at higher potential than 1.7 V/NHE.

A current/potential curve from lignite slurry (0.475 g/ml, 4.15M H_2SO_4 solution) at 75°C is shown in Fig. 3. The behavior of the current is almost the same as in anthracite, except that the limiting current density is 10 mA/cm² (*cf.*, the difference in concentration of the coal slurry).

To compare with data from the coal slurries, which contain impurities, pure carbon also was used as a slurry electrolyte. The current/potential curve for pure carbon (0.10 g/ml, 1M H_2SO_4 solution) is shown in Fig. 4. The voltamogram shows a maximum at 1 V/NHE, in contrast with the behavior shown in Fig. 2 and 3.

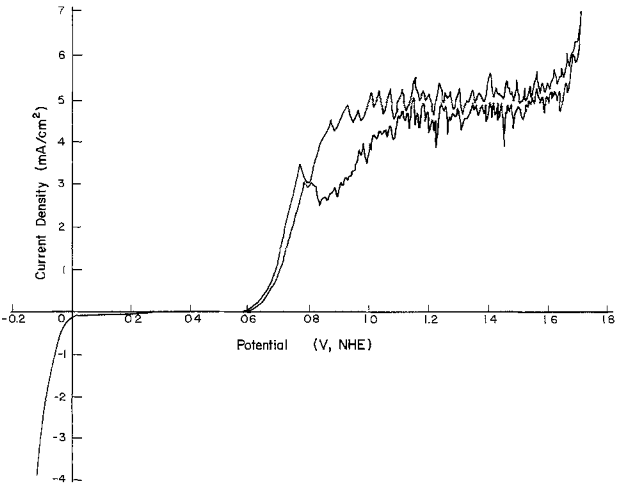

Fig. 2. Current/potential curve for oxidation of an anthracite slurry (0.137 g/ml, 4.15M H_2SO_4 solution) at 75°C. Cathodic potential vs. current density relation is also shown.

Anodic limiting current densities.—The limiting current densities observed in this work were similar to those of Coughlin and Farooque (6). The values depended on coal concentration, electrolyte temperature, and agitation speed. Figure 5 shows that there is an anodic limiting current proportional to the coal concentration.

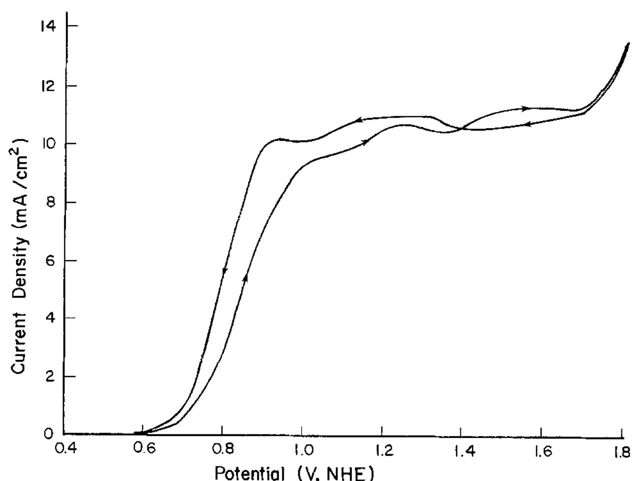

Fig. 3. Current/potential curve for oxidation of a lignite slurry (0.475 g/ml, 4.15M H_2SO_4 solution) at 75°C.

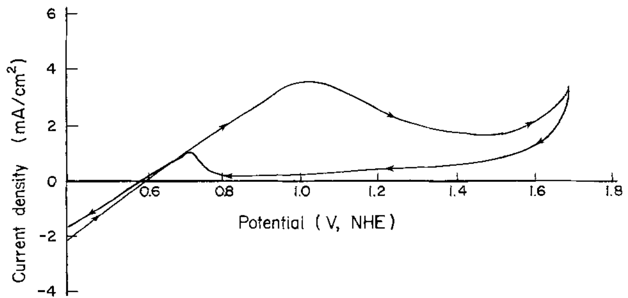

Fig. 4. Current/potential curve for oxidation of pure carbon slurry (0.10 g/ml, 1M H_2SO_4 solution) at 86°C.

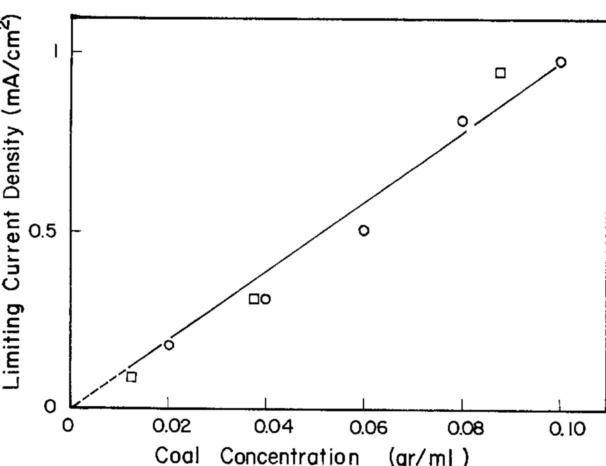

Fig. 5. Effect of coal concentration on the anodic limiting current at room temperature. □, lignite; ○, anthracite.

Limiting currents as a function of temperature (22.5°-75.8°C) are shown in Fig. 6. The activation energies for lignite and anthracite slurries are about 16 kcal/mole, as compared to 12-14 kcal, obtained by Coughlin and Farooque (6).

The time dependence of the limiting current on the anodic part of the voltamogram at room temperature after introducing coal into the solution is shown in Fig. 7. Smaller particles give larger currents.

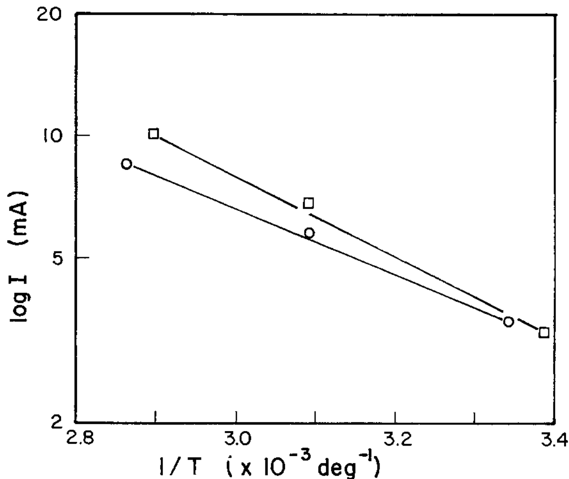

Fig. 6. Anodic limiting current as a function of temperature. □, lignite (0.088 g/ml); ○, anthracite (0.20 g/ml).

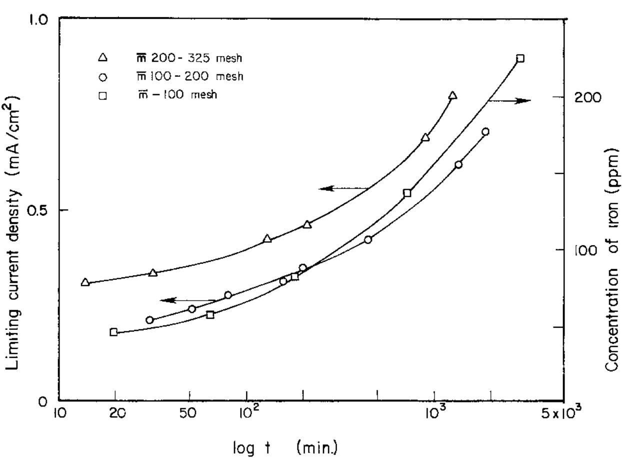

Fig. 7. Time dependence of the limiting currents for dissolution of iron in coal (without continuous electrolysis, at room temperature, anthracite 0.1 g/ml). △, 200 ~ 325 mesh; ○, 100 ~ 200 mesh; □, 100 mesh.

Effects of iron dissolved in the solution.—Iron is contained as pyrites and magnetite in coal (8). The concentration of the iron dissolved in the electrolyte from coal is shown as a function of time in Fig. 7. The time dependence of this value is similar to that of the limiting current density in the anodic electrolysis of coal.

To examine the effect of impurities, an experiment was made, in which coal had been washed for 20 hr at 75°C by agitation in 1M H_2SO_4 solution. Current/potential curves were thereafter measured at 75°C (Fig. 8), in fresh sulfuric acid containing the washed coal. The value of the limiting current was now only 0.1 mA/cm² at 75°C (5 mA/cm² with virgin coal) and varied little with time, even after 21 hr.

That the difference in limiting current densities between electrolytes containing the virgin and refined coal resulted from the concentration of Fe^{2+}, initially in solution, was evidenced by the fact that the higher limiting current in the former case was recovered (3.7 mA/cm²) by adding $FeSO_4$ (200 ppm as Fe^{2+}). The current/potential curves and agitation effects thereon in the washed coal slurries to which Fe^{2+} was added were the same as those with unwashed coal. Correspondingly, in sulfuric acid (1M) solution, to which had been added $FeSO_4$ (500 ppm as Fe^{2+})—no coal—the same kind of current/potential curve was observed (Fig. 9), with around the same limiting current as with unwashed coal slurries.

Evolution of gases.—After degassing by N_2 bubbling, electrolysis was performed. Evolved gases were analyzed by means of a gas chromatograph. After coal was introduced into the electrolyte,[3] large volumes of carbon dioxide evolution occurred before any current was switched on. 60 ml of CO_2 was evolved in 7 hr at 75°C from a suspension of anthracite of 0.137 g/ml in cell A and 300 ml in 9 hr from lignite of 0.475 g/ml, also in cell A.

[3] A reviewer of our paper has pointed out that there may be SO_2-containing species in the measuring solution, and these could contribute to the overall anodic current.

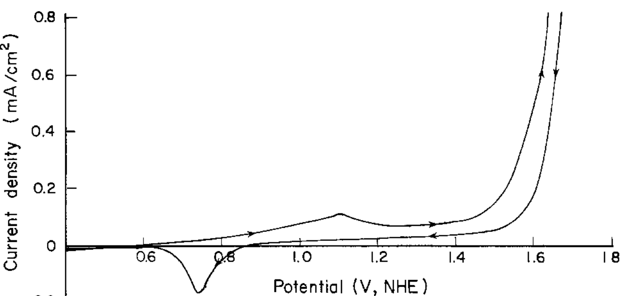

Fig. 8. Current/potential curve for oxidation of washed anthracite slurry (0.17 g/ml, 1M H_2SO_4 solution) at 75°C.

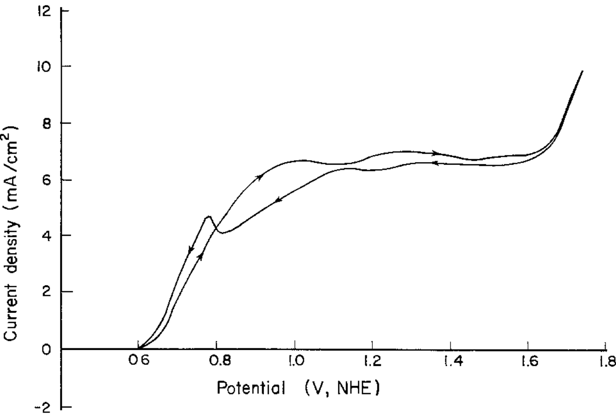

Fig. 9. Current/potential curve for oxidation of $FeSO_4$ solution (Fe, 500 ppm) at 72°C.

Figure 10 shows the current/time curve at 1V cell voltage in cell B. The current from the anthracite slurry falls with time. After about 100C (17 hr), current of 1.0 mA (<0.3 mA/cm^2) still remained for the anthracite.

In the cathodic current efficiency measurements using the gas chromatograph, no gas other than hydrogen was observed. By measurement with a flowmeter, the rate of hydrogen evolution observed corresponded to an apparent current efficiency of more than 90%. There is no reason to conclude that the true current efficiency at the cathode was less than 100%.

Evolution rate of CO_2 at the anode is shown in Fig. 11. In calculation of the anode current efficiency for CO_2 evolution, there are two difficulties. First, there is the strong initial chemical reaction which occurs between coal and the 4.15M sulfuric acid used as the electrolyte. After about 1 hr at a temperature of 80°C, this was 0.6 ml per hour from a suspension of anthracite (0.10 g/ml) in cell B. At a corresponding time, when the electrochemical current was 6 mA, the CO_2 at 100% current efficiency would have been of comparable magnitude, namely, about 1.4 ml per hour.

The chemical reaction was allowed to decay for several hours before electrolysis was commenced. In Fig. 11, an example is shown in which electrolysis was started 11 hr after the contact between the coal (anthracite) and the sulfuric acid had begun. The evolution of chemical CO_2 was now about 7×10^{-2} ml per hour. During electrolysis, the most uncertain part of the CO_2 evolution is the degree of the chemical reaction rate. No continuous recording of the chemical CO_2 rate was made after electrolysis was commenced. However, if we assume that the rate of decrease of the chemical CO_2 was exponential with time, it is possible to subtract the chemical reaction rate from the overall reaction rate by calculation, and this has been done for the results of Fig. 11. The value of the resulting current efficiency of CO_2 evolution is shown.

In respect to the influence of iron on the anodic results, strong in the early stages of electrolysis, Fig. 10 shows a plot of current in the absence of coal due to iron and how it varies with time, while the electrode is oxidizing the ferrous iron to ferric. It is, therefore, reasonable to suppose that after a time of some 200 min, the effect of Fe^{2+} oxidation is negligible, and this has been assumed in the plots of Fig. 11.

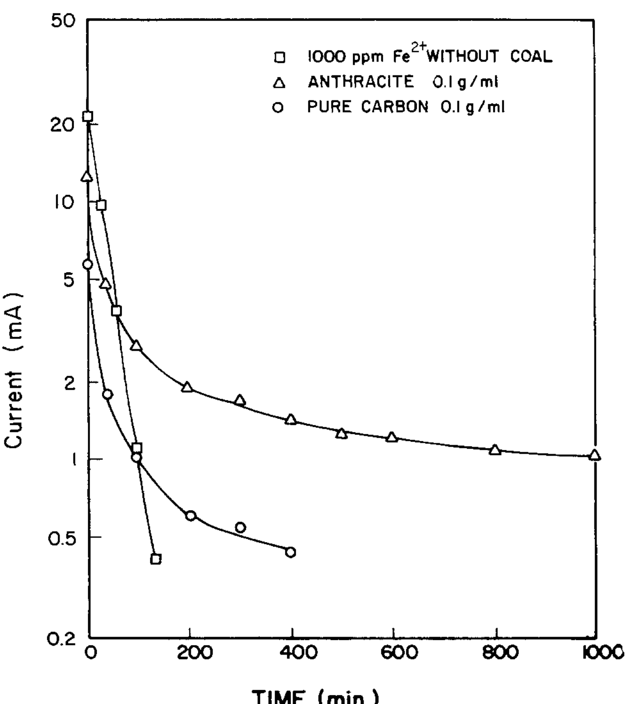

Fig. 10. Anodic current/time curve at 1V cell voltage in 4.15M H_2SO_4 solution (electrode area is 14 cm^2). □, 1000 ppm Fe^{2+} without coal; △, anthracite 0.1 g/ml, ○, pure carbon 0.1 g/ml.

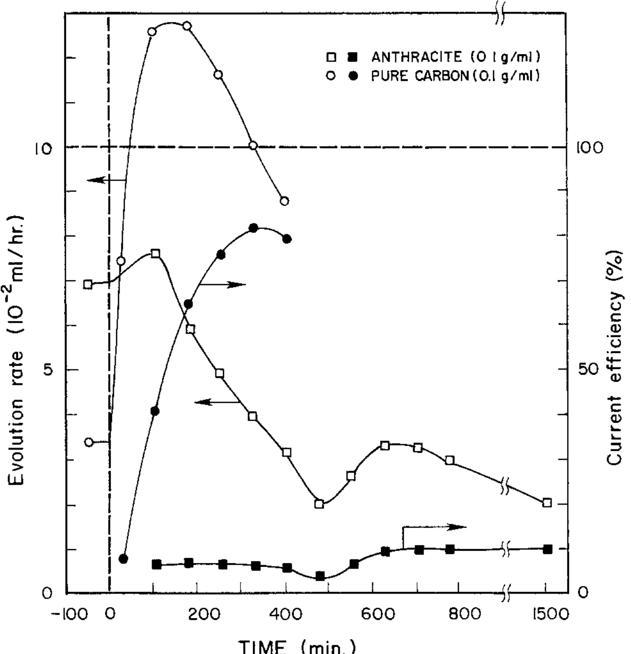

Fig. 11. Evolution rate and current efficiency for CO_2 production as a function of time in 4.15M H_2SO_4 solution at 80°C (cell B). □, ■ anthracite (0.1 g/ml); ○, ● pure carbon (0.1 g/ml).

Thus, the current efficiency measurements for CO_2 evolution at the anode are approximate. However, when electrolysis is commenced after 11 hr of contact of the coal with the sulfuric acid solution (4.15M), it is around 5%, rising to around 10% after 25 hr.

Differences in results obtained with pure carbon.—A slurry of pure carbon (2N5, 325 mesh), Alfa Products, was prepared at a concentration of 0.1 g/ml. The current/time curve obtained for these slurries is shown in Fig. 10. The current falls off faster than that for anthracite. The evolution rate of carbon dioxide was almost zero in the early part of the electrolysis, in spite of a current of 5 mA, but the current efficiency rises finally to around 80%. The electrolyte filtered from the carbon slurry revealed only small residual current (0.1 mA/cm^2). The concentration of iron in this electrolyte was less than 12 ppm.

Discussion

Comparisons between data of Coughlin and Farooque (6) and those of the present work are given in Table I. Discussions of these differences follow.

The current/potential relations.—The current in the typical voltamogram (Fig. 2) becomes significantly anodic in the region of +0.6 V/NHE. This may be compared with the reversible potential of iron (Fe^{2+}/Fe^{3+}), which is +0.77V. Assuming arbitrarily that the

Table I. Comparison between data of Coughlin and Farooque and those of the present work

Essentially same behavior	Different behavior
Cathodic current efficiency	Oxidation rate linear with slurry concentration
Initial current	Coughlin and Farooque's current efficiency for CO_2, 25-50%. Okada, Guruswamy, and Bockris, less than 10%.
Potential regions for CO_2 evolution	Pure carbon gives current efficiency for CO_2 around 80%. Currents due to iron-ferrous to ferric oxidation is important in the first few hours of electrolysis.
Effect of particle size, temperature, and concentration	Limiting currents in the absence of Fe^{2+}, other impurities <0.1 mA/cm^2.

ratio of ferrous to ferric iron at the beginning is about 10^3, then the reversible potential would become about +0.6 V/NHE, and if the i_0 were rather high, this would correspond with the observations made, *i.e.*, the beginning of the current in solutions from which ferrous iron has not yet been removed by electrolysis would be influenced strongly by the ferrous to ferric electrode reaction.

The limiting currents at the anode are largely dependent upon the iron (Fe^{2+}) concentration. From the activation energy value of 16 kcal/mole, such limiting currents are consistent with diffusion of Fe^{2+} in the solution.

On the other hand, the current at which the anodic process begins may also be interpreted in respect to the oxidation of carbon. Taking this as a standard potential at +0.21V for the hydrogen scale, the overvoltage would have to be in the region of 0.4V for a current of 0.1 mA/cm^2, and if the Tafel β value is 1/2, this corresponds to an i_0 of 10^{-6} A/cm^2

Comparison of the results obtained with slurry electrolysis of pure carbon and those with coal.—The results obtained with pure carbon powder (2N5) and anthracite are compared in Table II. Thus, when the coal has been thoroughly washed, it gives only a small current density, resulting from either further dissolution of impurities from the coal, or, more likely, collision of the coal with the electrode.

Therefore, the high limiting current densities for solutions filtered from the coal slurries are due to impurities which initially dissolve off the coal surface, or a larger amount of dissolved material, in particular, iron. On the other hand, the current from carbon under the same condition is very low. Evidently, in the case of the pure carbon, there is a smaller amount of dissolved impurities, and the current is largely due to the collisional reaction of carbon with the anode. That there is a greater current density from th carbon than from the coal arises from the surface area of the carbon (9). The latter had passed through a 325 mesh entity and the former through a 100 mesh entity. The surface areas were thence 10:1, consistent (spherical particles) with the observations.

The higher efficiency of CO_2 production at the anode from carbon compared with the low efficiency from coal arises because, for coal systems, there are more possibilities for reaction. First, there are impurities (iron, desorbed material); there are also dissolved materials which undergo oxidation reactions, though not to CO_2. Finally, the coal has carboxyl, nitrogen, and sulfur containing terminal molecules, which could also be reactive centers giving rise to other products. This is consistent with lignite, giving higher currents as it has more terminal groups.

In the early stage of electrolysis, the current efficiencies for CO_2 evolution are small (Fig. 11). Products of electrolysis may be initially adsorbed on the particles (10), reducing apparent current efficiencies, a suggestion made by Coughlin and Farooque (6).

The CO_2 arising in the presence of coal (Fig. 11) reaches 10% after some hours. Competing organic reactions are, therefore, probably present. However, with pure carbon, the possibilities for these are small, and most of the reaction current arises from active carbon sites at the electrode; the efficiency for CO_2 production is, therefore, high.

The decrease of current with time is greater with carbon than with anthracite (Fig. 10). Thus, with carbon, the reaction is the collisional one of carbon with the electrode. The efficiency of this depends on the amount of material adsorbed upon the surface (10, 11). For carbon, some products other than CO_2, speculatively, formaldehyde, also arise, and these may adsorb upon the carbon increasingly with time, thus reducing the efficiency of reaction in collision. The decrease with carbon would be expected to be faster, because in carbon the predominant mechanism is collisional, affected by adsorption, whereas with coal (because of the lower current efficiency for CO_2 evolution), there must be other organic reactions (12). Even at extended periods of times, the situation is such that organic materials are oxidized by electrode reactions which may (in the anodic region concerned) be less dependent upon the effect of materials which hypothetically absorb on carbon. Such concepts are, of course, mere speculations, consistent with the results.[4]

General model for the anode reactions.—The situation at the anode is multidetermined, and work needs to be done in finding out what the anode products are and how they depend in respect to current efficiency on potential and electrocatalysts. First, much depends on the time of exposure of the coal in the solution. At short times and high temperatures, the CO_2-producing reaction is largely chemical. In the first 2 hr of contact of the coal with the solution, its chemical reaction with sulfuric acid gives an amount which would come from electrolysis at a few mA/cm^2. The chemical reaction decreases rapidly; after about 10 hr at 80°C, it is negligible compared with the electrochemical reactions. The chemical reactions are, therefore, probably connected with removal of surface impurity. Correspondingly, ferrous ions undergo oxidation to ferric ions in about 2 hr of electrolysis (Fig. 10).

Thus, when electrolysis has taken place for this time, iron is removed from contributing to the anodic reaction. The electrode reactions are those with the products of coal, and the collisional reaction of the coal with the electrode. For times in the 10-25 hr region, some 90% of the anodic current is taken up with non-CO_2-forming organic reactions (12, 14), arising from dissolved products from coal undergoing anodic reactions, and some 10% arises from direct contact, coal electrode-giving CO_2 or CO_2-forming organic reactions. These conclusions are made in the absence of sufficient analysis of anodic products and insufficient knowledge of the adsorption of CO_2 on coal.

Coal slurries and the production of hydrogen.—Pure hydrogen is produced in the electrolysis of coal slurry, in agreement with Coughlin and Farooque. It arises from water decomposition. From the difference between the anodic and cathodic potential, it is possible to estimate the cell potential. Table III shows the cell potential deduced from Fig. 2. These lower cell potentials in the limiting current region are due to the alternative reactions at the anode, which replaces the evolution of O_2. The economic question is, "At what rate do such reactions occur in the absence of the consumption of the impurities, *e.g.*, iron?"

[4] The observation by Coughlin and Farooque, that placing coal samples at 250°C for 6 hr caused a reactivation of the coal, is consistent with our hypothesis of the inhibiting buildup of organic adsorbates, which would be removed upon heating. Further, Fe may diffuse to the surface and be redissolved.

Table II. Comparative behavior of coal and carbon slurries

Phenomenon	Coal (anthracite)	Carbon
Current/time at constant applied potential	Decreases	Decreases substantially more quickly than with coal
Current efficiency of CO_2 production after 7 hr in 4.15M H_2SO_4	About 10%	About 80%
Currents obtained from solutions which had been filtered free of coal or carbon	High current density, *e.g.*, 5.9 mA/cm^2	Low current density, *e.g.*, 0.1 mA/cm^2
Result of remaking slurry with fresh solution of 4.15M H_2SO_4 after washing coal or carbon.	Current density obtained low, *e.g.*, 0.1 mA/cm^2	Current density same as before filtering, *e.g.*, 3.4 mA/cm^2

Table III. Cell potentials as function of current equivalent to electrolysis of coal slurries to yield hydrogen

Cell potential (V)	Current density (mA/cm^2)
0.7	1.4
1.0	4.9
1.7	4.9
1.8	6.3

For unwashed coal, in the first few hours of electrolysis, the current densities were those observed by Coughlin and Farooque, *i.e.*, several mA/cm^2. However, here, the anodic reaction is the oxidation of ferrous to ferric ion. When the coal has been thoroughly washed and the iron removed, the current density in the region of about 0.6-0.1 V/NHE is only 0.1 mA/cm^2. This would not give rise to economical hydrogen production, which needs current densities of 100-500 mA/cm^2.

Depolarization of the anode to obtain H_2 is well known, and it is possible to use more convenient materials than coal. Thus, SO_2 has been used by a number of other workers (15) for obtaining hydrogen at potentials of about 0.8V at 25°C and 100 mA/cm^2. The situation is more energy efficient than that with slurry electrolysis at about 85°C. Would carrying out the electrolysis at 200°C be effective? The competing chemical reaction at this temperature may offer a difficulty. Electrocatalysis, increase in temperature, decrease in particle size of the coal, and increase in stirring are possible variables. Removing iron, sulfur, and other impurities in coal by removal of Fe^{2+} may be of interest.

Products from anodic reactions in coal slurries.—The evidence that after contact times in the neighborhood of 25 hr, 90% of the current is utilized for non-CO_2-producing electrochemical reactions at 1 V/NHE makes it reasonable to suggest that useful organic chemicals from coal may be produced in this way. The decay of current with time adds caution to this suggestion.

Conclusions

1. In the presence of Fe^{2+} originating from coal, current densities of 5-10 mA/cm^2 at a cell potential of 0.8V can be obtained for the electrolyte production of hydrogen in 4.15M H_2SO_4 solution at 80°C. The anodic reaction is predominantly Fe^{2+} oxidation and the cathodic reaction is $H_3O^+ + e \rightarrow 1/2\ H_2 + H_2O$.

2. In the absence of Fe^{2+}, the evolution rate of H_2 is reduced at the low cell potential (*ca.* 0.8V), to the impractical order of 0.1 mA/cm^2. Anodic reactions involving coal are of two kinds. Direct collision of slurry particles, including pure carbon, with the electrode, gives CO_2 (with pure carbon, the current efficiency for this reaction is about 80%). However, with lignite and anthracite, the current efficiency for CO_2 generation is reduced to *ca.* 10%. A secondary anodic reaction occurs in the presence of coal and involves the partial anodic oxidation of products dissolved therefrom.

3. The anodic depolarization route to H_2 production using the derivatives of coal to depolarize the anodic reaction (avoiding the evolution of oxygen) would provide H_2 at a lesser moles per watt hour than, say, the use of waste gas SO_2 in a similar concept.

An Electrochemical Investigation of Coenzyme A

Michael H. Shiu[1] and Robert D. Braun*

Department of Chemistry, University of Southwestern Louisiana, Lafayette, Louisiana 70504

ABSTRACT

A polarographic, controlled-potential coulometric, and triangular-wave voltammetric study of coenzyme A was undertaken. Coenzyme A is reversibly electrochemically oxidized to dimeric coenzyme A. The pK_a of coenzyme A was estimated from polarographic data to be 9.77. The diffusion coefficient of coenzyme A was determined to be 2.6×10^{-6} cm²/sec. The heterogeneous rate constant for the electrochemical dimerization was estimated from triangular-wave voltammetric data to be 3×10^{-3} cm/sec at *p*H 6.5.

Coenzyme A (CoA) primarily functions as acyl group carriers in biological systems (1). Its structure is shown in Fig. 1. The active site on CoA is the thiol group to which acyl groups can esterify. For simplicity CoA is symbolically represented throughout much of this paper as RSH where R represents all of the molecule except the thiol group. Many electrochemical studies have been done on compounds which contain a thiol group, but which are structurally simpler than CoA. Typical examples include cysteine (2), butanethiol, benzyl mercaptan, 1-decanethiol, β-phenylethyl mercaptan, and others (3). In most of these cases the compound reacts to form a dimer with linkage through the sulfur atoms. Since CoA is a biologically important compound, and since apparently no thorough electrochemical study of the compound has been done, the present study was undertaken.

Experimental

Chemicals.—Coenzyme A (RSH) and the dimer (RSSR) were obtained from the Sigma Chemical Company, and were used without further purification. The purity of each batch of CoA was spectrophotometrically assayed at 259 nm using a molar absorptivity of 16,400 (4). Typically each batch assayed at 85-90% CoA. The concentrations reported throughout this paper have been corrected for purity of the CoA. Any impurity in the CoA was not electroactive within the potential range used in this study.

The components of the buffer solutions were acetic acid and sodium acetate (*p*H 4-6), potassium dihydrogen phosphate and dipotassium hydrogen phosphate (*p*H 6-8), tris(hydroxymethyl)-aminomethane and its protonated salt (*p*H 8-9), potassium hydrogen carbonate and potassium carbonate (*p*H 9-11), and dipotassium hydrogen phosphate and potassium phosphate (*p*H 11-13). Enough of the buffer components were added to the buffer solutions to adjust the ionic strength to 0.5M except when the minor buffer component would have exceeded 0.1M. In those cases the minor buffer component was maintained at 0.1M, and the ionic strength of the solution was adjusted to 0.5M with potassium chloride. The *p*H 6.5 buffer solution was used for all of the electrochemical studies except the study of the variation of $E_{1/2}$ with *p*H. It consisted of 0.16M potassium dihydrogen phosphate, 0.10M dipotassium hydrogen phosphate, and 0.04M potassium chloride. The buffer solutions were used as the supporting electrolyte solutions in the electrochemical studies.

Apparatus.—A Model 174a Polarographic Analyzer (EG&G Princeton Applied Research) was used for the polarographic, coulometric, and triangular-wave voltammetric studies. It was coupled to an Omnigraphic 2000 X-Y recorder (Houston Instrument) for the voltammetric studies, and to an Omniscribe strip chart recorder (Houston Instrument) for coulometric studies. A saturated calomel reference electrode and a platinum foil auxiliary electrode were used. The indicator electrode used for the triangular-wave voltammetric studies was a hanging mercury drop electrode (area = 2.2 mm²). The working electrode used for controlled-potential coulometry was a mercury pool. All potentials reported in this paper are relative to the saturated calomel electrode. The water-jacketed, three-compartment cell was maintained at 25.0°C except in the temperature studies. The two outer compartments in the cell were separated from the center compartment by medium-porosity glass frits.

Solutions were deaerated prior to each study with high purity nitrogen which was passed through two wash towers containing acidic ammonium metavanadate and amalgamated zinc, and a final wash tower containing deionized water. Polarographic measurements of diffusion current were made at the end of the drop life, *i.e.*, on the top of the polarographic wave. All *p*H measurements were made with a Corning Model 7 *p*H meter. Spectrophotometric studies were done with a Beckman DK-2A spectrophotometer.

Results and Discussion

Polarograms of CoA contain a single anodic wave (Fig. 2) throughout the entire *p*H range examined in this study (*p*H 4.7-12.6). At concentrations above 0.7 mM, a maximum of the second kind was associated with the wave. The half-wave potential ($E_{1/2}$) of the polarographic wave of 0.7 mM CoA varied with *p*H as shown in Fig. 3. The linear portion between *p*H 4.7 and 8.5 obeyed Eq. [1] (least squares fit, correlation coefficient = −0.999). Between *p*H 10.9 and 12.6, the $E_{1/2}$ remained constant

$$E_{1/2} = -0.0525\ p\text{H} - 0.0056 \quad [1]$$

at −0.519V. The remainder of the studies were performed at *p*H 6.5.

The diffusion current (i_d) of the anodic wave increased linearly with the square root of the corrected mercury column height (h_{corr}) for column heights between 38.8 and 100.5 cm, and $i_d/h_{corr}^{1/2}$ slightly decreased with h_{corr} (slope = −0.015 μA/cm). These results were taken as evidence that the electrochemical reaction obeys the Ilkovic and Koutecky equations, and that the height of the polarographic wave is diffusion controlled.

A polarographic study performed on a 0.8 mM CoA solution at five temperatures ranging from 15° to 35°C revealed no variation in half-wave potential with temperature. This is within the expected range of variation for a reversible electrode process (5a). The corresponding relative temperature coefficient for the diffusion current of the wave was 1.9%/degree, indicating the absence of slow chemical steps (relative to the rate of the polarographic measurement) in the electrochemical oxidation (5b).

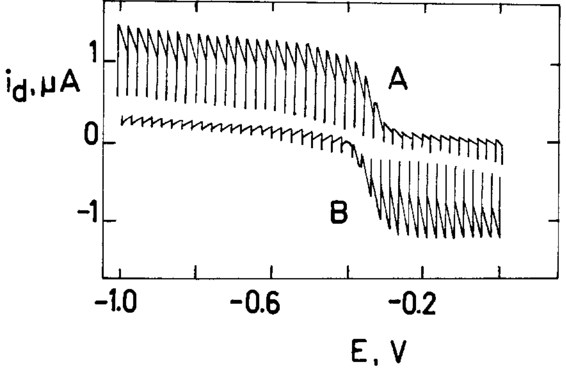

Fig. 2. Polarograms of 0.54 mM coenzyme A before (B) and after (A) exhaustive controlled-potential coulometry on a mercury pool at 0V.

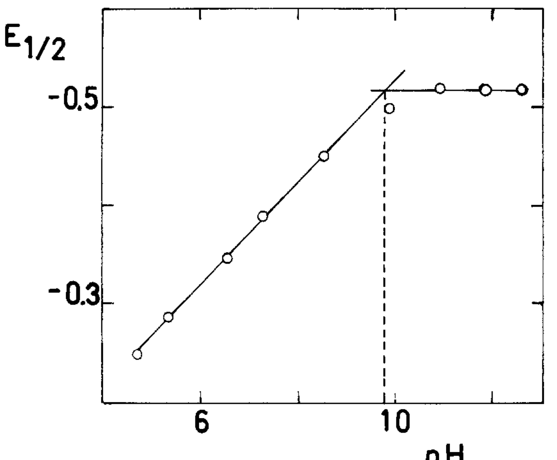

Fig. 3. Variation of the polarographic half-wave potential of 0.7 mM coenzyme A with *p*H.

Several log plots were made on the rising portion of the anodic wave assuming different reaction mechanisms in order to deduce the mechanism of the electrochemical reaction. Plots of potential as a function of $\log[(i_d - i)/i]$ were obtained for four samples of varying concentration. These log plots were linear with a slope of −0.050 ± 0.004 V/decade. All uncertainties listed in this paper are expressed as standard deviations. The theoretical slope for an electrochemical reaction of the general form Red = Ox + ne^- is −0.059/n V/decade. For a reversible dimerization reaction of the general form 2RSH = RSSR + $2H^+$ + $2e^-$, the theoretical slope of a log plot of potential as a function of $\log[(i_d - i)^2/i]$ is −0.030 V/decade. Plots of potential as a function of $\log[(i_d - i)^2/i]$ on the rising portion of four CoA samples of varying concentration were linear with an average slope of −0.030 ± 0.002 V/decade. These data suggest the possibility of a reversible dimerization reaction taking place at the electrode surface.

For a reversible oxidation of the general form Red = Ox + ne^-, the half-wave potential theoretically should be independent of concentration of the electroactive species and of *p*H. For a dimerization reaction of the form, 2RSH = RSSR + $2H^+$ + $2e^-$, at 25°C the half-wave potential should be dependent on both *p*H and concentration, *i.e.*, on i_d, as shown in Eq. [2]. As has already been shown, the half-wave potential

$$E_{1/2} = \text{constant} - 0.059\ p\text{H} - 0.030 \log(i_d/2) \quad [2]$$

of 0.7 mM CoA at *p*H's below 8.5 varied linearly with *p*H. The slope of a plot of $E_{1/2}$ as a function of *p*H was −0.053 as compared to the theoretical value of −0.059 predicted by Eq. [2].

Above *p*H 10, the half-wave potential did not vary with *p*H indicating that hydronium ion was not involved in the electrochemical reaction. This behavior would be expected for CoA if the CoA were dissociated to yield RS^- rather than RSH at higher *p*H's (Eq. [3]). The RS^- could then undergo a dimerization reaction of the form $2RS^-$ = RSSR + $2e^-$. Assuming this is the case, the interception of the two extrapolated linear portions of the plot of $E_{1/2}$ as a function of pH should correspond to the *p*H at which CoA exists as an equimolar mixture of RSH and RS^-. This *p*H corresponds to the pK_a of CoA. The value

$$\text{RSH} = \text{RS}^- + \text{H}^+ \quad [3]$$

determined from Fig. 3 was 9.77. This value compares favorably with the 9.6 obtained from titrimetric data (6).

A plot of $E_{1/2}$ as a function of $\log(i_d/2)$ for nine solutions of concentration ranging from 0.4 to 3.9 mM was linear with a slope of −0.0386 (least squares fit; correlation coefficient = −0.914). This compares to the theoretical value of −0.030 predicted from Eq. [2] for a dimerization reaction.

Controlled-potential coulometry was performed at 0V on six CoA solutions of varying concentration. The average calculated n was 0.97 + 0.07, indicating that a single electron is transferred for each molecule of CoA. A polarogram obtained on a typical sample prior to and after an exhaustive electrolysis is shown in Fig. 2. Polarograms of purchased CoA dimer (RSSR) showed a single cathodic wave at a half-wave potential identical to that observed after the electrolysis of CoA solutions. The half-wave potential of the anodic wave obtained before each electrolysis was within experimental error of the half-wave potential of the cathodic wave obtained after electrolysis.

A sample of the purchased dimer was exhaustively reduced at −1.1V on a mercury pool. The polarogram after the reduction showed a single anodic wave at a half-wave potential identical to that of CoA. These observations lead to the conclusion that, within the time frame of polarographic measurements, CoA is reversibly electrochemically oxidized to the dimer.

Ultraviolet spectrophotometric studies were performed on CoA, the purchased dimer of CoA, and on the electrolysis product of CoA. In all cases the spectra were nearly identical, and contained a maximum at about 259 nm. This result is to be expected since the absorption is due to the adenine moiety which is not significantly affected by formation of the dimer.

The diffusion current of the polarographic wave increased linearly with concentration. The slope of the plot of diffusion current as a function of concentration was used with the measured capillary characteristics (m = 1.43 mg/sec; t = 4.68 sec), and the coulometrically determined value of n, to calculate the diffusion coefficient (D) of CoA. This was accomplished by setting the slope of the plot equal to the terms in parentheses in the Ilkovic equation (Eq. [4])

$$i_d = (708\, n\, D^{1/2}\, m^{2/3}\, t^{1/6})\, C \qquad [4]$$

The observed slope was 1.85 μA/mM (12 solutions), and the calculated diffusion coefficient was 2.5×10^{-6} cm^2/sec.

The results listed earlier in this paper have demonstrated that the overall electrochemical reaction taking place at the electrode surface is that shown in Eq. [5]. In order to determine

$$2RSH = RSSR + 2H^+ + 2e^- \qquad [5]$$

the mechanism of this overall reaction, a triangular-wave voltammetric study was undertaken. Five samples of CoA were studied at the hanging mercury drop electrode at six scan rates varying from 0.02 to 1 V/sec. A typical triangular-wave voltammogram is shown in Fig. 4.

The diagnostic criteria of Nicholson and Shain (7) for nondimerization reactions, and the diagnostic criteria of Andrieux, Nadjo, and Saveant (8) for dimerization reactions without complicating chemical steps were applied to five solutions of varying CoA concentration. Typical results obtained using the criteria of Nicholson and Shain are shown in Fig. 5. These results indicate that the reaction mechanism obeyed by CoA consists of a relatively slow preceding chemical equilibrium followed by rapid reversible electron transfer.

Plots of the anodic peak potential as a function of the log of the scan rate, and as a function of the log of the CoA concentration were not those expected for simple dimerization reactions, thereby indicating that the electrochemical reaction was not kinetically identical to any of the dimerization reactions studied by Andrieux, Nadjo, and Saveant. Taken together these data suggest that the dimerization reaction involves a rate-determining dissociation to yield an anion which subsequently reacts at the electrode surface to yield a dimer. The type of dimerization reaction (DIM1, DIM2, etc.) cannot be determined from triangular-wave voltammetric data at pH 6.5. The electrochemical reaction apparently proceeds as shown in Eq. [6] at pH's less than 9.8

$$RSH = RS^- + H^+ \text{ (slow)} \qquad [6a]$$

$$2RS^- = RSSR + 2e^- \text{ (fast)} \qquad [6b]$$

and as shown in Eq. [6b] at higher pH's.

The rate of the electrochemical reaction at pH 6.5 is determined by the rate of the dissociation step. The heterogeneous, first-order rate constant for the overall electrochemical reaction at this pH can be estimated at the standard potential of the redox couple from triangular-wave voltammetric data using the method of Nicholson (9). The values of n and D calculated earlier were used in this calculation. A series of five CoA solutions were used at various scan rates for the kinetics study. The calculated rate constant was $(3 \pm 1) \times 10^{-3}$ cm/sec (20 trials). This rate constant is for the overall electrochemical reaction as shown in Eq. [5]. The limiting factor in the rate of Eq. [5] is the preceding chemical reaction shown in Eq. [6a].

Electrochemical Glucose Oxidation on a Platinized Platinum Electrode in Krebs-Ringer Solution

IV. Effect of Amino Acids

ABSTRACT

Physiological amino acids of varied composition in Krebs-Ringer solution both with and without glucose behave qualitatively similarly during fast potential sweeps using platinized platinum electrodes. The degree of observed amino acid electrooxidation and the inhibition of glucose oxidation are strongly related to a parameter which represents the strength of adsorption of the amino acid. This parameter, in turn, is a function of the intrinsic adsorbability of the amino acid and its concentration. A ranking of amino acids according to their ability to inhibit glucose oxidation shows that basic and sulfur-containing amino acids are the most inhibitory. Investigations with lysine and leucine at various concentrations confirm these findings. Amino acid mixtures behave qualitatively similarly to the individual acids, but under certain conditions the mixtures totally inhibit glucose oxidation. Sensitivity to glucose (in the cathodic potential sweep) can be restored by increasing the anodic prepolarization potential, the potential sweep rate, and the real surface area, and by decreasing convective transport to the electrode surface. Mixtures of strongly and weakly inhibiting amino acids (lysine and leucine) behave in the same way as a solution of the single strong inhibiting amino acid (lysine) alone.

In previous publications (1, 2) we have described the concept of an implantable glucose sensor for the determination of glucose concentration in intercellular fluid, with the ultimate goal of controlling glucose levels in diabetics. This sensor is based on the use of high surface area platinum as the glucose sensing electrode. Platinum was selected because of its good cycling characteristics, which provide for good reproducibility over extended periods of time.

As proposed, the glucose sensing electrode is operated in a transient mode using a potentiostat. In this mode the electrode is activated by an anodic prepolarization potential pulse (or pulse sequence), which may be followed by a cathodic prepolarization pulse to remove any oxide (PtO) previously formed. After the anodic/cathodic prepolarization pulses, a potential-step or a potential-time function $E(t)$ is applied to the working electrode, and the current $i(t)$ is measured. A special case of this applied transient potential method involves the use of a continuous trapezoidal $E(t)$ function with constant potential plateaus at high and low potentials, *e.g.*, +1000 mV and −800 mV *vs.* the saturated calomel electrode (SCE), and with an ascending (anodic) linear potential sweep and a descending (cathodic) linear potential sweep. Work with Krebs-Ringer solutions containing glucose alone as a reactant has shown (3, 4) that good sensitivity and excellent reproducibility of the current response to changes in glucose concentration can be obtained with platinized platinum or Teflon-bonded platinum electrodes operated in this mode, with or without hydrophilic membranes covering the electrode surface. If this type of sensor and measuring method is to find *in-vivo* application, it is necessary to obtain glucose selectivity with respect to the large variety of coreactants present in physiologic fluids. Interference by macromolecules is eliminated in the proposed sensor by using a membrane which separates the sensing electrode from the body fluids. Interference by low molecular weight species depends on their reactivity and concentration and have to be the subject of study. In a previous publication (5) we have reported the effect of urea on the glucose response using fast linear potential sweeps and have suggested methods to measure glucose concentration in the presence of urea of varying concentrations. The addition of an amino acid mixture to Krebs-Ringer solutions containing glucose has also been shown (6) to greatly modify the voltammogram by providing additional oxidation currents in the anodic sweep at high potentials. This effect is due to amino acid electrooxidation as well as to a substantial inhibition of glucose oxidation.

Key words: anodic oxidation, inhibition, glucose sensor.

Rao *et al.* (7) have investigated the effect of sixteen individual amino acids and a mixture of seven amino acids on the fast potential-sweep voltammogram and on the steady-state current obtained at constant potential using platinum-based electrodes. They used a phosphate buffer as the supporting electrolyte. When investigating individual amino acids using fast potential sweeps, smooth Pt was used as the working electrode and chloride was added to the supporting electrolyte. No chloride was used with the amino acid mixtures nor with any of the steady-state measurements. A platinized platinum electrode was used when testing mixtures with fast potential sweeps, and high surface area Pt-Ni electrodes were used with all steady-state measurements. Based on the results of the steady-state experiments, they classified the amino acids as strongly or weakly inhibiting and speculated that higher inhibition is caused by stronger amino acid adsorption.

Other than the aforementioned study (7), the electrochemistry of amino acids has received little attention when the working electrode is platinum. In contrast, the mercury electrode has been used repeatedly for polarographic investigations of amino acids and for adsorption studies (*i.e.*, measurement of electrocapillary curves) (8-14). These latter studies have been motivated by the zwitterion nature of amino acids. Two factors governed the adsorption properties of amino acids on mercury: the chain length (for the aliphatic amino acids) and the contribution of the zwitterionic amino and carboxylic groups. It has been suggested (14) that near the potential of zero charge of the mercury electrode, the amino acid molecule is adsorbed with its zwitterionic groups as well as the other substituent group in contact with the mercury surface. At more positive or negative potentials, the amino acid adsorption is controlled exclusively by the zwitterionic groups. It is not obvious whether the findings obtained using a mercury electrode are directly applicable to the platinum electrode.

Gold electrode and vitreous carbon electrode were used by Reynaud *et al.* (16) and Malfoy and Reynaud (17). They concluded that out of 20 amino acids examined only six (cystine, cysteine, methionine, tyrosine, tryptophan, and histidine) were specifically oxidized on gold or carbon electrodes. They concluded that on gold the electrochemical oxidation is catalyzed by a labile oxide .

The present investigation was aimed at further clarifying and quantifying the effect of amino acids in the context of the physiological conditions to be encountered when using the glucose sensor we envision, *i.e.*, high surface area Pt electrode, bicarbonate-based buffer with physiologic concentrations of chloride, and fast linear potential sweeps. We have extended the number of amino acids studied individually and have investigated in more detail the effect of amino acid concentration with two amino acids, lysine and leucine, which are representative of strongly and weakly inhibiting species, respectively. Lastly, we have explored possible interactions between amino acids in a simple mixture of lysine and leucine and in a very complex mixture of 24 amino acids.

Experimental

The working electrode was a platinized platinum rotating disk electrode operated at 10 rev/sec. Our previous work (3, 4) established that electrode processes are kinetically controlled at this rate of rotation. The geometrical area of the platinized platinum electrodes was 0.28 cm^2. The real surface area ranged from 260 to 100 cm^2 and was measured before each set of experiments using galvanostatic, anodic hydrogen stripping. No significant changes were observed between consecutive measurements. Only two electrodes were used in this study, each with a single platinization which occurred at the start of the investigation. The decay in real surface area was due mostly to mechanical fragmentation of Pt crystallites during handling and rotation of the electrode (4). To account for the change in surface area in the interpretation of data from electrodes with different surface areas, results are reported in terms of (*i*) current densities (currents divided by real surface area), or (*ii*) relative currents (*i.e.*, ratios of currents or current differences). The reference electrode was a saturated calomel electrode (SCE) and all the reported potentials were determined against this electrode. The supporting electrolyte was a modified (calcium-free) Krebs-Ringer solution equilibrated with a gas mixture containing 95% N_2 and 5% CO_2 (pH = 7.3). The temperature was 37°C. The electrochemical cell and measuring circuit have been described previously (3).

All of the reported data were obtained using single linear potential sweeps following a prepolarization potential sequence. Unless otherwise stated, the potential sweep and prepolarization conditions were as follows: anodic and cathodic linear potential sweeps at 0.5 V/min extending between −600 mV and +1000 mV; cathodic prepolarization prior to an anodic sweep consisting of the application of a 1000 mV pulse for 1 min followed by 1 min at −600 mV; and anodic prepolarization sequence immediately before the cathodic sweep consisting of the application of a −500 mV pulse for 1 min followed by 2 min at 1000 mV.

Voltammograms with supporting electrolyte, glucose, amino acid, and glucose plus amino acid were compared. When doing so the generating sequence of the voltammogram was (*i*) buffer (B) alone; (*ii*) amino acid (AA) in buffer; (*iii*) glucose and amino acid (G, AA) in buffer; (*iv*) buffer (B) alone (fresh solution); (*v*) glucose alone (G) in buffer; and (*vi*) glucose and amino acid (G, AA) in buffer.

The solutions were prepared from concentrated stock solutions of glucose and amino acids by adding 2.5-5.0 ml of stock solution to 250 ml of Krebs-Ringer solution. The test solution was replaced after step (*iii*) with fresh buffer following a thorough washing and rinsing of all cell parts in contact with the test solution. Excellent reproducibility was observed between steps (*i*) and (*iv*) and between steps (*iii*) and (*vi*) provided that 1 min was allowed for mixing and equilibrating prior to recording the current-potential curves; this reproducibility confirmed the lack of hysteresis in the voltammogram sequence. The first sweep was not recorded, the following sweep and all consecutive sweeps displayed identical current-potential characteristics. A similar approach was used to investigate simple mixtures of leucine and lysine and more complex amino acid mixtures.

Results

Electrochemical behavior of individual amino acids.—Figure 1 shows anodic and cathodic current-potential curves obtained with fast linear potential sweeps for Krebs-Ringer buffer solution alone (curve A), Krebs-Ringer buffer plus the addition of the amino acid alanine alone (curve B), both glucose and alanine added to the buffer (curve C), and glucose alone added to the buffer (curve D). Similar curves were obtained with the 24 amino acids listed in Table I, each at its normal physiological concentration and also at 3 mg/dl if its physiological concentration was less than 1.7 mg/dl or greater than 3.6 mg/dl. These curves have been used to evaluate the electrochemical behavior of amino acids in pure Krebs-Ringer solution, as well as in glucose-containing Krebs-Ringer solutions.

Electrooxidation and adsorption of individual amino acids.—Comparison of curves A and B in Fig. 1a shows that the second anodic current peak, occurring in the potential range of −250 to +250 mV, for the buffer alone is depressed and shifted by alanine to more positive potentials. It has been previously concluded (15, 3, 4) that this peak is due to the oxidation of "reduced CO_2" formed during the cathodic prepolarization step

Table I. Inhibitory ranking of individual amino acids

Amino acid	Average physiol. conc., C (mg/dl)†	Molecular weight	Chemical characteristic of substituent group	Sequence of increasing inhibition: At physiologic conc.	Sequence of increasing inhibition: At comparative conc.
Aspartic acid*	0.16	133	Acidic, hydrophilic	1	7

by the reductive adsorption of carbon dioxide or a related species (*e.g.*, carbonic acid, bicarbonate). The data show that the reduced CO_2 is displaced by chemisorbed amino acid. In the potential sweeps of Rao *et al.* (7) this peak does not appear because phosphate was used instead of bicarbonate buffer. The extent of the decrease in the height of this current peak or its shift toward more positive potentials can be used as a measure of the degree of chemisorption of the amino acid at low potentials. The degree of chemisorption is itself determined by the strength of the intrinsic interaction between the amino acid and the surface as well as by the amino acid concentration. We have chosen to use the relative decrease in the height of the second anodic current peak $(i_B - i_{AA})/i_B$ as an indication of the degree of electrode coverage by chemisorbed amino acid. Other measures obtained from the current-potential curves might be equally valid. For example, we have also examined the difference in the electrode potential (evaluated at a constant current equal to two-thirds of the background peak current) between the results for buffer plus amino acid and buffer alone. In fact, as shown in Fig. 2a, good correspondence exists between these two parametric measures, either of which could be used to characterize the degree of amino acid adsorption. The numbered points in Fig. 2 indicate the specific amino acid corresponding to the numbers in the fifth column of Table I.

Fig. 1. $i(E)$ curves (at 0.5 V/min). (a) Anodic sweeps; (b) cathodic sweeps. A, Krebs-Ringer (K-R) alone; B, K-R with alanine (5.0 mg/dl); C, K-R with alanine (5.0) + glucose (100); D, K-R with glucose (100).

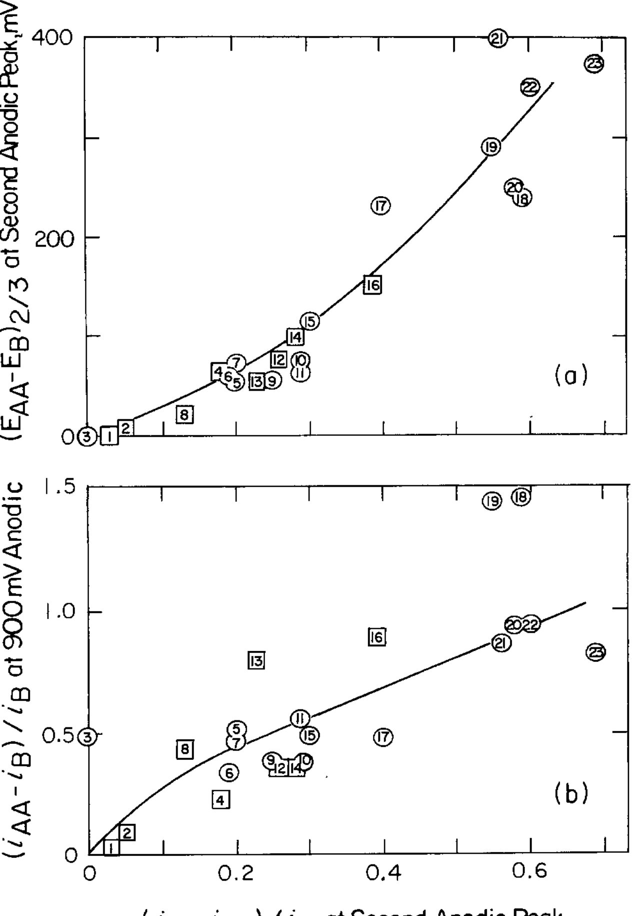

Fig. 2. Dependence of $i(E)$ curve parameters on decrease of second anodic peak for amino acids studied individually (identified by the number in column 5, Table I). Measurements were carried out at physiological amino acid concentrations.

The current plateau observed with Krebs-Ringer buffer solution alone at potentials between 750 and 1000 mV (curve A, Fig. 1a), which results from formation of surface platinum oxides (PtO) or chemisorbed oxygen, is enhanced by the presence of amino acids (curve B). This result indicates that substantial amino acid oxidation occurs at these potentials. The relative increase in current induced by amino acids at 900 mV is plotted in Fig. 2b *vs.* the relative decrease in the height of the second anodic peak. The correlation suggests that the oxidation current increases with an increase in the degree of adsorption of the amino acid. However, the observed amino acid oxidation current at +900 mV is a transient current which may result largely from oxidation of a previously chemisorbed amino acid and need not reflect oxidation of additional amino acid adsorbed from the bulk solution. It is unclear whether any residual, steady-state current due to bulk amino acid oxidation would be proportional to the degree of amino acid adsorption. Since no steady-state current was measured in this work, this question cannot be answered. The steady-state currents reported by Rao *et al.* (7) are not comparable because they were obtained under very different experimental conditions.

Figure 1b shows the effect of amino acids on the current-potential curve obtained in the cathodic direction. At high potentials (above approximately 300 mV) the small current difference between curves A (buffer alone) and B (buffer plus amino acid) reflects further oxidation of the amino acid after the anodic prepolarization period. The presence of amino acids brings about a small reduction in the magnitude of the PtO reduction peak (at about −300 mV). A small shift in current toward the anodic direction (or less cathodic current) is also observed for potentials more negative than about −450 mV. The effect of amino acid additions in the region of the cathodic PtO reduction peak is different from the effect of urea addition (5) which causes a broadening of the cathodic PtO peak toward negative potentials with the consequent reduction of both the height of the peak and the cathodic currents at potentials negative to the peak. This difference suggests that amino acids slightly inhibit the formation of PtO during the preceding anodic prepolarization while urea inhibits its reduction during the cathodic sweep.

Effect of individual amino acids on glucose electrooxidation.—Comparison of curves C (addition of glucose + amino acid) and D (addition of glucose alone) in Fig. 1a shows that the second current peak of the anodic sweep in the potential range from about −100 mV to about +350 mV is substantially increased in the presence of glucose and that this increase in current is strongly inhibited by the presence of amino acids. Figure 3a shows that there is a good correlation between i_G-i_{GAA}, the decrease of the current in the second anodic peak of glucose electrooxidation resulting from addition of amino acid, and the degree of amino acid adsorption. At high potentials (+600 mV), the current obtained when glucose and an amino acid are added together (curve C) is higher than when the amino acid is added alone (curve B), but in general is smaller than with glucose added alone (curve D). Figure 3b indicates that the relative current increase at 900 mV when glucose and an amino acid are added to the buffer, as compared to addition of amino acid alone, is inversely related to the degree of adsorption of the amino acid.

The glucose-dependent "anodically directed peak" observed in the cathodic potential sweep between about −250 and −400 mV has been interpreted (3) as resulting from electrooxidation of glucose after a substantial amount of PtO has been reduced. Comparison of curves C and D in Fig. 1b shows that the presence of amino acids also decreases the height of this peak. The reduction of the height of the anodically directed peak is also accompanied by a shift of the peak toward more negative potentials. This would be expected if less glucose were electrooxidized simultaneously with PtO reduction. Figure 3c demonstrates a good correlation between the relative decrease in the height of the glucose-dependent anodically directed peak of the cathodic potential sweep resulting from amino acid addition and the degree of adsorption of the individual amino acids.

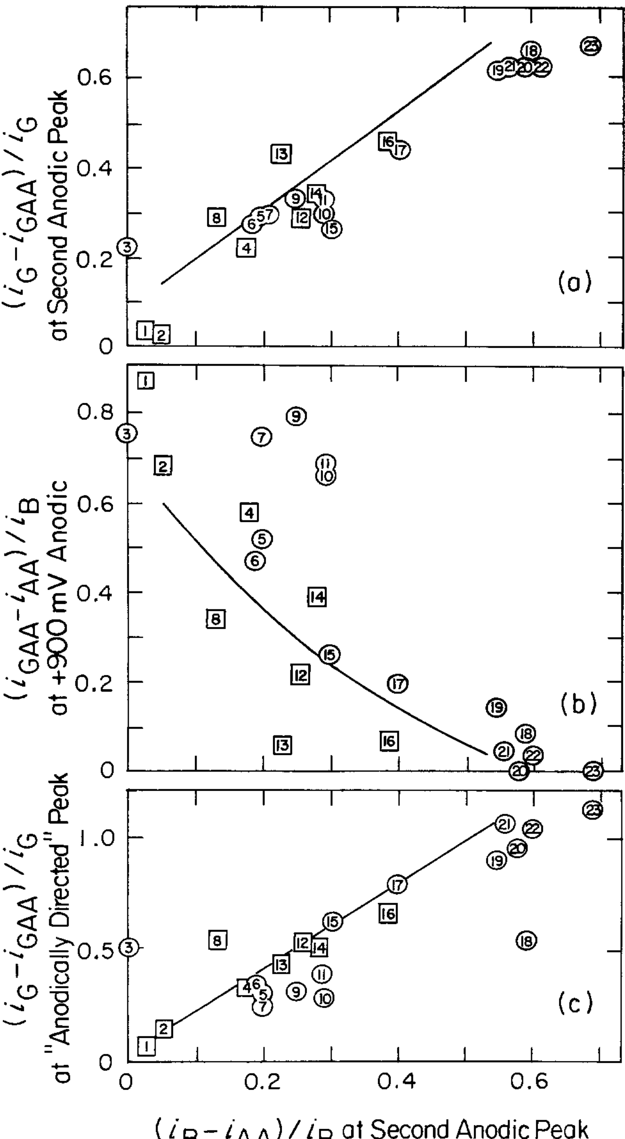

Fig. 3. Dependence of parameters in *i(E)* curves with glucose and amino acids on amino acid-induced decrease of second anodic peak (amino acid identification same as for Fig. 2). Physiological amino acid concentrations.

The effect of amino acids on glucose electrooxidation is summarized in Table I in which the different amino acids are ordered according to their inhibitory power. This sequence was obtained by calculating the average of (*i*) the degree of amino acid adsorption $(i_B - i_{BAA})/i_B$ at the second anodic current peak, (*ii*) the inhibiting power on glucose oxidation at the same current peak $(i_G - i_{GAA})/i_G$, and (*iii*) the degree of inhibition of glucose oxidation at the anodically directed current peak in a cathodic sweep, $(i_G - i_{GAA})/i_G$. The most inhibitory amino acids are those with an excess of basic character imparted by the presence of free NH_2 groups. In addition, there is a suggestion that the presence of sulfur may add to the inhibitory nature of the amino acids.

A brief investigation was conducted to compare the behavior of amino acids with very low (<1.7 mg/dl) or with high (>3.6 mg/dl) physiological concentrations at a constant concentration level of 3 mg/dl. Since the

molecular weight of physiologically significant amino acids in Table I does not differ greatly, the molar concentrations of the different amino acids were also comparable. The results showed that the ranking of the different amino acids according to their inhibitory power changes in some cases (citrulline, methione, alanine) when comparison is made at comparable concentrations (sixth column of Table I) rather than physiological concentration.

Concentration effects of amino acids and glucose.— Leucine and lysine were selected for further study because, while inhibiting glucose electrooxidation to quite different degrees, their physiological concentration and molecular weight differ only slightly, and both are aliphatic saturated molecules. They differ structurally in their substituent groups, $(CH_2)_3$-NH_2 for lysine and $CH(CH_3)_2$ for leucine, which make lysine a basic and hydrophilic amino acid and leucine a neutral and hydrophobic amino acid.

Figures 4a and 4b show the effect of increasing concentrations of leucine and lysine, respectively, on the current-potential curves obtained with a fast potential sweep. In these experiments, the sweep rate was 2 V/min, and the electrode prepolarization treatment consisted of a 2 min pulse at −700 mV prior to an anodic sweep and a 2 min pulse at 1150 mV prior to a cathodic sweep. The qualitative effect of increasing amino acid concentration is consistent with the results discussed with respect to Fig. 1. The stronger adsorption of lysine (*vs.* leucine) is consistent with the more pronounced shift of the second anodic peak at about 200 mV and the higher rate of lysine oxidation at the high potentials. A plot of the net amino acid oxidation current density at 950 mV ($i_{AA} - i_B$ divided by real surface area) as a function of amino acid concentration is presented in Fig. 5. There is a higher current density for lysine than for leucine with an indication of saturation in the case of lysine.

Figure 6 is analogous to Fig. 2 and shows the correlations between (*i*) the electrode potential shift in the second anodic peak at two-thirds of the background peak current, and (*ii*) the net relative current increase induced by amino acid oxidation at 900 mV in the anodic potential sweep as a function of the degree of amino acid adsorption expressed as the relative decrease in the height of the second anodic current peak. The data were obtained with lysine and leucine individually and with simple mixtures of the two at varying concentrations in buffer. The solid curves fitting the data points of Fig. 6a and 6b have been drawn also in Fig. 2a and 2b, respectively. Good agreement is observed for the correlations with the individual amino acid and mixture data obtained at varying concentrations.

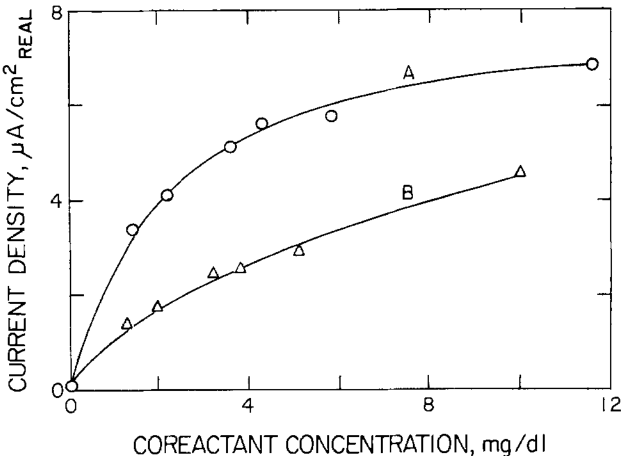

Fig. 5. Net current density at 950 mV during anodic sweep. ○ Lysine (R_f = 411); △ leucine (R_f = 518).

Figure 7 contains current-potential curves for a series of different glucose concentrations taken under the following conditions: alone with buffer (Fig. 7a), with 3.1 mg/dl leucine added (Fig. 7b), and with 3.6 mg/dl lysine added (Fig. 7c). Comparison of these three sets of curves demonstrates the decreased electrode sensitivity to glucose concentration changes in both the anodic and cathodic potential sweeps in the presence of added amino acid. The sensitivity is smaller with the more inhibitory lysine than with the less in-

hibitory leucine. The effects of glucose and amino acid concentrations on the net glucose oxidation current ($i_{GAA} - i_B$) in the anodically directed peak of the cathodic potential sweep is shown in Fig. 8. The current density is plotted in Fig. 8a as a function of glucose concentration at several concentration levels of lysine and leucine. These data have been replotted in Fig. 8b where the net glucose current is normalized by that measured in the absence of amino acid in order to show the relative decrease in the net glucose oxidation current as a function of coreactant (leucine or lysine) concentration. Each data point is the mean of the data at each glucose concentration plotted in Fig. 8a. The relative decrease of current is independent of glucose

concentration in the range of 50-300 mg/dl. These results show that addition of amino acids decreases the electrode sensitivity to glucose concentration changes.

The normalized net glucose oxidation current at the anodically directed peak is plotted in Fig. 9 as a function of the second coreactant concentration for leucine-lysine mixtures. With a constant physiologic lysine concentration (3.6 mg/dl) and increasing leucine concentrations from 0 to 5 mg/dl, the net current is virtually constant, and the solution behaves as if it contained only the more strongly inhibiting lysine. In contrast, mixtures with a physiological concentration of leucine (3.1 mg/dl) and varying amounts of lysine

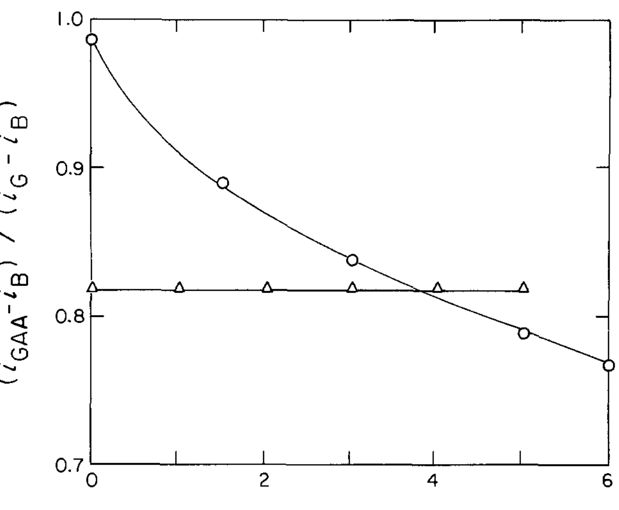

Fig. 9. Net current of anodically directed peak during cathodic sweep, in the presence of both lysine and leucine. Sweep rate 1 V/min. Glucose concentration constant at 100 mg/dl. R_f = 779. ○ Leucine (3.1 mg/dl); △ lysine (3.6 mg/dl).

show increasing inhibition of glucose electrooxidation with increasing lysine concentration. This again demonstrates that the more strongly inhibiting component controls the behavior of simple amino acid mixtures. Figure 10 relates three measures of the extent of inhibition of glucose electrooxidation to the degree of lysine and leucine adsorption. The data used to construct these plots were taken from current-potential curves obtained with potential sweep rates of 0.5 V/min and with varying concentrations of lysine and leucine studied individually and in mixtures. These plots correlate very well with those in Fig. 3. The solid curves fitting the data points in Fig. 10 are also drawn in Fig. 3; they show the same general trend as the data. The lysine and leucine data obtained at different concentrations agree well with these same curves that correlated a large number of amino acids at their physiological concentration. Although the two mixtures in Fig. 9 behaved very differently, all of the mixture data falls smoothly on the same correlations as that for the individual amino acids in Fig. 6 and 10. This finding further validates the use of the relative current decrease at the second anodic peak as a measure of the degree of amino acid adsorption.

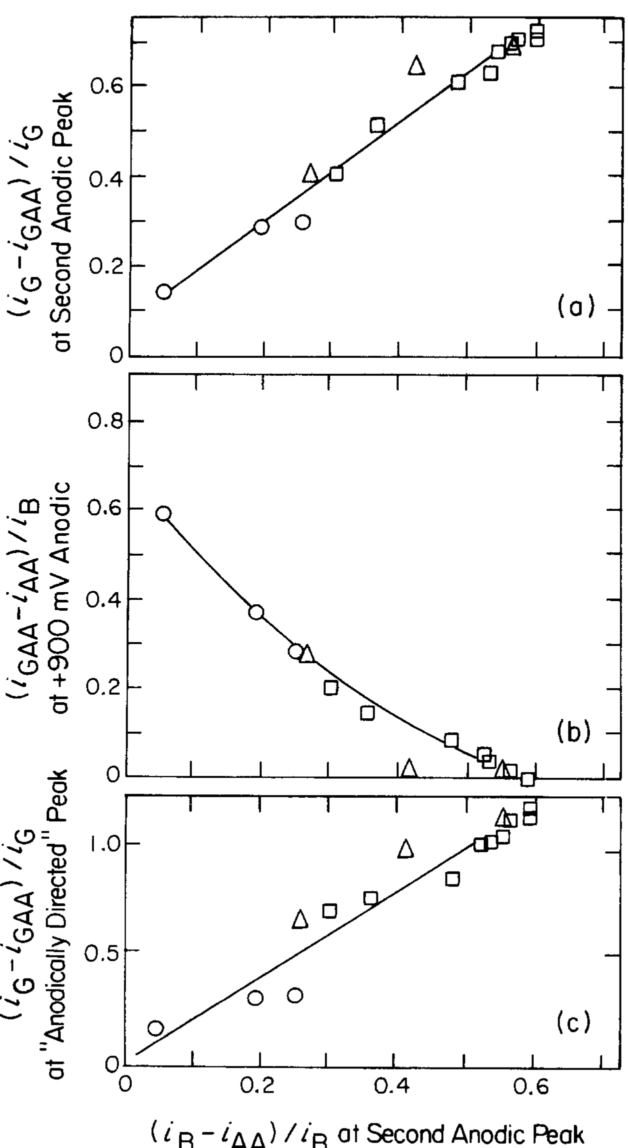

Fig. 10. Dependence of glucose electrooxidation characteristic parameters from *i(E)* curves at 0.5 V/min on decrease of second anodic peak induced by leucine and lycine. Glucose concentration constant of 100 mg/dl. Symbols and concentrations of leucine and lysine are the same as in Fig. 6.

Electrochemical behavior of complex amino acid mixtures.—In order to assess the behavior of complex amino acid mixtures at physiological concentration, a mixture of 14 amino acids with the composition shown in Table II (total concentration of 50 mg/dl) was used to generate the current-potential curves shown in Fig. 11. Comparison with Fig. 1 shows that the electrochemical response of this mixture and its effect on the glucose current-potential curves is qualitatively similar to that of the individual amino acids. As would be expected, under equivalent conditions of electrode real surface area, prepolarization, and potential sweep rate, the amino acid mixture almost totally inhibits glucose electrooxidation. Further study showed that the sensitivity to glucose in the cathodic potential sweep can be

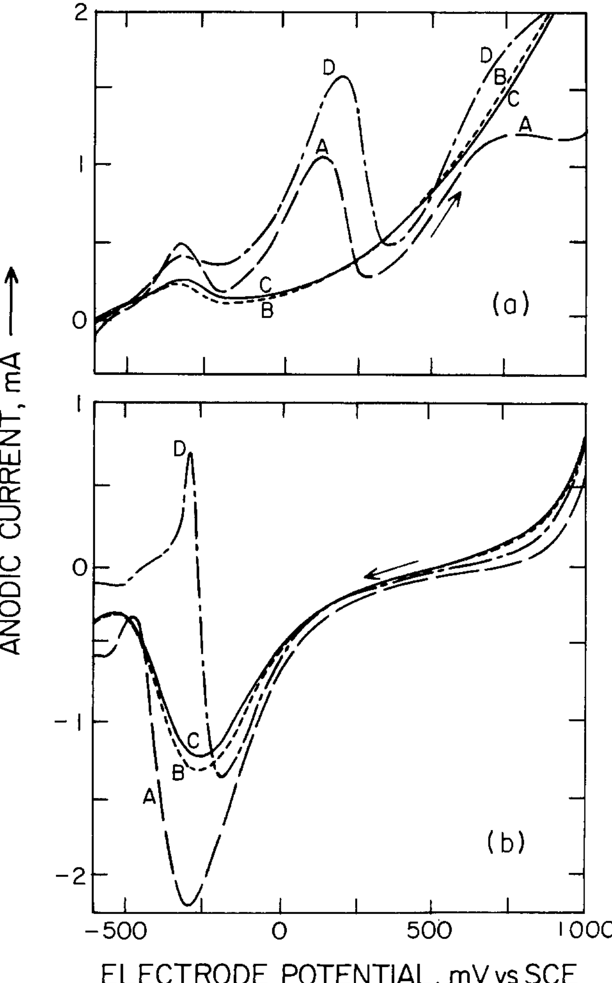

Fig. 11. Current-potential curves (at 0.5 V/min). (a) Anodic sweeps; (b) cathodic sweeps. A, Krebs-Ringer alone; B, K-R with amino acid mixture (Table II, 50 mg/dl); C, K-R with amino acid mixture (50) + glucose (100); D, K-R with glucose (100).

restored by one or more of the following changes: (*i*) increase of the prepolarization potential from 1000 to 1100 mV; (*ii*) increase of the potential sweep rate (*e.g.*, from 0.5 to 2 V/min; (*iii*) increase in the electrode roughness factor; and (*iv*) reduction of transport to and from the surface by placing a membrane over the electrode. Considerably less effort was spent investigating factors which improve glucose sensitivity in the anodic potential sweep. However, experiments with leucine and lysine mixtures at two sweep rates did indicate that a decreased potential sweep rate can increase glucose sensitivity in the anodic potential sweeps. Figure 12 shows the anodically directed current peak of the cathodic potential sweep obtained with different glucose concentrations in the presence of 50 mg/dl of a commercially available amino acid mixture (Freamine, McGaw Laboratories, Chicago) comparable in composition to the mixture of Table II. Glucose sensitivity is restored by the use of a higher prepolarization potential and a higher sweep rate.

The effect of total amino acid concentration is shown in Fig. 13. The net current density at the anodically directed glucose-dependent peak of the cathodic sweep is plotted *vs.* glucose concentration for Freamine concentrations of 50 and 85 mg/dl in Fig. 13a. Even at 85 mg/dl there is still considerable glucose sensitivity, but there is also a large effect of amino acid concentration. For example, change in Freamine concentration from 50 to 85 mg/dl causes the current to decrease to one-third of its initial value. The same data are plotted on reciprocal coordinates in Fig. 13b. The good linearity of the data on these coordinates suggests that the net glucose oxidation current density can be represented empirically as a hyperbolic function of glucose concentration. No attempt was made to interpret

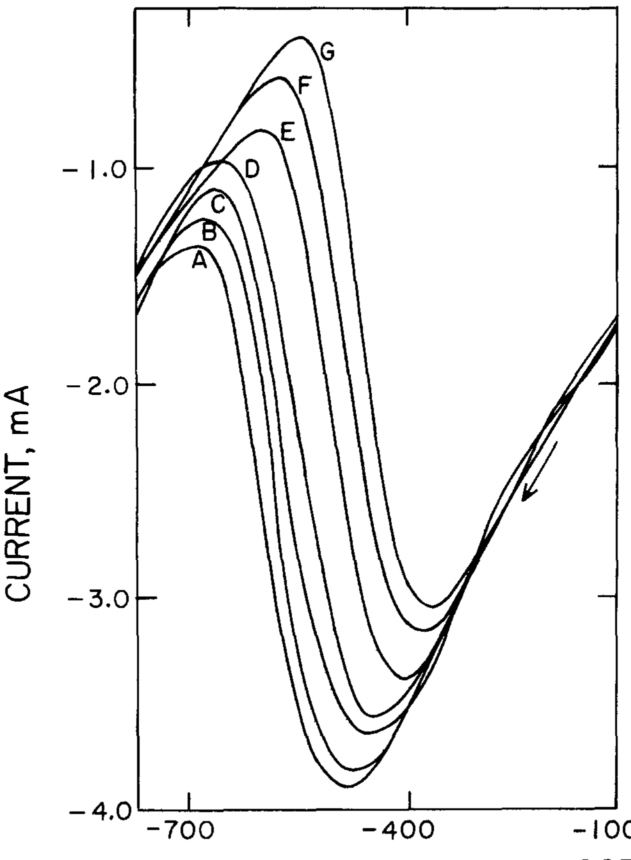

Fig. 12. Anodically directed current peak during cathodic sweep with 50 mg/dl of Freamine amino acid mixture. Prepolarization potential: 1100 mV; sweep rate: 1.8 V/min; R_f = 600. Glucose concentrations: 0, 20, 40, 80, 180, 280, 380 mg/dl (A to G).

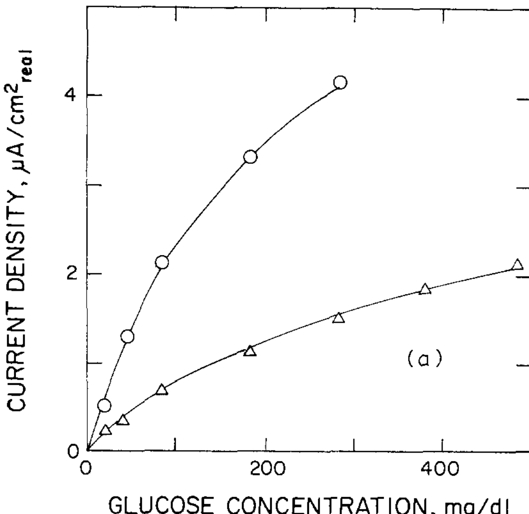

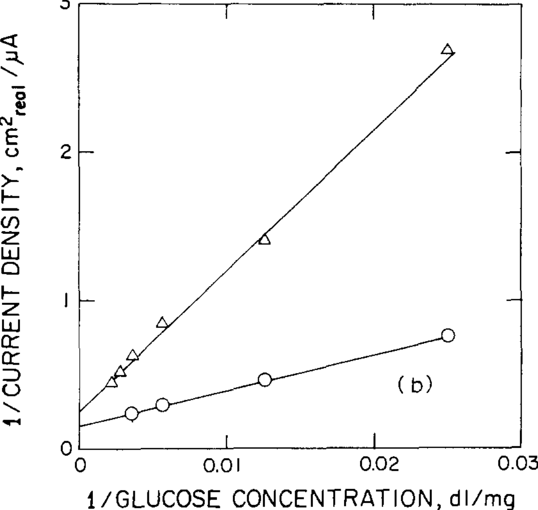

Fig. 13. (a) Net anodically directed peak current density during cathodic sweep as a function of glucose concentration: ○ 50 mg/dl Freamine (from Fig. 12), △ 85 mg/dl Freamine (experimental conditions as in Fig. 12); (b) reciprocal plot of same data.

kinetically the effect of amino acids on the current since the conditions under which the current is measured involve a number of transient electrode processes such as PtO reduction, glucose oxidation, double layer charging or discharging, and probably some amino acid oxidation.

Conclusions

A number of conclusions can be drawn regarding the effect of amino acids on fast potential sweeps obtained in Krebs-Ringer buffer solutions with and without glucose:

1. In the presence of amino acids the electrochemical activity of the platinum electrode can be reproduced by applying periodic potential-time functions in such a way that no cumulative effect of amino acid action is present. No hysteresis in the sequence of addition of glucose and amino acids is observed.

2. Individual amino acids are adsorbed on platinum at low potentials. They are oxidized at high potentials (above + 650 mV) and inhibit glucose oxidation in all potential regions of glucose activity. Good correlation exists between both the oxidation at high potentials and the glucose inhibition of a given amino acid and a parameter obtainable directly from voltammograms with and without amino acid which indicates the degree of adsorption of the amino acid. These relationships appear to override any effects caused by the variation in chemical composition.

3. Ordering of individual amino acids according to their level of glucose inhibition indicates that the main factor determining their inhibitory power is their basic character. The presence of excess NH_2 groups causes amino acids to be more inhibitory.

4. Lysine and leucine at the same molar concentration display very different behavior in terms of adsorption, oxidation rate, and glucose inhibition. These differences are attributable to the presence of an NH_2 group at the end of the lysine molecule. This result suggests that the adsorption of lysine on the platinum electrode does not occur solely through the zwitterionic groups of the molecule but must also involve the substituent group.

5. Changes in the concentration of lysine and leucine alter their degree of adsorption coverage, the rate of oxidation at high potentials, and the glucose inhibition power. These changes can be described by the same curves which correlate individual amino acid data.

6. Mixtures of amino acids near physiological concentration behave qualitatively as individual amino acids. Under conditions used to study individual amino acids, but with the amino acid mixtures used, the inhibition is so overwhelming that there is no glucose concentration response.

7. Glucose sensitivity in the cathodic potential sweep can be restored by increasing one or more of the following parameters: the prepolarization potential, the potential sweep rate, and the real surface area of the electrode. Reducing the transport rate to the surface can also increase the glucose concentration sensitivity.

8. Mixtures of lysine and leucine behave as individual amino acids with regard to their adsorption, oxidation rate, and glucose inhibition. They fit the same plots relating the various parameters of the $i(E)$ curves for individual amino acids at physiological concentrations and for individual solutions of leucine and lysine at various concentrations.

9. Both leucine and lysine cause a relative decrease in the glucose oxidation current which is nearly independent of the glucose concentration.

10. When leucine is added from 0 to 5 mg/dl to lysine solutions at the physiological concentration of lysine (3.6 mg/dl), the solutions behave with respect to glucose inhibition and to amino acid oxidation as if they contained only lysine.

The Electrosorption and the Potentiodynamic Electrooxidation of Ethane on Platinum at Different Temperatures

V. Solís, A. Castro Luna, W. E. Triaca, and A. J. Arvía*

Instituto de Investigaciones Fisicoquímicas Teóricas y Aplicadas, División Electroquímica, Sucursal 4, Casilla de Correo 16, 1900 La Plata, Argentina

ABSTRACT

The electrosorption and the potentiodynamic electrooxidation of ethane on platinized platinum in 1*N* H_2SO_4 has been studied in the 20°-80°C range. The potentiodynamic *I/E* profiles run immediately after the potentiostatic electrosorption of the hydrocarbon show that three different species participate in the electrooxidation process. The various electrosorbed species are tentatively related to the electrosorbed species which are formed during the electrosorption of both methane and ethylene on platinum. The electrochemical process is discussed through a complex reaction pathway involving electrosorption, interconversion, and electrooxidation processes.

The electrooxidation of ethane on platinum has been studied both in acid and alkaline electrolytes. Data for the electrochemical reaction are reported at different temperatures using conventional galvanostatic and potentiostatic techniques and multipulse potentiodynamic perturbations (1-14). Although the available information is to some extent not straightforwardly comparable, it has been established that the reaction occurs through the participation of different adsorbed species which were denoted as type I species and type II species. The former was assigned to an O-type species and the latter to a CH-α-type species, respectively (15-19). These assignments were made on the basis of triangular potential sweep *I/E* displays which were also compared to those resulting from the potentiodynamic electrooxidation of other related substances and from the charge balances based on the potentiodynamic data (3, 5-9). From the correlation of results obtained for different hydrocarbon electrooxidation on platinum in acid electrolytes various general reaction pathways were postulated (5-8, 12-14).

Recent results on the electrooxidation of ethylene (20, 21) and of methane (22) indicate that the initial stage of the electrochemical reaction is a dissociative electrosorption of the hydrocarbon. For ethylene the principal adsorbed species is assigned to a CH-containing species, while for methane, there are, in principle, two O-containing electrosorbed species predominating on the electrode surface, their relative surface concentration depending on the electrosorption potential and on the electrosorption time (22). These results suggest that for a saturated hydrocarbon such as ethane at least three main adsorbed species could participate in the electrochemical reaction, their relative contributions depending on the physicochemical characteristics of the electrochemical interface and on the potential program applied to the interface.

The present paper deals with the electrosorption and the potentiodynamic electrooxidation of ethane on platinum in acid electrolyte at different temperatures. It shows that three main electrosorbed species contribute to the electrochemical reaction. The potentiodynamic characteristics of these species correlate reasonably well with those derived from ethylene and methane electrooxidation and they suggest the possibility of presenting a general reaction scheme for the short chain aliphatic hydrocarbon electrooxidations which takes into account the hydrocarbon electrosorption reaction, the possible hydrogenation reactions, the interconversion reactions involving the different electrosorbed species, and the proper electrooxidation of the various adsorbed species yielding CO_2 and hydrogen ions as final products at the platinum anode.

Experimental

A conventional-type three-compartment electroysis cell was employed. The different cell compartments were connected through cup-type glass stopcocks lubricated with the electrolyte solution. Conventional procedures for the glass cell cleaning were used. The working electrodes consisted of a platinized-platinum electrode prepared as indicated in a previous work (21). The actual electrode areas were evaluated through the charge corresponding to the hydrogen adatom electrosorption current peaks. The potential of the working electrode was measured against a hydrogen reference electrode at 1 atm hydrogen gas saturation pressure in the base electrolyte solution (ethane-free acid electrolyte). The electrode potentials in the text are referred to the reversible hydrogen electrode scale (RHE). The counterelectrode was a large area platinum sheet.

The acid electrolyte (1*N* H_2SO_4) was prepared from Merck p.a. 95-97% H_2SO_4 and triply distilled water. The electrolyte solution satisfied the purity standards indicated in the literature (22, 23). Runs were made at 20°, 50°, and 80°C in the electrolyte saturated with ethane (C. P. Matheson) at 1 atm pressure. For the sake of comparison blanks were systematically made using the base electrolyte solution under 1 atm nitrogen gas saturation.

Prior to the hydrocarbon adsorption measurements the working electrode was subjected to the pretreatment already described in a recent publication (21). After the electrode pretreatment the potential of the working electrode was held during a preset time, t_{ad}, at a fixed value, E_{ad}, for the ethane adsorption. Immediately afterward a triangular potential sweep was applied from E_{ad} (Fig. 1) either toward the positive (program a) or the negative potential direction (program b), at a potential sweep rate, v. The charge required to electrooxidize the layer of adsorbed hydrocarbon, Q_E, was evaluated by substracting from the total anodic charge, previously corrected for the double

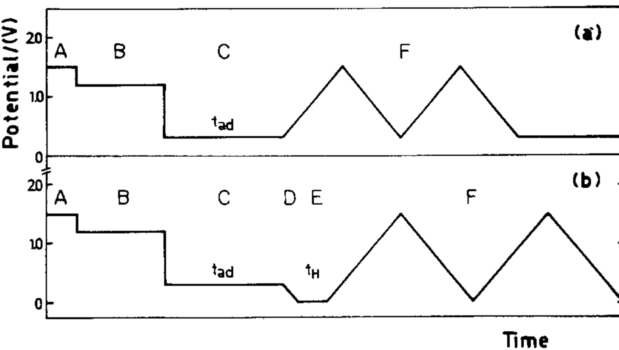

Fig. 1. Potential perturbation programs. Time axis arbitrary scale. Step width: A = 5 sec; B = 60 sec (gas bubbling) + 120 sec (quiescent solution); C = t_{ad}; D = negative going potential sweep; E = t_H; F = triangular potential sweep.

layer effect, the cathodic charge pertaining to the electrodesorption of the oxygen-containing layer formed during the anodic scan. In this sense blank experiments served as reference (20). In order to select the suitable v range for the ethane electrooxidation under hydrocarbon readsorption-free condition runs were made at preset values of E_{ad} and t_{ad} between the cathodic ($E_{s,c}$) and the anodic ($E_{s,a}$) switching potentials and different v's. From the Q_E *vs.* v plot (20) it was concluded there is practically no ethane readsorption interference when $v \geqq 0.3$ V/sec.

The electrosorption of ethane on platinized platinum was studied at a constant t_{ad} over a reativey wide E_{ad} range ($0.1V \leqq E_{ad} \leqq 0.6V$) and at a constant E_{ad} over a large t_{ad} range (5 sec $\leqq t_{ad} \leqq$ 90 min).

Results

The potentiodynamic I/E displays in the ethane-saturated electrolyte.—The potentiodynamic I/E displays depend strongly on the characteristics of each potential perturbation program. Thus, the I/E display resulting from the first potential scan in the positive potential going direction run at $E_{ad} = 0.250$V, $t_{ad} =$ 10 min, $v = 0.4$ V/sec, and 80°C (Fig. 2) shows that the adsorbed ethane electrooxidation occurs in the range *ca.* 0.4-1.5V. The process is associated with a composite anodic current peak (peak I) at *ca.* 0.69V which consists of a doublet and with another composite anodic current peak lying at *ca.* 1.05V (peak II). The latter overlaps with that related to the oxygen electrosorption on platinum. Likewise, the appearance of current peaks I and II is related to the remarkable decrease of the current related to the electrooxidation of the hydrogen adatoms, which are located in the 0.25-0.4V range. The negative potential going excursion exhibits the already known cathodic current peak at *ca.* 0.75V related to the oxygen electrodesorption and the cathodic current related to the initiation of the hydrogen adatom electrosorption at potentials close to $E_{s,c}$. During the second potential scan the I/E profile rapidly approaches the characteristics obtained in the blanks.

The I/E displays run at a constant E_{ad} and different t_{ad} reveal the doublet structure of current peak I (Fig. 3). Thus, at the shortest t_{ad}'s the current peak component which is located at more positive potentials (peak I_b) predominates over that (peak I_a) which is located at more negative potentials. Likewise, the contribution of current peak II is practically absent.

On the other hand, when $t_{ad} \geqq 1$ min the contribution of current peak II becomes appreciable and simultaneously the largest charge contribution to current peak I is due to peak I_a.

At a constant E_{ad}, the total charge related to the electrooxidation of adsorbed ethane attains a limiting value after a certain time, $t_{ad,ss}$. This time can be con-

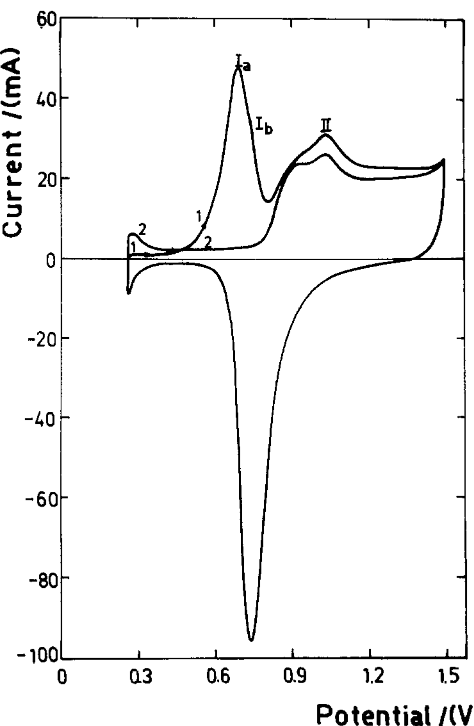

Fig. 2. Potentiodynamic I/E profiles run at 0.4 V/sec using the perturbation program (a) shown in Fig. 1. $E_{ad} = 0.25$V; $t_{ad} =$ 10 min; 80°C; real electrode area = 87 cm^2. Numbers 1 and 2 indicate the first and the second potential scans, respectively. Profile 2 approaches the blank contour (nitrogen saturated electrolyte).

sidered as the minimum time required to reach the stationary surface coverage by the adsorbed species. Thus, at 80° and $E_{ad} = 0.250$V, $t_{ad,ss} = 10$ min. Under the same E_{ad} and temperature conditions, within the 1 min $\leqq t_{ad} \leqq$ 7 min range, Q_E increases linearly with the logarithm of t (Fig. 4). On the other hand, at a constant t_{ad}, the shape of the electrooxidation I/E profile changes with E_{ad} (Fig. 5). Thus, at $E_{ad} = 0.5$ and 0.15V the current peak I appears as a small plateau and the contribution of current peak II to the total charge Q_E becomes relatively important. At $E_{ad} =$ 0.6V no ethane adsorption is detected through the potential sweep technique. At $t_{ad} = t_{ad,ss}$, Q_E depends on E_{ad} (Fig. 6). The maximum charge related to the electrooxidation of adsorbed ethane is found at $E_{ad} =$ 0.250V, the corresponding charge being $Q_E = 0.27$ mC/cm^2 of real area. For this case, the major charge contribution to the total charge Q_E is that of current peak I_a (Fig. 2).

The influence of the electrochemical hydrogenation on the potentiodynamic I/E profiles (Fig. 7) is determined by including a variable potential holding during the time t_H at $E_{s,c} = 0$V (Fig. 1, program b). Thus, when t_H increases the current peak I becomes thinner and relatively more symmetric, but the corresponding anodic charge remains constant. The peak height to peak width at one-half peak height ratio changes from 7.7 for $t_H = 0.3$ sec to 11 for $t_H = 5$ min. Furthermore, after the ethane adsorption at $E_{ad} = 0.25$V, the potential sweep in the negative potential direction reveals a clear and systematic blocking of sites for the electrosorption of hydrogen atoms, particularly those sites corresponding in the highest hydrogen-platinum adsorption energy. On the other hand, the contribution of current peak II decreases as t_H increases. This indicates that the species related to current peaks I_b and II undergo electrochemical hydrogenation, the former yielding the adsorbed species related to current peak I_a and the latter yielding an apparently nonadsorbable species.

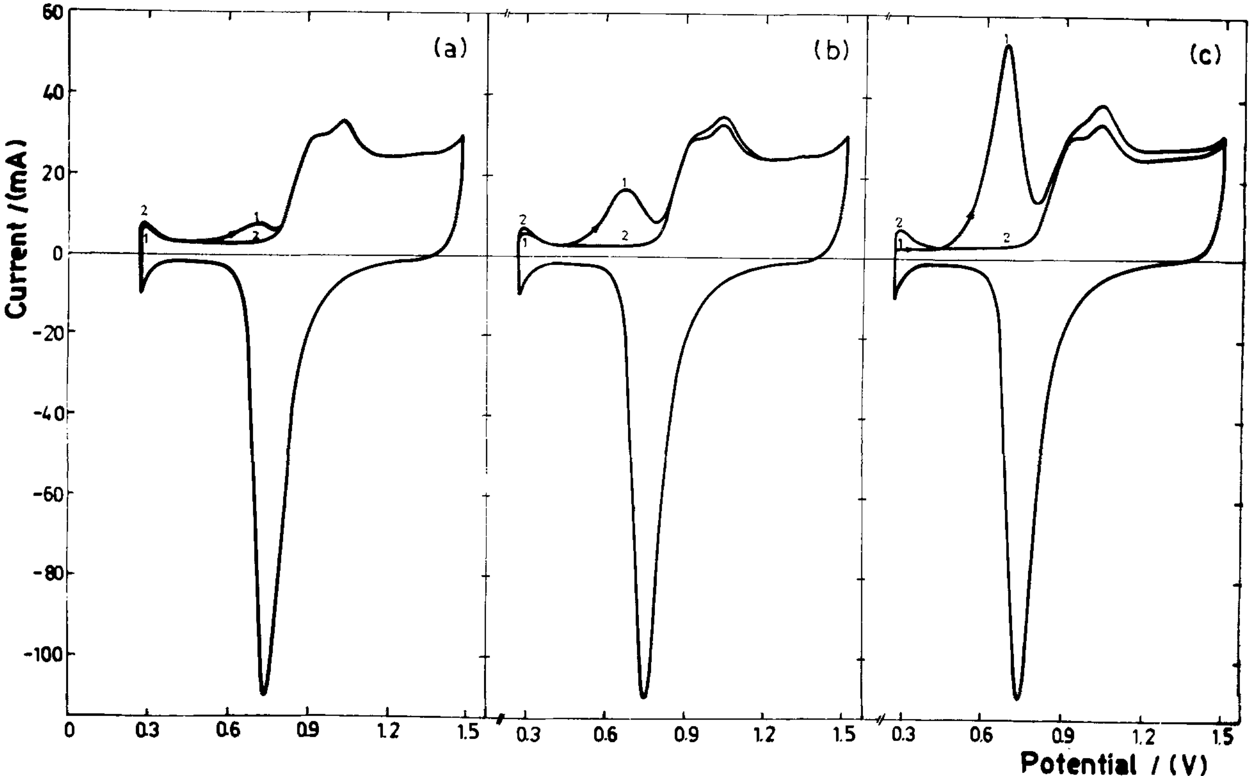

Fig. 3. Potentiodynamic I/E profiles run at 0.4 V/sec using the perturbation program (a) shown in Fig. 1 from E_{ad} = 0.25V at different t_{ad}; 80°C; real electode area = 100 cm^2. (a) t_{ad} = 15 sec; (b) t_{ad} = 1 min; (c) t_{ad} = 5 min.

At constant E_{ad} and t_H the distribution of the anodic current peaks is strongly dependent on t_{ad} (Fig. 8). Thus, for t_{ad} = 45 sec the current peak I_b becomes the most relevant one, while at $t_{ad} \geqq 1.5$ min the contribution of current peak I_a becomes progressively more important as t_{ad} increases. Furthermore, as t_{ad} decreases the current peak II appears within a narrower potential range.

The shape of the I/E contour depends also on t_H. Thus, when $t_H \geqq 5$ min the contribution of current peak II to the total charge Q_E appreciably decreases. After the electrochemical hydrogenation the current related to the oxygen electrosorption decreases in the 0.75-0.95V range. The corresponding charge decrease may be in part compensated by the charge increase observed in the 0.9-1.5V range, just in the potential range where the current peak II is recorded. The evaluation of the contribution of each reaction occurring in the 0.9-1.5V range exclusively from the potentiodynamic data is not feasible, but independently of it

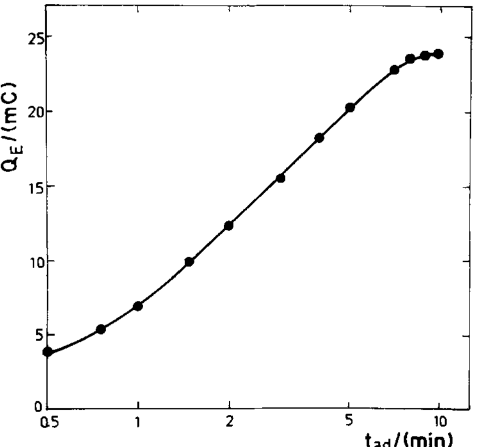

Fig. 4. Dependence of Q_E on t_{ad} at E_{ad} = 0.25V; 80°C, real electrode area = 88 cm^2.

the possibility that the current peak II results from the sum of the oxygen electrosorption current and the residual current of peak I should, in principle, be discarded.

The temperature influence.—The same type of experiments already described at 80°C were also made at 20° and 50°C. In principle, the different current peaks in the potentiodynamic I/E displays are more poorly defined as the temperature decreases because the potential range at which the ethane electrooxidation current peaks are observed becomes significantly more positive when the temperature decreases and, consequently, the potential regions corresponding to the oxygen electrosorption and to the ethane electrooxidation are partially overlapped (Fig. 9 and 10). At 20°C, the time required to attain the maximum steady surface coverage by adsorbed ethane at E_{ad} = 0.250V extends up to $t_{ad,ss}$ = 90 min. In this case, the current due to the electrodesorption of the hydrogen adatoms becomes appreciable (Fig. 9). The I/E display run at 1 atm ethane saturation pressure at 20°C resembles that obtained under 1 atm ethylene saturation pressure at 40°C (20) with the same acid electrolyte. The anodic current peak recorded at 20°C, decreases progressively by electrochemical hydrogenation at 0V when t_H is gradually increased. Therefore, the species formed during ethane electrosorption on platinum, at 20°C, behaves similarly to that obtained from the electrosorption of ethylene on the same electrocatalyst at relatively higher temperatures.

The potentiodynamic I/E displays obtained at 50°C show a behavior which is intermediate between those observed at 80° and 20°C (Fig. 10). At 50°C the I/E display presents the current peaks I and II and an appreciable hydrogen adatom electrosorption current. The time required to attain the steady surface coverage by the adsorbed species from ethane electrosorption at E_{ad} = 0.25V is $t_{ad,ss}$ = 30 min.

Charge measurements related to the electrosorption of ethane on platinum.—During the electrosorption of

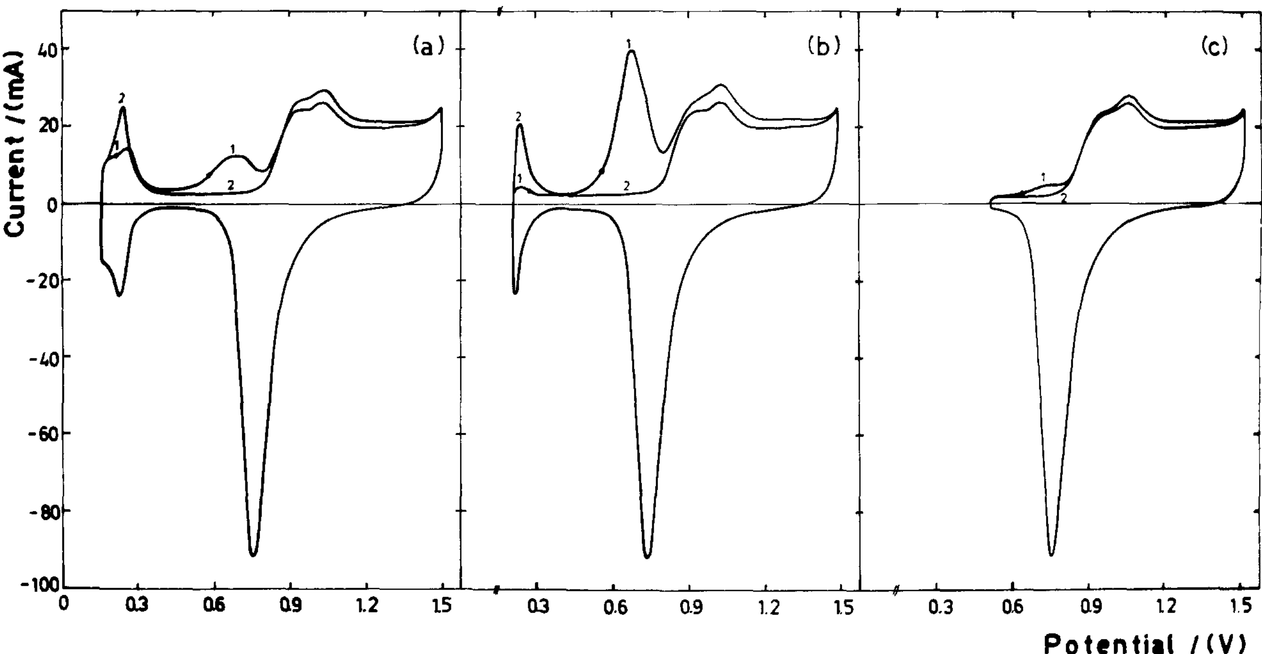

Fig. 5. Potentiodynamic I/E profiles run at 0.4 V/sec using the perturbation program (a) shown in Fig. 1 from different E_{ad} at t_{ad} = 10 min; 80°C; real electrode area = 84 cm^2. (a) E_{ad} = 0.15V; (b) E_{ad} = 0.2V; (c) E_{ad} = 0.5V.

ethane on platinum at 80°C at the maximum electrosorption potential a current transient is recorded whose integration from $t = 0$ up to the time required to reach the null current (after correction for the baseline) yields the charge (Q_D) associated with the hydrogen ions produced during the electrosorption process. Immediately after the null current condition is attained a linear potential sweep from E_{ad} up to $E_{s,a}$ is run so that the electrooxidation charge of the electrosorbed species (Q_E) can be evaluated. Thus, at E_{ad} = 0.250V the Q_D/Q_E ratio is 1.0 ± 0.1.

Kinetic relationships.—Various relevant kinetic relationships can be derived from the different potentiodynamic I/E profiles. For this purpose the runs made at 80°C are preferred since the different ethane electrooxidation current peaks are more clearly defined. Runs made from E_{ad} = 0.25V, after the ethane electrosorption during $t_{ad,ss}$ show that the height of current peak I, $(I_p)_I$, increases with v (Fig. 11). The low potential sweep data are corrected for the contribution of the ethane readsorption on the basis of the charges recorded in the second successive potential scan at different v. The experimental data fit a slight

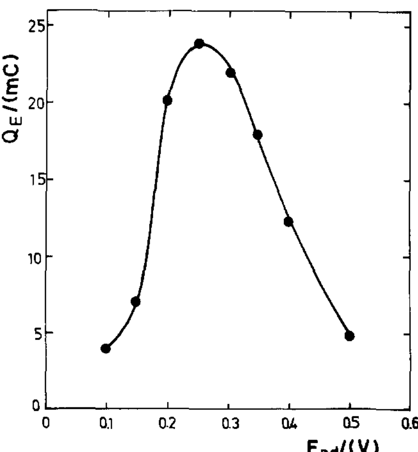

Fig. 6. Dependence of Q_E at $t_{ad,ss}$ on E_{ad}; 80°C; real electrode area = 88 cm^2.

curve, approaching a straight line which intercepts the origin of the plot as $v \rightarrow 0$.

The potential of current peak I, $(E_p)_I$, shifts toward more positive potentials as v increases, fitting a linear $(E_p)_I$/log v plot (Fig. 12). The slope of the corresponding average straight line is, at 80°, equal to 0.100 V/decade, a value which is intermediate between the 2.3(2RT/**F**) ratio and the 2.3(RT/**F**) ratio.

The E/log I plots derived from the initial portion of the current peak I (Fig. 13) correspond to smooth curves whose location in the E/log I plane depends on v. In the low potential range the slope of the E/log I plots decreases slightly when v decreases. As v decreases, this slope tends to the 2.3(RT/**F**) ratio.

Discussion

The number and possible nature of the adsorbed species.—The potentiodynamic I/E displays related to the electrochemical oxidation of ethane on platinum in 1N $HClO_4$ at 60°C (3, 5-7) consist of an anodic current peak lying at relatively low potentials and of a broad current maximum which extends from about 0.8V up to 1.2V. According to previously reported data (3, 5-7), the charge of the first current peak remains practically unchanged upon cathodic hydrogenation. The corresponding adsorbed species which are electrooxidized at near 0.7V behaves apparently similarly to the residual electrosorbed species observed during the electrooxidation of methane (14). Contrarily, the electrosorbed species associated with the second current peak is cathodically desorbed through electrochemical hydrogenation. The corresponding species was related to the same adsorbed C_2H_2 species formerly postulated for the ethylene electrosorption on platinum in the acid electrolyte (7). A comparison of the potentiodynamic electrooxidation of methane, ethylene, and ethane on platinum under hydrocarbon readsorption-free conditions seems to indicate that the electrochemical behavior of the latter is intermediate between that of methane and ethylene. The maximum charge for the electrooxidation of the ethane electrosorbed species in 1N $HClO_4$ at 60°C has been estimated as 0.56 mC/cm^2 (5), a charge which is more than triple of that found for methane adsorbate (14). This is partly due to the fact that ethane is more soluble in aqueous electro-

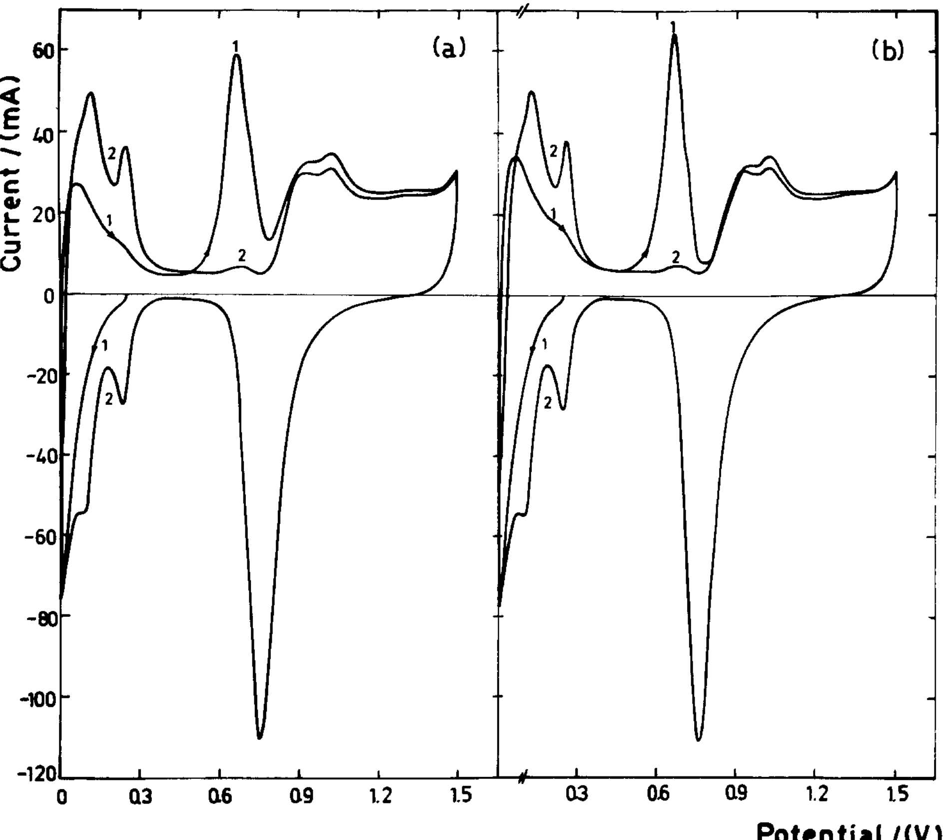

Fig. 7. Potentiodynamic I/E profiles run at 0.4 V/sec using the perturbation program (b) shown in Fig. 1 at different t_H at 0V. E_{ad} = 0.25V; t_{ad} = 10 min; 80°C; real electrode area = 101 cm². (a) t_H = 0.3 sec; (b) t_H = 5 min.

lytes than methane. Thus, the ethane solubility in water at 60°C and 1 atm is 1.8×10^{-6} mol/cm³ (5).

The present potentiodynamic I/E displays indicate that at least three different adsorbed species are produced during the electrosorption of ethane on platinized platinum. The relative surface concentration of the various adsorbed species depends on the temperature, on the electrosorption potential, and on the duration of the electrosorption process. Therefore, from the data presented in this paper it seems reasonable to conclude that the so-called type I species (14) actually corresponds at least to two different adsorbed species, whose relative contributions to the total electrooxidation charge depend on the electrosorption conditions. Thus, the current peak I appears as the sum of current peaks I_a and I_b. The splitting of current peak I is more evident at 80°C. The previously described experiments also indicate that an interconversion of the adsorbed species related to the current peaks I_a and I_b is feasible through cathodic hy-

drogenation. The interconversion process is more clearly distinguished in the potentiodynamic runs made at the shortest t_{ad}. These results correlate with those recently discussed for the potentiodynamic electrooxidation of methane on the same electrocatalyst

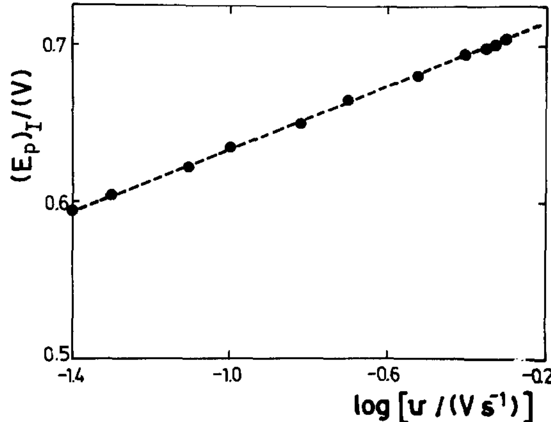

Fig. 12. Dependence of $(E_p)_I$ on log v. E_{ad} = 0.25V; t_{ad} = 10 min; 80°C; real electrode area = 85 cm^2. The slope of the dashed line is 0.100 V/decade.

where the current peak I_a was assigned to the electrooxidation of the COH adsorbed species and the current peak I_b was associated with the electrooxidation of the CO adsorbed species (22).

The current peak II obtained during the potentiodynamic oxidation of adsorbed ethane on platinized platinum in 1N H_2SO_4 coincides with that already observed in the electrooxidation of adsorbed ethylene (20). The latter was earlier attributed to the electrooxidation of a C_2H_2 adsorbed species (20). This species can be cathodically desorbed and it can be assigned to the type II species referred to in the literature (14). The C_2H_2 species seems to be particularly relevant during the electrooxidation of ethane at low temperatures. The relative contribution of type I species and type II species to the total electrooxidation charge is strongly influenced by the temperature. The contribution of the former becomes progressively more relevant than that of the latter as the temperature increases. Therefore, these results show that the potentiodynamic electrooxidation of ethane follows a reaction pattern which is rather more complex than those earlier thought (5, 6, 8, 12, 13), since at least three different adsorbed species can participate in the electrooxidation reaction. However, independently of the number of the adsorbed species the electrooxidation process can be accounted for through the occurrence of electrosorption processes in the early stages

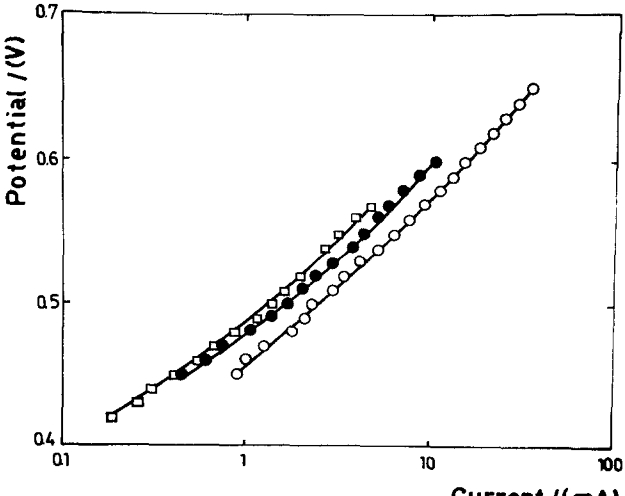

Fig. 13. E/log I plots derived from potentiodynamic runs at 80°C. E_{ad} = 0.25V; t_{ad} = 10 min; real electrode area = 85 cm^2. (□) v = 0.05 V/sec; (●) v = 0.15 V/sec; (○) v = 0.47 V/sec.

of the reaction, as earlier postulated by other authors (2, 4).

The data derived in this work on the ethane electrosorption process correlate with the change in the electrode potential with time approaching that of the hydrogen electrode that is observed upon contact of the electrocatalyst with the ethane-saturated electrolyte solution (2, 4). This was formerly explained by assuming that the corresponding open-circuit potential is determined by the equilibrium amount of hydrogen that is formed by dissociative adsorption of ethane on platinum in 5N H_2SO_4 at 25°C (2). In agreement with this the cathodic hydrogenation of the electrosorbed ethane at 25°C yields backward ethane as the main product with small quantities of methane (2).

The electrosorption and the potentiodynamic electrooxidation processes.—The results obtained for the ethane electrosorption at a constant potential and for the potentiodynamic electrooxidation of the residual electrosorbed species under ethane-free readsorption conditions ($v \geqq 0.3$ V/sec) can be interpreted in terms of an electrosorption process involving at least the following three overall reactions

$$C_2H_6 = (C_2H_2) + 4H^+ + 4e \quad [1a]$$

$$C_2H_6 + 2H_2O = 2(COH) + 8H^+ + 8e \quad [1b]$$

$$C_2H_6 + 2H_2O = 2(CO) + 10H^+ + 10e \quad [1c]$$

where the parentheses denote the different adsorbed species. The possibility that the different adsorbed species may be linked through interconversion surface processes can be formally expressed in the following way

$$(C_2H_2) + 2H_2O = 2(COH) + 4H^+ + 4e \quad [2a]$$

$$(C_2H_2) + 2H_2O = 2(CO) + 6H^+ + 6e \quad [2b]$$

$$(COH) = (CO) + H^+ + e \quad [2c]$$

Reactions [2a] and [2b] are comprised within the reaction formalism earlier proposed for the surface reactions taking part in the electrooxidation of propane on platinum in 37 mol percent HF at 90°C (24, 25). Otherwise, reaction [2c] has been recently postulated to interpret the cathodic hydrogenation of one of the species formed during the electrosorption of methane in 1N H_2SO_4 at 60°C (22).

As it can be deduced from the potentiodynamic I/E profiles the type of adsorbed species predominating on the electrocatalyst surface depends strongly on the temperature. According to the anodic current peak assignment already discussed at low temperatures the C_2H_2 species predominates over the other ones. In contrast, the participation of the CO and COH species in the potentiodynamic electrooxidation process becomes relatively more important as the temperature increases.

The simultaneous occurrence of three different electrosorbed species on the electrocatalyst suggests that their potentiodynamic electrooxidation should be formally interpreted through the following overall reactions

$$(C_2H_2) + 4H_2O = 2CO_2 + 10\,H^+ + 10\,e \quad [3a]$$

$$(COH) + H_2O = CO_2 + 3H^+ + 3e \quad [3b]$$

$$(CO) + H_2O = CO_2 + 2H^+ + 2e \quad [3c]$$

At 80°C, the value of the Q_D/Q_E ratio equal to one indicates that reactions [1b] and [3b] predominate in the electrosorption and in the potentiodynamic electrooxidation processes, respectively. Notwithstanding, the slight curvature of the $(I_p)_I$ *vs.* v plot (Fig. 11) should be related to the existence of more than one adsorbed species on the electrocatalyst. Furthermore, the linear $(E_p)_I$ *vs.* log v plot (Fig. 12) indicates that the corresponding electrochemical reaction is highly irreversible. The value of the Tafel slope derived from the latter which is intermediate between the 2.3(RT/F) and the 2.3($2RT/F$) ratios gives further support to the complexity of the electrochemical reaction.

The possible reaction pathway.—The present results together with the data recently reported (20-22) for the electrooxidation of ethylene and methane can be correlated through a generalized reaction pathway for the electrochemical oxidation of short chain aliphatic hydrocarbons. This reaction pathway (Fig. 14) involved three main groups of reactions, namely, the hydrocarbon electrosorption processes, the electrooxidation processes of the electrosorbed species, and the interconversion processes of the electrosorbed species.

From this reaction pathway two limiting cases can immediately be derived. Thus, when either the ethane electrooxidation reaction proceeds at a low temperature or the reactant is ethylene at any temperature in the 40°-80°C range (20), the main contribution to the electrosorption process is given by reaction [1a] and the potentiodynamic electrooxidation is mainly represented by the overall reaction [3a]. Under these circumstances, the group of species of type II, that is, the CH-α-type adsorbed species, predominates on the electrode surface. For the ethylene electrooxidation the corresponding kinetic equation is associated with a Tafel slope equal to $2RT/F$ (20, 21).

On the other hand, when either the ethane electrooxidation reaction takes place at high temperature or the reactant is methane the electrosorption process and the corresponding potentiodynamic electrooxidation proceed via reactions [1b], [1c], [3b], and [3c] as the main contributions. The principal interconversion process of the adsorbed species is given by reaction [2c] which explains the observed cathodic electroreduction of the CO-species. In this second limiting case, two

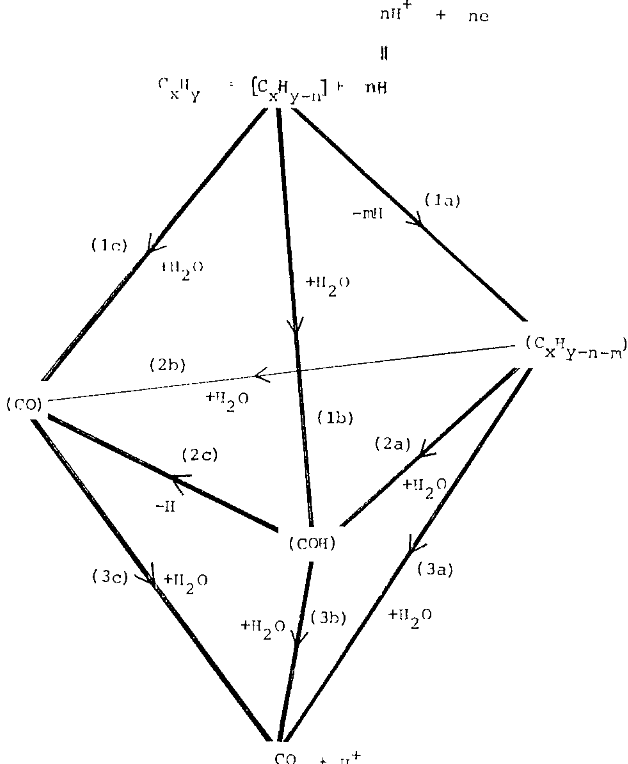

Fig. 14. Possible reaction pathway for the electrochemical oxidation of C_xH_y on platinum. C_xH_y represents either CH_4, C_2H_4, or C_2H_6. $[C_xH_{y-n}]$ corresponds to the intermediate formed in the initial hydrocarbon electrosorption process. The parenthesis denote potentiodynamically detectable adsorbed species. The numbers of the reactions correlate with those given in the text for the particular case of the electrochemical oxidation of ethane.

oxygen-containing adsorbed species are involved in the electrochemical reaction and no simple kinetic law can be obtained. However, at low v the $E/\log I$ plots can be approximated to a straight line with the slope $2.3(RT/F)$ within a relatively low potential range. A similar Tafel slope has been previously reported for the stationary electrooxidation of ethane on platinum (3).

At any situation comprised between the two limiting cases already referred to, particularly under stationary state conditions, the participation of all the above-mentioned reactions should be considered. The relative contribution of each particular reaction depending on the temperature, the applied potential, and the time the hydrocarbon saturated electrolyte is left in contact with the electrocatalyst.

The general scheme applied to the potentiodynamic electrooxidation of adsorbed ethane on platinum indicates that the overall anodic current, i, at any potential is the sum of the contributions of reactions [3a] to [3c]

$$i = i_{3a} + i_{3b} + i_{3c} \qquad [4]$$

where the i_{3a}, i_{3b}, and i_{3c} are potential and time dependent terms. The current associated with each adsorbed reactant can be expressed through conventional rate equations involving the interaction energy terms of the adsorbed species. Therefore, in this case it is difficult to derive a more detailed mechanistic conclusion for the electrochemical reaction from the corresponding kinetic data.

The postulated reaction pathway involving different chemisorbed species formed through a combination of consecutive and alternative steps correlates, in principle, with the general reaction scheme recently proposed for the electrooxidation of simple organic substances at platinum group metals (26).

Analysis of the Current-Voltage Characteristics of Photoelectrolysis Cells

William L. Ahlgren*

Materials Science Department, University of Southern California, Los Angeles, California 90007

ABSTRACT

A theoretical analysis of the current-voltage characteristics of photoelectrolysis cells is presented. The results are used to analyze experimental data for cells using n-type titanium or tungsten oxide semiconductor electrodes in acid electrolyte with platinum counterelectrode. From the i-V characteristics the quantum yield, optimum cell voltage, and maximum electrode efficiency can be derived, as well as the kinetic parameters of the semiconductor electrode (valence and conduction band transfer coefficients and exchange current densities). The theory highlights certain parameters, such as minority carrier exchange current density and diffusion length, which have an important effect on electrode efficiency.

The best-known type of photoelectrolysis cell consists of an n-type semiconductor anode and metal (usually platinum) cathode immersed in an electrolyte solution. When the semiconductor is illuminated and voltage applied to the cell, a family of current-voltage curves such as that shown in Fig. 1 is generated. The convention to be followed regarding sign of cell voltage and direction of current flow are as follows. The cell voltage is that of the semiconductor with respect to the metal and is positive when the semiconductor is the anode. The positive direction of current flow is into the semiconductor from the external circuit (and out of it into the electrolyte). If the electrolyte is only an acid or a base, hydrogen is evolved at the cathode and oxygen at the anode.

The purpose of this paper is to present a theory of these i-V characteristics and to show how it can be used to analyze experimental results. From the experimental i-V characteristics the quantum yield, optimum operating voltage, and maximum efficiency can be derived.

Theory

The theory presented here is due to Dewald (1) and Gerischer (2). The application to photoelectrolysis was developed in detail in (3). It will be assumed that the semiconductor is n-type, however there is no difficulty modifying the theory for p-type semiconductors or p-n cells in which both electrodes are semiconductors (3).

The i-V characteristics of Fig. 1 can be understood qualitatively as follows. When the semiconductor is the cathode (negative cell voltages) it is injecting electrons into the electrolyte. Since these are majority carriers in the n-type material, their concentration is hardly altered by illumination. Consequently the i-V characteristic for negative cell voltages shows no effect of illumination and is exponential, like an ordinary metal electrode. When the semiconductor is the anode (positive cell voltages) it injects minority carriers into the electrolyte. It thus becomes sensitive to illumination, which can alter the minority carrier concentration by orders of magnitude. Minority carrier flow is by diffusion in the bulk of the semiconductor, leading to plateaus in the i-V characteristics for positive cell voltage. These are reminiscent of the common-emitter characteristics of a bipolar transistor, and have a common origin. The limiting current proportional to minority carrier injection is typical of diffusion-controlled transport. The increase in current at high cell voltage is caused by a transition from minority to majority carrier dominance of charge transport.

To develop this theory quantitatively, the Butler-Volmer equation for semiconductors is postulated.[1] This equation relates the current density at the semiconductor-electrolyte interface to the overpotential η and to the electron and hole concentrations at the surface. These concentrations are then found from continuity conditions, leading to the complete solution for the i-η characteristic of the semiconductor. This is combined with that of the metal to yield the cell i-V characteristics.

The current across the semiconductor-electrolyte interface is

$$i = i_n + i_p \quad [1]$$

where i_n is the current due to charge exchange with the conduction band and i_p with the valence band. An additional term could be included for charge exchange with surface states, but for simplicity this will be subsumed in the valence band current. The relations between these currents and the overpotential at the interface is

$$i_n = i_{no}\left[\exp\left(\frac{\overleftarrow{\alpha}_c e\eta}{kT}\right) - \frac{n_s^*}{n_s}\exp\left(-\frac{\overrightarrow{\alpha}_c e\eta}{kT}\right)\right] \quad [2]$$

[1] The formulation of this equation for semiconductors is discussed in detail in Ref. (3).

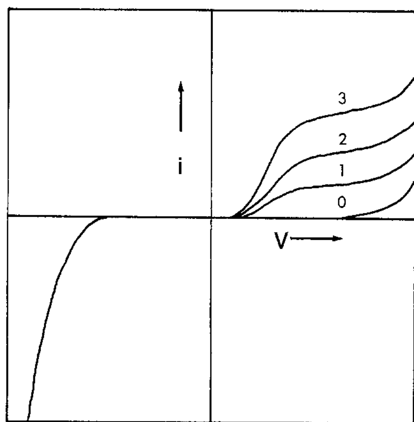

Fig. 1. Typical current-voltage characteristics for photoelectrolysis cells using an n-type semiconductor electrode and a metal counterelectrode. The parameter is light intensity in arbitrary units.

* Electrochemical Society Student Member.

Key words: solar energy, quantum yield, efficiency, titanium oxide, tungsten oxide.

$$i_p = i_{po}\left[\frac{p_s^*}{p_s}\exp\left(\frac{\overleftarrow{\alpha}_v \rho e\eta}{kT}\right) - \exp\left(-\frac{\overrightarrow{\alpha}_v \rho e\eta}{kT}\right)\right] \quad [3]$$

where i_{no} is the conduction band exchange current, $\overleftarrow{\alpha}_c$ is the transfer coefficient for electrons crossing the semiconductor-electrolyte interface from electrolyte to semiconductor, $\overrightarrow{\alpha}_c$ is the coefficient for transfer in the opposite direction, ρ is the fraction of the overpotential which occurs in the electrolyte, n_s is the electron concentration at the surface of the semiconductor in equilibrium, and n_s^* is the nonequilibrium value. In Eq. [3] the analogous quantities for the valence band occur (the arrows above the transfer coefficients always indicate the direction of electron transfer; hole transfer is in the opposite direction).

The fraction of the interface potential which occurs in the electrolyte depends roughly on the relative conductivities of the two phases. For a metal, $\rho = 1$ since metallic conductivity is much higher than the electrolyte. For a semiconductor, $\rho = 1$ if the semiconductor surface is accumulated or inverted, but $\rho = 0$ if the surface is depleted.

The currents in Eq. [2] and [3] are due to tunneling of electrons from an ion in the Helmholtz plane of the electrolyte to the surface of the semiconductor. When the surface of a heavily doped semiconductor is depleted the width of the space charge layer may be small enough to permit electrons to tunnel from the electrolyte to the interior of the semiconductor (4). Such tunneling currents would have to be represented by additional terms in Eq. [1]. For present purposes, however, it is not necessary to include these currents in the quantitative model.

The i-V characteristics are obtained by determining the ratios of nonequilibrium to equilibrium carrier concentrations at the surface of the electrode. These are

$$\frac{n_s^*}{n_s} = \frac{n_w^*}{n_o}\exp\left(-\frac{(1-\rho)e\eta}{kT}\right) \quad [4]$$

$$\frac{p_s^*}{p_s} = \frac{p_w^*}{p_o}\exp\frac{(1-\rho)e\eta}{kT} \quad [5]$$

where n_w^*/n_o and p_w^*/p_o are the values at the inside edge of the depletion layer, which is assumed to be of width w. Since electrons are the majority carriers their concentration is hardly changed by illumination, so

$$n_w^* \cong n_o \quad [6]$$

Following Dewald (1), the effect of illumination on the concentration of holes at the inside edge of the depletion layer can be found from the steady-state balance equation for holes within the depletion layer:

Net pair generation rate within depletion layer

= minority carrier flux out of depletion layer

The net generation rate within the depletion layer is the generation due to photon absorption minus the recombination. Dewald assumes that the minority carrier diffusion length is much larger than the width of the depletion region, and consequently within the depletion layer, that surface recombination dominates so that the recombination rate is $v_s(p_w^* - p_o)$, where v_s is the surface recombination velocity. This assumption will be adhered to, although others are possible.

The minority carrier generation due to photon absorption at a depth x in the semiconductor is

$$g(x) = \int_{E_o}^{\infty}\frac{a(E)W(E,x)dE}{E} \quad [7]$$

where $E = h\nu$ is photon energy, E_o is the threshold energy for pair creation, $a(E)$ is the absorption coefficient, and

$$W(E,x) = (1 - R(E))W_o(E)\exp(-a(E)x) \quad [8]$$

$R(E)$ is the reflectance of the surface (thin film effects are ignored) and $W_o(E)$ is the spectral radiation intensity striking the surface of the semiconductor. As an approximation it will be assumed that

$$g(x) = \frac{\bar{a}\gamma I}{e}\exp(-\bar{a}x) \quad [9]$$

where $\gamma I/e$ and $\bar{a}$ are defined in such a way that [7] and [9] give the same total number of pairs created and also the same number of pairs created within a distance x_o from the surface. The details are given in the Appendix. I is the total radiation intensity (W cm^{-2}) striking the surface of the semiconductor, e is the elementary charge, and γ is a conversion factor from light intensity to current density (mA W^{-1}). $\bar{a}$ is an average absorption coefficient whose value depends on the depth x_o as specified in the Appendix. The approximation is expected to be most valid when x_o is chosen equal to the depletion layer width.

The minority carrier flux out of the depletion layer is the hole current (i_p) exiting from the semiconductor-electrolyte interface, minus the hole current entering from the bulk. Since minority carrier flow in the bulk is by diffusion, this flux is $J_p = -D_p(dp^*/dx)$, where D_p is the hole diffusion coefficient and the derivative is evaluated at the inside edge of the depletion layer. The minority concentration profile $p^*(x)$ is found from the steady-state minority carrier continuity equation

$$\frac{L_p^2}{\tau_p}\frac{d^2p^*}{dx^2} - \frac{p^* - p_o}{\tau_p} = -g(x) \quad [10]$$

where L_p and τ_p are the minority carrier diffusion length and bulk lifetime, respectively. These are related to the diffusion coefficient by $D_p = L_p^2/\tau_p$. Equation [10] can be solved subject to the boundary conditions $p^* \to p_o$ as $x \to \infty$ and $p^* = p_w^*$ at $x = w$. The solution $p^*(x)$ is then differentiated and the derivative evaluated at $x = w$ in order to find J_p. The result is

$$J_p = \frac{L_p}{\tau_p}(p_w^* - p_o) - \frac{\bar{a}L_p\gamma I\exp(-\bar{a}w)}{e(1+\bar{a}L_p)} \quad [11]$$

The minority carrier balance on the depletion layer can be expressed as

$$\int_0^w g(x)dx - v_s(p_w^* - p_o) = \frac{i_p}{e} - J_p$$

Using Eq. [9] and [11], this can be solved to yield

$$\frac{p_w^*}{p_o} = 1 + \frac{\gamma\phi_s I - i_p}{i_s} \quad [12]$$

where

$$\phi_s = 1 - \frac{\exp(-\bar{a}w)}{1+\bar{a}L_p} \quad [13]$$

and

$$i_s = ep_o\left(\frac{L_p}{\tau_p} + v_s\right) \quad [14]$$

ϕ_s and i_s are the saturation values of the quantum yield and dark current density which are approached in the plateau region of the i-V characteristics. The dark saturation current is due to thermal generation of electron-hole pairs, L_p/τ_p representing bulk generation and v_s surface generation.

The i-η characteristics of the semiconductor electrode are obtained by substituting Eq. [2]-[6] and [12] into Eq. [1], and the i-V characteristics of the cell follow from the relations between the electrode overpotentials

and the free energy change for the cell reaction.[2] For positive cell voltages, $\eta = V - V_{tc}$ where V_{tc} is the threshold voltage for current flow with the metal counterelectrode as cathode

$$V_{tc} = \Delta G/e - \xi_c \qquad [15]$$

in which ΔG is the free-energy change per electron transferred and ξ_c is the overpotential at the metal cathode (a negative number). For negative cell voltages, $\eta = V - V_{ta}$, where

$$V_{ta} = -\Delta G/e - \xi_a \qquad [16]$$

ξ_a being the overpotential at the metal anode (a positive number).

For cell voltages greater than a few kT/e more negative than V_{ta}, Eq. [1] becomes

$$i(v) = -i_{no} \exp(-\vec{\alpha}_n(V - V_{ta})e/kT) \qquad [17]$$

In this case $\rho \approx 1$ since the surface of the semiconductor is accumulated. Since the metal anode also follows a Tafel law, it can be shown (5) that

$$i(V) = -i_{o,cell} \exp(-A(eV - \Delta G)/kT) \qquad [18]$$

where

$$A = \frac{\vec{\alpha}_n \overleftarrow{\alpha}}{\vec{\alpha}_n + \overleftarrow{\alpha}} \qquad [19]$$

$$i_{o,cell} = (i_{no})^{A/\vec{\alpha}_n} (i_o)^{A/\overleftarrow{\alpha}} \qquad [20]$$

and $\overleftarrow{\alpha}$, i_o are the anodic transfer coefficient and exchange current density at the metal electrode.

For positive cell voltages the semiconductor surface is depleted and $\rho \approx 0$. Equation [1] then becomes[3]

$$i(V) = \phi(V)\gamma I + i_d(V) \qquad [21]$$

where

$$\phi(V) = \frac{\phi_s}{1 + \exp\left(-\dfrac{\overleftarrow{\alpha}_p e(V - V_{1/2})}{kT}\right)} \qquad [22]$$

and

$$V_{1/2} = V_{tc} - \frac{kT}{\overleftarrow{\alpha}_p e} \ln \frac{i_{po}}{i_s} \qquad [23]$$

The dark current is

$$i_d(V) = i_s \frac{1 - \exp\left(-\dfrac{e(V - V_{tc})}{kT}\right)}{1 + \exp\left(-\dfrac{\overleftarrow{\alpha}_p e(V - V_{tc})}{kT}\right)} \qquad [24]$$

This reaches the saturation value i_s for $V - V_{tc}$ greater than a few kT/e. For $V >> V_{tc}$, however, the dark current increases rapidly for two reasons. When the surface becomes inverted its conductivity increases and ρ approaches unity, *i.e.*, the interface potential drop begins to occur in the electrolyte rather than the semiconductor. The dark current is then

$$i_d(V) = i_s + i_{no} \exp\left(\frac{\overleftarrow{\alpha}_c \rho e(V - V_{tc})}{kT}\right) \qquad [25]$$

The increase in dark current is due to majority carriers, which are not limited by diffusion in the bulk of the semiconductor.

Another cause for the increase of dark current is electron tunneling from the electrolyte to the interior of the semiconductor rather than its surface (4). This is only possible if the surface depletion layer is thin enough and is therefore most likely in heavily doped semiconductors. Electrons can then tunnel from the electrolyte through to empty states in the conduction band in the interior of the semiconductor. This component of the dark current, which is also due to majority carriers, has not been included in the present analysis.

The factors γ and ϕ determine the efficiency of the cell as a solar energy converter. The light-to-current conversion factor γ expresses the fraction of all photons in the solar spectrum which are absorbed by the semiconductor creating electron-hole pairs. Details are given in the Appendix. It depends only on the optical properties of the semiconductor (principally the bandgap and refractive index) and the spectral distribution of the incident radiation. It does not depend on the cell voltage.

The quantum yield ϕ is the fraction of electron-hole pairs created which are collected. It depends on the cell voltage in two ways. Increasing cell voltage decreases the minority carrier concentration at the inside edge of the depletion layer, and thereby decreases surface recombination. This is the effect of the denominator in Eq. [22]. The fraction of minority carriers lost to recombination falls to one-half at $V_{1/2}$, given by Eq. [23]. This is also the voltage at which the photocurrent ($i - i_d$) reaches half its limiting (plateau) value. As the voltage is increased further the minority carrier concentration at the inside edge of the depletion layer and hence the recombination falls to zero. The quantum yield then approaches its saturation value given by Eq. [13]. This equation shows that the limiting value of quantum yield depends on the absorption coefficient, depletion layer width, and minority carrier diffusion length, reflecting the fact that only those holes created in the depletion layer or within a diffusion length from it will be collected.

The cell voltage also affects quantum yield by modulation of the depletion layer width

$$w(V) = \sqrt{\frac{2\epsilon\epsilon_o\psi_b(V)}{eN_D}} \qquad [26]$$

where ϵ is the dielectric constant of the semiconductor, ϵ_o the permittivity of free space, N_D the donor concentration, and $\psi_b(V)$ the voltage barrier height at the surface of the semiconductor. To relate this to cell voltage requires knowledge of the structure of the double layers at both electrodes under nonequilibrium conditions. A detailed solution to this problem will not be attempted. It should be noted, however, that the barrier height and hence the width of the depletion layer will increase with increasing cell voltage, leading to an increasing value of ϕ_s. This is probably the reason why the plateau region of the i-V curves slopes upward rather than being perfectly flat.

Electrode Efficiency

The efficiency of the semiconductor photoelectrode can be defined as the net free energy produced divided by the solar input. The net free energy is the free energy content of the chemical product minus the electric power consumed by the electrode. Thus

$$\text{Efficiency} = \frac{\dot{n}\Delta G - iA(V - \xi_c)}{IA} = \frac{i(V_{tc} - V)}{I} \qquad [27]$$

where n is the rate of production (molecules per second) and A is the area of the photoelectrode. The overpotential ξ_c at the metal counterelectrode has been subtracted from the cell voltage since this loss should not be charged to the photoelectrode.

The electrode efficiency depends on cell voltage through Eq. [21]-[27]. There is an optimum voltage

[2] Cell resistance and concentration overpotentials in the electrolyte are ignored for simplicity.
[3] Substitute [6] and [12] into [2] and [3], and these into [1], making use of $\eta = V - V_{tc}$.

since increasing V increases the quantum yield but also the electric power consumption. Neglecting i_d, which is usually small at low cell voltages where the optimum occurs, it is found that the condition for maximum efficiency is

$$\exp x + x + 1 + \delta = 0 \quad [28]$$

where

$$x = \frac{\overleftarrow{\alpha}_p e (V_{max} - V_{1/2})}{kT} \quad [29]$$

$$\delta = \frac{\overleftarrow{\alpha}_p e (V_{1/2} - V_{tc})}{kT} = -\ln \frac{i_{po}}{i_s} \quad [30]$$

and V_{max} is the cell voltage which maximizes the electrode efficiency.

Application to Experimental Current-Voltage Characteristics

The foregoing theory can be applied to the analysis of i-V characteristics obtained by experiment. As an example the photoelectrolysis cells reported in (6) will be used. These consist of TiO_2 or WO_3 semiconductors immersed in 1M H_2SO_4 with a platinum counterelectrode and illuminated by a xenon lamp (chosen to simulate the solar spectrum). The semiconductor electrodes were prepared by heating the corresponding metal foil in air for 1 hr at 500°-600°C. The cell reaction is $H_2O \rightarrow H_2 + \frac{1}{2} O_2$, for which $\Delta G = 1.23$ eV. The i-V characteristics, which are presented in (6), resemble Fig. 1 of the present paper.

With negative cell voltage hydrogen is evolved at the semiconductor cathode and oxygen at the platinum anode. Figure 2 is a plot of $\ln|i|$ *vs.* $|V|$ which shows that Eq. [18] is obeyed. The kinetic parameters $\overrightarrow{\alpha}_n$ and i_{no}, obtained from Fig. 2 using Eq. [18] to [20], are listed in Table I. The kinetic parameters $\overleftarrow{\alpha}$ and i_o of the platinum anode were taken from Table II.

When the cell voltage is positive, oxygen is evolved at the semiconductor anode and hydrogen at the platinum cathode. It will be assumed for the sake of analysis that the overpotential at the platinum cathode, instead of following a Tafel law, remains constant at its value for a current density of 1 mA cm^{-2}, which is -0.01V (from Table II). Thus V_{tc} is also assumed constant and equal to 1.24V.

Table I. Kinetic parameters of forward-biased n-type oxidized metal electrodes in 1M H_2SO_4

Semiconductor	A	$-\log i_{o,cell}$ (mA cm^{-2})	$\overleftarrow{\alpha}_n$	$-\log i_{no}$ (mA cm^{-2})
TiO_2	0.16	2.6	0.22	1.1
WO_3	0.35	5.2	0.84	3.1

Table II. Kinetic parameters of platinum electrode in acid medium

Electrode function	Gas evolved	α	$-\log i_o$ (mA cm^{-2})	Overpotential at i = 1 mA cm^{-2} (V)
Cathode	H_2	0.5	0.1	-0.01
Anode	O_2	0.6	6.7	0.66

The quantum yield ϕ can be obtained by plotting current as a function of illumination intensity with cell voltage as a parameter. This yields a family of straight lines with slope dependent on the voltage. The quantum yield is obtained, according to Eq. [21], by dividing this slope by γ

$$\phi(v) = \frac{1}{\gamma} \left. \frac{\partial i}{\partial I} \right|_V \quad [31]$$

The saturation value ϕ_s is obtianed by choosing V in the plateau region. Rearrangement of Eq. [22] gives

$$\frac{\phi}{\phi_s - \phi} = \exp \frac{\overleftarrow{\alpha}_p e (V - V_{1/2})}{kT} = \frac{i_{po}}{i_s} \exp \frac{\overleftarrow{\alpha}_p e (V - V_{tc})}{kT} \quad [32]$$

Figure 3 shows a plot of $\ln \phi/(\phi_s - \phi)$ *vs.* V for TiO_2 and WO_3 anodes. The values of $\overleftarrow{\alpha}_p$ and $\ln i_{po}/i_s$ determined from these plots are listed in Table III.

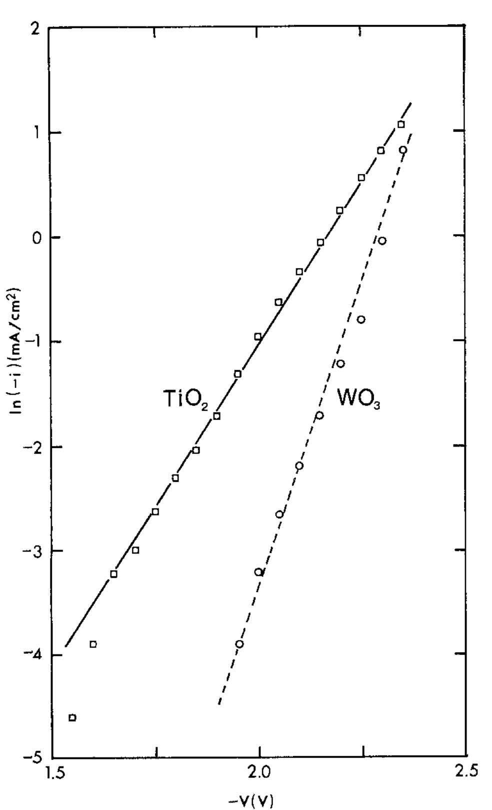

Fig. 2. Plot of ln(−i) vs. −V for negative cell voltages and currents.

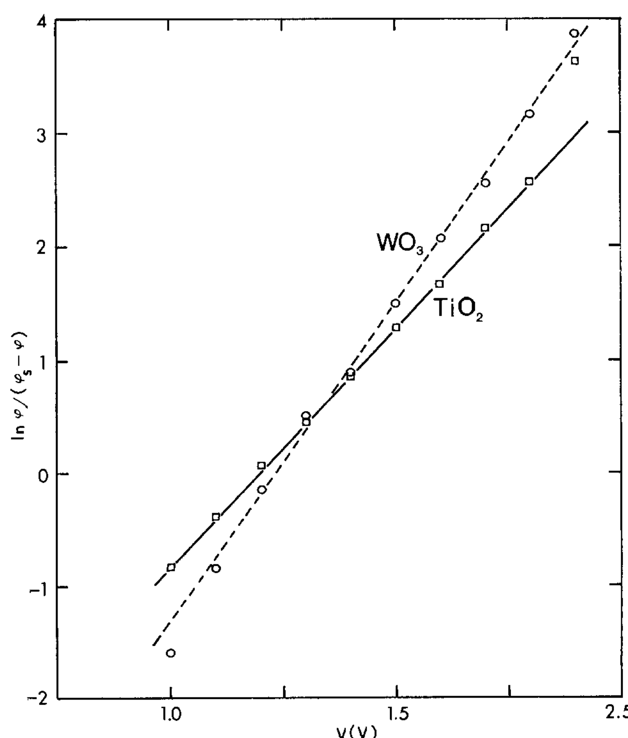

Fig. 3. Plot of ln $\phi/(\phi_s - \phi)$ vs. V for positive cell voltages

Table III. Kinetic parameters of reverse-biased n-type oxidized metal electrodes in 1M H_2SO_4

Semiconductor	γ (mA W^{-1})	ϕ_s	$\overleftarrow{\alpha_p}$	$\ln \frac{i_{po}}{i_s}$	i_s (mA cm^{-2})	$-\log i_{po}$ (mA cm^{-2})	$V_{1/2}$ (V)
TiO_2	36.2	0.05	0.12	0.2	0.004	2.3	1.20
WO_3	47.9	0.10	0.14	0.1	0.007	2.1	1.22

The current density i_s is the value of the dark current in the plateau region and can be read directly from the i-V characteristic. The hole exchange current for the semiconductor electrode, i_{po}, can then be calculated. The voltage $V_{1/2}$ can also be read directly from the i-V characteristic, or can be calculated using Eq. [23].

The optimum operating voltage can be found using Eq. [28]-[30] and the information in Table III. It is found that for TiO_2, $V_{max} = 0.9V$ and the maximum electrode efficiency is 0.02%. For WO_3 the corresponding values are 1.0V and 0.01%. The low efficiencies are probably caused by the very defective nature of the semiconductor electrodes used, leading to a short hole diffusion length and, hence, low saturation quantum yield ϕ_s. It is instructive to insert some values into Eq. [26] and [13]. Assuming a donor density of 10^{20} cm^{-3}, dielectric constant of 100, and surface barrier of 1V, the depletion layer width is about 10^{-6} cm. The absorption coefficient is about 5×10^4 cm^{-1} (see Appendix). Ghosh and Maruska (7) found the hole diffusion length to be about 10^{-4} cm in single-crystal TiO_2. According to Eq. [13], this would lead to $\phi_s \approx 0.8$, sixteen times greater than that observed, and a correspondingly larger efficiency ($\sim 0.3\%$), which has been observed with single crystal electrodes. This suggests that the minority carrier diffusion length in TiO_2 prepared by oxidizing the metal foil is about 10^{-6} cm, 100 times smaller than that in the single crystal. The minority carrier diffusion length is then about the same as the depletion layer width. Since the two are of comparable magnitude, modulation of the depletion layer width by the cell voltage has a strong effect on the quantum yield, giving the observed upward sloping plateaus in the i-V characteristic. Flatter plateaus are to be expected from the single crystal material.

Discussion

Although Dewald's paper (1) is often cited, the theory embodied in it does not seem to have been applied previously to photoelectrolysis. It is useful to do so since it allows the derivation of quantum yields, optimum operating voltage, and maximum efficiency from experimental i-V curves. It also provides a different viewpoint on the effect of fundamental material parameters on cell performance. Thus, for example, Eq. [22] and [23] indicate that a cell capable of operating at zero cell voltage requires a material with a large minority carrier exchange current density and a small dark saturation current, that is, the ratio of photogenerated holes participating in the cell reaction to those which merely recombine with electrons should be large. A large hole exchange current density means that holes are extracted from the semiconductor rapidly, preventing their recombination. The hole exchange current density may be as important a parameter as the electron affinity, which has been highlighted by previous theories (11). Similarly, Eq. [13] focuses attention on the importance of the minority-carrier diffusion length. If the absorption length of the material is much larger than the width of the depletion layer, a large quantum yield can only be achieved if the diffusion length is large enough

APPENDIX

The parameters occurring in Eq. [9] are defined as follows. The average absorption coefficient $\bar{a}$ is given by

$$\exp(-\bar{a}x_0) = \frac{\int_{E_0}^{\infty} \exp(-a(E)x_0)(1 - R(E))W_0(E)\frac{dE}{E}}{\int_{E_0}^{\infty} (1 - R(E))W_0(E)\frac{dE}{E}} \quad \text{[A-1]}$$

where x_0 is an arbitrary length, best chosen equal to the width of the depletion layer (about 10^{-6} cm for the electrodes studied in this paper). The light-to-current conversion factor γ is defined by

$$\gamma = \frac{e}{I}\int_{E_0}^{\infty} (1 - R(E))W_0(E)\frac{dE}{E} \quad \text{[A-2]}$$

where I is the total radiation intensity striking the surface

$$I = \int_0^{\infty} W_0(E)dE \quad \text{[A-3]}$$

To compute $\bar{a}$ and γ it is convenient to approximate the solar spectrum by that of a black body at 5800 K. Thus

$$W_0(E) \propto \frac{E^3}{\exp(E/kT_s) - 1} \quad \text{[A-4]}$$

where $kT_s = 0.50$ eV. For $E >> kT_s$

$$W_0(E) \propto E^3 \exp(-E/kT_s) \quad \text{[A-5]}$$

which can be used to evaluate the integrals in Eq.

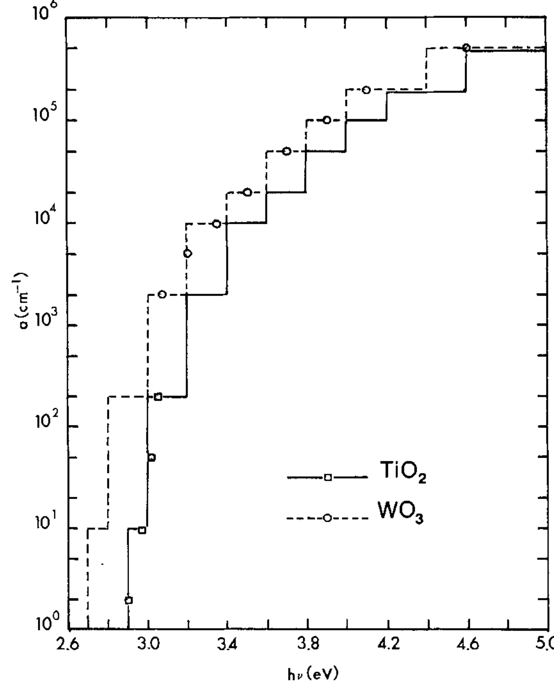

Fig. 4. Absorption coefficient a as a function for photon energy $h\nu$ for TiO_2 and WO_3. Experimental points are taken from Cronemeyer (9) and Deb (10). The lines indicate values assumed in this paper for the purpose of estimating $\bar{a}$.

[A-1] and [A-2] provided $E_0 >> kT_s$ (true of wide bandgap semiconductors such as TiO_2 and WO_3).

The reflectance is equal to $(n-1)^2/(n+1)^2$ where n is the refractive index, which is assumed to have no dispersion. Equation [A-1] then becomes

$$\exp(-\bar{a}x_0) = \int_{E_0}^{\infty} \exp(-a(E)x_0)\, f_{ph}(E_0, E)\, dE \quad [A-6]$$

where

$$f_{ph}(E_0, E) = \frac{W_0(E)}{E \int_{E_0}^{\infty} W_0(E) \frac{dE}{E}} \quad [A-7]$$

$f_{ph}(E_0, E)$ is the fraction of all photons with energy greater than E_0 which have energy E. Equation [A-2] becomes

$$\gamma = \frac{4n}{(n+1)^2} \frac{15e}{\pi^4 kT_s} \left(1 + \left(1 + \frac{E_0}{kT_s}\right)^2\right) \exp\left(-\frac{E_0}{kT_s}\right) \quad [A-8]$$

The threshold energy E_0 may be less than the bandgap due to band-tailing and other effects (8). For TiO_2 and WO_3 it is assumed that E_0 is 2.9 and 2.7 eV, respectively, (6, 9, 10), leading to the γ values listed in Table III when $n = 2.5$.

The absorption coefficients $a(E)$ assumed for TiO_3 and WO_3 are shown in Fig. 4, together with some experimental points from Ref. (9) and (10). With $x_0 = 10^{-6}$ cm, Eq. [A-6] leads to $\bar{a} = 5 \times 10^4$ cm^{-1} for both TiO_2 and WO_3.

ABSTRACT

The influence of dissolved sulfide ion and the ferri/ferrocyanide redox system on the photoelectrochemical behavior of iron oxide has been investigated. Particular attention was given to transient behavior and to dark current phenomena. An interpretation of the results is given in terms of a back-reaction of photogenerated species with conduction band electrons via surface states.

Ferric oxide is a potentially interesting semiconductor material for use in semiconductor-liquid junction solar cells. It is very easily produced, resists photodecomposition, and possesses a flatband potential close to the hydrogen evolution potential. Its bandgap of 2.2 eV allows, in principle, a solar energy conversion efficiency of up to 20%.

Unfortunately ferric oxide always displays a low quantum yield of photocurrent when used as a photoanode. Even single crystal samples showed a quantum yield of only 20% at high anodic polarization (1). One reason for this may be that two optical absorption processes occur in ferric oxide, only one of which leads to electrochemically active holes (2).

Other unusual complexities in the behavior of ferric oxide have been revealed; relatively important transient effects exist (3) which can be modified by preparation (4), and there is strong evidence from anomalous differential space charge capacity behavior of a high density of a second deep donor level (5, 6). High anodic and cathodic dark currents (7) may be linked with this latter phenomenon.

In the work described below, the influence of redox reagents on the behavior was examined in order to try to establish the role of the electrochemical charge-transfer mechanism in determining the overall behavior of ferric oxide.

Experimental

Electrodes were made by thermal oxidation of "ARMCO" iron in which the total concentration of all the elements C, Mn, P, S, and Si was less than 0.1% and the concentration of Cu less than 0.15%. Iron disks were mechanically polished and maintained for 4 hr at 610°C in air. The resulting oxide films were approximately 30 μm thick, the outer 2 μm consisting of α-Fe_2O_3. Some experiments were also performed with α-Fe_2O_3 films on iron prepared by reactive sputtering of ferric oxide of 99.99% purity in an Ar/O_2 atmosphere. The disks were mounted in Perspex holders.

* Electrochemical Society Active Member.

Key words: charge-transfer, solar cells, surface states.

The electrodes were mounted in single compartment cells with a calomel reference and platinum counter-electrodes.

All chemicals used were of Analar Grade. Water was deionized. A PAR Model 173 potentiostat was used in conjunction with a PAR Model 186 lock-in amplifier, a PAR Model 175 Universal Programmer, and a PAR Model 4202 Signal Averager to determine transient behavior. Illumination was from a 500W xenon lamp filtered by 10 cm of water and the light was interrupted by either a PAR Model 192 chopper or a Spindler & Hoyer rapid manual shutter. Capacity measurements were made by superimposing on the potentiostatically controlled d-c voltage an a-c voltage of approximately 100 mV amplitude at 50 or 100 kHz. The a-c amplitude and phase angle were measured in a circuit in which the cell was placed in series with a resistance (8).

Rotating disk electrode experiments were made with equipment supplied by Oxford Electrodes Limited. The absorption of sulfide ion on iron oxide was measured using a Beckman 39610 specific electrode.

Results

The current-voltage dependence of iron oxide electrodes in the presence of sulfide ion and ferrocyanide ion are displayed in Fig. 1, together with the behavior in the blank electrolyte, 1M NaOH. The electrodes were illuminated intermittently in the course of an anodic potential scan (20 mV sec^{-1}) with rather short light pulses, in order to demonstrate general features of their overall behavior (full line). The dashed line shows the photocurrent under continuous illumination with white light. The overall photocurrent is increased markedly in the presence of both redox systems and there is an obvious suppression of the transient effects observed in the blank electrolyte. Simultaneously the anodic dark currents are enhanced at potentials positive of the standard redox potential of the couples concerned. Measurements with ferrocyanide present in lower concentration (5, 7) did not reveal these effects on the photocurrent clearly.

The changes in behavior shown in Fig. 1 are unlikely to be due to the specific adsorption of the charged redox species, as is for example the case with CdS/S^{2-} (9). Differential capacitance measurements and the direct measurement of Sn^{2-} and $Fe(CN)_6^{4-}$ adsorption by an Fe_2O_3 powder suspension, in experiments similar to Ginley and Butler's (10) show no evidence of adsorption.

The transient behavior was examined in more detail using the signal averager technique. In Fig. 2 the relaxation of photocurrent is shown for different light intensities using an argon laser (λ = 488 nm). These measurements were performed in solutions free from any redox system at a constant electrode potential (U_E = + 0.2V). The potential dependence of the relaxation effects is given in Fig. 3 as obtained with and without a reducing agent (Sn^{2-} and $[Fe(CN)_6]^{4-}$). This figure shows quite clearly that the transient be-

havior disappears if a reducing agent is added to the electrolyte.

It is interesting to note that the relaxation phenomena can also be influenced by addition of an oxidizing agent such as $[Fe(CN)_6]^{3-}$ as shown in Fig. 4. According to this figure the decay disappears nearly completely at cathodic potentials with respect to the standard potential of this redox system. The relaxation of the photocurrent is shown in detail for different concentrations of $[Fe(CN)_6]^{3-}$ at an electrode potential of − 0.1V in Fig. 5. In this potential range also a considerable dark current was observed (see Fig. 4). Its concentration dependence is given in Fig. 6. It should be emphasized that these measurements were performed using a rotating disk electrode (rotation speed of 30 rps) so that the current limitation was not due to a limiting ion transport in the solution.

Discussion

The transient characteristic relaxation times reported above are typically in the range of milliseconds. They are thus clearly distinct from those measured in hours or even days which can also be observed with metal oxide electrodes (15). In the latter case Butler

has proposed an explanation in terms of electromigration of donors within the space charge layer. In the present work we consider only much more rapid transient behavior.

It has previously been suggested that the transient behavior and the low quantum yield of photocurrent for O_2-evolution at Fe_2O_3-electrodes are due to the occurrence of a back-reaction of the photogenerated species with electrons originating from the conduction band (3). Previous work in our laboratory revealed the influence of sample preparation on the transient behavior (4).

We have analyzed the transient behavior now in more detail using the concept of a possible back-reaction involving electrons from the conduction band. Here already problems arise. These are demonstrated by the energy diagrams in Fig. 7a-7c. Figure 7a shows qualitatively the band bending for the equilibrium case assuming as redox system Sn/Sn^{2-} (dashed curve) and $[Fe(CN)_6]^{3-/4-}$ (full curve), respectively. As shown in Fig. 1b and c the relaxation of the photocurrent disappears if a reducing agent such as Sn^{2-} or $[Fe(CN)_6]^{4-}$ is added to the electrolyte. It disappears, however, only at potentials above the standard potential of the redox system. The band bending at such polarization is shown in Fig. 7b assuming as redox couple $[Fe(CN)_6]^{3-/4-}$. Here the electron hole pairs created by light were well separated by the electric field across the space charge layer. At cathodic potentials with respect to the standard potential, however, a relaxation of photocurrent is still

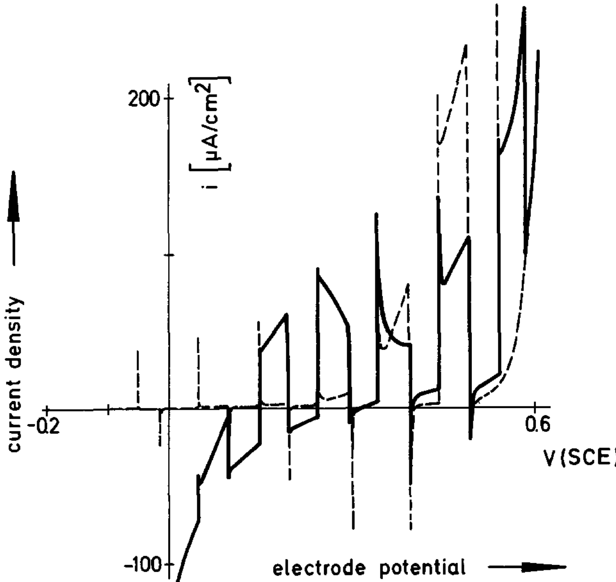

Fig. 4. Potentiostatic current-voltage curve for ferric oxide (vs. SCE) under periodic illumination by white light, level approximately AM2, scan rate 10 mV sec^{-1}. visible. Assuming the relaxation is due to a cathodic back-reaction, the question arises how electrons from the conduction band can reach the surface. Since the band bending is still very large ($U_{sc} \approx + 1.1V$ at the standard potential) the electron density at the surface must be extremely small. The other possibility for electron transfer could be tunneling through the space charge layer as indicated in Fig. 7c. However, this process is also rather unlikely because the thickness of the space charge layer will be far too great (13, 14) (in the order of at least 1000Å) as derived from capacity measurements.

These considerations throw some doubt on the concept of back-reaction by electrons from the conduction band to the photogenerated species. On the other hand, however, we have also observed a large cathodic dark current upon addition of the oxidized species of the redox system $[Fe(CN)_6]^{4-/3-}$. According to the relative position of energy levels at the interface this cathodic dark current can only be explained by electron transfer from the conduction band. Consequently, we must conclude that electrons from the conduction band in the bulk of Fe_2O_3 reach the surface somehow. We have no model for this process. Since Fe_2O_3 has not a very well-defined composition one could assume a large density of states within the forbidden zone of the space charge layer and one could speculate that the electrons are transported via these states.

All results are now further analyzed on the basis of this model (Fig. 7c) although we leave open the actual electron transfer mechanism through the space charge region.

Let us first examine the cathodic dark current upon addition of an oxidized species such as $[Fe(CN)_6]^{3-}$. Since the cathodic current does not linearly increase with concentration (Fig. 6) we have to assume that the electrons used for the reduction of Ox are directly transferred to Ox. Assuming a two-step process via surface states the cathodic current i^- is given by

$$i^- = ek_{ox}fN_Tc_{ox} \quad [1]$$

k_{ox} is the rate constant for the electron transfer from the surface states to Ox, N_T the density of surface states, f the occupation factor of these states and c_{ox} the concentration of Ox. The number of electrons being transferred from the conduction band into surface states is given by

$$dn_e/dt = k_Tn_e\,(1 - f)N_T \quad [2]$$

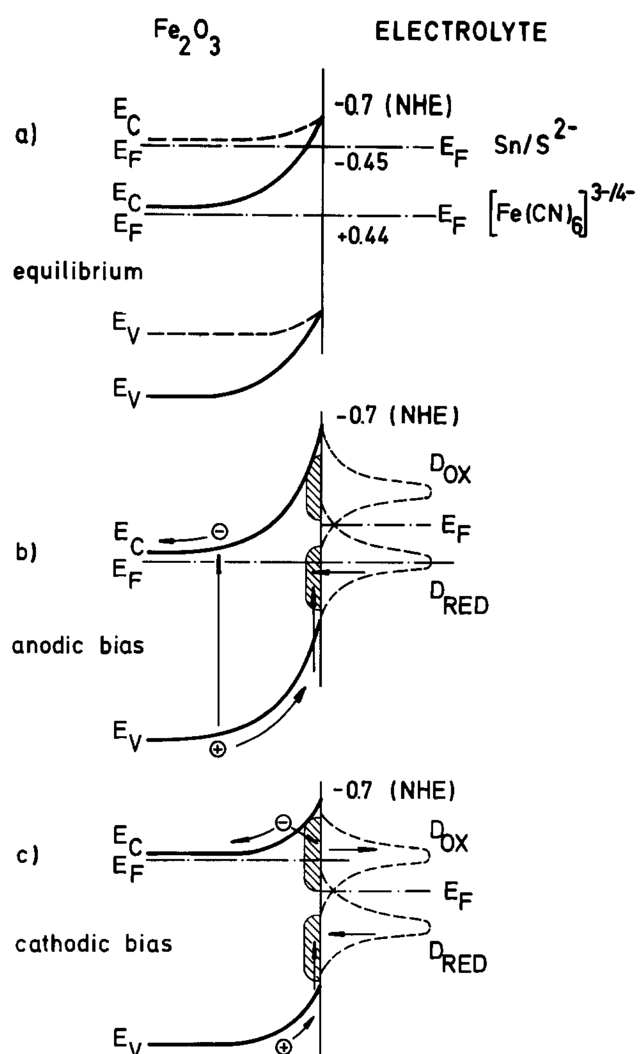

Fig. 7. Energy diagram of a Fe_2O_3-redox system interface at pH 14. (a) At equilibrium conditions with the Sn/Sn^{2-} (dashed curve) and the $[Fe(CN)_6]^{3-/4-}$ redox couple (full curve); (b) at anodic; and (c) at cathodic polarization assuming as redox system the $Fe(CN)_6{}^{3-/4-}$ couple. The dashed curve indicates the distribution of the energy levels of the oxidized and reduced states, respectively.

and the number of electrons being transferred to Ox by

$$dn_e/dt = k_{ox}fN_Tc_{ox} \quad [3]$$

Inserting Eq. [2] and [3] into [1] one obtains

$$1/i^- = 1/N_Te\,[1/k_Tn_e + 1/k_{ox}c_{ox}] \quad [4]$$

A similar model has also been applied recently to TiO_2 and $SrTiO_3$ (11).

We replotted the data from Fig. 6 according to Eq. [4] ($1/i^-$ *vs.* $1/c_{ox}$) and obtained straight lines as shown in Fig. 8. From the intercept with the $1/i^-$-axis one obtains a value for $N_Tek_Tn_e$. Since the rate constant k_T is expected to depend on the band bending the intercept should also depend on the electrode potential. In the potential range investigated here the intercept varies only slightly and the average value is given by

$$i^- = eN_Tk_Tn_e = 2.5\ 10^{-5}\ Acm^{-2}$$

i.e., $N_Tk_Tn_e = 1.7\ 10^{15}\ cm^{-2}\ sec^{-1}$. The slopes of these curves yield values of N_Tk_{ox}. They vary from $6.5 \cdot 10^{15}$ to $1.6 \cdot 10^{16}$ liters/mol. It is rather surprising that the k_{ox} depends on the electrode potential. This effect can only be understood if the relative position of the energy levels at both sides of the interface and conse-

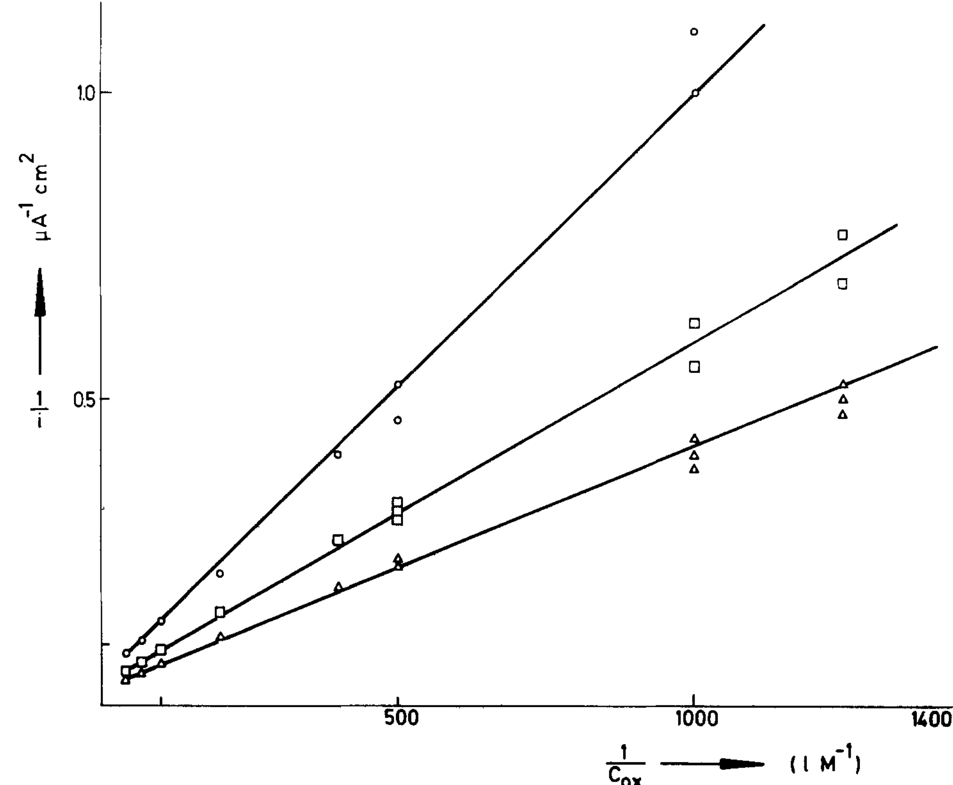

Fig. 8. Reciprocal cathodic dark current vs. reciprocal concentration of $[Fe(CN)_6]^{3-}$. Data from Fig. 6.

quently the Helmholtz layer varies with the electrode potential. The fact that the Mott-Schottky plots of the capacity are not linear with potential (4) may be an indication that the Helmholtz potential is changed.

The relaxation process of the anodic photocurrent as observed with and without redox systems can be interpreted if we include the same cathodic back-reaction as discussed above. An anodic photocurrent i_{ph}^+ occurs immediately after light is turned on (Fig. 1 and 2). In this process either a redox couple or water is oxidized. The products can be either an intermediate in the water oxidation (or oxygen) or the oxidized species (ox) of the redox couple. The latter are reduced by electron transfer from the conduction band leading to the cathodic current i^-. The sum of both currents is given by

$$i_{ph} = i_{ph}^+ - i^- \quad [5]$$

The anodic current is assumed to be determined only by the light intensity I and the quantum yield ϕ and to be independent of time, *i.e.*

$$i_{ph}^+ = e\phi I \quad [6]$$

whereas i^- is given by Eq. [1].

The kinetics of the formation and decay of Ox are given by

$$dc_{ox}/dt = \phi I - k_{ox} f N_T c_{ox} - k_D c_{ox} \quad [7]$$

in which k_D is the rate constant describing the diffusion of Ox away from the surface. The corresponding term $k_D c_{ox}$ is only a rough approximation because normally a diffusion should be described by a concentration gradient. The electron transfer from the conduction band into surface states and from here to Ox is described by

$$N_T df/dt = k_T n_e (1 - f) N_T - k_{ox} f N_T c_{ox} \quad [8]$$

in which n_e is the electron density in the conduction band and k_T the rate constant for the electron transfer from this band into the surface states.

Since it is impossible to give an analytical solution of these differential equations we only consider some limiting cases. Under stationary conditions c_{ox} and f and consequently the stationary photocurrent $i_{ph,st}$ can easily be derived. This current is not a linear function of the light intensity as also found experimentally and displayed in Fig. 9a, where $i_{ph,st}$ and i_{ph}^+ are replotted from the data of Fig. 2. It should be mentioned, however, that the initial photocurrent i_{ph}^+ does depend linearly on the light intensity as required by Eq. [6]. At very high light intensity the cathodic current i^- is expected to be independent of light intensity. Then one obtains

$$i_\infty^- = eN_T k_T n_e \quad [9]$$

i.e., the cathodic current is entirely determined by the electron transfer from the conduction band into the surface states. In this case the total stationary photocurrent is given by

$$i_{ph,st} = i_{ph}^+ - i_\infty^- = e(\phi I - N_T k_T n_e) \quad [10]$$

or the ratio of $i_{ph,st}$ and i_{ph}^+ can be expressed by

$$(1 - i_{ph,st}/i_{ph}^+) = (N_T k_T n_e/\phi) 1/I \quad [11]$$

using the data given in Fig. 9a one obtains the curve in Fig. 9b. According to this our light intensity was just sufficient to get a linear dependent of $(1 - i_{ph,st}/i_{ph}^+)$ *vs.* $1/I$. From the slope of the linear part of the curve in Fig. 9b we obtain $N_T k_T n_e/\phi = 5 \cdot 10^{17}$ cm^{-2} sec^{-1}. Using the value $N_T k_T n_e = 1.7\ 10^{14}$ cm^{-2} sec^{-1} as obtained from the dark current measurements (see above) then the quantum yield ϕ can be determined. We obtained $\phi \approx 4 \cdot 10^{-4}$ which is an extremely low value. One can check this value by determining ϕ directly from the peak photocurrent i_{ph}^+. In this case we obtained $\phi \approx 5 \cdot 10^{-4}$ which is in reasonable agreement with the first value. This low quantum yield must be due to strong recombination effects in the bulk of the material.

In principle the relaxation phenomena also give some information about the density of surface states N_T. A quantitative determination, however, requires a solution of Eq. [7] and [8].

Conclusions

We have investigated two aspects of the photoelectrochemistry of ferric oxide in detail; the influence of

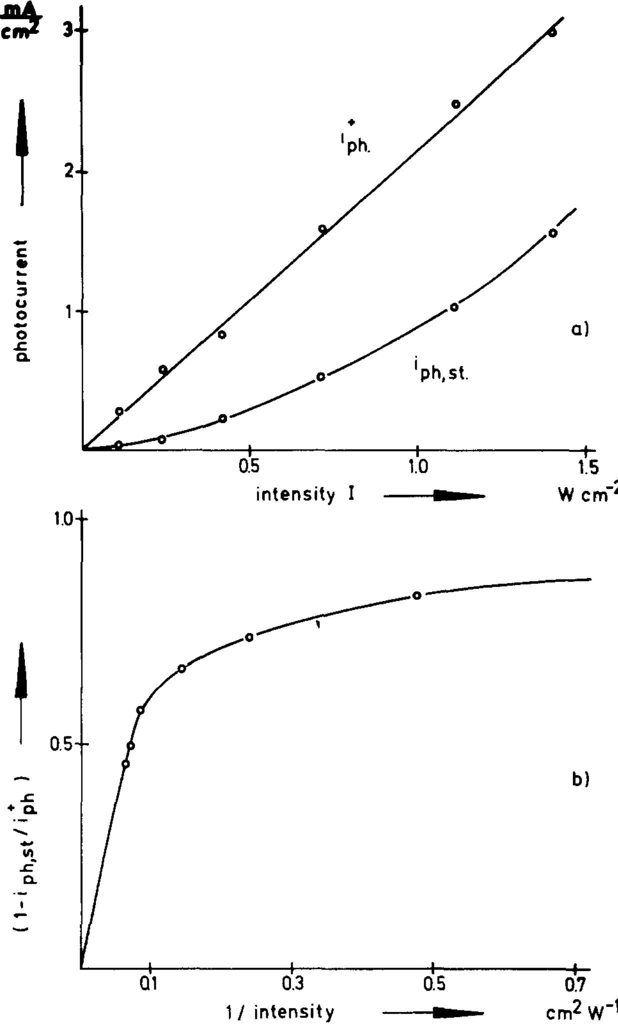

Fig. 9. (a) Peak photocurrent i_{ph}^+ and stationary photocurrent $i_{ph,st}$ (taken from the curves of Fig. 2) vs. the light intensity *I*. (b) Plot of the function $(1 - i_{ph,st}/i_{ph}^+)$ vs. the light intensity *I*.

redox reagents on the cathodic dark current and the anodic photocurrent. In the former measurements a nonlinear dependence of the dark current on redox species concentration has been revealed. We take this as evidence for the intervention of surface states. Insofar as photocurrents are concerned, the main observation is that the marked transient behavior is suppressed, if a redox system is added or sufficiently high intensities are used. Especially with redox systems having a rather negative standard potential such as Sn/Sn^{2-}, the relaxation of photocurrent can be avoided over a large potential range. This leads us to an overall interpretation of the photocurrent behavior of this electrode in terms of cathodic back-reactions of the photogenerated species. The surface states invoked for the explanation of the cathodic dark current behavior are also active in the back-reaction mechanism. The influence of sample preparation on photocurrent transient behavior (4) is consistent with this explanation, since surface-state densities and electron tunneling probabilities are sure to be influenced by crystallinity.

In spite of the fact that the photocurrent relaxation can be virtually eliminated in the presence of the S^{2-} redox species, the Sn/Sn^{2-} redox system is not suitable for use in a solar cell because of the cathodic standard redox potential. Although Fe_2O_3 is an interesting material for a photoanode in a photocell because of its stability against anodic decomposition, the preparation of the material and the surface properties have to be considerably improved in order to avoid the cathodic back-reaction via the conduction band.

ABSTRACT

Photoelectrochemical cells based on layer-type semiconductors (*i.e.*, transition metal sulfides and selenides) have gained substantial interest due to their reasonably high solar efficiency and good stability against photocorrosion. However, the performance of this type of cell may be limited by irregularities in the semiconductor, since edges of the van der Waals surface exposed to the electrolyte may act as recombination centers. To control this effect, chemical surface treatments, based on specific agents which perform selectively on the transition metal atoms at the edge sites, have been studied. In particular, the effect of the disodium salt of the ethylene diamine tetracetic acid (EDTA) molecule (as well as that of many other organic molecules) on the performance of an n-$MoSe_2/I^-$, I_2/Pt sample cell has been investigated. The treatment with EDTA generally improved both short-circuit current and power output, even if a considerable variation in the response from crystal to crystal was observed. The stability of the EDTA effect under prolonged cell operation was also examined.

In recent years many efforts have been directed to the investigation of new semiconductor compounds suitable for use as electrodes in photoelectrochemical solar cells. In this connection, Tributsch (1-10) has proposed transition metal dichalcogenides (such as $MoSe_2$, MoS_2, and WSe_2) as stable electrode materials.

Indeed, these layer-type semiconductors are characterized by optical transitions which occur between two d-bands of the metal and do not involve metal and chalcogen bonding orbitals, thus assuring good stability against photocorrosion. Furthermore, the values of the energy gap (1.4-1.8 eV) open possibilities of good energy conversion efficiencies.

Detailed studies have been carried out by various authors on the behavior of these photoanodes in contact with different aqueous redox electrolytes. The results have indicated the I^-, I_2 system as the optimal redox couple. Using this couple, relatively high efficiencies and long stabilities have been obtained with $MoSe_2$- and WSe_2-based cells (8).

However, many authors (11-15) have also pointed out that the surface morphology of single crystal layered photoanodes plays a key role in determining the relative photoelectrochemical cell behavior, since surface states and defects greatly increase the rate of electron-hole pair recombination, thus reducing the performance in terms of photovoltage, maximum power output, and thus efficiency.

Unfortunately, even under the most accurate growing procedure, defects (crack-like steps, ruptures, etc.) are inevitably present on the van der Waals surfaces of transition metal dichalcogenide single crystals (12).

In order to assure optimum photoelectrochemical behavior for the layered semiconductors and eventually open the possibility of their use in the polycrystalline state, it is necessary to develop surface treatments which may act selectively on the recombination sites and which also maintain their effect under the drastic conditions of an illuminated electrode during prolonged anodic operation.

To understand the possible blocking mechanism of a chemical agent, it is necessary to briefly examine the structure of the bonding sites of the semiconductor surface. Let us then consider a "step" as a defect model. Within the step it is possible to have "dangling bonds" of both the transition metals and the chalcogene atoms, which may easily act as bonding points for various ionic species in solution (14). The absorption of a new species onto a surface parallel to the c-axis (reactive surface) by means of free metal bonds may produce new surface states near the conduction band, which determine electron tunneling and high electron-hole pair recombination. Moreover, the contact with the electrolyte of a reactive surface, in addition to the surface perpendicular to the c-axis (van der Waals surface), causes a new space charge region and electric field. These determine a high drift of holes moving toward the semiconductor/electrolyte interphase on the reactive surface, as a consequence of the higher conductivity of the minority carriers along the van der Waals planes (12).

These undesired effects may be limited by specific chemical agents which, upon blocking the free metal bonds situated at the defect sites, prevent the electron-hole pair recombination, thus finally improving the performance of the semiconductor photoanode. Such an approach has been proposed by Parkinson *et al.* (15), who have shown that large organic molecules, such as 4-tert-butyl-pyridine, may indeed temporarily block, by a "semi-intercalation" process, the transition metal atoms responsible for the surface state.

In this work we have extended the study by examining the blocking behavior of many organic molecules, using as a typical testing system the n-$MoSe_2/I^-$, I_2/Pt cell.

Key words: photoelectrochemical cells, layer-type semiconductors, surface treatments.

Experimental

$MoSe_2$ single crystals were kindly provided by Dr. F. Lévy of the Ecole Polytechnique Fédérale de Lausanne, Switzerland. These crystals, grown by chemical transport reaction in the vapor phase, using halogens as transport agents (16), were n-type semiconductors with a typical thickness of 0.1-0.3 mm and an apparent surface of 0.2-0.5 cm^2.

The 1M KI, 0.01M I_2 aqueous electrolyte was prepared using high purity chemicals and distilled water. All the blocking agents tested were high purity chemicals.

The $MoSe_2$ single crystal was assembled and welded with a conductive silver paste on a brass current collector. This was then embedded with epoxy resin on a Teflon holder in such a way that only the van der Waals surface remained in contact with the electrolyte. The counterelectrode was a platinum wire spirally arranged around the semiconductor photoanode.

The semiconductor surface was illuminated through an optical window situated at the bottom of the cell. The light source was a 100W tungsten iodine lamp with an intensity of 100 mW cm^{-2}, simulating an AM1 irradiation.

The illumination intensity and uniformity were regularly controlled and measured by a Haenni Solar 118 light intensity meter.

The output characteristics of the cell were obtained by controlling the voltage with a potentiostat driven by a function generator and recording the current-voltage curves with an X-Y recorder.

To test the effect of various surface chemical treatments, the semiconductor crystal was kept in contact with an aqueous solution of a given blocking molecule for periods varying from 1 to 15 hr at room temperature. In the case of polyvinylpyridines an alcoholic solution was used. After washing with distilled water, the crystal was again assembled in the cell and the related current-voltage curves were determined under illumination and in the dark. The results were then compared with those obtained previously with the same untreated crystal.

All the measurements were carried out at room temperature and in air. In certain cases the chemical treatments were also tested at 50-70°C, but the results were not very different from those obtained at room temperature.

Results and Discussion

As already pointed out, the surface of the layer-type semiconductors inevitably presents some defects. However, depending on the amount and the type of these defects, the various single crystal samples may be broadly classified as having "smooth" or "stepped" surfaces.

In the present investigation, to better evidence the effect of the chemical treatments, $MoSe_2$ crystals with many superficial defects were preferentially considered.

Various organic molecules were tested as possible blocking agents. Among these, by-products of pyridine, with structures similar to the 4-tert-butyl-pyridine investigated by Parkinson *et al.* (15), were examined. As indicated in Table I, where the effects of these products are summarized, some amino-pyridines show certain favorable blocking effects (as indicated by the improvements in the related cell *I-V* characteristics) accompanied, however, by poor stability. Indeed, after short-term operation of the electrode under illumination, drastic decreases in performance were observed. Moreover, the electrode response became frequently worse than that originally offered by the untreated crystal.

This behavior is probably due to a degradation of the amino group, which in turn causes a change in the physicochemical characteristics and in the interaction mechanism with the crystal surface. The change in in-

teraction mechanism may result in the formation of new superficial states which can increase the recombination rate of the electron-hole pairs.

Attention was therefore directed to other molecules having different structure and different bonding mechanism with the semiconductor surface. Particularly interesting appear in this respect the disodium salt of the ethylene diamine tetracetic acid (EDTA), the nitrilo triacetic acid (NTA), and the cyclohexane diamine (1-2)-tetracetic acid (CDTA). These materials, which are well known for their capability to react with transition metal ions to form coordination compounds, acted quite favorably on the performance of "stepped" $MoSe_2$ crystals.

For instance, as typically illustrated in Fig. 1, a crystal with a high reactive surface and low photovoltage, showed a substantial improvement in power output and dark current, after having been treated with EDTA. Improvements of this kind, even if not to a comparable extent, were also obtained with crystals which, even if with comparable highly defective structure, presented higher photovoltages, *i.e.*, of the order of 400-500 mV.

Also beneficial in terms of electrode response appears to be the treatment of the $MoSe_2$ crystals with aqueous solutions of CDTA and NTA.

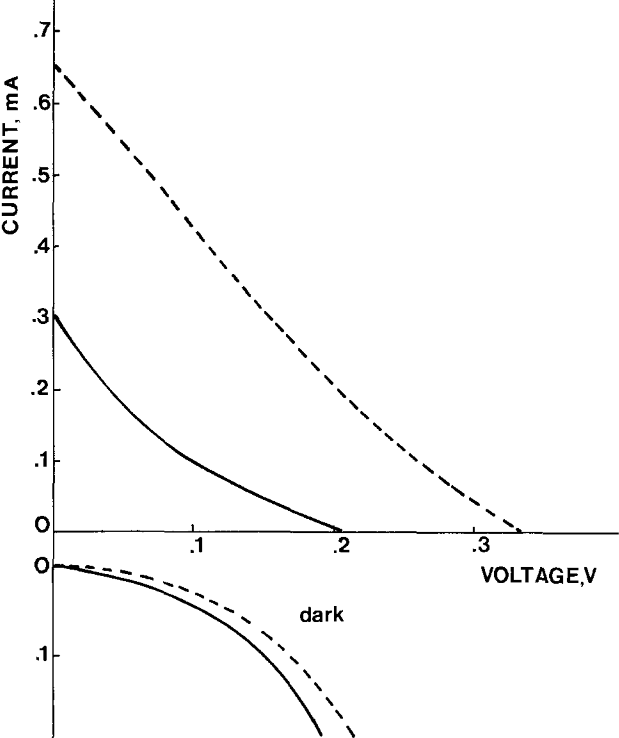

Fig. 1. Illuminated (top) and dark (bottom) current voltage curve before (———) and after (- - - - -) surface treatment of n-$MoSe_2$ with EDTA.

However, it must be emphasized that the effect of EDTA and related compounds, varied consistently from sample to sample of $MoSe_2$. In fact, some crystals with a highly stepped surface and having original low photovoltages showed appreciable improvements in response after the treatment, while others, still having a comparable defective surface, were affected either a little or not at all.

This discrepancy may be explained on the basis of different impurity levels in the various samples considered. Indeed, low photovoltage values may be due either to superficial defects or to impurities or to both of them. When the low values are prevalently related to surface defects, the blocking action of EDTA may induce consistent improvements, whereas EDTA treatment cannot be effective when the low response is primarily due to impurity levels.

To finally evaluate the EDTA effect on the surface states of layer-type semiconductor photoanodes, the following experiment was carried out. The surface of a crystal, whose output characteristics had been recorded previously, was scratched with the point of a thin needle and the current-voltage curve was again recorded. As shown in Fig. 2, output power and dark current deteriorated (to an extent proportional to the number of scratches), this being further evidence of the great influence of the condition of the surface on the electrode performance. The crystal was then dipped for 15 hr in a concentrated EDTA solution. As again shown in Fig. 2, the performance of the electrode improved after this treatment, but not up to the original level. Therefore, it appears that the EDTA molecules are not capable of blocking all the active sites produced by the scratching procedure.

No attempt to discuss in detail the binding mechanism of EDTA and related compounds is made here. This would require a series of independent measurements, some of which are in progress in our laboratories.

In the present work it has appeared of more immediate interest to evaluate the stability of the EDTA action under prolonged anodic operation at the condition of maximum power output. Figure 3 shows that the EDTA effect decreases with operation time, even if with a rate consistently lower than that reported elsewhere for other types of blocking molecules (15). The observed decay of the EDTA effect is probably related to a modification of its molecular structure, produced by the drastic working conditions, such as those determined by the oxidant medium (iodine), illumination, and anodic oxidation.

Conclusions

Because of the short duration of their action, the treatment with EDTA, CDTA, and NTA, respectively, is certainly of not immediate practical importance. However, the results reported here, in addition to all those concerning other attempts of controlling the surface state of the photoanodes (15), may be useful in this very initial stage of the research on layer-type semiconductor electrochemical solar cells to profitably address future efforts in the development of more effective and stable blocking compounds.

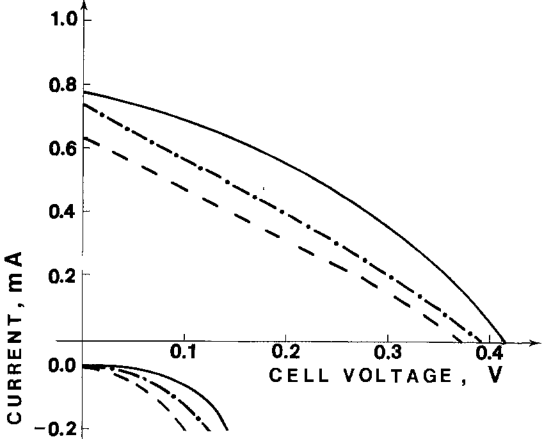

Fig. 2. Illuminated (top) and dark (bottom) current voltage curve before (———) and after (- - - - -) surface scratching and subsequent EDTA treatment (- - ● - ● -) of the scratched surface.

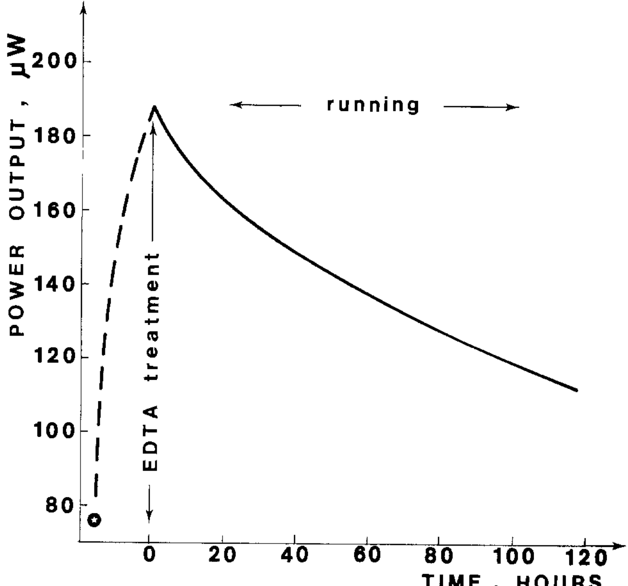

Fig. 3. Time dependence of the power output of an n-$MoSe_2$/I^-, I_2/Pt solar cell monitored during EDTA treatment and illuminated by a 100W tungsten lamp light. ○ refers to the power output before EDTA treatment.

At the present level of knowledge in the field, the properties that such compounds should have appear to be mainly the following: (*i*) capability of easily reacting with the defective "stepped" surfaces, forming stable and strong bonds at the edge sites; (*ii*) stability to solar light; (*iii*) absence of functional groups sensitive to anodic oxidation and/or to oxidizing chemical agents present in the electrolyte; (*iv*) absence of double bonds in the structure; and (*v*) low steric hindrance.

Acknowledgments

The Role of Electron-Hole Recombination at MoS_2 and $MoSe_2$ Photoelectrodes

M. L. Phillips and M. T. Spitler*

Department of Chemistry, Mount Holyoke College, South Hadley, Massachusetts 01075

ABSTRACT

Analysis of impedance and current-voltage data has revealed that electron-hole recombination plays a significant role in the aqueous photoelectrochemistry of $MoSe_2$ and MoS_2 single crystals. It is proposed that this recombination shortens the lifetime of the photoproduced hole to such an extent that few solution reductants are able to react with holes at the surface of these electrodes. The role of this recombination in diminishing photocurrents and photopotentials is discussed within the context of the Gerischer model for semiconductor electrochemistry.

Considerable interest has been displayed recently in the use of semiconducting layer-type transition metal dichalcogenides as photoelectrodes in electrochemical cells (1-16). These investigations result from Tributsch's suggestion (1-4) that these materials would be stable against photodecomposition under visible illumination while employed in an electrochemical solar cell. In particular, the group VI dichalcogenides such as $MoSe_2$, have been studied with regard to stability and energy conversion efficiency (1, 4, 9, 10, 12, 14); the best reported efficiencies of stable photoelectrochemical cells using these materials under simulated solar illumination have been 10.2% for a WSe_2 electrode and 9.4% for $MoSe_2$ (16), both using I_2/I^- as the redox couple. In addition, possibly the single longest continuous operation of a photoelectrochemical solar cell has been made using an $MoSe_2$ electrode in an I_2/I^- electrolyte which ran for ten months with an efficiency of 4-5% (13).

Although it has been demonstrated that the presence of halides, in particular I^-, profoundly influences the power output of these cells (1, 2, 4), the nature of this effect is not fully understood. An understanding of the electrochemistry of the halides at these electrodes would require the determination on a potential scale of the positions of the semiconductor valence and conduction bandedges over a wide range of electrode bias and a correlation of these energetics with the kinetics of the current producing reactions. Such a complete picture of the system has not yet been established beyond question.

In this work a suitable model was sought to explain the kinetics of photooxidation of reductants at $MoSe_2$ and MoS_2 electrodes with the hope that some insight might be gained into the interaction of these solids with iodide. Using new results in conjunction with existing data on the photocurrent-voltage and photopotential behavior of these compounds, we have determined that electron-hole recombination plays a significant role in their photoelectrochemistry, a factor which has not been previously discussed for MoS_2 and $MoSe_2$. We demonstrate how such a recombination process can be described by a minor extension of the Gerischer model for semiconductor electrochemistry; with this model the photocurrent and photovoltage results lend themselves to a straightforward interpretation. However, the character of the transition metal dichalcogenide/iodide interaction still eludes satisfactory explanation.

Key words: semiconductor, electrode, energy conversion.

Experimental

Crystals of MoS_2, and $MoSe_2$ grown by vapor transport were obtained from F. Lévy of the Ecole Polytechnique, Lausanne, Switzerland. Through impedance measurements, the donor density of the n-type crystals used in these studies was determined to be $1 \times 10^{17}/cm^3$ for MoS_2 and 6×10^{17} for $MoSe_2$.

The thickness of crystals used for electrodes varied but did not exceed 0.5 mm. A razor blade was used to separate single crystals from aggregates and to cut them to an appropriate working size. An electrical contact was made with conductive silver paint between the Van der Waals surface at the back-side of the crystal and a wire; the crystal was then affixed to Teflon mountings with 3M insulating epoxy, leaving an exposed surface area of 4-10 mm^2. Surfaces were renewed through pressing a piece of adhesive tape onto the crystal and peeling off a thin layer. Before each experiment, electrodes were rinsed for 5 sec in 1M nitric acid followed by deionized water.

All solutions were prepared with Baker analyzed reagent grade chemicals in deionized water. The supporting electrolyte in all experiments with the dichalcogenide electrodes was 0.500M KNO_3. The pH was adjusted with KOH and HNO_3.

The semiconductor electrode was immersed in electrolyte in a Pyrex, three-electrode cell under potentiostatic control with a platinum counterelectrode and an Ag/AgCl reference electrode in 0.5M KCl. The potentials in this work are referenced to this silver/silver chloride electrode. The crystal was illuminated through a Pyrex window with the 578 nm line of a 200W mercury arc lamp which had been passed through a Bausch and Lomb high intensity monochromator set at a bandwidth of 10 nm.

A PAR Model 175 function generator supplied the input potential to a Wenking 70 HVI/90 potentiostat at a sweep rate of 10 mV/sec. Impedance measurements were made with this system using the lock-in technique.

The photopotential measurements represent the potential difference between a Pt button electrode and the semiconductor electrodes under illumination from a 100W tungsten lamp using a 680 nm interference filter with a bandwidth of 10 nm. Before illumination the two electrodes were shorted. The redox potential of the electrolyte was determined using the Pt electrode and the Ag/AgCl reference electrode, except for the cerium solution where the dark potential of the semiconductor electrode was taken as the solution potential.

Results

To gain a better understanding of the photooxidation reactions at MoS_2 and $MoSe_2$ electrodes, photocurrent and photopotential measurements were made with dilute halides and other reductants at MoS_2 and $MoSe_2$ electrodes.

Single crystals of these compounds were selected and mounted in such a way as to show maximum photoeffect. In order to insure a constant pH for the duration of a series of experiments, the electrolyte was adjusted to pH 1.0. Halide concentrations were 100 times less than those of the supporting electrolyte to permit resolution of features in the current-voltage curves not distinguishable in the higher concentrations of halide used in most published work in this field.

When positively polarized in 0.50M KNO_3, the $MoSe_2$ crystals showed an anodic photocurrent in a reaction with water which eventually leads to lattice decomposition, as has been determined by Tributsch and Bennett (5). A typical current-voltage curve for $MoSe_2$ in the KNO_3 electrolyte is shown in Fig. 1(a). The onset of anodic dark current consistently occurred at +900 mV in the inert electrolyte; photocurrents started at +500 mV and rose with more positive potential to about 800-1000 mV.

For these compounds, the following equation (25) can be used to describe its current-voltage behavior when a depletion layer is formed at the surface of the electrode

$$I = \alpha \cdot [L_p + W(V - V_{FB})^{1/2}] \quad [1]$$

This holds for monochromatic radiation where V is the electrode potential, V_{FB} is the flatband potential, I is the photocurrent, and α is a constant. L_p is the hole diffusion length which for these compounds is $\sim 10^{-4}$ cm (25); W is the width of the depletion region which will be less than 10^{-5} cm when the band bending is less than 0.3V. Given these values for L_p and W it is clear that the photocurrent should be independent of potential once a depletion layer is formed. This behavior has been observed for $MoSe_2$ and MoS_2 electrodes in electrolytes containing high concentrations of iodide where the onset of photocurrent is marked by a steep climb of the photocurrent to saturation within several tens of millivolts.

The current voltage curves shown here for $MoSe_2$ do not follow from Eq. [1]. Instead, they show a gradual increase in photocurrent with potential that requires several hundred millivolts to reach a saturation level. It is useful, however, to establish a parameter which will serve to designate the potential at which the slow kinetics of lattice decomposition dominates photocurrents induced by reductants in the electrolyte; this has been done by noting the potential at which the current reaches 20% of its saturation value. These potentials are indicated in Fig. 1 and compiled in Table I for a number of crystals in nitrate solutions.

The effects of 5.00 mM KBr or 5.00 mM KI on dark and illuminated current-voltage curves are shown in Fig. 1(b) and (c). Saturation photocurrents were reached at +780 mV in Br^- solution and +900-950 mV

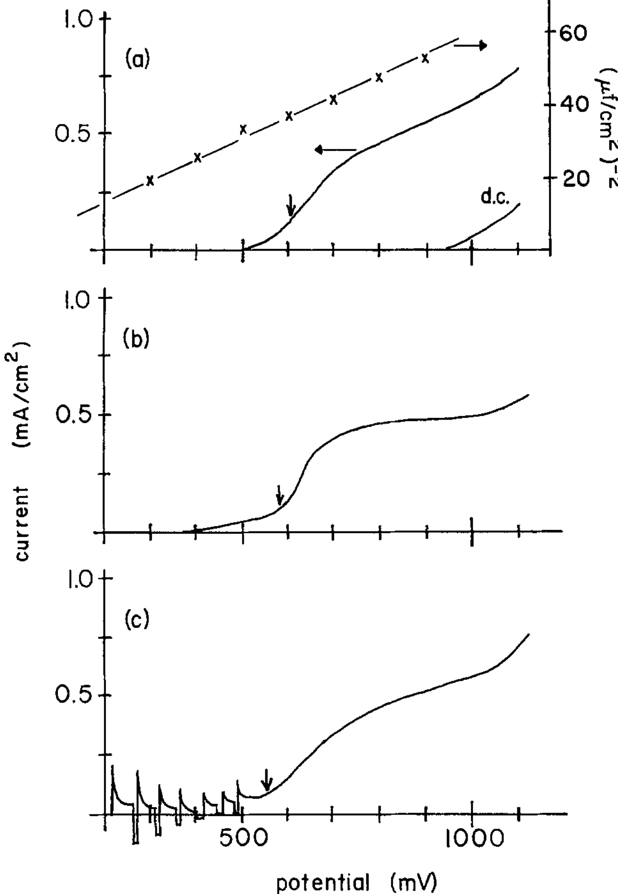

Fig. 1. Current-voltage curves are shown for illuminated $MoSe_2$ electrodes immersed in: (a) 0.50M KNO_3; (b) 0.50M KNO_3 and 5.0 mM Br^-; (c) 0.50M KNO_3 and 5.0 mM I^-. Light intensity was 5 mW/cm^2 at 578 nm with a solution pH of 1.0 and an Ag/AgCl reference electrode. In (c) illumination was chopped. A current-voltage curve in the dark is also provided (d.c.) in (a). The photocurrent onset parameter is shown as a vertical arrow and denotes the potential at which the photocurrent has reached 20% of its maximum value. Also included in (a) is a Mott-Schottky plot used to derive the flatband potentials from impedance measurements.

in I^- solution. The light was chopped as the electrode potential was swept positive to allow comparison of dark and photocurrents. It is seen clearly that photocurrents arose in the presence of halides at potentials substantially negative of the photocurrent onset in the absence of halides. The photocurrent onset potentials for Br^- and I^- solutions are listed in Table I. No increase in photocurrents was evident upon addition of 5 mM Cl^- to the electrolyte.

It is evident that at higher halide concentrations substantial changes in the current-voltage curves do appear; the concentration dependence of these changes has been studied in detail by Tributsch (2). The data here show that in the presence of 5 mM halides, whatever changes that occur in the onset potential for the photodecomposition reaction do not change by more than 50 mV. Therefore we conclude that the energies of the semiconductor bandedges remain fixed with re-

Table I. Photocurrent onset and flatband potentials for MoS_2 and $MoSe_2$ (vs. Ag/AgCl)

Photocurrent onset parameter:	MoS_2	$MoSe_2$
0.50M NO_3^-	530 (±20) mV	600 (±15) mV
+5 mM Br^-	530 (±30)	550 (±10)
+5 mM I^-	500 (±20)	560 (±30)
Flatband potentials:		
0.50M NO_3^-	+150 (±50) mV	−60 (±50) mV

spect to energy levels in solution within this 50 mV range.

The n-type MoS_2 crystals were in general of poorer crystalline quality than the $MoSe_2$ crystals, as evidenced by their appearance and by larger dark currents relative to photocurrents at positive potentials. In the inert electrolyte, the onset of anodic dark current came around +750 mV. From an onset at +300 mV, photocurrents rose to saturation around +920 mV and fell again after +980 mV, while dark currents continued to increase. Current-voltage curves were measured for MoS_2 in inert electrolyte, in 5.0 mM KBr, and in 5.0 mM KI. Only the iodide solution showed any significant photocurrents negative of a bias of +550 mV. The potentials for photocurrent onset using the 20% parameter are listed in Table I.

A closer examination of current-voltage curves for $MoSe_2$ in electrolytes containing Fe^{+2}, $Fe(CN)_6{}^{-4}$, and hydroquinone is shown in Fig. 2 wherein the most positive potential depicted in this figure is still negative of the onset of the current from lattice decomposition.

Photopotential measurements at these electrodes were made in solutions containing a variety of redox couples as have been reported by other authors (4, 8, 9, 11, 12, 15). The results are plotted in Fig. 3, showing the dark potential of the electrode and its potential under illumination as a function of the redox potential of the electrolyte. Solution concentrations for these redox couples were much higher than the 5 mM used in the halide experiments, being 0.1M in the reduced component in most cases. For redox couples with potentials negative of +600 mV, the photopotential of $MoSe_2$ electrodes attains more negative values than the MoS_2 electrodes.

Through a Mott-Schottky analysis of impedance measurements, flatband potentials were obtained for a number of electrodes used in this study and are to be found in Table I. These results agree fairly well with those values reported by Gobrecht (13). However, the analyses for a number of crystals yielded nonlinear slopes and frequency dispersions. This behavior is not unusual (13, 20) and probably reflects the sensitivity of impedance measurements to defects at the electrode surface which are known to exist for these compounds. A Mott-Schottky plot for $MoSe_2$ has been included in Fig. 1(a).

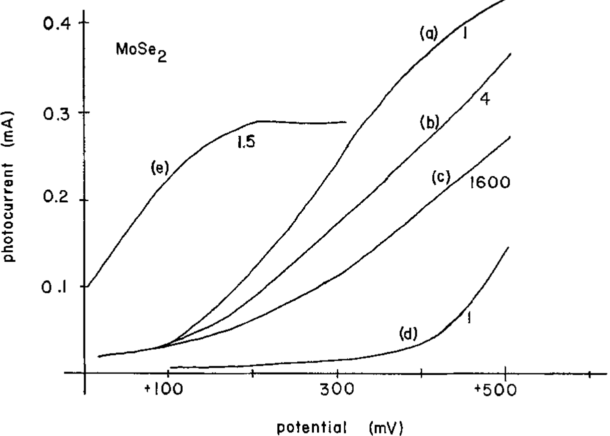

Fig. 2. The potential dependence of photocurrents at $MoSe_2$ as measured against an Ag/AgCl reference electrode is depicted for solutions containing 0.50M KNO_3 and (a) 50 mM hydroquinone, (b) 50 mM $Fe(CN)_6{}^{-4}$, (c) 15 mM $FeSO_4$, (d) 30 mM Br^-, (e) 15 mM I^-. The solution was maintained at pH 1.0 with illumination conditions as in Fig. 1. The numbers on each curve are the enlargement factors necessary to bring the curves onto the current scale on the left; photocurrent resulting from lattice decomposition does not begin until about +500 mV.

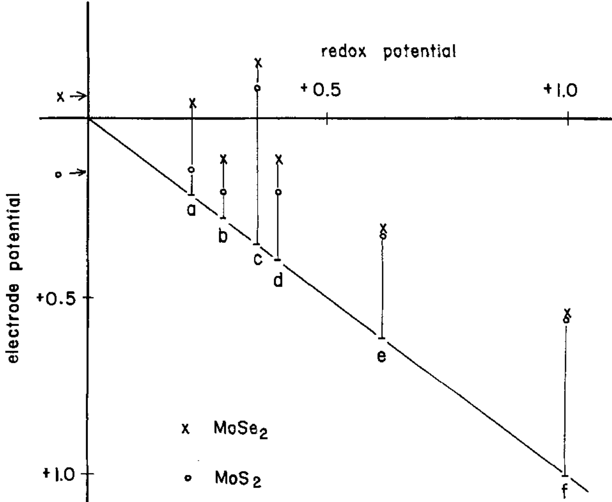

Fig. 3. Along the diagonal line are plotted the measured dark potentials (vs. Ag/AgCl) of $MoSe_2$ and MoS_2 electrodes immersed in solutions with varying redox couples. Under illumination $MoSe_2$ (x) and MoS_2 (o) acquire a more negative potential with the former being generally more negative than the latter. The flatband potentials of these electrodes, as determined by impedance measurements, are indicated at the upper left. The electrolyte contains (a) quinone/hydroquinone, (b) $Fe(CN)_6{}^{-3/-4}$ (c) I_2/I^-, (d) $Fe^{+2/+3}$, (e) $Ru^{+2/+3}$, and (f) $Ce^{+3/+4}$, all at pH 1.0.

Discussion

Electron-hole recombination in $MoSe_2$ and MoS_2.— Of immediate note in the experimentally observed characteristics of these electrodes is the discrepancy between the photocurrent onset potential and the flatband potential obtained from Mott-Schottky analyses. For $MoSe_2$ this difference is ~650 mV while for MoS_2 it is only ~400 mV. This observation is not peculiar to these investigations alone as a close examination of the data in the literature (1-15) will reveal it to be the case in most all current-voltage curves reported for these compounds.

With the flatband potentials derived from impedance measurements it is evident that lattice decomposition does not occur until a depletion layer is formed with a maximum band bending of 650 mV for $MoSe_2$ and 400 mV for MoS_2. This excess band bending can only be explained by a recombination of electrons with holes which is faster than the initial hole transfer step in the lattice decomposition reaction.

At a potential bias of +600 mV, this recombination mechanism must become deactivated so that lattice decomposition occurs. A model which could account for such behavior involves assumption of an electron trap, or distribution of traps, within the energy gap of the semiconductor as is depicted in Fig. 4. When the Fermi level of the electrode is negative of this trap, it is filled by electrons which can recombine with holes faster than the holes can react with the solution reductant. Once the Fermi level becomes more positive than this trap, it is emptied of electrons and recombination ceases. Such a recombination mechanism has been used previously to explain similar phenomena at GaP (21) and WSe_2 (9) electrodes. Heretofore, however, there has been only minimal discussion (13) of the possibility that recombination may play a role at MoS_2 and $MoSe_2$ electrodes.[1]

It is not clear whether this trap is a bulk state as is found in GaP (21) or purely a surface state as is described for WSe_2 in Ref. (9). With these data for $MoSe_2$ and MoS_2, it is not possible to make a definite statement. However, the effect on the photoelectrochemistry is the same: A fast electron-hole recombination precludes hole oxidation of reductants whenever the Fermi level of the electrode is negative of +600 mV.

[1] Note added in proof: This point has also been mentioned in the recent publication F. F. Fan and A. J. Bard, *This Journal*, 128, 945 (1981).

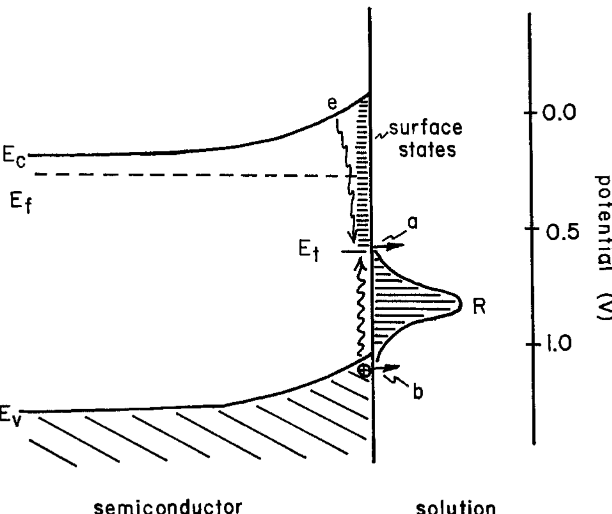

Fig. 4. A schematic representation of the $MoSe_2$/electrolyte interface is given here, featuring surface states extending below the conduction bandedge to a level denoted by the energy E_t at +0.6V (vs. Ag/AgCl). A distribution of occupied energy levels is also depicted for a solution reductant *R* which may react with holes at the electrode surface. The reductant may be oxidized at level "a" or "b." Recombination of the electron and hole through these surface states appears to compete effectively with the hole oxidation of *R* as long as the Fermi level, denoted by E_f, is negative of E_t.

Competition between recombination and photooxidation.—With this model, production of anodic photocurrent at a bias negative of +600 mV is possible only if hole capture by the reductant occurs faster than recombination with an electron. From Fig. 1(b) and (c) it is evident that Br^- and I^- can do this effectively at $MoSe_2$ electrodes. A faster recombination may be in effect at the poorer quality MoS_2 electrodes because only I^- photooxidation is evident in this potential range. Photooxidation of hydroquinone, ferrocyanide, and Fe^{+2} is also evident in this region implying that they, too, must capture holes at a rate faster than the recombination can. However, this is not true for Cl^- which produced no detectable increase in photocurrents.

It is unclear, however, at which point in the recombination pathway the reductant captures the hole, at a vacant trap or at the valence band level. It is possible, and indeed likely, that electron exchange occurs at both as is depicted in Fig. 4.

It can be shown in a straightforward manner how recombination can be interpreted in terms of the Gerischer model for semiconductor electrochemistry (22). The discussion here will focus on the domain within this model where the bandedges remain fixed with respect to energy levels in solution. In this situation it is instructive to examine an expression for the current resulting from the oxidation of reductants by holes at the electrode surface

$$I = e \int_{-\infty}^{0} k(E) C_{red} \cdot W_{red}(E) \cdot D(E) \cdot (1 - f(E)) dE \quad [2]$$

where C_{red} is the concentration of the reductant, $W_{red}(E)$ is the distribution function for the energy, E, of the electron in the reductant in solution, $D(E)$ is the density of states of the semiconductor; $f(E)$ is the Fermi function, and $k(E)$ is the constant for the electron transfer itself. The product of the last two terms in this integral, $D(E)(1 - f(E))$, represents the concentration of holes, $p(E)$, at the surface with energy E

$$p(E) = D(E)(1 - f(E)) \quad [3]$$

In a steady-state situation, $p(E)$ can also be expressed as the product

$$p(E) = G(E) \cdot \tau(E) \quad [4]$$

where $G(E)$ is the rate of generation of holes with energy E and $\tau(E)$ is the lifetime of the hole at that energy level. $G(E)$ is a complicated function of illumination intensity, electric field strength, hole mobility, and surface hole generation; $\tau(E)$ reflects the kinetics of the phenomena which consume holes, such as electron-hole recombination and electron transfer to the electrolyte, both of which are a function of E.

From Eq. [2], [3], and [4] it is clear that a fast electron-hole recombination will shorten the overall lifetime of the hole at the surface, and if the reductant cannot compete successfully for this hole, that is, if $k(E)$ is not large enough, oxidation will not occur.

With this conclusion, we have found it useful to define a quantum efficiency for oxidation of the reductant by a hole at the valence bandedge (path b in Fig. 4) for the potential depicted in Fig. 2

$$\Phi = k_{et}/[k_{et} + k_{rec}(V)] \quad [5]$$

Here, k_{et} is a pseudo-first order rate constant for electron transfer which includes the concentration of the reductant at the electrode surface, and $k_{rec}(V)$ is the recombination rate which is a function of potential V. At a particular potential V_o, within the range spanned in Fig. 2 where $k_{et} << k_{rec}(V_o)$, this reduces to $\Phi = k_{et}/k_{rec}(V_o)$. Consideration of pathway "a" in Fig. 4, where the reductant is oxidized at the trap, changes this result, but as long as the rate constant for oxidation through "a" is much smaller than that through "b," this approximation for Φ will hold. This neglect of pathway "a" is based on the observation (23) that the more exoergic hole oxidation of reductants at semiconductor electrodes proceeds faster than the less exoergic oxidation.

With this formulation for Φ it can be seen that at potentials in Fig. 2 where lattice decomposition does not occur, the relative magnitudes of the photocurrents for the various reductants should reflect their relative k_{et} values quantitatively because $K_{rec}(V)$ is independent of the nature of the redox couple in solution.

Unfortunately, real information about the rate of the electron transfer is obscured by the concentration term in k_{et}, which reflects, as has been noted in Ref. (15), specific surface interactions, such as adsorption, which disrupt the expected redox potential ordering of the rates of photooxidation at these electrode surfaces.

As the potential of the electrode is changed, $k_{rec}(V)$ should also change as the Fermi level approaches and passes through the energy levels of the traps responsible for recombination. On the other hand, k_{et} through pathway "b" should not be a function of potential. Consequently, one would expect that the relative ratios of the photocurrents in Fig. 2 would be independent of potential, a prediction which holds to within 10% for curves (a) through (d) between +100 and +400 mV.

The exception to this behavior is the current-voltage curve for I_2/I^- which has reached a diffusion limited plateau by +200 mV. Photooxidation of I^- must then proceed very fast, probably assisted by a strong interaction of unknown character between I^- and the crystal surface which has already been shown to have a catalytic effect in the photooxidation of Br^- (15). The high velocity of this reaction is also manifest in the very negative photopotentials depicted in Fig. 3 for these electrodes in I_2/I^- containing solutions.

This is an unexpected result considering the energetics of the hole transfer reaction. The I^- oxidation proceeds much faster than hydroquinone or hexacyanoferrate (II) oxidation even though the latter have more negative redox potentials. One would expect the more exoergic electron transfer to occur faster (23), but this is not the case here. It is likely that a unique mechanism is in operation for the photooxidation of I^-, such as the Fermi level pinning model discussed for this system in Ref. (2) and (12). We can offer no new evi-

dence to support this picture of the I^- interaction, but note that any such model would be compatible with the recombination scheme presented above, so long as it allows a fast hole exchange with iodide that competes effectively with the electron-hole recombination.

Back-reactions at the electrode surface.—Through the $MoSe_2$ data in Fig. 1(c) it can be seen that I^- functions as a recombination agent for the photogenerated holes and electrons. In this figure a net photooxidation of I^- is evident at $MoSe_2$ electrodes polarized negative of +500 mV. However, the chopped illumination reveals that a dark reduction current also flows at these potentials even though they are positive of the flatband potential. Given the observation that there is not a significant change in the flatband potential with the 5 mM I^- used in these experiments, this reduction reaction must proceed through surface states which exist below the conduction band as is shown in Fig. 4.

Thus, the I^- is simultaneously oxidized by holes from the valence band and regenerated through a reduction reaction. The degree to which I^- functions as a recombination center will depend on the quality of the crystal surface; a lesser number of surface defects will result in a diminished dark reduction reaction, an increased photooxidation current, and a greater photopotential. This back-reaction and its effect on the photopotential have been discussed in Ref. (9).

Photopotentials.—Inspection of the photopotential measurements depicted in Fig. 3 reveals that illumination of the semiconductor does not always result in the electrode attaining the flatband potential. These photopotentials are a function of light intensity with more negative potentials possible through an increase in illumination intensity. Consequently, the values presented in Fig. 3 can only be considered as indicative of trends in the photoelectrochemistry of the redox couples at these electrode surfaces. As has often been reported (4, 8, 9, 15), the photopotential appears to plateau for redox electrolytes with potential positive of 0.4V.

The role of recombination in this saturation of the photopotential can be seen through the expression (22) for the photopotential, $\Delta\Phi$, generated at an n-type semiconductor under illumination

$$\Delta\Phi = \frac{kT}{e} \cdot \ln (p^*/p)$$

Here p is the integral of $p(E)$ over all E where p and p^* are the hole concentrations at the surface in the dark and under illumination.

For the redox couples with potentials positive of 600 mV it is clear that the recombination process is responsible for limiting the photopotential of electrodes immersed in these solutions. For these very positive redox systems, once the potential of the electrode under illumination becomes sufficiently negative, this recombination becomes the predominant factor in determining the lifetime, $\tau(E)$, of Eq. [4] and thereby effectively reducing any further increase in p^*. Such a recombination mechanism has also been assumed to play a role in diminishing photopotentials observed with GaAs electrodes (24). Between +0.6V and the flatband potential, the photopotential attained by these electrodes in a redox solution will depend on the relative kinetics of the oxidation and recombination reactions. For redox systems with potentials positive of the energy of the valence band, which is +1.2V for MoS_2 and +0.9V for $MoSe_2$ (25), the dark potential of the electrode should be limited through formation of an inversion layer at the surface, as has been reported for these electrodes in aprotic solvents (8).

Modification of Apparent Electrocatalysis for Anodic Chlorine Evolution on Electrochemically Conditioned Oxide Films at Iridium Anodes

J. Mozota*[,1] and B. E. Conway*

Chemistry Department, University of Ottawa, Ottawa, Canada

ABSTRACT

Studies of Cl_2 evolution kinetics on iridium anodes on which oxide films of various thicknesses from a monolayer upwards were formed by a potential cycling program, are reported. The multilayer oxide films were of the kind that exhibit reversible reduction/oxidation behavior. The kinetic experiments conducted in aq. KCl at pH 2 give log [current] *vs.* overpotential relations having a constant Tafel slope of 2.3 $RT/\mathbf{F}$ for all anode oxide surfaces prepared, indicating that the Cl_2 evolution mechanism is independent of the thickness of the oxide film produced. However, the apparent exchange current densities increase in an almost linear way with thickness. The latter behavior is attributed to an increase in the real area of the electrode available for Cl^- discharge, coupled possibly with improved electrocatalysis, *e.g.*, on account of changes that can arise in the band structure of the oxide. Increases of Cl_2 evolution rates of up to *ca.* 180× are found. Effects of Cl^- adsorption on the development of the initial monolayer of oxide of Ir were also studied and compared with the behavior at Pt. Cl^- adsorption is found to inhibit the formation of the thick oxide films at Ir.

The study of the electrochemical properties of metal and metal oxide anodes in reactions such as Cl_2 and O_2 evolution has been a subject of great interest in recent years (1-5), especially since the development by Beer of DSA® electrodes for the chlor-alkali industry (6).

These anodic reactions normally proceed on a surface that is completely or partially covered with an oxide film and it is this oxide that is associated with the electrocatalytic properties of the anode, as shown by Conway and Novak (7) for the case of Pt, in their comparative studies using anhydrous trifluoroacetic acid as solvent which enabled them to obtain oxide-free surfaces for Cl_2 evolution on Pt.

Although, in the case of Pt, the enhanced acitivity is due only to a monolayer, or less, of oxide, since under normal conditions O_2 evolution takes place before a thicker oxide can develop (8), other metals, such as Ir and Ru, are known to develop, under the proper conditions, anodically formed oxides thousands of angstroms thick (9-14), the characteristics of which can be controlled by means of experimental variables such as growth program, pH, type and concentration of the electrolyte, etc.

In early work, the Cl_2 evolution reaction had been studied by various authors (1-3, 15) on Ir "metal" (presumably bearing some oxide film) and on IrO_2 anodes prepared by thermal methods. Thus, Chang and Wick (15), using the reaction order approach, concluded that the rate-determining step on Ir "metal" was the discharge of Cl^- ion in a "Volmer-Heyrovsky" type of mechanism. Consistent with this conclusion they found a Tafel slope of $2RT/3\mathbf{F}$. Yokoyama and Enyo (1) arrived at a similar conclusion, but they found the rate-determining step to be dependent on the overpotential. Arikado *et al.* (3), studying Cl_2 evolution on IrO_2 anodes, proposed the same mechanism, but Kuhn *et al.* (2) found their data to be consistent with the "Volmer-Tafel" type of mechanism (Tafel slope of $RT/2\mathbf{F}$).

In the above studies, however, the states of the surfaces on which Cl_2 evolution took place were not in any way characterized, *e.g.*, in terms of the thickness and reversibility of the oxide films, or in terms of the oxide interface and changes of its state which may occur during the Cl_2 evolution process.

It is the purpose of this paper to present results which show how the electrocatalytic properties of Ir anodes depend on their surface oxidation history. At Ir, as at Ru (13) or Rh (16), an oxide film of controllable and electrochemically characterizable thickness and state of reversibility can be formed by an anodic/cathodic potential cycling regime. The development of a reversibly oxidizable/reducible state of the oxide film on Ir, very different from the behavior of Pt, was first described by Stonehart, Kozlowska, and Conway (17) and studied by means of reflectivity by Gottesfeld and Conway (18). The formation of such films was studied further by various authors, *e.g.*, Capon and Parsons (9), Otten and Visscher (10), Woods (11, 12), who observed how thickening of the oxide film on Ir is determined by the extent of anodic/cathodic cycling. The apparent thickness of a developed oxide film on Ir can be conveniently characterized by a parameter measuring the extent to which the charge for oxidation of the film in the anodic sweep of a cyclic voltammogram exceeds that for initial monolayer formation on the bare metal. This parameter will be referred to as the "charge enhancement factor" (CEF).

In the present work, Cl_2 evolution kinetics have been studied on a series of oxidized Ir electrodes having varying CEF values and are related to the CEF and other features of the oxide film. Also, as the adsorption of Cl^- ions at noble metals is known to influence their surface oxidation (19), the effects of Cl^- ion with regard to the development and stability of the anodic oxide film at Cl_2-evolving Ir anodes were studied.

Experimental

General.—Cyclic voltammetry experiments for Ir oxide growth and characterization were performed in the usual way (20). The real area of the Ir electrodes was determined, at the monolayer stage of surface oxi-

* Electrochemical Society Active Member.

[1] CONICIT Scholar, on leave of absence from Universidad Simon Bolivar, Caracas, Venezuela.

Key words: chlorine electrocatalysis, iridium oxide films, electrocatalysis, at Ir oxide films; oxide films.

dation, by integration of the H desorption charge, taking the coverage, θ_H, of H species as 0.65 (21-22) (relative to that for an H monolayer at Pt) for measurements made between potentials of 0.060 and 0.5V E_H, and a charge of 218 $\mu C\ cm^{-2}$ for $\theta_H = 1$ (23). Comparison of real and geometric area gave a roughness factor of 2.5-3.

Electrodes.—Oxidized Ir electrodes, with variable but controlled CEF's, were prepared by electrochemical growth of oxide films using a cyclic-voltammetry program with potential varied between 0.060 and 1.460V E_H, at a sweep rate of 100 mV sec^{-1}, in 015M H_2SO_4 at 298 K. Electrodes were made from Engelhard high purity grade Ir wires.

The electrodes bearing the conditioned oxide films were then transferred to an all-glass cell (24) which contained 1M KCl + 0.02M HCl and in which the Cl_2 evolution experiments were performed.

IR drop measurements were made by means of a current interruption technique using a Nicolet digital oscilloscope to record the transients; the determined resistances were $\simeq 1\Omega$.

Solutions and salts.—A.C.S. analytical grade KCl used in this work was recrystallized twice and dried at 150°C. The KCl solutions at various concentrations were made up with analytical grade aqueous HCl to give solutions 0.02M in the acid. BDH "Aristar" grade H_2SO_4 was used to make up the electrolyte solutions in which the conditioned Ir oxide films were prepared and characterized, and in which effects of added Cl^- ion on oxide film formation were studied. Water used as a solvent was pyrodistilled, following two regular distillations, according to the procedure described previously (25).

Reference electrodes.—For all experiments, a hydrogen electrode in the same solution as that under study was employed. Potentials on this scale are referred to as V "E_H" in this paper.

Kinetic measurements.—In order to determine the electrocatalytic properties of the anode surfaces under study, steady-state current *vs.* potential relations for anodic Cl_2 evolution were obtained potentiostatically. The potential was stepped in increments of 10 mV by means of a PDP-11/34 computer-based system (26) and held constant for 10 sec at each value to allow current readings to be collected. Currents were recorded for ascending and descending directions of potential change. Cl_2 (g) (1 atm) was bubbled through the solution. All polarization data were corrected for *IR* drop since most of the electrode surfaces were very active for Cl_2 evolution.

Cl^- ion adsorption.—Chloride ion adsorption experiments at Ir were performed in 0.5M H_2SO_4 by successive additions of known amounts of standard KCl solutions by means of a micrometer pipette fitted with 1 mm Teflon spaghetti tubing terminating in a fine glass tip. The effects of Cl^- adsorption at the monolayer stage of oxidation were evaluated from changes in the Ir surface oxidation charge measured from cyclic voltammograms taken after each addition of Cl^- ion, as previously carried out in work at Pt (27).

Results and Discussion

The states of oxide films at cycled Ir anodes.—The electrochemical behavior of Ir electrodes is characterized by *i vs. V* profiles that are strongly dependent on the pretreatment and electrochemical history of the electrode (9-12).

Thus, intially, a fresh Ir electrode that has not been repetitively cycled up to potentials higher than 1.2V E_H, behaves like any other noble metal, as shown in Fig. 1 (this state is labeled "A"). Such electrodes exhibit an H adsorption/desorption region between 0.050 and *ca.* 0.45V E_H, a double-layer charging region that overlaps with the onset of upd of OH/O species and a region of surface oxidation with two broad peaks that span the potential range 0.5-1.45V E_H. A nominal monolayer of IrOH is completed at 1.1V E_H (10) and that of IrO is nearing completion when O_2 gas evolution starts. On the cathodic sweep, the *i vs. V* profile shows that the reduction of the IrOH monolayer is relatively reversible but that of the IrO and higher oxide species is quite irreversible, so that there is much hysteresis between the potential ranges for surface oxide formation and reduction, as at Pt (17).

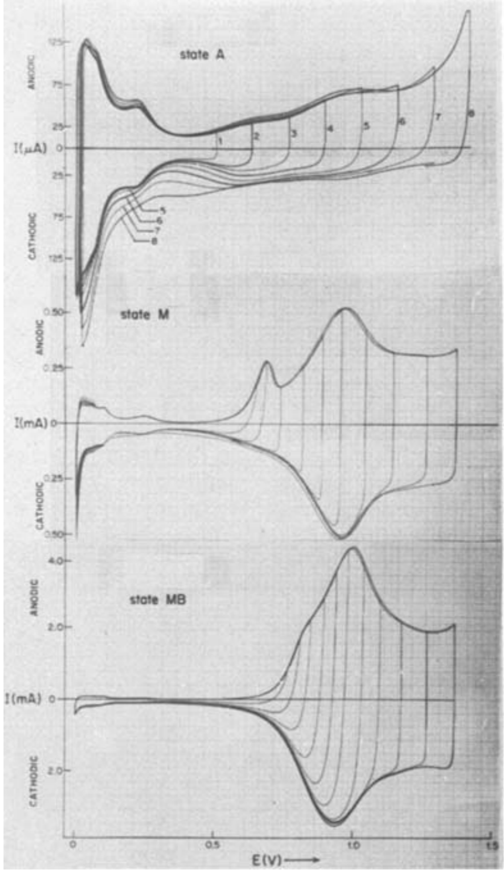

Fig. 1. Cyclic voltammetry *i vs. V* profiles for Ir electrodes at 5×10^{-2} $Vsec^{-1}$, 298 K in 0.5M H_2SO_4. State A, CEF = 1; state M, CEF = 8; state MB, CEF = 50.

When the potential of this type of electrode is repetitively cycled between anodic limits $E_a > 1.4V$ (*e.g.*, 1.5 ~ 1.7V) and cathodic limits $E_c < 0.3V$ E_H, the *i vs. V* profile undergoes drastic changes, as shown in Fig. 1. The electrode in a state corresponding to Fig. 1 still appears metallic; this state is designated "M." The oxidation/reduction charge increases continuously with extent of repetitive cycling (11), and the *i vs. V* profile becomes very reversible (9). At the same time, the H charge decreases by about 20% but the double-layer charging current observed between *ca.* 0.40 and 0.50V remains essentially constant. The latter behavior has been interpreted previously (4, 12, 28) as indicating that no change of real area takes place as the oxide grows.

The fact that the charge for H adsorption also remains almost unchanged is most difficult to account for and has led to conflicting views in the literature; thus Buckley and Burke (13) proposed that an outer layer of the oxide was reduced to Ir metal in the cathodic scan, thus providing sites for H deposition. On the other hand, Woods and others (12, 29) consider that H

deposition takes place on bare metal sites at the metal/metal oxide interface below the oxide film.

As the oxide grows thicker, the first oxidation peak is shifted positively until it overlaps with the main oxidation peak as shown in Fig. 1. This state exhibits a metallic-to-black transition [the electrochromic effect recently described in the literature (30)] and is designated "MB."

In the case of Ir anodes prepared for the study of Cl_2 evolution, with CEF values between 1 and 182, the states of the electrodes span those labeled as A, M, and MB (Fig. 1). The modifications to the oxide are as follows: State A is essentially a monolayer surface oxide state on Ir. In going from A to M or MB, a thicker, phase oxide is formed, consisting (5) probably of an Ir(III)/Ir(IV) hydrated oxide. Once the state M is attained (after a few cycles), the type of oxide does not change further except that the thickness and probably the roughness or porosity increases. As greater film thicknesses are attained (CEF $>$ 100), the film starts to crack macroscopically (Fig. 2).

Although experimental conditions such as rate of growth, pH, nature of electrolyte, etc., also affect the microstructure of these films, in the present work only changes of Cl_2 evolution rates due to an increase in CEF were studied, so that changes of other variables were minimized.

The state of Ir electrode surfaces in H_2O as a function of Cl^- ion concentration.—As mentioned in the section above, in a cyclic voltammetry experiment, an Ir electrode in state A behaves like most other noble metals (31). In this state, when Cl^- is present, the following effects, shown in Fig. 3, are observed: H deposition is blocked by the competitive adsorption of the Cl^- ion, so that the charge under the i *vs.* V curve decreases and the peak potentials are shifted to less positive values with increasing Cl^- concentration.

Also, a double-layer charging region becomes better resolved since Cl^- ion adsorption shifts the onset of upd of O species towards more positive potentials and of H to less positive ones. This eliminates the overlap between the regions of H ionization and commencement of deposition of oxygen species which otherwise almost obscures the double-layer charging region at Ir [and Ru (28)].

Of particular interest here is the displacement of the surface oxidation region at Ir to more positive potentials by blocking on account of strong competitive adsorption of Cl^- ion, as also occurs at Pt (19, 27) but in a somewhat different manner. This blocking of surface oxide formation is conveniently measured from the diminution of oxide formation charge on each anodic sweep following successive additions of Cl^- ion [*cf.* Ref. (27)].

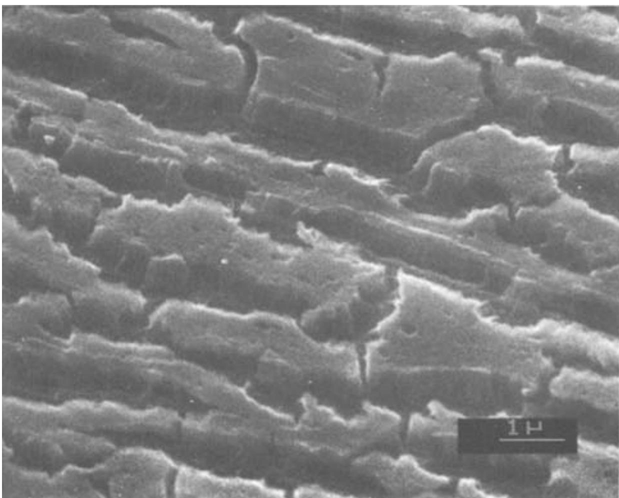

Fig. 2. SEM micrograph of an anodic iridium oxide film CEF $\simeq$ 100, showing cracking of the film.

The percent blocking of formation of the monolayer surface oxide as a function of concentration of Cl^- ion is shown in Fig. 4, compared to that observed (27) at Pt under similar conditions. As can be seen, both relations have the same initial slope, but to achieve the same percent blocking, the concentration of Cl^- ion in the case of Ir must be 10 times larger than that for Pt. This is because surface oxidation of Ir starts already at a potential of 0.45-0.5V E_H, making the metal surface less sensitive to competitive adsorption by Cl^-.

The charge isotherm for monolayer surface oxide formation as a function of Cl^- concentration, measured at various end potentials in anodic sweeps, is shown in Fig. 5, which indicates two regions of influence of Cl^- corresponding to the two broad oxidation peaks (previous section) observed in the absence of Cl^- ion.

In the case of Ir anodes on which a thicker oxide has been grown in the absence of Cl^- ion, the addition of this ion produces similar effects in the H region to those observed on the bare metal in that region, as described above.

Figure 6 compares these two situations; with the thicker oxide (curve 1), it is experimentally observed that H deposition is diminished to some extent by the oxide itself so the percent blocking of the H region at low Cl^- concentrations is higher than that (curve 2) for Cl^- adsorption effects at the "bare" metal since the blocking effect is calculated as a percentage of the H charge measured at the "bare" (oxide free) metal. As the Cl^- concentration increases, the behavior of both types of surface referred to above is remarkably similar. This indicates that the oxide film is porous enough to allow the Cl^- ion to reach the "base" metal sites underneath the oxide film. No time effects are experimentally observed in the Cl^- ion blocking effect, so that diffusion-controlled movement of Cl^- ion through the pore system does not seem to be involved in any way.

However, in the oxide region, the Cl^- ion seems to have no effect whatsoever. This is as expected, since the oxide is already deposited (see the previous section) and does not get reduced to bare metal in every cycle (11) as does an oxide film at Pt. For these conditions, therefore, Cl^- ion can have no influence on the oxide film behavior at Ir. Continuous cycling of a previously oxidized Ir electrode in Cl^- solution causes only a slight decrease in the CEF, probably due to some dissolution of the oxide. On the other hand, attempts to continue growing the thick, reversibly oxidizable/reducible film in the Cl^- solution were unsuccessful; this may be for various reasons, *e.g.*, enhanced rate of dissolution of Ir and/or (more likely) interference of adsorbed Cl^- ions with the growth mechanism either by blocking H deposition that could be needed indirectly for the growth (since a minimum potential in the cathodic sweep of *ca.* 0.2V is required for oxide growth to be maintained in the cyclic regime) or by inhibiting the underlying metal surface from participating in the film growth reaction;[2] such inhibition is most likely responsible for the observed effect of Cl^- ion in preventing continued oxide film growth at Ir.

Cl_2 evolution kinetics on the conditioned Ir oxide films.—The *IR* drop-corrected log [current-density] *vs.* potential curves for Cl_2 evolution on the oxide films at Ir, prepared to various extents of oxidation (CEF), are shown in Fig. 7. As can be seen, the apparent electrocatalytic effectiveness of the surfaces of these electrodes increases with increasing CEF up to a limit, after which the Cl_2 evolution currents become inde-

[2] A separate paper is in preparation which discusses the kinetics and growth mechanism for formation of thick oxide films on Ir.

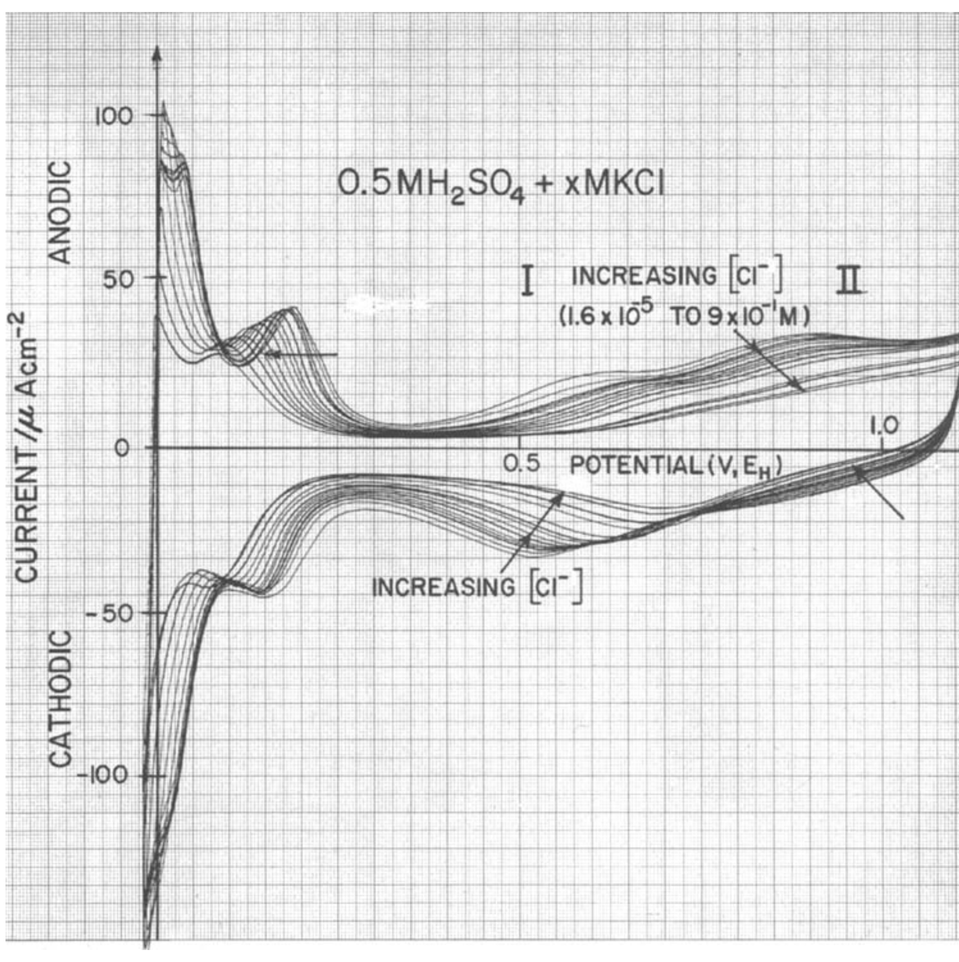

Fig. 3. Series of superimposed cyclic-voltammetry i vs. V profiles for Ir in 0.5M H_2SO_4, with successive additions of Cl^- ion from 1.6×10^{-5} to 9×10^{-1} mol dm^{-3}. Arrows show directions of change of curves with increasing $[Cl^-]$.

pendent of the CEF. The relation between current at a given overpotential and CEF can be represented by a linear log-log plot (up to the limit mentioned above), as shown in Fig. 8. This line has a slope close to 1. A similar slope was obtained by Trasatti *et al.* (32) for O_2 evolution on RuO_2, and was attributed to increasing concentration of defects in the films, although in their case (32) no limiting region was found.

As the overpotential values are quite small, *viz.* $<$ 150 mV from the reversible potential, it is important to eliminate the influence of the back-reaction in the polarization plots of Fig. 7. When this is done by plotting $\ln i/(1 - \exp[-\eta\mathbf{F}/RT])$ *vs.* η, as in Fig. 9, the data become represented by straight lines the slopes of which are $\alpha\mathbf{F}/RT$ and the intercepts of which represent $\ln i_o$. For all of the Ir oxide electrode surfaces, the value of $\alpha\mathbf{F}/RT$ was $34 \pm 4V^{-1}$, which corresponds to a value of $\alpha = 1$ (or a Tafel slope $RT/\mathbf{F}$) for the Cl_2 evolution reaction at these surfaces. That the slope remains constant over all the range of CEF values is rather important since such behavior indicates that the mechanism is the same for all the surfaces developed. This allows us to speculate on the reasons for the ob-

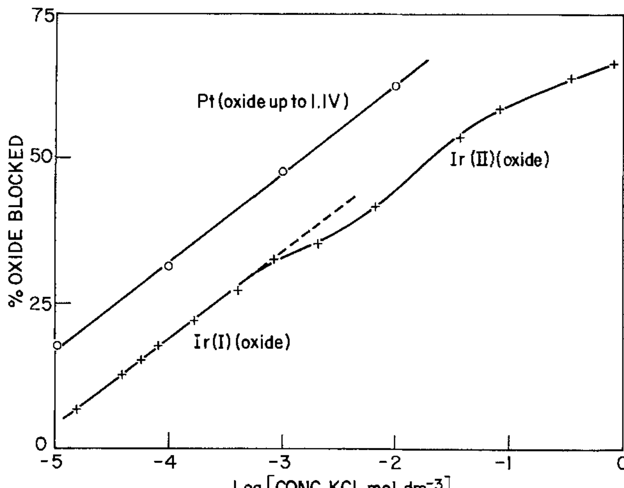

Fig. 4. Percentage of surface oxide, measured as charge for its anodic formation, blocked by Cl^- as a function of log $[Cl^-]$ for Ir as compared to Pt (27). Supporting electrolyte is 0.5M H_2SO_4 for Ir and 0.1M H_2SO_4 for Pt. (Regions I and II, respectively, correspond to the two broad peaks indicated in the cyclic-voltammetry curves of Fig. 3).

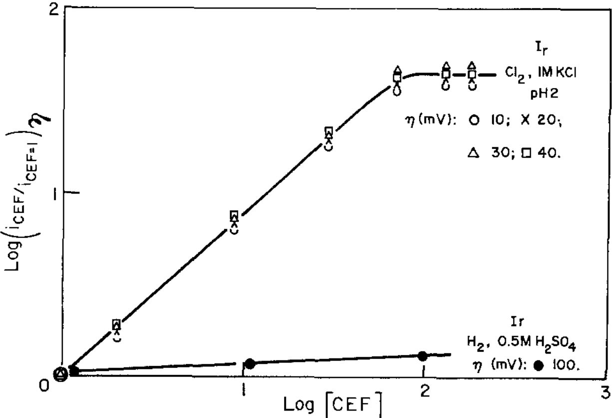

Fig. 8. Plots of Cl_2 and H_2 evolution rates at various indicated constant overpotentials as a function of CEF, expressed relative to currents for CEF = 1, for Ir anodes at 298 K in 1M aq. KCl + HCl to pH 2.

served apparent enhancement of Cl_2 electrocatalysis on a common basis for each of the CEF values and corresponding states of the oxide films.

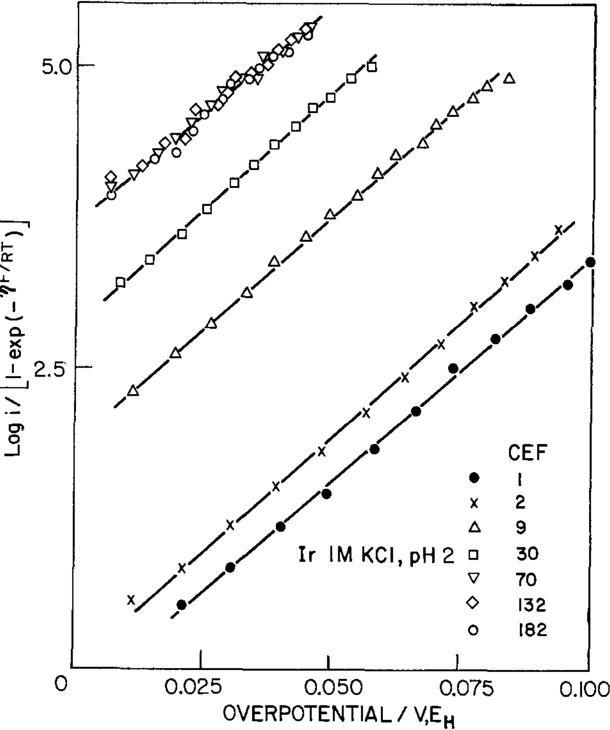

Fig. 9. Steady-state log [current-density] vs. overpotential plots, corrected for back-reaction current component, for anodic Cl_2 evolution at Ir, as in Fig. 7.

The well-defined Tafel slope of $RT/\mathbf{F}$ is an unusual value in electrode kinetics but three types of explanations for such a value have been proposed for other observed examples: (*i*) The rate is controlled by a heterogeneous chemical recombination step in which "activated" adsorption of the Cl· intermediate applies (33); (*ii*) the Cl^- discharge step is followed by a rate-controlling quasi-chemical surface-diffusion step (to sites where Cl· is desorbed) (34); or (*iii*) barrierless discharge (35) applies.

We shall not try to argue a preference for applicability of one or other of these mechanisms to the present result except that (*iii*) is unlikely since a transition to a Tafel slope of *ca.* $2RT/\mathbf{F}$ (β changing from 1 to 0.5) is not found with increasing η (Fig. 9). This then implies that the discharge step is not rate controlling. Also it should be mentioned that Kuhn and Mortimer (2) found Tafel slopes from $RT/2\mathbf{F}$ to $2RT/\mathbf{F}$ for Cl_2 evolution on RuO_2, Srb and Mraz (36) the same range for MnO_2, and Morita *et al.*, (37) the value $RT/\mathbf{F}$ for MnO_2 doped with Ir or Ru.

Stability of the Ir oxide films.—From a practical point of view it is important to note that the anodes with bigger CEF were more stable with respect to their activity as a function of time. Thus, an electrode with a CEF of 123, when held at η = 120 mV (apparent Cl_2 evolution current density = 0.10 A cm^{-2}) for 2 hr, lost only 7% of its activity, measured as Cl_2 evolution current, at a given η. Afterwards a potentiostatic polarization for 60 sec at 0.0V E_H, restored the activity to within 1% of the original value, without significant change of the CEF as measured by the oxide redox charge. In contrast, electrodes with intermediate degrees of oxide formation were less stable.

Electrodes having a CEF higher than 50 bore a visibly black oxide film when polarized anodically [known electrochromic effect (33)]. This served as a secondary feature enabling flaking of the film, which occurs under certain conditions, to be observed. This phenomenon is quite evident during O_2 evolution in the absence of Cl^- ion, indicating that this reaction is in some way intimately connected with the state of the

oxide film. For Cl_2 evolution at comparable rates, however, no flaking is observed and mechanical intactness is preserved.

Cyclic voltammograms of the anodes taken in 0.5M H_2SO_4 after prolonged Cl_2 evolution indicate that the electrochemical redox behavior of oxides having higher CEF's remained essentially unchanged, as expected, since IrO_2 does not grow on anodic potential holding (17). However, electrodes with intermediate CEF values lost some of their charge (as much as 60%) over a time period of 10 hr of Cl_2 evolution which explains the time effects in their activity for Cl_2 evolution which appear to arise for mechanical reasons due to loss of some oxide material.

SEM examination of the films.—Our own SEM studies on Ir oxide films grown in H_2SO_4 show that as the CEF increases, an apparently macroporous, initially relatively uncracked film (Fig. 10) develops wide cracks in between oxide patches (Fig. 2). This cracking is also observable under the optical microscope with very thick films while they are wet. This rules out the possibility that the cracking is an artifact due to exposure to vacuum in the SEM.

The oxide structure remains unchanged in going from a cycling regime in H_2SO_4 to one in Cl^- solutions. Thus, it appears that Cl^- ion does not chemically attack or modify the film, although it probably enhances its dissolution rate by facilitating the formation of $[Ir_xCl_y]$ soluble complexes.

However, after the Cl_2 evolution experiments, SEM observation of the morphology of the oxide film showed that substantial changes had occurred. The film had developed widespread cracking as shown in Fig. 11 but, under high magnification (Fig. 12), some porosity was still observable. Also the surface was quite homogeneous in terms of its cracked appearance and no oxide fragments had fallen off due to mechanical failure. On the contrary, after O_2 evolution had taken place for 10 min at 50 mA/cm^{-2} apparent on the same electrode preparation, pieces of oxide film could be seen to have become detached from the surface. The underlying roughened metal is then exposed and the remaining oxide patches appear rough and spongy (Fig. 13). This observation may be understood if O_2 evolution involves, in an intimate chemical way, the O species of the oxide film itself, *e.g.*, as an intermediate.

Electrocatalysis in the Cl_2 evolution reaction at Ir oxides.—In discussing the electrode kinetics of a reaction at an oxide electrocatalyst substrate which is being modified in some way, two factors must be taken into account: (*i*) The possible change of real area (of

technological importance) and (*ii*) changes of intrinsic electrocatalytic activity (of fundamental and technological interest).

Factor (*ii*) may be due to changes of energy of adsorption of intermediates, changes of transition state of the reaction, modifications of electronic band structure of the material due to changes of valence states of metal ions in the oxide structure, etc. (43).

Cl_2 evolution appears to proceed by either the Volmer-Tafel or Volmer-Heyrovsky types of mechanism (1, 3, 38). The fact that the observed Tafel slopes remain unchanged (Fig. 9) with radically changed thickness of the surface film, means that the mechanism remains unchanged. Although the value of $RT/\mathbf{F}$ for the Tafel slope cannot unambiguously be interpreted (see above) in terms of mechanism, it is reasonable to suppose that the surface modification could affect the binding energy of $Cl\cdot$ intermediates in the reaction.

However, the observed changes of rate of the Cl_2 evolution reaction must first be considered in terms of possible changes of real area of the substrate. Although the Ir oxide films are porous and rough, and will thus have an area that tends to increase with thickness, the important parameter that relates the observed currents to an area factor, is the distribution of the applied potential difference across the metal/oxide/electrolyte system, as a function of thicknesses and oxidation state of the film.

Recent a-c impedance measurements (39) indicate a C_∞ value of $\simeq$ 60 μF cm^{-2} at *ca.* 0.36V E_H and of $\simeq$ 760 μF cm^{-2} at 0.96V E_H (under the capacitance maximum) of the *i vs. V* profile; thus an area increase would seem to have taken place simply by increasing the oxidation state of the film. At the same time, the conductance of the film was found to change from 10^{-2} Ω^{-1} cm^{-2} to 10^2 Ω^{-1} cm^{-2} [units as given in Ref. (39)] in going from the cathodic end potential to the anodic end potential in a cyclic potential change.

These results indicate that the film is not a very good conductor at low anodic potentials; for these conditions, it can therefore be assumed that the applied p.d. is located mainly at the metal/oxide interface. This could provide an explanation for the unchanged H ionization/deposition and double-layer charging potential regions, since the system behaves as Ir metal in contact with electrolyte. The latter would be available at the metal/oxide interface on account of the porous nature of the film. The behavior in the H region is consistent with the observed effect of Cl^- ion on the H adsorption/desorption region, discussed earlier, which seems to be independent of the film thickness.

In order to account for the observed results for Cl_2 evolution rates, we propose the following. As the potential increases in the anodic direction, the conductance of the film increases (39) and the oxide becomes a metallic conductor; thus, the oxide film as a whole assumes a potential with respect to the electrolyte as a result of the applied potential difference. Microscopically, of course, in a porous structure, such a situation would require a distribution of oxide-to-solution interfacial potential drops throughout the thick film when it is in the conducting state. The real equivalent circuit for such a situation is then quite complex but elements of it will be like the circuit for a low resistance transmission line. Some potential difference remains, of course, at the metal/oxide interface and a fraction of the applied potential is lost across the film, due to residual *IR* drop, this amount being a linear function of the film thickness.

This would account for the observed value of C_∞ under the capacitance maxima (39) (760 μF apparent cm^{-2}) characteristic of a surface of large real area and would be consistent with the optical appearance of the film.

Thus, Cl_2 evolution, which occurs at high positive potentials, takes place under conditions where, in principle, the whole surface of the oxide is available for electron transfer, that is, the outer surface + interface of the pore structure. As the thickness of the film increases, an increasing *IR* drop, coupled with some mass-transport limitations at the bottom of the pores, restricts the real area available for the reaction.

This model is supported by the behavior of the $Fe(CN)_6^{4-}/Fe(CN)_6^{3-}$ redox couple at a rotating disk of Ir metal compared with that at a disk of oxidized Ir, as shown by Gottesfeld (40).

Furthermore, the change of location of the applied potential difference with change of conductance of the film, has been confirmed in the present work by carrying out H_2 evolution studies on the same modified Ir anodes.

According to the proposed model, at cathodic potentials, the applied potential difference is located mainly at the metal/oxide interface; thus any increase in real area of the oxide film with increasing CEF is irrelevant for the H_2 evolution reaction, since the oxide cannot support electron transfer at the interfaces of its pore structure if it is essentially nonconducting. Experimental results indicate that the polarization curves for the H_2 evolution reaction remain essentially constant, regardless of the CEF (see curve for H_2 in Fig. 8), and exhibit a Tafel slope of $\simeq 2RT/\mathbf{F}$.

Related work from this laboratory, to be published elsewhere (41), on the electrocatalytic behavior of oxidized Ru electrodes for Cl_2 evolution showed that a changed state of monolayer surface oxidation could be induced by cycling at that metal, over a restricted potential range, and then Cl_2 evolution rates were enhanced some 30×, independently of any area change, which was unambiguously less than 5%. On the other hand, at the thickened oxide films that can be formed at Ru in a similar way to those at Ir, Cl_2 evolution rates are not found to increase with increasing CEF of the Ru oxide film. This is due to the different, impervious character of the oxide film at Ru in comparison with that at Ir as can be observed microscopically.

The rather sharp limit in activity enhancement, which is eventually reached with increasing CEF (Fig. 8), could then be explained in terms of two factors: (*i*) An increasing *IR* drop within the film (which would not be included in the experimentally measured *IR* drop in the solution due to the "RC" coupling in the equivalent circuit of the film itself) with increasing thickness that would account for falloff of the rate of activity increase with CEF, but hardly as sharp an inflexion as observed (Fig. 8); and (*ii*) a mass-transport problem that renders the innermost regions of the film inactive because of diffusion control limitation in Cl^- migration into pores and gas exit.

We can conclude, then, that the apparent large enhancement of electrocatalysis of the modified iridium oxide film for Cl_2 evolution is due mainly to an increase in real, microscopic surface area with increasing CEF. Also, that *IR* drop across the film, coupled with diffusion limitations, accounts for the leveling off of the activity at CEF's > 100. By comparison with the behavior of RuO_2 films, it is apparent that the d-electron configuration of the Ir oxide films could play some small but perhaps significant role in the electrocatalytic process, along lines suggested by Arikado *et al.* (3) for IrO_2, although compared to the area factor in the present case, it is a minor one. A model for the interfacial potential distribution across the metal/oxide/electrolyte system, dependent on state of oxidation of Ir in the oxide films, has been proposed and will be dealt with in more detail in a forthcoming publication (42).

Acknowledgments

Grateful acknowledgment is made to the Natural Sciences and Engineering Research Council of Canada for support of this work. One of us (J.M.) acknowledges the award of a CONICIT (Venezuela) graduate research scholarship.

We also wish to express our thanks to Mr. R. Myers for carrying out the SEM work and to Drs. H. Angerstein-Kozlowska and V. Birss, for discussions on noble metal surface oxidation.

Manuscript submitted Jan. 6, 1981; revised manuscript received *ca.* May 1, 1981.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1982 JOURNAL. All discussions for the June 1982 Discussion Section should be submitted by Feb. 1, 1982.

Publication costs of this article were assisted by the University of Ottawa.

Characteristic Differences in the Surface Space Charge Layer of the Red and Green Forms of Lutetium Diphthalocyanine

S. C. Dahlberg, C. B. Reinganum, C. Lundgren, and C. E. Rice*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The surface photovoltage of red and green forms of lutetium diphthalocyanine has been measured in a low pressure ($2 \cdot 10^{-9}$ Torr) environment and these two electrochemically interesting compounds have characteristic differences in their surface space charge layers. The green lutetium diphthalocyanine has an electron depletion layer, while the red material, prepared by iodization, has an electron accumulation layer. The photovoltage spectra are distinctive and are correlated with the differing optical absorptions of the colored films. The dependence of the dynamical response of the photovoltage on incident light indicates that photoinduced changes in the electronic populations of slow traps and/or surface states appear to be present.

The unusual electrochemical properties of the rare earth diphthalocyanines were first reported in 1965. Kirin, Moskalev, and co-workers reported that films of lutetium diphthalocyanine in aqueous potassium chloride could be changed from their initial green to either a blue or cinnamon red color with a variation of the applied voltage of less than 2V (1-6). This early work was reproduced by Nicholson and Pizarrello who also discovered several new colors and established that the switching times were on the order of 50 msec and thus were of obvious interest for use in electrochromic displays (7-11). The chemical species responsible for this behavior have not yet been completely established, but EPR observations by Corker *et al.* suggest that changes in the oxidation state of the phthalocyanine rings are responsible for the distinctive color changes (12). Nicholson and Pizzarello have reported that the color changes are sensitive to the presence of ambient gases, particularly oxygen, and that this could be due to the chemical binding of oxygen throughout the bulk of the film (10). Since these materials are organic semiconductors, their color change may be associated with changes in their surface space charge layer. Therefore, in order to further characterize the surface space charge regions of the differently colored forms, we have measured the photovoltaic change in the energy band bending at the surfaces of these films.

Experimental

The synthesis of the lutetium diphthalocyanine followed that reported by Moskalev and Kirin (4), and resulted in a mixture of mono- and diphthalocyanine complexes, which are green and blue, respectively, in DMF solution. The two products were separated by liquid chromatography in DMF on an alumina column, using DMF as eluent. Removal of the solvent from the faster-eluting blue fraction yielded the green form of lutetium diphthalocyanine along with some phthalonitrile starting material. This material was heated to 200°C in flowing N_2 gas to drive off the excess phthalonitrile and thin films were grown by vacuum sublimation ($3 \cdot 10^{-5}$ Torr) on both Ni substrates and glass slides. A red form of lutetium diphthalocyanine containing iodide counterions was prepared by heating the green films to 200°C for a few minutes in flowing I_2/N_2 gas, followed by pure N_2 gas to remove unreacted I_2. Films prepared in this manner appeared reddish-purple under reflected light and brown with transmitted light. This chemical approach to producing the red lutetium diphthalocyanine film is based on the work of Moskalev and Kirin (6), who found that the red films formed by iodization had a spectrum similar to those formed electrolytically. Both the red and green forms appeared to be stable in the air and their photovoltage did not degrade following the 250°C bakeup which was necessary to achieve a low pressure ($\sim 2 \cdot 10^{-9}$ Torr) in the surface photovoltage apparatus.

The retarding potential electron beam technique used for measuring the photovoltage has been described in detail in the literature (13, 14), and involves measuring the optical modulation of the transmission of low energy electrons incident on the surface. Measurement of the photovoltage spectra was obtained with phase sensitive lock-in detection and a mechanically chopped Xenon lamp, while the measurement of the dynamics of the photovoltage response were obtained with signal averaging and a pulsed dye laser. All of the reported photovoltage spectra have been corrected for variations in the relative lamp intensity. Optical absorption spectra were measured with a Cary 14 spectrometer.

Results and Discussion

Figure 1 illustrates the photovoltage spectrum measured for the green lutetium diphthalocyanine film in comparison with the optical absorption spectrum of the film on a glass slide. The optical absorption of the film has maxima at 705 and 670 nm and shoulders at 645 and 620 nm, in fairly close agreement to the 660 nm peak and shoulder reported for the green lutetium diphthalocyanine in solution (12). The photovoltage spectrum, on the other hand, is dominated by the peak at 800 nm, and has smaller maxima at 593 and 445 nm. Discrepancies between optical absorption and photovoltage spectra have been observed for other semiconductors, and are attributed to the fact that the photovoltage spectrum is determined both by the optical absorption and associated exciton creation, and by the subsequent dissociation of these excitons into free charge carriers (15, 16). Since this latter process depends both on the distance of the exciton from the surface and on the "allowed" or "forbidden" nature of the electronic transition, it depends on the wavelength of the light and the photovoltage spectra can thus differ somewhat from the optical absorption spectra. Figure 2 shows the photovoltage spectrum of the red lutetium diphthalocyanine film in comparison with the optical absorption of the yellow-red lutetium diphthalocyanine reported in the literature (12). The photovoltage spectrum has

* Electrochemical Society Active Member.
Key words: photovoltage, spectra, surface states.

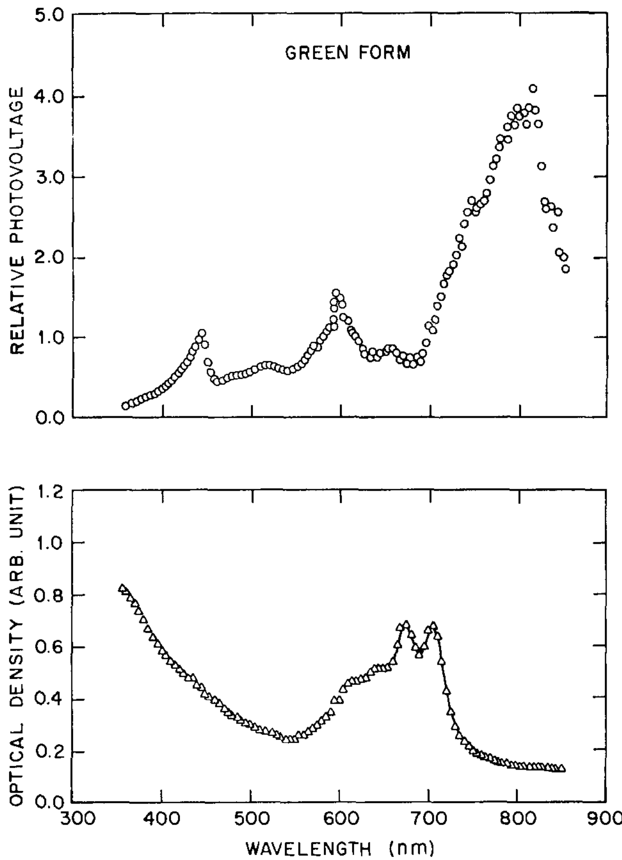

Fig. 1. Comparison between the photovoltage and optical absorption spectra of the green lutetium diphthalocyanine film. The photovoltage spectrum has been normalized to its value at 580 nm.

maxima at 742 and 427 nm, which is in reasonable agreement with the optical absorption maxima at 690, 660, and 470 nm. As with the green film, the slight discrepancy is attributed to a wavelength dependence for exciton dissociation. Comparing the data in Fig. 1 and 2 indicates that the distinctive differences in the photovoltage spectra of the two forms are associated with their differing optical absorption spectra.

Figure 3 illustrates the dynamical response of the photovoltage for both the green and red forms of the lutetium diphthalocyanine following 7 nsec laser pulse at time zero. The pulse repetition rate was 7 Hz, which allowed the samples sufficient time to recover a steady-state "dark" signal between pulses. The time dependence in Fig. 3 has the form $PV_0e^{-t/\tau}$, where PV_0 is the initial response to the laser pulse and τ is a characteristic exponential decay time. A nonlinear least squares fit of this equation to the data was used to obtain the values of PV_0 and τ reported in the figure caption. This exponential form of the photovoltage decay is consistent with the differential equation.

$$\frac{dPV}{dt} = -\frac{1}{\tau}PV \quad [1]$$

It is evident from Fig. 3 that the two forms differ in the sign of PV_0: The positive signal observed for the green form is consistent with electron depletion at the surface while the negative signal observed for the red form is indicative of electron accumulation at the surface (17).

Figure 3 showed the dynamic photovoltage response at 100% of the laser intensity. This experiment has been repeated for smaller intensities which were achieved with suitable neutral density filters and the

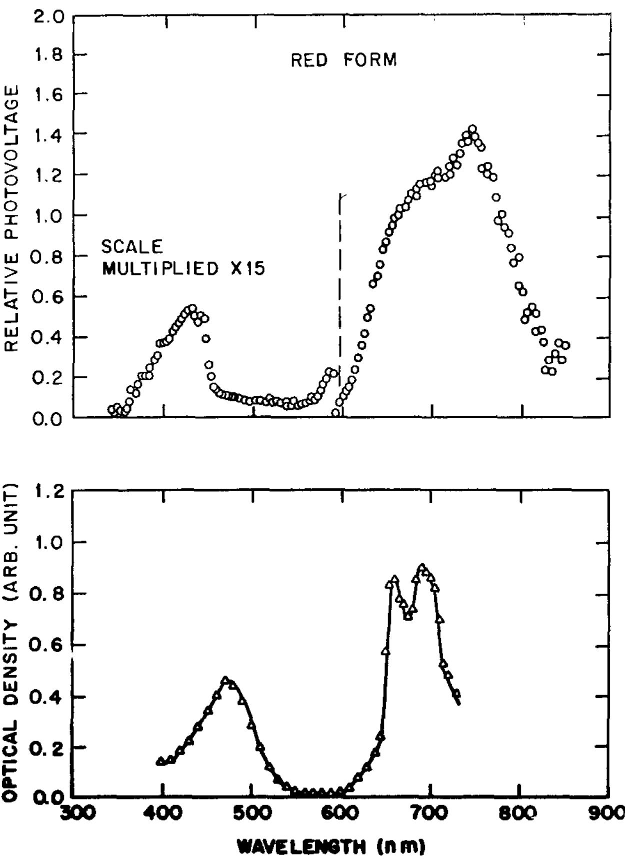

Fig. 2. Comparison between the photovoltage spectrum of the red lutetium diphthalocyanine film and its optical absorption in solution [Ref. (12)]. The photovoltage spectrum has been normalized to its value at 640 nm.

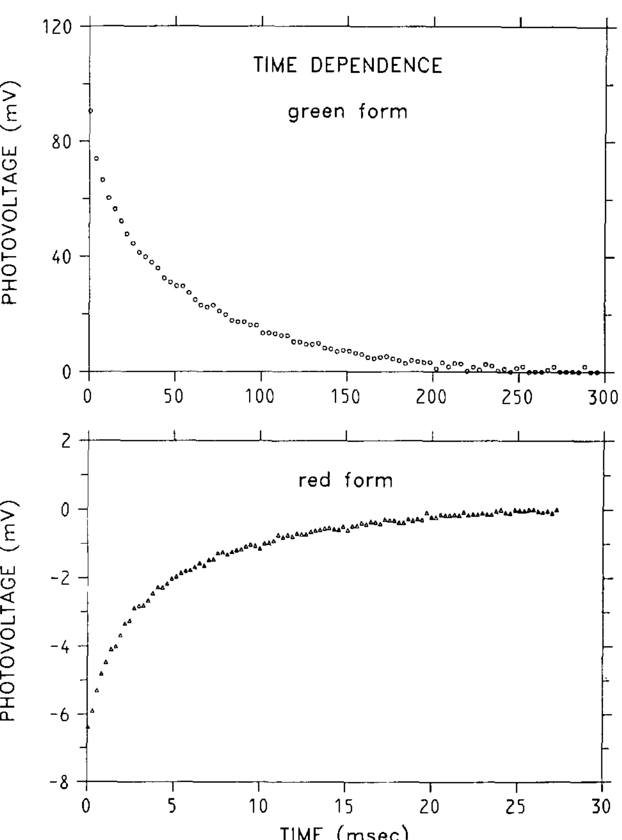

Fig. 3. The exponential decay of the photovoltage signal following a 7 nsec laser pulse at time zero. Because of differences in spectral response, the data for the green form were obtained at 580 nm while the red was at 640 nm. A nonlinear least squares fit was used to fit Eq. [1] to the experimental data: green (PV_0 = 90.5 mV, τ = 57.3 msec), red (PV_0 = −6.4 mV, 2.3 msec).

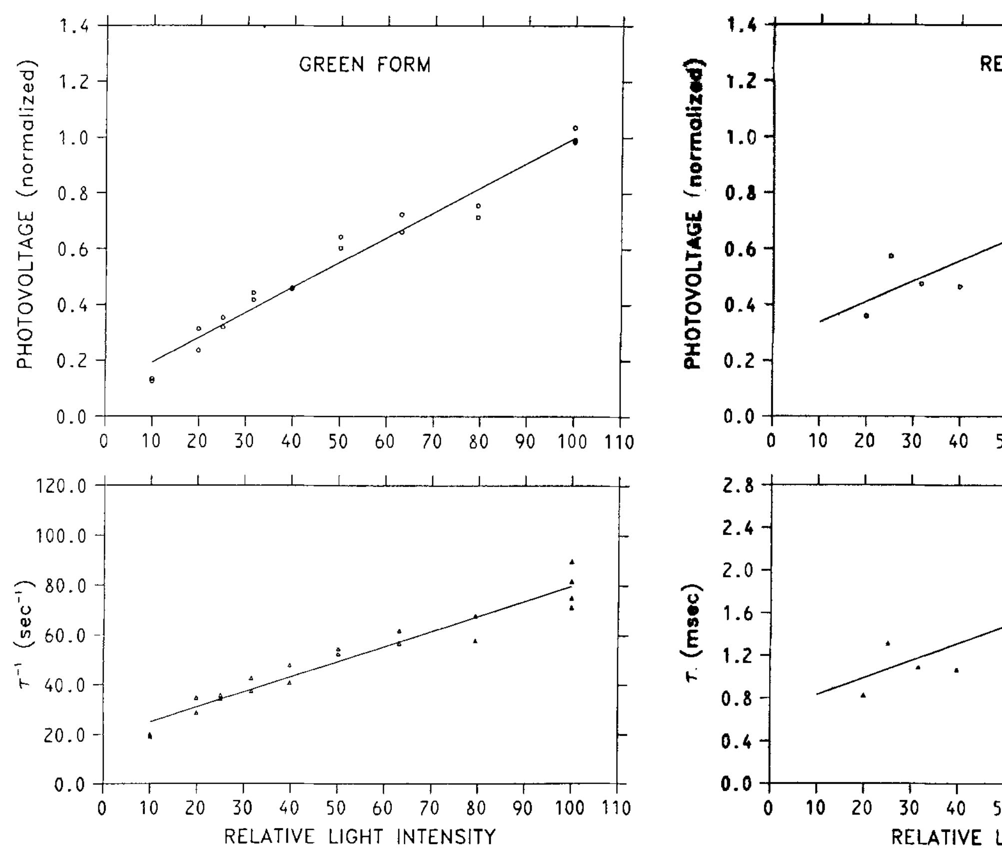

Fig. 4. The dependence of PV_0 and τ on light intensity for the green lutetium diphthalocyanine.

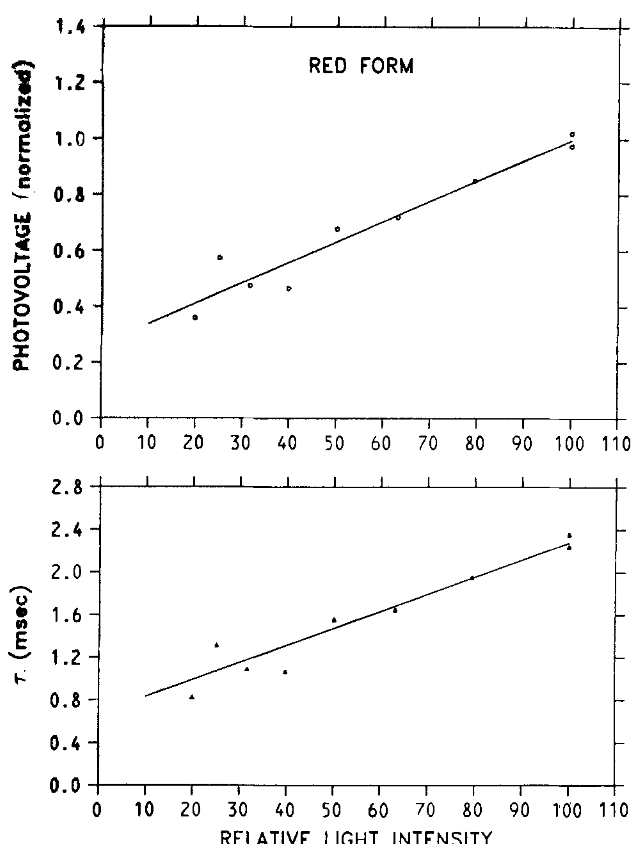

Fig. 5. The dependence of PV_0 and τ on light intensity for the red lutetium diphthalocyanine.

dependence of the resulting PV_0 and τ are illustrated in Fig. 4 and 5. For both the red and green forms of lutetium diphthalocyanine, PV_0 increases linearly with increasing light intensity over the range of intensities examined. This linear intensity dependence is observed when the photovoltaic change in the energy band bending is small compared to the total amount of band bending at the surface (V_d). This corresponds to the situation where the photovoltage is proportional to the minority carrier injection (Δ_{min}) which, in turn, is proportional to the light intensity (I) (18)

$$PV_0 \propto \Delta_{min} \propto I \quad \text{for} \quad PV_0 << V_d \qquad [2]$$

The data in Fig. 4 and 5 indicate, however, that the red and green forms differ in the intensity dependence of τ: τ is directly proportional to light intensity for the red form, but inversely dependent for the green form. In order to understand the underlying mechanism for this difference, it is necessary to consider the decay kinetics for the photoinjected minority carriers in these materials. Combining Eq. [1] and [2] yields

$$\frac{d\Delta_{min}}{dt} = -\frac{1}{\tau}\Delta_{min} \qquad [3]$$

This phenomenological rate law can be compared to the analogous expression derived from the photovoltage data for polyarene (16) and metal phthalocyanine (19) films

$$\frac{d\Delta_{min}}{dt} = \frac{-k \cdot PV}{V_d} \cdot \Delta_{min} \qquad [4]$$

where k is determined by the mobility of the minority carrier under flatband conditions. Equation [4] is obtained by assuming that the decay of the photovoltage is determined by the leakage current of minority carriers in the bulk to the surface against the opposing field of the space charge layer. Thus the rate at which photoinjected carriers can reach the surface varies with time since the electric field in the space charge layer is dependent on the decaying photovoltage. The decay kinetics in Eq. [4] therefore depend linearly on PV and this formula is applicable when PV_0 is appreciable compared to V_d. As noted previously in Eq. [2], however, the experimental results for lutetium diphthalocyanine indicate that PV_0 is small compared to V_d and therefore Eq. [3] is simply the limiting form of Eq. [4] which is appropriate when the electric field in the space charge layer is, to a first approximation, unchanged by the decay of the photoinjected minority carriers. Comparing Eq. [3] and [4] yields

$$\tau \propto \frac{V_d}{k} \qquad [5]$$

On the basis of Eq. [5], the dependence of τ on incident light intensity illustrated in Fig. 4 and 5 is simply originating in an intensity dependence of V_d and/or k. Not enough is known about the electrical characteristics of these rare earth diphthalocyanines to be able to predict with any certainty the exact origin of this intensity dependence. One reasonable possibility is that these materials have either bulk traps or surface states which change electronic population on a time scale which is slow compared to the 7 Hz repetition rate used in these experiments. (Faster electronic transitions would cause deviations from the experimentally observed exponential decay.) For example, both the red and green form of lutetium diphthalocyanine could have a photoexcited electronic transition from a filled surface state into the conduction band. For the green form, this would lower the band bending at the depletion layer and thus decrease τ with increasing intensity as seen experimentally in Fig. 4. In contrast, the same transition would increase the band bending at the accumulation layer of the red form and thus increase τ with increasing intensity which is consistent with the observations illustrated in Fig. 5.

Summary

The surface photovoltage of the red and green forms of lutetium diphthalocyanine have photovoltage spectra which are characteristically different and are related to the optical absorptions of these two electrochromic forms. Dynamical measurements indicate that the green form has an electron depletion layer, while the red form has an electron accumulation layer. Both films have a photovoltage which is linearly dependent on light intensity, which implies that the photovoltaic change in the band bending is small compared to the total amount of energy band bending at the surface. The photovoltaic relaxation is linearly dependent on light intensity for the red form and inversely dependent for the green form, and this is shown that this is consistent with the presence of long-lived traps which make the band bending and/or flatband mobility dependent on light intensity.

Mechanistic Study of Photoelectrochemical Reactions at a p-GaP Electrode

Kohei Uosaki and Hideaki Kita

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060, Japan

ABSTRACT

The photocurrent-potential relations of a p-GaP electrode in various solutions are studied potentiostatically. Both the cathodic and anodic photocurrents are observed, *i.e.*, the sign of photocurrent changes at a certain potential which we name the potential of zero photocurrent, V_{zp}. The potential of zero photocurrent is close but not equal to the flatband potential. The origin of the anodic photocurrent is presented. The log (photocurrent)-potential relations follow the Tafel line at medium bias potentials and deviate from it at large and small bias potentials. The mechanism of the cathodic reactions is proposed based on the experimental results. The rate-determining step is the supply of photoexcited electrons to the semiconductor surface at large bias potentials and is the electrochemical, *i.e.*, surface, process at medium and small bias potentials. At the small bias potentials, the photocurrent is enhanced by the photoelectrochemical reduction of oxidized species created by holes in valence band.

Photoeffects on electrochemical reactions at semiconductor electrodes have been studied very actively (1-10), particularly after Fujishima and Honda drew attention to the possibility of direct hydrogen production by a photo-driven electrochemical cell without any external electrical energy (11).

However, fundamental aspects of photoelectrochemical reactions such as reaction mechanism seem not to have been well understood. Most theoretical analyses neglected the potential drop in the electrochemical double (Helmholtz) layer (12) and the contribution of the charge transfer process to the overall reaction rate (13), although the importance of these contributions on the kinetics at semiconductor electrodes was pointed out by Green many years ago (14). We have been stressing the importance of the above contribution (15, 16) and have reported some supporting evidence (17). Recently, Bard *et al.* have used the word "Fermi-level pinning" to express the situation where the entire potential drop occurs within the Helmholtz layer and reported that this situation is not unusual (18).

In this work, we studied the photocurrent-potential relations at p-GaP, which is one of a few stable photocathodes (19), in various solutions to evaluate the reaction mechanism. The photoelectrochemical behavior of p-GaP has been studied very extensively (6, 15, 20-24) and it is reported that the flatband potential

Key words: semiconductor, photoelectrochemistry, energy conversion.

determined by capacitance measurement differs from the so-called critical potential or photocurrent onset potential (20, 21). This difference is usually explained by surface recombination without considering the electrochemical steps (20). The main concern of this paper is to analyze the photoelectrochemical behavior of p-GaP at small potential biases which represent the significant region for practical devices.

Experimental

A Zn-doped p-GaP single crystal wafer was used as a working electrode. The carrier density and the specific resistance of the sample are 6.7×10^{17} cm^{-3} and 1.3 Ω · cm, respectively. An ohmic contact was made by using In-Zn alloy and a copper wire was attached onto the ohmic contact by soldering. The semiconductor electrode surface was covered with epoxy resin except for (111) face (Ga) and was placed in a PTFE electrode holder. The surface area of the electrode was 0.0315 cm^2. The electrode surface was etched in HNO_3-HCl (1:1) solution before experiment. The electrochemical cell is similar to the one reported previously (15). An Ag/AgCl electrode and a Pt wire were used as a reference and a counterelectrode, respectively. A 500W Xe lamp (Ritsu Oyo Kogaku) was used as a light source and a potentiostat (Wenking Model 68 FRO.5) was used to control the electrode potential. An IRA-20 (Toshiba) filter was placed between the light source and the electrochemical cell to avoid a heat effect. Current-time relations were recorded by using a Toa Model CDR 11A recorder.

All solutions used in this work were prepared with triply distilled water and reagent grade chemicals. Purified helium gas was passed through the solutions for at least 30 min before experiments. All experiments were carried out at room temperature.

Results

The current-time relations of the p-GaP electrode in 1M NaOH at several electrode potentials illuminated with pulsed light are shown in Fig. 1. Steady photocurrents are observed at all potentials investigated, even at potentials very close to the flatband potential, V_{FB}, which is ~ −0.04V *vs.* Ag/AgCl (15). Further, the anodic photocurrent, which has not been reported at p-type semiconductor electrodes, is observed here at relatively positive potentials. Thus, the sign of the photocurrent changes at a certain potential. The steady photocurrents of this electrode in various solutions are plotted against the electrode potential in Fig. 2. In all cases, both the cathodic and anodic photocurrents are observed and the photocurrent-potential (I_{ph}-V) relations shift towards more negative potentials when the pH of the solution increases. The addition of methyl viologen changes the shape of the I_{ph}-V relation drastically.

The effect of time length kept in dark prior to the illumination is also examined. The steady photocurrent is not affected by changing the time length kept in dark at all potentials but the longer the time kept in the dark, the larger the initial photocurrent just after the illumination at potentials close to the flatband potential, as shown in Fig. 3.

Discussion

Origin of anodic photocurrent.—Usually, only a cathodic photocurrent is reported at p-type semiconductors and only an anodic photocurrent is reported at n-type semiconductors with the exception of a cathodic photocurrent observed at TiO_2 (n-type) (25). However, in this work, we found both the cathodic and anodic photocurrents at p-GaP electrode. The origin of the anodic photocurrent and the reason why it has not been reported are as follows.

The anodic currents at a semiconductor electrode in the dark, i_a, and under illumination, i_a*, are given by Eq. [1] and [2], respectively, with the assumption that

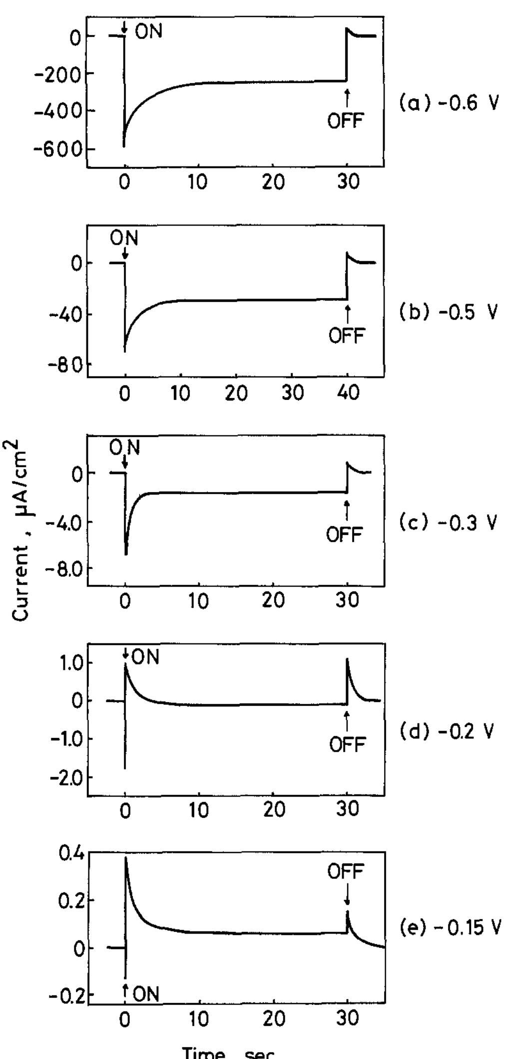

Fig. 1. Current-time relations of p-GaP in 1M NaOH at several potentials illuminated with pulsed light. Currents before illumination were taken as zero. Electrode potentials are with respect to Ag/AgCl.

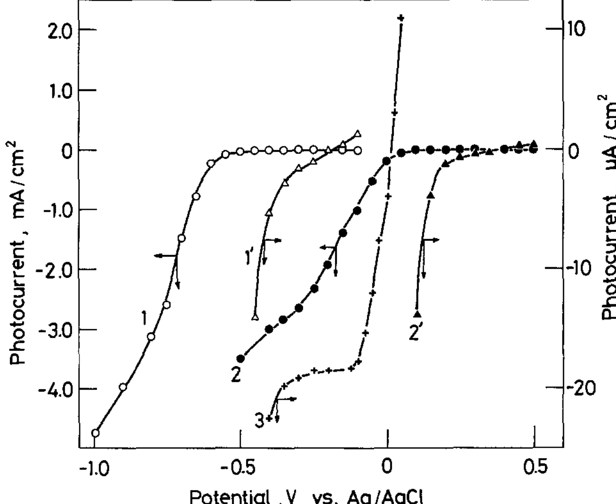

Fig. 2. The photocurrent-potential relation of p-GaP in various solutions with two current scales. 1,1′ in 1M NaOH, 2,2′ in 0.5M H_2SO_4, 3 in 1M NaOH + 1.7 mM methyl viologen.

the electron transfer takes place in a narrow energy range below the valence band energy, E_v (1)

$$i_a \propto c_R p_s W(E_v) G_R(E_v) \quad [1]$$

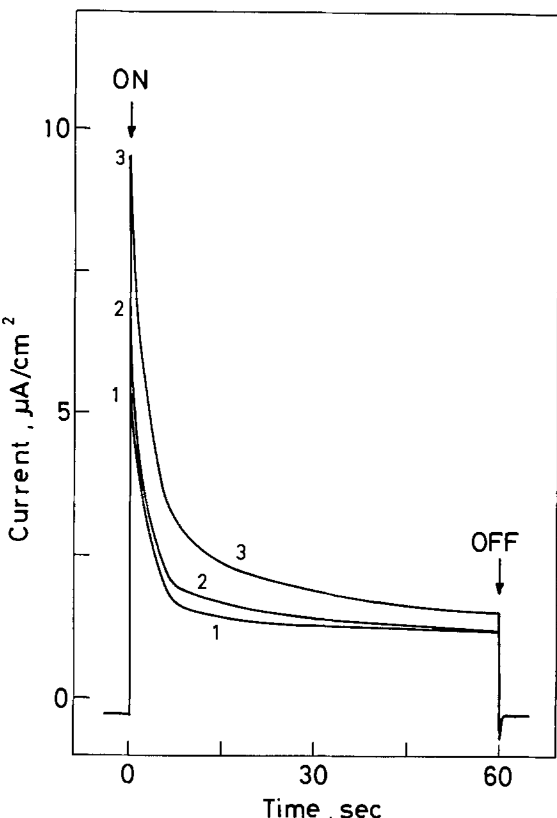

Fig. 3. The current-time relations of p-GaP in 0.5M H_2SO_4 at 0.2V *vs.* Ag/AgCl, for various lengths of time kept in the dark before illumination. Curve 1, 30 sec; curve 2, 2 min; curve 3, 10 min.

$$i_a^* \propto c_R p_s^* W(E_v) G_R(E_v) \quad [2]$$

where c_R is the concentration of reduced species and p_s and p_s^* are the number of holes at the semiconductor surface in dark and under illumination, respectively, $W(E_v)$ is the tunneling probability at the valence bandedge and $G_R(E_v)$ is the distribution function for finding the reduced species at the energy E_v. Thus, the anodic photocurrent, $i_{a,ph}$, is given by

$$i_{a,ph} = i_a^* - i_a \propto c_R(p_s^* - p_s) W(E_v) G_R(E_v) \quad [3]$$

Therefore, when $p_s^* - p_s > 0$, the anodic photocurrent should be observed at both n-type and p-type semiconductor electrodes. Since holes are the majority carriers of p-type semiconductors, p_s is large and, therefore, anodic dark current is large at the potentials where the anodic photocurrent is expected. Usually $p_s >> p_s^* - p_s$ and hence $i_a \simeq i_a^*$. This is why anodic photocurrent has not been reported at p-type semiconductor electrodes. For example, in the present work, $i_a = 8.54$ $\mu A/cm^2$ and $i_a^* = 10.0$ $\mu A/cm^2$ at $-0.1V$ *vs.* Ag/AgCl in 1M NaOH. The small difference between the two could be measured by the potentiostatic method employed in this work but is not possible to be detected by the sweep method which is usually employed in studying the current-potential relations at semiconductor electrodes.

In this system, the anodic reaction is the decomposition of the electrode itself, since no redox reagent is added (6, 26). The anodic decomposition potential of GaP has been calculated only at $pH = 7$ by assuming the following reaction (24, 27)

$$GaP + 6p^+ + 6H_2O \rightleftarrows Ga(OH)_3 + H_3PO_3 + 6H^+ \quad [4]$$

We reexamined the thermodynamic data (28-30) and calculated the anodic decomposition potentials of GaP for a wide pH range as shown in Table I. Anodic dissolution occurs at $pH < 2.56$ and $pH > 11.7$ and passive film is formed at $2.56 < pH < 11.7$. The decomposition potentials are within the bandgap of GaP for all pH range concerned and the reactions expected from the calculation agree with experimental findings (26). The existence of the anodic (dark) currents even at the potentials more negative than V_{FB} suggests that the reaction is very efficient in acid and alkaline solutions (6, 26).

Table I. The anodic decomposition reactions of GaP and corresponding potentials at various *p*H

$pH < 2$
$GaP + 6p^+ + 3H_2O \rightleftarrows H_3PO_3 + 3H^+$
$E = -0.357 - 0.0295\,pH + 0.00985 \log [Ga^{3+}] + 0.000985 \log [H_3PO_3]$
$2 < pH < 2.56$
$GaP + 6p^+ + 3H_2O \rightleftarrows Ga^{3+} + H_2PO_3^- + 4H^+$
$E = -0.337 - 0.0394\,pH + 0.00985 \log [Ga^{3+}] + 0.00985 \log [H_2PO_3^-]$
$2.56 < pH < 8.32$
$GaP + 6p^+ + 9/2\,H_2O \rightleftarrows 1/2\,Ga_2O_3 + H_2PO_3^- + 7H^+$
$E = -0.315 - 0.0690\,pH + 0.00985 \log [H_2PO_3^-]$
$8.32 < pH < 11.7$
$GaP + 6p^+ + 8\,OH^- \rightleftarrows 1/2\,Ga_2O_3 + HPO_3^{3-} + 7/2\,H_2O$
$E = -0.233 - 0.0788\,pH + 0.00985 \log [HPO_3^{2-}]$
$pH > 11.7$
$GaP + 6p^+ + 11\,OH^- \rightleftarrows GaO_3^{3-} + HPO_3^{2-} + 5H_2O$
$E = 0.170 - 0.108\,pH + 0.00985 \log [GaO_3^{3-}] + 0.0985 \log [HPO_3^{2-}]$

The thermodynamic values used for calculation are all taken from Ref. (28) for phosphorous compounds and from Ref. (29) for gallium compounds except for $\Delta G^\circ_f(GaP) = 91.54$ $kJ \cdot mol^{-1}$ which is taken from Ref. (30).

Photocurrent onset potential and flatband potential.—The photocurrent onset potential has a practical importance in a solar energy conversion. However, it is usually defined very vaguely (20, 21) in a similar way to the decomposition potential in electrode processes at metal electrodes which has no theoretical significance. In fact, the value of the photocurrent onset potential varies depending on the current scale chosen, as shown in Fig. 2. We propose here the definition of the photocurrent onset potential as the potential at which the sign of the photocurrent changes. By doing so, no ambiguity is introduced in determining the photocurrent onset potential. To distinguish this potential from the apparent photocurrent onset potential formerly used, we name it the "potential of zero photocurrent," V_{zp}. At V_{zp}

$$i_{ph} = |i_{ph,c}| - |i_{ph,a}| = 0 \quad [5]$$

$$\text{i.e.,} \quad |i_{ph,c}| = |i_{ph,a}| \quad [6]$$

Butler and Ginley reported that the difference between V_{FB} and the photocurrent onset potential is 0.7V for p-GaP (20). However, V_{zp} determined in this work are much closer to V_{FB} in various solutions, although there still exists some difference between them up to *ca.* 200 mV. It is usually believed that one would expect no photocurrent at V_{FB}, because holes and electrons created by illumination recombine easily under the absence of a potential gradient in the semiconductor. However, this is not necessarily true. If the diffusion length of holes is large and the anodic reaction at the valence band is faster than both the cathodic reaction at the conduction band and the surface recombination reaction, the photogenerated hole accepts either an electron from a reduced species in solution or a valence electron of the semiconductor before deactivation. Thus, an anodic photocurrent should be observed at V_{FB}, because the photocurrent observed, i_{ph}, is given by

$$i_{ph} = |i_{ph,a}| - |i_{ph,c}| \propto |c_R(p_s^* - p_s) W(E_v) G_R(E_v)| - |c_o(n_s^* - n_s) W(E_c) G_o(E_c)| \quad [7]$$

where c_o is the concentration of the oxidized species, n_s^* and n_s are the concentration of the electrons at the surface under illumination and in the dark, respectively, $W(E_c)$ is the tunneling probability for the cathodic reaction at the conduction bandedge, and $G_o(E_c)$ is the distribution function of oxidized species at the

energy E_c. Similarly, a cathodic photocurrent should be observed in the corresponding conditions. In other words, only when one of the conditions given in Eq. [8] and [9] is satisfied at V_{FB}, V_{FB} should coincide with V_{zp}

$$p_s^* - p_s = n_s^* - n_s = 0 \quad [8]$$

$$|c_R(p_s^* - p_s)W(E_v)G_R(E_v)| = |c_O(n_s^* - n_s)W(E_c)G_O(E_c)| \quad [9]$$

In the present system, the existence of the anodic dark current even at the potential more negative than V_{FB} (6, 26) suggests that the anodic reaction is considerably faster than the cathodic reaction near V_{FB}. Thus, from the above argument the presence of the anodic photocurrent is expected at V_{FB} in this case as experimentally observed.

In the solution containing methyl viologen, the V_{zp} is almost identical to the flatband potential. In this case, for the reaction $MV^{++} + e \rightleftarrows MV^{+\cdot}$ the condition given in Eq. [9] seems to be satisfied.

The photocurrent-potential relations and the reaction mechanism of photoelectrochemical reduction reactions.—The photoelectrochemical processes at cathodically polarized semiconductors are divided into two parts, namely, the bulk and the surface processes. The bulk processes are (*i*) absorption of photons and photoexcitation of electrons to the conduction band, *i.e.*, photogeneration of electron-hole pairs, (*ii*) migration of the photoexcited electrons to the semiconductor surface, and (*iii*) deactivation of the photoexcited electrons to the valence band, in parallel with (*ii*), *i.e.*, recombination in the bulk including space charge layer of the semiconductor. The surface processes are (*i*) electron transfer to an oxidized species followed by chemical, electrochemical, and/or desorption processes in some cases, (*ii*) deactivation of the photoexcited electrons to the valence band at the surface directly or via surface states, *i.e.*, surface recombination.

Equations [10]-[12] summarize the bulk processes

$$h\nu \rightarrow p_v^+ + e_c^- \quad [10]$$

$$e_c^- \rightarrow (e_c^-)_s \quad [11]$$

$$e_c^- + p_v^+ \rightarrow \text{recombination} \quad [12]$$

where p_v^+ is the hole in the valence band and $(e_c^-)_s$ and e_c^- are the electrons in the conduction band at the surface and at other places, respectively. The surface processes for hydrogen evolution reaction are

$$(e_c^-)_s + H_3O^+ + S.C. \rightarrow H_2O + S.C. - H \quad [13]$$

$$(e_c^-)_s + H_3O^+ + S.C. - H \rightarrow H_2 + H_2O + S.C. \quad [14]$$

$$S.C. - H + S.C. - H \rightarrow H_2 + 2S.C. \quad [15]$$

$$p_v^+ + H_2O + S.C. - H \rightarrow S.C. + H_3O^+ \quad [16]$$

and those for the recombination are

$$(e_c^-)_s + (p_v^+)_s \rightarrow \text{Surface recombination} \quad [17]$$

$$(e_c^-)_s + \square_{ss} \rightarrow \blacksquare_{ss}$$
$$\blacksquare_{ss} + (p_v^+) \rightarrow \square_{ss} \quad [18]$$

where S.C. is the semiconductor, S.C. – H represents hydrogen atom adsorbed on the semiconductor, $(p_v^+)_s$ is the hole in the valence band at the surface, $\square_{ss}$ is the unoccupied surface state, and $\blacksquare_{ss}$ is the occupied surface state. The step expressed in Eq. [18] is the surface recombination via surface state. The combination of step [13] and step [16] could be called the surface recombination via adsorbed hydrogen state (31). For the reduction of methyl viologen, Eq. [13]-[16] should be replaced by the following

$$(e_c^-)_s + MV^{++} \rightarrow MV^{+\cdot} \quad [19]$$

$$MV^{+\cdot} + (p_v^+)_s \rightarrow MV^{++} \quad [20]$$

To elucidate the mechanism of the photoelectrochemical reduction reactions at the p-GaP electrode in a wide potential range, the photocurrents in logarithmic scale are plotted against the electrode potential in Fig. 4. The log (i_{ph}) – V relations follow the Tafel line at medium biased potentials (–0.4 ~ –0.7V in 1M NaOH and +0.2 ~ –0.05V in 0.5M H_2SO_4) and deviate from it at large and small bias potentials. It is interesting to note that the slopes of the Tafel line are similar to those of hydrogen evolution reaction at metal (Ga) electrodes (32).

The shape of log (i_{ph}) – V relations at large cathodic potential biases suggests that the rate-determining step in this potential region is some transport-limited process. The deviation occurs at *ca.* –0.7V *vs.* Ag/AgCl in 1M NaOH both with and without methyl viologen. This potential coincides with the apparent photocurrent onset potential determined by $i_{ph}^2 - V$ relation based on a simple Schottky barrier model with the assumption that electrochemical processes are fast and step [11] is the rate-determining process (20). Thus, the supply of the photogenerated electrons to the semiconductor surface seems to be the rate-determining step at the potentials more negative than *ca.* –0.7V *vs.* Ag/AgCl in 1M NaOH and *ca.* –0.05V *vs.* Ag/AgCl in 0.5M H_2SO_4.

Butler and Ginley proposed that step [18], *i.e.*, surface recombination via surface state, is responsible for the discrepancy between V_{FB} and the apparent photocurrent onset potential determined by $i_{ph}^2 - V$ relation (20). They concluded from *IR* photoresponse measurement that the localized state which is ~0.7 eV above the top of the valence band acts as the recombination center. According to their model, the photocurrent at steady state, i_{ph}, is given by

$$i_{ph} \propto j - k_r[e_c^-]_s N_{ss}(1 - f_t) \quad [21]$$

where j is the flux of the photogenerated electrons arriving at the surface, k_r is the rate constant of the surface recombination reaction, N_{ss} is the number of surface states, and f_t is the Fermi distribution function

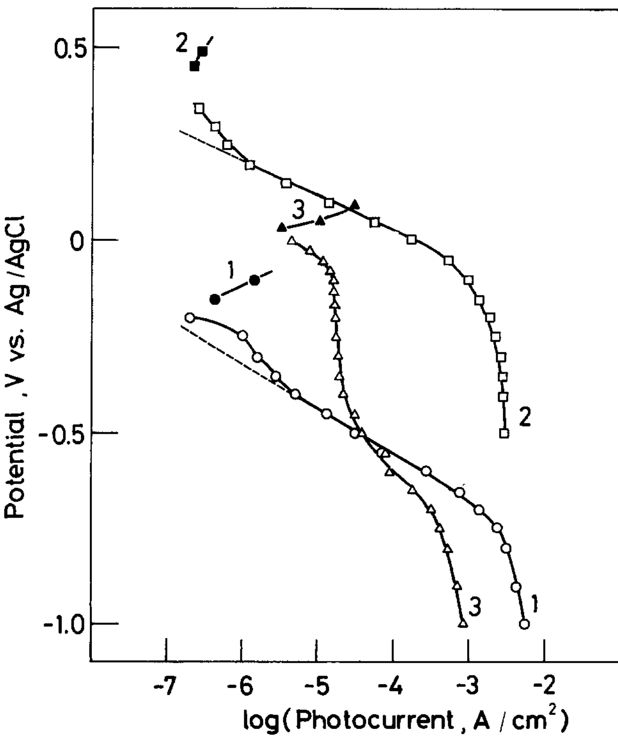

Fig. 4. Tafel plots of the photocurrents of p-GaP in various solutions. Curve 1, 1M NaOH; curve 2, 0.5M H_2SO_4; curve 3, 1M NaOH + 1.7 mM methyl viologen.

for the surface states. For the present system, if all potential drop occurs within the semiconductor, f_t is given by

$$f_t = 1/[1 + \exp\{E_t - E_F/kT\}]$$
$$= 1/[1 + \exp\{0.7 - (V_{FB} - V)/kT\}] \quad [22]$$

where E_t is the energy of the surface states and V is the electrode potential concerned. Since $(1 - f_t)$ changes from 0 to 1 sharply around -0.7V *vs.* V_{FB}, one would expect sharp change in the photocurrent potential relation at that potential and not be able to explain the potential dependence of the photocurrent at relatively small bias potential (Tafel relation) where $1 - f_t = 1$ by considering the surface recombination via surface states only.[1] The effect of methyl viologen on $i_{ph} - V$ relation gives some clue to evaluate the mechanism. In this case, the photocurrent is larger than that without MV^{++} at low bias potentials. This can be explained as follows.

The rate-determining step of the hydrogen evolution reaction at this potential range is one of the steps expressed by Eq. [13], [14], or [15], *i.e.*, the electrochemical process. The electrochemical reaction rate of MV^{++} is faster than that of hydrogen evolution reaction and therefore much larger current is observed when MV^{++} is added. The fact that V_{zp} with MV^{++} is more positive than that without MV^{++} also supports the fact that the cathodic reaction of MV^{++} is faster than hydrogen evolution reaction. The i_{ph} with MV^{++} is smaller than that without MV^{++} at relatively negative potentials. It is due to absorption of light by $MV^{+\cdot}$ created by photoelectrochemical reduction of MV^{++}.

The log $(i_{ph}) - V$ relations deviate from the Tafel line again at the potentials near V_{FB}, suggesting some faster reaction is involved. At this region, the initial photocurrent just after illumination depends on the length of time kept in the dark prior to illumination, as shown in Fig. 3. Also, the anodic dark current starts to flow at this potential region. Thus, this deviation should be due to the photoelectrochemical reduction of oxidized species created by dark oxidation reaction by holes in the valence band, as shown in Fig. 5. If the reduction of the oxidized species is faster than the hydrogen evolution reaction, much larger current is expected at a given potential. It is essentially the same effect as the addition of MV^{++}. The effect of the time kept in the dark is explained as the accumulation of oxidized species in the dark.[2]

In the small bias potential region where log $(i_{ph}) - V$ relation deviates from the Tafel line, the stability of p-GaP is in doubt even though the net cathodic photocurrent is observed, because the deviation is caused by the photoelectrochemical reduction of oxidized species which is the anodic decomposition product of GaP in this case. Since for practical devices, the potential bias would be small, the stability of p-GaP in this potential region should be studied more in detail.

[1] R. H. Wilson proposed a model which takes into account both the surface recombination rate and charge transfer rate for n-type semiconductors (33, 34).

[2] The fact that the height of the photocurrent spike just after illumination is much smaller when the solution is stirred supports this mechanism.

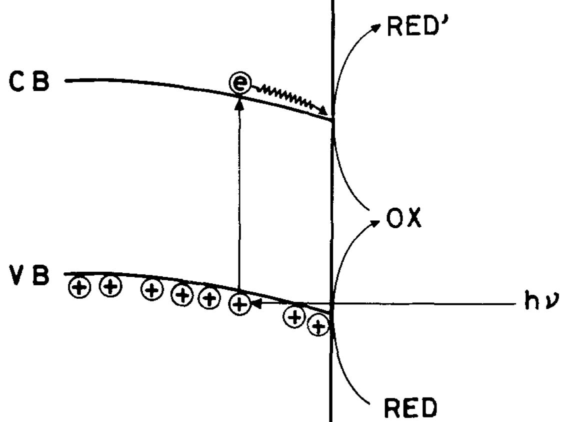

Fig. 5. Contribution of oxidized species created by hole to photocurrent enhancement at relatively small bias potential.

Semiconductor Electrodes

XXXVII. Photoelectrochemical Behavior of p-Type Cu_2O in Acetonitrile Solutions

G. Nagasubramanian, Alberto S. Gioda, and Allen J. Bard*

Department of Chemistry, The University of Texas, Austin, Texas 78712

ABSTRACT

The photoelectrochemical behavior of polycrystalline p-Cu_2O in acetonitrile solutions containing a number of redox couples [*e.g.*, phthalonitrile (0/−1), nitrobenzene (0/−1), methyl viologen (+2/+1)] was investigated. The p-Cu_2O, grown by oxidation of Cu metal by thermal methods or anodization, showed stable behavior under optical irradiation in these solutions. The bandgap, estimated from photoacoustic spectroscopy (PAS) and the photocurrent action spectrum in solution, was ~2.0 eV and the flatband potential was ~ +0.16V *vs.* SCE. Scanning electron micrographs of the thermally grown samples reveal well-developed crystallites with distinct boundaries. A PEC cell of the form p-Cu_2O/$Ph(CN)_2$,MeCN/Pt was shown to have an overall optical-to-electrical energy conversion efficiency of only 0.05%. The low efficiency for such a cell is ascribed to rapid recombination processes in the bulk semiconductor and at the interface.

Cuprous oxide (Cu_2O), which crystallizes in a cuprite structure is a catalyst of choice for a diverse variety of chemical reactions (1-4). The optical and electrical properties of p-Cu_2O depend upon the conditions of preparation from Cu and O_2, *i.e.*, the temperature and oxygen pressure (5). Several workers (6-11) have studied the electrical properties of single crystals of this material and demonstrated that it is a p-type semiconductor whose hole conductivity can be attributed to copper ion vacancies which act as acceptors for electrons from the valence band. Recently, Trivich *et al.* (12) studied solid-state photovoltaic cells based on this material and reported an overall conversion efficiency of optical to electrical energy approaching 1% and stated that efficiencies of 6-12% should be possible. Aqueous photoelectrochemical (PEC) cells involving p-Cu_2O have also been described (13-14). In these cells the p-Cu_2O photocathode is unstable and under irradiation is reduced to Cu metal

$$Cu_2O + 2H^+ + 2e \rightarrow 2Cu + H_2O \quad [1]$$

Similar instability was observed with CuO electrodes (15). In an aprotic solvent such as acetonitrile (MeCN), however, such a reduction reaction is less favorable because of the unavailability of protons. Since the bandgap is 1.9-2.0 eV, and the reported efficiencies for photovoltaic devices appeared interesting and the material is inexpensive, abundant, and capable of being readily produced in thin film form, we undertook a study of the PEC properties of p-Cu_2O prepared by thermal and anodic oxidation of metallic copper in MeCN. The polycrystalline compacts were prepared by heating a Cu plate in air to minimize the grain boundary effects encountered in the case of sintered powder compacts (16). Studies of the PEC behavior of p-Cu_2O were carried out with MeCN containing several redox couples including phthalonitrile, $Ph(CN)_2$(0/−1), nitrobenzene, $PhNO_2$(0/−1), and methyl viologen MV (+2/+1). Photocathodes of p-Cu_2O were shown to be stable in these solutions under intense optical irradiation. However, the overall optical-to-electrical energy conversion efficiencies in the PEC cells based on this material were low (< 0.1%).

Experimental

Chemicals.—The procedures for the purification of chemicals and solvent (MeCN) are given elsewhere (17). All compounds were stored inside a helium-filled Vacuum Atmosphere Corporation (Hawthorne, California) glove box. Polarographic grade, tetra-n-butyl ammonium perchlorate (TBAP), dissolved and recrystallized from ethanol thrice and dried under vacuum ($< 10^{-5}$ Torr) for three days, was used as supporting electrolyte. The cell employed was a conventional two-compartment cell of 25 ml capacity containing the p-Cu_2O, a Pt counterelectrode, and a quasi-reference electrode which was an Ag wire immersed in the solution and separated from the main compartment by a medium porosity glass frit. The potential of the electrode was checked against an aqueous saturated calomel electrode (SCE) at regular intervals and was found to be constant. All potentials reported here, unless specified otherwise, are given in V *vs.* SCE.

P-Cu_2O was prepared by the method of Trivich *et al.* (12, 18). A Cu plate, 0.8 mm thick (Alfa Ventron), was cut to a 2 × 2 cm square, polished with Al_2O_3 (0.5 μm), washed with acetone, and rinsed thoroughly with double distilled water. The plates were dried and heated in a muffle furnace at about 900°C for 24 hr. Subsequently, the furnace temperature was raised to 1030°C and the samples were heated for an additional 160 hr. The furnace temperature was then reduced to 500°C and at this temperature, the samples were annealed for a day, before quenching them in air at room temperature. Upon quenching, the CuO layer formed

at the surface peels off, exposing the Cu_2O sintered compacts. The resistivity of the material after polishing with an ultrafine emery paper was ~ 30-40 Ω cm. An ohmic contact can be formed by either electroplating the back with gold or partial reduction in an H_2 atmosphere at 100°-125°C for 30 min. A copper wire lead formed the electrical contact and was attached to the gold-coated side with silver epoxy cement (Allied Product Corporation, New Haven, Connecticut). This contact was subsequently covered with 5 min epoxy cement. The assembly was mounted into 7 mm diam glass tubing and was held in position with a silicone rubber sealant (Dow Corning Corporation, Midland, Michigan), which also served as an effective seal against the seepage of electrolyte solution to the rear of the semiconductor electrode. The exposed area of p-Cu_2O was 0.14 cm^2. The etching procedures are given below. The material produced by the Cu-air reaction was shown to be Cu_2O by x-ray diffraction. The x-ray diffraction patterns corresponded to those reported in the literature (ASTM card Index No. 5.0667).

The p-Cu_2O films formed by anodic polarization of a Cu electrode were grown under either linear potential sweep or constant current conditions in aqueous NaOH solutions, mainly, following the procedures described by Marchiano *et al.* (19) and Ashworth and Fairhurst (20). The pretreatment of the Cu electrodes prior to oxidation described in the above papers was employed. Prepurified N_2 was bubbled for 1 hr through the NaOH solutions, prior to and during the experiments, and an N_2 atmosphere was maintained over the solutions during the anodizations. The potential sweeps were performed at scan rates of 0.02, 0.2, or 1.0 mV/sec with the initial potential at −0.8V (for 0.02 mV/sec) or −1.20V (for 0.2 and 1.0 mV/sec) *vs.* SCE. The galvanostatic runs were performed at the current densities reported in Ref. (20).

Apparatus.—A Princeton Applied Research (PAR) Model 173 potentiostat and PAR Model 175 Universal programmer were used in all experiments with positive feedback *iR*-compensation employed to compensate for solution resistance and internal resistance of the electrode. The *i-V* curves were recorded on a Model 2000 X-Y recorder (Houston Instruments, Austin, Texas). In solar cell experiments, the photovoltage and photocurrent between the working electrode and counterelectrode as a function of load resistance were measured with a Keithley Model 179, TRMS Digital Multimeter. The light source was an Oriel Corporation (Stamford, Connecticut) 450W xenon lamp. Differential capacitance was measured with a PAR Model HR 8 lock-in amplifier. All of these solutions were prepared in the glove box and the cell then sealed and removed for the experiments.

Etchants.—(A) For thermally grown p-Cu_2O, the following etchants were tried: (1) 12M HNO_3, (2) 6M HNO_3, (3) H_2SO_4:H_2O_2:H_2O; 3:1:1 (by volume), (4) HNO_3:H_3PO_4:acetic acid; 17:41.5:41.5 (by volume). In etchants (1), (2), and (3), the etching time was limited to 10-15 sec while for (4) the samples were kept immersed for 15 min. Procedure (1) exposed well-developed large Cu_2O-crystallites while (2) and (3) showed small Cu_2O crystallites. Procedure (4) produced a smooth and shiny surface. (B) The anodically produced films were etched with either (1) 0.01M or (2) 0.1M HNO_3 for 1-2 sec.

Results and Discussion

Capacitance measurements.—The location of the energies corresponding to the edges of the valence and the conduction bands, E_v and E_c, respectively, of the semiconductor electrode with respect to solution energy levels, is useful in the selection of appropriate redox couples for optimizing PEC cell performance. These are usually found by determination of the flatband potential, V_{FB}, by measurement of the electrode capacitance as a function of applied potential. If this capacitance corresponds to the semiconductor space-charge capacitance, V_{FB} and the acceptor density (N_A) can be computed from Mott-Schottky plots (21-23). From these values, the known or estimated effective mass of charge carrier and the bandgap, the band positions (*i.e.*, E_c and E_v) can be located.

A dielectric constant of 7.11 (24) and an effective mass of charge carriers $0.84m_o$ (25) was employed. The bandgap was measured by two methods which are described in the next section; the value determined from the photocurrent action spectrum was employed in the location of the bandedge. The capacitance of p-Cu_2O was measured in MeCN containing TBAP as supporting electrolyte at different frequencies from 100 to 5000 Hz; Mott-Schottky plots are given in Fig. 1. The V_{FB} value determined at low frequencies (100 and 500 Hz) was located ~ 20 mV positive of that at high frequencies (2 and 5 kHz). Hence, an average value was taken for computation. These plots were essentially the same after repeated experiments over several hours and were unaffected by the addition of the reducible compound phthalonitrile to the solution. From these plots we estimate V_{FB} as + 0.16V *vs.* SCE and $N_A \cong 4.9 \times 10^{16}$ cm^{-3}.

Bandgap.—The bandgap energy, E_g, of p-Cu_2O was determined by two independent methods: From the photoacoustic spectrum of the sample in air (26) and from the photocurrent action spectrum in MeCN/TBAP, $Ph(CN)_2$. The results of these experiments are shown in Fig. 2(a) and (b). Note that a plot of $(\eta h\nu)^2$ *vs.* $h\nu$ gives a straight line, suggesting that the optical transition in Cu_2O is direct and yields an E_g of 2.00 eV. The photoacoustic spectrum signals an onset of light absorption at 638 nm, corresponding to an E_g = 1.94 eV. The bandedge energies were obtained by assuming the Fermi-Dirac equation

$$N_A = N_v \left[1 + 2e^{(E_v - E_f)/kT}\right]^{-1} \quad [2]$$

$$N_v = 2(2\pi m_p^* kT/h^2)^{3/2} \quad [3]$$

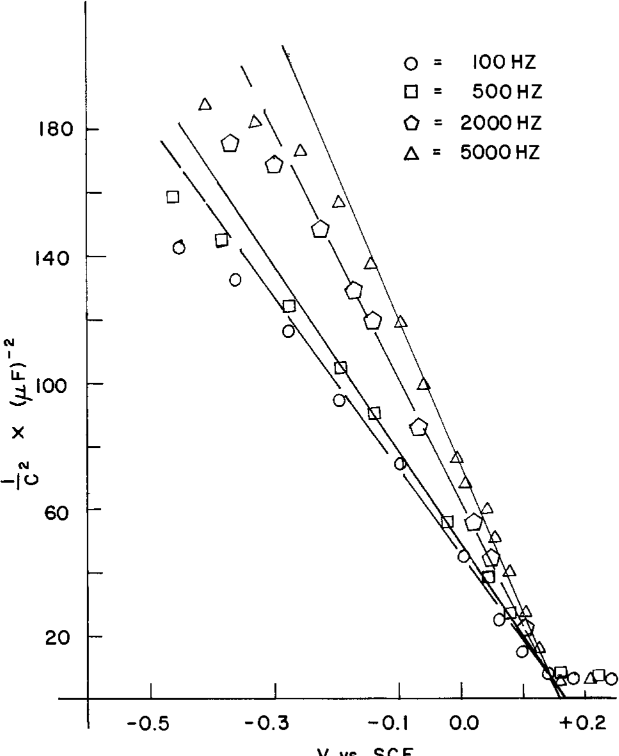

Fig. 1. Mott-Schottky plot of p-Cu_2O, in MeCN containing 0.1M TBAP supporting electrolyte. ○ = 100 Hz; □ = 500 Hz; ⬠ = 2000 Hz; and △ = 5000 Hz.

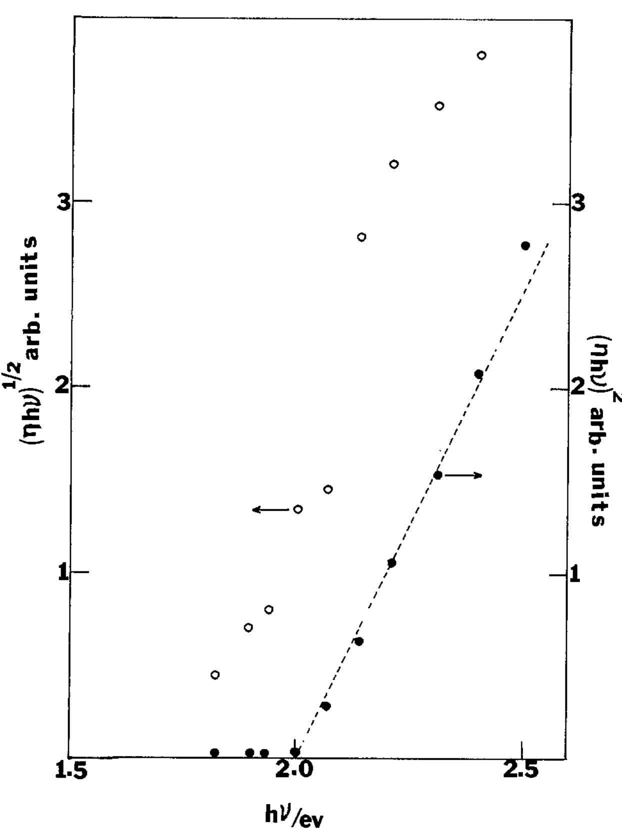

Fig. 2a. Plot of $h\nu$ vs. $(\eta h\nu)^{n/2}$ where $n = 1$ and 4. The value of η at different wavelengths has been computed from photocurrent action spectrum for p-Cu_2O in MeCN/0.1M TBAP, 10 mM $Ph(CN)_2{}^{0/-1}$/Pt solar cell.

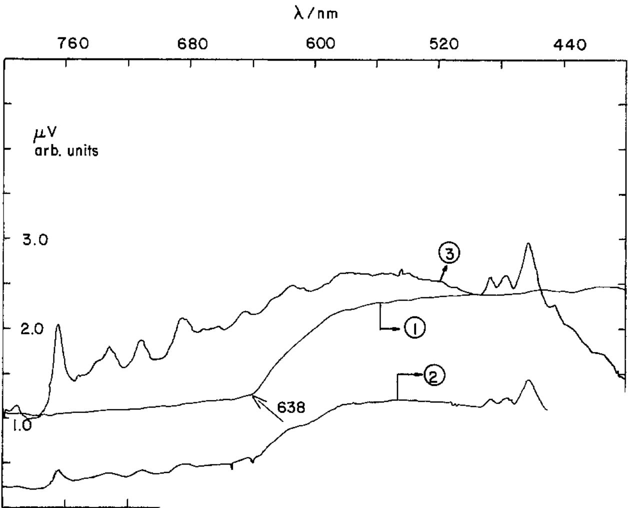

Fig. 2b. Absorption spectrum of p-Cu_2O (photoacoustic technique) (curve 2). Corrected action spectrum of the short-circuit photocurrent of p-Cu_2O (curve 1). Curve 3, background action spectrum of the 2.5 kW xenon lamp.

where N_v is the density of states in the valence band; E_f is the Fermi level energy (corresponding to V_{FB}); and $m_p{}^*$ is the effective mass of holes. This yielded the position of the VB edge about 0.1 eV below the Fermi level, *i.e.*, at + 0.26V *vs.* SCE. From the value of E_g, 2.0 eV, E_c is placed at − 1.74V *vs.* SCE. These levels are shown in Fig. 3, along with the potentials for the solution redox couples employed in this study.

Cyclic voltammetry.—To study the photoinduced electron transfer to reducible molecules in solution, the cyclic voltammetric (CV) response at p-Cu_2O in the dark and under illumination was compared to that ob-

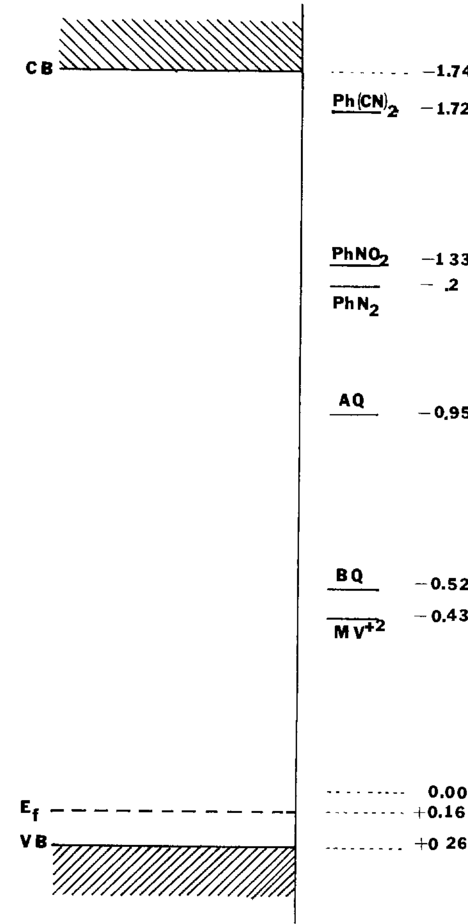

Fig. 3. Schematic representation of the energetic situation at p-Cu_2O/solution interface along with V_{redox} of various redox couples investigated in this work. served for these systems at a platinum electrode. At platinum, near-reversible CV behavior is observed, so that the redox potential of the couple can be obtained. The procedures and interpretations generally followed previous studies from this laboratory (17, 27-29).

The range of stability for the electrode in the absence of an added redox couple was determined from the CV behavior of p-Cu_2O in MeCN containing TBAP alone, as shown in Fig. 4(a). The dark current was very small up to − 1.8V *vs.* SCE. Under illumination, no photocurrent was observed up to − 1.5V. However, at more negative potentials a small and unstable photoinduced cathodic current was found, which probably involves reduction of the Cu_2O electrode perhaps involving trace impurities (*e.g.*, H_2O) in the solvent.

The addition of a reducible substance to the MeCN/TBAP solution generally did not produce an appreciable increase in the dark cathodic current for potentials up to − 1.60V, demonstrating the expected absence of dark electron transfer to solution species at the p-type semiconductor/liquid interface. Under illumination, however, the photogenerated electrons at energies corresponding to the conduction bandedge can transfer to solution species, and significant photocathodic currents are produced. For example, the CV reduction of phthalonitrile [$Ph(CN)_2$] on Pt, given in Fig. 4(b), shows a reversible wave for the reduction to the radical anion at − 1.72V *vs.* SCE. On p-Cu_2O, only a small dark reduction current is seen (Fig. 4c). However, under illumination, significant cathodic current flows with the onset at potentials more positive than those for reduction at Pt (Fig. 4d). Note, how-

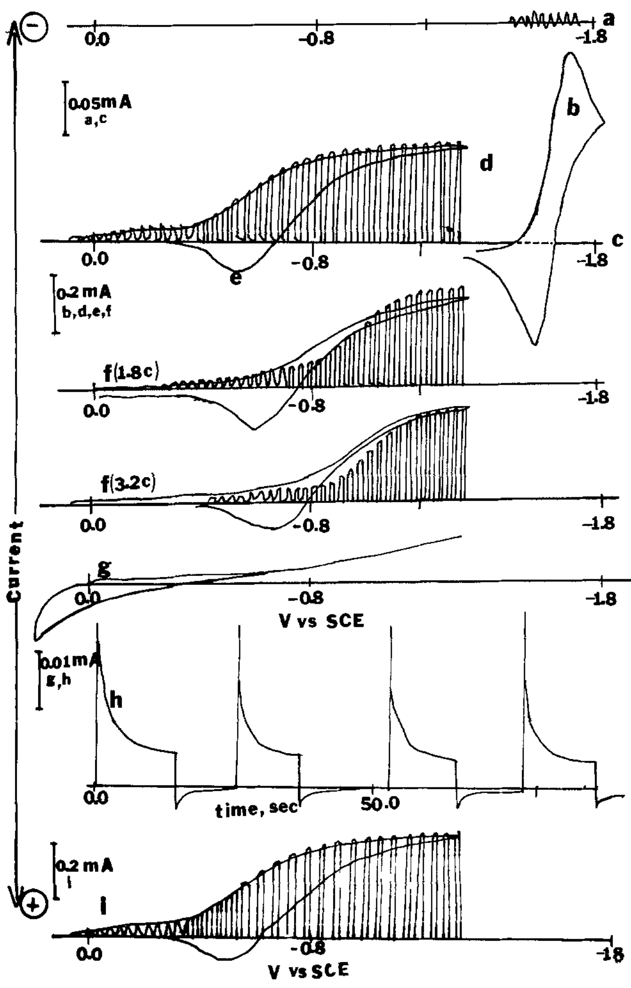

Fig. 4. Voltammetric curves of Pt and p-Cu_2O in MeCN containing 10 mM ($Ph(CN)_2$; 0.1M TBAP (supporting electrolyte). Light source, 450W xenon lamp. Scan rate = 50 mV/sec. (a) C-V curve on p-Cu_2O in dark and under illumination in MeCN containing 0.1M TBAP only; (b) cyclic voltammogram at Pt; (c) dark voltammetric curve on p-Cu_2O; (d) C-V characteristics under chopped light in p-Cu_2O before generating radical anions, in the dark; (e) C-V characteristic curve of p-Cu_2O under continuous illumination; (f) same as in (a-e) but after electrochemically generating anion radicals; (g) C-V curves on p-Cu_2O in dark after electrochemically generating anion radicals; (h) transient i-t curves of p-Cu_2O. The electrode was biased at −0.5V vs. SCE; (i) same as in (a-e) but after irradiation for 6 hr, p-Cu_2O electrode was biased at −0.3V vs. SCE.

ever, that although there is a considerable "underpotential" for the start of the reduction of $Ph(CN)_2$, the cathodic photocurrent rises rather slowly with potential and only attains a limiting value at ~ −0.9V. This slow rise in cathodic photocurrent can be attributed to appreciable oxidation of the photogenerated reduced species, $Ph(CN)_2^{\overline{\cdot}}$, at potentials between the onset potential and the limiting one. This oxidation of the reduced form is apparent from the reverse scan (Fig. 4e), where the current crosses the zero current axis at more negative potentials than the original onset potential and the presence of photogenerated radical anion, $Ph(CN)_2^{\overline{\cdot}}$ causes an anodic current flow. Similarly, if the initial scan is carried out with a solution that contains both parent and radical anion, the onset potential occurs at more negative values, ~ −0.6V *vs.* SCE (Fig. 4f). Moreover, as the concentration of radical anion is increased, the onset potential also shifts toward more negative values. In Fig. 4g is shown the effect of radical anion on the behavior of p-Cu_2O in dark. The dark oxidation current begins at −0.6V. Thus the back-oxidation of $Ph(CN)_2^{\cdot}$ leads to the observed shape of the photocurrent-potential curve and the fact that the photocathodic current remains small up to −0.5V *vs.* SCE, even though the onset of photocurrent occurs near the flatband potential. The presence of surface recombination or back-reaction below −0.5V *vs.* SCE is also demonstrated by the transient photocurrent-time behavior of p-Cu_2O in MeCN containing TBAP, $Ph(CN)_2^{0/-1}$ (Fig. 4h). Upon illumination, the cathodic current shows a sharp increase, but then rapidly drops off as radical anion accumulates at the electrode surface. When the light is turned off, the current drops and an anodic current spike appears, representing oxidation of radical anion. At more negative potentials (*e.g.*, −0.9V), only a flat photocathodic current transient appears, with no anodic dark transient. After continuous illumination for 6 hr, with the p-Cu_2O electrode held at −0.3V *vs.* SCE, the CV behavior was essentially unchanged (Fig. 4i), thus demonstrating the stability of the semiconductor electrode. The behavior of p-Cu_2O with $Ph(CN)_2$ was typical of that found with other redox couples. From the location of the energy levels of these couples with respect to the bandedges (Fig. 3), one would predict, based on the "ideal" model of the semiconductor/liquid interface, that all of the couples would be photoreduced with the potential of the onset of photocurrent V_{on}, located near V_{FB}. This was found to be the case for solutions initially containing only the oxidized form of the couple. The values of V_{on} and V_{redox} are given in Table I. In all cases appreciable photocurrent flowed only at potentials significantly more negative than V_{on}. The limiting quantum efficiency for the photogeneration of $Ph(CN)_2^{\overline{\cdot}}$, defined as the ratio of the current (in electrons/s-cm^2) to the absorbed light flux (in photons/s-cm^2), with the p-Cu_2O electrode held at a potential of − 1.0V where the limiting current is attained, was estimated at 500 nm. This value of λ corresponds to an energy greater than the bandgap of p-Cu_2O. The 500 nm radiation was obtained by interposing a Jarrel-Ash Company (U.S.A.) monochromator between the PEC cell and the xenon lamp (2500W operated at 1600W); the monochromatic light was focused on the p-Cu_2O electrode. The photocurrent, recorded on a Model 2000 X-Y recorder (Houston Instruments, Austin, Texas), was 0.70 $\mu A/cm^2$. The PEC cell was then replaced and the monochromatic light intensity, measured by a radiometer/photometer, Model 550-1 (Electro Optics Division) was 14.6 $\mu W/cm^2$. These values yield a monochromatic quantum efficiency of ~ 10.5%.

Effect of pretreatment.—The nature of the electrode surface pretreatment, *e.g.*, via etching, is known to affect the behavior and PEC performance of SC electrodes (30, 31). Four different etchants were used in this work, described in the experimental section. Electrodes treated with etchants (2), (3), or (4) gave large dark currents as compared to those with 1 (12M

HNO_3) (Fig. 5). Generally, electrodes that showed surfaces with large crystallites and grain boundaries, as produced by etching with 12M HNO_3, showed a better PEC performance than those with smooth and shiny surfaces [*e.g.*, as produced by etchant (4)].

Anodically grown Cu_2O films.—The PEC behavior of p-Cu_2O anodic films depended upon the electrochemical conditions employed for growing the oxide film and the pretreatment of the Cu electrode before film formation. The films produced in aqueous NaOH solutions by linearly scanning the potential showed better photoresponse than those prepared by galvanostatic oxidation. Among the Cu electrode pretreatments tried [etching with 6M HNO_3, etching with $FeCl_3$ in EtOH, electropolishing (20), or electropolishing with etching in $FeCl_3$], etching with HNO_3 produced electrodes which showed the largest photoeffects. Etching, with either $FeCl_3$ or the electropolished surfaces, yielded Cu_2O films which showed a poor photoeffect. For films grown by linear scans, the photoresponse depended upon the potential scan rate, v, for film growth. Films grown at very small v (0.02 mV/sec) exhibited better PEC behavior than those grown at higher scan rates (0.2 and 1.0 mV/sec). In the linear scan experiments, the formation of Cu_2O was characterized by a peak obtained at -0.4 to -0.5V *vs.* SCE (20). To avoid conversion of the Cu_2O to CuO, the potential was not scanned beyond -0.35V *vs.* SCE. Current-potential curves in the dark and under chopped illumination for p-Cu_2O films (grown at 0.02 mV/sec in 1M and 5M NaOH) in MeCN/TBAP containing $Ph(CN)_2$ are given in Fig. 6. The photoresponse was clearly much greater for films grown in 5M NaOH. The beneficial effect of slow scan rate and higher NaOH concentration is probably caused by the formation of a less random and thicker film (20). Some improvement in the onset potential and photocurrent was achieved by etching the anodic Cu_2O film with 0.01M HNO_3 for 1-2 sec. Etching with a more concentrated HNO_3 solution (0.1M) destroyed the photoeffect, presumably because dissolution of the Cu_2O film occurred. Films grown in 10M NaOH gave a photoresponse similar to those grown in 5M NaOH at 0.02 mV/sec. Generally, however, the photocurrents at the anodic films were much smaller than those at the thermally grown material for similar solution and illumination conditions.

p-Cu_2O/MeCN PEC cells.—The CV behavior can be used as a guide for the construction of PEC photovoltaic cells, where the open-circuit potential of the semiconductor ideally (in the absence of recombination) approaches V_{FB} and the metal counterelectrode is at V_{redox}. Although the photocurrents found in the CV experiments with p-Cu_2O were rather small, the behavior of actual two-electrode photovoltaic cells is of interest because observed responses under these conditions insure that the effects seen are not merely caused by conductivity changes under illumination and allow an estimation of the actual power conversion efficiency of such devices. From the energy level diagram (Fig. 3) and the voltammetric measurements (Table I), cells containing $Ph(CN)_2$ would be expected to show the highest open-circuit voltage, V_{oc}, and the best performance. The following cell was constructed: p-Cu_2O/MeCN, TBAP (0.1M), $Ph(CN)_2$ (10 mM), $Ph(CN)_2^{\overline{\cdot}}$ (0.1 mM)/Pt. The p-Cu_2O photocathode (0.14 cm^2) and the Pt gauze (40 cm^2) counterelectrode were spaced about 1.0 cm, with the p-Cu_2O electrode about <0.1 cm from the cell window. The i-V characteristic of such a cell, obtained with different load resistances, is shown in Fig. 7. The open-circuit photovoltage was 0.3V, the short-circuit photocurrent density was 0.4 mA/cm^2, and the fill factor was 0.51. Note that this open-circuit voltage is considerably lower than the value predicted from voltammetric measurements conducted with solutions in the absence of appreciable $Ph(CN)_2^{\overline{\cdot}}$. It is, however, about the same as that found with solid-state p-Cu_2O cells (12). From the

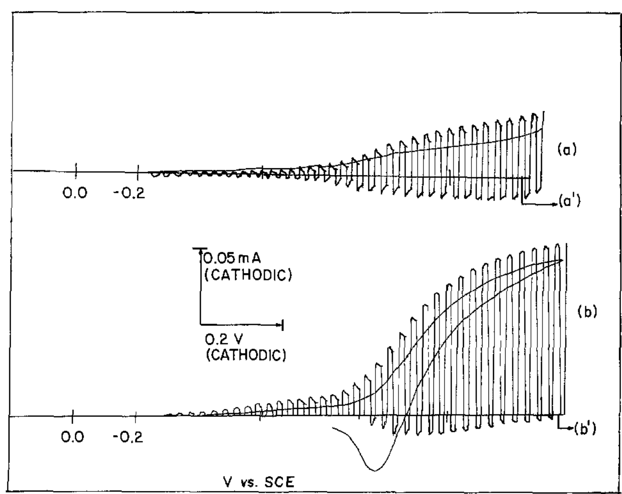

Fig. 6. Current-potential characteristics under chopped light on p-Cu_2O (anodically oxidized) in MeCN containing 10 mM $PhCN_2$; 0.1M TBAP. Light source, 450W xenon lamp. Scan rate, 50 mV/sec. (a) p-Cu_2O prepared in 1M NaOH; (b) p-Cu_2O prepared in 5M NaOH. a' and b' are in the dark.

data in Fig. 7 and the light flux of 120 mW/cm^2, the overall optical-to-electrical energy conversion efficiency, uncorrected for absorption and reflectivity losses, was calculated to be ~0.05%. This low value can probably be attributed to rapid recombination processes both within the bulk p-Cu_2O and at the interface. The currents were not limited by mass transfer and were unaffected by stirring. The $Ph(CN)_2^{\cdot-}$ was intentionally kept at a low concentration to decrease the light adsorption by this intensely colored species and to minimize the back-reaction at the p-Cu_2O surface. The photocurrent as a function of time is shown in Fig. 8. The photocurrent was fairly stable for at least 6 hr at which time the experiment was terminated.

Scanning electron micrographs of different thermally grown specimens after etching or polishing are given in Fig. 9. Samples etched with HNO_3 (Fig. 9a) showed well-developed crystallites with distinct boundaries. While some of the crystallites were rather large, zones of smaller crystallites were also found. There was no marked change in the morphology of p-Cu_2O surfaces after the PEC measurements (Fig. 9b). The surfaces of electrodes either polished with Al_2O_3 (0.5 μm) or etched with HNO_3: acetic acid: H_3PO_4 were smooth (Fig. 9c, d). To test if the small crystallites and numerous grain boundaries found with the 12M HNO_3 etched samples were responsible for the low photovoltages and efficiencies, an electrode was prepared in which all of the small crystallites were covered with silicone rubber sealant, leaving only a single large crystal exposed to the solution. However, PEC measurements with this electrode showed no apparent increase in either the photovoltage or photocurrent density. This suggests that there may be inherent problems in the efficiency of p-Cu_2O itself, and that marked improvement in the efficiency with this material may be difficult.

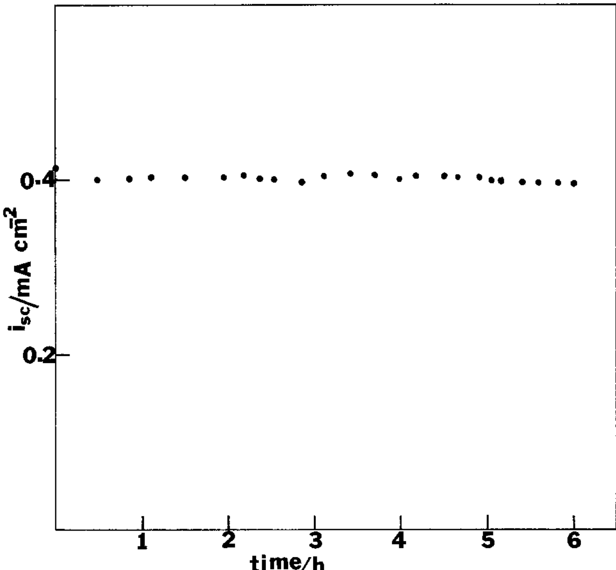

Fig. 8. Plot of photocurrent-output density of the cell p-Cu_2O/MeCN, 10 mM $Ph(CN)_2$, 0.1 mM $Ph(CN)_2^{\cdot-}$; TBAP = 0.1 M/Pt as a function of time. Light source, 450W xenon lamp.

Conclusions

The p-Cu_2O photocathode is stable in MeCN containing a number of different redox couples under irradiation. The photopotential, V_{ph}, equal to (V_{redox} − V_{on}), increases linearly with V_{redox}, with a slope near one. The onset of photocurrent is located, for all couples investigated, near the flatband. Pretreatment of the electrode plays an important role on the PEC performance of p-Cu_2O, and etching with 12M HNO_3 was found to give a reasonable photocurrent and small dark cathodic current. The 12M HNO_3 etched surface, which looks matte and polycrystalline with distinct grain boundaries, exhibited better PEC behavior than the one which was shiny and smooth (*e.g.*, produced by an HNO_3:acetic acid:H_3PO_4 etching).

The overall conversion efficiency of optical-to-electrical energy for the PEC photovoltaic cells was low, $< 0.1\%$. A brief comparison of the liquid junction photovoltaic cells with the solid-state cells is in order. Under similar irradiation intensities, the Schottky barrier Cu/p-Cu_2O cells under the best conditions are reported to show an efficiency of 0.8% (12). The observed open-circuit photovoltage (0.30V) and fill factor (0.39) are comparable to the values in the liquid junction cells, so that the lower efficiency can be traced to lower short-circuit photocurrents. Indeed, even in the solid-state cells, encapsulation of the cell with epoxy is required for optimum performance. This encapsulation not only reduced reflection losses but also decreased the observed dark current. Moreover, the resistivity of our p-Cu_2O was ~ 3-4 times that of the Cu_2O used in the solid-state cells and, in the absence of more promising efficiencies, we did not find it worthwhile to attempt to optimize the semiconductor material. In general, the low photocurrents and efficiencies in the liquid junction cells probably can be attributed to rapid surface and bulk recombination of the photogenerated charge carriers. On the basis of these results and the fact that efficiencies $> 1\%$ have not been reported for solid-state cells, unless a significant improvement in the materials, characteristics, and efficiency can be obtained, p-Cu_2O does not seem to be a promising candidate for PEC solar energy conversion devices.

Acknowledgment

The support of this research by the Robert A. Welch Foundation and the Solar Energy Research Institute (in a cooperative project with SumX Corporation) is gratefully acknowledged. We also acknowledge a fellowship to ASG by the Consejo Nacional de Investigaciones Científicas y Técnicas de la República Argentina and a helpful discussion with Professor D. Trivich which assisted in the initiation of this research. The assistance of Victor A. Fishman in obtaining the PAS spectrum of p-Cu_2O is also appreciated.

Technical Note

Intermetallic Growth Dependence on Solder Composition in the System Cu-(Pb-Sn Solder)

K. Kumar, A. Moscaritolo, and M. Brownawell[1]

The Charles Stark Draper Laboratory, Incorporated, Cambridge, Massachusetts 02139

This study examines the dependence of the growth kinetics of the intermetallic phases Cu_3Sn and Cu_6Sn_5 (formed in the copper, Cu, and lead-tin, Pb-Sn, solder laminated structure that exists in conventional printed circuit boards) on the Pb-Sn solder composition that is employed. We have recently shown that in some of the commercially produced circuit boards, thermally activated growth of the intermetallic regions leads to eventual solder separation at the Cu-Cu_3Sn interphase boundary (1).

To evaluate and reasonably accurately predict the time-dependent performance of these circuit boards during service, it is important to devise accelerated tests at temperatures much in excess of operating temperature. The design of such a test, however, requires a knowledge of growth parameters, principally the activation energy. Its knowledge allows calculation of equivalent time at operating temperature to that used for exposure at the temperature of the test. Since the value of this activation energy is expected to be a function of the composition of the Pb-Sn solder, one needs to know the variation of the activation energy as a function of solder composition, over a reasonably narrow composition range of interest. The solder composition usually used is about 60 weight percent (w/o) Sn. The activation energy variation, therefore, needs to be systematically examined for solder compositions on either side of this value to take into account the effects of variations in plating processes from lot to lot and vendor to vendor. Data generated in earlier studies (2, 3) were considered inadequate in that only discrete, widely separated solder compositions were evaluated. The compositions examined in these earlier studies consisted of solder materials containing 10, 30, 60, and 100 w/o Sn. We have now examined the growth of the intermetallics using solder compositions of 45, 50, 55, 60, 65, and 70 w/o Sn. The samples were fabricated by electrodepositing the selected solder composition on high purity electrolytic grade copper sheets which were about 0.0175 cm thick.

Five specimens, each approximately 1 cm square, were sectioned from each solder-plated copper sheet, using a jewler's saw. Four of these five specimens were heat-treated for a fixed time (100 hr) at temperatures of 348, 373, 398, and 423 K. The fifth specimen was retained in the as-plated condition. The intermetallic bandwidths in the as-plated samples constituted the starting conditions and these were used to calculate further growth of the bands which resulted from heat-treatments.

All of the as-plated and heat-treated samples were mounted at room temperature (with the copper-solder interface slightly inclined to the plane of polishing) in a resin containing cast and polished for metallographic examination using standard techniques. The selected angle of tilt of the copper-solder interface allowed amplification of the intermetallic regions, upon polishing, by a factor of ten. The intermetallic regions were photographed on an American Optical Metallograph at 1000 magnification. Figure 1 is typical of what was observed. The intermetallics appeared as a set of two blue bands sandwiched in between the copper substrate and the electrodeposited solder. The two bands, as indicated in Fig. 1, were composed of the phases Cu_3Sn and Cu_6Sn_5.

The majority of the photographs did not show a clear separation of the intermetallic phases. The Cu_3Sn and Cu_6Sn_5 intermetallics were found to coexist in a narrow region across their interface, with Cu_3Sn particles dispersed in a Cu_6Sn_5 matrix. In this case, the interphase boundary was assumed to exist at the midpoint of this two phase region. The Cu_3Sn-Cu and Cu_6Sn_5-(Pb-Sn solder) boundaries were also not always smooth. The effective widths were taken as the average of 9 measurements made along each interface. A typical selection criterion for the different boundaries is shown in Fig. 1. The widths of the Cu_3Sn,

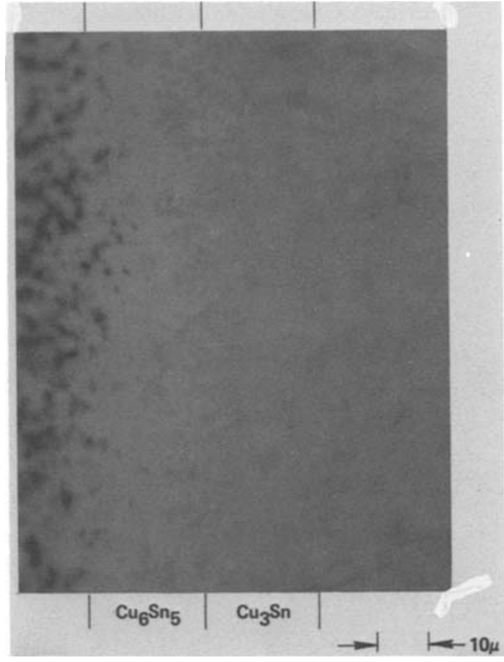

Fig. 1. Typical micrograph showing Cu_3Sn and Cu_6Sn_5 intermetallic regions after polishing on a 10 to 1 bias. (Actual width is less by a factor of ten than what is observed.)

[1] Permanent address: Massachusetts Institute of Technology, Cambridge, Massachusetts 02139.

Key words: activation energy, percent Sn variation, Cu_3Sn, Cu_6Sn_5.

Cu_6Sn_5, and $Cu_3Sn + Cu_6Sn_5$ intermetallic regions were all measured separately.

An Arrhenius plot was then constructed with the log values of the widths (of the different intermetallic regions) plotted on the vertical axis, and the reciprocal values of the heat-treatment temperatures plotted on the horizontal axis. Separate plots were obtained for the Cu_3Sn, Cu_6Sn_5, and $Cu_3Sn + Cu_6Sn_5$ widths for each composition. The data were made to fit a straight line using a least squares analysis (4).

The equation of this line is given by the expression

$$\ln x = \frac{\ln A}{2} - \frac{E_a}{2RT}$$

where: x [in cm] is the increase in the intermetallic bandwidths for Cu_3Sn, Cu_6Sn_5, and $Cu_3Sn + Cu_6Sn_5$, respectively, E_a is the activation energy in cal/mol, R is the gas constant in cal/mol/K, T is the temperature in K, and $A = D_0t$ in cm^2 (where D_0 is the diffusion constant in cm^2/sec and t is fixed time in sec at temperature).

The activation energy for each solder composition and each intermetallic phase was then calculated from the measured slopes of the various Arrhenius plots using the above expression. The values of the activation energies obtained in this way were then replotted as a function of the weight percent Sn in the solder. The study was then repeated, independently of the first study, and the second set of values of the activation energies were likewise plotted as a function of the solder composition. The two different sets of values of the activation energies were then averaged into one plot (see Fig. 2). The values of the activation energy measured in the second study were all within 10% of the values obtained in the first study. The scatter observed in the data obtained for the Cu_3Sn activation energy plot was partly attributed to the difficulty in determining the position of the Cu_3Sn-Cu_6Sn_5 boundary.

This study shows that the activation energy decreases with increasing amounts of Sn over the range of solder compositions that were examined. This variation of the activation energy was interpreted as being related to the presence of varying amounts of Pb in the solder material. As the reaction between the copper and the solder progresses, most of the Pb is rejected out of the reacted zones into the solder regions close to the Cu_6Sn_5-(Pb-Sn) solder boundary as a Pb-rich phase (1). The diffusion rate of the Sn through this Pb-rich phase must, therefore, strongly influence the kinetics of the growth of the different intermetallic bands. According to this interpretation, the Pb-rich phase, which accumulates at the Cn_6Sn_5-(Pb-Sn) solder boundary, must serve as a diffusion barrier to the Sn atoms for growth of the several intermetallics to proceed. Thus the rate of intermetallic growth is directly influenced by the accumulation of this Pb-rich species, which is obviously a function of the overall chemical composition of the solder. The calculated activation energy is, therefore, indicative of the effect of solder composition on intermetallic growth kinetics.

These observations dispute earlier suggestions that the concentration of Pb has little effect in determining the rate of growth of the various compounds (2). Our results also do not show the presence of a maximum value for the activation energy at solder compositions close to 60 w/o Sn, the possibility of which was indicated in Ref. (3). The value for the activation energy of $Cu_3Sn + Cu_6Sn_5$ at this composition is stated to be 49.64 kJ/mol K (11.86 kcal/mol K) in this reference.

It should be noted that the grain size of the copper sheets used in this study was quite coarse, typically ranging from 20 to 50 micrometers. The grain size present in the copper base that exists in conventional printed circuit boards, on the other hand, is considerably more refined—by at least one order of magnitude. The rate of reaction of the copper base with the Pb-Sn solder in the conventional circuit boards is, therefore, expected to be substantially more rapid than what was observed for the coarse-grained samples of this study. (This grain size effect will show up as a reduced value for the activation energy, in the fine-grained circuit boards, for any given solder composition. In agreement with this analysis we have measured values of about 12.7, 14.4, and 13.5 kcal/mol in commercially produced circuit boards formed with a Pb-Sn solder of nominal 62% Sn composition for the intermetallic phases Cu_6Sn_5, Cu_3Sn, and $Cu_3Sn + Cu_6Sn_5$, respectively.) The variation of the activation energy with changes in Sn concentration in the Pb-Sn solder should, however, be similar to what was shown in Fig. 2, since this is believed to primarily depend on the diffusion of Sn through the Pb-rich phase located on the solder side of the Cu_6Sn_5-(Pb-Sn) solder boundary and this is not expected to be a strong function of the grain size of the copper.

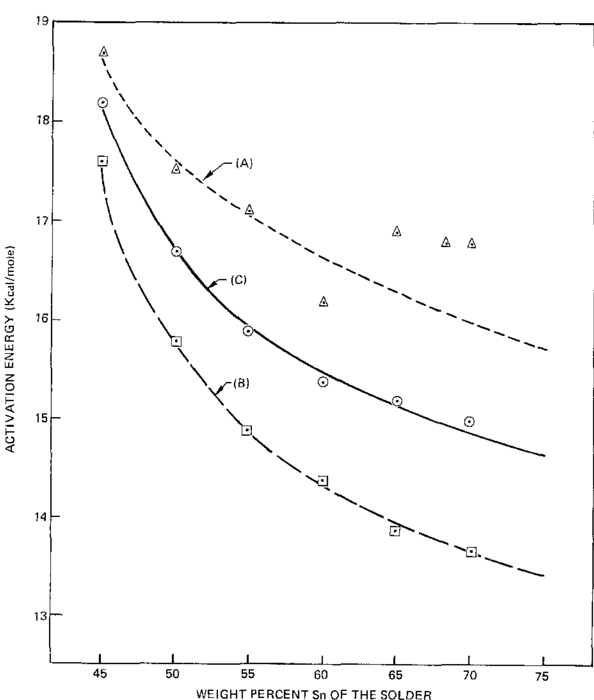

Fig. 2. Activation energy variation with weight percent tin in the solder for (A) Cu_3Sn, (B) Cu_6Sn_5, and (C) $Cu_3Sn + Cu_6Sn_5$.

Rotating Ring- and Split Ring-Disk Electrodes with Interchangeable Disks

S. Menezes,* L. F. Schneemeyer,* and B. Miller*

Bell Laboratories, Murray Hill, New Jersey 07974

The electrochemical insights gained with ring disk electrodes (RRDE) have generated an enduring interest in making their construction easier and more flexible (1). One such means is to provide a readily demountable disk (2-5) to facilitate many types of RRDE investigations during which one ring material may serve generally. Any study depending on varying the disk composition or morphology, or comparing a series of disk materials in given electrolytes, would be expedited by disk interchangeability. In a prime example of particular current relevance to us, the study of semiconductor disk photoelectrochemistry, these are all prominent requisites. The power of the methodology can be extended in certain complicated systems by use of a split ring variation (SRRDE) which provides two independent monitors of the disk reaction rather than one (6).

We have taken a proven design (6) for making either RRDE or SRRDE's of relatively easy permanent construction, compatible with virtually any 1/4 in. shaft rotator, and modified it to accept demountable disks. Important to us in this development is obtaining a simple interchange (perhaps 15 min of easy steps) without sacrificing any theoretical advantages of the system, such as speed invariant collection efficiency, not found in a most recent demountable electrode design (5). The predecessor permanent version to ours (6) is based on an epoxy adhesive, concentric coupling of a disk (rod) and ring (tube), with the split ring form completed by appropriate subsequent slotting of the tube. Electrodes already constructed of either form, or freshly made up with active disk material omitted, are readily adapted to take a threaded mount for the disk and it is only required to have a solvent-removable, gap-filling polymer of reasonable adhesive quality to have the necessary demountability, as will be shown below.

Demonstration of the practicability of the new electrodes is given for several ring disk combinations, including metal and semiconductor disk examples. Confirmation of theoretical behavior and the demounting, remounting, and replacing of disks are amply examined.

Experimental Section

Apparatus and materials.—The galvanostat-potentiostat (6) and motor control-$\omega^{1/2}$ scanning circuitry (7) have been described earlier. Scans were recorded using an HP Model 7046A X, Y, Y' recorder. Current ratios were obtained with a Burr Brown 4291 analog divider. Electrochemical experiments were performed under an N_2 atmosphere in a three-electrode cell with platinum counterelectrodes and saturated calomel (SCE) reference electrodes. Experiments employing a semiconductor disk utilized a cell with an optical flat bottom, permitting disk illumination with a 100W tungsten-halogen lamp. Electrolytes were prepared with reagent grade chemicals and triply distilled water. Single crystal n-CdS from Cleveland Crystals was etched for a few seconds in concentrated HCl before scans.

Electrodes.—The fabrication of permanent ring disk and split ring disk electrodes has been detailed earlier (6). Easy mounting and demounting of a desired disk have been achieved with modifications shown in Fig. 1. The center rod is drilled and tapped to a convenient screw size (4-40 in this case) as pictured, following rod-tube alignment and bonding. The active disk material may be machined out of an already constructed electrode and the hole tapped, as was actually done for our electrodes.

Stainless steel Fillister head screws (1/4 in.) with the head machined flat serve as convenient disk mounts. The active disk material is fastened to the screw using solder or conducting silver epoxy. Shaping of the disk may be completed on a lathe with appropriate cutter or abrasive. In the case of the CdS disk, an ohmic contact was formed on the back of the crystal with Ga/In eutectic prior to silver epoxy bonding.

The disk is threaded to approximate planarity to the ring, and then the remaining gap between the ring and the disk is filled with Loctite 430 adhesive (Loctite Corporation, Newington, Connecticut). Cure within minutes was obtained using Loctite Tak Pak Accelerator. Excess adhesive was removed, and the ring and disk made coplanar, by polishing. To demount, the gap-filling adhesive was removed by dipping the electrode assembly in ultrasonically agitated dimethylformamide (DMF) at ~40°C for several minutes, after which it is readily unthreaded. To assure facile removability, the threads were protected from the gap-filling adhesive by coating those nearest the disk with Fluorolube Grease GR-90 before insertion. Care was taken to keep the sides of the ring and disk free of this grease.

Results and Discussion

An Au ring-Pt disk assembled as above was examined in 5 mM $Fe(CN)_6^{-4}$ + 1M KCl. The disk was

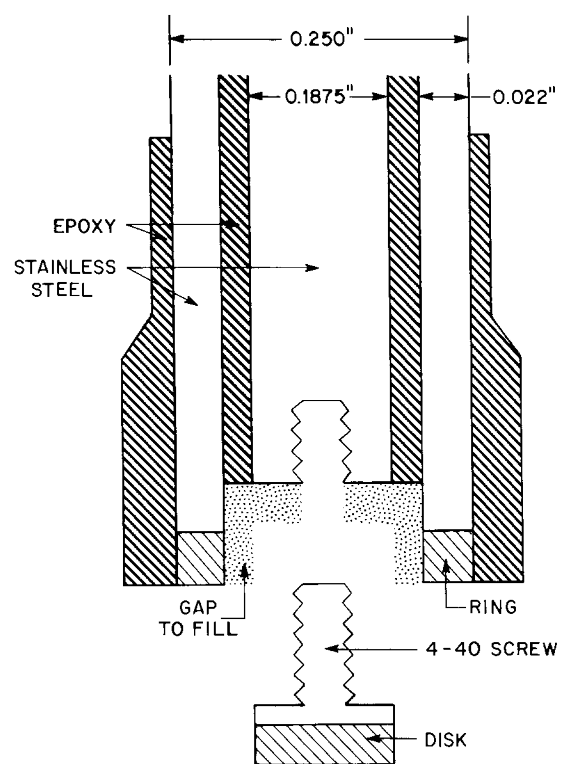

Fig. 1. Schematic diagram of a demountable disk, ring disk electrode.

Key words: ring disk electrodes, demountable disk, electrolytes.

potentiostatted at 0.5V and the ring at −0.2V *vs.* SCE to oxidize $Fe(CN_6^{-4}$ and reduce product $Fe(CN)_6^{-3}$ at their respective limiting currents. Figure 2(a) shows Levich plots of the disk and ring-limiting currents, i_D and i_R, *vs.* $\omega^{1/2}$ for speed scanned at 1 $rpm^{1/2}$ sec^{-1} between zero and 10,000 rpm. Both plots are linear above ~400 rpm as expected (8) and the ratio of their slopes yields a collection efficiency of 0.34 in good agreement with that calculated (9) from the nominal geometry of the RRDE in Fig. 1.

To test the RRDE reproducibility after repeated demounting and remounting by the described procedure, the disk electrode was unthreaded after dissolving the adhesive in DMF, reassembled, and polished lightly to assure its planarity. The ring collection experiment of Fig. 2(a) was then repeated. The second set of Levich plots obtained in a fresh solution of the same composition essentially superimposed those of Fig. 2(a). In this run, the constancy of the collection efficiency of the ring disk in the above configuration was examined over the same range of rotation speed by obtaining the ratio of ring to disk current, *N*, directly with the analog divider in Fig. 2(b). Ring current was corrected for a small measured residual before division. This plot also gives a value of 0.34 for $\omega^{1/2} > 20$ $rpm^{1/2}$.

Figure 3 shows $i_D - E_D$ and $i_D - i_R$ plots obtained in 0.1M $Fe(CN)_6^{-4}$ + 1M KCl at an illuminated n-CdS electrode acting as a photoanode. The higher concentration of $Fe(CN)_6^{-4}$ was employed in this case to suppress the competition of surface corrosion processes under the given illumination intensity. The leveling of i_D above 600 μA occurs from photon flux limitation. In the accompanying $i_D - i_R$ scan, the ring is held on the reduction wave of $Fe(CN)_6^{-3}$ to collect $Fe(CN)_6^{-3}$ resulting from photo-oxidation at the n-CdS disk. The slope of this trace yields an experimental value for *N* of 0.32, which compares closely with the calculated 0.34. This agreement of *N* values indicates that all the anodic photocurrent at n-CdS in the linear region of the plot results from efficient photo-oxidation of $Fe(CN)_6^{-4}$ and the current contribution to surface processes is minimal.

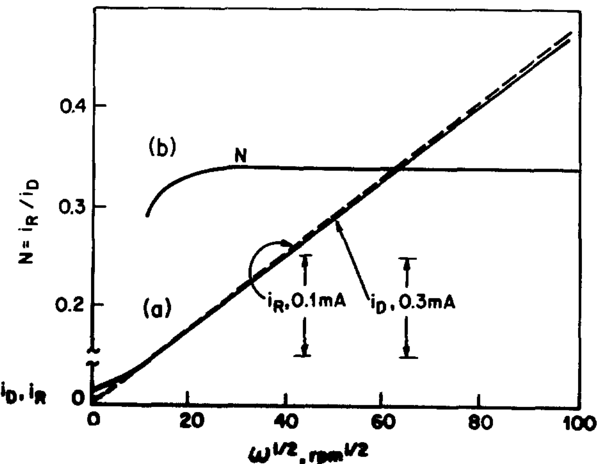

Fig. 2. Pt disk and Au ring potentiostatted at 0.5V and −0.2V vs. SCE, respectively, in 5 mM $Fe(CN)_6^{-4}$ + 1M KCl. Speed scanned at 1 $rpm^{1/2}$ sec^{-1}. (a) First mounting of disk, i_D (solid line) and i_R (dashed) vs. $\omega^{1/2}$. (b) Remounting of disk, $i_R/i_D = N$ vs. $\omega^{1/2}$.

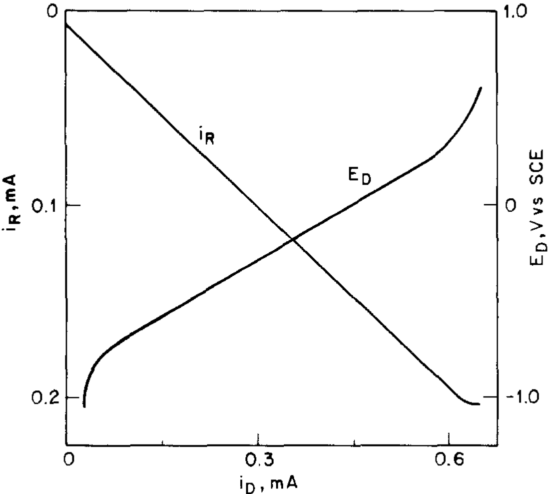

Fig. 3. $i_D - E_D$ and $i_R - i_D$ curves under disk potential scan at 5 mV/sec for illuminated n-CdS disk Pt ring in 0.1M $Fe(CN)_6^{-4}$ − 1M KCl. Ring potential −0.2V vs. SCE, speed 1600 rpm.

We applied an SRRDE, constructed by mounting the Pt disk used above in a gold split-ring, to a situation where simultaneous monitoring of two oxidation states of a redox species is very helpful in resolving the disk reactions. Figure 4 show ring collection (product detection) and shielding (reactant removal) measurements during reduction of Cu(II) at a Pt disk. The Pt disk trace shows a two-step reduction, Cu(II) to Cu(I), and Cu(I) to Cu(0), labeled A and B, respectively, before the onset of H_2 evolution. The dashed curves show currents i_R^+ and i_R^- at the two Au half rings which were potentiostatted at $E_R^+ = 0.4V$ and $E_R^- = -0.1V$, respectively. The current in the upper half-ring trace, i_R^+, results from the oxidation of Cu(I) generated at the disk. For the first reduction wave, it reaches a corresponding limiting value and drops back to zero when the second reduction wave, B, starts. At these potentials, the Cu(II) is reduced further to Cu(0) at the disk and no product reaches the ring. The ring-shielding curve, i_R^-, monitors Cu(II) species at a potential corresponding to the limiting current of the first disk step, A. When no current flows at the disk at positive potentials, i_R^- measures the limiting current of Cu(II) which can be quantitatively related to i_D at A by the relation $i_R^- = 0.52 i_D$ for this half-ring geometry. i_R^- decreases by the amount Ni_D when the disk consumes Cu(II) on the A plateau. Since the flux of Cu(II) to the ring is unchanged during the second reduction wave, i_R^- remains constant. The ring and disk curves shown in Fig. 4 are scaled by approximately the geometric factor for a half ring, *N*/2. We note that agreement between the experimental *N*/2 of 0.140 and 0.145 for the two individual methods of detection and the calculated 0.29 for the combined half rings is as expected.

Conclusions

The variety of experiments performed illustrating the desired demountability, interchangeability, and theoretical performance of these electrodes confirms the design objectives. The methylcyanoacrylate gap-filling adhesive selected provided both easy removal in the presence of the primary epoxy mounting and shrink polyethylene tubing used above it, and good

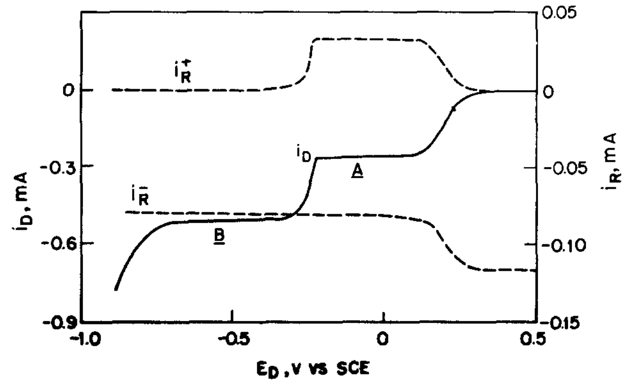

Fig. 4. Pt disk potential scan at 5 mV/sec in 2 mM $CuCl_2$ + 0.5M KCl with Au split ring. Half rings held at 0.4V (i_R^+) and −0.1V (i_R^-) vs. SCE. Speed 1600 rpm.

evidence of adequate sealing properties and resistance to typical aqueous environments. The savings in time, effort, and cost by having a few basic RRDE or SRRDE structures, as in Fig. 1, to mate with the readily prepared disk-tipped screws can be amply testified to from our own experience with the construction of many dozens of such permanent electrodes.

Acknowledgment

The authors are grateful to S. G. Seger, Jr. for providing the adhesive and information on its use.

Manuscript received March 31, 1981.

Any discussion of this paper will appear in a Discussion Section to be published in the June 1982 JOURNAL. All discussions for the June 1982 Discussion Section should be submitted by Feb. 1, 1982.

Publication costs of this article were assisted by Bell Laboratories.

A Model for Oxidation of Silicon by Oxygen

S. S. Cristy and J. B. Condon

Union Carbide Corporation, Nuclear Division, Oak Ridge Y-12 Plant, Oak Ridge, Tennessee 37830

ABSTRACT

Insights into the transport and deposition of oxygen in silicon oxidation at 700°C have been obtained by isotope labeling and use of the ion microprobe mass analyzer for profiling. The results are consistent with interstitial diffusion of O_2 as the prime support of the interfacial oxidation reaction. Vacancy migration was observed near the surface with a very low diffusion coefficient. The SiO_2-Si interface is found to be diffuse with the interface reaction following a perfusive-precipitation model. This model is shown to explain the profile features observed and agrees well with literature data for diffusion coefficient and rate of reaction with silicon.

W. A. Tiller (1) expressed the point of view that the oxidation of silicon is controlled by the migration of $O^{=}$ interstitials. In his treatment, a "free volume supply condition" is assumed to be a problem for the O_2 migration proposed by Doremus (2) since this condition requires greater free energy than O_2 transport and requires large vacancy migration. Significant amounts of vacancy migration have been eliminated by Rosencher, Straboni, Rigo, and Amsel (3) in their article which utilized $^{18}O_2$ labeling and depth profiling with a Van de Graaff accelerator. The depth resolution of this technique, however, is insufficient to obtain profiles usable for modeling of the reaction.

To obtain better profiles for modeling, the ion microprobe mass analyzer (IMMA) was used in a similar isotope labeled study. The resolution of this instrument is sufficient to yield diffusion coefficients that are of the order of those for oxygen in silicon over the temperature range studied by Deal and Grove (4), Law (5), and Irene (6). The conditions of sample preparation were selected to allow a linear rate for most of the reaction. This simplifies the modeling problems and also allows clear inspection of the interface reaction if the model by Blanc (7) is operative.

Experimental Method

The silicon samples were obtained from Electronic Space Products, Incorporated, as 0.25 mm thick, single crystal wafers of about 2 cm diam. The three samples used were a p-type, 100 oriented, with a resistivity of 29.2 Ωcm, a p-type, 111 oriented, with a resistivity of 181 Ωcm, and an n-type, 111 oriented, with a resistivity of 36.3 Ωcm. These samples were oxidized in a tube furnace capable of an ultrahigh vacuum. The temperature chosen for oxidation was 700°C. According to Deal and Grove (4), the oxidation at this temperature is linear for at least 5 days. After evacuation to an ultrahigh vacuum ($< 2 \times 10^{-6}$ Pa outside the tube furnace area), the container tube was backfilled with 3.3 kPa of $^{16}O_2$ and the reaction allowed to proceed for 10 days. After 10 days, the tube was evacuated and backfilled with 3.3 kPa of $^{18}O_2$ and the reaction allowed to proceed for another ten days.

Key words: oxidation, silicon, ion microprobe, SIMS.

The cooled samples were transferred through air into the IMMA. The depth profiling capability of this instrument was utilized by sputtering with a 5 nA, 21.5 keV N_2^+ ion beam and measuring the evolved $^{16}O^-$ and $^{18}O^-$ ions. The sputtering was confined to a rastered area of 31 by 39 μm. Electronic aperturing minimized etch pit edge effects and maximized the depth resolution. Experience with other samples indicates that the depth resolution of the IMMA for these conditions is better than 10 nm of real distance per decade drop in signal. A sputtering rate of 17.7 nm min^{-1} in silicon metal was determined for these beam conditions using a boron-implanted silicon calibration standard. This translates into 9.0-15.0 nm min^{-1} equivalency of silicon metal in SiO_2 depending upon the assumption made. An equivalency rate of 12 nm min^{-1} was chosen as a compromise until a more accurate calibration is available. (The distance equivalency of silicon metal in SiO_2 is given by 0.47 of real distance since it is assumed that the expansion is constrained by the rigid surface geometry and takes place almost completely in the vertical direction.)

Results

Some typical profiles are shown in Fig. 1. Four main features may be identified in these profiles:

1. A very sharp tailing of the $^{18}O^-$ signal from the surface inward accompanied by a rise in the $^{16}O^-$ signal. Some surface enhancements are probably present, but the inward tailing is real since it is reflected in the ^{16}O to ^{18}O ratio. If the gradient is due to diffusion of some species, then the diffusion coefficient is between about 3×10^{-23} m^2 sec^{-1} for the N(111) sample, and about 1.7×10^{-23} m^2 sec^{-1} for the P(111) sample. A diffusion gradient of this magnitude is insufficient to sustain the overall rate of oxidation. (These values were obtained by assuming that the ^{18}O gradient from the surface was established during the 10 day $^{18}O_2$ exposure. Diffusion equations imply that the natural logarithm of the gradient as shown in the discussion is $1/\sqrt{\pi D t}$ for a semi-infinite solid (8) where D is the diffusion coefficient and t is the exposure time.)

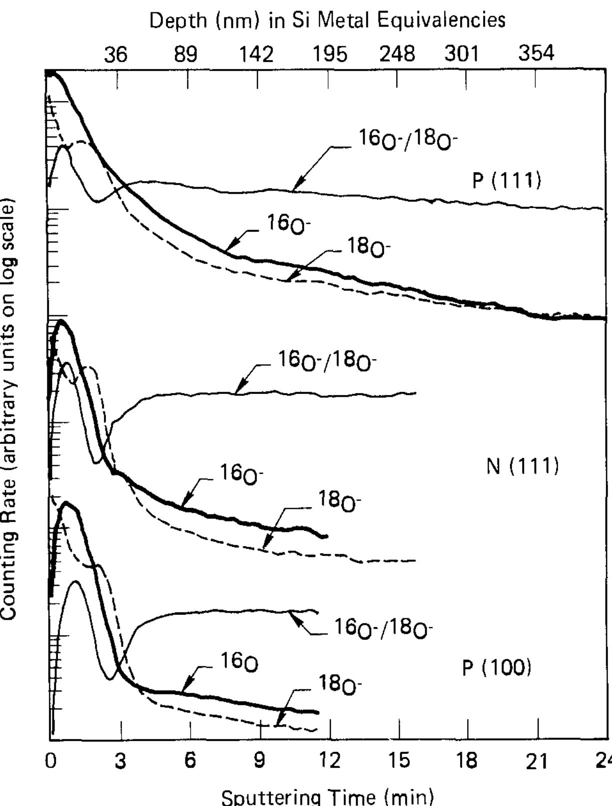

Fig. 1. Typical IMMA depth profiles of oriented silicon wafer which had been oxidized at 700°C with $^{16}O_2$ for 10 days followed by $^{18}O_2$ for 10 days. (Actual oxide depth is about twice the silicon metal equivalence depth. The location of x_S, the defined transformation boundary, is at about 3 min sputtering time.)

2. An increase in the $^{18}O^-$ signal at about 20 nm and a maximum at about 30 nm into the sample. This hump was observed in the Van de Graaff experiments (3). However, this is not a sharply defined layer as previously assumed but rather a broadened peak. This cannot be explained by lack of depth resolution of the IMMA profiling which is better than 10 nm real distance per decade of signal drop. Indeed, this apparent lack of resolution can be explained along with the shallow valley of $^{18}O^-$ at about 20 nm silicon equivalent by the model which will be presented here.

3. A relatively rapid decay of the $^{16}O^-$ signal at about the position of the $^{18}O^-$ hump followed by a similar drop in the $^{18}O^-$ signal. On a linear scale, this decay is S-shaped, and the position of an inflection point may be identified within a 3 nm distance.

4. A very broad tailing of both the $^{16}O^-$ signal and $^{18}O^-$ signal into the silicon metal phase. This latter tailing may be interpreted as the decay of oxygen into the metal by diffusion. The calculated diffusion coefficient from this tail is, within experimental error, the expected value from the literature data (9).

Discussion

General feature.—The overall conclusion, which is the same as Rosencher *et al.*, is that the species that migrates through the product layer and supports the interfacial oxidation reaction does not involve oxygen lattice positions. The sharp diffusion gradient in the $^{18}O^-$ signal at the outer surface, feature 1 described in the results section, is probably the result of vacancy migration on the oxygen sublattice of SiO_2 phase. It is not due to the diffusion gradient of oxygen-bearing species responsible for most of the oxidation, since the diffusion coefficient of $\leq 3 \times 10^{-23}$ m^2 sec^{-1} is much too low to support the overall reaction rate. Even with a concentration of migrating oxygen of 1.0 mol fraction, a product film of ≤ 7 nm would be formed in 20 days with this diffusion coefficient.

Elimination of point defect migration mechanisms.—Deduction of the most likely migrating species is accomplished by eliminating possibilities. One possibility is the migration of charged monatomic interstitials where the local equilibrium with oxygen vacancies is assumed as required in the treatment by Wagner (10). Diffusion of these interstitials is from the high concentration region of the gas-product interface to the low concentration region of the product-silicon interface (as required whenever the activity follows the concentration). For this first possibility, it is further assumed that the interstitial concentration profile is too low and flat to be seen by the IMMA. If this second assumption were not true and the feature 1 gradient were indeed due to the interstitial concentration, then the measured diffusion coefficient of 3×10^{-23} m^2 sec^{-1} is insufficient to support the overall reaction rate.

With these assumptions, the feature 1 tailing of the $^{18}O^-$ signal would be due to exchange of the interstitial oxygen with lattice oxygen by way of formation and filling of vacancies. The local equilibrium condition requires that this process be very fast compared to the diffusion process. The tailing would, therefore, be a reflection of the diffusion gradient. This again yields a diffusion coefficient of $\sim 10^{-23}$ m^2 sec^{-1} for the overall diffusion of oxygen which is too low to support the overall reaction rate.

Another possibility is to eliminate the local equilibrium condition and allow oxygen gas to react with vacancies on the product surface to yield a charged atomic interstitial. Under these conditions, the flux of vacancies to the surface must equal the flux of oxygen interstitials through the product layer. Again, the observed diffusion coefficient of $\sim 10^{-23}$ m^2 sec^{-1} for these vacancies is insufficient.

Further evidence for eliminating all atomic interstitials, charged or uncharged, from importance in the reaction arises from the fact that in the parabolic realm the rate is proportional to the oxygen pressure. The only way for atomic oxygen migrant to yield this behavior is for oxygen gas (molecular oxygen in general) to react with a steady and large supply, *i.e.*, constant, of vacancies on the oxygen sublattice. This would yield atomic oxygen interstitials whose concentration is proportional to the oxygen pressure. The IMMA profile yielding a diffusion coefficient of $\leq 3 \times 10^{-23}$ m^2 sec^{-1} for the vacancies eliminates this possibility.

The conclusion is, therefore, that the mechanism is basically that postulated by Doremus (2), *i.e.*, dissolved O_2 migration, and modeled by Blanc (7) to take into account the complete linear-parabolic behavior. The O_2 must decompose on the silicon metal itself, and other preconditioning of the oxygen on the outer surface such as reaction with vacancies, decomposition to ions, etc., lead to either insufficient rates, incorrect gradients, or scrambled profiles.

Details of the proposed model.—The question raised by the profile shape, especially feature 3, is "why is the ^{18}O hump smeared out?" Since it is concluded that Doremus' model for thick film oxidation is correct, then the assumption that the dissolved O_2 concentration is about 0.01 mol fraction is correct. If one then assumes that the SiO_2-Si interface is atomically sharp, as assumed by Rosencher *et al.* and by Tiller but not explicitly in Blanc's model, then the tailing is due to draining of the interstitial oxygen. However, there is insufficient oxygen stored up in the oxide film to explain the gradual tailing into the ^{18}O hump. Furthermore, this still does not explain the tailing into the metal phase, that is features 3 and 4, at any concentration of O_2 in the film.

This question can be resolved by assuming that the interface is not sharp, but is rather diffuse as clearly seen from features 3 and 4. Blanc's model is still opera-

tive except that the interface reaction follows the perfusive-precipitation model. In this model (11), the O_2 is assumed equilibrated with oxygen dissolved in the silicon. Precipitation of oxide from the supersaturated silicon proceeds internally until the metal is distorted sufficiently to drastically increase the diffusion coefficient of oxygen. The mathematics of the model have been derived analytically with some reasonable approximations by Kirkpatrick (12) and applied to water oxidation of uranium (13). The equations of interest in this case are

$$d \ln P/dx|_{x=x_s} = [U_s (\ln U_s)/(1 - U_s)] \sqrt{akU_s/D} \quad [1]$$

where P = the fraction of material that is product (SiO_2), x = the distance into the sample from gas-solid surface, x_s = the position where D becomes "large", *i.e.*, the reaction front, U_s = the mol fraction of metal remaining at x_s, a = the stoichiometric ratio ($a = 2$ for SiO_2), D = the diffusion coefficient of oxygen in silicon metal, and k = a microscopic rate constant per Avrami's limited growth case (14).

The rate constant, k, in some cases can be measured independently, and U_s should be calculable from the metal's mechanical properties. U_s in the present case may be obtained by noting that x_s is the inflection point (12) of the $^{18}O^-$ profile tailing into the metal. (The procedure used to obtain this inflection point was as follows. The total oxygen signal was plotted, point by point, on a linear scale. The slope of this plot was taken as the linear connection of each point. The inflection point was assumed to be between the two points whose connecting line segments had the greatest negative slope.) Once the position of the inflection point is found, the extent of the reaction is calculated as the ratio of the total oxygen content at x_s (or the average of the two points on either side of inflection) to the total oxygen content at the outer plateau or oxygen maximum. The rate constant, k, may be obtained by measuring the distance for one decade drop in the log tangent of the product at the inflection point, $\Delta x_{0.1}$, and rearranging Eq. [1] to

$$k = (5.3)\, D\, (1 - U_s)^2\, (\Delta x_{0.1})^{-2}\, U_s^{-3}\, (\ln U_s)^{-2}\, a^{-1} \quad [2]$$

The diffusion coefficient, D, is obtained from the long tail of oxygen into the metal, feature 4. The concentration profile for pure diffusion is given by the expression

$$c = c_o\, [1 - \mathrm{erf}(x/\sqrt{4Dt})] \quad [3]$$

The slope of the log of the concentration as a function of depth can, therefore, be shown to be

$$\partial \ln c/\partial x = \partial c/c\partial x = -\exp(-x^2/4Dt)/\sqrt{\pi Dt}\,[1 - \mathrm{erf}(x/\sqrt{4Dt})] \quad [4]$$

The log tangent of the total oxygen content by a diffusion process as $x \to 0$ is therefore

$$\partial \ln c/\partial x|_{x=0} = 1/\sqrt{\pi Dt} \quad [5]$$

For determining this tangent from the IMMA output, it was convenient in this case to define a $\Delta x_{1/2}$ as the distance over which the tangent line decreased by a factor of 2. This quantity was estimated graphically from the output of the IMMA in the feature 4 tail. This gives the diffusion coefficient as

$$D = 0.66\, (\Delta x_{1/2})^2/t \quad [6]$$

A more precise method of determining D does not appear to be justified for this study. If Eq. [2] and [6] are combined, it is noticed that the k is independent of the IMMA depth profiling rate calibration.

The overall linear rate, v_s, may be calculated by the equation

$$v_s = -(kc_o/\ln U_s) \sqrt{D/akU_s} \quad [7]$$

where c_o is the dissolved oxygen content at x_s. The usual method of calculating c_o is to extrapolate the ideal solubility law (Sieverts' or Henry's law) beyond the terminal solubility. According to Logan and Peters (9), the terminal solubility, c_T — the mol fraction of oxygen dissolved in silicon metal in equilibrium with SiO_2, is given by the equation

$$c_T = 278 \exp(-26{,}700/T)$$

The activity of oxygen from SiO_2 is given by

$$P_o = 1.46 \times 10^9 \exp(-108{,}800/T)$$

according to the listed thermodynamic data (15) on cristobalite. Extrapolating by ideal solubility

$$c_o = c_T/(P_{O_2})^{1/2}$$

c_o thus calculates to be 1.7×10^{10} mol fraction at 100 kPa O_2 pressure, a result which is much too large. Ideal solubility apparently does not apply in this case, and an alternate scheme of determining c_o is required. This alternate scheme is to back-extrapolate the tail due to diffusion in the metal to x_s. This extrapolated value is then divided by the total oxygen content at the outer plateau and multiplied by 0.67 (*i.e.*, the mol fraction of O in SiO_2 is 0.67). All of these measurements have a great deal of uncertainty, especially the U_s and c_o. Furthermore, it may be possible that diffusion of O_2 through the product may begin to be a limiting factor. Nevertheless, the calculated v_s is fairly close to the v_s observed by the direct measurement to x_s. The values for the eight profiles measured are given in Table I. The diffusion coefficient is in good agreement with the extrapolated value from Logan and Peters (9) data, since the extrapolation of their data introduces an uncertainty of a factor of 10^4 (10^{-18}-10^{-22} $m^2\,sec^{-1}$). The overall rate is in good agreement with the linear rate by Deal and Grove (4) of 3×10^{-14} $msec^{-1}$, and by Law (5) and Irene (6) for which the extrapolated values are 1.5×10^{-13} $msec^{-1}$ and 7×10^{-14} $msec^{-1}$. The pressure used in the present study was about 0.33 that used by Deal and Grove, and Irene, but about 5000 times that used by Law, yet the linear rates for all four measurements are about the same. This is probably indicative of the nonideal oxygen solubility, and that the silicon metal is simply saturated at x_s even at very low pressures. The value of k of 4×10^{-5} sec^{-1} found is quite low compared to other oxidation reactions such as copper where k is about 0.11 sec^{-1} as determined by IMMA, and iron where k is 150-300 sec^{-1} calculable from data by Turkdogen *et al.* (16, 17). It may be that the SiO_2 precipitates are not formed by the limited isometric growth but rather formed as needles or platelets.

Given the agreement between the model and observations of linear rates, it is concluded that the perfusive-precipitation model applies. Knowing this, the shallowness of the valley in the $^{18}O^-$ signal can be explained without assuming exchange between the migrating interstitials and the oxygen on the oxygen sublattice, although a small amount of exchange may be present but, as previously demonstrated, unimportant. The ^{18}O enters into the permanent sublattice by reacting with the residual silicon metal which remains unreacted after the boundary, at x_s, passes. (The movement of the boundary is very similar to a shock front which leaves a decaying trail behind it.)

Several problems arise using only the IMMA profiles to analyze for the various constants needed for the perfusive-precipitation model. The depth profiling calibration enters directly into both the calculated and observed v_s. However, if the calibration changes from the oxidizing layer to the metal, then the calculated v_s is more affected than the observed v_s. The reason is that the calculated v_s is proportional to (calibration

in metal)^2 divided by the calibration in the oxide; whereas the observed v_s is proportional only to the calibration in the oxide to the first power. The selection of the final inflection on the $^{18}O^-$ signal is difficult. This produces a large uncertainty in U_s which is most serious in the calculation of v_s since the term ($\ln U_s$) is used. The uncertainty in the position of the inflection point does not greatly affect the position of x_s or the value of $\Delta x_{0.1}$ or c_o. Uncertainties in the log scale slopes of $\Delta x_{0.1}$ and $\Delta x_{1/2}$ arise mainly from background oxygen signals for which no compensation was made. Background also produces an uncertainty in the value of c_o. It will cause the measurement of both $\Delta x_{0.1}$ and $\Delta x_{1/2}$ to be high; whereas since c_o is a back-extrapolated number dependent on both $\Delta x_{1/2}$ and the background in opposite senses, the relationship between c_o and background is uncertain. One would probably expect the background to produce a high calculated value for v_s; whereas it had no effect on the observed v_s. The sensitivity of the IMMA to the evolved ions has no effect provided it is equal for both $^{16}O^-$ and $^{18}O^-$ which is the normal case.

As a final point of interest, if the presented model is correct, then the linear rates should be calculable at other temperatures. The constant k has been shown for other systems to be relatively temperature insensitive, and the value for c_o should not change, since it is at the saturation value even at very low oxygen pressures. This leaves only the diffusion coefficient with a significant temperature dependence. This dependence can be obtained using the diffusion coefficient found in this work and the high temperature diffusion coefficient found by Logan and Peters (9) to yield a ($H^‡/R$) of 44×10^3. The extrapolated calculated linear rate is given in Fig. 2 along with the experimental data. Again, the agreement is good.

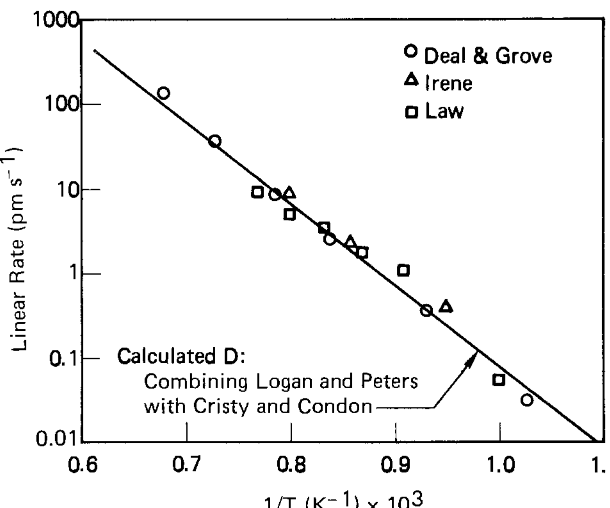

Fig. 2. Comparison of the experimental linear reaction rates for silicon oxidation with the calculated linear rate using a k of 4×10^{-5} sec^{-1} and diffusion coefficient from combined data of Logan and Peters and the value found from IMMA.

Conclusion

For silicon oxidation at 700°C, it is concluded from IMMA data that:

1. The only migrating species of importance in the product layer is dissolved O_2.
2. Generally, the kinetics follow the kinetics proposed by Doremus (2) and modeled by Blanc (7).
3. The silicon-oxide interface reaction is a perfusive-precipitation reaction and can be modeled to yield the measured linear rates with no variable parameters.
4. Vacancies in the product oxygen sublattice are probably present at very low concentrations and migrate with a diffusion coefficient of about 10^{-23} m^2 sec^{-1} and are unimportant in the overall reaction kinetics.
5. Atomic ionic oxygen interstitials in the oxidized layer are not present to any great extent since lattice-dissolved O_2 mixing is not observed, and the IMMA profiles may be modeled by the perfusive-precipitation model alone. Furthermore, the reaction order with respect to oxygen in the parabolic range and the limited mobility of vacancies indicates that atomic oxygen interstitials of any type are not relevant to the overall reaction.
6. The values of the kinetic constants obtained from the IMMA profiles are:

D(O in Si) = about 3.4×10^{-21} m^2 sec^{-1} at 700°C

k (the microscopic, rate constant) = about 4×10^{-5} sec^{-1},

U_s (mole fraction silicon remaining at "interface") = about 0..80.

These parameters yield a calculated velocity for the interface penetration of about 4×10^{-14} msec^{-1} which is in good agreement with the observed velocity and the values obtained from the literature.

LIST OF SYMBOLS

- P — fraction of material that is product (SiO_2)
- x — distance into the sample from the gas-solid surface
- x_s — position where D becomes "large," *i.e.*, the reaction front
- U_s — mole fraction of metal remaining at x_s
- a — stoichiometric ratio ($a = 2$ for SiO_2)
- D — diffusion coefficient of oxygen in silicon metal
- k — a microscopic rate constant per Avrami's limited growth case (14)
- $\Delta x_{1/2}$ — the distance for the log tangent of total oxygen content to decrease by a factor of 2 in innermost tail

t the total time of oxygen exposure, *i.e.*, 1.7×10^6 sec
$\Delta x_{0.1}$ the distance for the log tangent of the product at the inflection point to drop by one decade
v_s overall linear rate or reaction front movement velocity
c_0 the dissolved oxygen content at x_s
$H^\ddagger$ activation enthalpy of the oxidation reaction

Comparison of the Etching and Plasma Characteristics of Discharges in CF_4 and NF_3

N. J. Ianno, K. E. Greenberg, and J. T. Verdeyen*

Gaseous Electronics Laboratory, Department of Electrical Engineering, University of Illinois at Urbana-Champaign, Urbana, Illinois 61801

ABSTRACT

Experiments were performed to explore the correlation (or lack thereof) between the surface effect and plasma characteristics of discharges in CF_4 and NF_3. The optical emission from excited fluorine can be greatly enhanced by the dilution of these gases with helium, yet the etch rate of Si (or SiO_2) is decreased by this dilution. The effect of biasing the sample with respect to the plasma potential was investigated, and for NF_3, evidence was found for a reaction involving a negative ion.

There have been many reports on the effects of various additives on the characteristics of discharges used for etching semiconductors. Most of these studies have concentrated on the effects of hydrogen or oxygen as an additive to the various fluorine donor gases such as CF_4 (1-8). Due to the highly reactive nature of free hydrogen or oxygen atoms, it is difficult to determine which of several processes, occurring either on the surface or within the volume of the discharge, affects the etch rate.

Helium was used as a diluent in these experiments since it will not react chemically with either Si, SiO_2, or Si_3N_4. In addition, the first excited state of helium is metastable, 19.8 eV above the ground state, which is sufficient to excite, dissociate, or ionize any other gas (with the exception of neon) (9). Thus, while ground state helium is chemically inert, excited helium reacts vigorously in the volume of a discharge.

A d-c hollow cathode discharge (10) was used to excite the gases in order to simplify the diagnostics such as measurements of ion current to the sample. Unlike a positive column discharge, the hollow cathode discharge is an electron beam produced plasma, and thus is capable of producing a stable, uniform, glow discharge in CF_4 and NF_3 (a highly electronegative gas), at low pressures and low power levels.

Figure 1 is a schematic diagram of the hollow cathode used for the experiments. The cathode was a 5 in. long, 1-3/8 in. ID stainless steel nipple. Six stainless steel rods were attached to the aluminum anode plate and wrapped with nickel wire to form a coaxial metal basket. A retaining plate held a quartz window over a 5/8 in. hole in the anode plate and a Maycor insulator separated the anode from the cathode. The etchant gas flowed into the cathode, past the sample which was mounted on the front of the water cooled probe, and was pumped through a fore line trap and out of the system by a mechanical pump. The pressure was monitored using a capacitance manometer and the optical emission was observed through the quartz window using a McPherson 350 mm monochromator and an RCA 31034 photomultiplier.

During the experiments, the anode was grounded, the cathode was driven negative, and the probe con-

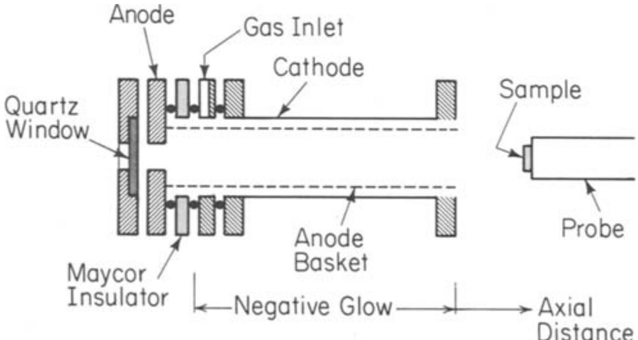

Fig. 1. Schematic of the hollow cathode discharge used in these experiments.

Key words: plasma processing, negative ions, emission enhancement, gas discharge.

taining the sample was biased with respect to floating potential, which was a few tens of volts negative with respect to the anode. The gas flow rate, total pressure, and discharge current were all held constant at 3.3 l/min (STP), 0.25 Torr, and 50 mA, respectively. For these operating conditions, the discharge voltage varied between 300 and 1000V. The remaining controlled parameters were gas mix, probe bias, distance from the plasma, and etch gas (CF_4 or NF_3).

Experimental Results

Optical emission.—In recent years, a strong correlation has been demonstrated between the intensity of the optical emission of excited fluorine from a $CF_4:O_2$ discharge and the etch rate (1, 3, 5, 7, 8). To investigate this correlation further, helium was added to a CF_4 discharge.

Figure 2, a partial energy level diagram of helium and CF_4, illustrates the possibilities afforded by the addition of helium to a CF_4 discharge. The first two excited states of helium, the 2^1S and 2^3S, are both metastable. Either metastable can ionize the CF_4 to create CF_4^+, or to create CF_3^+ and a free fluorine, via the Penning reactions shown in Eq. [1a] and [1b].

$$He^* (M) + CF_4 \rightarrow CF_4^+ + e + He \quad [1a]$$

$$He^* (M) + CF_4 \rightarrow CF_3^+ + e + F + He \quad [1b]$$

In addition, the 2^1S state has enough energy to simultaneously dissociate and excite a fluorine atom to the ^2D state, according to Eq. [2], greatly enhancing the fluorine emission at 704 nm (and also the lines of the quartet system) (11)

$$He^* (2^1S) + CF_4 \rightarrow CF_3 + F^* + He \quad [2]$$

Figure 3 demonstrates the dependence of the relative intensity of the 704 nm emission and the etch rates of Si and SiO_2 upon the concentration ratio of CF_4 to helium. These data were taken with the sample at floating potential and located at the edge of the negative glow. As illustrated, the 704 nm emission can be enhanced by a factor of approximately 12, using a 5:1 mixture of He:CF_4. While the optical emission is enhanced and passes through a maximum, the Si etch rate decreases monotonically as the helium concentration increases. Also, it should be noted that while the SiO_2 etch rate is enhanced by the addition of helium, the maximum does not coincide with the fluorine emission peak. These trends are not particular to the CF_4:He mixtures as the same general behavior is observed when a more conventional etchant gas mixture, 95% CF_4 + 5% O_2, is diluted with helium; the variations of the fluorine emission and the etch rates of Si and SiO_2 with these mixtures are similar to those shown in Fig. 3. Furthermore, these characteristics are not a peculiarity of the electron distribution of the hollow cathode as similar effects are seen when the plasma is excited by an rf induction discharge (12).

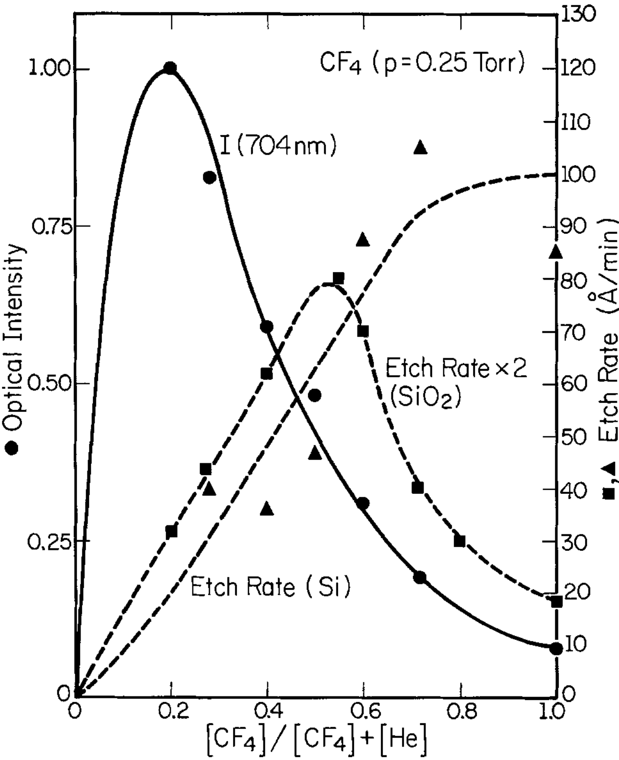

Fig. 3. Variation of 704 nm intensity, Si, and SiO_2 etch rates as a function of the helium partial pressure in CF_4 at a constant total pressure and current density. Note the increase in emission and lack of correlation between it and the etch rates.

There is a point which should be clear from this data: The spectral emission of atomic fluorine is not necessarily correlated with the etch rate of either Si or SiO_2, for different gas mixtures. Within a particular gas mixture, however, the spectral emission will be indicative of the excitation density of the plasma, and thus, as a discharge parameter affecting the optical emission is varied, the etch rate should correlate well with the emission. For example, the etch rates of Si and SiO_2 and the 704 nm emission were monitored as a function of discharge current, for a constant gas mix. As the current was varied, the optical emission and the etch rates changed in a synchronous manner.

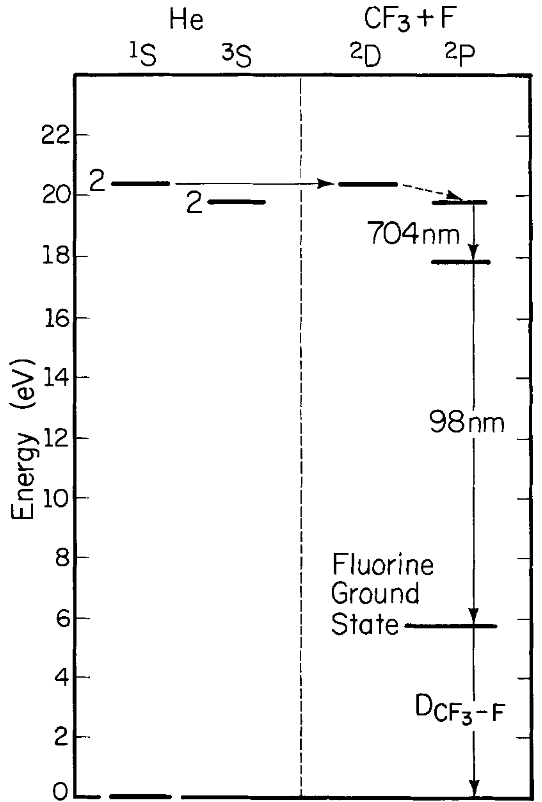

Fig. 2. Partial energy level diagram of helium and CF_4 showing the energy transfer from the helium 2^1S metastable to CF_4.

Correlation with ion current.—The relationship between the etch rate and the saturated ion current to the sample was investigated. To measure this current, the sample probe was replaced by a double probe which consisted of an inner conducting rod insulated from an outer tube. A nickel wire mesh covered the open end of the outer tube. By biasing the inner rod 300V negative with respect to the outer case, the electron current to the rod became negligible and only the current carried by positive ions was measured. Therefore, the saturated ion current consisted of ions that

were formed in the discharge and diffused to the nickel mesh.

The data in Fig. 4 were taken by moving the sample and double probes downstream from the edge of the visible glow. As shown, there is an excellent correlation between the etch rate of Si_3N_4 and the saturated ion current to the sample; the etch rate tracks the current over two orders of magnitude. The Si and SiO_2 etch rates behaved quite differently, however. As the sample is moved downstream from the active plasma, the etch rates decrease rapidly at first, and then continue to decline very slowly. It would appear that the dominant etch mechanism for Si_3N_4 is associated with positively charged species impinging upon the sample. For Si and SiO_2 though, it seems that the etch rates close to the discharge are dominated by processes involving positively charged species, whereas neutral species, due to their longer lifetimes, have a greater effect farther away from the active plasma.

To explore the effect of charged species on the etch rate further, the sample probe was maintained in a fixed position at the edge of the negative glow and its bias was varied with respect to the grounded anode (13-15). As shown in Fig. 5, when the probe was biased more negative with respect to floating potential, the positive ion current to the sample increased due to pair production in the sheath. The SiO_2 etch rate tracked this current, implying that positively charged species may contribute to the etch mechanism. When the probe was biased positive with respect to floating potential, an increased current due to negative carriers reaching the sample had no effect on the etch rate.

To determine how much of the etch rate increase could be attributed to physical sputtering when the probe was biased negative with respect to the anode, an argon discharge was used under conditions similar to the CF_4 discharge. When the sample probe was biased 300V negative, an etch rate of 100 Å/min was observed. (Etching did not occur in the absence of the bias.) This etch rate is comparable to the enhancement obtained when pure CF_4 was used, indicating that physical sputtering was responsible for the enhanced etch rate as opposed to the decomposition of chemisorbed species or chemical reactions involving the ions (13, 14). This will be discussed in further detail along with the results of the NF_3 experiments.

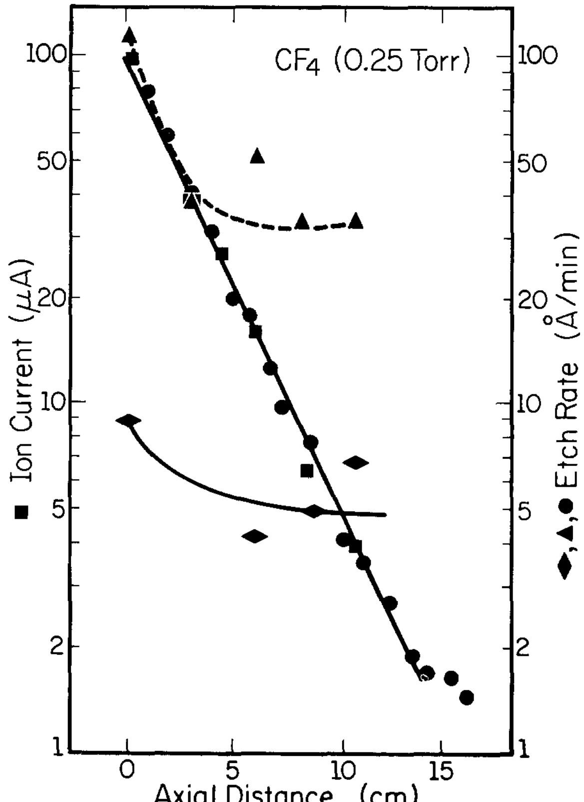

Fig. 4. Variation of the saturated ion current to the sample (■), the etch rate of Si_3N_4 (●), Si (▲), and SiO_2 (♦) as a function of distance from the edge of the visible glow. The Si_3N_4 etch rate tracks the ion current over two orders of magnitude and the etch rates of Si and SiO_2 rapidly become independent of the ion current.

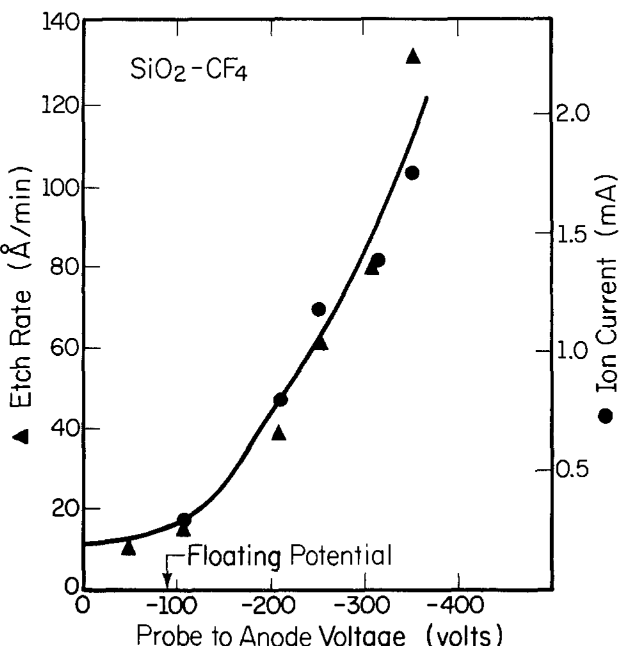

Fig. 5. Etch rate of SiO_2 and ion current to the sample as a function of probe to anode voltage.

Etching with NF_3.—While there have been many papers and discussions associated with the etching characteristics of discharges in CF_4 (and with O_2), comparatively little has been published for NF_3 (16, 17). Some of the practical aspects of etching with this gas are listed below.

1. The etch rates of Si, SiO_2, and Si_3N_4 are at least a factor of 10 faster with discharges in NF_3 as opposed to CF_4.
2. The etch rate of Si can be 25 times that of SiO_2.
3. The products of a discharge attack photoresist very slowly.
4. NF_3 does not etch Si, SiO_2, Si_3N_4, or photoresist in the absence of a discharge.

Presumably, much of the contrast in the etch rates of NF_3 and CF_4 can be attributed to the fact that all constituent products of the NF_3 discharge are gases and the problem of carbon build up is nonexistent (13).

The same type of experiments, as described for CF_4, were performed using NF_3 as the etch gas. The 704 nm emission intensity from a discharge in NF_3 is much larger than from a discharge in CF_4 and can be enhanced as shown in Fig. 6. In contrast to the results using CF_4, the etch rates of both Si and SiO_2 show a monotonic decrease with an increase of helium concentration.

Figure 7 shows the variation of the etch rates and saturated ion current as a function of distance from the edge of the negative glow. The etch rates of Si and SiO_2 exhibit a slow decrease with distance from the glow, as opposed to the ion current which drops rapidly. Unlike CF_4, there appears to be no relationship between the ion current and the etch rate, even in the immediate vicinity of the discharge (compare Fig. 7 with Fig. 4 for equal values of distance). This would imply domination of the etch rate by processes involving neutral species, even close to the glow, whereas

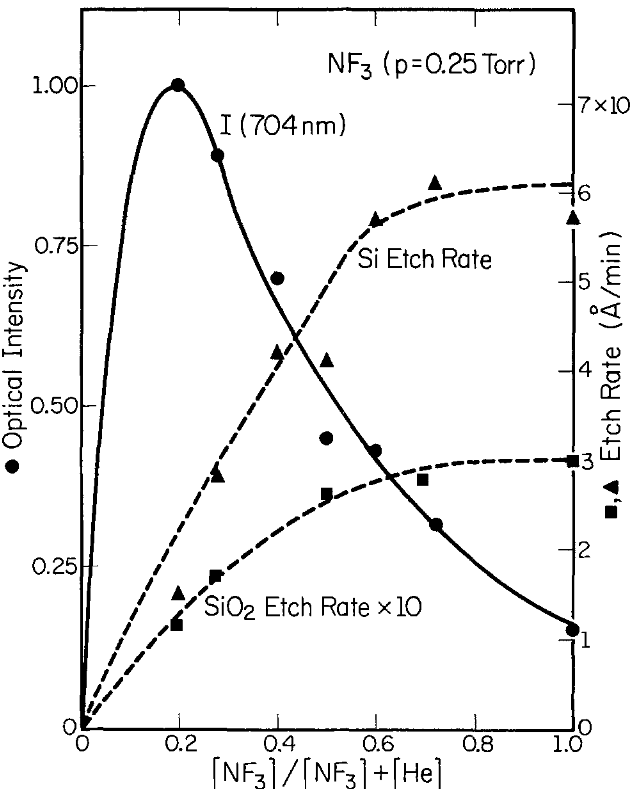

Fig. 6. Variation of 704 nm emission, Si, and SiO_2 etch rates as a function of the He partial pressure in NF_3 at a constant total pressure and current density. There is a large increase in the optical emission, similar to CF_4, yet the etch rates of both Si and SiO_2 decrease monotonically.

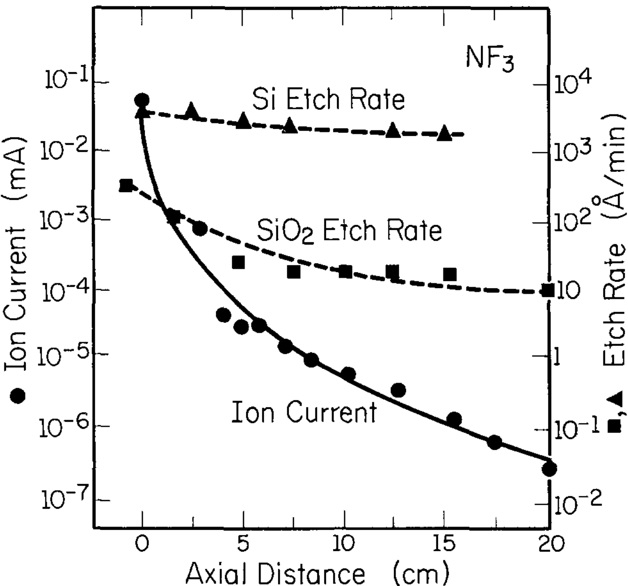

Fig. 7. Variation of the saturated ion current to the sample and etch rates of Si and SiO_2 as a function of distance from the edge of the glow.

CF_4 exhibited a stronger dependence on positively charged species near the discharge.

Although it appears that neutrals play the dominant role in the case of NF_3, it is interesting to note the effect of increasing the flux of charged particles to the sample. As shown in Fig. 8, the etch rate is enhanced for a bias below floating potential and follows the positive ion current similar to the data in Fig. 5 for CF_4. When the probe is driven above floating potential, however, there is a rapid increase in the etch rate which was not observed in CF_4.

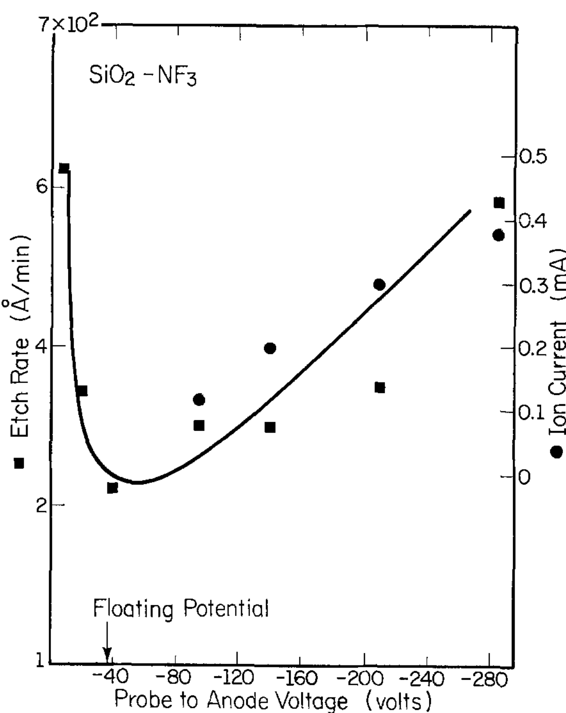

Fig. 8. Variation of the etch rate of SiO_2 and positive ion current to the sample as a function of the probe to anode voltage. There is a large etch rate increase for the small potential change when the probe is driven above floating potential, in contrast to CF_4.

To explore this difference in behavior, a simple cylindrical Langmuir probe was inserted into the discharge. The probe consisted of an 8 mil diam tungsten wire protruding 1/2 cm from the end of a glass support. The end of the wire was placed at the edge of the negative glow.

When biased below floating potential, the probe characteristics are similar for discharges in CF_4 and NF_3; however, when biased positive, there is a distinct difference as shown in Fig. 9. In the CF_4 discharge, the current increases dramatically for a 30V change above floating potential which is indicative of electrons as current carriers. This large increase does not occur in the NF_3 discharge. Instead, the current rises very

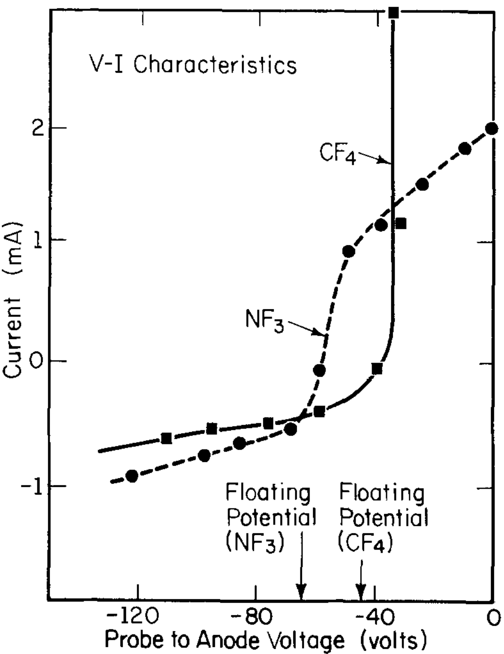

Fig. 9. Variation of the current to a Langmuir probe as a function of anode to probe voltage.

slowly, indicating that the carriers are massive negatively charged ions formed in the discharge. These characteristics are very similar to the probe characteristics of an iodine discharge, as observed by Emeleus and Woolsey, where negative ions are known to exist (18).

Conclusions

The experiments investigating the correlation between the optical emission and the etch rate of the sample show that the addition of helium to NF_3 or CF_4 discharges increases the generation rate, and thus emission, of excited fluorine; nevertheless the etch rate does not correlate with the excited state population. These data are not necessarily in contradiction with previous theories as will be discussed below.

A number of reactions should be considered in formulating a hypothesis to explain these results

$$e + CF_4\ (NF_3) \rightarrow e + CF_3\ (NF_2) + F^* \quad [3]$$

$$e + F \rightarrow e + F^* \quad [4]$$

$$F^* \rightarrow F + h\nu \quad [5]$$

$$e + CF_4\ (NF_3) \rightarrow e + CF_3\ (NF_2) + F \quad [6]$$

Excited fluorine may be produced by the resonant energy transfer from the helium metastable according to Eq. [2] or by direct electron impact as described by Eq. [3] and [4]. On the other hand, ground state fluorine, which can be a major contributor to the etch mechanism (1, 3, 4, 19), may be produced by an electron dissociation (Eq. [6]) in addition to the processes described by Eq. [2] through [4], coupled with Eq. [5].

The dependence of the optical emission on the helium partial pressure could be attributed to a shift in the mean energy of the electron distribution function which, in turn, would affect the excitation rate of either CF_4 (NF_3) or atomic fluorine as described by Eq. [3] and [4]. This is not very likely to occur with the hollow cathode discharge, however, since most of the excitation is caused by high energy electrons which were accelerated through the cathode fall. Even though improbable, this possibility was tested by adding a trace amount of argon to CF_4 (NF_3):He mixtures and monitoring an argon emission line (20, 21). Virtually no dependence of the Ar* emission upon the helium to fluorine donor concentration was found. Consequently, for creating excited fluorine under the experimental conditions used here, the data in Fig. 3 and 6 indicate that the excitation transfer from helium to CF_4 (or NF_3) via Eq. [2] is much more important than direct electron impact excitation.

The optical emission monitors the excited population (F^*) and not the more numerous fluorine ground state density (which was not measured during these experiments). Thus the data of Fig. 3 and 6 show that the contribution of the excitation transfer (Eq. [2]) to the production of atomic fluorine is small. This can explain why the etch rates of Si and SiO_2 in NF_3, and Si in CF_4, behave as shown in Fig. 3 and 6. As the helium concentration increases, the production of fluorine by reaction [6] decreases due to a dilution effect. Even though the fluorine produced via Eq. [6] is diminished, it still overwhelms the amount of fluorine produced by the reactions of Eq. [2]-[5].

The probe biasing experiments show that the etch rate of SiO_2 increases in proportion to the ion current when the probe is biased negative with respect to floating potential, for both NF_3 and CF_4 discharges. In the case of CF_4, the increase can be attributed to physical sputtering. This does not imply, however, that ions formed in the CF_4 discharge do not contribute to the etch mechanism in other ways. In fact, the saturated ion current data in Fig. 4 indicate that processes involving positive ions dominate the etch rate near the discharge. Since the Langmuir probe characteristics indicate that the plasma potential for the CF_4 discharge is only a few volts above floating potential, these ions will be nonballistic and contribute to the etch mechanism through a chemical process as opposed to physical sputtering (13, 22).

The probe data for NF_3 also indicate that ions formed in the discharge can contribute to the etch mechanism via chemical processes. When the probe was biased 280V negative with respect to the anode, an etch rate increase of 400 Å/min was observed (Fig. 8). Recalling that an argon discharge yielded an etch rate of only 100 Å/min, it would appear that this increase cannot be accounted for solely by physical sputtering. In addition, when the probe was biased just 20-30V above floating potential, the etch rate was enhanced by 400 Å/min for NF_3. The Langmuir probe characteristics and electron impact studies both indicate the production of negative ions in the NF_3 discharge (23, 24). Since these negative ions could only gain 20-30V crossing the sheath, it is highly unlikely that sputtering can account for the 400 Å/min enhancement observed. Once again, the ions seem to be reacting chemically at the surface or participating vigorously in the decomposition of chemisorbed species.

In summary, there appear to be a number of processes and etchant species contributing to the etch mechanism for discharges in NF_3 and CF_4. It is apparent, for both gases, that positive ions have the capability of contributing to the etch mechanism through chemical reactions. In addition, large quantities of negative ions also appear to be formed in NF_3 discharges; there is evidence that these ions can participate vigorously in the etch mechanism.

Dielectric Breakdown and Device Evaluation of Fritted Glass Compositions

D. L. Flowers*

Motorola, Semiconductor Research and Development Laboratory, Phoenix, Arizona 85008

ABSTRACT

Dielectric breakdown studies have been conducted on glass compositions of interest for device passivation. It was found that a 900°C sealing glass, 50 weight percent (w/o) lead oxide, 10 w/o alumina, 40 w/o silica gave dielectric breakdown protection two to three times greater than 1 micrometer of thermal SiO_2 or CVD phosphosilicate glass. The dielectric strength of this glass (168 V/μm) is lower than that of thermal SiO_2 (780 V/μm) or CVD phosphosilicate glass (840 V/μm). When 3% or 11% B_2O_3 is substituted for small amounts of the constituents in a 70 w/o PbO, 20 w/o SiO_2, 10 w/o Al_2O_3 glass, sealing temperature is lowered from 850° to 650° or 560°C, respectively. Dielectric strength is also lowered from 300 to 50 V/μm. It is shown that these low sealing temperatures, low dielectric strength glasses, could protect moat etched devices from arcing with avalanche breakdowns to a targeted 1.3 kV but reverse leakage is quite high, *i.e.*, 300-500 μA at 1 kV. This compares to the 50 w/o PbO glass with 20 μA leakage and the 70 w/o PbO glass (850°C) with 10 μA leakage at 1 kV. In an attempt to obtain lower fusion temperatures and to overcome the high leakage seen with the boron-containing glasses, a new glass without boron was made. It contains 5 w/o GeO_2 and 5 w/o ZnO in place of like amounts of SiO_2 and Al_2O_3 in the 70 w/o PbO glass mentioned above. The fusion temperature was reduced from 850° to 650°C. When used on moat etched devices as a passivant, the new glass protected easily to 1.3 kV with only 10 μA reverse leakage at 1 kV similar to the parent 850°C fusing glass. The properties of this glass make it an excellent candidate as a passivant for devices where a relatively low fusion temperature is required.

Dielectric breakdown of device passivation is of prime importance to the semiconductor industry. Both yield and reliability are directly impacted by the quality and type of passivation used. Dielectric breakdown of thermally grown films of silica and phosphosilicate glass have been reported by Snow *et al.* (1). The effect of processing parameters on the breakdown has also been reported (2). Distefano *et al.* (3) developed a theoretical model which explains the "primary" or electronic breakdown of the films categorized by Fritzsche (4). According to the latter author, there are also "secondary" and "tertiary" breakdown modes. The secondary breakdown mode is postulated to be due to inhomogeneities in the film, perhaps crystallites of quartz in the amorphous silica in the case of SiO_2. The tertiary, lowest voltage breakdown is assumed to be due to pinholes or weak spots in the film.

Passivation of semiconductor devices by fused, fritted glass films has been used extensively in the industry but no studies of the dielectric breakdown behavior of these films on silicon have been reported. It was the purpose of this work to determine the dielectric breakdown of some glass compositions fusing between 560° and 900°C (5). They can be described as derivatives of lead-alumino-silicates containing small amounts of boron, germanium, zinc, and/or cadmium oxides to modify fusion temperature. It was a further objective to determine their limitations for device use. Some unexpected differences in behavior compared to that of silicon dioxide and phosphosilicate glass passivation were noted.

Experimental

Wafers used in this study were 5.1 cm in diameter, 430 μm thick. They were <100> phosphorus-doped, CZ, 0.001-0.074 Ω-cm material. Cleaning before glass application was done by: (*i*) 1 min 10:1 H_2O:48% HF at 50°C; (*ii*) 20 min DI cascade water rinse; (*iii*) 20 min piranha (85% H_2SO_4, 15% H_2O_2) at 100°C; (*iv*) 20 min DI cascade water rinse; (*v*) 1 min 10:1 H_2O:48% HF at 50°C; (*vi*) 20 min DI cascade water rinse; (*vii*) blow dry-N_2.

The fritted glass, suspended in an organic solvent-polymeric binder, was spun on the wafers and photolithographically patterned with a conventional contact aligner. They were then fused in an air ambient for 5 min at temperatures noted in the text.

To compare with the dielectric breakdown for the fritted glass compositions, some wafers were steam oxidized at 1000°C and tested. Thicknesses obtained were 550 and 960 nm. In addition CVD passivation was also applied to test wafers and evaluated. The CVD film was a sandwich structure of 200 nm of undoped SiO_2 at the air and silicon interface and 400 nm of 4 weight percent (w/o) phosphorus-doped SiO_2 in the middle. Aluminum dots, 500 nm thick, were evaporated on the glassed wafers through a metal mask (cold substrate.) Two patterns were evaluated to determine the effect of dot size and proximity on the dielectric measurements. These were 500 μm dots, 1240 μm apart, or, 940 μm dots, 6000 μm apart.

Wafers were probed with a Tektronix Model 576 curve tracer with either a standard 2.5 kV or a high voltage 5 kV attachment. Applied voltage was ramped at ~100 V/sec until breakdown occurred. Probing was done in the d-c mode with the dots biased positively or negatively as follows: (*i*) In an air ambient; (*ii*) wafer surface covered with xylene; (*iii*) wafer surface dehydrated by a hexamethyl disilazane (HMDS) treatment. This consisted of spinning the material on the wafer (3K rpm, 30 sec) and baking 2 min, 200°C, N_2.

Four of the glasses were tested on p^+n moat-etched, high voltage diodes. The moat depth was 80 ± 5 μm.

Results and Discussion

Dielectric breakdown of steam oxide and phosphosilicate glass (CVD).—To compare the results of this study of glass compositions, the dielectric breakdown of steam grown SiO_2 and a CVD phosphosilicate glass sandwich was evaluated. The measured dielectric strength of steam SiO_2 was 675 ± 60 V/μm for the 550 nm film and 781 ± 130 V/μm for the 960 nm film. The phosphosilicate glass sandwich had a somewhat higher value, 846 ± 104 V/μm. The dielectric strength for steam oxide is in the midrange of that reported by Klein *et al.* (6, 7) and is somewhat higher than that reported by Deal (8). The higher value for phosphosilicate glass, also observed by Chou and Eldridge (2), is attributed to the phosphorus in the glass.

For device types having high avalanche breakdown voltages, (>1 kV), the use of steam oxide as a passivant is not commercially attractive because the time required to grow very thick oxide is quite long and thick oxide films tend to crack. Also, the inherent positive charge at the oxide interface tends to limit the breakdown (avalanche) that can be achieved. The glass passivation process overcomes these drawbacks of time and positive interfacial charge (9). In addition, the higher dielectric constant (ϵ = 10-17) of the glasses compared to amorphous SiO_2 (ϵ = 3.9) can drop a greater portion of the applied voltage across the glass thickness to minimize the danger of air ionization.

Dielectric breakdown of 900°C sealing glasses.—The composition of the glasses examined in this section are shown in Table I and results of breakdown studies are shown in Table II. The effect of probe ambient and glass thicknesses on the breakdown properties are also included. It is seen that the breakdown voltage for 5-16 μm films is much higher than that for commonly used thicknesses of steam oxide or phosphosilicate glass passivation discussed earlier. However, the dielectric strength of the glasses is seen to be lower than that of steam oxide or the phosphosilicate glass sandwich. It is interesting to note that the dielectric strength of these glasses is much greater when measured on thinner films. This is taken as evidence that a higher strength dielectric region above silicon is formed when fusing the glass powder. The nature of the high dielectric strength interface is unknown. If one considers that only 50A of oxide should be grown on silicon in the 10 min fusion of the fritted glass powder at 900°C in dry oxygen, only about 4V can be added to the breakdown voltage of the film.

The mode of breakdown for these glasses is different than that for steam oxide or phosphosilicate glass. The latter two passivants broke down in a single event. This has been attributed by Fritzsche to be ultimate or electronic breakdown occurring between 700 and 900 V/μm (4). The deposited glasses however, in the thickness used, break down by a different mechanism, which occurs before the ultimate or electronic breakdown potential is reached. Further, it takes place by an arcing mechanism from the edge of the dot being probed and to several millimeters across the glass. Arcing continues until part of the metal on the dot has burned away, the glass fails, and the device shorts. This manner of breakdown has been described by Klein *et al.* as a single hole event propagating to adjacent sites (6, 7). The ultimate dielectric strength of the glass was not determined because the films were too thick to reach ultimate breakdown before arcing occurred.

By using a xylene film on the wafers being probed, a closer approach to electronic breakdown was made but not reached. Treatment of the glassed wafer surface by HMDS which removes adsorbed water gave effects similar to xylene.

Dielectric breakdown of glasses fusing at or below 850°C.—There is often a need in device technology for passivation glasses fusing well below 900°C, *e.g.*, premetallized wafers, shallow junction devices, etc. A number of such glasses were prepared and their breakdown properties were evaluated and correlated with composition. The glasses, their composition, and fusion temperature are shown in Table III. As can be seen in glass H and glass I, small amounts of boron added to the glass system lead, alumino silicate greatly depress the sealing temperature. As a result these are of great interest in extending device technology.

Dielectric breakdown associated with these glasses is shown in Table IV. The highest dielectric breakdown

Table I. Composition of 900°C sealing glasses

Glass	Composition
A	40 w/o SiO_2 : 50 w/o PbO : 10 w/o Al_2O_3
B	3 w/o V_2O_5 replacing PbO in A
C	2.8 w/o Mn_2O_3 replacing PbO in A
D	1.3 w/o V_2O_5 + 1.3 w/o Mn_2O_3 replacing PbO in A

6.0 ± 1	HMDS	310 ± 20	52 ± 3.3	Single spark event breakdown

strength of the glasses tested in the entire study was seen in glass E. The value of 301 V/μm is much higher than that of glass A, 162 V/μm. A notable observation separating these glasses from those reported in Table II is that the breakdown mode (except for glass F—air probe ambient) has changed from continuous surface arcing to a single hole or spark event similar to that reported by Fritzche (4). Single event breakdown occurs before surface leakage causing arcing type breakdown. Changing the probe ambient from air to xylene or HMDS changes the measured dielectric strength very little for the boron glasses consistent with single event breakdown. For the zinc containing glass F, however, the use of xylene changed the mode of breakdown from multiple event (arcing) to single event. As such, the breakdown strength was improved 62%. This illustrates how changing constituents in the glass can change the breakdown mode.

Correlation of dielectric strength and fusion temperature with composition.—Figure 1 compares dielectric strength and fusion temperature as they are varied by glass composition. It is seen that the addition of only 3% boric anhydride, to glass A lowers the fusion temperature from 900° to 650°C. However, the dielectric strength is depressed 60%. The addition of 10% zinc oxide, glass F, lowers the fusion temperature 100°C yet depresses the dielectric strength only slightly. Increasing the concentration of lead oxide from 50%, glass A to 70%, glass E, decreases the fusion temperature 50°C but raises the dielectric strength 83%. In the glasses fusing at 900°C, the addition of 3% vanadium pentoxide, glass B, raises the dielectric strength 21% but the addition of 2.8% Mn_2O_3, glass C, lowers it 44%. These results illustrate an important effect that small changes in glass composition have on fusion temperature and dielectric strength.

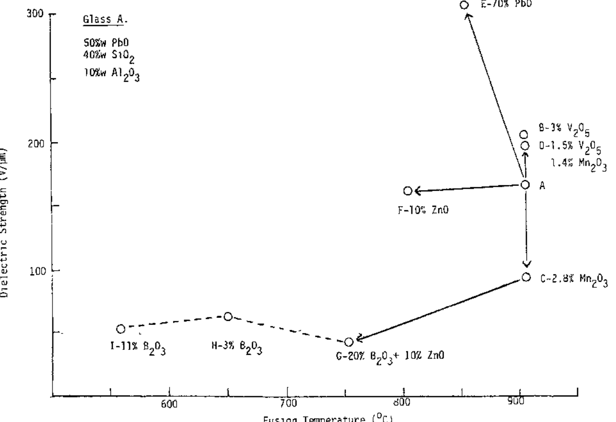

Fig. 1. Dielectric strength and fusion temperature for various glass compositions (ref: Table I and Table III).

Evaluation of moat etched diodes passivated with low temperature fusion glasses.—Because the breakdown voltage of many devices used with glass passivation is considerably higher, BV = 1-2 kV, than the observed dielectric breakdown of the passivation, particularly the boron-containing glasses, it was decided to test the 11% boric anhydride glass, I, on a moat-etched, high voltage diode. Comparison with diodes passivated by higher dielectric strength glasses A and E would help qualify the boron-containing, low temperature glasses for high voltage device use. In addition, a glass containing 5% germanium oxide, and 5% zinc oxide to depress the fusion temperature of glass A was also tested, glass 3, 650°C fusion, for potential use if the boron-containing glass failed to qualify. The germanium oxide glass was expected to have better dielectric properties than the boron glass because of germanium's relation to silicon in the periodic table. Results are shown in Table V.

The breakdown voltages at avalanche on the diodes with all four glasses were about the same. The leakage of the boron containing glass I was quite high. This means that boron in the glass is introducing easily activated surface states at the interface. Photosensitivity experiments also confirm the presence of added surface states as shown later. In addition, immediately after sealing, the boron-containing glass evidences some electronic instability which disappears after 24 hr storage at room temperature. The germanium zinc containing glass J with no transient electronic instability has the lowest leakage of all.

Table V. Breakdown (avalanche) properties of moat-etched diodes passivated with selected glass composition

	Glass fusion T (°C)	Composition (w/o)	I_R at 1 kV (μA)		BV at I_R (μA) (kV)
			After fuse	After 24 hr	After 24 hr
1.	No glass	~10A native oxide	Walkout to ~400V, tendency to arc		
2.	A (900°C)	40 50 10 SiO_2-PbO-Al_2O_3	20 ± 8	20 ± 8	1.25 ± 0.04 (20 ± 5 μA)
3.	J (650°C)	15 5 70 5 5 SiO_2-GeO_2-PbO-Al_2O_3-ZnO	12 ± 5	12 ± 5	1.29 ± 0.03 (10 ± 2 μA)
4.	I (560°C)	22 62 11 5 SiO_2-PbO-B_2O_3-Al_2O_3	Channel off scale ~500V	220 ± 80	1.30 ± 25 (>500 μA)
5.	E (850°C)	20 70 10 SiO_2-PbO-Al_2O_3	—	10 ± 2	1.28 ± 0.06 (10 ± 2 μA)

In another set of experiments to further qualify and characterize glass J and glass I, the firing temperature of these glasses on moat etched diodes was investigated. Results are shown in Table VI. The breakdown and leakage obtained in both these glasses are improved by raising the firing temperature about 50°C. The wafers were tested with and without a film of xylene on them to determine any change in breakdown voltage or leakage due to the added dielectric film. There was none.

The final point that was briefly studied here concerns photocurrent in the glasses diodes. On first testing it was noted that glass I caused the diodes to become very photosensitive with large channel currents developing. To test the photocurrent in a semiquantitative way, wafers with no glass, glass J, and glass I were probed in darkness and in dimmed room light at 5 and 10V. Details are shown in Table VII.

These data show that the diode without passivation has leakage currents that are enhanced by light due to photosensitive states that are at or near the silicon oxide interface. Passivation with glass J does very little to change that leakage. Glass I, on the other hand, introduces additional surface states illustrated by higher leakage, enhanced by illumination. The reason for these states is evidently related to the boron in the glass. Although not studied in this work, qualitative earlier observations indicated that glass A has light sensitivity similar to glass J.

Summary and Conclusions

Eight glass compositions were studied with respect to their dielectric breakdown behavior. This was done to help characterize fritted glass device passivation and screen new candidates for product use. Fusion temperatures for the glasses tested ranged from 900° to 560°C. To achieve the fusion temperature range noted, the base glass A composition was suitable modified. This was most noticeably effected by varying the composition ratios and by the addition of small amounts of ZnO, B_2O_3, CdO, or GeO_2. The dielectric breakdown of steam oxide and a CVD phosphosilicate glass sandwich were compared with that of the fused glass powders.

It was shown that the dielectric breakdown of glass A, 1.1-1.8 kV, for thicknesses of 1-16 μm, is considerably higher than that of steam oxide (0.73 kV for 1 μm). The application of a film of xylene or HMDS treatment on the surface of the test device did not change the value of the breakdown voltage of steam oxide or phosphosilicate glass. It did increase the measured breakdown voltage to 2.0-2.3 kV for the tested lead aluminosilicates, glasses A and E.

The mode of breakdown for steam oxide or the phosphosilicate glass sandwich is a single hole event indicative of electronic (primary) breakdown of the passivation. The mode of breakdown for the lead aluminosilicates was distinctively different. Electronic breakdown was not reached before surface arcing occurred. This has been described as a multiple site event with initiation at the probe site followed by propagation (arcing) to adjacent sites. The application of the xylene film or HMDS treatment on the lead aluminosilicates did not change this mode of breakdown. It significantly raised the threshold value. This is taken to mean that surface leakage causing significant voltage drops along the surface is causing arcing. The xylene film or HMDS treatment reduces the leakage and hence raises the threshold voltage for arcing.

The calculated dielectric strength increased for all of the fritted glass powder passivants tested as the thickness decreased. This is taken to mean that a higher dielectric strength region exists between the fused glass film and the silicon wafer. The reason for this is unknown. The highest dielectric strength measured, 305 V/μm, was that of glass E which contains 20 w/o more PbO than does glass A which has a dielectric strength of 168 V/μm, both being measured 6 μm thick. Lowest dielectric strengths were seen with the glasses containing small amounts of boron, 40-50 V/μm. The lead aluminosilicates breakdown in a multiple event without reaching electronic breakdown, while the boro lead aluminosilicates display primary or single event breakdown with the low dielectric strength noted.

To determine if low dielectric strength boron containing glass I fusing at 560°C could be used to passivate high voltage devices, it was applied, patterned, and fused on p^+n diode wafers with targeted avalanche breakdown to ≥1.0 kV. A new glass, J, was also prepared using germanium and zinc to lower the fusion temperature to 650°C. Probe results showed the boron-containing glass I did allow the diodes to reach stable, high voltages, >1.0 kV, without breakdown of the passivation. Reverse leakage was quite high, however; >300 μA at 1 kV. The germanium-zinc glass also allowed high, stable voltages, >1.0 kV, to be reached with the additional advantage of low reverse leakage, i.e., ~10 μA at 1 kV cf. 20 μA for glass A, the standard 900°C fusing glass.

From these results it is concluded that glasses without boron could be used for high voltage passivation. The new glass, J, using germanium and zinc to lower fusion temperature, is a strong candidate for a lower temperature glass passivant.

Table VI. Comparison of diode breakdown voltage for glass I and glass J fused at different temperatures*

Glass	Firing temp. (°C)	BV (kV) at I_R (μA)	
1. J	650°	1.29 ± 0.03 avalanche	10 ± 2
	700°	1.38 ± 0.04 avalanche	5 ± 2
2. I	560°	1.30, soft, no avalanche	>500 μm
	600°	1.60, soft, no avalanche	333 ± 28

* Evaluated 24 hr after glass fusion.

Table VII. Determination of photocurrent in glass I and glass J

Glass	Voltage	Reverse current (nA)		Photocurrent (nA)
		Light off	Light on	
1. None	5	100 ± 50	800 ± 50	700 ± 100
	10	150 ± 50	1000 ± 50	850 ± 100
2. J (5% Al_2O_3, 5% ZnO, 5% GeO)	5	150 ± 33	750 ± 50	600 ± 88
	10	250 ± 50	1050 ± 50	800 ± 100
3. I (11% B_2O_3)	5	450 ± 150	1500 ± 200	1050 ± 350
	10	550 ± 250	1600 ± 100	1050 ± 350

ABSTRACT

The results of a study of laser-annealed Au-Ge ohmic contacts to GaAs are presented. The specific contact resistivity was observed to decrease with increasing laser energy density while the grain size of the polycrystalline microstructure (as observed by transmission electron microscopy) increased. At higher energy densities, both parameters were found to remain constant within the experimental conditions used. Transmission electron micrographs, and sputtering Auger electron spectroscopic data showing Ga, As, and Ge redistribution within the Au-Ge film are also presented.

Recent research has focused on using laser irradiation for making ohmic contacts to GaAs because the localized, short duration heating of a laser beam was expected to result in negligible GaAs decomposition and therefore improve contact quality. Results obtained for laser-annealed ohmic contacts (1, 2) have so far shown no significant improvement in contact properties over contacts made by conventional furnace alloying. A more detailed study of laser-annealed ohmic contacts, focusing on the materials properties, therefore seems necessary.

Transmission electron microscopy (TEM) is useful not only for microstructural study of materials but also for identification of material types and phases. It has been used to study the alloying of thin films of Au (3) and Au-Ge-In (4) on GaAs. However, only the microstructural properties of these contacts were investigated.

We report here a study of laser-annealed Au-Ge/GaAs ohmic contacts using TEM to correlate the microstructure and the electrical properties as obtained from specific contact resistivity measurements. Specifically, the variation of the specific contact resistivity as a function of the laser energy density was measured and is presented along with variations in the microstructure and the compositional depth profile as measured by Auger electron spectroscopy (AES).

Sample Preparation and Experimental Procedure

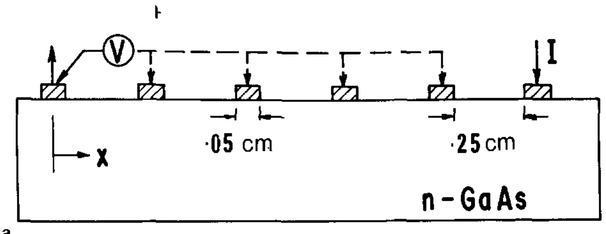
Te-doped (100) n-GaAs substrates of carrier concentration, 2×10^{18} cm^{-3} were used. They were first cleaned in trichlorethylene, acetone, and methanol. An oxide was then grown in deionized water and etched off with HCl. An Au-Ge layer of 1000Å thickness was deposited in vacuum (2×10^{-6} Torr) from an alloy of eutectic composition [Au-Ge(12%)] which was evaporated to completion in a resistance heated tungsten boat. This deposition was done through a metal evaporation mask of parallel slits that resulted in the contact structure shown in Fig. 1.

* Electrochemical Society Active Member.

Key words: semiconductor, alloy, contacts, analyses, infrared.

Ohmic contacts were formed by single pulse irradiation of the AuGe film with a pulsed Nd-YAG laser of 1.06 micron wavelength, 30 nsec pulse duration, and beam spot diameter of 0.1 cm. The pulse energy density was varied from 0.6 to 3 J/cm^2.

The ohmicity of the contacts was determined from curve tracer I-V plots while the specific contact resistivity was determined by a four-probe measurement technique as shown in Fig. 1. Current (10 mA) is passed through two of the contact pads while the voltage between one of the current-carrying pads and



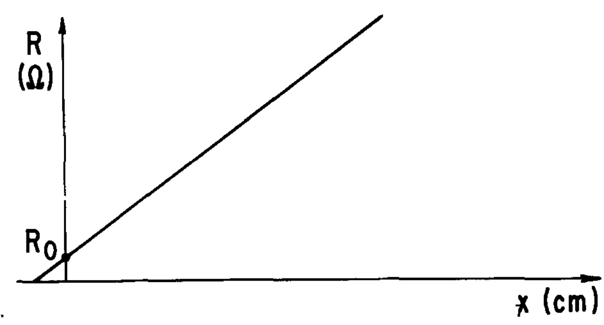


Fig. 1. (a) Four-point probe geometry for ohmic contact measurements; (b) resistance measured as a function of distance.

each of the inner pad is measured. The resistance variation as shown in Fig. 1b has been derived by Schuldt (5) by solving Laplace's equation numerically with the ohmic contact plane as a boundary and is given by

$$R(x) = (\rho_B/HW)X + (\rho_B/\pi w) \ln 4/(1 - \exp(-\pi D/H) + f\left(\rho_c, \frac{D}{H}\right) \quad [1]$$

where ρ_B is the bulk resistivity, H is the sample thickness, W sample width, D contact length, and $f(\rho_c, D/H)$ is a resistance parameter which is a function of the specific contact resistivity ρ_c and the ohmic contact geometry. Using R_o, the intercept from the four-probe measurements, the specific contact resistivity ρ_c, was obtained from numerical solutions for $f(\rho_c, D/H)$ (5). Prior to the measurements, the sample was scribed into rectangular strips in a direction perpendicular to the Au-Ge stripes. This was to ensure current flow paths only in the planes perpendicular to the contact plane and along the length of the GaAs strip. Equation [1] is valid only for this geometry.

The samples were prepared for TEM examination by chemical jet polishing with bromine methanol from the back side of the substrate so that only the top surface was observed.

Results

Figure 2 shows the *I-V* characteristics of contacts formed under various conditions. The as-deposited Au-Ge film is a rectifying contact as Fig. 2a shows, but after laser irradiation at 0.6 and 1.1 J/cm^2, the contact becomes ohmic (Fig. 2b, c). The change in the specific contact resistivity as the laser energy density is varied is shown in Fig. 3. It can be seen that the electrical properties of the contacts are improved at higher laser energy densities. The corresponding microstructural changes are shown in Fig. 4 in which the microstructure of the contact irradiated at 0.6 J/cm^2 appears similar to that of the as-deposited Au-Ge film. The grain size of the contacts irradiated at 1.1 J/cm^2 has increased significantly while the grains show features which were not observed in the other contacts fabricated at lower energy densities. The results obtained are summarized in Fig. 5 which compares the measured residual resistance R_o of the contacts and the corresponding grain size. At energy densities higher than 1.1 J/cm^2, both the specific contact resistivity and the grain size seem to remain constant.

The TEM diffraction patterns also showed changes corresponding to the formation of ohmic contacts by laser irradiation. For example, three rings can be observed in the diffraction patterns of Fig. 4b and c which do not exist in the diffraction pattern of the as-deposited AuGe film shown in Fig. 4a. By matching lattice spacings, these extra rings have been identified with germanium. The dark field image shown in Fig. 6 was obtained with the objective aperture of the TEM on the Ge(111) ring. It indicates segregation of Ge at the grain boundary. The white spots within the grains were also found to be germanium.

Using Auger analysis combined with argon ion sputtering, measurements were made on the as-deposited samples as well as the laser irradiated samples in order to observe the changes in the composition depth profile of the contacts corresponding to the observed electrical and microstructural changes (as a function of laser energy density). The elemental depth distributions of oxygen (503 eV), gallium (1070 eV), germanium (1147 eV), arsenic (1228 eV), and gold (2024 eV) are shown in Fig. 7 for the as-deposited AuGe film. The essential features of this profile (such as the sharp interface) do not change with laser irradiation. There appears, however, to be an increasing redistribution of all the elements present with increasing laser energy density. In Fig. 8, the profiles of Ga and As show a significant redistribution of these two elements.

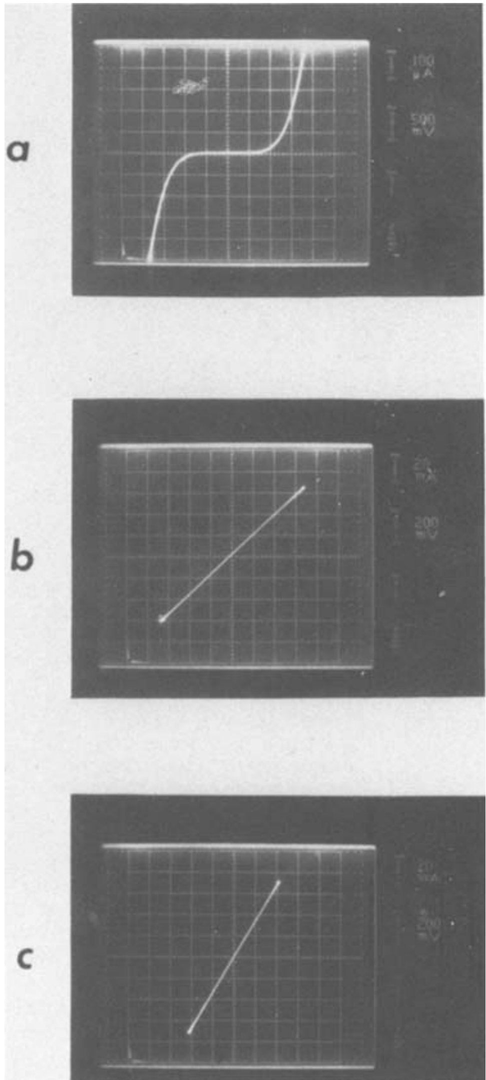

Fig. 2. Current-voltage characteristics of Au-Ge contacts. (a) As-deposited; (b) laser-irradiated at 0.6 J/cm^2; (c) laser-irradiated at 1.1 J/cm^2.

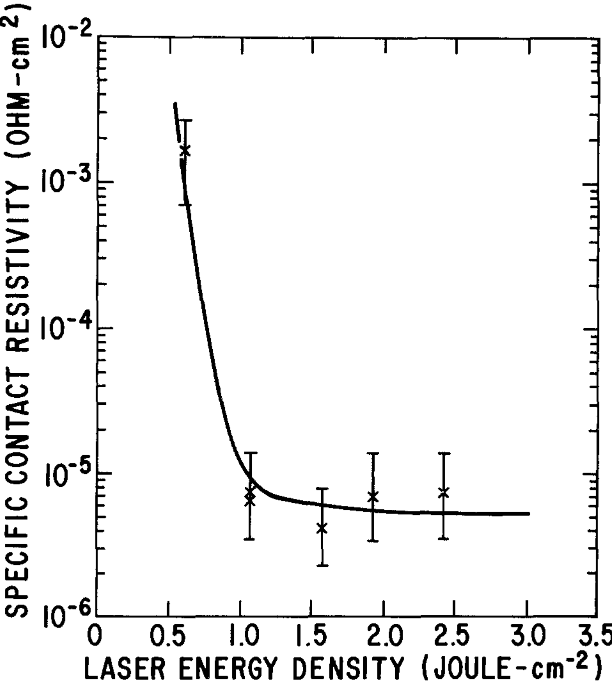

Fig. 3. Specific contact resistivity *vs.* laser energy density

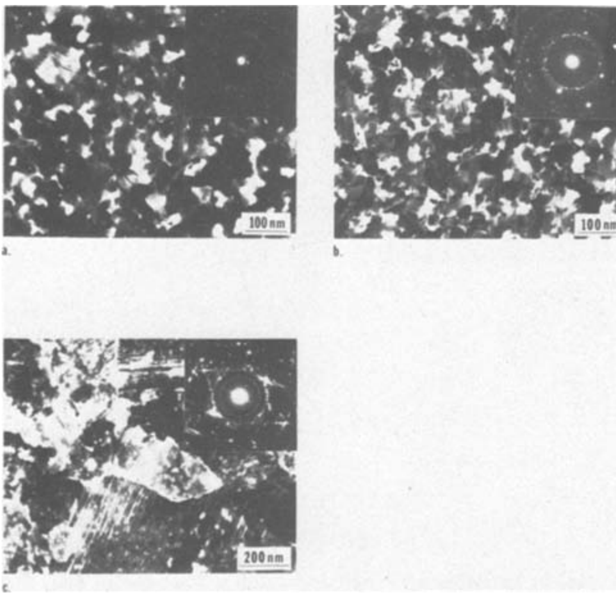

Fig. 4. TEM micrographs and diffraction patterns of Au-Ge contact films. (a) As-deposited; (b) laser-irradiated at 0.6 J/cm^2; (c) laser-irradiated at 1.1 J/cm^2.

Within the energy density range used, this redistribution does not reach the surface and thus no gallium segregation at the surface was observed as was the case with furnace alloyed Au-Ge (and Au-Ge-Ni) ohmic contacts (6). Figure 9 shows a corresponding decrease in the Ge profile which indicates a redistribution of Ge into GaAs. This could not be confirmed by the present AES data because of the coincidence of the arsenic and germanium Auger electron transitions at 1147 eV.

Discussion

It has been observed that pulsed laser annealing of implanted semiconductors results in melting, the duration of which is longer than the pulse width of the laser beam (7, 8). Specifically, it was found that the duration of melting increased with the laser energy density and that for Te-implanted GaAs, the melt duration was approximately 1 μsec at an energy density of 1 J/cm^{-2} (7). In view of the short time periods involved in laser annealing, it seems that the drastic change in microstructure observed in this work

could not be due to solid-state diffusion (the solid-state diffusion length is much less than the grain sizes observed). This kind of microstructural change is therefore due to melting of the Au-Ge film and an adjacent layer of the GaAs substrate. By analogy with observations of laser annealing of aluminum on silicon (9), this melting is followed by rapid regrowth of Ge-rich GaAs with a top layer of alloys or compounds of Ga-Ge, Au-Ga, and Au-Ge. This kind of structure, consisting of successive layers of GaAs heavily doped with Ge; Au-Ge, Ni-Ga, and Au-Ga alloys and compounds has been observed in furnace alloyed Au-Ge-Ni ohmic contacts (10).

The grain size of a polycrystalline structure which has regrown from a melt is related to a growth parameter which is known to vary inversely as the regrowth velocity (11). The regrowth velocity however, has been shown to also vary inversely as the energy density of the laser beam (7). Thus, the increase in grain size observed in this work may be attributed to an increase in the growth parameter as a result of a decrease in the regrowth velocity with energy density. The decrease of the specific contact resistivity on the other hand may be due to an increased Ge doping of the Ge-rich GaAs layer (12). In GaAs, Ge may go into either Ga or As vacancies depending on the temperature and the vapor pressures (13) of As and Ga. It appears that the constancy of the specific contact resistivity at the higher laser energy densities is due to an increasing concentration of Ge in As sites, instead of in Ga sites as is required for n-type doping.

Our AES results showing limited redistribution of Ga and As are in contrast to previous results obtained for furnace alloyed Au-Ge-Ni ohmic contacts (6) which showed significant Ga and As concentrations at the contact surface. Limited Ga and As segregation as was found here may be due to an incomplete mixing of the melt from which the regrowth takes place. It was found for implanted Si, from numerical calculations, that the melt-front velocity is substantially greater than the velocity of mass diffusion (14). The observed AES profiles for Ga and As are thus probably related to the distribution of Ga and As in the melt which is "frozen" into the ohmic contact layer during solidification.

The observed redistributions of Ga and As can result in Ga and As vacancies in the GaAs substrate. Hence, the substrate concentration of vacancies should be higher in the furnace alloyed contacts than in the laser-annealed ones since there is less redistribution in the latter. One would therefore expect laser-annealed ohmic contacts to have improved contact reliability, since contact reliability has been suggested to depend on vacancy formation in GaAs (15).

Conclusion

We have presented results showing a decrease in the specific contact resistivity with energy density for laser annealed Au-Ge ohmic contacts. We have at the same time shown the correlation between the measured contact resistivity and the microstructure observed by the TEM. In addition, AES results were presented to show the redistribution of Ga and As as a result of the laser annealing.

ABSTRACT

The transients associated with the deposition of silicon epitaxial films in a horizontal reactor have been investigated. An understanding of these transients is important for the fabrication and control of the submicron films that will be required to accommodate VLSI designs. In order to investigate these transients, several experiments were carried out in which the steady-state deposition of epitaxial silicon was perturbed by abruptly varying the flow of silicon species entering the reactor. The response of the epitaxial system to these perturbations was determined by measuring the resulting dopant distribution in the silicon film. A physical model that emphasizes the role of the adsorbed layer on the silicon surface was used to explain and simulate the behavior of the epitaxial system. By comparing theoretical simulations and experimental results, the time constant of the silicon deposition process was estimated to be in the 20-30 sec range.

Submicron silicon epitaxial films are becoming increasingly important with the development of VLSI technology. Epitaxial layer thicknesses in the 0.5-1.5 μm range are needed to accommodate the small cell sizes required for VLSI designs. The transients associated with the first few minutes of growth, however, impose severe limitations on the fabrication of such thin films. As is described elsewhere (1), the dopant incorporation process in a silane/arsine epitaxial system requires several minutes to regain steady state when a perturbation such as a step change in dopant gas flow is imposed on the reactor. Similarly, the dopant incorporation process requires several minutes to reach the expected steady-state condition at the beginning of the deposition step (2). Consequently, the epitaxial dopant concentration reaches the expected doping level only for films thicker than that corresponding to this initial transient. Because this transient period corresponds to a transition layer 1-2 μm thick, the expected steady-state doping level may not be achieved in submicron silicon films.

In addition to the dopant incorporation process, the silicon deposition process must also go through a transient period during the initial stages of growth, *i.e.*, some time is required before the expected steady-state epitaxial growth rate is established. A complete understanding of the transients associated with both the dopant incorporation and silicon deposition processes is critical to the fabrication and control of submicron epitaxial films.

The dopant incorporation process has been the subject of previous investigations (1-4). The work presented here deals primarily with the silicon deposition process. The main objective of this work was to investigate the transient associated with the establishment of a steady-state silicon growth rate and the effect of this transient on the epitaxial doping level. The simplest technique that could have been used to determine this transient was to carry out a series of depositions for different growth times and then measure the resulting epitaxial layer thicknesses. However, this method is imprecise because very short initial time intervals are needed in order to obtain information on the initial transient. Moreover, the effect of the initial transient on the film thickness could get compensated by that of the final transient, thereby concealing the information being sought. The most desirable approach would be to measure the film thickness continuously as the film is being deposited. Dumin (5) developed an interferometric technique that measured the thickness of silicon films as they were being deposited on sapphire substrates. This technique utilized the infrared emission from the sapphire substrate and from the growing film. The radiation from the sapphire substrate was partially transmitted through the silicon and partially reflected in the silicon, establishing an interference pattern which was used to determine silicon film thickness. Shaw (6), on the other hand, developed a gravimetric technique in which the weight of the growing gallium arsenide crystal was continuously measured. The use of these techniques, however, poses several difficulties when applied to the epitaxial deposition of silicon. The interferometric technique is best suited to cases in which the index of refraction of the film being deposited is different from that of the substrate, while the gravimetric technique measures not only the weight of the substrate but that of the substrate support as well.

In this paper, a different technique is used to investigate the transient associated with the silicon deposition

Key words: semiconductor, growth, doping, integrated circuits.

process. As discussed below, it consists of perturbing the steady-state deposition of silicon by abruptly changing the flow of silicon species entering the reactor. This perturbation introduces a transient period during which the silicon growth rate varies with time, thereby affecting the dopant concentration of the growing epitaxial film. By studying the resulting epitaxial dopant profile, the transient in the silicon deposition process can be investigated (7). In the following sections, the experiments carried out to study the transient response of the silicon deposition process are described. Following this, a physical model capable of explaining the results of the experiments is discussed. Finally, epitaxial dopant profiles calculated using the model are compared to measured profiles, and the time constant associated with the transient response of the silicon deposition process is estimated.

Equipment and Experimental Details

The epitaxial reactor used in this work was a horizontal, rf-heated Unipak VI (Sola Basic-Tempress) that operates at atmospheric pressure. The quartz reactor tube has an effective cross section of 26 cm^2 above the susceptor. The silicon carbide-coated graphite susceptor has the dimensions 56 cm (length) $\times$ 11.4 cm (width) and is tilted at an angle of 1.5°. Hydrogen was used as the carrier gas at a velocity of 67 cm/sec above the susceptor (at room temperature). Silane was used as the silicon source with partial pressures adjusted in the 10^{-4} atm range to produce silicon growth rates of 0.34 and 0.17 μm/min. Arsine diluted in hydrogen was used as the dopant source with partial pressures adjusted in the 10^{-11} atm range to produce epitaxial doping levels in the $10^{15}/cm^3$ range. The corrected deposition temperature at the wafer surface was approximately 1050°C. The operating conditions used in this work were optimized so that (*i*) the silicon growth rate was a linear function of the silane partial pressure and (*ii*) the growth rates and film resistivities along the length of the susceptor were uniform.

The dopant profiles in the epitaxial layers were determined by capacitance-voltage measurements on planar p-n junctions and deep-depletion MOS structures (8). The fabrication details of the *C-V* structures are explained elsewhere (1). Because of the low diffusivity of arsenic in silicon (9), the heat cycling during the fabrication of these structures produced a diffusion length of only 0.01 μm (1). The epitaxial doping levels used in this study ($\sim 10^{15}/cm^3$) were low enough to allow the required depth profiling and high enough to produce a relatively short Debye length (10).

Experiments and Results

The experiments carried out to study the transient response of the silicon deposition process are described in this section. These experiments take advantage of the fact that, as illustrated in Fig. 1 (1), the arsenic concentration in an epitaxial film varies with silicon growth rate for a given arsine partial pressure. This growth-rate dependence allows the study of growth-rate variations during silicon deposition by examining the corresponding variations in epitaxial arsenic concentration.

Five experiments are described in this section, each of them addressing a different aspect of the transient phenomena. The first experiment is described with the aid of Fig. 2. At time $t = 0$ (see Fig. 2a) silane and arsine were injected into the reactor tube to begin the deposition. Both flows were adjusted to establish the deposition condition 1 in Fig. 2b, corresponding to a uniform epitaxial arsenic concentration N_1 and a silicon growth rate g_1. The arsine flow was held constant throughout the entire deposition cycle. At $t = t_0$ the silane flow was abruptly lowered by decreasing the flow setting on the silane rotameter. The new steady-state deposition condition is indicated by 2 in Fig. 2b, corresponding to a uniform epitaxial arsenic concentration N_2 and a growth rate g_2. The resulting arsenic profile in the epitaxial film (Fig. 2a) contained information on the response of the silicon epitaxial system to the abrupt step change in silane flow. Figure 3 shows the measured arsenic concentration as a function of distance from the surface of the epitaxial film for the decreasing step in silane flow shown in the inset. The epitaxial system gradually moved from one steady-state condition to the next. The transition occurred over a distance of approximately 1 μm, corresponding to several minutes of deposition. Figure 4 shows the result of an experiment similar to that described in Fig. 2, except that the silane flow was abruptly increased rather than decreased as indicated in the inset. The profiles in Fig. 3 and 4 show similar behavior, with the transition occurring approximately over the same distance, and indicate the presence of significant transients in the silicon deposition process. The similarity in the

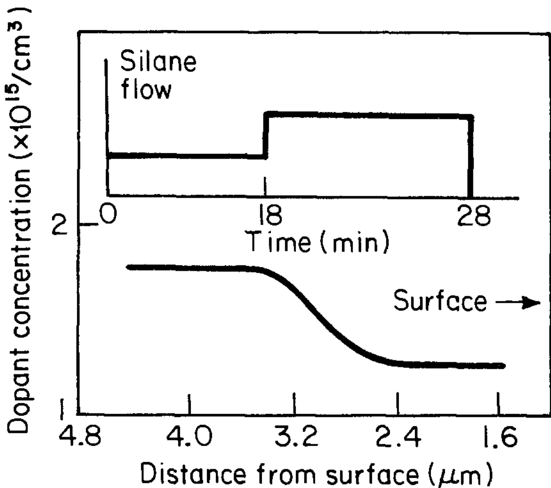

Fig. 4. Experimental dopant profile for an increasing step change in silane flow.

dopant profile for increasing and decreasing silane gas flows suggests the importance of analogous physical mechanisms in the two cases. In an attempt to study the importance of gas flow dynamics, epitaxial dopant profiles were measured at different positions along the length of the susceptor. To this effect, three wafers were used in each of the experiments described above as indicated in Fig. 5, and dopant profiles were measured in each wafer. No differences were observed in the measured profiles from wafer to wafer in a given experiment. The physical mechanisms responsible for the transients observed here are discussed in the following section.

The next experiment is described with the aid of Fig. 6. Silane and arsine were injected into the reactor at $t = 0$. At $t = t_1$, the silane flow was interrupted, and at $t = t_2$ silane was injected back into the epitaxial system. The arsine flow was not interrupted until the end of the second deposition step at $t = t_D$. The dashed line in Fig. 6 represents the response of the silicon growth rate to the abrupt changes in silane flow conditions at $t = t_1$ and $t = t_2$. It considers the fact that the silicon deposition process needs some time to stop after $t = t_1$ and, similarly, that it needs some time to reestablish a steady-state silicon growth rate after $t = t_2$. As a result of these growth-rate variations, the epitaxial arsenic concentration can be expected to increase after $t = t_1$ (see Fig. 6) and decrease after $t = t_2$ until the steady-state epitaxial condition is reestablished. Figure 7 shows the measured epitaxial arsenic profile corresponding to this experiment. The actual gas flow conditions are indicated in the inset. The pronounced peak in the arsenic profile clearly indicates the presence of appreciable transients in the silicon epitaxial system.

In the experiments described above the silane flow conditions were varied while the arsine flow was held constant. In the following experiments both the silane and arsine flows were varied with time. The next experiment is described with the aid of Fig. 8. Figure 8a shows the silane and arsine flows as functions of time,

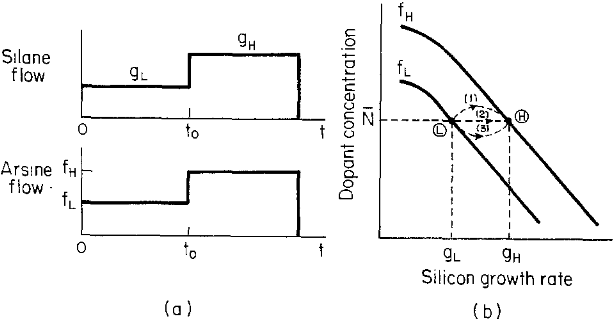

Fig. 8. Experiment to study the transient response of the silicon epitaxial process (see text).

and Fig. 8b shows schematically the variation of epitaxial arsenic concentration with silicon growth rate for two different arsine flows. At $t = 0$ silane and arsine were injected into the reactor tube and their flows were adjusted to produce a silicon growth rate g_L and an arsine flow f_L. This deposition condition is indicated by L in Fig. 8b. The epitaxial system was then allowed to reach steady state and establish a uniform epitaxial arsenic concentration $\overline{N}$ (see Fig. 8b). At $t = t_0$ both the silane and arsine flows were abruptly increased and adjusted to produce a growth rate g_H and a flow rate f_H, respectively. The new deposition condition H (see Fig. 8b) was designed to produce the same epitaxial arsenic concentration $\overline{N}$. The epitaxial system was expected to change its steady-state operat-

ing condition from L to H following path 1, 2, or 3 in Fig. 8b. Path 2 was expected if the duration of the transient period was negligible, while path 1 or 3 was expected if the transient time was non-negligible. (It is shown in the next section that path 3 is not physically possible in this experiment.) In order to determine which path was followed the dopant profile in the resulting epitaxial film was measured. A peak or dip in the otherwise uniform dopant profile would indicate whether path 1 or 3, respectively, was followed. Figure 9 shows the measured arsenic concentration as a function of distance from the surface of the epitaxial film for this experiment. The corresponding silane and arsine flows as functions of time are indicated in the inset. The profile shows a definite peak, indicating that the epitaxial system went from L to H via path 1 (Fig. 8b). The two steady-state doping levels in Fig. 9 are not the same. This is believed to be due to lack of very accurate control on the flow settings of the rotameters. The presence of a peak in this experiment confirms the existence of non-negligible transients in the silicon epitaxial system.

An experiment similar to that described in Fig. 8 except that the silane and arsine flows were abruptly decreased rather than increased at $t = t_o$ was also carried out. In this case, the operating condition of the epitaxial system was changed from H to L in Fig. 8. As mentioned above, path 2 was expected to be followed if the duration of the transient period was negligible. Figure 10 shows the measured epitaxial dopant profile for the silane and arsine flows as functions of time indicated in the inset. The profile shows a definite dip, indicating that the epitaxial system went from H to L following path 3 (see Fig. 8b) and confirming the presence of significant transients in the silicon epitaxial system. The extent of the dip in Fig. 10 is approximately equal to that of the peak in Fig. 9. The magnitudes of the dip and peak, however, differ slightly. This discrepancy in the magnitudes is smaller than $2 \times 10^{13}/cm^3$ and is believed to be due to artifacts in the measurement technique.

In this section, the experiments carried out to study the transients associated with the silicon deposition process were described. The results of these experiments indicated the presence of transients of non-negligible duration in the silicon epitaxial system. A physical model capable of explaining the results obtained here is discussed in the next section.

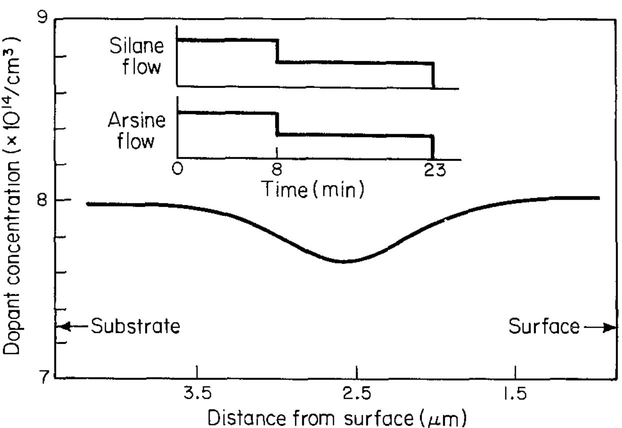

Fig. 10. Experimental dopant profile for the gas flows as functions of time indicated in the inset.

Physical Model

In order to explain the experimental results described in the previous section, a physical model of the deposition process is required. The model used here builds on the model for arsenic incorporation in silicon epitaxy reported elsewhere (2, 3). In this section, the basic features of the arsenic incorporation model are reviewed and then used to explain the experimental results.

The arsenic incorporation model can be summarized with the aid of Fig. 11 as follows. When an arsenic-containing species in the gas phase is in the vicinity of the silicon surface (Fig. 11a) it undergoes a process of adsorption. The adsorbed arsenic species diffuses on the surface until it finds an incorporation site to which it can attach. This incorporated arsenic atom is then quickly covered by subsequently arriving silicon atoms. r_1 (Fig. 11) is the rate at which arsenic species are adsorbed on the silicon surface, and is given by (2)

$$r_1(t) = k_{mf}\left[P_D^\circ(t) - \frac{N_s\theta_D(t)}{K_AK_P}\right] \quad [1]$$

where k_{mf} is a kinetic coefficient associated with the rate-limiting step of the arsenic incorporation process (2), P_D° is the input arsine partial pressure, N_s is the surface density of adsorption sites per unit area, θ_D is the fraction of adsorption sites occupied by arsenic species, and K_A and K_P are thermodynamic constants relating the epitaxial arsenic concentration to the concentration of arsenic species in the adsorbed layer and gas phase, respectively (2). r_2 (Fig. 11) is the rate at which arsenic is covered by silicon atoms and is given by (2)

$$r_2(t) = g(t)\,\frac{N_s\theta_D(t)}{K_A} \quad [2]$$

where g is the silicon growth rate. The adsorbed layer plays an important role in this model. It consists of a population of hydrogen, silicon, and arsenic species occupying adsorption sites and capable of moving on the solid surface. The model assumes that the concen-

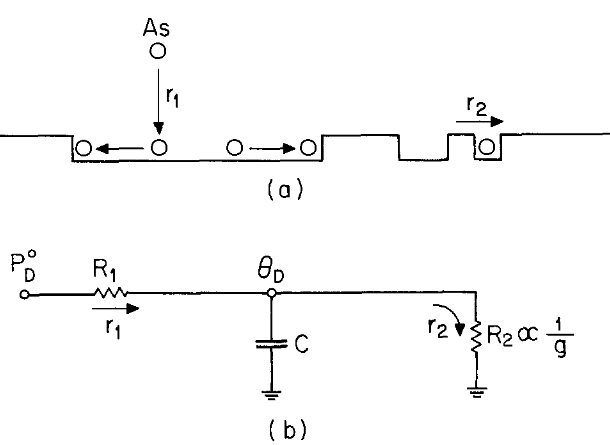

Fig. 11. Simplified model for dopant incorporation into growing silicon epitaxial films: (a) steps taking part in the doping process; (b) equivalent circuit representing the doping process.

tration of arsenic in the growing epitaxial film (N) is proportional to the concentration of arsenic species in the adsorbed layer, *i.e.* (2)

$$N = \frac{N_s \theta_D}{K_A} \qquad [3]$$

In this model, r_1 is viewed as the rate at which the adsorbed layer increases its population of arsenic species. Similarly, r_2 is viewed as the rate at which the adsorbed layer decreases its population of arsenic species due to the silicon-covering step. In steady state, *i.e.*, when the arsine and silane flows entering the reactor have remained unchanged for a "long" time, $r_1 = r_2$. Consequently, θ_D remains unchanged (see Eq. [1] and [2]) and so does N (see Eq. [3]). However, when the arsine and/or silane flows vary with time r_1 and r_2 may not be equal and, as a result, θ_D and N may also vary with time. In this case, the rate of change of θ_D (and N) can be calculated from (2)

$$r_1(t) - r_2(t) = N_s \frac{d\theta_D(t)}{dt} \qquad [4]$$

By using Eq. [1], [2], and [3], Eq. [4] can be rewritten as (2)

$$k_{mf}\left[P_D{}^\circ(t) - \frac{N(t)}{K_P}\right] - g(t)N(t) = K_A \frac{dN(t)}{dt} \qquad [5]$$

Equation [5] summarizes the arsenic incorporation model and relates $P_D{}^\circ(t)$, $g(t)$, and $N(t)$. The redistribution of arsenic in the epitaxial film during silicon deposition was neglected here because of the low diffusivity of arsenic in silicon.

Figure 11b shows an equivalent circuit (3, 4) representing the arsenic incorporation model described above. The "current" in the circuit represents the net flow of arsenic species. R_1 represents the limitation imposed by the rate-limiting mechanism on the flow of arsenic species. R_2 represents the step by which silicon atoms cover arsenic atoms during growth. $P_D{}^\circ$ represents the "voltage" which drives the current, *i.e.*, the driving force for the arsenic incorporation process. The capacitor accounts for the accumulation of arsenic species in the adsorbed layer. In the equivalent circuit of Fig. 11b, $R_1 \equiv (k_{mf})^{-1}$, $R_2(t) \equiv [g(t)K_P]^{-1}$, and $C \equiv K_A K_P$, and the voltage across the capacitor is proportional to θ_D and N (see the Appendix). Notice that R_2 is proportional to the reciprocal of the silicon growth rate.

The arsenic incorporation model described above can now be used to explain the results of the experiments described in the previous section. Because all experiments can be explained analogously, only the experiment described in Fig. 8 is discussed here with the help of Fig. 12. In that experiment the arsine and silane flows were both adjusted, before and after $t = t_o$, to produce the same epitaxial arsenic concentration N in steady state. The abrupt increase in arsine flow at $t = t_o$ results in an abrupt increase in the rate r_1 at which arsenic species adsorb on the silicon surface (see Eq. [1]). Similarly, the abrupt increase in silane flow at $t = t_o$ increases the silicon growth rate thereby increasing the rate r_2 at which arsenic species in the adsorbed layer are covered by silicon atoms (see Eq. [2], Fig. 12a). If the silicon growth rate reaches the new steady-state rate "instantaneously," then both r_1 and r_2 increase by the same amount and reach the new steady-state rates instantaneously. Consequently, θ_D remains unchanged during the transition (see Eq. [4]) and so does N. This situation corresponds to the epitaxial system moving from L to H via path 2 (see Fig. 8). However, if the silicon growth rate requires some non-negligible time to reach the new steady-state rate, then $r_1 > r_2$ for a brief period of time which results in an increase in θ_D (see Eq. [4]) and, consequently,

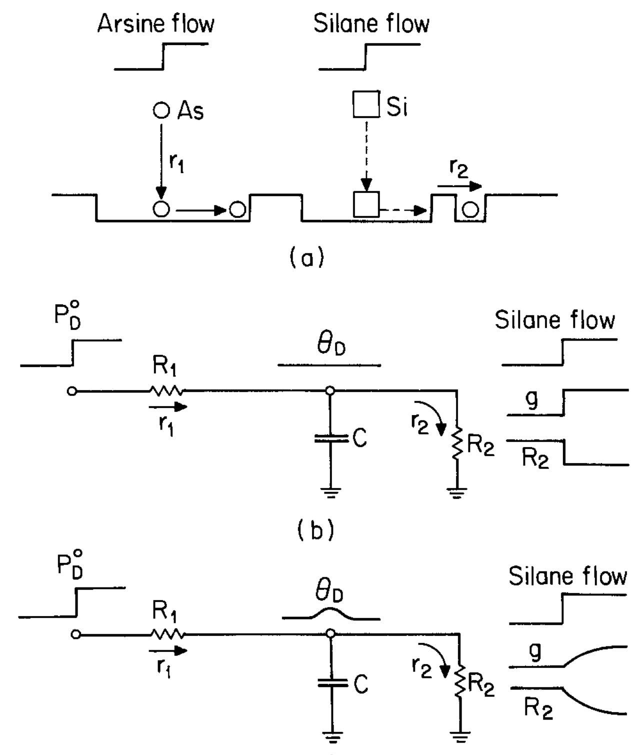

Fig. 12. Physical model used to explain the behavior of the epitaxial system: (a) steps taking part in the doping process and silicon growth; (b) equivalent circuit with R_2 changing "instantaneously;" (c) equivalent circuit with R_2 changing gradually.

an increase in N. Eventually, as the silicon growth rate approaches the new steady-state rate, both θ_D and N gradually fall back to their steady-state levels. The end result is a "peak" in the resulting epitaxial arsenic profile, in agreement with the experimental observation shown in Fig. 9.

The equivalent circuit in Fig. 12 can also be used to explain the experiment. Figure 12b shows the situation that exists when the silicon growth rate reaches the new steady-state rate instantaneously. In this case, R_2 decreases abruptly and, consequently, r_2 increases abruptly compensating the abrupt increase in r_1. As a result, the amount of charge accumulated in the capacitor (which corresponds to θ_D in the model) remains unchanged. Figure 12c shows the situation that exists when the silicon growth rate approaches the new steady-state gradually. In this case, R_2 decreases gradually and $r_1 > r_2$ for a brief period of time. This increases the amount of charge stored in the capacitor. Eventually, as R_2 reaches its steady-state value, the charge in the capacitor falls back to the steady-state level.

In this section, the arsenic incorporation model was reviewed and then used qualitatively to explain the result of one of the experiments described in the previous section. It was concluded that the experimental results can be explained if it is assumed that the silicon deposition process needs some non-negligible time to regain steady state after a perturbation is imposed on the silane flow. A more quantitative discussion is given in the next section in which arsenic profiles calculated from Eq. [5] are compared to experimental profiles.

Comparison of Theory and Experiments

Equation [5] has been used successfully to simulate epitaxial depositions in which the arsine flow varied with time while the silane flow was kept constant (2). It is shown in this section that Eq. [5] can also be used to simulate epitaxial depositions in which both the arsine and silane flows vary with time. Epitaxial dopant profiles corresponding to the experiments de-

scribed above are computed here using Eq. [5] and are compared to measured profiles.

As discussed by Johnson and Panousis (10), the profiles measured by the capacitance-voltage technique are a closer representation of the majority carrier distribution than they are of the impurity distribution. For this reason, the theoretical profiles shown in this section do not correspond to impurity distributions but to majority carrier distributions. The theoretical majority carrier distributions were obtained by using the impurity distributions obtained from Eq. [5] and computing a one-dimensional solution to Poisson's equation. The computer program SEDAN was used to obtain the Poisson solution (11).

In order to use Eq. [5] to calculate impurity profiles, the silicon growth rate was assumed to respond exponentially to an abrupt change in silane flow. As an illustration, the equations solved numerically to obtain the impurity profiles corresponding to the experiment described in Fig. 8 are given below:

$0 < t \leq 15$ min

$$k_{\mathrm{mf}} \left[P_1 - \frac{N(t)}{K_{\mathrm{P}}} \right] - g'(t)N(t) = K_{\mathrm{A}} \frac{dN(t)}{dt} \quad [6]$$

$$g'(t) = g_1 [1 - \exp(-t/\tau_s)] \quad [7]$$

$$x = \int_0^t g'(t)dt \quad [8]$$

$15 < t \leq 23$ min

$$k_{\mathrm{mf}} \left[P_2 - \frac{N(t)}{K_{\mathrm{P}}} \right] - g''(t)N(t) = K_{\mathrm{A}} \frac{dN(t)}{dt} \quad [9]$$

$$g''(t) = g_1 \exp[-(t-15)/\tau_s] + g_2 \{1 - \exp[-(t-15)/\tau_s]\} \quad [10]$$

$$x = \int_0^{15} g'(t)dt + \int_{15}^{t} g''(t)dt \quad [11]$$

where τ_s is defined here as the time constant of the silicon deposition process. The values of k_{mf}, K_{P}, and K_{A} for a given epitaxial system and operating conditions can be obtained experimentally (2). For the epitaxial reactor and deposition conditions used in this work these values are $k_{\mathrm{mf}} = 4.85 \times 10^{19}/\mathrm{cm}^2$ sec atm, $K_{\mathrm{P}} = 1.05 \times 10^{26}/\mathrm{cm}^3$ atm, and $K_{\mathrm{A}} = 5.7 \times 10^{-5}$ cm (2). P_1, P_2 and g_1, g_2 were obtained from the corresponding arsine flows and silane flows, respectively. Therefore, the only unknown in the above equations is τ_s. Figure 13 shows measured (solid line) and calculated (dashed and dotted lines) dopant profiles corresponding to this experiment. Three simulations are shown, each corresponding to a different value of τ_s. All simulations predict the peak in the dopant profile observed experimentally. In order to fit the steady-state levels of the calculated profiles to those of the measured profile the values of P_1 and P_2 (see Eq. [6] and [9]) were slightly adjusted. The best fit to the measured profile was obtained with $\tau_s = 30$ sec.

Figure 14 shows measured (solid line) and simulated (dashed and dotted lines) dopant profiles corresponding to the experiment described in Fig. 10. The equations used in these simulations are similar to Eq. [6]-[11]. Three simulations are shown, each corresponding to a different value of τ_s. All simulations predict the dip in the dopant profile observed experimentally. The best fit to the measured profile was obtained using $\tau_s = 20$ sec. The disagreement between the values of τ_s obtained from Fig. 13 and 14 is due to the discrepancy in the magnitudes of the peak and dip, respectively. As mentioned earlier, this discrepancy is believed to be due to limitations in the resolution of the capacitance-voltage technique used to measure the profiles.

The experimental results shown in Fig. 3, 4, and 7 were also simulated using $\tau_s = 20$-30 sec. The simulated and measured profiles were almost indistinguishable, confirming the validity of the physical model and the time constant for the silicon deposition process discussed here.

Summary and Conclusions

In this work, the transients associated with the deposition of silicon epitaxial films in a conventional chemical vapor deposition reactor were investigated. The objectives of this work were (*i*) to estimate the duration of the transient period that precedes the establishment of a steady-state deposition rate and (*ii*) to study the effect of this transient on the dopant concentration of the growing epitaxial film. The technique used to investigate these transients consisted of perturbing the steady-state deposition of silicon by abruptly varying the silane gas flow and then studying the effect of this perturbation on the epitaxial dopant concentration. A physical model capable of explaining the behavior of the epitaxial system during the transient period was described. Epitaxial dopant profiles corresponding to the experiments carried out in this work were calculated using the model by assuming that the silicon growth rate responds exponentially to an abrupt variation in silane flow. The theoretical profiles were found to agree fairly well with the measured profiles when the time constant used for the exponential response of the silicon deposition process was in the 20-30 sec range. The physical mechanisms responsible for the transient behavior of the silicon deposition process are currently under investigation. Preliminary results seem to indicate that gas flow dynamics do not play a dominant role, as suggested by the fact that the mea-

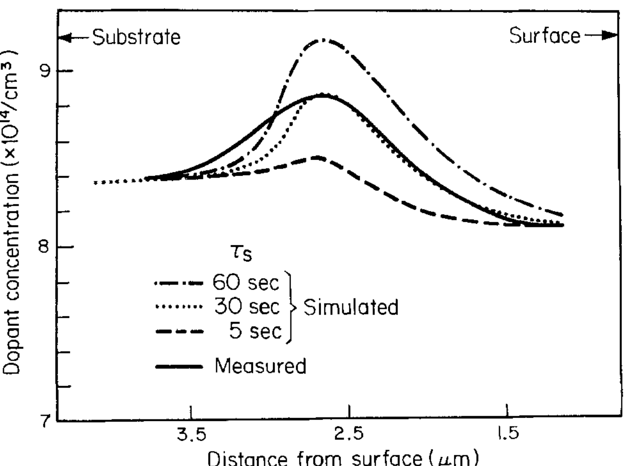

Fig. 13. Solid line: experimental dopant profile. Dashed and dotted lines: simulated dopant profiles for different values of τ_s.

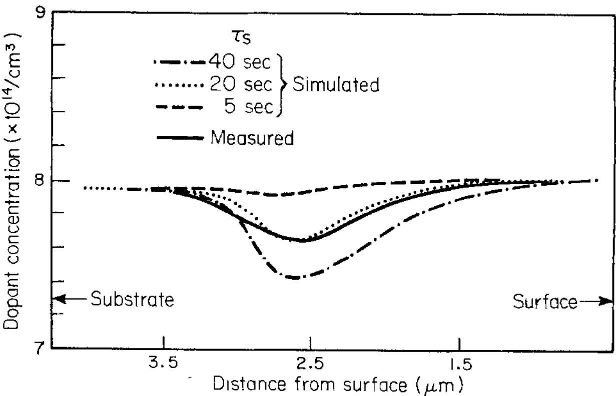

Fig. 14. Solid line: experimental dopant profile. Dashed and dotted lines: simulated dopant profiles for different values of τ_s.

sured profiles shown in Fig. 3 and 4 were independent of the position of the substrate along the length of the susceptor. Equation [5] summarizes the model described here and can be used to design the silane and arsine gas flows as functions of time that produce the desired impurity distribution in the epitaxial film. Therefore, Eq. [5] should allow a better control of the doping level in submicron epitaxial films.

APPENDIX

The arsine partial pressure in equilibrium with the epitaxial arsenic concentration is given by (2)

$$P_{D,eq} = \frac{N}{K_P} \qquad \text{[A-1]}$$

By using Eq. [A-1], Eq. [5] can be rewritten as

$$k_{mf}[P_D^\circ - P_{D,eq}] - gK_P P_{D,eq} = K_A K_P \frac{dP_{D,eq}}{dt} \qquad \text{[A-2]}$$

which can also be written as

$$\frac{P_D^\circ - P_{D,eq}}{R_1} - \frac{P_{D,eq}}{R_2} = C\frac{dP_{D,eq}}{dt} \qquad \text{[A-3]}$$

where $R_1 \equiv (k_{mf})^{-1}$, $R_2 \equiv (gK_P)^{-1}$, and $C \equiv K_A K_P$.

By substituting Eq. [3] into Eq. [A-1]

$$P_{D,eq} = \frac{N_s \theta_D}{K_A K_P}$$

The Application of Temperature Gradient Zone Melting to Silicon Wafer Processing

Mike Chang* and Richard Kennedy

General Electric Company, Syracuse, New York 13221

ABSTRACT

High voltage semiconductor devices fabricated with deep p-type isolation regions are now practical. By employing the temperature gradient zone melting technique (TGZM), structures can now be fabricated that were not possible before using only solid-state diffusion techniques. In this study, various processing alternatives are discussed and analyzed. High voltage SCR devices have been made using the TGZM approach and process limitations, based on the current state-of-the-art, are described. Carrier lifetimes, blocking voltage capabilities, and leakage current levels have been measured and indicate that the processes used are effective.

The temperature gradient zone melting (TGZM) process can yield deep p-n junctions at a much faster rate than conventional solid-state diffusion techniques (1, 2, 6-10). As an example, an aluminum pattern can migrate through a 400 μm thick silicon wafer in just about 10 min at 1200°C. By contrast, conventional boron diffusion would require approximately one month at 1250°C, diffusion simultaneously from both sides, to achieve a comparable structure. This unique feature of the TGZM method allows p-type connections to be made through any thickness of silicon wafer.

In one application, this type of deep connection can be used to join two p-layers, diffused from opposing sides of a silicon slice. Thus, the p-n junctions themselves never extend to the edge of the structure. Separation and passivation of the two blocking junctions can be achieved by etching grooves on one side of the slice to expose the junctions. followed by backfilling the grooves with a suitable passivant. A typical SCR structure fabricated via TGZM isolation is shown in Fig. 1 (2).

It is also of interest that the material presented here can also be used for other applications such as field grids of a field control thyristor (FCT), vertical solar

cells, etc. In this paper, the technique of TGZM isolation, together with its processing characteristics, is described.

Experimental

The TGZM technique was used to introduce an isolation region into a silicon structure. The necessary active p-n junctions were formed by conventional solid-state diffusion processes. The TGZM procedure and the complete structure fabrication process will be described separately. In actual practice, these separate processes can proceed in any sequence.

Migration.—An aluminum-silicon droplet was allowed to migrate through a silicon slice at a given temperature, with a specific temperature gradient through the slice. A quartz lamp system Fig. 2) was used as a heat source. It performed quite well; however, there are alternative systems, such as a modified epitaxial reactor, that perform equally well. The details of the quartz lamp system have been discussed elsewhere (3) but the wafer supporting mechanism is worth mentioning here.

Any finished surface of a silicon wafer, be it lapped, chemically etched, or mechanically polished, is not microscopically flat, nor is any other solid surface. Therefore, it is impossible for a silicon wafer to lie on another solid surface and maintain a continuous, uniform contact. Rather, there are numerous point contacts, which means that uniform thermal conduction is not possible. In such a situation, the required unidirectional temperature gradient cannot be maintained and the direction of migration will be unpredictable.

The use of an air cushion is the ideal way of achieving uniform thermal conduction. In this work, an air-cushion effect was simulated by using a 3 quartz pin system to support the wafer. The results were reasonably good across the wafer except in the immediate vicinity of the point contacts. The next most likely way of achieving a continuous contact would be to use a liquid support system. Molten tin and aluminum support systems are possibilities currently being investigated by the author.

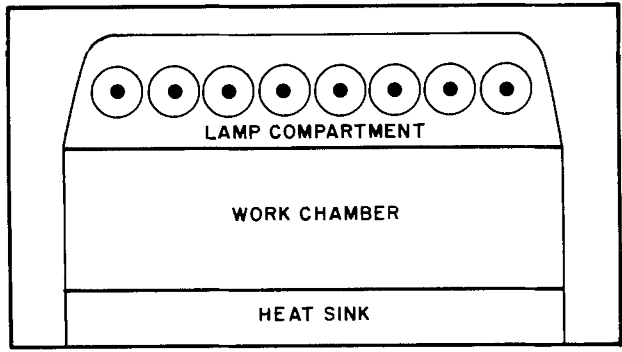

Fig. 2. A schematic diagram of a quartz lamp system for TGZM operation.

In order to produce a p-type isolation grid in an n-type silicon wafer by TGZM, liquid aluminum-silicon droplets must be migrated through the wafer. A simple calculation shows that 8.128×10^{17} aluminum atoms/cm^2 is adequate to dope a 400 μm thick silicon wafer to a concentration of 2×10^{19} atoms/cm^3. This is equivalent to a 0.1349 μm thick slice of solid aluminum. However, for migration of an aluminum-silicon droplet, approximately 1 μm of aluminum is required. In this study, four methods (Fig. 3) were developed for interfacing an aluminum array with the silicon surface.

Groove method.—A network of grooves 10-20 μm deep is etched into the silicon surface. The aluminum pattern is then introduced into the grooved regions. These grooves contain the aluminum grids and keep the molten aluminum from spreading over the wafer surface during the thermomigration process.

Oxide channels.—An array of windows is opened into an oxidized silicon wafer surface by conventional photolithographic techniques. After the aluminum is patterned into these windows, the oxide borders contain the molten aluminum during processing in much the same way as the grooves.

MOS method.—The aluminum pattern is applied directly to an oxidized silicon surface (4). This investigation showed that the aluminum reacts with the oxide forming a porous material, probably mostly aluminum oxide. The rest of the aluminum then migrates through this porous material and alloys with the silicon forming the aluminum-silicon droplet. This porous oxide has the effect of confirming the aluminum to the patterned area.

Direct application method.—It was determined that none of the above methods are necessary to keep the aluminum from spreading out on the silicon surface during migration, provided that the aluminum pattern is sintered before migration takes place. Thus, the pattern can be applied directly to the silicon wafer surface without any prior surface preparation.

The aluminum pattern can be formed by any of several conventional methods. In one case, the entire surface of the silicon slice is first coated with aluminum, and then the pattern is delineated photolithographically using a suitable aluminum etch. In another photolithographic technique, a photoresist pattern is first formed on the wafer followed by a layer of evaporated aluminum. Then the photoresist material is de-

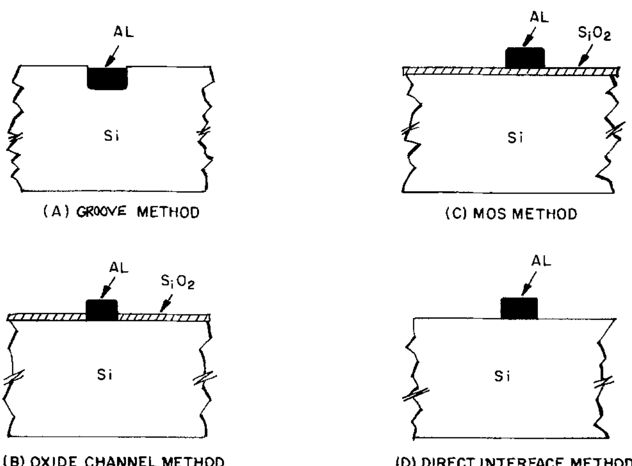

Fig. 3. Four different methods of creating aluminum patterns on the surface of a silicon wafer for TGZM operation.

composed. Since the aluminum adheres only to the uncoated area, the excess aluminum outside these areas can be easily removed. The aluminum pattern can also be formed by evaporation through a metal shadow mask.

The prepared wafers are loaded into the TGZM chamber with the aluminum pattern side facing the heat sink. This study showed that best results were achieved using a three-part temperature cycle, a ramp-up period, a soak period, and a ramp-down period. During the ramp-up period, the aluminum begins to react with the silicon to form the aluminum-silicon solution. By proper manipulation of the ramp-up cycle, the required sintering operation, mentioned earlier, can be instituted. Migration begins during this period, though at a relatively slow rate; it proceeds at its highest rate during the soak period. The aluminum gradually freezes out of the emerged aluminum-silicon droplet on the hot surface of the wafer during the ramp-down part of the cycle. The ramping portion of the cycle has the added benefit of reducing thermal shock stresses. In a typical run, a 10 mil wide pattern with 4 μm thick aluminum will migrate through a 400 μm thick silicon slice using the following cycle: 1 min ramp-up; 8 min soak; 3 min ramp-down. The soak temperature is 1200°C with a temperature gradient around 50°C/cm.

Device fabrication.—Most power semiconductor device fabrication processes involve at least two diffusion operations. For example, an n-base thyristor can be made with a deep p-type diffusion followed by an n-type emitter diffusion. In certain instances, these two diffusion cycles can be combined into a single simultaneous operation. The purpose of TGZM isolation is to connect a diffused p-layer, on one side of the slice, to an opposing p-layer on the other side. Three different sequences of TGZM and diffusion were studied.

Diffusion first.—The TGZM isolation operation is performed after all the diffused junctions have been created. A surface clean-up follows TGZM to remove rough areas. Subsequent operations, such as groove etching, passivation, and metallization, can then proceed.

TGZM first.—The TGZM operation is first performed on the raw silicon wafers, after which the wafers are mechanically lapped or chemically etched (or both) to yield smooth surfaces. Conventional wafer processing operations, *i.e.*, oxidation, diffusion, etc., can now be performed on these wafers treating them as if they were raw silicon slices.

TGZM intermediate.—In some applications, for example, certain power transistor structures, more than two diffusion operations are required. In these cases, it may prove advantageous to insert the TGZM operation after one or more diffusion steps have been performed, but before completion of the entire structure. In this work, TGZM was employed in a power transistor fabrication process just after the initial deep collector diffusion cycle was completed.

During the course of this investigation, SCR (silicon control rectifier), diode, and power transistor structures were fabricated using the TGZM process.

Results and Discussion

Migration results vs. aluminum pattern preparation.—In the groove method of pattern preparation, the mechanical strength of the silicon wafer is significantly reduced by the etched grooves. This limitation can be devastating to product yield if the groove depth becomes a substantial fraction of the total wafer thickness. This method is, however, the most effective way of keeping the aluminum pattern from surface spreading. The oxide channel and MOS methods do not mechanically weaken the structure but do introduce another problem. That is, the material formed by the reaction of molten aluminum with the silicon oxide is extremely tough and difficult to remove. Its presence inhibits the growth of good oxide in those areas during subsequent processing. Because of its abrasive nature, it can decrease photoresist mask life due to mechanical damage. The direct aluminum-silicon coupling eliminates the above mentioned problem. But, it may leave a somewhat bumpy surface (Fig. 4), which can be reduced to a reasonable level by adequate control of migration conditions.

Limitations and problems.—There are some instabilities inherent in the TGZM process (1, 2, 6); ways have been found to overcome some of these and to deal with the others.

Linewidth.—The surface tension of a liquid pattern line varies inversely with the linewidth. If the linewidth decreases to a specific size, the surface tension becomes high enough to cause the liquid line to break up into discrete surface droplets, which may or may not migrate (6-8). Of course, there will be no migration in those areas void of the liquid. The critical point at which breakup occurs depends on TGZM conditions, the thickness of aluminum, and the surface condition and crystal orientation of the silicon. These studies have shown no problems with linewidths greater than 2 mils.

Silicon wafer thickness.—There seems to be no upper limit on wafer thickness for successful migration. Aluminum has been migrated through a 0.25 in. thick slice of silicon in 4 hr with no difficulty whatsoever. However, since the TGZM process, by its very nature, causes damage on the silicon slice that tends to weaken the wafer structure, there probably is a lower limit on wafer thickness. This work shows that wafers less than 8 mils thick are too fragile after TGZM to allow processing without excessive breakage.

Stress and damage.—Even though care is taken to minimize stresses due to thermal shock, TGZM does, after all, employ high temperature and short times, which often leave the silicon stressed and damaged. These defects become visible when the wafer surfaces are etched.

Silicon crystal orientation.—As the width of the aluminum line approaches its lower limit, a critical situation occurs between the silicon crystal orientation and the direction of pattern lines on the wafer (9). If the lines are not properly oriented with the crystal lattice, broken lines, distortions, and other undesirable phe-

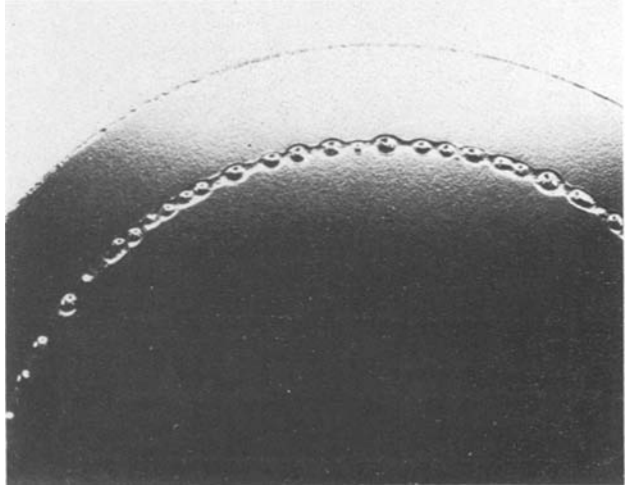

Fig. 4. A picture shows the roughness of TGZM surface in which the TGZM aluminum pattern was directly applied to a bare silicon surface.

nomena will occur. This problem disappears as the width of the line increases. For example, 10-20 mil wide circle patterns have been successfully migrated through polycrystalline silicon which, of course, had many crystal subdomains with different orientations as shown in Fig. 5, where the right-hand side wafer is top side up and the left-hand side wafer is bottom side up.

Silicon surface condition.—When the quartz lamp system is used, the effectiveness of migration depends highly on the reflectivity of the silicon surface. The lower the reflectivity (the greater the absorption), the faster the droplet migrates. Silicon wafers with a rough or darkened surface have a favorable ratio of absorption rate to reflection rate. This investigation has shown that a lapped surface yields faster migration than a chemically etched surface which, in turn, is better than a mechanically polished surface. It was also discovered that a layer of silicon oxide, which acts as an antireflection barrier, provides additional increases in migration rates.

Device fabrication.—In this section the processing sequence experiments, *i.e.,* TGZM first *vs.* diffusion first, are compared and analyzed. This study shows that, when conditions permit, the best approach is to do the TGZM operation first.

"Diffusion first.—In this approach, the TGZM operation is accomplished after all of the semiconductor junctions have been formed. Since the structure is basically complete at this point, it is obvious that the active area of the structure should not be significantly damaged or altered. As noted earlier, TGZM always leaves some surface scars, which must be removed before subsequent processing can proceed. It is almost impossible to remove all of the TGZM damage without adversely affecting the active structure. If all of the damage is not removed, the oxide quality in the TGZM area will be poor, and the remaining rough spots may cause problems in photolithographic processing. Figure 6 shows the process sequences for both "diffusion first" and "TGZM first" methods.

"TGZM first".—When TGZM is performed first on raw silicon wafers, practically all of the TGZM scars can be removed before junction formation takes place. Lapping followed by chemical etching, or lapping alone, has been effective in obtaining acceptable wafer structures after TGZM. All subsequent diffusion, oxidation, and photolithographic processing steps can be performed in the same way as with raw materials. An additional advantage from employing TGZM as a first processing step is the lateral diffusion from the isolation region that occurs during regular junction diffusion. This lateral diffusion expands the TGZM region an additional 10-20 mils on each side (Fig. 7). An abrupt junction is changed to a highly graded junction resulting in a considerably better blocking voltage capability. This diffusion of the TGZM region also tends to close any gaps in the TGZM region that might have occurred during migration. Finally, since the junction has diffused to an area remote from the original border, it is less affected by residual stress or damage in the original TGZM region. In spite of the advantage associated with lateral diffusion, it must be noted that extra area is required, which can be prohibitive in fabricating very small devices.

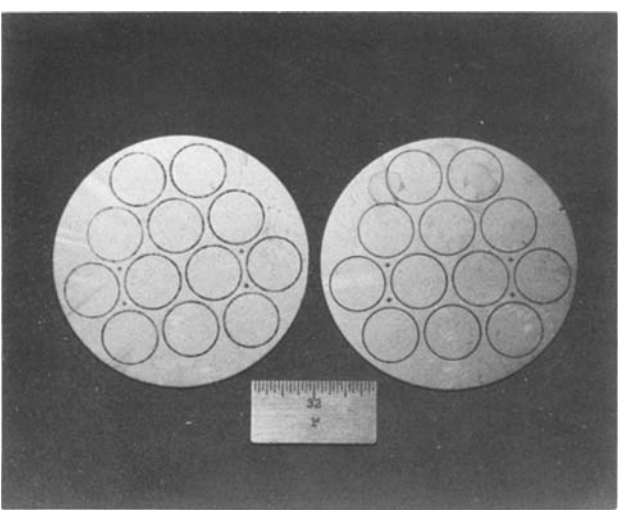

Fig. 5. A circular aluminum pattern migrated through a polycrystalline silicon wafer. The right-hand side wafer is top side up and the left-hand side wafer is bottom side up.

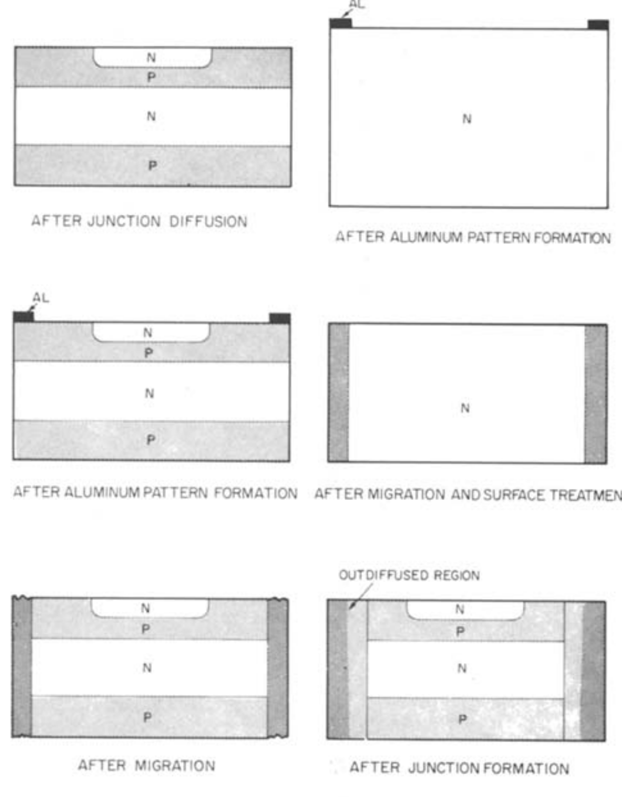

Fig. 6. Process sequences for the "diffusion first" method and the "TGZM first" method.

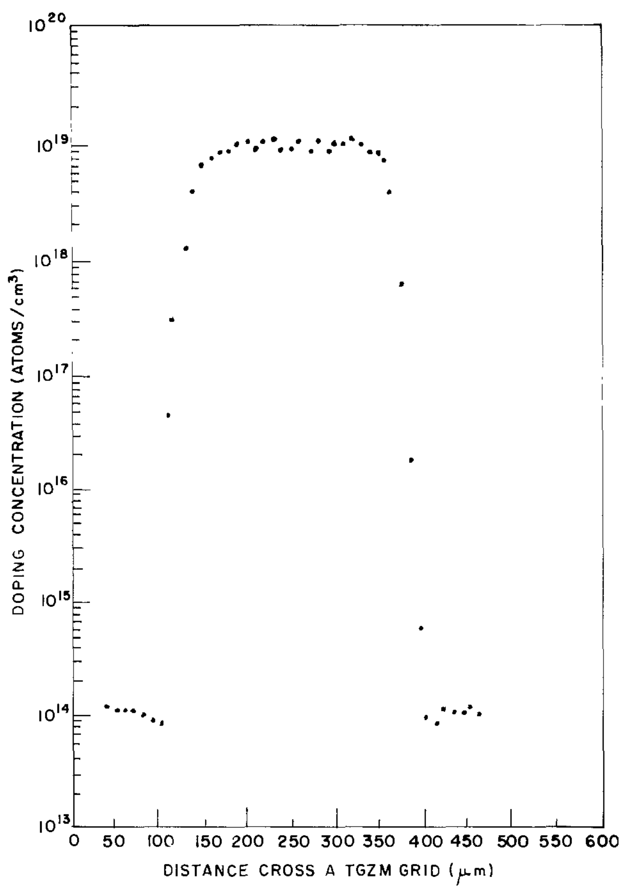
Out-diffusion of the aluminum atoms during subsequent diffusion operations can also be handled advantageously. In this investigation, out-diffusion has been used with a p-type impurity source, during closed-tube diffusion, to form graded deep blocking junctions. A boron source is also included to enhance the surface concentration of the p-layer. The results of one of these diffusion experiments are shown in Fig. 8. In open-tube diffusion, these out-diffused aluminum atoms can be oxidized and purged away, without affecting diffusion or oxidation results, by providing a sufficient oxygen flow.

An additional advantage from a process yield point of view is that, since TGZM occurs first, the starting thickness of the wafer is not limited. The wafer is reduced to its final thickness only after the TGZM operation has been completed.

Device evaluation.—In this study, TGZM is used only to introduce an extra p-type isolation wall into an existing device, which, obviously, alters the physical structure of the device. Any possible negative effects on device characteristics resulting from the



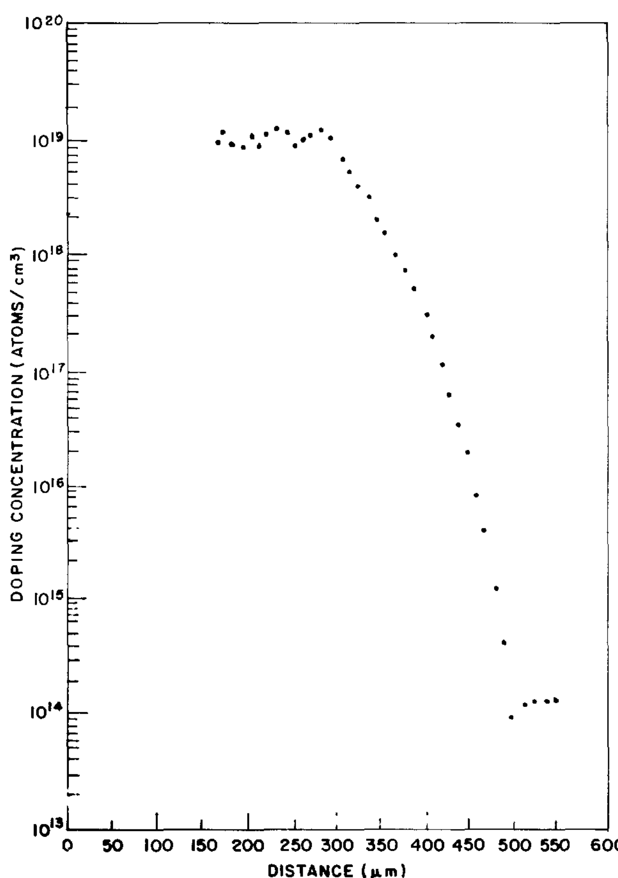


Fig. 7. The effect of side expansion from a post-TGZM diffusion. (a, left) The concentration profile of a TGZM trail before the post-TGZM diffusion; (b, right) the concentration profile after the post-TGZM diffusion.

TGZM operation can be detected by device evaluation. In a typical example, an SCR was fabricated from 50 Ω-cm, 400 μm thick n-type silicon wafers. The carrier lifetime measurements (open-circuit decay method) showed values of 10-20 μsec at high injection levels, which is comparable to equivalent devices processed without TGZM. Another way of evaluating the effectiveness of the TGZM operation is to compare blocking-voltage capabilities. These SCR's showed a blocking capability of 1600V in both directions, which is approximately 80% of the theoretical bulk avalanche breakdown voltage for this resistivity range. The leakage current level at 1600V was about 1.5A, as shown in Fig. 9, which suggests a good lifetime. The low leakage is a function of the superior surface passivation obtained with glass. It should be noted that the planar structures studied in this investigation are more adaptable to glass passivation than conventional mesa types.

Various devices have been made with this process. These devices have blocking voltages as high as 2500V and a current-carrying capability of up to 600A. Some of these devices are shown in Fig. 10. Their characteristics are listed in Table I. This table does not imply any limit for devices fabricated by the TGZM technique; it is presented only to indicate the extent of the present work.

Table I. The characteristics of some devices made with TGZM isolation and glass passivation

Device	Current ratings (RMS)	Blocking (volts)

Summary

The temperature gradient zone melting technique was used to create deep p-n junctions in silicon at greatly reduced processing times. In this study, TGZM process variations related to power semiconductor structures have been investigated. The specific results of this investigation are summarized as follows.

1. TGZM has proven to be an effective means of fabricating power semiconductor structures that could not be made solely by solid-state diffusion.

2. A method of loading wafers in the TGZM work chamber to assure a unidirectional temperature gradient was demonstrated.

3. Of the four methods of interfacing an aluminum array with a silicon wafer, the direct application approach proved to be the simplest.

4. The introduction of slow heating and cooling segments of the TGZM temperature cycle was effective in reducing thermal shock stresses and eliminated the need for presintering the aluminum pattern.

5. Of the two basic processing sequences studied, the "TGZM-first" approach proved to yield significant advantages.

6. Based on the current state-of-the-art, TGZM is limited to 2 mil aluminum pattern linewidths and silicon wafer thicknesses greater than 8 mils.

7. Alignment of the aluminum pattern to the crystal lattice was shown to be necessary only on very narrow linewidths.

8. It was demonstrated that a rough and darkened silicon wafer surface yielded the highest rate of migration.

9. Characteristics of a typical SCR structure fabricated with TGZM isolation regions have been described.

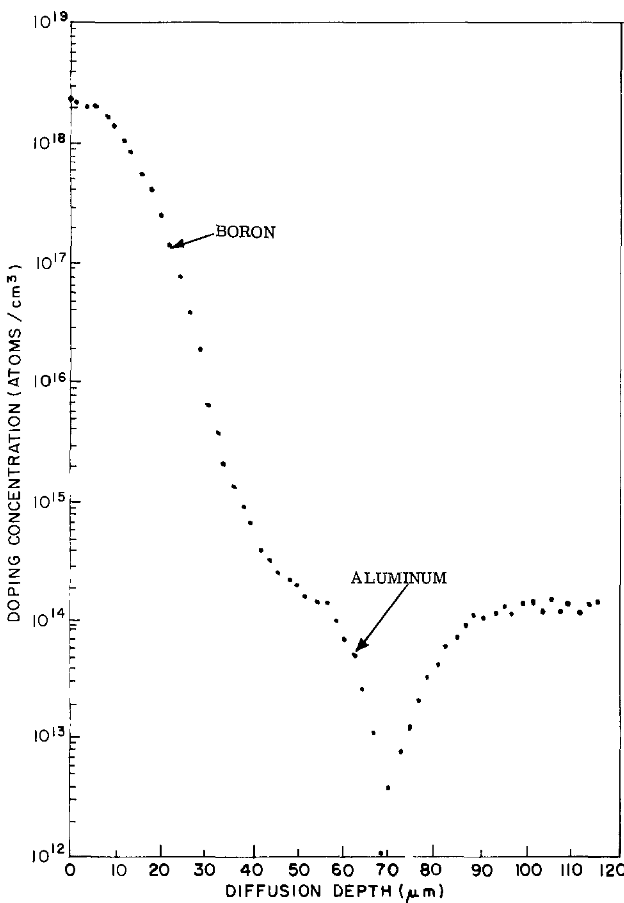

Fig. 8. A plot of a concentration profile shows the result of a closed tube diffusion where the TGZM trails in the silicon wafers served as an aluminum diffusion source and where an extra boron source was added to enhance the surface concentration.

ABSTRACT

Good control of the diffusion profile on Zn in GaAs is essential in many practical applications. By photoluminescence measurements the Zn distribution obtained in several diffusion runs at 850°C with GaZn:GaAs sources was determined. Under well-defined diffusion conditions, complementary error function distributions of the impurity were found. This is justified admitting that a nonequilibrium in gallium vacancy concentration may be noticeable for a relatively long time (up to 60-90 min); in this case the substitutional-interstitial mechanisms are no longer valid and the diffusion becomes purely substitutional. The coefficient for substitutional diffusion is $D_s = 1.5 \times 10^{-11}$ $cm^2\ sec^{-1}$. Complications due to the source composition and to the surface status of the substrate are also described.

The Zn diffusion mechanism in GaAs can be well understood on the basis of a substitutional-interstitial model (1) in which the equilibrium concentration of Ga vacancies is the controlling factor for the impurity diffusion. The diffusion is explained by means of the existence of a "fast" interstitial ion Zn_i^{m+} (m = 1, 2 degree of ionization), which reacts with a gallium vacancy V_{Ga} to produce a "stationary" substitutional ion Zn_s^- and (m + 1) holes

$$Zn_i^{m+} + V_{Ga} = Zn_s^- + (m+1)\, e^+ \qquad [1]$$

The amount of interstitial Zn_i depends on $[V_{Ga}]$ and hence from the As partial pressure P_{As4} through the equilibrium constants K_1 and K_2

$$\frac{[Zn_i^{m+}]}{[Zn_s^-]} = \frac{K_1}{[V_{Ga}]} = \frac{K_2}{[P_{As4}]} \qquad [2]$$

In this model, the effective diffusion coefficient D is a function of a power of the dopant concentration C_{Zn}, whose exponent goes from zero [very high P_{As4} (2, 3)] to three [low P_{As4}, low temperature (4, 5)]. In the first case, for $P_{As4} \geq 2$ atm, $[V_{Ga}]$ is so high that $[Zn_i]$ falls to negligible values (Eq. [2]); only the diffusion of Zn_s is significant and the diffusion process reverts to the substitutional one, with D_s = cost = $\simeq 10^{-11}\ cm^2\ sec^{-1}$ even at $C_{Zn} \simeq 10^{20}\ cm^{-3}$ at 900°C. Lowering P_{As4}, $[Zn_i]$ increases and interstitial diffusion becomes dominant; if the equilibrium of $[V_{Ga}]$ exists, D is proportional to C_{Zn}^{m+1} and a "supergaussian" profile is obtained

$$C_{Zn} = C_S\left(1 - \frac{x}{x_j}\right)^{1/(m+1)} \qquad [3]$$

with C_S = surface concentration and x_j = junction depth.

More complex profiles are known with noninteger values of (m + 1) (6, 7) and with a double diffusion front (2, 7).

With properly prepared GaAs substrates, diffusions performed at 850°C and with an As pressure which corresponds to the GaAs dissociation pressure, gave a complementary error function distribution of the Zn (D = const), which apparently contrasts with all published experimental data. For an interpretation, it is assumed that, in our diffusion conditions, the $[V_{Ga}]$ is out of equilibrium for a time which is not negligible. This must be taken into account in order to achieve complete control of the diffusion process.

Key words: GaAs technology, photoluminescence measurements on GaAs:Zn, diffusion profiles of Zn in GaAs.

Experimental

In order to optimize a Burrus-type diffused LED, we needed a diffusion process which allowed precise control of the Zn profile, of the Zn surface concentration (between 10^{19} and $4 \times 10^{19}\ cm^{-3}$), and of the junction depth (between 4 and 7 μm).

More than thirty tests were performed on 2×10^{18} cm^{-3} Si doped GaAs wafers, (100) oriented, dislocation content (EPD) less than 300 cm^{-2}, polished on one side, supplied by Sumitomo. Before Zn diffusion about 70 μm were etched away by chemical-mechanical polishing employing a solution (1000 H_2O_2:5 NH_4OH); after the final chemical etching (5 H_2SO_4:H_2O_2:H_2O) the correct value of EPD was found, indicating that all work damage was removed.

Slices of 4 cm^2 area were sealed in a quartz ampul of about 70 cm^3, evacuated at 10^{-6} Torr. The total weight of the source was 1g, with Zn concentrations x_{Zn}^l between 3.5 and 13 atomic percent (a/o). A quantity of GaAs varying from 0 to 150 mg was added to the source.

Diffusion times varied from 15 min to some hours. The C_S and Zn profiles were measured by photoluminescence (PL) on a bevelled ($\sim 2°$) sample using as excitation light the 6471Å line of a Kr laser, focused to a 5 μm spot.

It is well known that both the peak wavelength λ_m and the full width half maximum $\Delta\lambda$ of the PL spectrum are related to the Zn concentration in GaAs. However, the spectra are rather flat and therefore λ_m cannot be accurately identified and $\Delta\lambda$, in nonuniformly doped samples, depends on the concentration gradient below the excitation spot.

For these reasons we chose a different calibration which is shown in Fig. 1. The normalized PL spectra of four uniformly Zn-doped samples whose carrier concentration was measured by the Hall effect are shown in the figure; the axis labeled d goes through the 80% relative intensity of the spectra and gives the abscissa for the required calibration curve, shown in Fig. 2.

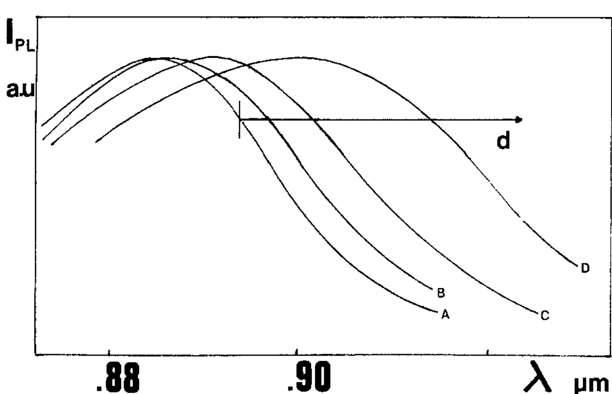

Fig. 1. PL spectra of uniformly doped GaAs:Zn samples. Curves A, B, C, and D refer to doping levels of 10^{18}, 3.5×10^{18}, 9×10^{18}, and 4×10^{19} cm^{-3}, respectively.

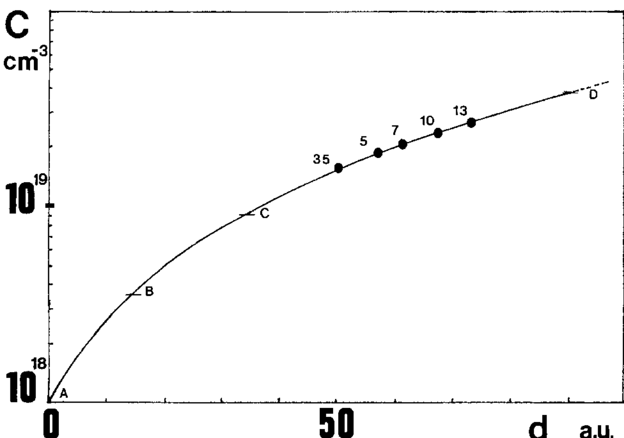

Fig. 2. Calibration curve C_{Zn} vs. d, obtained from Fig. 1. The closed circles are experimental C_S values for diffusions with As-saturated sources having the indicated a/o of Zn content.

Although this choice may be considered empirical, we found that the shift in the low energy side of the PL spectrum is much more sensitive to the doping level variations; furthermore, it is the least affected by the PL contribution arising from the material underlying the point under measurement, which may severely influence the whole PL spectrum, particularly when measurements are made close to the p-n junction (8).

An absolute accuracy better than 10% was estimated for this method.

x_j measurements were made by SEM on reverse biased samples and sheet resistance R_S was measured by the four-point method. The residues of solid GaAs, if present, were removed from the liquid source and weighed to know the final composition of the source.

To understand the importance of surface status, diffusions were added for comparison on intentionally damaged wafers; these were obtained by lapping their surfaces with 5 μm Al_2O_3 (measured depth of the damage 40-50 μm) and removing only 10-20 μm by polishing.

Results

Figure 3 shows the relationship between x_j and $\sqrt{t}$ for diffusions performed with more than 100 mg of solid GaAs in the source.

By the procedure illustrated in the preceding section, it was verified that this quantity of GaAs (corresponding to an As content of about 5-6 a/o) was necessary to reach the equilibrium composition of the source at the diffusion temperature, so as to have an As saturated source. This agrees with published experimental data about the ternary phase diagram GaAsZn (9).

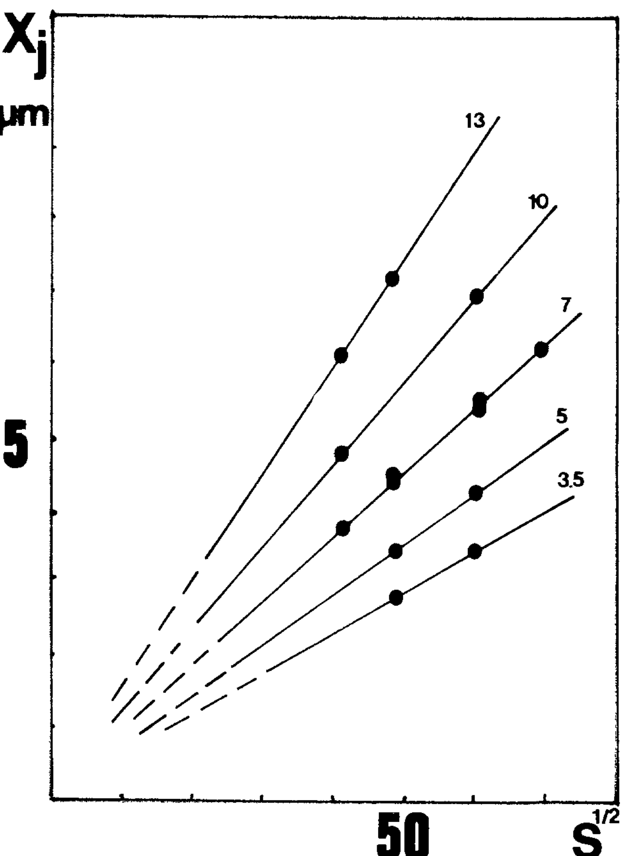

Fig. 3. Plot of x_j vs. $\sqrt{t}$, at different x_{Zn}^l, for As-saturated sources.

All sources having a lower amount of solid GaAs gave deeper profiles with some single defects on the wafer surface, due to As out-diffusion, and with fair reproducibility of C_S, for constant x_{Zn}^l and diffusion times.

Figure 4 refers to diffusions with As saturated sources and shows the correct dependence of C_S from $(x_{Zn}^l)^{1/2}$, C_S being lower than the Zn solubility limit in GaAs (10).

Among the profiles of Fig. 5, A is typical for equilibrium sources with $t \leq$ 60-80 min: It is a complementary error function distribution with $D_s \simeq 1.5 \times 10^{-11}$ cm^2 sec^{-1}; diffusion with $t < 60$ min on damaged substrates showed a double front profile (Fig. 5B).

For $t \geq 120$ min, "supergaussian" profiles ($m + 1 = 2$) were always found both for damaged and normally processed wafers. Diffusion conditions and experimental results for the data reported in Fig. 5 are summarized in Table I.

Figure 6 compares the calculated values of R_S for erfc and "supergaussian" ($m + 1 = 3$) distributions; experimental points confirm PL profile measurements.

Discussion and Conclusions

Erfc profiles are quite unusual for Zn in GaAs; they are expected for very high As pressures and for C_{Zn}

Table I. Experimental conditions for profiles shown in Fig. 5

Profile	A	B	C
Source: x_{Zn}^l (a/o)	7	7	7
GaAs (mg)	150	150	150
GaAs residue (mg)	50	50	50
Diffusion time (min)	60	60	120
Cs ($\times 10^{19}$ cm^{-3})	2.1	2.1	2.1
x_j (μm)	5.5	6.3	8.5
Surface status	Good	Damaged	Good

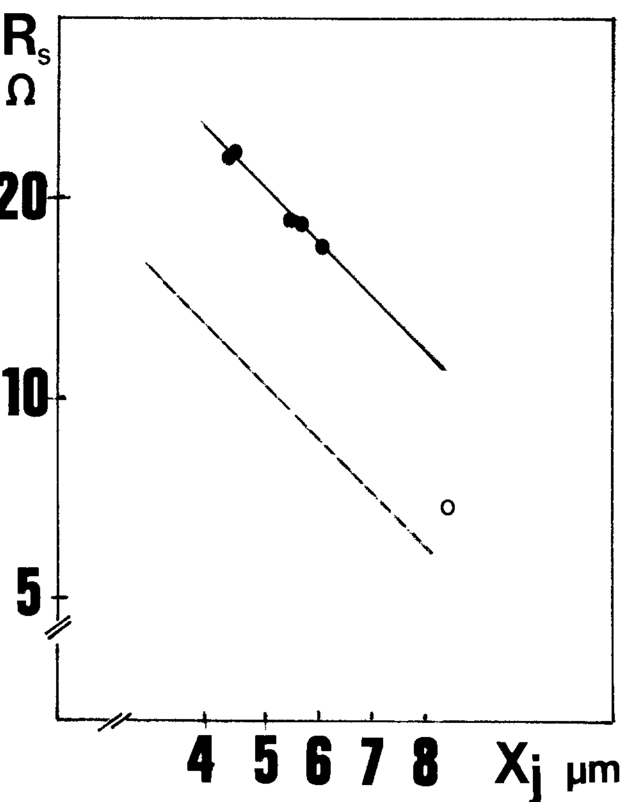

Fig. 6. Calculated dependence of R_S from x_j, for erfc and "supergaussian" ($n = 3$) distributions at $C_S = 2.1 \times 10^{19}$ cm^3. Closed circles refer to 40, 60, 80 min diffusions with As-saturated source and $x_{Zn}{}^{l} = 7\%$. Open circle comes from a 120 min diffusion, with the same source.

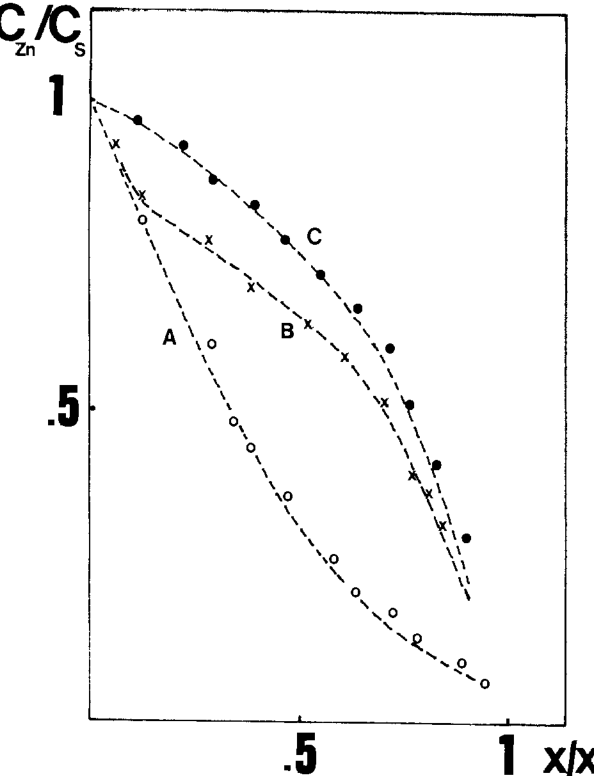

Fig. 5. Dopant profiles for diffusions of Table I

lower than intrinsic carrier concentration n_i [2×10^{17} cm^{-3} at 850°C (11)] possibilities that are excluded in our experiments, where the As partial pressure is 10^{-4} atm or less (12) and $C_{Zn} >> n_i$.

However, we observed erfc profiles in more than ten diffusion runs (profile 5A).

On the other hand, with similar sources and the same substrates, double front and "supergaussian" profiles were found also (profiles 5B, 5C).

The main difference between the two sets of diffusions regarded only the treatment of the surfaces and the diffusion times.

The situation can be understood by considering that, if growing and processing the crystals permit the exclusion of consistent sources of Ga vacancies in the bulk, their diffusion from the surface must control the final distribution of Zn_s. Actually, the assumption that $[V_{Ga}]$ is always near its equilibrium value during the diffusion may be correct for highly dislocated crystals and for diffusion times large enough to permit the V_{Ga} equilibrium. However, if the defect content of the substrate is low, V_{Ga} must be considered out of equilibrium in the first step of the diffusion. In this case the reactions [1] and [2] indicate that the slowly diffusing vacancies control the diffusion process by decreasing $[Zn_i]$.

The diffusion becomes a purely substitutional one, with a constant D_s.

From the profile 5A we found $D_s \simeq 1.5 \times 10^{-11}$ cm^2 sec^{-1} which is very close to the diffusion coefficient measured for diffusions performed in excess As pressure (2, 3) and agrees with the value 6×10^{-10} cm^2 sec^{-1} at 1000°C (7), if one assumes a decrease of 1-2 orders of magnitude for a temperature reduction from 1000° to 850°C.

By comparison of profiles 5A and 5C, it may be concluded that a time between 60 and 120 min is needed to reach the V_{Ga} equilibrium at 850°C.

A nonlinear relationship between x_j and $\sqrt{t}$ leads to shorter diffusion depth for $t \leq$ 60-80/min; this is in agreement with the conclusions of other works

employing a lower temperature range 600°-750°C (13), and confirms other experimental results at 875°C [Ref. (14), Fig. 3].

We may conclude that in practical applications, when shallow junctions are required, the sublinear dependence $x_j \rightarrow \sqrt{t}$ and the existence of profiles less steep than the "supergaussian" must be taken into account to ensure a good reproducibility of the diffused region.

ABSTRACT

Deposition of GaAs from the Ga-AsH_3-HCl-H_2 system at 1023 K and pressures from 1 down to 0.01 bar leads to controlled growth rates ranging from 40 to 1 μm/hr. Due to the surface kinetic limitation of the process, very uniform films are obtained at reduced pressures. The background impurity level is low; 77 K electron mobilities of 73,000 cm^2 V^{-1} sec^{-1} were obtained for not purposely doped samples with electron concentrations in the upper 10^{14} cm^{-3} region. Using H_2S as a dopant, the electron concentration increases linearly with the H_2S pressure. The sulfur-doped films show the same values for the mobility and the saturation concentration of electrons as layers obtained at atmospheric pressure.

Transport in a chlorine system (1, 2) provides a convenient technique for the preparation of GaAs layers of reproducible thickness and well-defined impurity content. These features make the transport approach attractive for the fabrication of optoelectronic and microwave devices. However, in the classical tube-type reactor, operating at atmospheric pressure, uniform epitaxial growth is only possible on a limited substrate area. Moreover, the rates tend to be of such a magnitude that thickness control in the submicron region presents some difficulties.

Suitably low growth rates of approximately 1 μm/hr may be obtained with the MBE method (3) at the price of using rather complicated equipment. Experience from the silicon technology indicates that both low growth rates and excellent control of film thickness over a substantial number of samples may be obtained by carrying out the deposition of silicon or insulators from the vapor phase at low pressures (4, 5). Such uniform deposition can only be expected if all substrates are exposed to the same gas phase composition, which means that no appreciable depletion of the gas phase should occur in the deposition region. This condition will be met if the growth process is slow, *i.e.*, the growth rate should not be determined by mass transfer (diffusion) in the gas phase, but be limited by the kinetics of the reaction at the surface.

For III-V compound semiconductors the feasibility of the low pressure technique has only been demonstrated for the organometallic chemical vapor deposition (MOCVD) process, using trimethyl gallium and AsH_3. However, in this case the growth process is apparently limited by mass transfer rather than by surface kinetics (6, 7). The study described in the present paper was concerned with the behavior of the inorganic system Ga-AsH_3-HCl-H_2, also at low pressures. It will be shown that for typical experimental conditions the deposition rate is kinetically limited and that a wide range of growth velocities is available by varying the hydrogen pressure.

The Growth Rate for Mass Transport Limited Conditions

The maximum possible growth rate will be obtained for conditions where the process is mass transport controlled in the limiting case of complete removal of the supersaturation in the gas phase. The value of the maximum rate for a given flow rate and surface area

of the sample may be calculated from the actual and equilibrium concentrations of the reactive components in the system

$$GaCl + \frac{1}{4} As_4 + \frac{1}{2} H_2 \rightleftharpoons GaAs + HCl \qquad [1]$$

Figure 1 shows the calculated maximum growth rate for a substrate area of 1 cm^2 and a gas velocity of 0.8 cm/sec (the same value as used in our experiments) as a function of the hydrogen pressure. The GaCl and AsH_3 pressures have been indicated in the figure; they are typical for the operation of this system at atmospheric pressure. The rate exhibits a square root dependence below $2 \cdot 10^{-2}$ bar. At higher pressures the slope decreases because the growth process becomes limited by the amount of gallium available in the gas phase. Therefore, at higher GaCl pressures the curve not only shifts to the right, but the square root dependence also extends to higher hydrogen pressures. It can be recognized from the figure that the rates are in the range of 50-1000 μm/hr. Varying the AsH_3 and GaCl pressures around the values used in Fig. 1 will affect the rate data. However, for the combinations of parameters covered in the experimental part of this study the above-mentioned range still applies for the calculated rate values.

In practical cases the diffusion limitation will lead to slower deposition. For surface limited growth not only lower rates should be observed, but also different pressure dependences than those derived from thermodynamic considerations may be expected.

Experimental

The growth of GaAs in an inorganic chlorine transport system at low pressures presents some specific problems. As shown above, thermodynamic considerations predict that for a given pressure and flow rate of the GaCl and AsH_3 entering the substrate zone the amount of material available for deposition, and thus the growth rate, will decrease when lowering the hydrogen pressure. Due to the increased diffusivity of the gas species at lower pressures, the wall of the reactor downstream of the deposition zone, which is generally at a lower temperature than the substrate, will more effectively compete with the substrate for the reactants. For the same reason one expects the reactor design to become increasingly critical for obtaining efficient reaction between HCl and the Ga source.

With these considerations in mind a low pressure deposition apparatus was designed capable of operating at low gas flows, for example 30 cm^3 STP/min at $6.5 \cdot 10^{-2}$ bar through a reactor of 60 mm diam. In our experiments we used a gas velocity of 0.8 cm/sec, which was held constant in all cases. Figure 2 shows a schematic of the reactor. The source chamber was

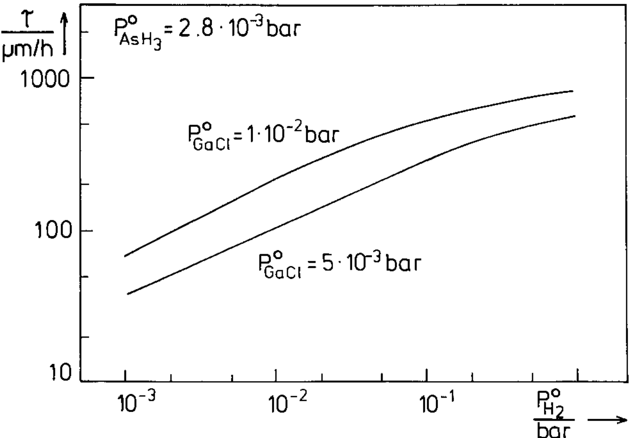

Fig. 1. Calculated dependence of maximum growth rate on H_2 pressure for two GaCl pressures for complete exhaustion of gas phase; surface area: 1 cm^2; gas velocity: 0.8 cm sec^{-1}.

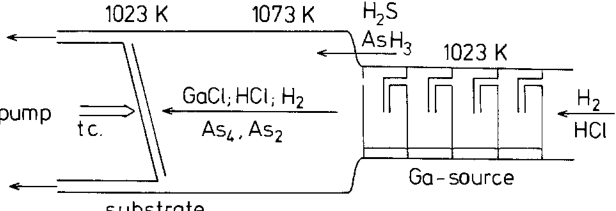

Fig. 2. Schematic diagram of low pressure reactor

constructed to achieve optimum interaction between the Ga melt and the gas phase and thereby efficient production of GaCl. Furthermore, the present design minimizes back-diffusion of AsH_3 to the Ga melt. Similarly, the layout of the deposition chamber is such that diffusion to the colder part of the reactor, where condensation on the walls might take place, is impeded. The temperature of the source was 1023 K in all experiments, that of the substrate was the same except in the experiments where the temperature dependence of the rate was investigated. To allow a high supersaturation of the gas phase without risking deposition at the reactor walls the temperature in the central part of the reactor, where pure AsH_3 was injected, was higher than that at the substrate. HCl was generated by reduction of $AsCl_3$ with hydrogen at 1023 K and subsequent condensation of the arsenic. The doping gas H_2S was injected together with AsH_3 over a bypass directly into the deposition zone. The sulfur concentration in the gas phase was determined photometrically using the methylen blue method. (8). Total pressures in the range of 0.01-1 bar could be maintained using a rotary pump of 30 m^3/hr capacity. Cooling traps and an activated carbon filter between pump and reactor provided adequate protection of the pump against the reactive gases from the deposition system and impeded back-diffusion of oil into the reactor.

Substrates were semi-insulating (100) oriented GaAs wafers which were etched in an $H_2O_2/H_2SO_4/H_2O$ mixture before deposition. The epitaxial system was purged by a number of pumping and flushing cycles, the latter with hydrogen at atmospheric pressure. Before each epitaxial run the substrate was annealed for 5 min in an AsH_3 atmosphere at 1023 K in order to remove residual contaminants such as oxygen and carbon (3) from the surface.

The thickness of the epitaxial layers was determined microscopically after staining (9) to an accuracy of approximately 0.3 μm. Hall mobilities and electron concentrations were measured using the method of van der Pauw (10).

Results

Figure 3 shows the dependence of growth rate on the pressure of the carrier gas (hydrogen), which was varied over a wide range (0.01-1 bar). Below 0.2 bar the growth rate increases linearly with hydrogen pressure (closed circles), whereas at a higher pressure this linearity turns into a square root dependence (open circles). It may be seen that the growth rate can be varied from approximately 1 to 40 μm/hr. In the following figures the dependence of rate on experimental parameters is shown for two hydrogen pressures: one in the linear range at lower pressure and one in the square root range at higher pressures.

The influence of growth temperature on the rate is demonstrated in Fig. 4. The curves exhibit a maximum at the same temperature, independent of hydrogen pressure, but the slope of the low temperature flank is larger in the low hydrogen pressure region.

The dependence of the rate on the GaCl and AsH_3 pressures is shown in Fig. 5 and 6, respectively. In the former case it exhibits a maximum which moves to a higher GaCl pressure for the higher hydrogen pressure region. The rate exhibits a 1/4 order dependence on AsH_3 pressure for both ranges of hydrogen pressure.

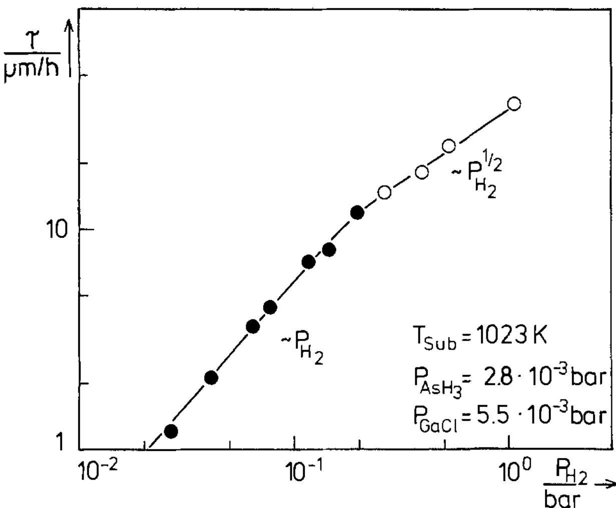

Fig. 3. Growth rate vs. hydrogen pressure

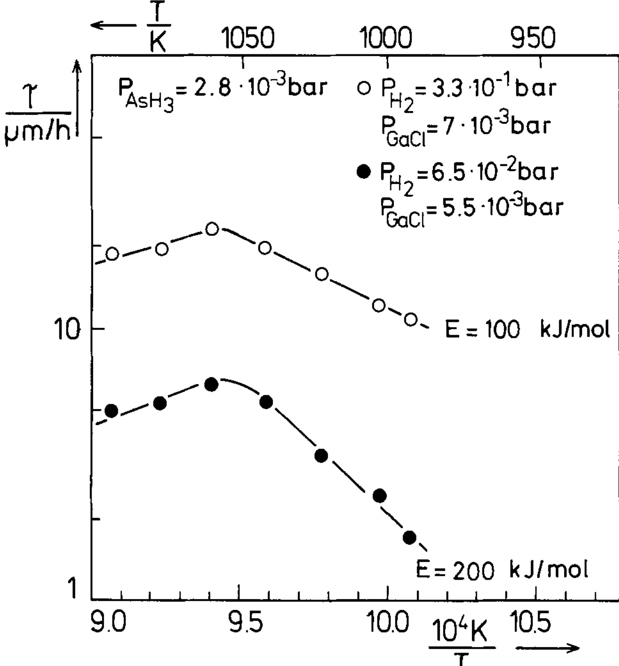

Fig. 4. Growth rate vs. reciprocal growth temperature for two hydrogen pressures.

It reaches a saturation value which shifts to a higher AsH_3 pressure for the higher hydrogen pressure range. In all experiments the substrate was kept at 1023 K. To obtain the higher hydrogen pressure data in Fig. 4, the GaCl pressure was increased from 5.5 to $7 \cdot 10^{-3}$ bar in order to remain in the region of the descending flank to the right of the maximum in Fig. 5. The same change was made to obtain the upper curve in Fig. 6.

A study of the uniformity of film growth obtained in our apparatus indicated within experimental error (0.3 μm) the same thickness over the entire sample area of 12 cm^2 for a 6.0 μm deposit grown at $6.5 \cdot 10^{-2}$ bar. This should be compared with a thickness variation of 0.7 μm on a layer of the same area and 4.7 μm total thickness grown at 1 bar.

Besides the influence of the epitaxial parameters on the growth rate, the doping behavior has also been investigated. Figure 7 represents the results of doping experiments in the low pressure system. It shows the electron concentration (n) measured at 77 K as a function of H_2S pressure for two hydrogen pressures. Both curves show a linear increase of n with H_2S pressure and a rather abrupt saturation of the electron concen-

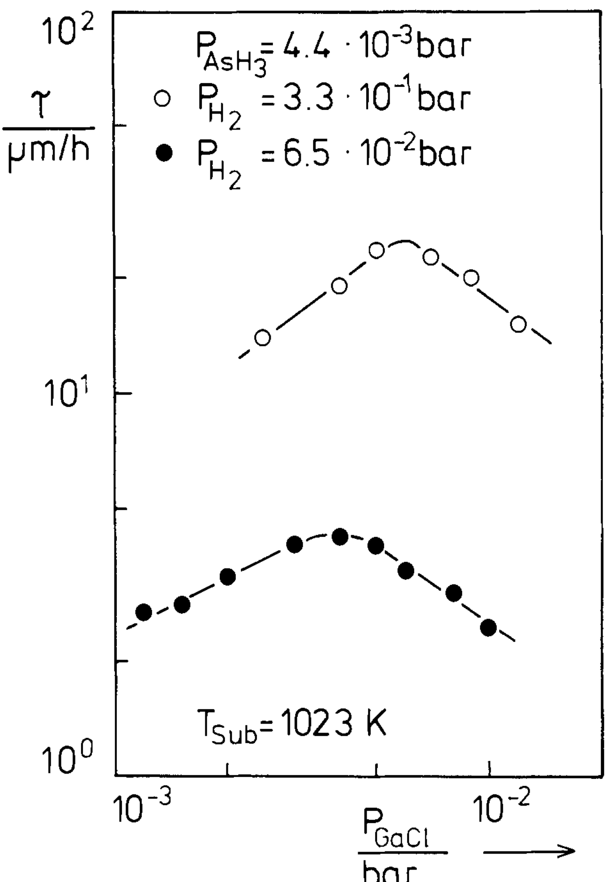

Fig. 5. Growth rate vs. GaCl pressure for two hydrogen pressures

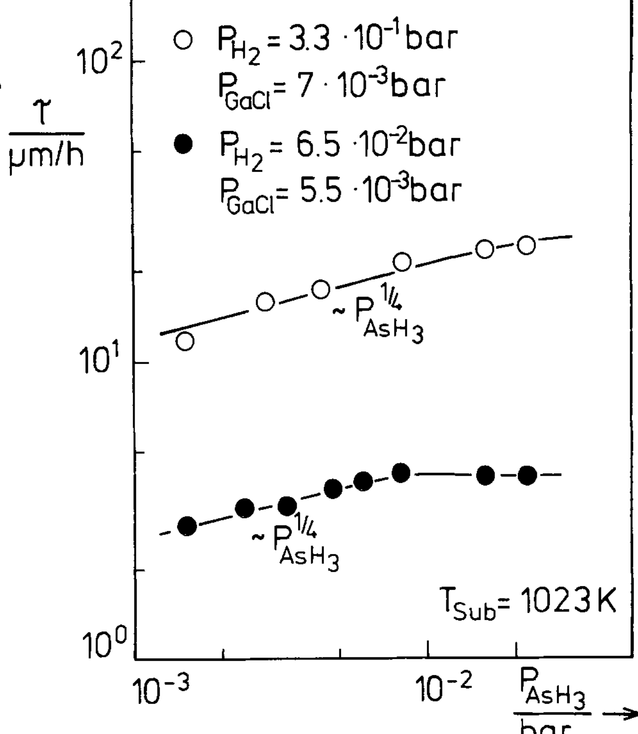

Fig. 6. Growth rate vs. AsH_3 pressure for two hydrogen pressures

tration at approximately $3 \cdot 10^{18}$ cm^{-3}. A decrease in hydrogen pressure by a factor of 5 requires the same reduction in H_2S pressure in order to obtain films with same electron concentration. However, the saturation value does not appear to be affected by this decrease.

The corresponding Hall mobilities are plotted in Fig. 8 together with the data from Hall measurements for

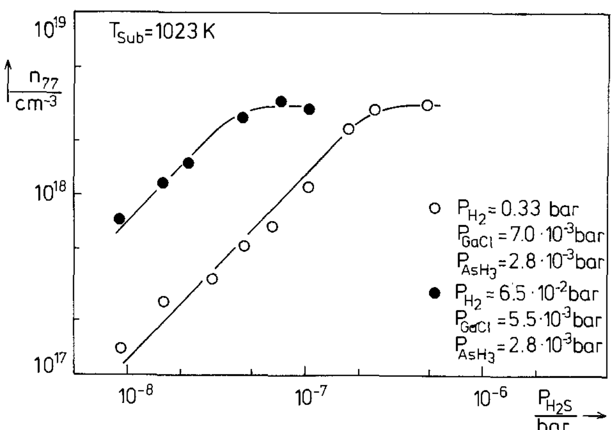

Fig. 7. Electron concentration (77 K) *vs.* H_2S pressure for low pressure VPE GaAs; parameter: hydrogen pressure.

unintentionally doped material. The solid line represents the phenomenological curve from Ref. (11); it is based on samples grown from the vapor phase at atmospheric pressure. Our data points are close to this curve except at electron concentrations below $2 \cdot 10^{15}$ cm^{-3}, where the mobility data systematically lie above the curve. Mobilities up to 73,000 cm^2/Vsec were obtained for samples with n in the high 10^{14} cm^{-3} region.

Discussion

As may be seen in Fig. 3, the growth rate can be varied over more than one order of magnitude by changing the hydrogen pressure between 10^{-2} and 1 bar. However, the square root dependence expected from thermodynamic considerations (Fig. 1) only appears at higher pressures. The linear relationship at low pressures indicates that the hydrogen molecule is involved in the rate-limiting step. This behavior would fit the simple model that the reduction of adsorbed GaCl to Ga by H_2 is the rate-limiting process in the growth reaction. The same considerations have been made to explain the behavior of a chlorine transport system with a hydrogen-inert gas mixture (12). In this case also a linear relationship was found between rate and hydrogen pressure, but at a hydrogen pressure between 0.2 and 1 bar at a total pressure of 1 bar.

The different slopes of the growth rate above and below 0.2 bar (Fig. 3) suggest that the rate-limiting steps are different in these two regions. This was the reason for studying the dependence of the rate on growth temperature (Fig. 4) for a hydrogen pressure in the linear range and one in the square root range of Fig. 3. The curves show the familiar maximum (13, 14). Especially the increasing growth rate with increasing temperature below 1050 K is indicative of a surface reaction limited regime. The slopes at temperatures below the maximum, *i.e.*, the activation energies, are indeed different in the two regions of hydrogen pressure.

On the other hand, it was reported for the organometallic low pressure system (6, 7) that the growth rate depends neither on growth temperature for any hydrogen pressure nor on the hydrogen pressure itself at a constant molar fraction of trimethyl gallium. Because of these results, and since the rate can only be varied by the flow of trimethyl gallium, it has been concluded that the rate is always limited by the mass transfer of trimethyl gallium.

The model mentioned at the beginning of this chapter implies that adsorbed GaCl plays an important role in the growth mechanism and that at large surface concentrations of this compound blocking of growth may occur. At a low hydrogen pressure the density of adsorbed GaCl molecules at the surface will be higher because less GaCl will be reduced to Ga than at a higher hydrogen pressure. This model is supported by the dependence of the growth rate on GaCl and AsH_3 pressure (Fig. 5 and 6). The maximum in the rate *vs.* GaCl pressure plot is observed also at atmospheric pressure (13, 14) and has been explained by a similar GaCl adsorption model (15, 16) where growth is assumed to be inhibited by adsorbed GaCl molecules at high GaCl pressures. The maximum value is reached earlier at lower hydrogen pressures, since under these conditions the density of adsorbed GaCl will be higher. Because of this higher density, fewer sites will be available for arsenic adsorption at lower hydrogen pressure, which would lead to a retardation of growth. Indeed, this behavior is observed (Fig. 6). Also, saturation of the growth rate is reached at a lower AsH_3 pressure in the case of a lower than at a higher hydrogen pressure.

A comparison of Fig. 1 and 3 shows that the growth rates, which are calculated assuming the maximum conversion permitted by thermodynamics, exceed the measured rates by more than an order of magnitude. This result and the observed dependence of growth rate on gas phase composition all fit the contention that at temperatures below 1050 K the growth process is kinetically controlled (13, 14). This finding indicates that below 1050 K the chloride growth process meets an important condition for uniform growth. The temperature region above 1050 K was not investigated in this study, since the temperature dependence of the rate in this range points to mass transfer limited growth.

For the fabrication of devices the doping behavior in this low pressure system is equally important. As can be seen from Fig. 7, reproducible doping is possible using H_2S as a doping gas. We have argued in an earlier paper (17) that at atmospheric pressure the sulfur uptake appears to be kinetically determined. Furthermore, we found in the latter case for (100) substrates a linear increase of electron concentration with H_2S pressure, which abruptly saturates at $3 \cdot 10^{18}$ cm^{-3}, whereas the sulfur incorporation goes on beyond $3 \cdot 10^{18}$ cm^{-3}. SIMS measurements (17) indicate for this region a continuation of the linear uptake.

The solubility curves from the low pressure system (Fig. 7) thus show the same behavior as those obtained at atmospheric pressure. Therefore, we propose that the incorporation mechanism is the same in both cases. Since H_2S is the dominant sulfur species in the gas phase at our experimental conditions the data suggest that H_2S could react directly with an adsorbed GaCl molecule followed by the incorporation of sulfur at the same site. A lower hydrogen pressure implies a larger density of unreacted GaCl and consequently a larger rate of sulfur uptake would result, as observed in Fig. 7.

Above the saturation of the electron concentration, sulfur probably continues being incorporated as at atmospheric pressure, but in an electrically neutral impurity complex (17). This contention is supported by the strong decrease of the Hall mobility near $3 \cdot 10^{18}$ cm^{-3} (Fig. 8).

From Fig. 8 we recognize that the background doping can be reduced to values below 10^{15} cm^{-3}. This

residual impurity level might be predominantly due to silicon, as found for films obtained from VPE systems operating at atmospheric pressure (18), because the material of the epitaxial apparatus and the starting materials are the same in both cases. As discussed in an earlier paper (11) the solid line is based on data for undoped and sulfur-doped VPE samples and represents the "universal" behavior of the mobility in the range $10^{16} \leq n \leq 10^{18}$ cm^{-3}, independent of growth system and experimental parameters. At higher concentrations the mobility becomes dependent on the type of dopant due to the different solubility limits of donors in GaAs. At lower concentrations the mobility is very sensitive to residual contaminants in the growth system, such as copper (19) or carbon (20), which may cause compensation of the material. The good fit of our experimental data to the phenomenological curve indicates that the layers grown in the low pressure system have the same low compensation as those obtained from systems at atmospheric pressure. Furthermore, the data at low electron concentrations suggest that the level of residual contamination in this system appears to be lower than in those operating at atmospheric pressure.

Conclusions

We have investigated a new method for the growth of GaAs layers, the inorganic chlorine transport system at low pressures. As in the system operating at atmospheric pressure, the growth process as well as the incorporation of the dopant sulfur from H_2S appear to be kinetically controlled. The growth mechanism depends on the hydrogen pressure. The dependence of growth rate on gas phase composition indicates that the rate-limiting step is determined by the specific composition of the gas phase; particularly at low hydrogen pressures the reduction of GaCl to Ga by hydrogen appears to play an important role. The growth rate can be varied continuously over the wide range of 1-40 μm/hr; it is constant across a relatively large area.

This behavior of the growth rate indicates that this low pressure system presents some specific advantages compared to the systems operating at atmospheric pressure. The uniformity of the growth rate across larger areas makes the system particularly interesting for production purposes. Furthermore, growth rates, which so far could be obtained only in the very different VPE and MBE systems separately, can in the low pressure approach be achieved in one run in a single system by only varying the hydrogen pressure. This makes feasible the controlled growth of multilayer structures with thicknesses of the single layers differing by more than one order of magnitude. Examples are the growth of a buffer layer followed by the thin active layer for field effect transistors or the growth of laser structures.

The background doping can be reduced to a level below 10^{15} cm^{-3}. Using sulfur as a dopant electron, concentrations up to $3 \cdot 10^{18}$ cm^{-3} are easily obtained. The high 77 K mobility value of approximately 73,000 cm^2/Vsec for electron concentrations in the upper 10^{14} cm^{-3} region, is also indicative of the easy purity of the material.

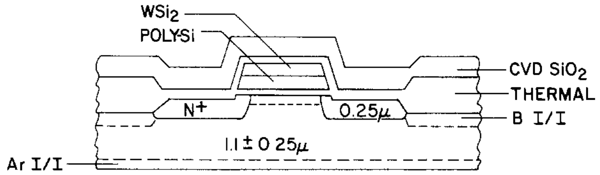
ABSTRACT

An n-channel single level polycide (WSi_2 on poly-Si), 22.5 nm gate oxide technology, using electron-beam direct writing for lithography with minimum feature size of 1 μm, has been developed to fabricate NMOS circuits. Low resistance (2.7 Ω/□) polycide interconnections and small dimension (1 μm) devices are the unique features of this process. The overall process is described in this paper. Polycide deposition, annealing, etching, and oxidation are discussed in detail. Cross sections (0.5K to 2K) of polycide dynamic RAM arrays have been successfully fabricated by this polycide technology. The advantage of using low resistance polycide in integrated circuits is demonstrated.

Polycrystalline silicon is commonly used as a gate-electrode and interconnection-line material in MOSFET integrated circuits. Decreasing lithographic dimensions and scaled-down device structures (1) have led to a higher level of integration and increasing importance of interconnection technology. The extendibility of poly-Si to small devices in a VLSI circuit environment is limited by its relatively high sheet resistance (33-50 Ω/□). A metallic silicide layer on poly-Si (called polycide) could reduce the sheet resistance by over an order of magnitude, thereby reducing *IR* drops and *R-C* time constants. This composite metal-silicide/poly-Si structure combines the advantages of a well-understood and characterized SiO_2-to-polysilicon interface with a low resistivity silicide. These metal silicides must be able to withstand processing chemicals, high temperatures, and oxidation. In addition, it must be possible to pattern them into fine-line structures. The utilization of evaporated WSi_2 on poly-Si for interconnections in FET's was first proposed by Crowder and Zirinsky (2, 3). Since then, WSi_2, $MoSi_2$, $TaSi_2$, and $TiSi_2$ deposited on poly-Si for interconnection applications have been investigated (4-10). Most of the work has concentrated on the material properties of the silicides or characteristics of single devices, such as a comparison between the polycide and poly-Si devices in terms of resistance in poly-Si lines, flatband voltage, threshold voltages, and gate integrity (2, 6, 7). From these previous studies, it is clear that polycide devices have all the advantages of poly-Si devices and, in addition, much lower sheet resistance. This paper reports the first successful attempt to apply WSi_2 polycide in integrated circuits with minimum feature size of 1 μm. To develop this well-controlled polycide process, it is necessary to gain a detailed understanding of deposition, annealing, etching, and oxidation of polycide. These studies as well as work related to polycide gate integrity are described. Polycide devices and cross sections (0.5K to 2K) of single polycide dynamic RAM arrays (11) have been fabricated by this process. The circuit performance is shown to be greatly enhanced by the low resistance polycide interconnections. The results of this work demonstate the feasibility and advantages of applying polycide to VLSI with extremely high density circuits.

A 1μm Polycide Device Process

This process has evolved from a 1 μm single poly-Si process (12) reported before with tighter dimensional control. Figure 1 shows the schematic of the basic polycide MOSFET along and across the channel length direction. In the cross sections, a composite layer of 150 nm WSi_2/150 nm poly-Si is shown as the gate electrode and interconnection. Electron-beam direct writing for lithography (13), reactive ion etching (RIE) (14), and plasma etching, as well as ion implantation are used extensively throughout the process to achieve control of fabricating small-dimension devices. Six masks are used to fabricate arrays of single polycide dynamic RAM's. Mask 1 is for the alignment marks, which are used for automatic chip alignment during all subsequent mask exposures. This is the first mask level and also the only one defined by optical lithography, because no alignment is required at the first level. The alignment marks, consisting of 200 nm WSi_2, are defined via WSi_2 lift-off. The automatic registration signal in a vector-scan E-beam exposure system (15) is obtained as an averaged signal from many unidirectional beam sweeps across the mark by detecting backscattered high energy electrons (13). The signal acquired by signal averaging from a pedestal of 0.2 μm WSi_2 on an Si substrate is approximately five times larger than that acquired by a pedestal of 0.5 μm poly-Si which was used before (12). The improvement of the alignment signal sub-



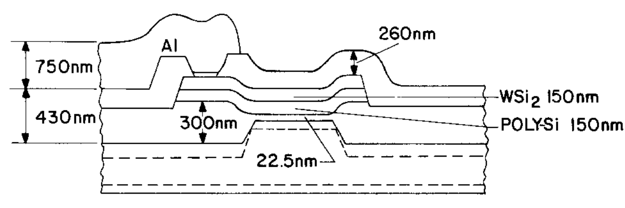


Fig. 1. Schematic cross sections along and across the channel length direction of the basic single polycide MOSFET structure.

Key words: polycide interconnections, processing, annealing, etching, oxidation, gate integrity, device characteristics.

stantially reduces the time required for alignment, which, in turn, enhances the throughput of E-beam lithography. An oxidation mask for semi-recessed field oxidation, consisting of nitride on oxide, is etched with mask 2 outside the active device areas. The field threshold-adjustment implant for isolation is performed after patterning and before the semi-recessed oxide is grown. After field oxidation, the oxidation mask is completely removed from the active device areas. Mask 3 defines the area for As^{75} and B^{11} HiC (high capacitance) implants (16) in the storage region of the dynamic RAM cells. The patterned resist shields the rest of the wafer from the HiC implants. An enhancement channel implant occurs after the gate oxide is grown. WSi_2 is deposited by E-beam co-evaporation onto $POCl_3$-doped poly-Si. A crystallization anneal is followed by the deposition of a layer of CVD SiO_2. This passivation of WSi_2/poly-Si (polycide) is then followed by a homogenization anneal to obtain a homogeneous WSi_2 film. The polycide gates are patterned by mask 4. The self-aligned source/drain As^{75} implantation is done after gate patterning. The final metal Al is isolated from the polycide and diffusion lines by an oxide stack consisting of both thermal and CVD SiO_2. The contact holes are etched in this isolation stack using mask 5, and the final metal is delineated by mask 6 via lift-off. Table I outlines the process sequence for this polycide technology.

In this process, lithography is achieved by a vector-scan electron-beam exposure system with positive resists. Since exposure areal fraction is kept less than 0.5 at the mask levels to reduce E-beam exposure time, an Al pattern transfer technique is used on masks 2 and 4. A double-layer resist system is exposed and developed first, and an evaporated Al film is then lifted off to obtain the desired pattern. Patterns are etched by reactive ion etching (RIE). Interferometric *in situ* detection of the etching process is utilized (17). The general etching strategy is to etch ~80% of the stack by RIE for near-zero etch bias. The etching is then completed by a selective plasma etch (mask 4 polycide pattern) or wet-etching (mask 2 oxidation mask and mask 5 contact holes). The etching of contact holes was reported before (12), and it is not repeated here.

Polycide Studies

The polycide technology is an enhancement of poly-Si technology. Its major variations from poly-Si technology occur in the deposition, annealing, etching, and oxidation of polycide. These steps have been studied in detail and the results are summarized below. Since polycide gate integrity (dielectric strength)

Table I. Process sequence for 1 μm polycide technology

Starting substrate—P-type <100> 4 Ω-cm silicon
Back-side I/I—Ar^{40} I/I for gettering
Mask 1—define alignment marks
WSi_2 deposition, lift-off
Form nitride/oxide stack
Mask 2—define oxidation mask in the active device area
Field I/I—low dose B^{11} I/I
Grow semi-recessed oxide
Strip oxidation mask
Grow screen oxide
Mask 3—define HiC implant mask
HiC I/I—low dose As^{75} and B^{11} I/I
Form WSi_2/$POCl_3$ doped poly-Si stack
Crystallization anneal
CVD SiO_2 deposition
Homogenization anneal
Mask 4—define polycide gates
Source/drain I/I—high dose As^{75} I/I
Etch back
Form thermal oxide, CVD oxide, PSG
Mask 5—define contact holes
Form a thin metal barrier
Mask 6—define Al-Si-Al stack

was found to be different from poly-Si gates under some conditions, it is also discussed in this section.

Deposition of Polycide

In the polycide process, 150 nm poly-Si is deposited on the wafer by LPCVD and doped with $POCl_3$. A layer of 150 nm WSi_2 is then deposited on this film by dual electron-beam evaporation (9). To ensure a clean interface between poly-Si and WSi_2, the wafers are cleaned and dip etched in a buffered HF solution immediately prior to WSi_2 deposition. To obtain stoichiometric WSi_2, evaporation rates of 0.5 nm/sec for Si and 0.2 nm/sec for W are controlled automatically through a feedback circuit. The Si evaporation rate is low enough to prevent the development of a large thermal gradient in the evaporator hearth, thereby avoiding the "spitting" of Si. The substrate Si wafers are kept at room temperature in a vacuum of $3\text{-}6 \times 10^{-6}$ Torr during the evaporation. The thickness uniformity is within ±4% and the composition of W and Si is within ±5%. The final thickness of WSi_2 is 75-80% of the sum of the two evaporation components W and Si. It was found that 57 nm tungsten and 143 nm Si form 150 nm WSi_2. It will be shown in the sections "Homogenization Annealing" and "Polycide Gate Integrity" that 150 nm WSi_2/150 nm poly-Si provides sufficient conductivity and good gate characteristics.

Annealing of Polycide

As-deposited tungsten silicide is an amorphous mixture of W and Si and, as a result, post-deposition anneal is essential for controllable processing. The details on the annealing characteristics of tungsten silicide have been reported (10). In this paper, only the process-related studies are discussed. Since silicide films can be prepared with various W-to-Si ratios using the co-evaporation technique, $WSi_{1.6}$, WSi_2, and $WSi_{2.3}$ films were examined. The annealing of these as-deposited films was performed in a purified Ar or N_2 ambient, but no difference was observed. However, the O_2 and H_2O content in the annealing furnace must be minimized to prevent film corrugation, which is related to the undesired oxidation during film annealing. The normal annealing furnaces and operation procedures were modified to facilitate silicide annealing.

Crystallization.—The as-deposited amorphous tungsten silicide crystallizes after appropriate annealing. Based on x-ray diffraction analysis, the evaporated tungsten silicides with the above three W-to-Si ratios crystallize between 600° and 700°C. The diffraction pattern of tetragonal WSi_2 is clearly observed after the films are annealed above these temperatures (10). However, the Si-rich $WSi_{2.3}$ and WSi_2 films crystallize at the low end of this temperature range (625°C). The W-rich $WSi_{1.6}$ crystallizes at 675°C. It is speculated that the difference lies in the availability of Si atoms near the W atoms in the silicide films.

The reason for crystallizing tungsten silicide is to stabilize the as-deposited film. The as-deposited film is sensitive both to normal processing chemicals (for example, cleaning solutions containing NH_4OH or HCl) and to oxygen at elevated temperatures. Therefore, the crystallization annealing should be done immediately after the film is deposited. Crystallization of tungsten silicide can be achieved by annealing the silicide films above 700°C.

Homogenization annealing.—From He^+ backscattering analysis, the as-deposited film does not always have a uniform W-to-Si ratio of 1:2 throughout the entire film. A homogeneous WSi_2 film is desirable to obtain controllable etching as described in the next section. In a study of homogenization of $WSi_{1.6}$, WSi_2, and $WSi_{2.3}$ (10), it was found that the homogenization of $WSi_{1.6}$ can be obtained at 800°C; however, $WSi_{2.3}$

requires an anneal at 1000°C. To ensure that the film is homogeneous, 1000°C annealing is carried out.

Annealing of the WSi_2 film also reduces the film resistivity. Figure 2 shows the sheet resistance *vs.* annealing temperatures and times. The reduction of the resistivity occurs during the first 10 min of the anneal, after which resistivity reaches a saturation-like stage. As shown in Fig. 2, the resistivity of WSi_2 is a strong function of temperature. The minimum resistivity of WSi_2 can be obtained after 1000°C annealing. It is also observed that the resistivity of WSi_2 film is only determined by the highest temperature treatment. As shown in Fig. 2, the samples annealed first at lower temperatures (800° or 900°C) can readily reach low resistivity by a subsequent high temperature (1000°C) anneal. Hence, the various low temperature treatments in a typical process do not affect the final resistivity of the silicide.

The grain size of the silicide film appears to correlate with the resistivity of the silicide. TEM micrographs of WSi_2 annealed at 800°-1000°C are shown in Fig. 3. Small and nonuniform grains are observed in films annealed at 800° or 900°C [Fig. 3(a) and (b)]. Prolonged heat-treatment at these temperatures does not increase the grain size (TEM pictures not shown here). This corresponds well with the saturation-like behavior of resistivity observed in Fig. 2. A 1000°C anneal results in uniform grains ~100 nm [Fig. 3(c)]. This grain size is suitable for fine-line patterning. As is shown in the section "Polycide Etching," 1 μm polycide lines can be defined with small etching bias.

Surface morphology and adhesion.—The $WSi_{2.3}$ and WSi_2 films have very smooth surfaces even after 1000°C annealing. However, the surface of W-rich $WSi_{1.6}$ film is rougher, more grainy (10), and less adhesive to the underlying poly-Si layer than are the other films. After annealing, the $WSi_{1.6}$ film has a tendency to peel at the edge of the wafer. On the other hand, the Si-rich film, $WSi_{2.3}$, requires a longer annealing time (15-30 min) at 1000°C to become homogeneous. This has an impact on device design due to the diffusion of dopants during the prolonged anneal. Table II summarizes and compares the different compositions. For device fabrication, stoichiometric WSi_2 was chosen rather than W-rich or Si-rich films.

Phosphorus diffusion in polycide.—During annealing, the dopant phosphorus atoms in poly-Si migrate into the WSi_2. This P migration is observed by SIMS measurements as shown in Fig. 4, where P concentrations are plotted *vs.* the depth from the surface of the WSi_2/poly-Si stack. All the P atoms are confined to the poly-Si layer prior to annealing. If the polycide is passivated by a thin CVD SiO_2 prior to annealing at 1000°C, the phosphorus atoms diffuse into and accumulate at the surface of the WSi_2. The CVD SiO_2 effectively prevents P from out-diffusing into the annealing ambient. If the SiO_2 is absent, significant out-diffusing of P from polycide occurs and the dopant is lost to the ambient. This out-diffusion of P has two important effects. First, the concentration of P in WSi_2 has a drastic effect on the plasma etch rate of WSi_2. Out-diffusion of P atoms results in an uncon-

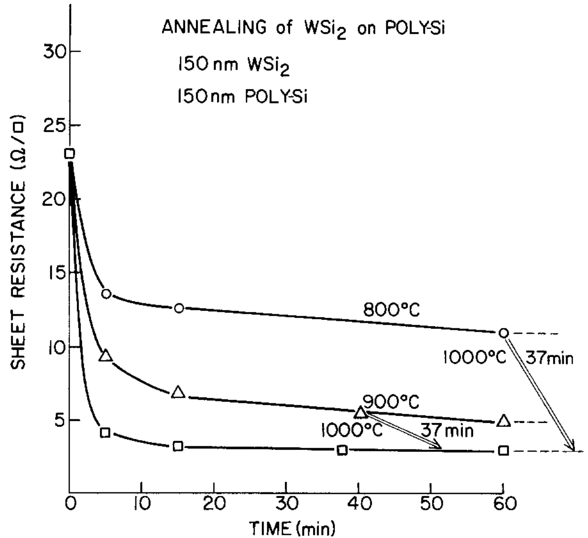

Fig. 2. Resistivity of WSi_2 on poly-Si *vs.* annealing time and temperature.

Table II. Tungsten silicide annealing

	$WSi_{2.3}$	WSi_2	$WSi_{1.6}$
Crystallization	625°C	625°C	675°C
Homogenization	1000°C	800°-1000°C	800°C
Adhesion	Good	Good	Peeling
Surface Morphology	Smooth	Smooth	Rough

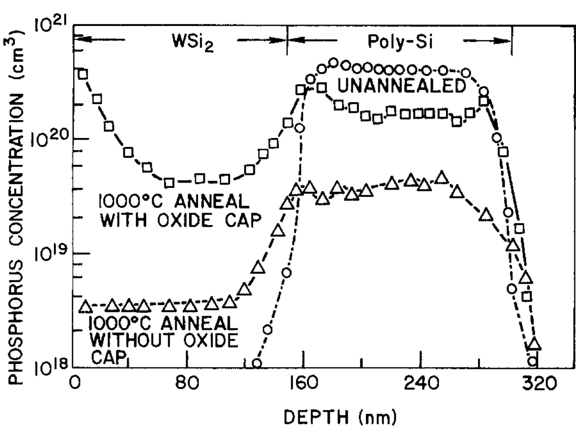

Fig. 4. Atomic distribution of P in WSi_2 polycide. Before annealing, P atoms are confined to poly-Si. After 1000°C annealing with an oxide cap layer, P diffuses into WSi_2. Without the oxide cap, a large amount of P outdiffuses into the annealing ambient. The oxide cap is not shown in this figure.

trollable concentration of P in the polycide, and is an important source of etching variations. Secondly, the P concentration in poly-Si affects the flatband voltage of the MOSFET's. If the remaining activated P in the poly-Si is too low ($<5 \times 10^{19}$ cm^{-3}), the threshold voltage of the device could shift from the designed value. For these two reasons, a layer of SiO_2 on the polycide during annealing is essential for a controllable polycide process.

Polycide Etching

Polycide etching is a critical step in polycide MOSFET technology, because the channel-length control depends on etch-bias control. In this 1 μm FET technology, an etching technique has been developed to achieve a bias of less than 0.1 μm per line. In other words, the difference between the etched polycide line and its etch mask is less than 0.05 μm per edge. The basic requirement of the process is to etch the WSi_2/n^+ poly-Si stack shown in Fig. 5 selectively to a thin gate oxide. The difficulty in etching polycide has been reported (5, 6). The probelm is to etch the top layer of silicide and then poly-Si without a significant loss of definition by overetching the silicide or undercutting the poly-Si. In addition, the thermal oxide must not be attacked. A two-step etching strategy was utilized and the Al pattern transferred from resist lift-off was the mask for etching. This two-step etching technique uses an RIE step to control the linewidth, followed by a plasma etching

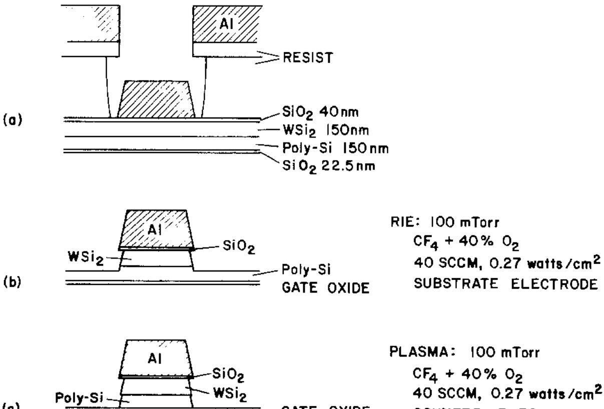

Fig. 5. Schematic diagrams of polycide etching. (a) Al patterns defined via resist lift-off, (b) RIE to etch WSi_2 and half of the poly-Si layer, (c) plasma etching to remove the remaining poly-Si.

step to stop at the underlying oxide. The RIE step removes the top CVD oxide, the WSi_2 film, and about half of the n^+ polysilicon. Plasma etching selectively but isotropically removes the remaining polysilicon. The RIE step was relatively straightforward but the plasma etch rate of WSi_2 varied considerably. After it was found that the O_2 content in the CF_4 etchant gas and the amount of phosphorus remaining in the polycide significantly affect the plasma etch rate of WSi_2, a well-controlled process was developed. Sequential RIE and plasma etching of polycide is performed in a flexible diode system. The reactor has two independent electrodes, each with a matching network and rf power supply. A more detailed description of the flexible diode system is given elsewhere (18). In this apparatus, RIE and plasma etching can be performed by sequentially powering the substrate and the counterelectrode. This flexible diode etching system is well suited for polycide etching (19).

Reactive ion etching step.—The CVD oxide, WSi_2 film, and approximately half of the poly-Si film are etched by RIE. That is, power is applied to the substrate electrode while the counterelectrode floats. This step is carried out in $CF_4 + O_2$. It is characteristic of RIE that etch rates are insensitive to the doping level, method of deposition, degree of crystallinity, etc. Indeed, the etch rate of WSi_2 was observed to be constant from run to run even though details of the processing varied. The etch profile of the polycide stack is vertical when etching is carried out in 25 mTorr $CF_4 + O_2$. A slope is introduced when the pressure of the etchant gas is raised to 100 mTorr, which is the RIE condition used in this technology as shown in Fig. 5(b), because a sloped polycide etch profile is preferred.

Plasma etching step.—The poly-Si remaining after RIE is etched by plasma etching. That is, rf power is applied to the counterelectrode while the substrate electrode is allowed to float. The underlying gate oxide provides an etch stop because the n^+ poly-Si to SiO_2 etch-rate ratio in this etching mode is 50:1. The final profile of the etched polycide stack depends on the WSi_2 to poly-Si etch-rate ratio during plasma etching. Initially, the ratio was unacceptably large and variable from run to run (between 2.5 and 5 to 1) in CF_4 + 20% O_2 as the result of a variation in the plasma etch rate of WSi_2. The fast lateral attack of WSi_2 often resulted in a gross undercut with respect to the mask. Based on numerous experiments, it was found that the P concentration in polycide and the O_2 content in the etchant gas are the two critical parameters affecting the plasma etch rate. These effects are discussed next.

Effect of phosphorus concentration in polycide.—As discussed in the section "Phosphorus diffusion in polycide," homogenization annealing causes P to migrate into the WSi_2 (Fig. 4). Since 1000°C anneal is normally required to homogenize WSi_2, this migration is inevitable. As shown in Fig. 4, a 40 nm CVD SiO_2 on the WSi_2/poly-Si stack provides a barrier against phosphorus out-diffusion. The etch rate of WSi_2 passivated with CVD SiO_2 (solid curve in Fig. 4) is about 60% higher than that without the oxide film (dashed curve in Fig. 4) (333 nm/min *vs.* 200 nm/min); while the etch rate of the n^+ poly-Si with SiO_2 passivation is only 20% higher than that without SiO_2 (83.5 nm/min *vs.* 62.2 nm/min). The rapid change of etch rate of WSi_2 suggests that the SiO_2 cap layer is important. The samples without the SiO_2 cap layers have an unstable etch rate of WSi_2 mainly because the out-diffusion of P is not controllable. By adding a CVD SiO_2 top layer on the polycide stack before annealing, reproducible etch rates of WSi_2 and n^+ poly-Si are achieved.

Effect of O_2 content in etching gas.—To better understand the etch rate sensitivity to variations in plasma conditions, the plasma etch rates of both WSi_2 and n^+ polysilicon were obtained for various concentrations of oxygen in CF_4. Figure 6 plots plasma etch rate *vs.* the percent of O_2 in CF_4 at constant pressure and incident power with only slight variations in gas flow. The curve indicates a moderate variation in the plasma etch rate of n^+ polysilicon, which reaches a maximum value at approximately 25%. The tungsten silicide etch rate also reaches a maximum at about 25%; however, the increase is much greater. The etch rate ratio of WSi_2 to n^+ polysilicon in the region between 10 and 30% O_2 in CF_4 is much greater than one. The large etch rate ratio during the plasma step is unfavorable since this would result in a substantial pull-back of the WSi_2 with respect to the polysilicon. The etch rate ratio is approximately one in the region between 30 and 35% O_2 in CF_4. However, the tungsten silicide etch rate in this region is sensitive to the composition of the etchant gas. In the region beyond 35% oxygen in CF_4, the tungsten silicide etch rate actually drops below that of the n^+ polysilicon, and becomes less sensitive to the percent O_2 in CF_4. Although the n^+ poly-Si-to-WSi_2 etch rate ratio is about 2:1 in this region, the slope introduced in the RIE step [Fig. 5(b)] minimizes the undercut of poly-Si [Fig. 5(c)]. An SEM micrograph of an etched polycide line is shown in Fig. 7. The sloped sidewall and an etch bias of less than 0.1 μm are the special features of this polycide etching process.

Oxidation of Polycide

An etch back procedure is required (12) to remove the trapped holes in the field oxide in order to improve the threshold voltage in a MOSFET process. P-etch (12) was utilized to remove ~70 nm of SiO_2 in the field region and also the thin gate oxide on the source/drain. In general, to ensure good insulation between the source/drain and gate electrode, a thermal oxidation is required after the etching. In this polycide technology, the oxidation involves polycide as well as Si substrate. The oxidation mechanism of polycide has been studied. It is generally agreed that the underlying silicon diffuses through the WSi_2 film to form SiO_2 on the surface (20). To oxidize polycide structures with a minimum feature size of 1 μm, an inert gas pre-annealing step is essential. This pre-annealing procedure allows the wafers to heat up to a temperature at which Si diffusion through WSi_2 is adequate before oxidation of polycide begins. Exposure of WSi_2 to O_2 at temperatures below 900°C usually results in film corrugation caused by the formation of volatile WO_3 or by the stress in the silicide film due to local formation of W-rich phases. With this pre-annealing procedure, 1 μm polycide lines can be oxidized successfully. Figures 8 and 9 show the cross sections of oxidized polycide lines on both the thin gate oxide and on thick oxide regions. CVD SiO_2 is then deposited conformally on the polycide structures.

The oxidation rate of WSi_2/poly-Si is roughly 60% of the rate of n^+ poly-Si. The dielectric strength of the oxide on polycide is 2-4 mV/cm which is similar to that of SiO_2 grown on poly-Si. The composite CVD SiO_2 and thermal oxide on polycide form a reliable isolation layer between the Al and devices.

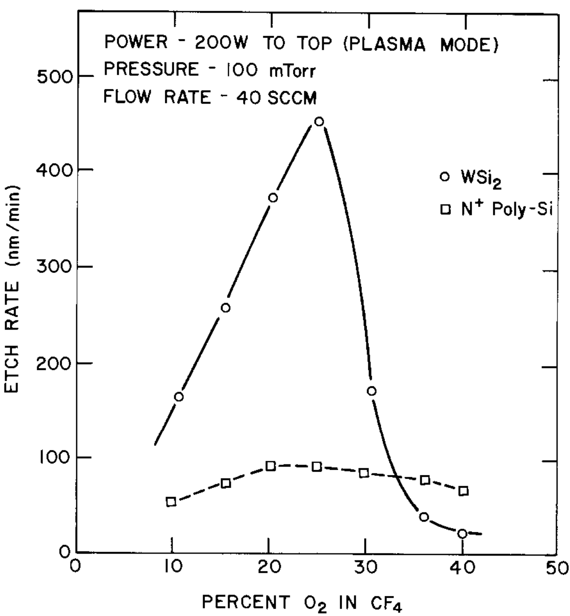

Fig. 6. Plasma etch rate of WSi_2 and poly-Si in CF_4 mixed with various percents of O_2.

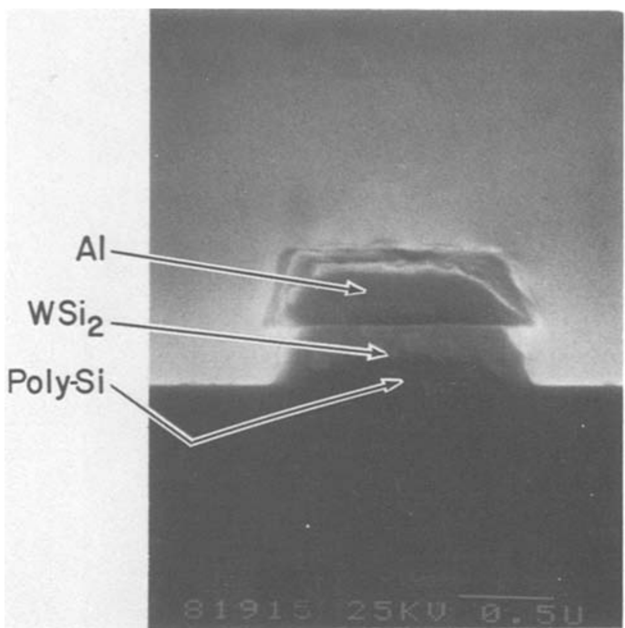

Fig. 7. SEM cross section of an etched polycide line ~1 μm. The etch bias is less than 0.1 μm.

Polycide Gate Integrity

The dielectric strength of gate oxide under the polycide is an important reliability issue in polycide technology. Experiments have been carried out to investigate the dielectric strength (gate integrity) of poly-Si gates *vs.* polycide gates. It was found that annealing and oxidation of polycide has a minimal effect on the gate integrity. For large area (1.82×10^{-2} cm^2) thin oxides (22.5 nm), a polycide gate yield of 95-99% (breakdown voltage > 2 MV/cm) is observed for samples annealed or oxidized at 1000°C. Therefore, for WSi_2 150 nm/poly-Si 150 nm/SiO_2 22.5 nm gate electrodes, the gate integrity is identical to poly-Si gate electrodes. However, there are two important factors which degrade polycide-gate integrity. First, the gate integrity depends on the thickness of poly-Si under the WSi_2 film. As shown in Fig. 10, the gate breakdown yield of polycide electrodes is a strong function of the poly-Si thickness, while the poly-Si gates without WSi_2 exhibit no such dependence. In fully processed device runs, 150 nm WSi_2/150 nm poly-Si/22.5 nm oxide has a yield above 90%. However, thinning down of the poly-Si reduces the yield. Therefore, poly-Si thickness is an important parameter in polycide processing. This observation agrees with the result reported before (8), obtained by measuring MSOS capacitors. Secondly, a buffered

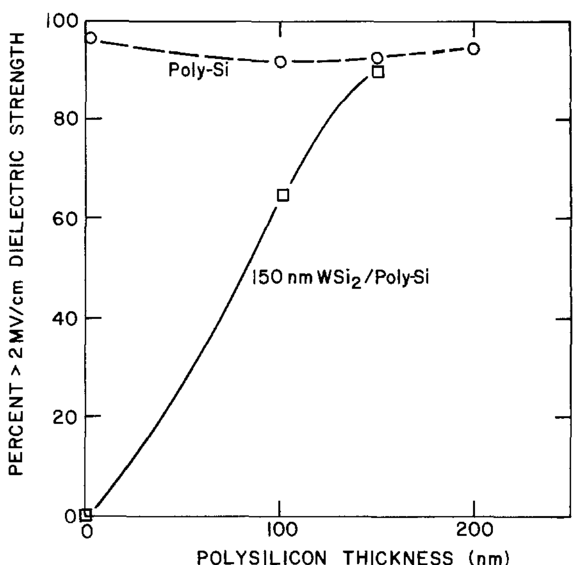

Fig. 10. Percentage of good gate breakdown devices for poly-Si and WSi_2/poly-Si electrodes with various poly-Si thickness.

HF (BHF) etch can readily penetrate the polycide stack and attack the thin gate oxide underneath, especially after the polycide is oxidized. Experiments show that samples not exposed to BHF have a polycide-gate yield of 99%. Samples prepared by an identical process, but with the addition of a 30 sec BHF dip on the polycide stack, have a gate yield of only 16%. The conclusion is that exposure of the polycide gate to BHF must be avoided. Since it is standard procedure for contact hole opening to expose wafers to BHF prior to deposition of metal, metal-to-polycide contacts must be located on the field oxide for reliability. In summary, the use of polycide gate electrodes/interconnections places some constraints on the processing to retain the integrity of the gate oxide. If care is taken to process within these constraints, the polycide gate is as reliable as the poly-Si gate.

Device and Circuit Results

This 1 μm polycide FET technology has been successfully applied to fabricate cross sections (0.5K to 2K) of single polycide dynamic RAM arrays (11), which are subsets of a 256K dynamic RAM. From this fully processed run, the sheet resistance of polycide was determined to be 2.72 ± 0.04 (1σ) $\Omega/\square$ compared to 38.2 ± 0.19 (1σ) $\Omega/\square$ for a poly-Si control. The metal-to-polycide contact resistance is also much lower than metal-to-Si contact resistance. For 1×1 μm^2 contacts, the metal-to-polycide contact resistance is $\leq 0.9\Omega$ per contact compared to metal-to-Si contact resistance of $\leq 15\Omega$ per contact. The ΔL (gate length at mask level-effective channel length) is 0.61 $\pm$ 0.05 μm (1σ), which is well within the process specification and is indicative of the tight control of this technology. Comparative I_{DS} (drain-to-source current) *vs.* V_{GS} (gate-to-source voltage) with $V_{SX} = -2V$ (substrate bias) and $V_{DS} = 0.1V$ (drain-to-source voltage) are plotted in Fig. 11. The difference between the I-V characteristics of poly-Si and polycide gates is less than 0.1V. It has been observed repeatedly that the threshold voltage of polycide thin gate devices is a little higher than that of poly-Si gates. However, the difference is within 0.1V, which is equivalent to the normal spread of threshold voltages in both the poly-Si and polycide gates. The reason for this difference is not yet known, but the difference is too small to be significant. The short-channel effect and the substrate sensitivity of polycide gate devices are identical to those of poly-Si devices. Hence, poly-

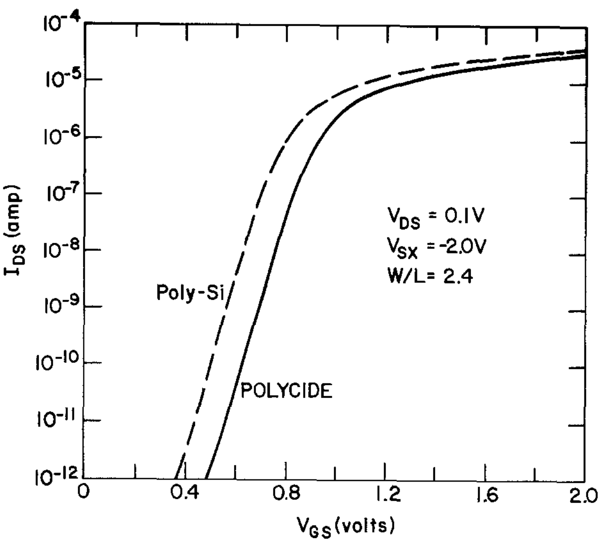

Fig. 11. Log I_{DS} vs. V_{GS} for WSi_2 polycide and poly-Si gate device with $W/L = 2.4$, $V_{DS} = 0.1V$, and $V_{SX} = -2V$.

cide devices are functionally equivalent to the poly-Si devices, even down to 1 μm dimensions. However, the sheet resistance is improved by a factor of 14 and the contact resistance by a factor of 18. Both of these are important improvements for VLSI circuits where a large number of interconnections and contact holes is utilized. Figure 12 shows an SEM micrograph of the dynamic RAM array. The uniform Al bit lines and clear polycide wordlines demonstrate good process control. No gate shorts are observed, and all of the cross sections (0.5K to 2K) are functional. Figure 13 shows the wordline (128 and 256 bits) risetime improvement achieved by polycide *vs.* poly-Si. The measured risetime agrees with circuit simulation results. A factor of ten improvement in the risetime of the polycide wordline over the poly-Si wordline clearly demonstrates the circuit advantage of polycide technology.

Conclusions

The 1 μm polycide (WSi_2/poly-Si) FET technology has been shown to be viable for VLSI circuits. The resistance of poly-Si interconnection lines is reduced by a factor of 14 by applying silicide on poly-Si. The metal-to-polycide contact resistance is also improved by a factor of 18 in contrast to the metal-to-Si contacts. Due to the reduction in resistance, the wordline risetime in a dynamic RAM array is improved by a factor of ten. The polycide MOSFET is measured to be functionally equivalent to the poly-Si FET even down to 1 μm dimensions. Functional polycide dynamic RAM arrays clearly demonstrate the validity of this polycide technology and also the circuit advantages of polycide electrodes/interconnections in a VLSI environment. Coupled with advanced lithographic and patterning capabilities, polycide can be used to fabricate dense circuits with low propagation delays for future VLSI.

Although this work is concentrated on single level polycide technology, with some modification, polycide should be applicable to a double poly process. With improvement of lithographic capability, the polycide technology should also be extendible to the submicron technology.

Kinetics of High Pressure Oxidation of Silicon in Pyrogenic Steam

Reda R. Razouk,* Liang N. Lie,* and Bruce E. Deal*

Fairchild Camera and Instrument Corporation,
Research and Development Laboratory, Palo Alto, California 94304

ABSTRACT

The kinetics of high pressure oxidation of silicon in pyrogenic steam were investigated for ambient pressures of 5-20 atm and for oxidation temperatures of 800°-1000°C. A linear-parabolic model was used in the analysis of the data. Both rate constants of the analytic model were found to be linearly proportional to pressure for the entire range of temperature and pressure. Fixed oxide charge and interface state densities for oxides grown at high pressure were found to be slightly higher at lower temperatures, particularly below 900°C, than for oxides grown at 1 atm. Electron trapping by avalanche injection in oxides grown on (111) Si at 5 atm in pyrogenic steam (800°C) yielded effective trap densities and capture cross sections similar to those obtained at 1 atm.

Higher packing densities and improved device performance are among the requirements for developing VLSI (very large scale integration) technology. In order to achieve these goals, both horizontal and vertical dimensions must be scaled downward. These reduced dimensions imply that better control of dopant diffusion and redistribution will be required and that defect formation during thermal oxidation and other thermal annealing processes must be minimized. In many cases junction movement may have to be reduced to almost zero. The use of high pressure oxidation may have a significant impact on ability to meet the above requirements. Oxidation of silicon in high pressure steam allows the growth of films of the order of 1 μm on (100) substrates at 800°C in less than 2.5 hr, thereby leading the way toward a substantial reduction in dopant redistribution. Furthermore, published reports by Tsubouchi *et al.* (1) and by Katz and Kimmerling (2) indicate a reduction in oxidation induced stacking faults during high pressure oxidation. This reduction may be due to the increased oxidation rate or the reduced oxidation time.

* Electrochemical Society Active Member.

Key words: rate constants, oxide charges, oxidation, high pressure.

Although high pressure oxidation of silicon was carried out almost 20 years ago (3), commercial units have only recently been available (4) for high pressure oxidation in high volume integrated circuit fabrication.

This report on the kinetics of high pressure oxidation in pyrogenic steam uses the linear-parabolic oxidation relationship (5) to describe the oxide growth and to characterize the pressure dependence of the linear and parabolic rate constants B/A and B. The oxidation parameters under investigation include silicon orientation, (100) and (111), temperature (800°-1000°C) pressure (1-20 atm pyrogenic steam), and time. Electrical properties of pressure grown oxides have been investigated. The dependence of oxide charge densities and trapping properties on oxidation and annealing conditions have been determined and compared with those of oxides produced at 1 atm.

The Thermal Oxidation Process

The thermal oxidation of silicon proceeds by: (*i*) absorption of the oxidizing species into the outer layer of oxide already formed; (*ii*) diffusion of the species through the oxide; and (*iii*) reaction of the oxidizing species with silicon at the Si-SiO_2 interface to produce new SiO_2. The growth kinetics of thermal silicon di-

oxide films have been the subject of intensive efforts by many investigators in the last 20 years, and a variety of relationships describing the growth of silicon dioxide films in dry oxygen and in steam have been proposed. The most generally accepted is the linear-parabolic relationship developed by Deal and Grove (5). This relationship is expressed as

$$x_o^2 + Ax_o = Bt + x_i^2 + Ax_i \quad [1]$$

which can be rewritten as

$$x_o^2 + Ax_o = B(t + \tau) \quad [2]$$

where B = parabolic rate constant (μm^2/hr), B/A = linear rate constant (μm/hr), x_i = initial oxide thickness, and $\tau = (x_i^2 + Ax_i)/B$.

The rate constants B and B/A are related to the oxidation process as follows

$$B = 2D_{\text{eff}}C^*/N_1 \quad [3]$$

$$A = 2D_{\text{eff}}(1/k + 1/h) \quad [4]$$

$$B/A = C^*/N_1(1/k + 1/h) \quad [5]$$

where D_{eff} is the effective diffusion coefficient of the oxidizing species and incorporates any enhancements in the transport rates, C^* is the equilibrium concentration of the oxidant in the oxide, N_1 is the number of oxidant molecules incorporated into a unit volume of the oxide layer, h is the gas-phase transport coefficient, and k is a constant dealing with the oxide silicon interface reaction.

The general oxidation relationship as summarized by Eq. [1]-[5] indicates a pressure dependence of both the parabolic rate constant (B) and the linear rate constant (B/A) through their dependence on the equilibrium concentration of the oxidant (C^*) in the oxide which is assumed to be related to the partial pressure by

$$C^* = KP \quad [6]$$

The activation energies of the rate constants have been examined by various authors and found to vary from 0.7 to 0.78 eV for B and 1.83 to 2.05 eV for B/A (5-8). An important aspect of the kinetics of oxide growth under pressure is the dependence of the rate constants on the pressure of the oxidizing species. Although questions about the charge state of the diffusion species are still a matter of controversy, it is known that the permeation of oxygen through fused silica is linearly proportional to oxygen pressure (9), and the dependence of the parabolic rate constant on pressure for oxidation below 1 atm (5) was found to agree quite well with the linearity predicted by a linear parabolic model for both dry O_2 and steam oxidations. Evidence indicates, although not conclusively, that the diffusing species is molecular oxygen in the case of dry O_2, and for steam oxidation it is some form of water molecule.

In this paper we deal exclusively with the linear-parabolic law of Deal and Grove and test its applicability to the modeling of oxide growth at high pressure and the resultant pressure dependence of the oxidation rate constants. Results published in this area indicate a linear pressure dependence on both rate constants for atmospheric and lower pressure oxidations (5, 10), and up to 10 atm (11). A less than linearly proportional dependence was observed by Tsubouchi *et al.* (1) (steam, 6.4 atm), and by Zeto (12) (dry O_2, 500 atm). The latter could quite possibly be due to a saturation of the oxygen solubility in the thermal oxide at these pressures.

Experimental Procedure

p-Type (100) and (111) silicon wafers of resistivity 5-9 Ω-cm and 1-3 Ω-cm, respectively, were used in the investigation of the oxidation kinetics as well as for oxide charge determination. The wafers were chemmechanically polished on one side and etched on the other. The preoxidation cleaning sequence consisted of hot sulfuric acid, aqua regia, and 1:10 HF/H_2O with appropriate deionized water rinses. The wafers were dried by a spin/dry cycle and subsequently loaded in the oxidation tube in a nitrogen ambient.

The high pressure oxidation system used in the experiments was purchased from GaSonics (Mountain View, California), and can operate at pressures up to 25 atm. The oxidation ambient is obtained by the reaction of hydrogen and oxygen at temperatures exceeding 700°C. All gases are obtained from liquid sources with booster pumps used to increase the pressure to the 1000-1200 psi needed for efficient system operation. Mass flowmeters are used to monitor gas flow. During oxidation the system pressure is increased with the shell pressure maintaining approximately 15 psi differential from the pressure inside the oxidation tube, the shell pressure being higher. Figure 1 illustrates a typical oxidation cycle and indicates the presence of pressure fluctuations when the system is fully pressurized as well as a linear increase in pressure during the initial phase of pressurization. The oxidation temperature was monitored continuously by means of a thermocouple and all experiments were carried out in a 3 in. tube. No temperature instability was observed during pressurization.

The oxidation cycle used in this work is summarized as follows: (*i*) Wafers are loaded in nitrogen at temperature; (*ii*) loading door is closed and system activated; (*iii*) system is purged for 5 min in dry O_2; (*iv*) system is purged for 5 min in steam; (*v*) pressurization starts with the wafers in the steam ambient; (*vi*) wafers are oxidized for the preselected time; (*vii*) depressurization starts. The steam flow terminates and is replaced by nitrogen flow. Depressurization is complete in 3-4 min; and (*viii*) the wafers are purged in nitrogen for an additional 7 min and pulled from the furnace in N_2 (pull time approximately 2 min). We will refer to this anneal/cool process as nitrogen slow pull or N_2 SP.

Table I indicates the pressurization time required to reach a given pressure. These times are used in the analysis of the data in the next sections. Pressurization in nitrogen was not used in order to avoid any interaction between nitrogen and the substrate at high pressure which could alter the oxidation kinetics.

Oxide thickness was measured by a Gaertner L-116 Automatic Ellipsometer and additional measurements were carried out on a Nanometrics "Nano Spec/AFT" micro spectrophotometer.

Wafers to be used for oxide charge measurements were metallized following oxidation with Al-4% Cu-2% Si by cold flash evaporation and given a postmetallization anneal (PMA) in a 10% H_2 in N_2 ambient at 400°C for 10 min. High frequency and quasistatic C-V

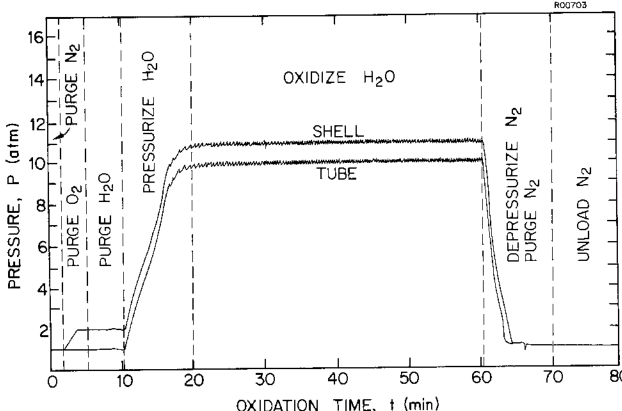

Fig. 1. Typical oxidation cycle in a GaSonics high pressure oxidation system showing the ambients used and the pressure change in both the tube and the shell.

Table I. Pressurization time for various pressures

Oxidation pressure (atm)	Pressurization time (min)
5	4 ± 0.5
10	8 ± 0.5
15	10 ± 1
20	13 ± 1.5

measurements were used to calculate the densities of fixed oxide charges (N_f) and interface traps or states (D_{it}); bias stress measurements were performed to obtain the mobile ionic charge density N_m. Electron trapping by avalanche injection was used to observe charge trapping in the oxides.

Results and Discussion

Oxide growth data.—Oxide growth data were obtained for 5, 10, 15, and 20 atm in a pyrogenic steam ambient. Temperatures investigated were 800°, 850°, 900°, 950°, and 1000°C. The minimum oxidation time was 30 min, which was selected to allow the system sufficient time to reach pressure and stabilize. Figure 2 shows the kinetic data obtained at a pressure of 20 atm for various oxidation temperatures. The orientation effect is clear and the results show that more than a micrometer of oxide can be grown in less than 30 min at 950° and 1000°C. Figure 3 shows the oxide thickness obtained for oxidations at 900°C at various pressures. The effect of pressure on the parabolic rate constant can be estimated from this graph by noting that a micrometer of oxide requires approximately 11-12 hr at 1 atm, but only 2.3, 1.2, and 0.6 hr at 5, 10, and 20 atm. The oxidation time shown in Fig. 2 and 3 is the time from the onset of pressurization to the onset of depressurization. The latter is carried out in a nitrogen environment.

Rate constant determination.—The determination of the oxidation rate constants is critical to the understanding of the role pressure plays in the oxidation process. Considerable care was taken in the calculation of the rate constants to ensure that the resulting comparisons with the 1 atm data are meaningful.

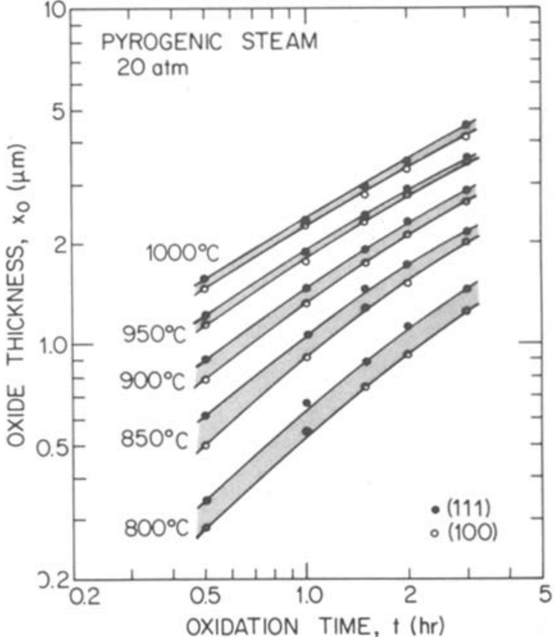

Fig. 2. Oxide thickness vs. oxidation time for (100) and (111) silicon oxidized in pyrogenic steam at a pressure of 20 atm and at temperatures of 800°, 850°, 900°, 950°, and 1000°C. Oxidation time includes pressurization time in steam.

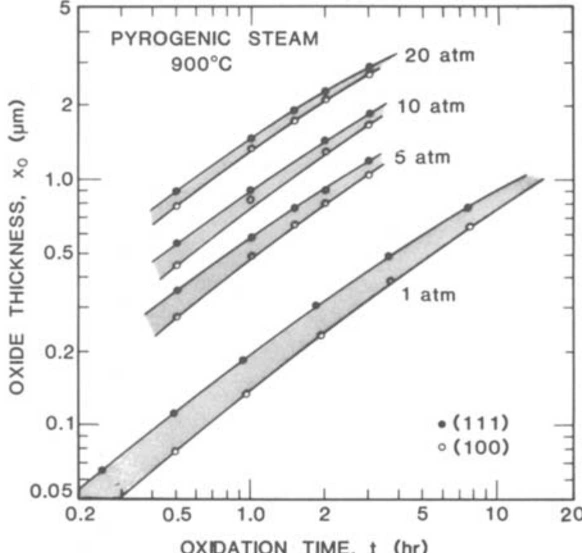

Fig. 3. Oxide thickness vs. oxidation time for (100) and (111) silicon oxidized in pyrogenic steam at a temperature of 900°C and at pressures of 1, 5, 10, and 20 atm. Oxidation time includes pressurization time in steam.

The general oxidation relationship [1] can be rewritten as

$$x_o^2 - x_i^2 + A(x_o - x_i) = Bt \qquad [6]$$

or

$$(x_o + x_i) + A = B\left(\frac{t}{x_o - x_i}\right)$$

A plot of $(x_o + x_i)$ *vs.* $(t/x_o - x_i)$ can be used to obtain the rate constants B and B/A. The initial oxide thickness used (x_i) is necessary in order to account for the pressurization time. During that time, pressure increases from 1 atm to the set pressure, resulting in a continuous change in the oxidation rate constants. By using an "initial run" long enough (30 min) for the system to pressurize and stabilize, the initial oxide thickness x_i can be obtained. In all subsequent figures x_i is the oxide thickness following a 30 min oxidation cycle.

Figure 4 shows a plot of $(x_o + x_i)$ *vs.* $(t/x_o - x_i)$ for oxidations at 850°, 900°, and 1000°C at 10 atm. The rate constants B and B/A can be extracted from the slope and intercept of the lines. It should be noted that this technique results in values of B and B/A based upon relatively thick oxides as a result of the minimum time requirements necessary for a reproducible x_i coupled with the fast oxidation rates in steam ambients at high pressure. Figure 4 also indicates that a larger number of data points is needed to obtain accurate values of the rate constants, and that slight variations in the fitting of the data, particularly at low temperatures, can result in considerable differences in the values of the rate constants. The calculation of rate constants based upon high temperature-thick oxide data can result in substantial variations in B/A while in the case of low temperature-thin oxide data large variations in the calculated values of B are obtained.

In view of the preceding discussion, a different approach for calculating the rate constants was taken. This approach allowed us to model the oxidation and supplied us with data on the relationship between B and B/A, allowing us to observe the effect of small variations in one rate constant on the other. In this method the oxidation cycle was divided into several intervals as shown in Fig. 5 with the oxide thickness at the end of each interval identified (x_1 through x_f). Equations were then written for each interval based upon the general oxidation relationship of Deal and Grove

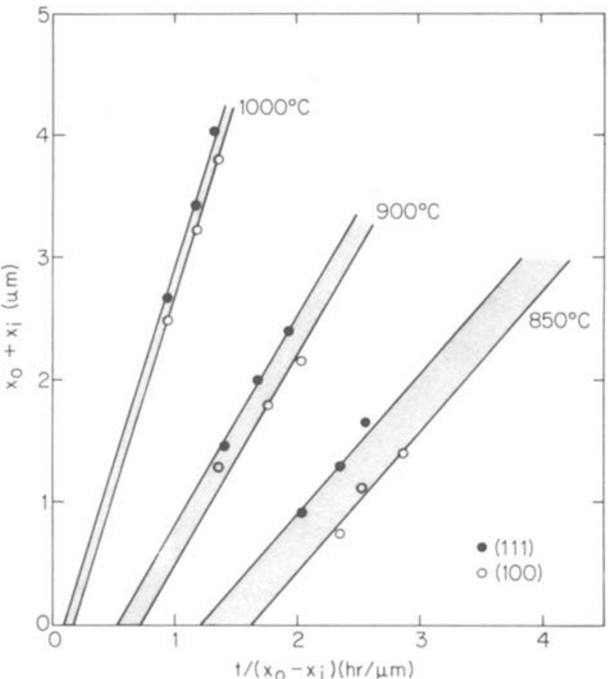

Fig. 4. ($x_o + x_i$) vs. ($t/x_o - x_i$) for (100) and (111) silicon oxidized at 850°, 900°, and 1000°C in pyrogenic steam at 10 atm. Slope of line is B and intercept is $-A$.

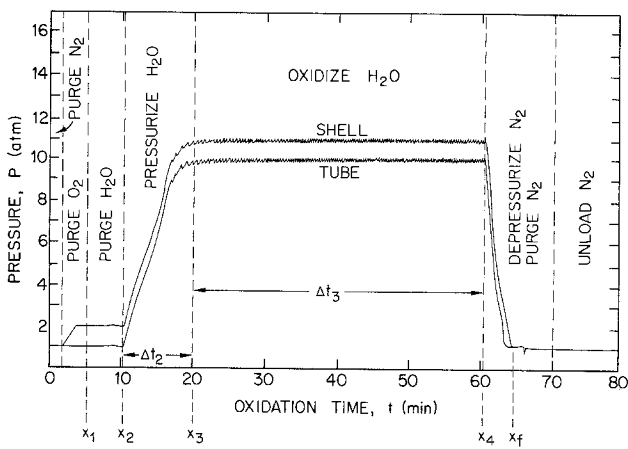

Fig. 5. Typical oxidation cycle showing the various regions considered in modeling the oxidation.

$$x_1 \simeq 0 \quad [7]$$

$$x_2 = \frac{1}{2}[-A + \sqrt{(A^2 + 4B'(t_2 - t_1))}] \quad [8]$$

$$x_3 = \frac{1}{2}[-A + \sqrt{A^2 + 2B'(t_3 - t_2)(P + 1) + 4x_2^2 + 4Ax_2}] \quad [9]$$

$$x_4 = \frac{1}{2}[-A + \sqrt{A^2 + 4B'P(t_4 - t_3) + 4x_3^2 + 4Ax_3}] \quad [10]$$

$$x_f = \frac{1}{2}[-A + \sqrt{A^2 + 2B'(t_f - t_4)(P + 1) + 4x_4^2 + 4Ax_4}] \quad [11]$$

where the parabolic rate constant $B = B'P$ and B' = rate constant at 1 atm. The above equations can be simplified by writing for a general oxidation interval

$$\Delta t_i = t_{i+1} - t_i$$

and

$$x_i^2 + Ax_i = B_i \Delta t_i + x_{i-1}^2 + Ax_{i-1}$$

Equations [7]-[11] can then be reduced to

$$x_f = \frac{1}{2}\left\{-A + \sqrt{A^2 + 4B'\left(\Delta t_1 + \left(\frac{P+1}{2}\right)(\Delta t_2 + \Delta t_4) + P\Delta t_3\right)}\right\} \quad [12]$$

Results obtained using rate constants determined through the use of Eq. [6] and plots of $(x_o + x_i)$ vs. $(t/x_o - x_i)$ are in very good agreement with experimental values for oxidation temperatures greater than 900°C. For lower oxidation temperatures, the rate constants could not be determined with sufficient accuracy by this technique and in some cases were found to model the experimental data poorly. Furthermore, the data suggested the presence of a second activation energy for B and possibly B/A and this result was in need of verification. A more direct method for rate constant determination, with immediate feedback on the modeling of the experimental data was therefore used. In this method, Eq. [7]-[11] are used to calculate the rate constants that would yield the best estimate of oxide thickness over the entire temperature range. The calculation was done by obtaining the locus of B/P and B/AP points that for a given oxidation will yield the experimentally measured oxide thickness. The intercept of the loci for various oxide thicknesses yields the values of B/P and B/AP that would, when used with this model, result in an oxide thickness estimate typically less than ± 3% of the experimentally obtained value. An example of this method is shown in Fig. 6 where for each of two oxide thicknesses a band is shown representing variations of ± 2%.

For a given oxidation condition (temperature, pressure, and silicon orientation) up to five oxide thickness values were used in the manner shown in Fig. 6 to determine the values of B and B/A. The rate constants thus obtained are summarized in Fig. 7 and 8 and include B and B/A values from data at 1, 5, 10, 15, and 20 atm. The solid and dotted lines in the figures represent 5, 10, 15, and 20 times the rate constants at 1 atm, while the data with error bars represent the values of B and B/A which will yield a fit of the experimental oxide thickness within ± 3% as determined by Eq. [7]-[11]. These results show that the rate constants

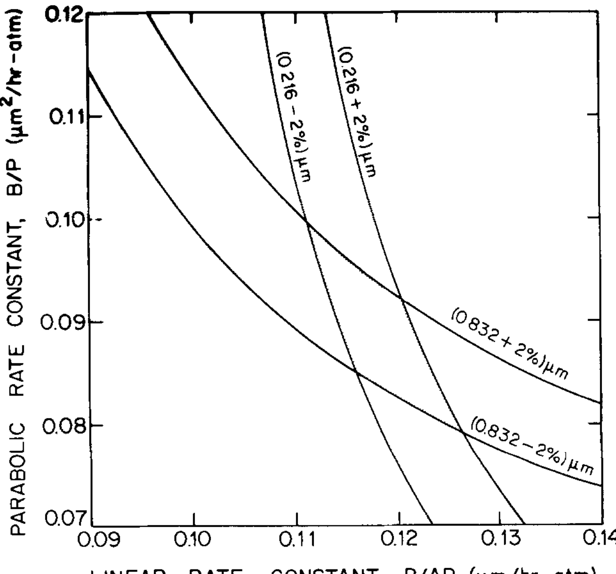

Fig. 6. Parabolic rate constant (B/P) vs. linear rate constant (B/AP). The shaded area represents values of B/P and B/AP which when used with Eq. [7]-[11] will yield oxide thickness values within ±2% of the experimental results.

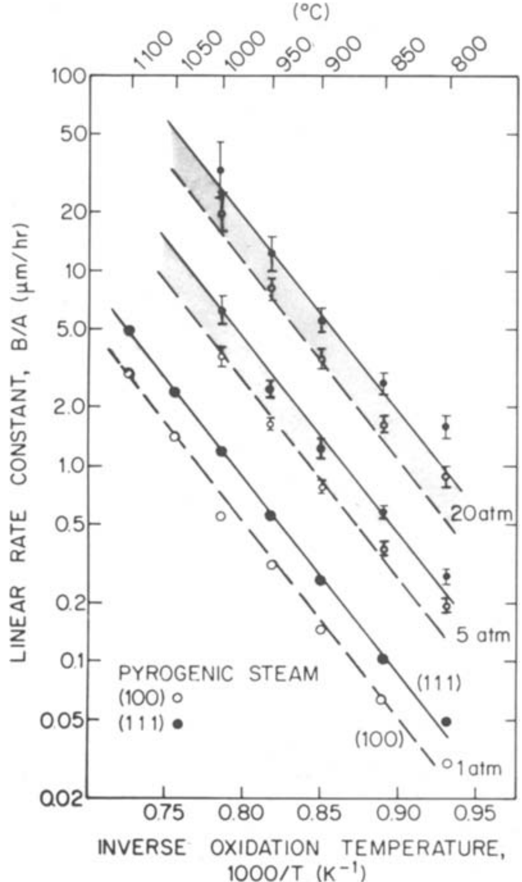

Fig 7. Linear rate constant B/A vs. 1000/T for (100) and (111) silicon wafers oxidized in pyrogenic steam as obtained from 1, 5, and 10 atm data.

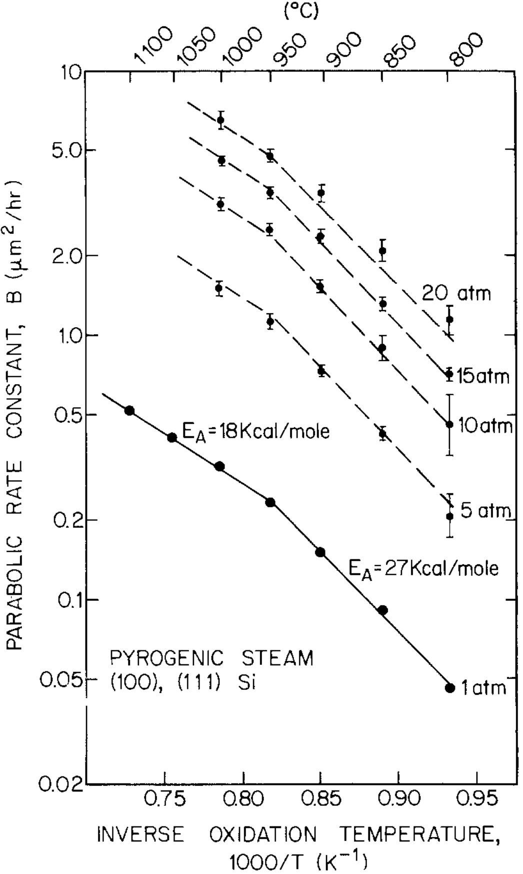

Fig. 8. Parabolic rate constant B vs. 1000/T for (100) and (111) silicon wafers oxidized in pyrogenic steam as obtained from data at 1, 5, 10, 15, and 20 atm.

are proportional to pressure and indicate the presence of a second activation energy at 900°C and below, particularly in the case of the parabolic rate constant. For B the activation energy increases from 18 kcal/mol (0.78 eV) above 900°C to approximately 27 kcal/mol (1.17 eV) below this temperature, while for B/A the activation energy change is less pronounced and varies from 47.4 kcal/mol (2.05 eV) to about 38 kcal/mol (1.60 eV). This change in activation energy is necessary when modeling the oxide growth by a linear-parabolic relationship. It should be noted that the change occurs at a temperature of 900°-950°C and could be indicative of structural changes in the oxide at these growth temperatures, possibly related to the viscous flow postulated by EerNisse (13, 14). The apparent increase in activation energy associated with the parabolic rate constant below 900°C was noted earlier in the results on atmospheric pyrogenic steam oxidation (8).

The normalized values of the parabolic rate constant B are shown in Fig. 9 as a function of pressure. The range shown at each pressure represents data gathered at five different temperatures (800°, 850°, 900°, 950°, and 1000°C). The results indicate clearly that in the range of 1-20 atm the parabolic rate constant is linearly proportional to pressure. Similarly B/A is also proportional to pressure, therefore indicating that the primary pressure effect is on the parabolic rate constant B and that the dependence of B/A on pressure comes about through the dependence of B.

Oxide charges.—High frequency, quasistatic, and bias stress C-V measurements were carried out on p-type (100) and (111) silicon MOS structures. In cases where the oxide thickness was too large to allow for a meaningful C-V plot, the oxide thickness was reduced by etching in a buffered HF solution prior to the evaporation of aluminum fieldplates (by cold flash) on the surface. Figure 10 shows the fixed oxide charge levels for oxidations at 5, 10, 15, and 20 atm for comparison purposes with those grown in the same tube at 1 atm. All oxides were cooled in N_2 following a 10 min anneal also in N_2. The high pressure oxides were found to yield higher fixed oxide charge densities particularly for (111) silicon at temperatures below 900°C. Bias stress measurements (300°C, +50 V/μm, −30 V/μm)

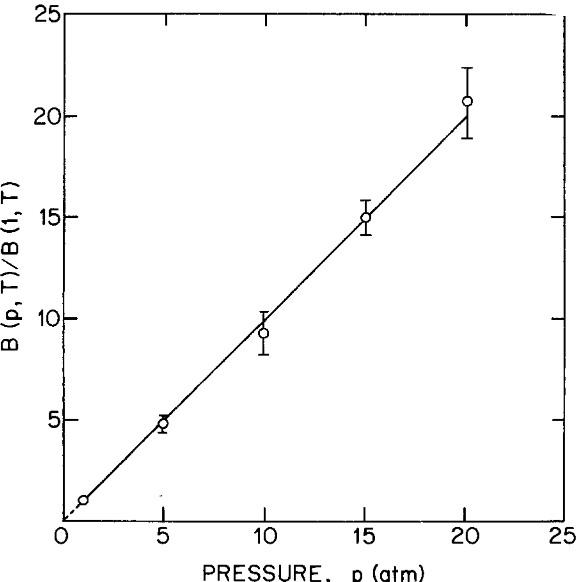

Fig. 9. Normalized parabolic rate constant $B(P, T)/B(1, T)$ vs. pressure for (100) and (111) silicon wafers oxidized in pyrogenic steam at 1, 5, 10, 15, and 20 atm for the temperature range 800°-1000°C.

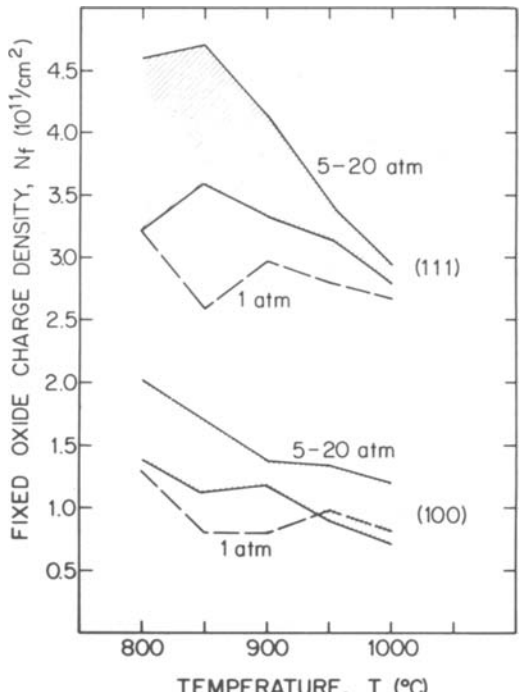

Fig. 10. Fixed oxide charge density vs. temperature for oxides grown on (100) and (111) silicon in pyrogenic steam at 1, 5, 10, 15, and 20 atm.

indicated a mobile ionic charge density (N_m) as low as $2 \times 10^{10}/cm^2$ and as high as $2.5 \times 10^{11}/cm^2$ with no particular pressure dependence. Interface state densities at midgap, as measured by the quasistatic technique, were very similar to those obtained at 1 atm and were characteristically low (15). It should be noted that no attempts were made at stabilizing the oxides by phosphorus gettering.

An investigation of the charge annealing characteristics of oxide charges in high pressure grown oxides was conducted in order to examine the differences, if any, in oxide charge annealing properties. Samples were oxidized at 800°C at 1 and 15 atm to grow about 2000Å of SiO_2. The wafers were cooled and pulled (2 min) in N_2. Following oxidation, the wafers were annealed in argon at 800°, 900°, and 1000°C for various times, and Fig. 11 presents the resultant anneal curves and indicates no observable difference between 1 and 15 atm oxides for anneals at 900° and 1000°C. At 800°C, some differences were noted with the 1 atm oxides yielding lower charge densities. Evidence indicates that the higher values obtained at 15 atm can be reduced (10-15%) by an anneal in N_2 at high pressure for 30 min.

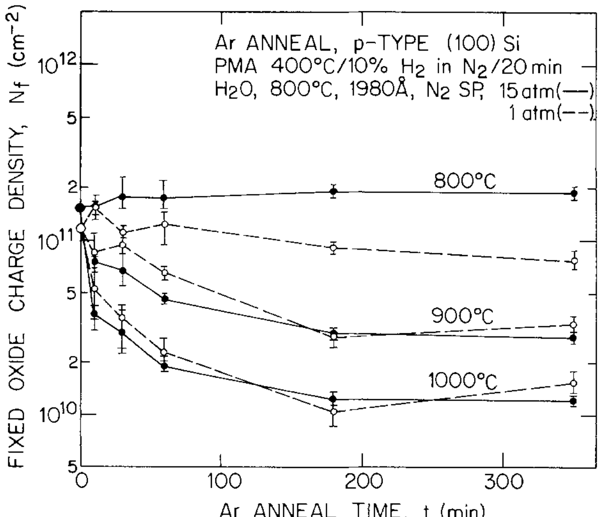

Fig. 11. Fixed oxide charge density vs. postoxidation Ar anneal time. Samples were initially oxidized in steam at 800°C at 1 or 15 atm and subsequently annealed in argon for various times.

It should be pointed out that values of fixed oxide charge are very sensitive to anneal gas purity and that the increasingly higher values of charge density with decreasing temperature may be a reflection of the presence of impurities such as oxygen in the nitrogen anneal ambient.

Electron trapping by avalanche charge injection was carried out on oxides grown on p-type (111) silicon wafers oxidized in pyrogenic steam at 5 atm (800°C, N_2 cooled). Typical flatband voltage shifts obtained are shown in Fig. 12; they first increase and then decrease in a manner typical of steam grown oxides. These results are similar to those obtained at 1 atm in pyrogenic steam at 800°C; values of effective trap densities of 5-6 $\times$ $10^{12}/cm^2$ and capture cross sections of 2-3 $\times$ 10^{-17} cm^2 can be obtained from the initial charging period.

Summary and Conclusions

The kinetics of high pressure oxidation in pyrogenic steam at temperatures of 800°-1000°C and pressures up to 20 atm have been investigated. A linear-parabolic model was used to analyze the data and a linear pressure dependence is observed for both the linear and parabolic rate constants. These results are in agreement with previous measurements carried out at pressures less than 1 atm (5) and at 10 atm (11).

The deviations from linearity observed by other authors (1, 12) may be due to the effect of pressurization time on the calculation of the rate constants as well as difficulties in obtaining both rate constants simultaneously for some temperature and pressure combinations. For the case of high temperature, high pressure oxidation, B can be calculated accurately whereas B/A values will have large errors. The reverse is true for low temperature situations.

Oxide charge density measurements have been carried out and charge levels compatible with MOS processing technology have been observed. In cases where high charge densities are obtained, they may be effectively reduced by short treatments at higher temperatures. Electron trapping characteristics in oxides grown at 5 atm are the same as those observed in 1 atm oxides.

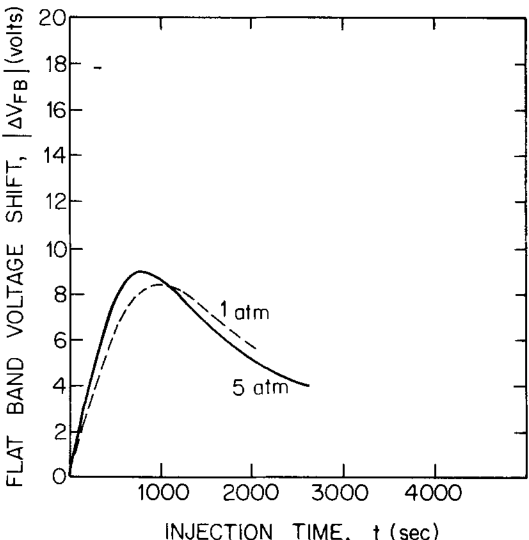

Fig. 12. Flatband voltage shift vs. electron injection time for electron trapping by avalanche charge injection in oxides grown on p-type (111) silicon oxidized at 1 and 5 atm in pyrogenic steam (800Å, $J = 1.5 \times 10^{-5}$ A/cm²).

A New Approach to Liquid Phase Electroepitaxy (LPEE) of III-V Compounds

S. Isozumi,[1] C. J. Herman, A. Okamoto,* J. Lagowski,* and H. C. Gatos*

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

A new configuration of LPEE is described in which the substrate is placed between two wells containing a solution. This configuration eliminates problems associated with the contact to the back-side of the substrate. It also enables simultaneous observation of electroepitaxial growth and dissolution processes on the opposite sides of the substrate, and provides a unique means for *in situ* monitoring of the growth (and dissolution) kinetics.

Increasing efforts have recently been devoted to liquid phase electroepitaxy (LPEE) as a novel approach to the growth of III-V compounds. In this method growth is initiated and sustained by passing an electric current through the growth cell containing the solution and the substrate. In most instances the growth process is primarily controlled by the electromigration of the solute toward the substrate (1). Peltier cooling at the solution interface can provide additional driving force for growth. Thus, the key advantages of electroepitaxy are associated with the direct control of the growth rate by electric current while the overall temperature of the system is maintained constant. These advantages have been demonstrated in the studies of microscopic growth rate (2), dopant modulation (3), composition modulation (4), and the modulation of recombination centers in the crystal (5).

In LPEE systems employed thus far (6) electric current is passed through the solution, substrate, and a metal contact at the back-side of the substrate. A thin metal foil (a) or multilayers (b) have been used for the contact between the substrate and a graphite pedestal. This type of contact to the substrate has a noticeable electrical resistance which can be comparable to the overall resistance of the system at growth temperatures (6). Thus, it leads to undesirable localized Joule heating, particularly at high current densities. Furthermore, local variations in the contact resistance lead to variations in the thickness of the electroepitaxial layers (6).

In the LPEE configuration developed in this investigation, the substrate is positioned between two identical large segments of saturated solution. Thus, preparation of back-side contact to the substrate is eliminated and the resistance between the metal and the graphite is physically separated from the substrate. Furthermore, *in situ* monitoring of the epitaxial growth process becomes possible through measurements of the resistance changes associated with the growing layer.

Growth System and Experimental Procedure

The apparatus employed in the present work is shown in Fig. 1. A boron nitride (BN) slider is positioned between the two segments of the graphite holder which contains the solution. With the aid of this slider the substrate is brought between the two segments of the solution. A stainless steel current electrode is threaded into each of the two graphite segments and a thermocouple shielded with stainless steel is positioned close to each of these segments (1 mm from the cell wall). The stainless steel shields are in electrical contact with the graphite segments and thus are used to determine the potential drop changes across the solution resulting from changes in the resistance (*i.e.*, thickness) of the growing layer

Key words: LPEE, dissolution, kinetics.

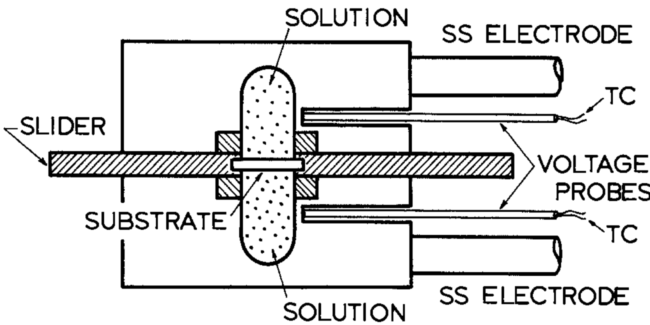

Fig. 1. Top view of apparatus for electroepitaxial growth without back-contact. The holder segments are of graphite and the slider of BN.

(all other electrical resistance components in the system are constant at a constant temperature).

Cr-doped (100) GaAs (500 μm thick) and Si-doped (100) GaAs ($n = 3 \times 10^{18}$ cm^{-3}, 340 μm thick) were used as substrates. Growth (or dissolution) area was 0.40 cm^2, and each solution segment contained 9g of Ga saturated with GaAs at 850°C. Undoped layers ($n = 3 \times 10^{16}$ cm^{-3}) were grown on the Si-doped n^+ substrates, and undoped or Se-doped ($n = 4 \times 10^{18}$ cm^{-3}) layers were grown on the Cr-doped substrates in an H_2 atmosphere. After saturation of the solution the substrate was brought into position and the electric current was passed through the two solid-solution interfaces. Thus, on the side of the substrate with a positive polarity with respect to the solution growth took place, whereas dissolution took place on the opposite side. The applied current, the temperature of the solution, and the voltage across the solution segments were measured at 1 min intervals and stored by a computerized measurement system.

After 100 min of current flow the substrate was separated from the solutions by the BN slider, and then temperature was rapidly decreased. During the 100 min runs the temperature variations were within 0.5°C. The samples were cleaved and etched in AB etchant for 30 sec for the determination of the thickness and thus for the determination of the average growth or dissolution rate.

Results and Discussion

Resistance measurements.—In order to achieve reliable monitoring of the resistance changes due to changes in thickness of growing layers and/or the substrate the component resistances of the system were determined (and their stability assessed) at the growth temperature (850°C). The resistance of the system including that of the stainless steel electrodes, of the solution and of the electrical contacts were found to be $1.1 \times 10^{-1}\Omega$. The resistance of the growth cell including the resistance of the solution and that of the contacts between the cell walls and the solution was measured employing the stainless steel shields of the thermocouples and was found to be $1.2 \times 10^{-3}\Omega$, while the resistance of the solution was estimated to be less than $3 \times 10^{-4}\Omega$. Thus, the resistance of the stainless steel electrodes is the major part of the resistance of the overall system. All of the above resistances were reproducible and exhibited no variations for extended periods of time at the growth temperature.

The resistances of the substrates at the onset of growth as determined by the stainless shield probes are shown in Fig. 2. These values include the cell resistance of $1.2 \times 10^{-3}\Omega$ pointed out above. Thus, the resistance of the Si-doped (n^+) substrates was $0.9 \times 10^{-3}\Omega$ (1.1×10^{-2} Ω-cm) and that of the Cr-doped substrates $9.9 \times 10^{-3}\Omega$ (7.9×10^{-2} Ω-cm). Cr-doped substrates behave as intrinsic ($n = 2 \times 10^{17}$ cm^{-3}).

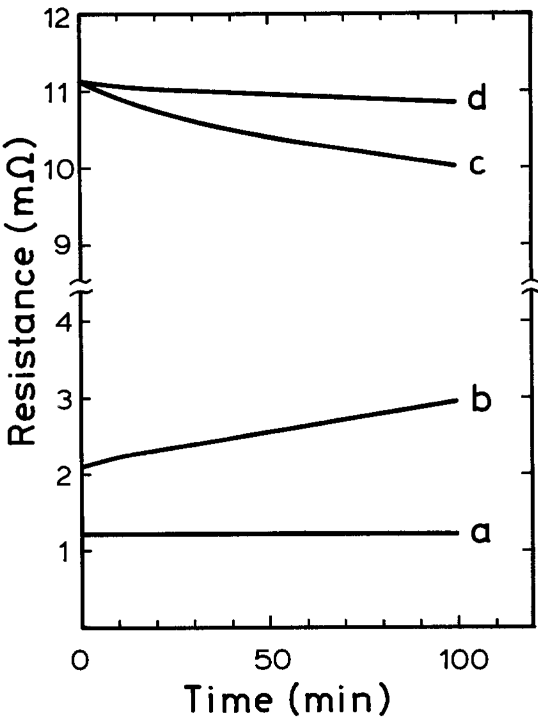

Fig. 2. Changes in the resistance in growth cell during current flow (9 A/cm^2) at 850°C. Each curve represents: (a) no substrate in cell; (b) undoped growth on n^+ substrate; (c) n^+ growth on Cr-doped substrate; (d) undoped growth on Cr-doped substrate.

The resistivity values obtained in the present measurement are quite reasonable.

The changes in resistance of the GaAs material during the growth process are also shown in Fig. 2. It is seen that a significant change in the resistance took place for the n^+ layer growing on Cr-doped substrate and for the undoped layer growing on n^+ substrate. For the undoped layer growing on a Cr-doped substrate, only a small change in resistance is observed.

In the present LPEE configuration, growth takes place on one side of the substrate and, simultaneously, dissolution on the other side. Thus, the resistance changes in Fig. 2 include contributions from both effects. If a growth and a dissolution proceed with velocities v_G and v_D, respectively, the rate of resistance change is

$$dR/dt = v_G \rho_L/S - v_D \rho_S/S \quad [1]$$

where ρ_L and ρ_S are the resistivities of the layer and of the substrate, respectively, and S is the growth area. v_G and v_D exhibit a transient behavior at initial stages of the growth. In general, ρ_L can also vary with time due to impurity segregation effects. It will be shown below that in the absence of interference from Joule heating at the substrate $v_G = v_D$, and the utilization of expression 1 for the analysis of experimental data is simplified.

Growth process vs. dissolution.—The experimental results on the average growth and dissolution rates as a function of electric current density are given in Fig. 3 and 4 for n^+ and Cr-doped substrates, respectively.

It is seen from Fig. 3 that the growth and dissolution rates are similar and increase linearly with current density up to about 12 A/cm^2. Such behavior is consistent with a theoretical model of electroepitaxial growth kinetics (1). According to this model, in the absence of convection, v_G and v_D can be expressed as

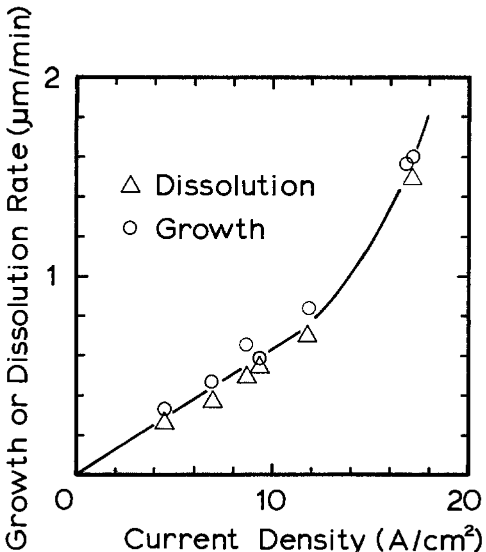

Fig. 3. Dependence of average growth and dissolution rates on current density with n+ substrate (340 μm thick) at 850°C.

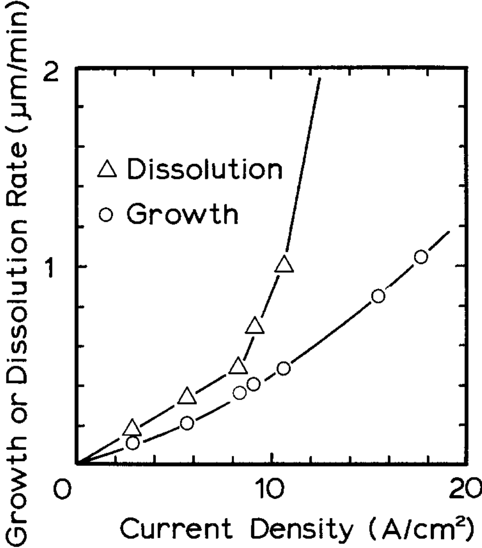

Fig. 4. Dependence of average growth and dissolution rates on current density with Cr-doped substrate (500 μm thick) at 850°C.

$$v_G = \frac{(|\Delta T_p| - \Delta T_j)}{C_s - C_o} \frac{dC}{dT}\bigg|_L \left(\frac{D}{\pi t}\right)^{1/2} + \mu E \frac{C_o}{C_s - C_o} \quad [2a]$$

and

$$v_D = \frac{(|\Delta T_p| + \Delta T_j)}{C_s - C_o} \frac{dC}{dT}\bigg|_L \left(\frac{D}{\pi t}\right)^{1/2} + \mu E \frac{C_o}{C_s - C_o} \quad [2b]$$

where ΔT_p and ΔT_j are the change of temperature at the interface due to the Peltier effect and Joule heating, respectively; C_s and C_o are the solute concentration in the solid and in the solution, respectively; D is the diffusion coefficient of the solute in the solution, t is the time, μ is the mobility of the solute, and E is the electric field in the solution.

For the polarity employed in the present experiments, ΔT_p corresponds to cooling at the growth interface and to heating at the dissolution interface. Thus, T_j will lead to a decrease in the growth rate and an increase in the dissolution rate. Since up to about 12 A/cm² v_G and v_D are approximately the same (Fig. 3), T_j must be insignificant for n^+ substrates.

At higher values of current density both growth and dissolution are significantly enhanced. This behavior can readily be expressed assuming that significant convection is generated in the growth and dissolution segments. In the presence of convection the expressions for v_G and v_D become (1)

$$v_G = \frac{|\Delta T_p| - \Delta T_j}{C_s - C_o} \frac{dC}{dT}\bigg|_L \frac{D}{\delta} + \mu E \frac{C_o}{C_s - C_o} \quad [3a]$$

$$v_D = \frac{|\Delta T_p| + \Delta T_j}{C_s - C_o} \frac{dC}{dT}\bigg|_L \frac{D}{\delta} + \mu E \frac{C_o}{C_s - C_o} \quad [3b]$$

where δ is the thickness of the boundary layer which decreases with increasing convective flow. Since the values of v_G and v_D remain the same (Fig. 3), ΔT_j is not significant as compared to ΔT_p. Thus, convection is apparently generated by Joule heating from the substrate, *e.g.*, at the solution-graphite contacts.

In the case of Cr-doped substrates, the growth and dissolution rates are different (Fig. 4). Even in the region of linear dependence on current density (up to about 8 A/cm²) v_D is greater than v_G. At higher current densities the difference between the two rates becomes even more pronounced. This behavior is apparently associated with Joule heating of the Cr-doped substrate, which, at the growth temperature, has a resistivity about one order greater than that of the n^+ substrate. For the geometric configuration of the present cell, the temperature increase at both sides of the substrate with resistance, R, is $\Delta T_j = RI^2/2G_l$ where I is the current and G_l is the heat conductivity of the solution. The value of G_l for the Ga-As solution is not known; however, a rough estimate based on the value of liquid Ga near room temperature [0.09 cal/sec-cm²-°C (7)], for current density of 10 A/cm² and $R = 9 \times 10^{-3}\Omega$, shows that ΔT_j values of the order of 0.5°C can be reached; these values are comparable to the magnitude of the temperature change due to the Peltier effect and account for the observed difference between v_G and v_D.

Above 9.5 A/cm² (Fig. 4) the dissolution rate increases precipitously apparently due to turbulent convection caused by increased Joule heating and thus increased thermal gradients. The higher Peltier coefficient of the Cr-doped substrates as compared to that of the n^+ substrates must also be a contributing factor. The observed nonuniform dissolution of the Cr-doped substrates is clear indication of turbulent convection at the substrate-solution interface.

As pointed out in previous studies (1) convective flow can be reduced by decreasing the solution thickness. However, depletion of a solution with reduced thickness would limit the maximum thickness of the LPEE layer. This limitation can be overcome with a multisubstrate configuration in which parallel substrates are positioned between thin solution layers. Joule and Peltier heating can also be reduced by employing thinner wafers. An LPEE cell into which these features are incorporated is currently being tested.

Resistance changes induced by growth.—On the basis of the above analysis of the dissolution and growth processes, the resistance changes shown in Fig. 2 can now be interpreted. In the case of Fig. 2b the resistance change corresponds to the growth of an undoped layer on n^+ substrate. As pointed out earlier, v_G can be here considered equal to v_D. Thus, Eq. [1] reduces to $dR/dt = (\rho_L - \rho_S)\, v_G/S$ and the overall resistance increase is due to the fact that ρ_L is greater than ρ_S. Indeed, after an initial transient period dR/dt becomes constant indicating that growth and dissolution proceed with a constant rate.

Consistent with the LPEE model (1) this steady-state growth is controlled by electromigration and

$v_G = v_D = \mu E C_o / C_s - C_o$. If $\rho_L >> \rho_s$, then $dR/dt \simeq \rho_L v_G / S$ and the resistance change provides a direct measure of the growth kinetics. If v_G is known the resistance change can be used for the determination of ρ_L. The results of such measurements are shown in Fig. 5, where the resistance of a growing undoped layer at 850°C is plotted against the layer thickness. For comparison the resistance of Cr-doped GaAs (which behaves as intrinsic material) measured in the cell at 850° is also shown as a function of thickness. It is seen that the resistivity is identical in both cases.

In the case of Cr-doped substrates, a decrease in the total resistance is observed during growth of both undoped and n^+ layers (Fig. 2d and c, respectively). The resistivity of the undoped layer at 850°C is very similar to that of the substrate (both behave as intrinsic material); thus expression [1] can be rewritten as $dR/dt \simeq (v_G - v_D)\rho_s/S$ and the resistance decrease indicates that $v_D > v_G$; this finding is consistent with the results of Fig. 4. A much larger decrease in the resistance takes place for the n^+ layer (Fig. 2b) since here not only $v_D > v_G$, but also $\rho_s >> \rho_L$. Accordingly, $dR/dt \simeq - v_D \rho_s / S$, and thus the resistance change provides a direct measure of dissolution rate.

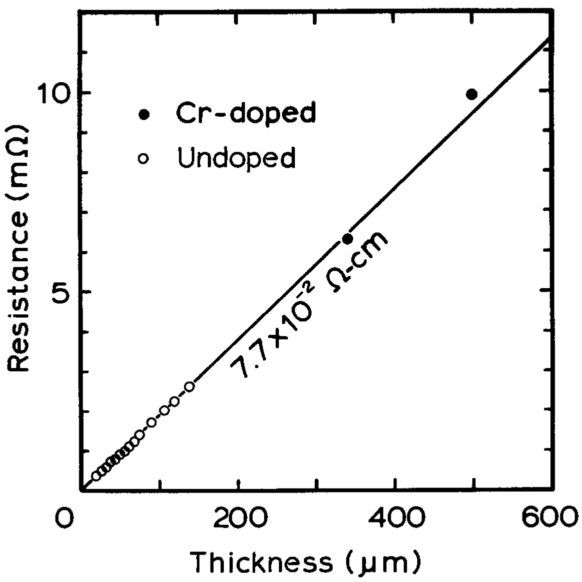

Fig. 5. Resistance of undoped LPE layers grown on n^+ substrate (○), and resistance of Cr-doped GaAs (●).

Summary

A new electroepitaxial configuration was developed in which the back-side electrical contact to the substrate is eliminated, thus rendering electroepitaxy more amenable to practical applications. This configuration can easily be extended to simultaneous growth on a number of parallel substrates separated by relatively thin layers of solution.

Utilizing this new configuration the simultaneous study of growth and dissolution processes on the opposite sides of a substrate became possible for the first time. Experiments with n^+ substrates showed that both processes exhibit the same rates, consistent with the theoretical model of electroepitaxial growth kinetics. In contrast, the high resistance of Cr-doped substrates leads to pronounced Joule heating which promotes dissolution over growth.

Detailed analysis of the resistance components in the growth system showed that *in situ* observation of the growth or dissolution process is possible utilizing the difference in the resistance between the substrate and the LPEE layer at the growth temperature.

Self-Diffusion of Gallium in Gallium Arsenide

Helen D. Palfrey, Margaret Brown, and Arthur F. W. Willoughby*

Mechanical Engineering Department, University of Southampton, Southampton SO9 5NH, England

ABSTRACT

The self-diffusion of gallium in gallium arsenide has been studied over the temperature range 1100°-1025°C using radiotracer techniques. Gallium arsenide samples were diffused with ^{72}Ga evaporated layers under known pressure of arsenic in sealed capsules. Following diffusion, layers were removed from the surface using anodic oxidation followed by oxide dissolution, and the ^{72}Ga concentration in each layer was measured by counting the γ-radiation. This sectioning method, which allows accurate determination of very shallow profiles, has allowed measurements of the diffusion coefficient to be made at lower temperatures than those employed by Goldstein, and the significance of the profile shapes measured is discussed in relation to the existence of possible "tails" in the profiles. It is concluded that there is only evidence for a single diffusion mechanism in the concentration and temperature range studied. Diffusion coefficients obtained in the temperature range 1025°-1100°C are from 3×10^{-15} cm^2/sec^{-1} to 9×10^{-15} cm^2/sec^{-1} under a constant arsenic pressure (P_{As_2}) of 0.75 atm, and lead to an activation energy of the order of 2.6 ± 0.5 eV and a pre-exponential factor of $4 \times 10^{-5} \pm 16 \times 10^{-5}$ cm^2 sec^{-1}. The results are discussed in comparison with previous measurements by Goldstein. The measured diffusion profiles are the first reported under known arsenic pressure and final surface concentration of gallium.

The conspicuous lack of GaAs self-diffusion data and conflict between the little existing data (1, 2) highlighted the need for information in this area of GaAs technology. It is hoped that the present self-diffusion data, carried out under controlled conditions, will help to clarify the native point defect situation and contribute to the understanding of impurity diffusion and redistribution of dopants during device preparation.

Material

GaAs was supplied by M.C.P. Electronics Limited. (100) slices were cut from an undoped Bridgman grown crystal and were n-type with a carrier concentration of 2.2×10^{16} cm^{-3}, mobility of 4270 cm^2 V^{-1} sec^{-1}, resistivity of 0.068Ω (at 300 K), and an initial etch pit density of 4000 cm^{-2}. The slices were mechanically/chemically polished on both sides, and as x-ray double crystal rocking curves showed the slice to be of good, uniform crystal perfection, it was considered unnecessary to do any further slice preparation. The final slice dimensions were $2.5 \times 2.5 \times 0.05$ cm.

Experimental Technique

Capsule design.—In order to prevent loss of arsenic from GaAs to the vapor phase (at temperatures in excess of about 640°C) it was necessary to employ an enclosed annealing technique. This was achieved by enclosing the slices in silica capsules. The capsule design was influenced by factors such as the slice dimensions, ease of loading and unloading, minimizing the capsule volume and thermal mass, heating the slice as little as possible during sealing, and the ability to offer support to the slices at the high annealing temperatures (1025°-1100°C). The final capsule design is presented in Fig. 1. It consisted of a semicylinder formed from silica and open at one end. After loading, an end cap with an outlet to vacuum was sealed onto the main body.

All the capsules were washed in 10% HF for 1/2 hr, followed by repeated rinsing and boiling in deionized water. They were then dried in the diffusion furnace (at the diffusion temperature) for several hours, with high purity nitrogen flowing through the furnace to sweep away any expelled vapors.

* Electrochemical Society Active Member.

Key words: anodic oxidation, radioisotope.

Annealing conditions.—In order to maintain the surface quality of the slices during the long annealing periods of about 24 hr, several factors were found to be of the utmost importance, these were: elimination of water vapor from the silica ware by baking, reduction of temperature gradients in the system to $<1°$C, the achievement of a good vacuum in the capsule prior to the final sealing, minimizing the volume and thermal mass of the capsules, and the addition of arsenic to create a minimum pressure of 0.75 atm during the anneal (see the Appendix).

Each slice was annealed in the following manner. Radioactive gallium, containing ^{72}Ga, half-life of 14.1 hr (obtained from the Isotope Production Unit, Harwell) was evaporated onto one face of the slice through a circular mask. The slice was introduced into the capsule along with the required amount of arsenic (see the Appendix). The end cap was then sealed onto the main body after which the capsule was flushed with argon then evacuated to about 8×10^{-8} atm before being finally sealed. The capsule was introduced into the furnace where it remained at the diffusion temperature ±1°C for roughly 24 hr. At the end of the anneal the capsule was allowed to air cool (about 2°C sec^{-1}). One end of the capsule was locally cooled on a lead block to avoid arsenic condensation on the slice.

Mesa preparation.—In order to obtain absolute Ga concentrations and to avoid high level contamination a

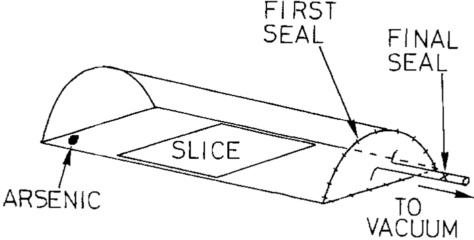

Fig. 1. Silica capsule design. Capsule length, width, and volume are 9 cm, 2.8 cm, and 24 cm, respectively. Capsule made from 0.2 cm thick silica.

mesa of known area was prepared for profiling, roughly in the middle of the Ga diffused area, after the anneal. However, it became evident during the experiments that the creation of the mesa had not fully achieved its aim and that radioactive Ga was present on the slice outside the mesa area. Contamination problems and the ways in which they were solved are discussed later.

The mesa was masked off by one of two methods. A solution of black wax was sprayed through a circular stencil to give a well-defined area. After careful removal of the stencil the slice was held just above a hot plate to ensure that the black wax coalesced leaving a pinhole-free mask. The slice was then left until the black wax was dry. The alternative was simply to stick a circular piece of polyvinyl chloride (PVC) adhesive tape onto the area to be masked. After masking, the slices were etched for 2 min in freshly prepared 1% Br_2/CH_3OH solution to remove approximately 9 μm from everywhere but the masked area, thus creating the mesa. Since the expected detectable Ga diffusion depth was less than 5 μm, the etching procedure should have removed all the radioactive Ga outside the mesa area. The black wax masks were removed after etching by repeated rinsing in trichloroethylene. The PVC masks were also removed by soaking in trichloroethylene, which swelled and lifted off the mask. In both cases the slices were finally thoroughly rinsed in deionized water. Both the wax and PVC masking techniques proved satisfactory. However the PVC mask was favored as it was a cleaner process.

Anodic oxidation.—The mesa area on each slice was profiled using the anodic oxidation technique, reported by Hasegawa and Hartnagel (3), followed by oxide dissolution, to remove thin (typically 250-500Å) parallel layers of GaAs from the mesa area. Hasegawa and Hartnagel (3) reported linear relationships between the anodization voltage, thickness of anodic oxide grown, and thickness of GaAs consumed during oxide growth. Earlier calibration work was in close agreement with these reported values. The thickness of each layer removed from the mesa could therefore be varied and was chosen by using the appropriate anodization voltage. Each anodic oxide had a well-defined interference color which was used to check that the anodization had proceeded correctly.

The equipment used for the anodizations is shown schematically in Fig. 2. It consisted of a hollow cylindrical polytetrafluoroethylene (PTFE) jig which contained a central hole (1.6 cm diam) at one end. The slice was placed on a silicone rubber washer and was positioned over the hole so the mesa was centrally positioned. The jig was clamped vertically and a circular platinum wire, placed just above the exposed portion of the slice, acted as the cathode. Electrolyte (a buffered 3% aqueous solution of tartaric acid and propylene glycol) was pipetted into the hole until the cathode was well covered ($\simeq$2 cm^3). All anodizations were carried out with 60W illumination directly above the jig and were for 7 min each.

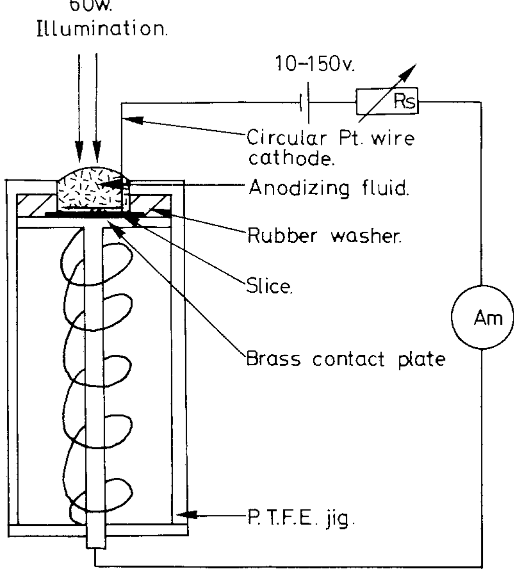

Fig. 2. Anodizing apparatus

After anodization the electrolyte was pipetted from the hole and retained in a 10 cm^3 plastic phial. The anodized area was rinsed with deionized water which was also collected. The slice was then removed from the jig (which was washed and dried before the next anodization) and the oxide color checked against a standard before a few drops of 20% HCl were pipetted onto the anodized area to remove the oxide. This fluid, containing the dissolved oxide, was very carefully poured into the phial via a funnel as was the final rinsing water. The slice was thoroughly washed in deionized water before the next anodization. All phials, pipettes, and funnels were used once only to prevent cross contamination. The electrolyte was retained for measurement as well as the dissolved oxide layer since finite dissolution of gallium and arsenic occurs during the oxidation process.

Radioactivity counting.—The ^{72}Ga present in the liquid collected in the phials following anodization and stripping was counted in a NaI (Tl) well scintillation counter, J. & P. Counter Ratemeter MS310. Absolute values of Ga concentration were obtained by comparison of the radioactivity in each sectioned layer to that of a known standard. The standard consisted of a known weight of irradiated Ga containing ^{72}Ga (specific activity identical to the ^{72}Ga diffusion source) dissolved in a known volume of aqua regia. It was chosen to be in the form of a solution since the radioactive Ga collected from the profiled areas was also in solution.

Observation and prevention of ^{72}Ga contamination outside the mesa area.—As mentioned above, effects due to the presence of ^{72}Ga outside the mesa area were observed during the course of the experiments. These took two forms, namely: type 1, the observation of some anomalously high values of Ga concentration deep in the profile, "spikes"; and type 2, the appearance of low concentration tails in the profiles.

The problem of contamination was not recognized initially since the final surface Ga concentrations were low. Under these circumstances the initial count rates from the sections were relatively low thus preventing deep profiling. Also, radioactive Ga was not present in sufficiently high concentrations to cause noticeable contamination. These conditions resulted from a poor evaporation technique, but when this was improved, and high final surface concentrations were achieved (through a larger quantity of ^{72}Ga diffusion source), type 1 and type 2 contamination effects were observed.

Autoradiographs were obtained from the slices on removal from the furnace and after mesa creation in order to see the radioactive Ga distribution over the slice at these two stages.

On removal from the furnace: The original ^{72}Ga evaporated area was clearly visible, but a high level of ^{72}Ga was also present on two edges of the front face (Fig. 3). ^{72}Ga was also found to be on the back face of the slice.

After mesa creation: The mesa area could be clearly seen. While there was no detectable ^{72}Ga on the back face, some ^{72}Ga still remained on the two edges of the front face.

The ^{72}Ga on the front face, outside the mesa area, was removed by careful lapping. The back face and four sides were also lapped off in order to be sure of complete removal of ^{72}Ga from these areas. After lapping the slice was washed thoroughly and then repeatedly boiled in concentrated HCl (to dissolve any

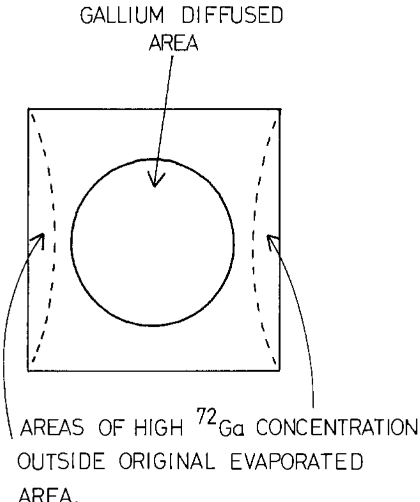

Fig. 3. Schematic representation of slice on removal from furnace

free gallium), until the radioactive level of the concentrated HCl fluids was reduced to near background.

Profiles obtained from slices using this preparation procedure were found to be free of Ga "spikes" (type 1 contamination). However, low Ga concentration "tails" were still apparent. It was thought that the "tails" may have been a result of some systematic but low level contamination. This type of contamination could arise if a proportion of radioactive Ga contained in the 20% HCl etch (used for anodic oxide layer removal) was adsorbed onto the slice. This adsorption phenomenon in acid solutions is well known (4), for example, gold onto silicon and silver and copper onto germanium. The amount of radioactive material adsorbed can be reduced to negligible proportions by addition of suitably large quantities of nonactive material to the acid solution (5). In this work adsorption of ^{72}Ga was minimized by the addition of nonactive $GaCl_3$ to the 20% HCl solution used during sectioning.

Systematic investigation of contamination showed that the following procedures must be followed in order to obtain a profile unaffected by contamination: (*i*) The use of autoradiographs to check that ^{72}Ga is present in the mesa area only. (*ii*) Removal (preferably by mechanical means) of radioactive Ga from all areas other than the mesa. This should be checked again by autoradiographs. (*iii*) The minimization of radioactive Ga adsorption, from acid solution, onto the slice by the addition of nonactive gallium to the acid solution.

A profile obtained, following these procedures, is presented in Fig. 4. It can be seen that neither type 1 nor type 2 contamination effects are observed. Pits in the original surface, or those that develop at high temperatures, can also give rise to "tails." However, since minimization of ^{72}Ga adsorption eliminated "tails" it appears, that in this case, pitting was not responsible for the observed "tails."

It is clear that great care must be taken to avoid contamination, however, comparison of the diffusion coefficients obtained from profiles affected and unaffected by contamination (24 hr diffusion anneals at 1050°C and 0.75 atm P_{As_2}) shows that the diffusion coefficient was relatively unaffected by both types of contamination effects observed. This is so since the diffusion coefficients were estimated from data covering the first two orders of magnitude drop in Ga concentration where the low level contamination was insignificant and where "spikes" were not observed.

Results and Discussion

The diffusion anneals were carried out over the temperature range 1100°-1025°C in order to obtain an estimate for the activation energy of gallium diffusion. Ga profiles (P_{As_2} = 0.75 atm) are presented in Fig. 4,

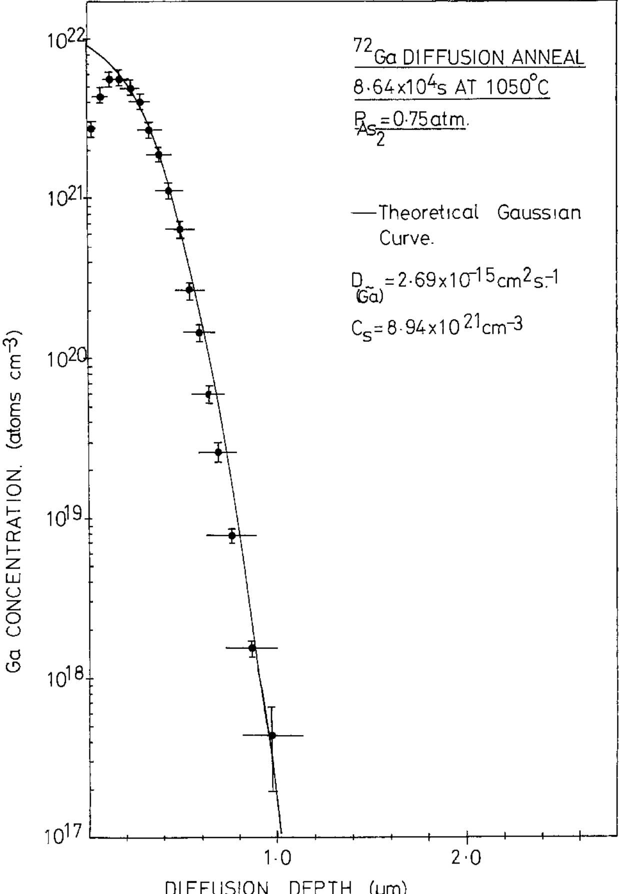

Fig. 4. Diffusion profile at 1050°C

5, 6, and 7. The arsenic pressure was held constant at 0.75 atm in order to observe the temperature dependence of the diffusion behavior. The diffusion coeffici-

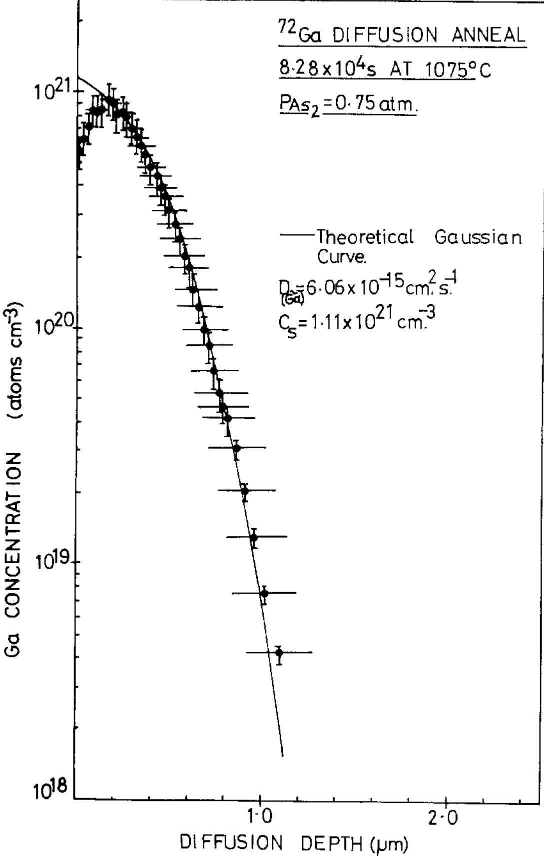

Fig. 6. Diffusion profile at 1075°C

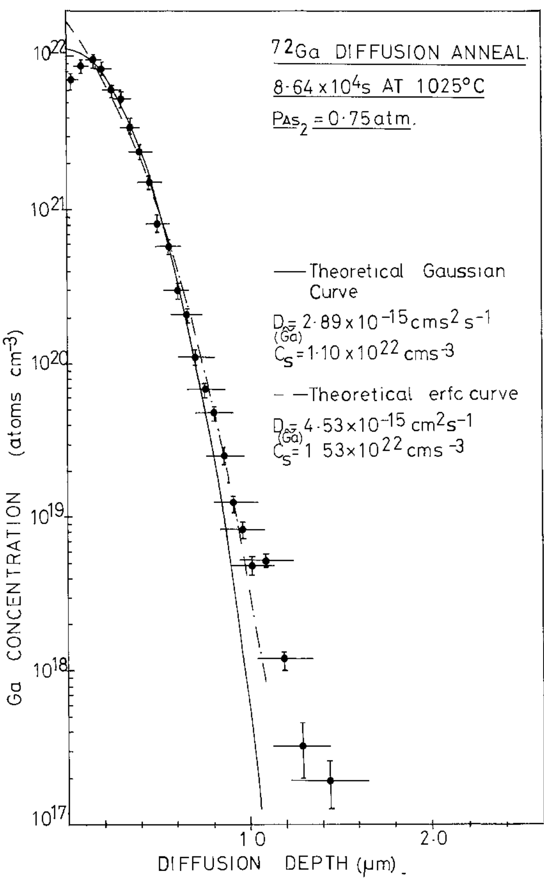

Fig. 7. Diffusion profile at 1025°C

ents, $D_{(\tilde{Ga})}$, obtained in the temperature range 1100°-1025°C (P_{As_2} of 0.75 atm) were from 8.85×10^{-15} to 2.89×10^{-15} cm^2 sec^{-1}. The diffusion coefficients were estimated from the profiles by using the method of least squares to obtain the curves of best fit. In most cases the evaporated ^{72}Ga acted as a limited diffusion source so a Gaussian solution was used. When it was unclear whether the source was limited or infinite, both Gaussian and erfc solutions were used to obtain curves of best fit to the experimental data. Diffusion coefficient data obtained in the present work and those reported by Goldstein (1) are plotted *vs.* $1/T$ and presented in Fig. 8. Q and D_0 values were calculated from a least squares fit to all points using unit weights and were found to be 2.6 ± 0.5 eV and $4 \times 10^{-5} \pm 16 \times 10^{-5}$ cm^2 sec^{-1}, respectively. The errors in Q and D_0 were calculated from the residuals of the least squares fit. It is stressed that the ranges of the calculated errors are only appropriate to the specific experimental conditions used in this work. Further data are required to obtain a more accurate estimate of the activation energy. However, the activation energy is significantly less than that reported by Goldstein (1) for Ga diffusion in GaAs. If Goldstein's experimental data are extrapolated to the temperature range studied in this work, then there is broad agreement between the two concerning the order of the diffusion coefficient. There is, however, a discrepancy between the two observed activation energies which is well outside the range of experimental error. It is known (6) that Goldstein conducted his diffusion anneals at the arsenic-rich side of the phase field, whereas the present results were obtained under comparatively gallium-rich conditions. The discrepancy in activation energies may be due to differences in arsenic pressure conditions and/or a change in the dominant diffusion mechanism.

The very small values of the Ga diffusion coefficients and the high Ga concentrations present in the profiles suggest that a simple interstitial mechanism (*i.e.*, no exchange with lattice vacancies) is not operative, and this seems highly unlikely also on theoretical grounds. Low diffusivity and high activation energies are often

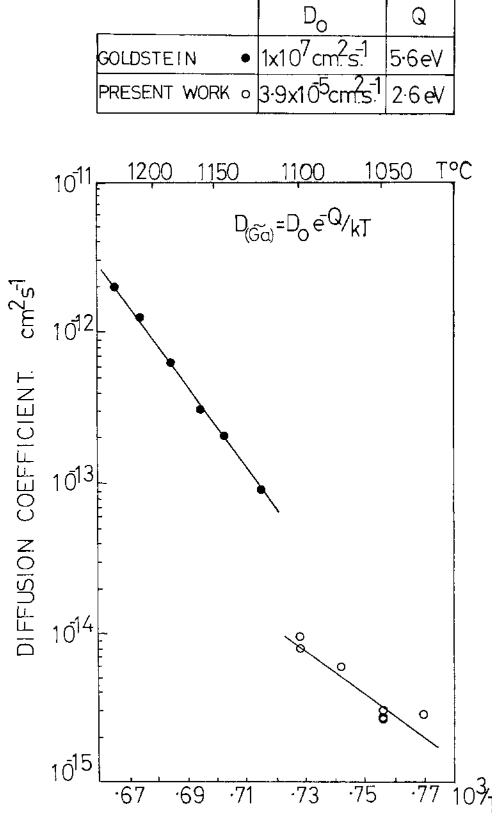

Fig. 8. $D_{(\tilde{Ga})}$ *vs.* temperature. ●, Goldstein: $D_0 = 1 \times 10^7$ cm^2 sec^{-1}; $Q = 5.6$ eV. ○, Present work: $D_0 = 3.9 \times 10^{-5}$ cm^2 sec^{-1}; $Q = 2.6$ eV.

associated with diffusion via vacancy mechanisms, and indeed this was the manner in which Goldstein chose to interpret his results. However, a rigorous evaluation of the diffusion mechanism of Ga in GaAs must consider all the possible mechanisms, including diffusion of Ga atoms via vacancies on the gallium sublattice, diffusion of Ga atoms via vacancies on the gallium and arsenic sublattices, and the various interstitial mechanisms such as the interstitialcy mechanism and the interstitial-substitutional (dissociative) mechanism. Although it is not possible yet to discriminate between these possibilities for gallium in gallium arsenide, some comments are possible. Self-diffusion of Ga via gallium and arsenic vacancies requires a significant concentration of anti-structure defects, but Van Vechten (7) has proposed that such defects should be present in significant concentrations in III-V compounds, and Schneider (8) has reported ESR evidence for As_{Ga} defects in GaAs. Regarding the interstitial-substitutional (dissociative) mechanism, it was pointed out by Casey and Pearson (9) that such a mechanism could lead to a relatively slow effective diffusion rate even for a fast interstitial diffusion. Considering next the interstitialcy mechanism, this would seem to be favored by models (10) involving "split-interstitial" gallium defects used to interpret lattice parameter (11) and internal friction (12) measurements on quenched GaAs. The mechanism suggested by Goldstein, namely, diffusion via vacancies on the gallium sublattice, must also be considered. Van Vechten's (7) calculated enthalpy of formation of V_{Ga} is 2.31 eV, and his calculated enthalpy of migration of V_{Ga} via second nearest neighbor sites is 2.7 eV, which would predict an activation energy of self-diffusion by this mechanism of 5 eV, assuming constant composition for the GaAs (compared with our estimate of 2.6 eV). These calculations are not yet well substantiated, however, and it is also extremely unlikely that constant composition was achieved in our experiments by keeping constant arsenic pressure, so we cannot at present rule out this mechanism either. It has also been suggested (2) that AB divacancies might be involved in self-diffusion of III-V compounds. However, it is not believed to be a valid suggestion for GaAs because of the low values of Q and D_0 obtained in this work. The most sensitive way of discriminating between the various possibilities is to investigate the dependence on arsenic pressure at constant temperature.

Two diffusion anneals were carried out at 1100°C ($P_{As_2} = 0.75$ atm) for times of 22.5 and 17 hr, see Fig. 5. Despite a sixfold increase in the amount of ^{72}Ga source, the diffusion coefficients of 8.85×10^{-15} and 7.54×10^{-15} cm^2 sec^{-1} were in close agreement with each other. This indicates that the techniques developed are reliable and enable reproducible results to be obtained. On all the profiles a fall in the Ga concentration is observed close to the surface ($\lesssim 0.3$ μm). It is believed that this depletion is a result of preferential removal of Ga from the sample surface. Reactions through which this is achieved are not clear, however it is known (13, 14) that gallium reacts with water vapor and also silica at high temperatures, forming volatile gallium suboxide

$$2Ga_{(L)} + H_2O_{(V)} \rightarrow Ga_2O_{(V)} + H_{2(V)}$$

$$2Ga_{(L)} + SiO_{2(S)} \rightarrow Ga_2O_{(V)} + SiO_{(V)}$$

If the vapor pressure of this volatile suboxide is relatively high at the diffusion temperature then an appreciable amount of gallium may be removed from the surface in order to fulfill reactions such as those above, resulting in a drop in Ga concentration close to the surface.

Two of the profiles also exhibited low concentration "tails." As discussed above these tails are due to low level contamination and not a complex diffusion mechanism. The tails may affect the interpretation of the profiles but not the estimate of the diffusion coefficients, since the diffusion coefficients were estimated from data over the first two orders of magnitude drop in Ga concentration where the low level contamination was shown to be insignificant.

No definite conclusion concerning the diffusion mechanism of Ga in GaAs may be drawn from the work carried out so far. However, it does indicate that over the temperature and concentration range investigated there is a single mechanism operative rather than a complex one. There is an obvious need for further information on diffusion, especially at different arsenic pressures. This work is currently in progress. It is clear, however, that Ga diffuses extremely slowly in GaAs even at elevated temperatures, a measurable diffusion depth of about 1 μm being achieved after a 24 hr annealing period at temperatures near 1050°C.

Phase Relationships in CaS-Rare Earth Sulfide Systems

H. L. Tsai and P. J. Meschter*

Department of Chemical, Metallurgical and Polymer Engineering, University of Tennessee, Knoxville Tennessee 37916

ABSTRACT

Phase relationships in the $CaS-Y_2S_3$, $CaS-Dy_2S_3$, $CaS-Er_2S_3$, and $CaS-Yb_2S_3$ systems have been determined between 800° and 1200°C at $p_{S_2} = 3 \times 10^{-6}$ atm. All four dopants show significant solid solubility in CaS (15-30 m/o at 1200°C). Approximate p_{S_2}/p_{O_2} ratios required to avoid oxygen contamination of the mixed sulfides are derived. Variation of the lattice parameter of the CaS phase with dopant content indicates an increase in size of the dopant ion upon dissolution. The x-ray diffraction pattern of monoclinic β-CaY_2S_4 has been determined. The β-phase may be regarded as a slight distortion of the orthorhombic low temperature α phase.

Calcium sulfide doped with a rare earth sesquisulfide such as Y_2S_3 has been proposed as a solid electrolyte system for sensing of sulfur activities by Worrell (1, 2). The dopant cation on a Ca site is effectively positively charged (*e.g.*, $Y_{Ca}^{\cdot}$), and is compensated for by the formation of vacancies on the cation sublattice V_{Ca}''. If enough dopant is added so that the number of extrinsic ionic defects greatly exceeds the number of defect electrons or electron holes over a wide range of temperature and p_{S_2}, then the mixed sulfide has $t_{ion} \simeq 1$ over this domain and can in principle be used as a solid electrolyte for sulfur activity or partial pressure measurement.

An effective dopant must have a significant range of solid solubility in CaS. Flahaut *et al.* (3, 4) have identified Y_2S_3, Dy_2S_3, Er_2S_3, and Yb_2S_3 as having extended solutions in CaS, with typical solubilities around 20 mole percent (m/o) rare earth sulfide. Their mixed sulfides were sintered in quartz capsules under vacuum, so that neither the sulfur nor the oxygen chemical potential was well defined. Worrell *et al.* (1) report very limited (<1 m/o) solubility of Y_2S_3 in CaS after heating for 14 hr at 900°C in an H_2-H_2S mixture of unspecified p_{S_2}. Worrell *et al.* attribute Flahaut's results to oxygen and/or carbon impurities in the latter's samples.

In order to resolve this discrepancy, we have determined phase relationships and lattice parameters in the binary systems of CaS with Y_2S_3, Dy_2S_3, Er_2S_3, and Yb_2S_3 containing up to 40 m/o rare earth sulfide over the temperature range 800°-1200°C at a fixed p_{S_2} of 3×10^{-6} atm. The chemical potential of oxygen in the system was approximately controlled by running all experiments in the presence of graphite. We have also determined the x-ray diffraction pattern and lattice parameters of monoclinic β-CaY_2S_4, which is in equilibrium with the saturated CaS solid solution above about 1100°C.

Sample Preparation and Experimental Procedure

Pure CaS (−325 mesh, 99.99%) and the doping materials, Y_2S_3, Yb_2S_3, Dy_2S_3, and Er_2S_3 (−200 mesh, 99.9%) were obtained from Cerac, Incorporated. Samples containing 1-40 m/o rare earth sulfide were prepared by mixing weighed amounts of each dopant powder and CaS powder in the required proportions, cold pressing in a hydraulic die at 90,000 psi, and sintering for 1 day at 1350°C in a purified 1:1 H_2-H_2S mixture. During the sintering, the pellets were surrounded by a bed of powder of the same composition within a graphite boat, which was in turn enclosed in a graphite tube plugged with graphite wool at both ends. Preliminary experiments showed that these precautions were necessary to prevent contamination of the samples with oxygen from traces of CO_2 or H_2O in the surrounding gas stream. The pellets after presintering were examined by x-ray diffraction to check for completeness of reaction and absence (to <5%) of oxide or oxysulfide phases.

A vertical resistance-wound furnace with a 1⅜ in. long hot zone (±1°C), controlled to better than ±2°C over any run, was used to equilibrate the samples. Platinum/Pt-13% Rh thermocouples placed near the furnace windings and next to the sample were used, respectively, to control the furnace temperature and measure the sample temperature. The quench tank was a brass cylinder filled with oil fitted directly to the bottom of the vertical reaction tube.

The equilibration atmosphere was a mixture of 99.99% H_2 (major impurity 5 ppm H_2O) and 99.5% H_2S containing nominally 2500 ppm C_2H_6, 800 ppm C_3H_8, 30 ppm $(CH_3)_2S$, H_2O, and CO_2, and 70 ppm N_2. The gases were purified by passage over successive columns of molecular sieves and P_2O_5. Flow rates and partial pressures of the gases were fixed and measured by constant-pressure-head capillary manometer/flowmeters. The gases were mixed in a column of glass beads before introduction into the furnace.

The presintered pellets were packed into a 1 in. long cylinder in a graphite crucible and the upper end plugged with graphite wool. The crucible was hung from graphite rods in the hot zone of the furnace. To start a run, the furnace was evacuated to check gas-tightness, the H_2S/H_2 mixture introduced, and the furnace heated to the desired temperature. The samples were kept at temperature for times summarized in Table I. To check whether these times were sufficient to achieve equilibrium, additional runs with prolonged holding times were performed at 1200° and 800°C to verify that the lattice parameters were unchanged with time. A run at 700°C, in which equilibrium was not achieved after 400 hr, was excluded. After equilibration, the samples were quenched by releasing the crucible into the oil bath.

Key words: doping, lattice parameter, x-ray diffraction.

Several preliminary experiments with $CaS-Y_2S_3$ samples had been done to determine the best equivalent p_{S_2} to use in the gas stream. Runs at 800°C and $p_{S_2} < 10^{-6}$ atm resulted in the formation of a hexagonal phase of stoichiometry Y_2O_2S, while no oxysulfide was found after a run at $p_{S_2} = 3 \times 10^{-6}$ atm and 800°C. Therefore, $p_{S_2} = 3 \times 10^{-6}$ atm was chosen for all equilibration runs. This p_{S_2} corresponds to the H_2S/H_2 ratio at each temperature shown in Table I. X-ray analysis showed minor amounts, at worst, of oxysulfide contaminants after equilibration runs except in the case of $CaS-Yb_2S_3$, where formation of "Yb_2O_2S" limited valid results to 1050°-1200°C.

The lattice parameters of the CaS solid solution phase present in the quenched samples were determined by a diffractometer method using CuK_α radiation. The parameters were determined from the high angle (620), (622), and (444) reflections of the CaS phase and extrapolation of a lattice parameter *vs.* $\cos^2 \theta$ plot to $\theta = 90°$. A Debye-Scherrer camera with CuK_α radiation was used to determine the diffraction pattern of $\beta-CaY_2S_4$ after quenching from 1200°C.

Results and Discussion

The solubility limits for each CaS-rare earth sulfide system were obtained by plotting the lattice parameter of the CaS solid solution *vs.* mol percent dopant as shown in Fig. 1 for $CaS-Y_2S_3$. The uncertainty in the measured lattice parameter is ±0.001Å for any composition in the CaS phase field. The lattice parameter varies linearly with m/o dopant to ±0.06% (±3 standard deviations) in any system. The intercepts of the least squares lines at 0% R_2S_3 are all in good agreement (±0.002Å) with the lattice parameter of pure CaS of 5.6948Å from The Powder Diffraction File. The solubility limits given in Table II were obtained from the intersections of the least squares lines for the single phase CaS solid solutions with the average lattice parameters of the CaS phase in the two-phase samples. The presence or absence of the second phase, which was in all cases CaR_2S_4, was confirmed directly from the diffraction pattern.

1200° Flahaut (4)	18	20	22	—

The phase diagrams of $CaS-CaR_2S_4$ systems are all qualitatively similar to the $CaS-CaY_2S_4$ system shown in Fig. 2. Agreement with Flahaut *et al.* (3, 4) for this system is good, although the solubilities of this study are noticeably larger above 1000°C. Flahaut's solubility limits for Dy_2S_3 and Er_2S_3 are larger than ours at 1200°C. Both studies show extended ranges of solid solubility of all dopants in CaS, with solubilities ranging up to 29 m/o Yb_2S_3 in CaS above 1200°C.

The reported solubility of Y_2S_3 in CaS of Worrell *et al.* (1) is much smaller than those found here. These workers had no internal getters near the sample to react with oxidizing impurities in the gas stream, nor did they identify the second phase in equilibrium with their saturated CaS solid solution. Results from our preliminary experiments at 700°-1000°C without graphite getters always showed the existence of hexagonal "Y_2O_2S" in $CaS-Y_2S_3$ samples. The diversion of yttrium to this compound, which is apparently nearly insoluble in CaS, lowers the apparent extent of the CaS phase field. In ex-

treme cases, virtually all of the yttrium was found in the oxysulfide and the CaS was nearly pure, thus reproducing the results of Worrell *et al.* (1).

Since the oxygen-sulfur balance in and around the samples during presintering and phase equilibration is critical to successful determination of phase equilibria in these systems, it is of interest to estimate the p_{S_2}/p_{O_2} ratios which obtain in the presence and absence of graphite getters, respectively. This estimation requires simultaneous solution of the reaction equilibria

$$C(gr) + CO_2 = 2CO \qquad K_I = p_{CO}^2/p_{CO_2} \qquad [I]$$

$$C(gr) + H_2O = CO + H_2 \qquad K_{II} = p_{H_2}p_{CO}/p_{H_2O} \qquad [II]$$

$$H_2 + \tfrac{1}{2} O_2 = H_2O \qquad K_{III} = p_{H_2O}/p_{H_2}p_{O_2}^{1/2} \qquad [III]$$

$$H_2 + \tfrac{1}{2} S_2 = H_2S \qquad K_{IV} = p_{H_2S}/p_{H_2}p_{S_2}^{1/2} \qquad [IV]$$

using reasonable assumptions of concentrations of H_2, H_2O, H_2S, CO, CO_2, and O_2 in the incoming gas stream. For example, in our presintering runs at 1350°C, $[p_{H_2}]_i = [p_{H_2S}]_i = 0.5$ atm. Assuming inefficient gettering of the incoming gas as a worst case, one may estimate $[p_{H_2O}]_i = 1 \times 10^{-4}$ atm and $[p_{CO_2}]_i = 3 \times 10^{-5}$ atm, with initial concentrations of CO and O_2 being negligible relative to these. The equilibrium constants K_I and K_{II} are large, so one may assume the function of carbon is to convert essentially all of the CO_2 and H_2O to CO and H_2. Then $p_{CO} \simeq 1.6 \times 10^{-4}$ atm, and using standard thermodynamic data for Eq. [I]-[III], $p_{CO_2} = 6.2 \times 10^{-12}$ atm, $p_{H_2O} = 8.0 \times 10^{-8}$ atm, and $p_{O_2} = 1.2 \times 10^{-24}$ atm are calculated. From the equilibrium of reaction [IV], $p_{H_2} = 0.64$ atm, $p_{H_2S} = 0.36$ atm, and $p_{S_2} = 0.07$ atm. Thus the p_{S_2}/p_{O_2} ratio is about 6×10^{22}. Similar calculations for the equilibration runs at 800°-1200°C yield p_{S_2}/p_{O_2} ratios on the order of 10^{19}-10^{22}. Small amounts of oxysulfide which appear in some of these runs show that this ratio is close to the ratio required to convert oxysulfide to sulfide. Without a carbon getter, on the other hand, the p_{S_2}/p_{O_2} ratio is about 10^{12} at 1350°C, which is clearly insufficient to produce the mixed sulfide system.

The presence of graphite at unit activity in our experiments raises the question of carbon contamination. In several sample preparation and equilibration experiments the samples had no measurable weight change (±0.5%) during the runs. In experiments where significant amounts of oxysulfides were formed, noticeable weight changes were recorded. Strictly speaking, our results refer to the quaternary Ca-R-S-C system, but it is considered that these results are reasonably representative of the Ca-R-S ternaries.

The least squares analyses of the lattice parameter variation of CaS doped with Dy_2S_3, Y_2S_3, Er_2S_3, and Yb_2S_3 within the solid solubility range are given in Table III. The values marked "calculated" are based on ionic radii derived by Flahaut *et al.* (4) for sixfold coordination from the lattice parameters of pure metal sulfides. These radii are 1.02, 0.93, 0.92, 0.90, and 0.88Å for Ca^{2+}, Dy^{3+}, Y^{3+}, Er^{3+}, and Yb^{3+} ions, respectively. A radius of 1.824Å was deduced for S^{2-} from the lattice parameter of pure CaS. Both our observed lattice parameter values and those of Flahaut (line 3 in Table III) are larger than the calculated values, and are in good agreement with each other (see also Fig. 1).

Because of the large ionic radius of S_2^-, the formation of interstitial anions is not favored. The difference between measured and calculated lattice parameters thus must be due to a small increase in size of the R^{3+} cation in the solid solutions, compared with the calculated value. The observed value was especially large in comparison with the calculation in the CaS-Yb_2S_3 system. This result may be due to a particularly large expansion of the Yb^{3+} ion, or to diversion of Yb to the oxysulfide, which it was impossible entirely to prevent in this system. It is noteworthy that there is no correlation beween solubility limits and the difference in radii between Ca^{2+} and the dopant ion. In fact, the ion Nd^{3+}, which is virtually the same size as Ca^{2+}, has virtually no solubility in CaS (4).

The lattice parameters of α-CaY_2S_4 and β-CaY_2S_4 were calculated from their x-ray diffraction patterns. The lattice parameters of orthorhombic α-CaY_2S_4 quenched from 1000°C (a = 12.89Å, b = 13.03Å, c = 3.87Å) are in agreement with those of Flahaut *et al.* (3) (a = 12.94Å, b = 13.03Å, c = 3.86Å). The x-ray pattern of monoclinic β-CaY_2S_4 taken from the 40% Y_2S_3 in CaS sample quenched from 1200°C is shown in Table IV. The lattice parameters are a = 12.88Å, b = 13.04Å, c = 4.02Å, β = 93.48°. The β structure may be regarded as a small distortion of the orthorhombic α lattice.

All the CaR_2S_4 compounds but $CaDy_2S_4$ showed conversion to the β-form below 1200°C. The major difference in the two patterns is the existence of the (200) line at small diffraction angles and the nonappearance of the (120), (220), and (130) lines in the β- as compared with the α-form.

Summary

Phase relationships in the CaS-Y_2S_3, CaS-Dy_2S_3, CaS-Er_2S_3, and CaS-Yb_2S_3 systems have been determined at $p_{S_2} = 3 \times 10^{-6}$ atm between 800° and

1200°C. The solubilities of the dopant sulfides are relatively large (15-30 m/o at 1200°C, depending on dopant), in agreement with results of Flahaut *et al.* (4). The much smaller apparent solubilities of Worrell *et al.* (1) are probably the result of oxygen contamination and formation of rare-earth oxysulfides. Variation of lattice parameter of the CaS solid solution indicates an increase in size of the dopant ion over theoretical predictions based on ion sizes in the pure sulfides. The x-ray pattern of β-CaY_2S_4 has been determined, and shows a monoclinic structure which represents a small distortion of the low temperature orthorhombic phase.

The Effect of SO_3 Gas on the Surface Tension of Molten Na_2SO_4

G. J. Yurek* and R. E. Deeter

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

The surface tension of molten Na_2SO_4 has been measured as a function of the partial pressure of SO_3 gas in equilibrium with the melt ($10^{-9} \lesssim P_{SO_3} \lesssim 10^{-1}$ atm) over the temperature range of 1175-1400 K. The surface tension, σ, is independent of P_{SO_3} over the range of partial pressures employed. The temperature dependence of σ is given by

$$\sigma = 2.568 \times 10^{-1} - 6.05 \times 10^{-5}T$$

where σ has units of N/m and T is the absolute temperature. The density of Na_2SO_4 is independent of P_{SO_3} for $10^{-9} \lesssim P_{SO_3} \lesssim 10^{-1}$ atm at 1200 and 1250 K, thereby confirming that Na_2SO_4 is virtually stoichiometric under these conditions.

The surface tension of molten salts has been determined by most investigators under conditions for which the thermodynamic state of the salt was not fixed precisely, *e.g.*, the surface tension of molten Na_2SO_4 has been determined only in the presence of nitrogen gas. Two exceptions to this general statement are noted. Kozakevitch (1) measured the surface tension of liquid FeO at ~1700 K and at 1 atm pressure as a function of oxygen partial pressure. Under these conditions, the composition of liquid FeO varies from about 23 to 24 weight percent (w/o) O as the oxygen partial pressure varies from ~10^{-10} to 10^{-8} atm. For this variation in P_{O_2}, the surface tension of liquid FeO decreases from 0.585 to 0.500 N/m, indicating that ferric ions are surface active.

Moiseev and Stepanov (2) measured the surface tension at 1 atm pressure of Na_2CO_3 and Li_2CO_3 melts that were equilibrated with gas mixtures containing varying amounts of N_2, O_2, and CO_2. The surface tension of Na_2CO_3 was not a function of the gas composition, but the surface tension of Li_2CO_3 was higher when the melt was in contact with CO_2 or CO_2-O_2 mixtures by about 0.006-0.008 N/m than when the melt was in contact with air. More significant changes in the surface tension of Li_2CO_3 resulted when additions of Li_2O were made to the melt. In the latter case, which is discussed more fully later in this paper, an increase in the surface tension with increasing concentration of Li_2O was attributed to the presence of a higher concentration of (O^{2-}) anions, which have a higher effective dipole moment than (CO_3^{2-}) anions.

Pure molten salts, such as Na_2SO_4, that contain polyatomic ions may be considered quasi-binary thermodynamic systems (*e.g.*, $Na_2O + SO_3$) if the composition of the salt can be given by a single variable, *e.g.*, the mole fraction of Na_2O, X_{Na_2O}. The effect of P_{SO_3} on the composition of molten Na_2SO_4 may be described by the following equilibrium

$$Na_2SO_4(l) = SO_3(g) + (Na_2O) \quad [1]$$

where the parentheses around Na_2O are used to indicate that this component is dissolved in the melt. The equilibrium constant for Eq. [1] is given by

$$K_1 = a_{Na_2O}P_{SO_3}/a_{Na_2SO_4} \quad [2]$$

The standard state for SO_3 gas is taken as pure SO_3 gas at 1 atm pressure at the temperature of interest. The thermodynamic state of the quasi-binary Na_2O-SO_3 system is determined fully if the temperature and the activity of either Na_2O or SO_3 are specified. This would be true regardless of the value of $a_{Na_2SO_4}$.

At very low P_{SO_3} and at high P_{O_2}, the composition of Na_2SO_4 may change by formation of peroxide

* Electrochemical Society Active Member.

Key words: surface tension, molten salts, Na_2SO_4.

(O_2^{2-}) or superoxide (O_2^-) anions, *i.e.*, by formation of Na_2O_2 or NaO_2 neutral species. At high P_{SO_3} the composition of Na_2SO_4 may change by formation of pyrosulfate anions, ($S_2O_7^{2-}$). If significant quantities of (O_2^-), (O_2^{2-}), or ($S_2O_7^{2-}$) anions were formed at very low or very high P_{SO_3}, respectively, then Na_2SO_4 could not be considered a quasi-binary mixture of $Na_2O + SO_3$.

Molten Na_2SO_4 may be considered a quasi-binary system for P_{SO_3} in the approximate range of 10^{-1}-10^{-9} atm because its composition does not change significantly in this range even though the activity of Na_2O according to Eq. [1] varies by eight orders of magnitude (3-6). Indeed, Na_2SO_4 is nearly stoichiometric ($x_{Na_2O}/x_{SO_3} = 1.0$) for this range of P_{SO_3}, so that changes in the concentration of (O^{2-}), as well as changes in the concentrations of (O_2^-), (O_2^{2-}), and ($S_2O_7^{2-}$), are very small.

In principle, the surface tension of molten Na_2SO_4 should be a function of P_{SO_3} (*i*) if the concentration of ions with higher or lower effective dipole moments than (SO_4^{2-}) were changed significantly with a change in P_{SO_3} or (*ii*) if one or more of those species that change in concentration by a small amount with a change in P_{SO_3} [*i.e.*, (O^{2-}), (O_2^-), (O_2^{2-}), or ($S_2O_7^{2-}$)] were highly surface active. Only the latter possibility could apply in the case of nearly stoichiometric Na_2SO_4. The purpose of this paper is to present the results of a study of the effect of P_{SO_3} ($10^{-9} \lesssim P_{SO_3} \lesssim 10^{-1}$ atm) on the surface tension of Na_2SO_4.

Experimental Procedures

The surface tension of molten sodium sulfate was measured using the double-tube maximum bubble pressure method. The apparatus employed is illustrated schematically in Fig. 1. The general principles involved in the determination of the surface tension of a liquid phase by the maximum bubble pressure method have long been established (7, 8). In this method, a gas is forced through a capillary tube that is partially immersed in a liquid to form a bubble at the tip of the tube. The pressure in the bubble relative to the surrounding pressure may be measured with an oil manometer or other suitable device for measuring pressure. The maximum pressure in the bubble, before the bubble detaches from the tube, comprises a contribution from the hydrostatic head of the liquid and a contribution from the surface forces that oppose an increase in the gas-liquid surface area. Thus, a knowledge of the depth of immersion, the maximum bubble pressure, and the radius of the capillary tube allows the surface tension of the liquid to be calculated. Standard tables are available (9) to correct the calculation for the formation of nonspherical bubbles, which always form unless extremely fine-bore capillary tubes are employed.

In the double-tube maximum bubble pressure method, the maximum bubble pressure is measured in two capillary tubes of different radii that are immersed the same depth in the melt. The difference in the maximum bubble pressures for the two tubes depends only on the radii of the tubes, thereby eliminating the need to measure the depth of immersion of the tubes.

The tubes used in this investigation were Pt-10% Rh that had diameters of approximately 0.1 and 0.3 cm. The tubes were tapered at their tips to provide a well-defined bubble diameter at the point of maximum pressure in the bubble. The inner diameters of the tubes were measured at low magnification (2-7×) using a split-image eyepiece that was calibrated against a stage micrometer. The reproducibility of these measurements was good, *i.e.*, the standard deviation from the average measured diameter was always less than 0.25% of the diameter. The change in the diameters of the tubes upon heating was taken into account using the thermal expansivity of the alloy.

The Pt-10% Rh tubes, which were about 17.5 cm long, were welded to stainless steel extension tubes,

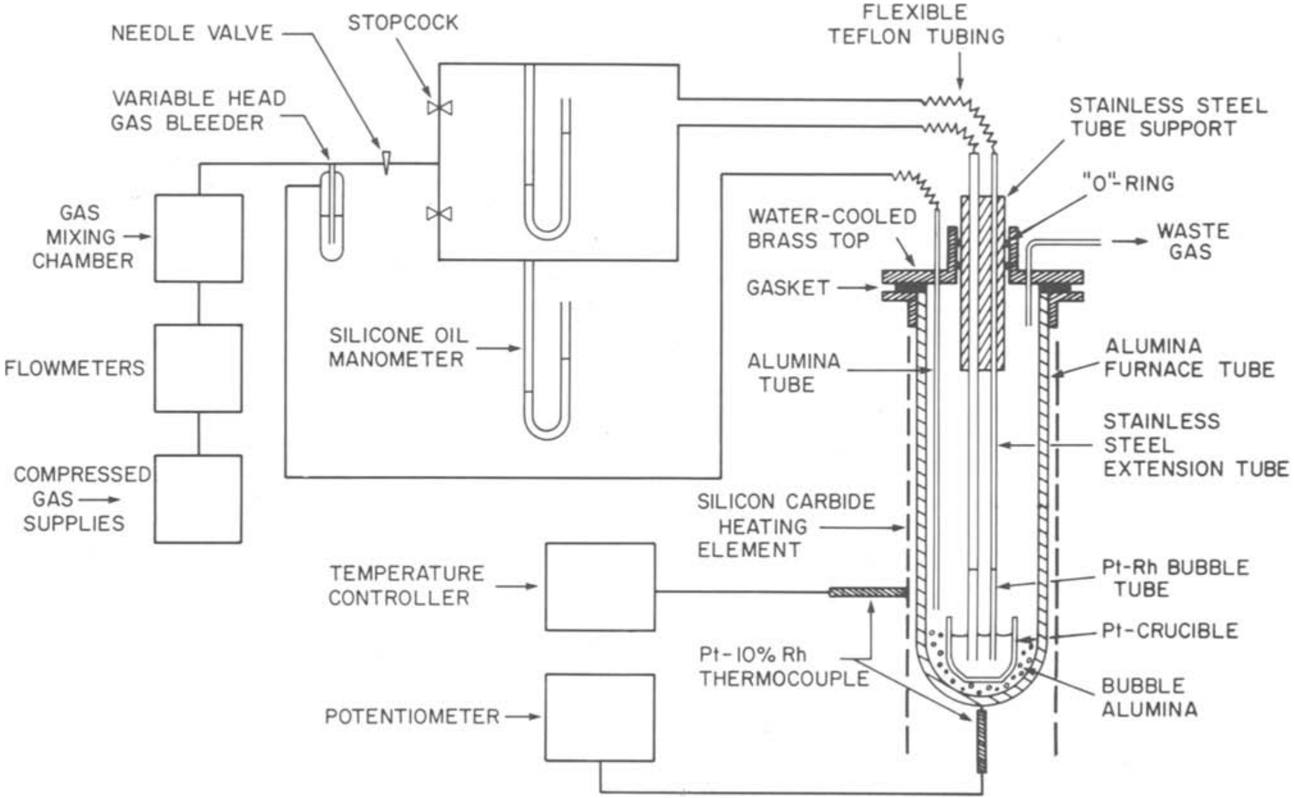

Fig. 1. Schematic illustration of the double-tube, maximum bubble pressure apparatus employed to measure the surface tension of molten Na_2SO_4.

which, in turn, were connected to the gas-supply line by flexible Teflon tubing. The stainless steel extension tubes were wrapped with Pt foil to prevent corrosion products on the stainless steel from falling into the melt. The bubble tube assembly was cemented firmly into a stainless steel support tube, which served to align the two tubes and maintain the two tubes at equal depths of immersion. The support tube could be moved vertically through the water-cooled brass top of the alumina furnace tube to vary the depth of immersion of the tubes in the melt.

The melt was contained in a Pt crucible at the bottom of the alumina furnace chamber, which was heated by a helical silicon carbide heating element and maintained at a constant temperature by a proportional controller. Although it is not shown in Fig. 1, the region of the furnace chamber between the Pt crucible and the stainless steel tube support contained alumina cylinders that were solid except for holes that were provided for the bubble tubes and a gas injection tube. These alumina cylinders acted as heat shields to help maintain a long constant temperature zone in the furnace chamber. The constant temperature zone, measured from the bottom of the furnace chamber, was about 15 cm long. An extended constant temperature zone helps minimize convective currents, which can cause rather severe fluctuations in the measured bubble pressures. The open ends of the silicone oil manometers depicted in Fig. 1 were actually connected to an alumina tube that was positioned just above the melt in the furnace chamber. Thus, the pressure in the bubbles was measured relative to the pressure in the furnace.

The temperature of the silicone oil manometers was monitored during each experiment using high precision mercury thermometers. Small changes in density of the silicone oil with a change in room temperature were taken into account in calculating the surface tension of the Na_2SO_4. The change in height of silicone oil in the two legs of the manometers were measured using a cathetometer.

Granular anhydrous Na_2SO_4 (see Table I for analysis) was employed in these experiments. The Na_2SO_4 was dried at 600°-650°C for 1-2 weeks under vacuum. After transferring the Na_2SO_4 to the surface tension apparatus, it was heated under flowing dry Ar at 600°C for about 12 hr before the temperature of the salt was raised above its melting point.

The surface tension of molten Na_2SO_4 at a constant temperature and total pressure of 1 atm was measured as a function of the partial pressures of SO_2 and O_2 (or, equivalently, SO_3) gases that were in equilibrium with the melt. The partial pressure of SO_3 gas in equilibrium with the melt was calculated using the equilibrium constants (16) for the reaction

$$SO_2(g) + 1/2\, O_2(g) = SO_3(g) \quad [3]$$

and the volume fractions of SO_2 and O_2 in the initial gas mixtures. The gas mixtures employed were either premixed $Ar\text{-}SO_2\text{-}O_2$ or mixtures produced by combining pure gases and/or premixed gases using constant-head capillary flowmeters. The compositions of the input gases, the flow rates, and the equilibrium values of P_{SO_3} at 1200 and 1250 K are presented in Tables II and III. Six gas mixtures were employed to measure the surface tension at 1200 and 1250 K for $10^{-9} \lesssim P_{SO_3} \lesssim 10^{-1}$ atm. Before mixing, the Ar, O_2, and the $Ar\text{-}O_2$ mixtures were passed through anhydrous $Mg(ClO_4)_2$ and P_2O_5 to remove water vapor and through "Ascarite" to remove CO_2. The SO_2 and $Ar\text{-}SO_2\text{-}O_2$ mixtures were passed through P_2O_5 to remove traces of water vapor.

The oxygen contents of the Ar-970 ppm SO_2 and the Ar-97 ppm SO_2 (Table II) were measured by Matheson Gas Products. We verified the oxygen contents by using a calcia-stabilized zirconia solid electrolyte cell with air as the reference electrode. The uncertainty in the analyses for O_2 and SO_2 in the premixed gases is reported to be less than 2% by Matheson. The gases were not analyzed further by us for the SO_2 content.

The time required to equilibrate $SO_2\text{-}O_2$ gas mixtures with molten Na_2SO_4 has been measured using sodium $\beta\text{-}Al_2O_3$ solid electrolyte cells (15). Equilibration is achieved in the presence of a Pt-wire catalyst in 1-2 hr for $10^{-2} < P_{SO_3} < 10^{-1}$ atm and in $\sim$3 hr for $P_{SO_3} \sim 10^{-3}$ atm. Lin (4) confirmed these times for equilibration using thermogravimetric techniques. Data are not available to indicate the time required to equilibrate molten Na_2SO_4 with a gas phase that has $P_{SO_3} < 10^{-3}$ atm. In the present investigation, the gases with low equilibrium values of P_{SO_3} were bubbled through the melt via Pt-Rh bubble tubes for at least 15 hr before a measurement was made to ensure that equilibrium was achieved. The surface tension did not change when these gas mixtures were bubbled through the melts for an additional 15 hr or more.

A variable head gas bleeder and a needle valve were located in the gas line after the gas mixing chamber but before the manometers and furnace assembly. These were employed to regulate the flow of gas to the bubble tubes. The rate of bubbling can affect the measurement of pressure in a bubble, and it is usually recommended that the rate of bubbling be in the range of one bubble per second for low viscosity melts and up to 60 sec for more viscous melts (10). In the present study, rates of one bubble per 15-20 sec were found to yield reproducible results.

Excess gas from the bleeder was passed into the furnace and flowed over the surface of the melt. Flowing the gas mixture over the melt during the entire experiment in addition to bubbling the gas mixture through the melt via the bubble tubes before the experiment served to equilibrate the melt with

the gas mixture, thereby fixing the thermodynamic state of the salt melt.

Gas that passed through the needle valve was directed, with the aid of stopcocks, to only one of the bubble tubes. While the pressure was being measured in one bubble tube, gas at approximately the maximum pressure was maintained in the other tube to eliminate changes in the depth of the melt that would occur if the melt moved up the tube that was not in use.

The surface tension apparatus was also used to determine the density of Na_2SO_4 by measuring the maximum bubble pressure in a single tube at two depths of immersion of the tube in the melt. By measuring the surface tension at two depths of immersion of the two tubes in each experiment, the data obtained could also be used to determine the density of Na_2SO_4.

Results and Discussion

Density of Na_2SO_4.—At least two measurements of the density of Na_2SO_4 were made at each of six values of P_{SO_3} employed at 1200 and 1250 K. In total, 27 measurements were made at 1200 K and 12 measurements were made at 1250 K. The results are plotted in Fig. 2. Within the precision of the measurements, the density of Na_2SO_4 is independent of P_{SO_3} in the range of 10^{-9}-10^{-1} atm. The average values of the density are 2.09 $\pm$ 0.04 and 2.06 $\pm$ 0.02 g/cm^3 at 1200 and 1250 K, respectively, the uncertainties being one standard deviation from the average values.

Constant values of the density of Na_2SO_4 over the range of P_{SO_3} employed indicate that the Na_2SO_4 is virtually stoichiometric over this range of P_{SO_3}. A variation in the density of Na_2SO_4 at higher values of P_{SO_3} could occur, however, by the dissolution of SO_3 in Na_2SO_4 to form pyrosulfate anions according to the reaction

$$SO_3(g) + Na_2SO_4(l) = Na_2S_2O_7(l) \quad [4]$$

The solubility of SO_3 in Na_2SO_4 at 1200 K varies from $\sim$0.1 atomic percent (a/o) $Na_2S_2O_7$ at P_{SO_3} = 0.01 atm to $\sim$0.3 a/o $Na_2S_2O_7$ at P_{SO_3} = 0.08 atm (4). Thus, changes in the concentration of $(S_2O_7{}^{2-})$ anions, and corresponding changes in the density of Na_2SO_4, are expected to be negligible for the low values of P_{SO_3} employed in the present study (maximum P_{SO_3} = 0.08 atm). At low values of P_{SO_3} and high values of P_{O_2}, the composition of Na_2SO_4, and its density, may change by formation of Na_2O_2 and NaO_2. Although data are not available for the relative concentrations of the latter oxides of Na in Na_2SO_4, the observation of constant values of the density of Na_2SO_4 for values of P_{SO_3} as low as 10^{-9} atm indicates that significant quantities of these oxides were not formed.

The densities measured in the present work are about 2% higher than those obtained by Jaeger, who used a hydrostatic weighing technique, which is a much better method to measure densities than the maximum bubble pressure method. Use of the latter method requires a measurement of the maximum bubble pressure in a single tube at two different depths of immersion and a measurement of the difference in the depths of immersion.

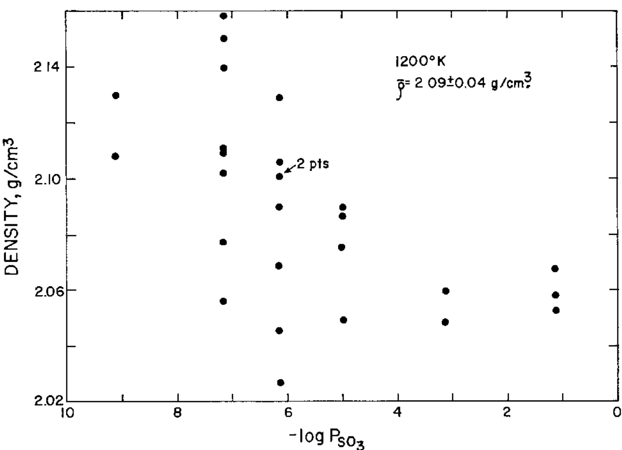
In the present investigation, the difference in the depths of immersion was measured using a Vernier scale on a rack and pinion that was used to support the bubble tubes. An error of 2% in the difference in the depths of immersion, which would correspond to about 0.02 cm in the present case, would yield an error of about 2% in the density.

The densities of Na_2SO_4 obtained by Jaeger (11) were employed in the present investigation to calculate the surface tension of Na_2SO_4 using the data obtained with the double-tube maximum bubble pressure method. Jaeger's measurements of the densities of molten salts are generally considered to be accurate (12). In any case, an error in the density of 10% yields an error of less than 0.5% in the surface tension when the double-tube method is employed.

Surface tension of Na_2SO_4.—The surface tension, σ, of molten Na_2SO_4 was measured at 1200 and 1250 K as a function of P_{SO_3} ($10^{-9} < P_{SO_3} < 10^{-1}$ atm). The results, which are presented in Fig. 3, demonstrate that σ is not a function of P_{SO_3} for the range of conditions studied.

The reproducibility of the measurements of the surface tension was good, *i.e.*, the largest value of one standard deviation for four measurements of σ at any one P_{SO_3} was $\pm$0.5% ($\pm$0.0009 N/m). The overall uncertainty of the measurements is estimated to be $\pm$1% ($\sim$ $\pm$0.002 N/m), which includes the uncertainties involved in measuring the diameters of the bubble tubes ($\pm$0.001 cm) and in measuring the maximum pressure in the bubbles with silicone oil manometers ($\pm$0.001 cm in the difference of the height of the legs of the manometer). Thus, the slight apparent variation of σ with P_{SO_3} shown in Fig. 3 is within the limits of the experimental uncertainty of the measurements. The bars around the points in Fig. 3 represent one standard deviation from the average value for two to four measurements at each P_{SO_3}. Each of the three points without bars represents the value of two measurements that yielded the same value of σ.

To test the accuracy of the measurements of the surface tension of Na_2SO_4, measurements of the surface tension of water at room temperature and of K_2SO_4 at 1400 K were made and compared to well-established values for these quantities. Six measure-



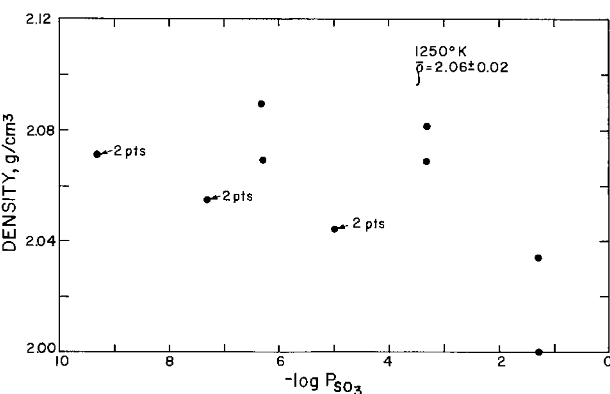


Fig. 2. Dependence of the density of molten Na_2SO_4 on SO_3 partial pressure at (a, left) 1200 and (b, right) 1250 K

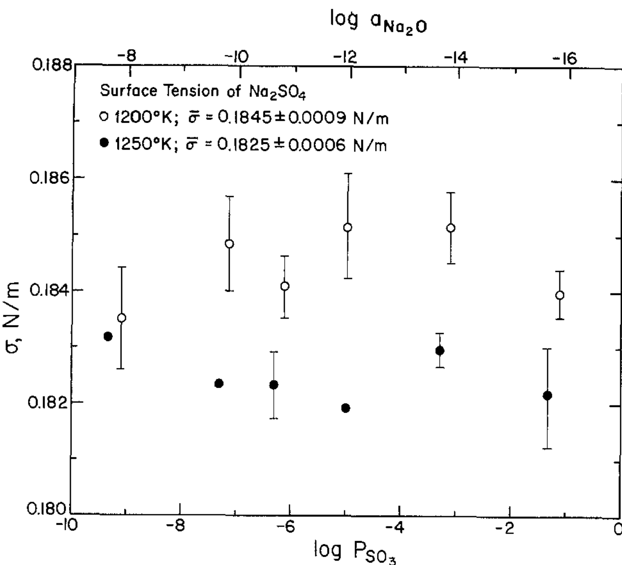

Fig. 3. Dependence of the surface tension of molten Na_2SO_4 at 1200 and 1250 K on the partial pressure of SO_3 gas.

ments of the surface tension of H_2O at 293 K yielded an average value of 0.07265 ± 0.00153 N/m, which is in good agreement with the value of 0.07275 N/m reported in the International Critical Tables (13). Two measurements of the surface tension of K_2SO_4 at 1400 K were made at each of two partial pressures of SO_3. The average values were 0.1381 and 0.1398 ± 0.0006 N/m at 2.2×10^{-2} and 10^{-5} atm of SO_3, respectively. Assuming that the surface tension of K_2SO_4 is independent of P_{SO_3}, one obtains an average value for the four measured values of 0.1389 N/m. The latter value agrees within 1% of the value of 0.1381 N/m obtained by Neithammer and Peake (14), who used a single-tube maximum bubble pressure apparatus with nitrogen gas. On the basis of these results, one can conclude that the accuracy of the present measured values of the surface tension of Na_2SO_4 is good.

The average values of σ at 1200 and 1250 K are 0.1845 ± 0.0009 and 0.1825 ± 0.0006 N/m, respectively, which were calculated from all of the measurements made at one temperature based on the conclusion that σ is independent of P_{SO_3}. The latter conclusion should be reserved for the range of values of P_{SO_3} employed in the experiments. At higher P_{SO_3} and lower temperatures, or at lower P_{SO_3} and higher temperatures, Na_2SO_4 may contain sufficient $(S_2O_7^{2-})$ or (O^{2-}) anions, respectively, to affect the surface tension.

Moiseev and Stepanov (2) measured the effect of various additives to Li_2CO_3 on its surface tension. Additions of Li_2O to molten Li_2CO_3 at 765°C caused a steady increase in the surface tension of Li_2CO_3 from about 0.242 N/m at 0 mole percent (m/o) Li_2O to about 0.260 N/m at 31 m/o Li_2O. The increase in surface tension was attributed to the increased concentration of (O^{2-}) anions in the melt, which have a higher effective dipole moment than (CO_3^{2-}) anions. Further increases in the concentration of dissolved Li_2O from 31 to 48 m/o caused a decrease in the surface tension, which was attributed to the formation of $(LiCO_3^-)$ complexes in the melt [at 31 m/o Li_2O in Li_2CO_3 there are approximately three (Li^+) cations per (CO_3^{2-}) anion].

By analogy with the results of Moiseev and Stepanov (2), the surface tension of Na_2SO_4 may increase at very low P_{SO_3} in equilibrium with the melt (high a_{Na_2O}) because of the increased concentration of (O^{2-}) anions. The surface tension of Na_2SO_4 at values of $P_{SO_3} < 10^{-9}$ atm has not been measured in the present study because the Pt-Rh bubble tubes and the Pt crucible would be dissolved by the highly basic salt (15).

To determine the temperature dependence of the surface tension of Na_2SO_4, measurements were made at a constant partial pressure of SO_3 gas equal to 10^{-5} atm over the temperature range of 1175-1400 K. Under these conditions, the activity of Na_2O in Na_2SO_4 varies from 3.1×10^{-13} at 1175 K to 4.3×10^{-9} at 1400 K, which is in the range of a_{Na_2O} for which σ is independent of P_{SO_3} (or a_{Na_2O}) at 1200 and 1250 K. A plot of the surface tension *vs.* temperature is shown in Fig. 4. The application of linear regression to the data yields,

$$\sigma = 2.568 \times 10^{-1} - 6.05 \times 10^{-5} T \quad [5]$$

where σ has units of N/m and T is the absolute temperature. The correlation coefficient for the linear regression analysis is 0.998. Note that σ changes by only ~0.013 N/m over the range of temperature investigated.

Jaeger (11) measured the surface tension of Na_2SO_4 using the single-tube maximum bubble pressure method over the temperature range of 1173-1350 K. His results, which were obtained using nitrogen gas, may be represented by the following quadratic equation (10)

$$\sigma = 4.765 \times 10^{-1} - 5.32 \times 10^{-4} T + 2.43 \times 10^{-8} T^2 \quad [6]$$

Jaeger's values for σ of Na_2SO_4 are about 5% higher than the values measured in the present investigation. Janz *et al.* (10) have pointed out that Jaeger's measurements of the surface tension of molten salts are generally 2-8% higher than measurements made more recently.,

The quadratic temperature dependence of σ found by Jaeger (11), if it is real, indicates that the surface tension at higher temperatures is greater than expected by a linear extrapolation of his data obtained at lower temperatures. Higher temperatures and low P_{SO_3} in the gas phase (pure N_2 was used by

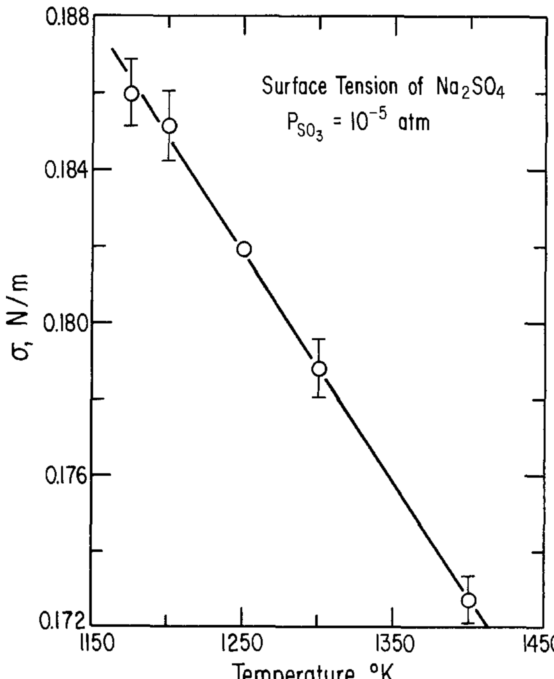

Fig. 4. Dependence of the surface tension of molten Na_2SO_4 on temperature.

Jaeger) causes the reaction in Eq. [1] to move to the right. Thus, it is conceivable that a sufficiently high a_{Na_2O} was attained in Jaeger's melts at the highest temperatures to cause a small increase in the surface tension of the Na_2SO_4. To test this premise, the surface tension of Na_2SO_4 should be measured as a function of temperature for well-defined, low values of P_{SO_3} (high a_{Na_2O}). In the meantime, the high accuracy of the measurements made in the present investigation indicates that Eq. [6] provides a better representation of the temperature dependence of the surface tension of Na_2SO_4 than that reported by Jaeger.

Summary

The density and the surface tension of Na_2SO_4 are independent of P_{SO_3} for partial pressures in the range of 10^{-1}-10^{-9} atm at 1200 and 1250 K. The constant value of the density indicates that Na_2SO_4 is virtually stoichiometric for this range of P_{SO_3}. A change in the surface tension of Na_2SO_4 with P_{SO_3} would require either a large change in composition with P_{SO_3} [large change in the concentrations of (O^{2-}), (O_2^{2-}), (O_2^-), or ($S_2O_7^{2-}$) with a change in P_{SO_3}], or a small change in the concentration of a highly surface-active species. The concentrations of (O^{2-}), ($S_2O_7^{2-}$), (O_2^-), and (O_2^{2-}) change by a small amount as P_{SO_3} is changed from 10^{-1} to 10^{-9} atm; however, because the surface tension of Na_2SO_4 is constant for this range of P_{SO_3}, none of these species can be considered to be highly surface active. The surface tension of Na_2SO_4 is a linear function of temperature (1175-1400 K) when P_{SO_3} is held constant at 10^{-5} atm.

Thermodynamics of Nickel-Aluminum-Oxygen System Between 900 and 1400 K

F. A. Elrefaie* and W. W. Smeltzer*

Department of Metallurgy and Materials Science, McMaster University, Hamilton, Ontario, Canada L8S 4M1

ABSTRACT

Equilibrium oxygen pressures of the univariant systems Ni-NiO-$NiAl_2O_4$, and Ni-$NiAl_{2.54}O_{4.81}$-Al_2O_3 were determined between 1123 and 1423 K using galvanic cells with calcia-stabilized zirconia as the solid electrolyte. Slip-cast tubes of a two-phase mixture of β- and α-Al_2O_3 were used as electrolyte in cells to determine the equilibrium oxygen pressures of the univariant Ni-$NiAl_{2.54}O_{4.81}$-Al_2O_3 between 923 and 1173 K and the dissociation pressure of Al_2O_3 equilibrated with (Ni-Al) alloys containing 0.17, 1.19, and 2.36 atomic percent Al at 1213 K. The free energy of formation of $NiAl_{2.54}O_{4.81}$ was determined between 923 and 1423 K. An electron probe microanalyzer was used to determine the composition of oxides and alloy phases of the ternary Ni-Al-O system that coexist with each other at 1273 K. The Ni-Al-O isotherm at 1273 K and Ni-Al-O equilibrium oxygen pressure diagrams at 1213 and 1273 K are presented.

Equilibrium oxygen pressures of the coexistences of the Ni-Al-O system have not been extensively investigated, probably due to the very low oxygen pressures encountered. The free energy of formation of nickel spinel, NiO · $(1 + x)Al_2O_3$, has been determined at temperatures in the range 973-1673 K using galvanic cells with calcia-stabilized zirconia as solid electrolyte (1-4) or by equilibrating the mixture Ni-NiO ·

Key words: solid electrolyte, emf, equilibrium.

$(1 + x)Al_2O_3$-Al_2O_3[1] with a CO/CO_2 atmosphere (5). Published data, however, are in poor agreement. Aluminum activities in Ni-Al alloys containing between 15 and 60 atomic percent (a/o) Al were studied over the temperature range 1185-1455 K using isopiestic measurements (6). Values of aluminum activities in alloys containing 69.96-99.46 a/o Al at temperatures in the range 956-1200 K have been evaluated from electromotive force measurements with $AlCl_3$ in $NaCl \cdot KCl$ liquid electrolyte (7). Nickel activities in Ni-Al alloys are reported at 1273 K (8, 9). The Ni-Al system is well established (10) and the phase relations in the subsolidius region of the NiO-Al_2O_3 quasi-binary system are reported between 1273 and 2193 K (11). The lack of compositional data for the ternary Ni-Al-O isotherm and the development of the two-phase mixture of β- and α-Al_2O_3 electrolyte to sense reversibly oxygen pressures as low as those of Al-Al_2O_3 equilibria (12, 13) led us to initiate this work to determine the Ni-Al-O isotherm and the oxygen pressures for equilibria involving alloy and oxide phases at temperatures in the range 923 and 1423 K.

Experimental

Equilibrium oxygen pressures of the coexistences Ni-NiO-$NiAl_2O_4$, $Ni_{(s)}$-$NiAl_{2.54}O_{4.81}$-Al_2O_3, and (Ni-Al) alloy-Al_2O_3 were determined from emf measurements on the following cells

$$\text{Ni, NiO, NiAl}_2\text{O}_4|\text{ZrO}_2(+\text{CaO})|\text{Ni, NiO} \quad [I]$$

$$\text{Ni, NiAl}_{2.54}\text{O}_{4.81}\text{, Al}_2\text{O}_3|\text{ZrO}_2(+\text{CaO})|\text{Ni, NiO} \quad [II]$$

$$\text{W, WS}_2\text{, Na}_2\text{S}|\beta\text{- and }\alpha\text{-Al}_2\text{O}_3|\text{Ni, NiAl}_{2.54}\text{O}_{4.81}\text{, Al}_2\text{O}_3 \quad [III]$$

$$\text{(Ni-0.17 a/o Al) alloy, Al}_2\text{O}_3|\text{ZrO}_2(+\text{CaO})|\text{Ni, NiO} \quad [IV]$$

$$\text{(Ni-Al) alloy, Al}_2\text{O}_3|\beta\text{- and }\alpha\text{-Al}_2\text{O}_3|\text{W, WS}_2\text{, Na}_2\text{S} \quad [V]$$

A previously described cell assembly (14) that contained a 30 cm long tube of calcia-stabilized zirconia was used to measure the emf's of cells [I], [II], and [IV] between 1123 and 1423 K. The emf of cell [III] was measured between 923 and 1173 K while the emf of cell [V] was measured at 1213 K using a previously described cell assembly (15) which contained a 10 cm long β- and α-Al_2O_3 tube as the electrolytic membrane between the anode and cathode compartments.

A potential shown by cells [I], [II], [III], and [V] at a temperature in the investigated range was very steady, within ±1 mV or less, for periods investigated up to 45 min. When the temperature was changed, a new steady state was reached after 2-4 hr with furnace temperature stabilization occurring within 20-40 min. Reversibility of cells [I] and [II] was checked by charging or discharging a cell through an external circuit momentarily; the cell emf returned very rapidly to a value within at most ±1 mV from the original value. A thermal disturbance method was used to check the reversibility of cells [III] and [V]. The cell temperature was cycled several times then fixed at the plateau-attaining temperature; the emf attained its original value, to ±1 mV, within 5 min and remained at this potential for the investigated period.

Reference Ni,NiO electrodes were tablets pressed from 1:1 mixture of Ni and NiO. The W, WS_2, Na_2S reference electrodes of cells [III] and [V] were prepared as described previously (16). The working electrodes were fabricated as tablets from mixtures of the metallic and oxide phases. Compositions of mixtures used for preparing tablets to be used as electrodes and for phase composition and identification analyses are given in Table I. Such tablets were annealed for a period of 30-60 days under flowing high-purity argon gettered of oxygen using Zr chips. X-ray analyses confirmed the presence of the desired phases in each tablet after annealing, while compositions of these phases were determined using EPMA (electrode probe microanalysis) technique. Materials used and their sources are listed in Table II.

[1] Al_2O_3 is used to represent α-Al_2O_3 in the text.

Table I. Starting compositions of coexisting alloy and oxide phases

* P-1 and P-2 tablets were annealed at 1000°C for 60 days while the other pellets were annealed for 30 days at 1000°C.
** $NiAl_2O_4$ was prepared as we described previously (11).

Results

Cell [I].—Electromotive force values of cell [I], Fig. 1, fit the least squares expression

$$E(\text{mV}) = 0.7(\pm 0.03) + 0.0032(\pm 0.0002)\ T\ (\pm 0.1\ \text{mV}) \quad [1]$$

Cell [II].—Electromotive force values representing the univariant equilibrium Ni, $NiAl_{2.54}O_{4.81}$, α-Al_2O_3 are plotted in Fig. 2; the linear plot fits the least squares expression

$$E(\text{mV}) = 64(\pm 2.5) + 0.047(\pm 0.002)\ T\ (\pm 1.0\ \text{mV}) \quad [2]$$

Cell [III].—The variation with temperature of the emf of this cell, Fig. 3, is described by the least squares line

$$\text{E(mV)} = 1117(\pm 3) - 0.444(\pm 0.003)\ T\ (\pm 2\ \text{mV}) \quad [3]$$

Cell [IV].—Unstable emf's were exhibited by this cell; this electrical instability was not amenable to correction by coulometric disturbance or by temperature cycling of the cell.

Cell [V].—The emf of cell [V] was determined only at 1213 K. The investigated working electrodes were Ni containing 0.17, 1.19, or 2.36 a/o Al alloys equilibrated with Al_2O_3; the emf values obtained were 19 ± 1, 119 ± 2, and 151 ± 1 mV, respectively.

Compositions determined by EPMA for the coexisting oxide and alloy phases at 1273 K are recorded in Table III. The intensity of the Al x-ray signals obtained from the metallic phases of Ni-NiO-$NiAl_2O_4$ and Ni-$NiAl_{2.54}O_{4.81}$-Al_2O_3 coexistences would not be distinguished from the background intensity which indicates that these phases were essentially pure nickel.

Discussion

Ni-NiO.—This coexistence was used as a reference electrode in cells [I] and [II]. Steele (17) has described the standard free energy of formation of NiO, $\Delta G°_f(\text{NiO})$, by

$$\Delta G°_f(\text{NiO}) = -55{,}965 + 20.29\,T \text{ cal/mol } (\pm 130 \text{ cal}), \quad (900\text{-}1400 \text{ K}) \quad [4]$$

The equilibrium oxygen pressure of the Ni,NiO coexistence, $P_{O_2}*$, is therefore given by

$$\log P_{O_2}* \text{ (atm)} = -\frac{24{,}464}{T} + 8.869\left(\pm\frac{57}{T}\right), \quad (900\text{-}1400 \text{ K}) \quad [5]$$

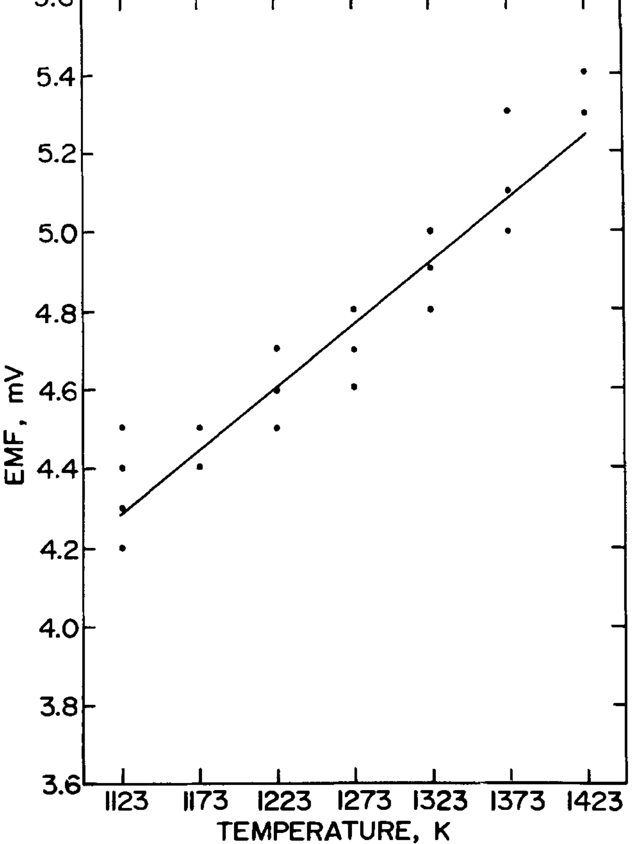

Fig. 1. The variation of emf with temperature for cell [I]

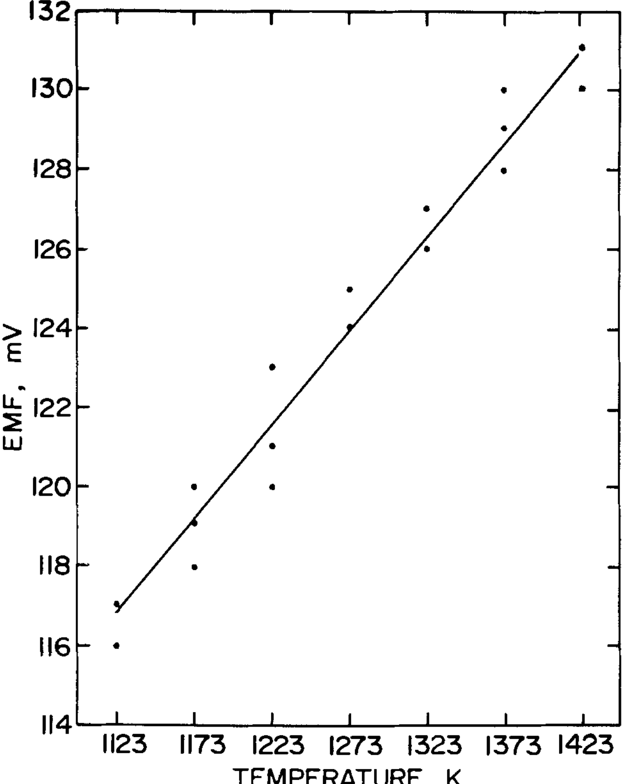

Fig. 2. The variation of emf with temperature for cell [II]

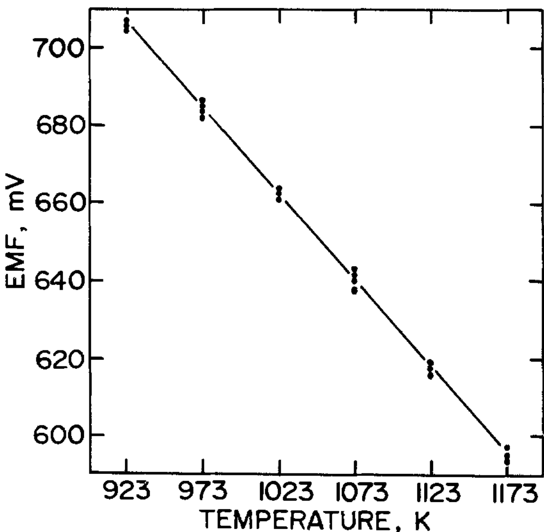

Fig. 3. The variation of emf with temperature for cell [III]

Ni-NiO-NiAl₂O₄ coexistence.—Since the overall reaction in cell [I] can be described by transfer of oxygen from the cathode to the anode compartment, the cell emf is given by

$$E = \frac{RT}{4F} \ln P_{O_2}*/P_{O_2} \quad [6]$$

where P_{O_2} is the equilibrium oxygen pressure of the Ni-NiO-$NiAl_2O_4$ coexistence. Values of P_{O_2} between 1123 and 1423 K, therefore, were calculated by means of Eq. [1], [5], and [6], and found to follow the relation

$$\log P_{O_2} \text{ (atm)} = -\frac{24{,}478}{T} + 8.804\left(\pm\frac{60}{T}\right), \quad [1123\text{-}1423 \text{ K}] \quad [7]$$

The oxygen pressure of this coexistence calculated from Eq. [7] at 1273 K is 3.76×10^{-11} atm which is

slightly less than the value of 4.48×10^{-11} atm for the dissociation pressure of NiO equilibrated with Ni. The EPMA analyses of the phases of this coexistence at 1273 K indicated the following: the spinel composition corresponded to the stoichiometric formula $NiAl_2O_4$, NiO dissolves approximately 1 mol percent (m/o) of Al_2O_3, and the metallic phase was essentially pure Ni.

Ni-$NiAl_{2.54}O_{4.81}$-Al_2O_3 coexistence.—Cells using calcia-stabilized zirconia as electrolyte with a Ni,NiO reference electrode, cell [II], or the two-phase β- and α-Al_2O_3 electrolyte and W, WS_2, Na_2S as standard electrode, cell [III], were investigated to study this system. The best line through the emf values obtained from cell [II] between 1123 and 1423 K was represented by Eq. [2]. Also the emf data of cell [III] obtained over the temperature range 923-1173 K is found to follow relation [3]. Electromotive force of the cell

$$W, WS_2, Na_2S|\beta\text{- and }\alpha\text{-}Al_2O_3|Ni, NiO$$

was measured between 923 and 1198 K (15) and found to follow the relation

$$E(\text{mV}) = 1180(\pm 4) - 0.396(\pm 0.004)\ T\ (\pm 2\ \text{mV}) \quad [8]$$

By subtracting expression [3] from [8], we obtained

$$E(\text{mV}) = 63(\pm 5) + 0.048(\pm 0.005)\ T\ (\pm 3\ \text{mV}) \quad [9]$$

Relation [9] describes the emf dependence of the cell

$$Ni, NiAl_{2.54}O_{4.81}, Al_2O_3|\beta\text{- and }\alpha\text{-}Al_2O_3|Ni, NiO \quad [VI]$$

on temperature. Excellent agreement between Eq. [9] and [2] demonstrates the applicability of using the two-phase β- and α-Al_2O_3 electrolyte in probes to sense oxygen potentials as low as those of the Ni-$NiAl_{2.54}O_{4.81}$-Al_2O_3 coexistence.

The reaction in cells [II] and [VI] can be written as

$$O_2{}^c = O_2{}^a \quad [A]$$

where $O_2{}^c$ and $O_2{}^a$ are oxygen in the cathode and anode compartments, respectively. Alternatively, the overall cell reaction can be written as

$$NiO + 1.27Al_2O_3 = NiAl_{2.54}O_{4.81} \quad [B]$$

By considering reaction [A], the variation of the equilibrium oxygen pressure of the Ni-$NiAl_{2.54}O_{4.81}$-Al_2O_3 univariant system with temperature is obtained by combining expressions [2], [5], and [6]; these calculations give

$$\log P_{O_2}\ (\text{atm}) = -\frac{25{,}754}{T} + 7.921\left(\pm\frac{60}{T}\right), \quad (923\text{-}1423\ \text{K}) \quad [10]$$

where P_{O_2} is the equilibrium oxygen pressure of the Ni-$NiAl_{2.54}O_{4.81}$-Al_2O_3 coexistence. The value of P_{O_2} at 1273 K equal to 4.90×10^{-13} atm is approximately two orders of magnitude less than the dissociation pressure of NiO equilibrated with Ni. At 1273 K, the spinel in this coexistence was found by EPMA to contain 56 m/o Al_2O_3; therefore, it can be represented by the formula $NiAl_{2.54}O_{4.81}$. The EPMA results also indicated that Al_2O_3 contains 0.4 a/o Ni but the solubility of Al in Ni necessary to stabilize this coexistence was found to be too small to be determined by this technique.

The variation with temperature of the free energy of formation of $NiAl_{2.54}O_{4.81}$ from its binary oxides, $\Delta G(NiAl_{2.54}O_{4.81})$, given by reaction [B], is related to emf values of cell [II] by

$$\Delta G(NiAl_{2.54}O_{4.81}) = -2\mathbf{F}E \quad [11]$$

Values for the ΔG-T relation obtained by combining relations [2] and[11] are given in Table IV together with those values obtained by various investigators. The temperature coefficient obtained in this investigation, -2.168 cal/deg-mol, is in good agreement with values reported by Jacob and Alcock (4), -2.31 cal/deg-mol, and Lenev and Novokhatskii (5), -2.44 cal/deg-mol.

(Ni-Al)-Al_2O_3 equilibria.—The EPMA results demonstrated that Al_2O_3 coexisted practically with the (Ni-Al) alloy over its entire composition range. The dissociation pressure of Al_2O_3, therefore, decreased from the equilibrium oxygen pressure of the Ni-$NiAl_{2.54}O_{4.81}$-Al_2O_3 univariant system to values defined by the Al-Al_2O_3 equilibria with increasing Al alloy content. In this investigation, the dissociation pressure of Al_2O_3 equilibrated with Ni-Al alloys containing 0.17, 1.19, 2.36 a/o Al was determined by relating the emf values of cell [V] with thermochemical data of the cell reaction

$$WS_2 + 2(Na_2O)_\beta = 2Na_2S + O_2 + W \quad [C]$$

where O_2 is oxygen of the (Ni-Al)-Al_2O_3 coexistence. For this reaction, we can write

$$\Delta G = 2\Delta G^\circ{}_f(Na_2S) - 2\Delta G^\circ{}_f(Na_2O) - \Delta G^\circ{}_f(WS_2) - 2RT \ln a_{Na_2O} + RT \ln P_{O_2} \quad [12]$$

Here, a_{Na_2O} is the Na_2O activity of the α-Al_2O_3 and β-Al_2O_3 coexistence and P_{O_2} is the dissociation pressure of Al_2O_3 equilibrated with the (Ni-Al) alloy. Upon substituting $\Delta G = -4\mathbf{F}E$ in relation [12] and rearranging, we obtain

$$\log P_{O_2} = \frac{1}{2.303RT}\left[2\Delta G^\circ{}_f(Na_2O) + \Delta G^\circ{}_f(WS_2) + 2RT \ln a_{Na_2O} - \Delta G^\circ{}_f(Na_2S) - 4\mathbf{F}E\right] \quad [13]$$

Values of P_{O_2} of the working electrodes of cell [V] were calculated at 1213 K using Eq. [13], the measured values of E and the thermochemical data reported in our previous publication (15). The obtained values of P_{O_2} are 5.7×10^{-24}, 1.2×10^{-25}, and 3.7×10^{-26} for Ni alloys containing 0.17, 1.19, and 2.36 a/o Al in equilibrium with Al_2O_3, respectively. It is apparent from these results that the electrical instability of cell [IV] can be explained on the basis of electronic conduction in the calcia-stabilized zirconia electrolyte because the oxygen pressures imposed by the coexistence (Ni-0.17 a/o Al)-Al_2O_3 at 1213 K, 5.7×10^{-24} atom, is less than the value of oxygen pressure defined by the lower electrolytic domain boundary of calcia-stabilized zirconia (18).

Thermodynamic properties of Ni-Al alloys.—The Al activity of an alloy, a_{Al}, equilibrated with Al_2O_3 is given by

$$a_{Al} = P_{O_2}{}^{-3/4} \exp\left[\frac{\Delta G^\circ{}_f(Al_2O_3)}{2RT}\right] \quad [14]$$

where P_{O_2} is the dissociation pressure of Al_2O_3 equilibrated with the alloy. Values of a_{Al} given in Table V were calculated using relation [14]. The value of the Al activity coefficient was essentially constant, $\gamma_{Al} \simeq 4 \times 10^{-8}$, at 1213 K over the range 2.36-0.17 a/o Al corresponding to Henrian solution behavior. This value is to be compared with $\gamma_{Al} = 8 \times 10^{-7}$ reported at 1273 K (9).

Table V. Activity and activity coefficient of Al in Ni-Al alloys (referred to liquid Al as standard state)

Coexistence	Temperature (K)	a_{Al}	X_{Al}	γ_{Al}
(Ni-2.36 a/o Al)-Al_2O_3	1213	1.0×10^{-9}	0.0236	4.2×10^{-8}
(Ni-1.19 a/o Al)-Al_2O_3	1213	8.0×10^{-10}	0.0119	6.8×10^{-8}
(Ni-0.17 a/o Al)-Al_2O_3	1213	4.0×10^{-11}	0.0017	2.4×10^{-8}
Ni-$NiAl_{2.54}O_{4.81}$-Al_2O_3	1213	2.0×10^{-18}	$\simeq 1 \times 10^{-11}$*	—
	1273	1.0×10^{-17}	$\simeq 1 \times 10^{-11}$*	—

* These values of X_{Al} were calculated using the relation $X_{Al} = a_{Al}/\gamma_{Al}$.

As emphasized previously, Al alloy contents necessary to stabilize the Ni-$NiAl_{2.54}O_{4.81}$-Al_2O_3 coexistence were too small to be detected by EPMA. If one considers the values of γ_{Al} at 1213 and 1273 K, an atom fraction of Al equal to $\simeq 1 \times 10^{-11}$, *i.e.*, $<< 1$ ppm of Al, is calculated for stabilization of the Ni-$NiAl_{2.54}O_{4.81}$-Al_2O_3 coexistence.

Ni-Al-O isotherm at 1273 K.—The isotherm shown in Fig. 4 was compiled from the results reported in Table III. In this diagram, the NiO and Al_2O_3 phase fields have been enlarged to illustrate the very limited solubility of Al in NiO, 1.87 a/o Al, and of Ni in Al_2O_3, 0.4 a/o Ni. A value of 0.051 a/o was reported (10) for oxygen solubility in Ni at 1273 K and molten Al dissolves $\simeq$ 0.005 a/o oxygen (10). Accordingly the curve representing oxygen solubility in the alloy is schematic because of the lack of information to establish a defined boundary. Limiting compositions of the metallic phases were taken from the Ni-Al binary system (10). As the figure indicates, Al_2O_3 equilibrates with Ni-Al alloys essentially over its whole composition range. Nickel solubility in Al_2O_3 decreases with increasing Al content of the alloy: Al_2O_3 equilibrated with Ni-0.17 a/o Al alloy contains 0.38 a/o Ni and 0.16 a/o Ni when equilibrated with a Ni-53.7 a/o Al alloy. The spinel phase, which has a homogeneity range between 50 and 56 m/o Al_2O_3, coexists essentially with pure nickel.

Equilibrium oxygen pressure diagram for the Ni-Al-O system.—Figures 5a and b show the variation of the equilibrium oxygen pressure with the Ni metal atom fraction, $X_{Ni} = n_{Ni}/(n_{Ni} + n_{Al})$, of the solid phases at 1213 and 1273 K, respectively. Dissociation pressures of pure NiO were calculated using relation [5] while the oxygen pressures of the univariant system Ni-NiO-$NiAl_2O_4$ and Ni-$NiAl_{2.54}O_{4.81}$-Al_2O_3 were obtained from relations [7] and [10], respectively. Dissociation pressures of Al_2O_3 equilibrated with alloys containing $X_{Al} \geq 0.0236$ at 1213 K were determined in this investigation while P_{O_2} values corresponding to alloys containing $0.6 \geq X_{Al} \geq 0.05$ were evaluated by considering the following relation

$$P_{O_2} = a_{Al}^{-4/3} \exp\left[\frac{2\Delta G^\circ_f(Al_2O_3)}{3RT}\right] \quad [15]$$

Values of a_{Al} used in Eq. [15] to calculate P_{O_2} at 1213 K were calculated by considering the a_{Al} and $\Delta \bar{H}_{Al}$ data reported by Steiner and Komarek at 1273 K over the composition range $0.6 \geq X_{Al} \geq 0.15$; a_{Al} at $X_{Ni} = 0.95$ was calculated from the thermochemical data reported by Schaefer (7) and Hultgren *et al.* (9) at 1273 K. Results given by Schaefer (7) for a_{Al} were used to calculate the dissociation pressure of Al_2O_3 at 1273 K. The diagrams show that the oxygen pressure of the Ni-$NiAl_{2.54}O_{4.81}$-Al_2O_3 coexistence is less than that of Ni, NiO equilibrium by $\simeq$ 2 orders of magnitude. With increasing Al content of the alloy, the oxygen pressure decreases most markedly over the alloy composition range $X_{Al} < 0.1$ and it subsequently decreases with Al content to the value corresponding to the Al-Al_2O_3 binary equilibrium (19).

Influence of Semiconducting Character of Synthetic PbS Crystals on their Corrosion in Nitric Acid

Claudio Gutiérrez

Instituto de Química Física "Rocasolano," Serrano 119, Madrid-6, Spain

Several contradictory results have been reported on the influence of semiconducting character of synthetic PbS crystals and/or natural galena crystals on its corrosion rate. Simkovich and Wagner (1) found that the corrosion rate in 6M HNO_3 at 60°C for synthetic PbS crystals increased in the order Pb-excess(n)PbS < S-excess(p)PbS < stoichiometric PbS ≈ Bi_2S_3 doped (strongly n) PbS < Ag_2S-doped (strongly p) PbS. The corrosion rate was highest for Ag_2S-doped (strongly p) PbS, and PbS with excess S (p-type) corroded at a slightly higher (30%) rate than Pb-excess PbS (n-type). However, this increase in corrosion rate of PbS with p-semiconducting character was not monotonic. On the other hand, Seltzer and Wagner (2) found that Bi_2S_3-doped (n)PbSe crystals dissolved much more rapidly than Ag_2S-doped (p) or undoped PbSe, a semiconductor very similar to PbS.

Eadington and Prosser (3) worked with PbS powder prepared by addition of a sodium sulfide solution to a lead nitrate solution, after which the nonstoichiometry of PbS was adjusted by heating in a sulfur atmosphere. They found that the oxidation rate by dissolved O_2 of the PbS powder in aqueous suspension increased monotonically with its p-character. On the contrary, Eadington (4) found that the initial dissolution rate of ground galena and synthetic PbS powder in 10^{-5}M HNO_3 at room temperature increased with the n-character of the sample, although the dissolution rate decreased to a much lower, constant value for all the samples before dissolution of a monolayer had been reached. This author believes that experiments with PbS powder are especially prone to artifacts, as it is known that polycrystalline n-PbS chemisorbs O_2 immediately after exposure to air.

The results reported here, although not quantitative, present a clearcut difference between n- and p-PbS.

Experimental

The synthesis and conditioning of PbS crystals have been described elsewhere (5). PbS powder was obtained by a wet method. Crystals were then obtained by the Bridgman-Stockbarger method in a vertical furnace, with the powder inside an evacuated, sealed silica tube. The semiconducting character of these crystals was changed by heating at 500°C in a controlled sulfur pressure. Resistivities of the crystals were in the range 0.002-0.02 Ω · cm. Unfortunately, the PbS ingot broke easily into small pieces, and the small size of the crystals prevented the measurement of Hall effect and corrosion rates; their semiconducting character was obtained from the sign of the thermoelectric power. The crystals were embedded in Araldit at the end of a length of Pyrex tubing, electrical contact to the inner side being made with mercury. They were polished with 5.0 μm alumina (Buehler No. 1) on AB Microcloth (Buehler).

Ultrapure water was obtained from a Milli-RO + Milli-Q system from Millipore. Reagents were of analytical grade. Potentials were measured against a saturated calomel electrode with a Leeds and Northrup pH-meter, Model 7415, input impedance > 10^{13} Ω. Experiments were conducted in the open and without stirring.

Key words: semiconductors, corrosion, potential.

Results

1:1 conc. HNO_3:water (6.5M HNO_3).—The n-type crystals acquired in about 1 min a potential of + 270 . . . + 325 mV, and took a black tarnish. On the other hand, the p-samples remained at −40 . . . +20 mV for about 8 min, after which the potential increased to + 250 . . . + 300 mV; the black tarnish was slightly less than for the n-samples.

1:1 conc. HNO_3:acetone (6.5M HNO_3).—After 1 min all the samples had very positive potentials, + 290 to + 350 mV. They took beautiful tarnishing colors, the n-samples more quickly (< 1 min) than the p-samples (> 2 min).

6M HNO_3, 10% in acetone.—The n-samples took in 2 min a potential of + 170 . . . + 330 mV, while the p-samples remained at potentials negative *vs.* SCE for at least 11 min. The most p-type sample kept a negative potential for 36 min, after which the experiment was interrupted. Correspondingly, it remained shiny, while the other p-samples took beautiful blue and red tarnishing colors. On the other hand, the n-samples became blackish.

1M HNO_3.—In all cases the potential increased with time, but after 10 min the rate of increase only was ≤1 mV/min. At 10 min the potential of the n-samples was + 155 . . . + 170 mV, while that of the p-samples was − 10 . . . 0 mV. All samples remained shiny.

10^{-4}M HNO_3.—After 10 min the potential changed less than 1 mV/min. It was + 270 . . . + 260 mV for the n-samples, and 40 mV for the p-samples. All samples remained shiny.

Deionized water from the Milli-Q + Milli-RO system, with dissolved oxygen as the only oxidant.—After 10 min the potential increase was of only a few mV/min. The potential increased with n-character, from − 130 mV for the more p-type to + 150 mV for the more n-type PbS. All samples remained shiny.

Discussion

For the six solutions studied, the potential of polished PbS crystals increased with n-semiconducting character. At least some of the corrosion products remain on the surface, affecting the value of the potential, which

will not correspond to the intersection of anodic and cathodic lines in an Evans diagram. This makes it impossible to correlate the corrosion mechanism with the potential following the classical study of Gerischer with germanium (6).

The opposite behavior of the potential (potential decrease with increasing n-semiconducting character) was reported previously (7) for PbS pellets sintered at 500°C with a density 80% of that of crystalline PbS. We attribute this difference in the behavior to the porosity of the pellets, as we have now found that the resistivity of n- (and also slightly p-) pellets had changed with time, undoubtedly due to bulk oxidation of PbS by atmospheric oxygen. This is clearly seen in Table I. Only the more p-type sample did not change its resistivity, while that of the more n-type sample increased by 2 orders of magnitude. This is a clear proof that the bulk of the PbS pellets was accessible to oxygen, which reacted with n-type (and also slightly p-type) samples, consuming free electrons.

It becomes obvious that the previous results (7) obtained with sintered PbS pellets could correspond to samples oxidized to a variable extent by atmospheric oxygen.

If it is accepted that larger positive potential increases correspond to higher corrosion rates, the higher corrosion rate of n-PbS crystals would imply a donation of conduction-band electrons to the oxidant. This does not seem probable, as typical oxidants take electrons from the valence band.

It is remarkable that a difference in corrosion behavior exists at all between n- and p-type PbS, as its bandgap is only 0.41 eV. Apparently there is only one similar case, that of silicon etching in $HNO_3 + HF$ aqueous solutions (8), where the corrosion rate was at a maximum for p-Si with a resistivity in the range 0.1-0.001 Ω · cm. Also a maximum in the thickness-resistivity curve has been reported for the insoluble "surface porous film" that grows on top of a thicker active "porous silicon layer" in the anodic oxidation of p-Si in 50% HF aqueous solution (9).

Silicon Sheet for Solar Cells

A. Sanjurjo*

SRI International, Materials Research Laboratory, Menlo Park, California 94025

The cost of photovoltaic devices can be lowered substantially if efficient photovoltaic solar cells can be fabricated from polycrystalline, rather than from single crystal, silicon. Polycrystalline silicon substrates for solar cell fabrication can be formed by solidifying molten silicon as unsupported sheets. Typical methods include the Web-Dendritic process (1) and the die-based techniques such as Edge Fed Growth (2) and Stepanov (3). Although solar cells of acceptable quality have already been manufactured from silicon sheet obtained by these techniques, certain problems still remain. Some of the problems result from the difficulty of maintaining constant sheet parameters such as width and thickness during sheet growth. The use of dies helps to minimize this problem, but introduces another problem that stems from the incompatibility of molten silicon with most materials. The use of silica as a die material is precluded because at the temperature of sheet growth (~ 1410°C), this material softens and the die loses its shape. Graphite is thermally stable at this temperature, but it reacts with silicon to form SiC. The formation of SiC can be reduced to a layer a few micrometers thick on the graphite surface (Fig. 1) by using high density graphite; however, SiC is soluble in molten silicon, and upon solidification of the sheet, SiC precipitates, thereby degrading the crystallinity of the Si. Attempts to coat the graphite with a variety of inert ceramic coatings—including oxides, nitrides, carbides, borides, and silicides (4)—have only been partially successful because the coatings can be attacked by the molten silicon transferring impurities to the silicon.

This paper describes a method to cast silicon sheet that uses graphite as the construction material for crucibles and dies and uses fused salts, such as NaF, to avoid the reaction between Si and graphite.

The major novelty introduced in this work consists of the development of a coating for the molten silicon,

* Electrochemical Society Active Member.
Key words: silicon sheet, solar cells, sodium fluoride.

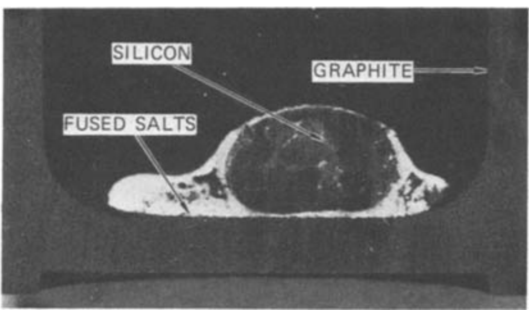

Fig. 1. Silicon melted in a graphite crucible with a liquid barrier coating.

rather than for the die itself. The method relies on favorable values of the surface tensions between molten salts, molten silicon, and graphite (5). For example, when Si and NaF are melted at 1430°C, silicon is strongly wetted by NaF, whereas the NaF does not wet the graphite. This combined surface tension behavior prevents silicon from contacting the graphite (Fig. 1) and thus from reacting appreciably with it. With the NaF coating, liquid silicon can be pressed in a graphite rod-piston system to form a flat pool of silicon that, upon cooling, solidifies into a sheet of silicon protected and separated from the graphite by the molten NaF salt. The sheet can then be removed or allowed to cool further until the salt solidifies. In the latter case, the sheet is removed by dissolving the salt in an aqueous solution. Finally, a brief discussion is presented on the effects of the impurities of the original materials on the purity of the resulting silicon sheet.

Experimental

High purity silicon particles were mixed with reagent grade NaF in proportions ranging from 20 to 50 weight percent (w/o) Si. The silicon particle sizes ranged from 0.1 to 1 cm. A shallow graphite crucible (2.5 mm high, 2.5 cm ID) was loaded with Si-salt mixtures so that the silicon would partially fill the graphite crucible (Fig. 2). Salt mixtures containing NaF-CaF_2 and NaF-Na_2SiO_3 were used in addition to pure NaF. The loaded crucible was covered with a graphite lid to which pressure was applied by means of a metal weight (Fig. 2). Pressures of 0.07-0.50 Nw/m^2 were applied. The ensemble was placed on an alumina pedestal inside a quartz chamber, and heating was provided by induction in the graphite crucible, lid, and metal weight. For each experiment the system was first evacuated and then flushed with argon during actual melting. The temperature was monitored by optical pyrometry. The rate of heating was about 100°C per min and the samples were kept at 1430° ± 20°C for 1-3 min to allow the silicon to melt and coalesce into a flat pool under the pressure of the metal weight. The power was then turned off, and the sample temperature was quenched by a rapid flow of argon. The cooling rate was about 300°C per min. After removal from the reactor, the ensemble was immersed in an aqueous acid solution. Typically, the graphite lid could be removed easily; however, the bonding layer of NaF between the Si disk and the graphite crucible required about 30 min in the acid solution before the Si disk could be detached from the crucible.

The surface of the silicon disk was etched and resistivity measurements were made with a four-point probe. In parallel experiments, the level of impurities in silicon before and after melting in contact with NaF was analyzed by plasma emission spectroscopy (PES) and arc emission spectroscopy (AES). X-rays, scanning electron microscopy (SEM), and energy dispersive analysis (EDAX) were also used to characterize the silicon disk and the graphite walls.

The silicon samples for PES analysis were prepared by slow digestion of silicon in an HNO_3-HF solution. To minimize interferences of the silicon signal with that of the other impurity elements, the final level of silicon in the acid solution was reduced to less than 100 ppm by weight by concentration in an excess of HF. The solution was then diluted with 1*N* HCl and injected in the PES system. Blanks of the solution (without silicon) treated in an identical manner were used to calibrate the system. In addition, small, well-determined amounts of silicon (as silicate) were introduced in the blank solution to determine its influence on the peak intensity of other elements. The interferences were very small or negligible. In any case, background blanks were used to correct the final readings.

Results and Discussion

The dimensions of the silicon disks produced by pressing in molten salts (Fig. 3a) ranged from 2 to 3 cm in diameter and 1 to 3 mm in thickness. For a given amount of silicon, the thickness depended basically on the pressure exerted by the metal weight. The mini-

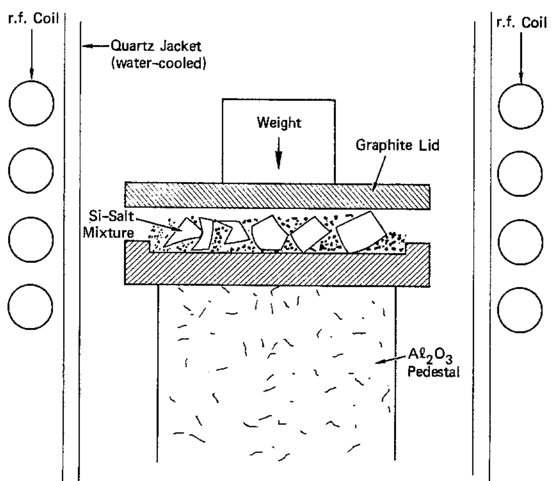

Fig. 2. Silicon pressing system

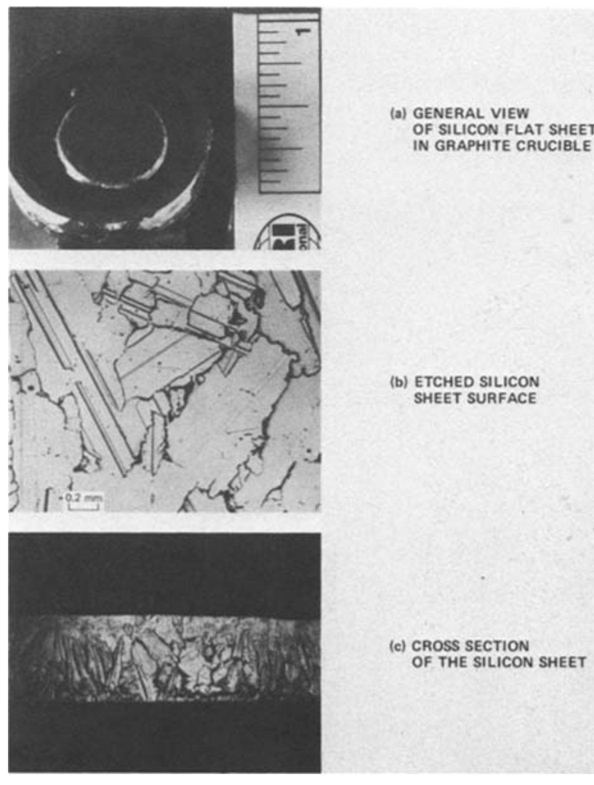

Fig. 3. Silicon sheet

mum thickness was limited by the height of the shallow crucible. Thinner sheets were produced by reducing the height of the crucible, but better control of pressing and temperature is required to obtain more consistent results than those achieved with the system described, which was designed only to demonstrate feasibility. As shown in Fig. 3a, the disks were slightly smaller in diameter than the graphite crucible. As a result of silicon expansion during solidification, it is desirable to reduce the diameter to avoid cracking of the silicon sheet or the walls of the graphite crucible.

Similar results were obtained with pure NaF, Na-CaF_2 (1:1) mixtures, and NaF-Na_2SiO_3 mixtures with up to 10 w/o of Na_2SiO_3. Mixtures with a higher content of Na_2SiO_3 (20 w/o) resulted in the formation of numerous small silicon spheres instead of a single silicon pool and were not used for pressing experiments.

The silicon sheets obtained by this technique were easily detached from the graphite cup by leaching the layer between the Si and the graphite with a 1*N* HCl solution. The solubility of this layer in HCl solutions indicates the presence of a salt between both phases (Fig. 1) instead of the strongly attached SiC phase that forms when molten silicon contacts high density graphite. SEM and EDAX analyses also showed that a layer of salt separated the silicon from graphite.

Since purity of silicon is a major requirement for good solar cell efficiency, the impurity transfer between Si and NaF was monitored by analyzing the silicon before and after melting in NaF. Emission spectrographic analysis of the starting NaF and plasma emission spectrographic analysis of the starting semiconductor silicon sample are shown in the second and third columns of Table I, respectively. The impurity level for the sample labeled "Semiconductor silicon" represents contamination during handling or limitations of the analytical instrument used, rather than true impurity content in the semiconductor itself. It is used exclusively as a background reference. Comparison with the values in the fourth column shows that some impurities such as B, Al, Cr, Fe, and also Na were transferred to the silicon from NaF.

The mechanism by which Na is transferred from NaF to Si probably starts with the reduction of NaF by Si to produce Na and SiF_4 according to

$$4NaF(l) + Si(l) \rightarrow 4Na(g) + SiF_4(g) \quad [1]$$

The generation of SiF_4 when an Si-NaF mixture was heated at 1400°C was experimentally verified by condensing the SiF_4 as a solid using liquid nitrogen and by hydrolyzing the collected gas with water to yield HF, H_2SiF_6, and silica gel. As written, reaction [1] has a free energy of reaction of +28.2 kcal/mol Si at 1700 K, as estimated from values from the JANAF tables. Assuming ideal behavior and unity activities for NaF and Si, this free energy corresponds to an equilibrium pressure of Na of 0.2 atm at the Si/NaF interface. Thus, reaction [1] provides a source of Na that can enter the Si phase. Most transition metals such as Fe and Co can be injected in the Si by a similar mechanism. The driving force for the transfer of other impurities such as Al is less clear. Assuming ideal behavior of the impurity fluorides in the molten NaF, the estimated equilibrium activities of the metallic impurities produced by reaction of their corresponding fluorides with silicon are very low and should not be driven into the silicon. Improved models used to explain the transfer of impurities into the silicon should probably include factors such as the presence of silicon surface oxide layers, and the production of silicon subfluorides in addition to SiF_4 (6).

Since impurities play such an important role in the performance of the Si solar cell, it is clear that we must use NaF of purity greater than indicated in Table I. However, the injection of Na will naturally occur with any type of NaF. Accordingly, we examine the ease of distilling the Na out of silicon. Mass spectrometric studies showed that Na is readily removed from silicon heated in vacuum at temperatures as low as 600°C. The removal of Na is much more complete at higher temperatures. For example, heating in vacuum at 1200°C for 5 min yielded silicon with less than 10 ppm of Na. The last two columns in Table I show the analysis of a silicon sample, intentionally doped with 80 ppm of Na, before and after melting under vacuum for 3 min. Although the effect of the Na contamination on solar cell performance is not well known, the residual 3 ppm of Na is not expected to greatly affect the quality of the formed silicon.

The transfer of impurities from NaF to Si affects the Si resistivity. Resistivities of semiconductor (Sm Si) and solar grade silicon (So Si) are substantially decreased after melting in the presence of reagent grade NaF, as shown in Table II. The information in Tables I and II suggest that the decrease in resistivity is due to the injection of boron, sodium in large quantities, and also other impurity elements such as Al and Fe. Since the resistivity of Sm Si doped with a few ppm of B will be around 0.1 Ω cm, and the reduction by two orders of magnitude of the Na content only resulted in a small increase in the resistivity, it seems that B content is the major factor contributing to the drop in resistivity produced by melting silicon in contact with reagent grade NaF. Na and the other impurities seem to exert only a minor effect on the resistivity. This feature could be of practical importance since impurities added to NaF can be used to dope Si and to tailor its resistivity.

It is clear from the above results and discussion that impurities can be easily transferred from the NaF to the silicon phase, and that if solar cells were manufactured from silicon sheets cast in reagent grade NaF, they would exhibit a poor performance. On the other

hand, it has been shown (6) that when silicon of lower purity (with an impurity content in the hundreds of ppm wt level) is melted with the same type of NaF, most of the metallic impurities concentrate in the salt phase; thus, the final content and distribution of impurities in silicon is very similar to the Sm Si case. These results indicate that the possibility of producing silicon sheet with acceptable impurity levels depends on the initial impurity concentration of the NaF and the relative amount of NaF used during melting.

Conclusion

A technique has been developed to form silicon sheet in a graphite die without the undesirable formation of SiC. Silicon is melted in the presence of a molten salt that wets the silicon, preventing it from reacting with the graphite walls. The silicon coalesces into a pool that is flattened to a disk by a graphite piston. Silicon is solidified in this condition to form flat sheets. High purity NaF can be used as coating salt. Some Na is chemically pumped into the silicon sheet during melting, but it may be readily extracted by vacuum evaporation. With improved mechanical and thermal control and the use of high purity NaF, it may be possible to produce silicon sheet with geometry and structures suitable for solar cell fabrication.

A New Anodic Etch for the Observation of Dislocations in n-GaAs

Kohei Nagata, Satoshi Komiya, Akihiro Shibatomi, and Sinji Ohkawa

Fujitsu Laboratories Limited, 1015 Kamikodanaka, Nakahara-ku, Kawasaki 211, Japan

There have been many reports on the relation between electrical characteristics of devices and crystal defects in semiconductor materials. It is well known that a threading dislocation in the epitaxial layer can effect the fast degradation of the double heterostructure lasers and light emitting diodes (1, 2). Dislocations in the epitaxial layer are due to dislocation propagation from the substrate crystal (3, 4). It is very important, therefore, to have high quality substrates for good device performance. For this purpose, many methods of revealing crystal growth defects have been developed. The chemical etching method is the simplest one. The AB-etch developed by Abrahams and Buiochi (5) and Stirland (6) and molten KOH etch as reported by Grabamaier and Watson (7) and Ishii *et al.* (3) are generally used for GaAs but these techniques are more difficult and elaborate. Electrolytic etching techniques of GaAs have been already reported by Tranchart *et al.* (8), and Faktor and Stevenson (9). Green has reported an anodic etch technique using ammonium and hydroxide as a simple method for revealing defects (10).

In this paper, we report a new anodic etch using sulfuric acid for the observation of etch pit in GaAs.

Experimental

Figure 1 shows the experimental arrangement for SAA etching. The dimensions of the container and a cathode of platinum were $8 \times 5 \times 7$ cm^3 and $3 \times 4 \times 0.05$ cm^3, respectively. The electrolyte in the container was stirred during SAA etching. The composition of the electrolyte was one part of 5% aqueous solution of sulfuric acid and three parts of propylenglycol.

Key words: anodic etch, dislocation, GaAs crystal, etch pit.

Native oxide films of GaAs are dissolved in the solution (pH $\leq$ 10). The pH value of the electrolyte used in this study, therefore, was held to 1.3 in order to etch GaAs crystal anodically. Propylenglycol in the electrolyte was used to make anodic oxidation stable and reproducible (11).

<001>-oriented n^+-GaAs wafers with carrier concentrations and defect densities of 10^{18} cm^{-3} and 5000 cm^{-2}, respectively, were mirror-polished mechanically and chemically after slicing. Then the wafer were etched chemically to remove a 9-11 μm thick layer with 90:5:5 = H_2SO_4:H_2O_2:H_2O. An aluminum ribbon was contacted onto the surface of the wafer as an anodic contact. D-C current was supplied by a constant voltage source through a variable resistor R_s. The etching current was controlled by adjusting the output voltage and the resistance of R_s which was much higher than the resistance of the electrolyte to keep the etching current constant. The current and voltage between anode and cathode were monitored and recorded by a multi-pen recorder. In this study, all of the SAA etches were carried out in the dark in order to eliminate possible effects of light illumination. The etched surface of the wafer was examined with an optical microscope.

Results and Discussion

Figure 2 shows a typical etch pit pattern revealed on a Si-doped GaAs wafer by the SAA etch under the current density of 1.5 mA/cm^2. It is clearly observed that there are two kinds of etch pits, that is, the cross-like pit and dot-like pit. The dependence of the shape of these pits on the current density, dopant, and etching time were examined. Current densities of 1-2 mA/

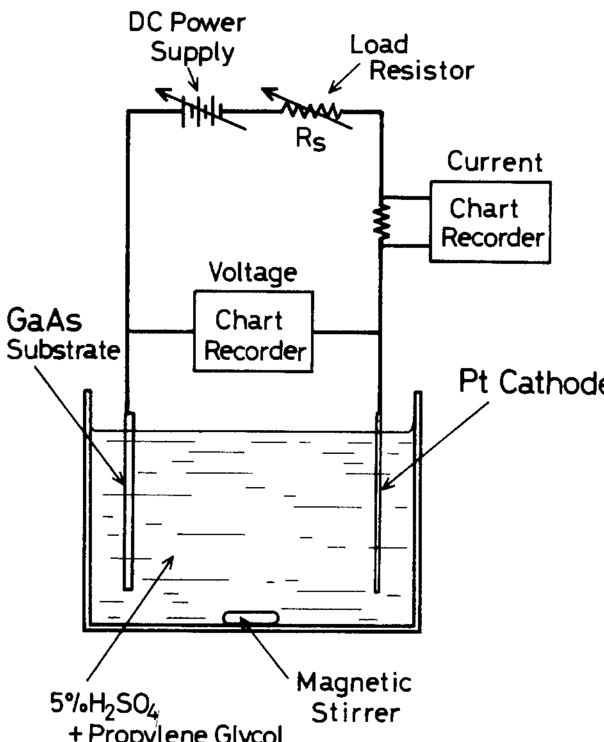

Fig. 1. Experimental setup for an SAA etch

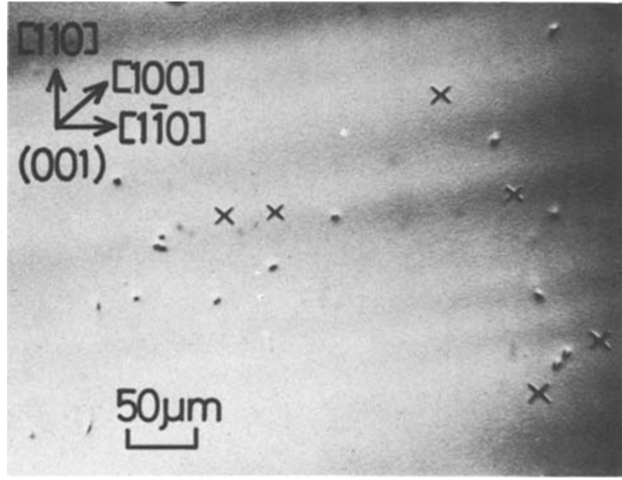

Fig. 2. Etch pit pattern revealed on an Si-doped GaAs wafer by the SAA etch at a current density of 1.5 mA/cm^2.

cm^2 and etching times of 10-15 min are sufficient to reveal defects as the cross-like and dot-like pits, and then the size of the cross-like pit increases with current density.

Figures 3 and 4 show the etching depth and the size of the cross-like pit under the same current density of 1.5 mA/cm^2 as a function of the etching time, respectively. For 10 min etching, the size of the cross-like pit is about 10 μm which is easily observed by using an optical microscope. The mean-etched thickness for 10 min is about 0.3 μm. Therefore, the crystal defects can be detected for the thickess less than 1 μm.

The etching properties of the SAA etch were examined for Te-, Zn-, and Sn-doped GaAs wafers in addition to Si-doped ones (see Fig. 2). Figure 5 (a)-(c) are the microphotographs of the etch pits on Te-, Zn-, and Sn-doped GaAs wafers, respectively. Both of the cross-like and dot-like pits were observed on the Te-doped GaAs, and no cross-like pit and only low density dot-like pits were observed on the Zn-doped GaAs. The Sn-doped GaAs has similar behavior to the Zn-doped GaAs. This indicates that electrochemical properties of the defect are related to the species of the doped impurities but detail of the interaction between defect and impurity is not clear.

In order to investigate the relation between the etch pits revealed by the SAA etch and crystal defects, these etch pits were compared to the etch pits by the molten KOH.

Si-doped GaAs wafer was etched by the SAA etch. The wafer was chemically polished by H_2SO_4-H_2O_2-H_2O etchant to remove the surface layer of about 10 μm in thickness. After that, the wafer was etched by the SAA etch once again in order to examine the reliability of these etch pits, and Fig. 6(a) shows this etch pit pattern. Each blurred shallow pit close to the cross-like pit indicates the afterimage of the corresponding cross-like pit first revealed by the SAA etch. Thus, each of the cross-like and dot-like etch pits was reproducible between the successive SAA etches. Finally, this wafer was etched for 4 min by the molten KOH at 360°C after polishing by H_2SO_4-H_2O_2-H_2O etchant, and the etch pit pattern is shown in Fig. 6(b). From comparison between these etch pit patterns, we can see that both of the cross-like and dot-like etch pits correspond to the etch pits by the molten KOH and dislocations in the GaAs wafer.

Figure 7 shows the detailed shape of the cross-like pit on the etched surface. Four bars which compose the cross-like shape are oriented to the four equivalent <100> directions on the (001) surface but do not intersect at one point. This detailed shape shows the nonequivalency between the two perpendicular <110> and <1̄10> directions in the (001) plane of GaAs. The

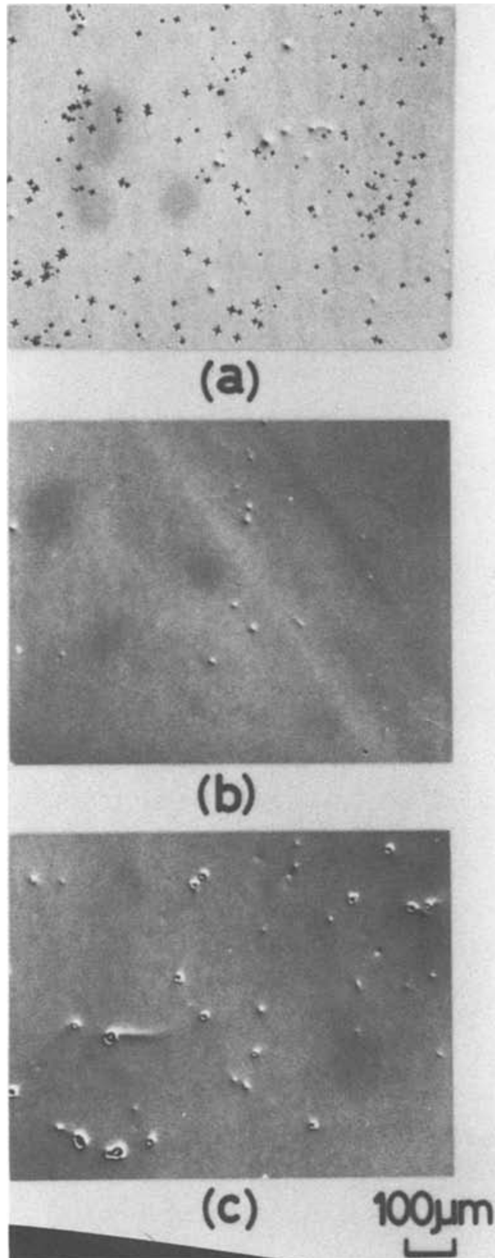

Fig. 5. The dopant dependence of the etching characteristics of the SAA etch. The photographs (a), (b), and (c) are the etch features on the Te-doped, Zn-doped, and Sn-doped GaAs, respectively.

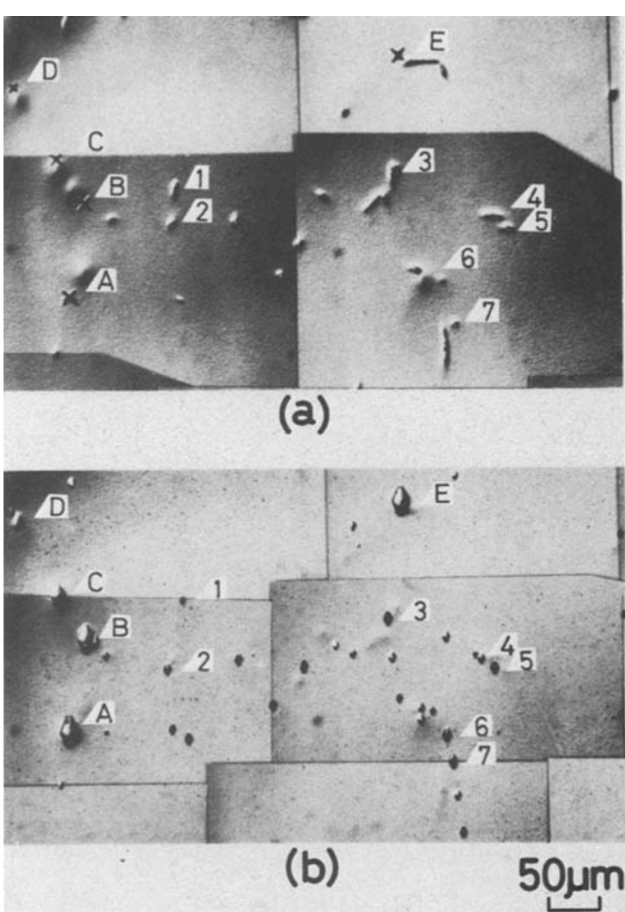

Fig. 6. (a) Etch pit pattern revealed on an Si-doped GaAs by the SAA etch. (b) Etch pit pattern revealed on the same area by the molten KOH etch for 4 min at 360°C, after it was polished by H_2SO_4:H_2O_2:H_2O = 90:5:5 for 6 min.

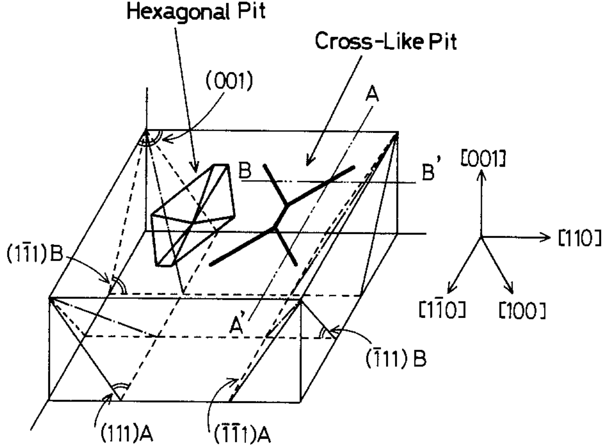

Fig. 7. The geometrical relationship between a cross-like pit and a hexagonal KOH-induced pit on GaAs (001).

nonequivalency has been observed in various phenomena and mostly attributed to the relation between the (001) face and (111)A or (111)B face (11-13), but the nonequivalency of the cross-like pit is not due to the different polarities between the two (111) planes because of its fine structure described recently. The geometrical relation between a cross-like pit and a hexagonal pit revealed by molten KOH is schematically shown in Fig. 7 (4). In order to examine the inner structure of the cross-like pit, two cleaved {110} surface, A-A' and B-B' in Fig. 8, were observed. It is found that the etched feature is clearly platelike, and these plates consist of the (10n) and (01n) plane because the intersection between their plates and (001) plane are oriented to the <100> or <010> direction. The value of n was determined from the angle (θ) between the (001) surface of the wafer and etched plate on the cleaned {110} surfaces. The calculated angle is 35.26° for $n = 1$ and the observed angle is 34 ± 2°. The fine structure of the cross-like pit estimated from these results is shown in Fig. 8. The platelike erosion progresses into the crystal and the cross-like etch pit consists of five plates, two {011}, two {101}, and one {110}. The {101} and {011} planes are crystallographically and geometrically equivalent. However, the ($\bar{1}$10) plate is not etched and only the arrangement of the five plates (as shown in Fig. 8) is revealed, though the two perpendicular (110) and ($\bar{1}$10) planes to the (001) surface are equivalent to each other. In addition, the formation of this cross-like pit depends on dopants. The etching due to electrochemical process should be related to the distribution of the electrical fields in

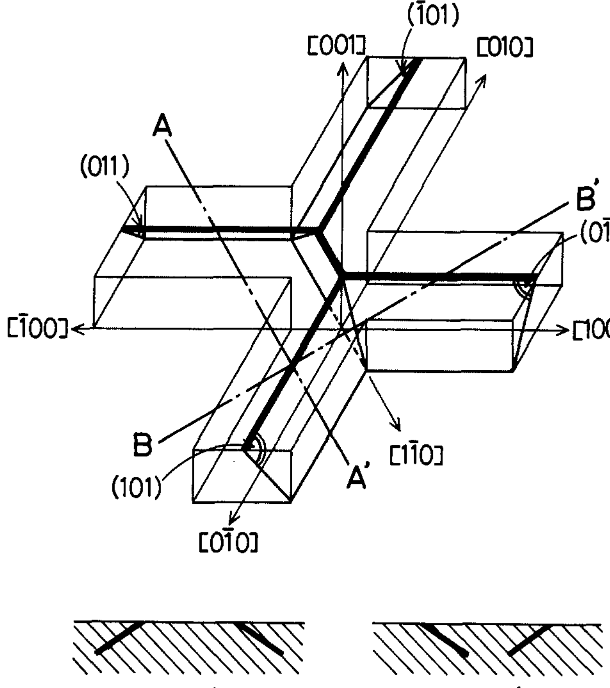

Fig. 8. Illustration of the fine structure of the cross-like pit

neighborhood of dislocations, while a chemical etch pit is frequently related to the (111)A or (111)B plane. However, it is not always clear whether this result means such distribution of dopants is due to interaction between dopants and dislocation.

Conclusion

The etching behavior of pits by the anodic etch using sulfuric acid and propylenglycol (SAA etch) are examined for n^+-GaAs.

1. Optimum conditions for the SAA etch are current density of 1 mA/cm^2 and pH value of 1.3. Clear etch pits can be revealed with small etching depth of 0.3 μm.

2. The SAA etch reveals two kinds of etch pits. A cross-like pit consists of four lines oriented to <100> and <010>. The cross-like pit is observed in the SAA-etched n^+-GaAs wafer doped with Si or Te while no cross-like pit is revealed in Zn- or Sn-doped GaAs. The dot-like pit was found in all GaAs samples.

3. Comparing the SAA-revealed pits with etch pits revealed by the molten KOH, the SAA-etch pit is found to correspond to dislocation.

4. The cross-like pit is formed by etching {110} plane selectively and its shape on the (001) surface indicates nonequivalency between the two perpendicular <110> directions.

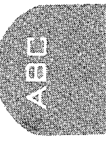
ESCA and SIMS Studies of the Passive Film on Iron

S. C. Tjong* and E. Yeager*

Case Laboratories for Electrochemical Studies and the Chemistry Department, Case Western Reserve University, Cleveland, Ohio 44106



The passivity of iron in borate buffer (pH 8.4) solution has been investigated by many researchers using various techniques (i.e., in-situ electrochemical methods, radiotracer measurements, Mössbauer spectroscopy, electromodulated reflectance, Raman spectroscopy and ellipsometry, ex-situ Auger, ESCA and electron diffraction techniques). Discrepancies exist, however, in interpreting these measurements and what they indicate concerning the structure of the passive film on iron. These discrepancies are not surprising in view of the difficulty of carrying out structural measurements on the very thin passive films (≤ 50 Å). The ex-situ methods are also complicated by the possibility of structural changes after removal from the passivating medium.

The question of the presence of protons and their chemical form on and in the passive layer of iron is of considerable importance in understanding passivation. Some advocates of the sandwich model (1) have suggested that the outer γ-Fe_2O_3 layer is produced from the inner layer of Fe_3O_4 through the substitution of protons for ferrous ion in the Fe_3O_4. Protons have been assumed to the most likely slow charge carriers in the passive film in the a.c. impedance studies of Chen and Cahan (2). The investigations of the existence of H in the passive films have been carried out by radiotracer (tritiated water) measurements. Using this method Okamoto and Shibata (3) showed that bound water was present in the passive film of stainless steel in 0.05 M sulphuric acid. Using a similar method, Kudo et al. (4) estimated the content of bound water in the passive film of iron, formed in sodium borate buffer solution, to be $Fe_2O_3 \cdot 1.99\ H_2O$. Yolken et al. (5) have also proposed that H in the passive film is present as part of the γ-Fe_2O_3 spinel lattice.

Recently O'Grady (6) used Mössbauer spectroscopy to examine in-situ the film on iron and reported that the film was not in any known forms of stoichiometric oxides or hydroxides. He proposed that the passive film was amorphous iron oxides and polymeric in nature. The proposed model consisted of FeO_6 octahedra in a chain-like structure bonded together by di-oxy and di-hydroxy bridging bonds. These chains are linked with each other by water molecules.

In the present work ex-situ ESCA and SIMS techniques were used to study the passive films on pure iron. The SIMS studies placed special emphasis on hydrogen in the films using both H_2O and D_2O borate buffer solutions, while ESCA allowed the study of oxygen in the film as OH^- and $O^=$. Of special interest is the question whether the protons are in the form of OH^- and H_2O in the film. It should be noted that SIMS is mostly a qualitative tool. The yield of various fragments ejected from the specimen during rare gas sputtering is strongly dependent on the chemical and physical properties of the specimens. Large working curve shifts occur even with small changes in chemical composition and physical structure. Calibration is very difficult and with the passive films probably impossible. Nonetheless qualitative identification of various mass fragments and depth profiling for minor constituents can prove quite interesting.

The SIMS measurements were carried out on a 3M Company ISS-SIMS spectrometer with a vacuum of typically 10^{-8} Torr. The operating parameters were: primary ion beam voltage of 3 keV, beam current of 100 nA, and pressure of 2×10^{-5} Torr Ar. The ion beam with FWHM of 670 μm was rastered over an area of 3mm x 3mm at a frequency of 1000 Hz in the x-direction and 100 Hz in the y-direction. The signal was gated so that the data were collected for only 4% of the rastered area located centrally. The pure iron specimens were polished with the final step using 0.05 μm alumina. They were cathodically reduced at -0.35 Vvs. RHE for 20 minutes in the borate buffer (pH 8.4) and then stepped to anodic potentials of 0.65, 1.05 or 1.45 V vs. RHE for

*Electrochemical Society Active Member

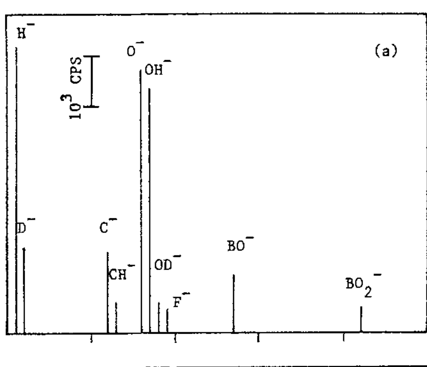
Key words: Passivity, borate buffer, ESCA, SIMS.

30 minutes. After passivation, the sample was removed from the electrochemical cell, rinsed with triply distilled water and then stored in a vacuum desiccator until just before introduction into the SIMS spectrometer.

A proton peak was observed in the positive and negative ion spectra although this peak was partially blocked by an instrument artifact. A strong mass 17 peak corresponding to OH^- was found in the negative ion spectrum without any appreciable positive or negative ion mass 18 corresponding to water. The mass OH^--17 peak was comparable to height to that of O^--16 peak. The most likely explanation for the OH^--17 peak is that the film contained protons only in the form of OH^- and not any significant amount of H_2O molecule as such. The failure to observe a positive or negative ion H_2O peak is not associated with any special difficulty in producing such charge species from H_2O or an instability problem. Various workers have observed both H_2O^+ and H_2O^- spectra in SIMS studies of oxide films containing water; e.g. the studies of vanadium oxide by Benninghoven et al. (7). The possibility exists, however, that the protons may be introduced into the film during transfer from the electrochemical cell to vacuum environment or from the vacuum environment and not during the passivation. Even with pre-bake out, the vacuum in the instrument only reached low 10^{-8} Torr because of the high contamination level in the spectrometer with its many users. Furthermore, the samples were in the instrument at higher pressure during the prolonged period necessary to achieve even this modest vacuum (up to 5 hr).

As a check on this question, the pure iron has been passivated in a borate buffer solution made up in 99.8% D_2O. Because of protons in the boric acid and water of hydration in the borax, the final deuterium concentration was only ∿ 98%. The passivation film was formed in this solution, rinsed with pure 99.8% D_2O and transferred into the SIMS spectrometer using the same procedure as before. The negative ion spectrum showed only a small mass 2 peak for D^- and a small mass 18 peak but the mass 17 peak remained high. Since no mass 18 peak was observed with the undeuterated buffer, this peak is most likely due to OD^-. Barring some large isotope discrimination effect during the passivation, these observations imply a rapid exchange of the deuterium in the film with protons originating from water in the environment during the transfer and/or in the spectrometer.

To check further into this situation, the passivation of iron in a borate buffer solution was made up from anhydrous sodium borate, boric acid and 99.8% D_2O to obtain an ∿ 99.8% deuterated solution. It was then rinsed with D_2O and transferred into a plastic bag directly connected to the sample inlet system of the spectrometer. The bag has been flushed with dry N_2 and the D_2O used for rinsing has been placed in an open beaker within the plastic bag so as to keep the D_2O vapor high compared to that of any H_2O which might diffuse through the plastic into the bag from the outside environment. The SIMS negative ion spectra obtained with this arrangement for the passive film on iron passivated in both the ∿ 98% deuterated borate buffer and ∿ 99.8% deuterated buffer are shown in Figs. 1a, b. The D^--2 and OD^--18 peaks are larger than without the glove bag but still much smaller than the corresponding H^--1 and OH^--17 peaks. The high OH^--17 peak and much smaller OD^--18 peaks undergo a rapid decrease in heights as the film is sputtered away. The OH^--17 peak decreased to 1/3 of its original height and the D^--2 and OD^--18 peak disappear. Simultaneous examination of the Fe^+, O^-, and FeO^+ peaks indicate that ∿ 12 min. is required to sputter away the passivation layer. On the basis of the apparent profile in Fig. 2, most of the D^-, OD^- and OH^- appear to reside on the surface of the film. The residual OH^--17 after removal of the film is instrumental background.



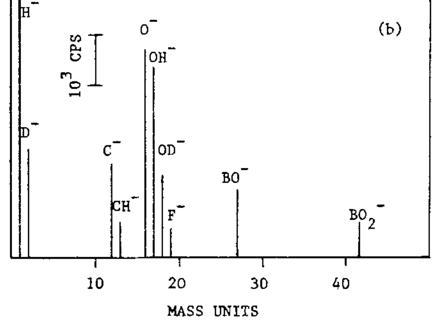


Fig. 1. SIMS negative ion spectra (initial) for iron
(a) Passivated in deuterated borate buffer (98% D) at 0.65 V vs RHE
(b) Passivated in deuterated borate buffer (99.8% D) prepared from anhydrous salt and boric oxide at 0.65 V vs RHE

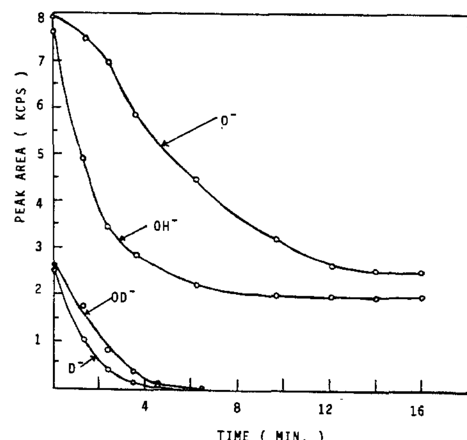

Fig. 2. SIMS peak area vs sputtering time for O^-, OH^-, D^- and OD^- for iron passivated in deuterated borate buffer at 0.65 V vs RHE

On the basis of these results, the deuterium in or on the film appears to be exchanging in some way with protons of the atmosphere or in the vacuum. In the experiments with the plastic bag containing D_2O vapor, the most likely proton source for this exchange is H_2O contamination in the spectrometer. This water vapor in the spectrometer does not contribute any direct OH_2-18 peak to the spectrum but can adsorb on the surface, exchange protons for deuterium in the film and/or dissociate to yield adsorbed H and OH. An OH^--17 peak also shows up in the spectrum for iron specimen covered with a Fe_2O_3 layer produced by air oxidation at 450°C but it is much smaller than for the passive film produced in borate buffer.

Another factor which may have also contributed to the large OH^--17 and H^+-1 peaks for the passivation layers produced in the deuterated borate buffer is possibly a large kinetic effect discriminating against D. For the 98% D - 2% H buffer, a kinetic isotope effect of $\sim 10^2$ would be needed to explain the ratio of OH^--17 to OD^--18 in Fig. 1a and even a larger effect for the 99.8% D - 0.2% H in Fig. 1b. Such a large kinetic isotope effect seems unlikely. On the other hand the substantial increment of 3.5 fold in the ratio of OD^-/OH^- for the buffer with close to 100% D vs. that with 98% D (Fig. 1a and b) cannot be explained on the basis of D - H exchange during the transfer or in the SIMS apparatus. It appears that a substantial amount of the OH^- in the films produced in the deuterated buffer originated from the small amount of H in these solutions. This implies a significant kinetic isotope effect but further work is required to confirm this.

The substitution of D for H in the buffer shifts the pH because of changes in the ionization constants K for boric acid as well as water. The extent of the shift has not yet been examined in the present research but would not be expected to be more than a fraction of a pH unit on the basis of the known shift in the pH for H_2O (pK = 13.9965) vs. D_2O (pK = 14.955 at 25°C) (8). The apparent pD and pH obtained with a glass electrode were the same within a tenth of a unit but this is not necessarily a direct indication that the D^+ and H^+ activities were the same.

On the basis of the comparison of the SIMS spectra for the films produced in the deuterated and undeuterated buffers with respect to various species (Fe^+, O^-, FeO^+, OH^-, OD^-), it does not appear that the deuteration perturbed the properties of the passivation layer significantly other than introducing OD and D on or in the surface layer.

The ESCA measurements were directed to the examination of oxygen in the film and particularly the question of oxygen in the form of OH^- as compared with $O^=$. The ESCA spectra have been run on a Varian IEE-15 spectrometer. The vacuum on this instrument is in the range 10^{-6} - 10^{-7} Torr. The specimens were handled in the same way as for the SIMS with the exception of the transfer technique. For the ESCA, the samples were transferred in air into the ESCA spectrometer. Fig. 3a shows the O(1s) spectrum for iron passivated at 0.65 V vs. RHE after deconvolution with a DuPont curve resolver. Before any sputtering, two peaks are evident at 532 and 529.4 eV and are assigned to OH^- and $O^=$, respectively, and a very small peak evident at 533.8 eV which may be due to water physically adsorbed on the surface. With argon ion sputtering, the OH^- peak in the ESCA spectrum at 532 eV decreases and finally disappears after 3 min. of sputtering (Fig. 3b). On the basis of Fe(2p) spectrum as well as that for O(1s) it appears that the passive film has been completely sputtered away at this time. The 529.4 eV peak then approaches a limiting value which does not decrease further with sputtering. This behavior is probably caused by residual oxygen or water in the relatively poor vacuum of the spectrometer.

The 532 eV peak for OH^- is much smaller before sputtering for the film produced at 1.05 V vs. RHE than 0.65 V. This agrees with the decrease in OD^--18 peak in SIMS negative ion spectrum for iron passivated at 1.05 V. With sputtering the spectrum on this film behaves similarly to that of the sample passivated at 0.65 V although 4 min. is now required to remove the film. It is questionable to reach any

quantitative conclusions concerning the O in the film from the ESCA measurements because of intrinsic oxygen contamination. Nonetheless they lend some support to the results obtained from SIMS.

Both the SIMS and ESCA data obtained with sputtering indicate that the OH in the passive film is principally at or very near the outer surface. While " static SIMS ", in principle is sensitive only to one and at the most two atomic layers, this depth resolution is not realized with sputtering in the present study because of the nonuniformity of the sputtering and the possibility of driving species further into the film. Nonetheless very little OH if any appears to be located more than 5 to 10 Å into the film and it is possible that most of the OH is just adsorbed in the surface. The major portion of the film appears to be free of protons in the form of OH or H_2O. Yolken et al. (5) in their radiotracer measurements also found that the H resided in the outer part of the passive film.

A decrease in the OH concentration in the film at more anodic passivation potentials is to be expected on the basis that the protons should tend to migrate out of the film upon standing at relatively anodic potentials. Further, the proton concentration in the film could be expected to be the lowest near the substrate if the protons slowly migrate out of the film into the electrolyte when the film is held at anodic potentials for prolonged periods. It is surprising, however to find the majority of the film so void of OH. One possibility is the loss of water from the film during the extended exposure to the 10^{-8} Torr vacuum of the spectrometer.

Emf Measurements on the Li-Al/FeS Couple in LiF-LiCl-LiBr Electrolyte

Zygmunt Tomczuk,* M. F. Roche,* and D. R. Vissers*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

In a previous paper (1), the reactions of the FeS electrode of LiAl/LiCl-KCl/FeS cells were determined by a combination of phase studies, cyclic voltammetry experiments, and emf measurements. In this earlier work, six electrochemical reactions were considered, with three of them involving the KCl of the electrolyte to form J phase ($\equiv LiK_6Fe_{24}S_{26}Cl$). Because of the interference from J phase, it was not possible to experimentally determine the emf *vs.* temperature curve for the FeS → Li_2FeS_2 ($\equiv$X) transition. In this paper we report our measurements on the LiAl/LiF-LiCl-LiBr/FeS cell in which the direct determination of the emf of the FeS → Li_2FeS_2 transition is possible. Additionally, the emf of the Li_2FeS_2 → Li_2S transition was measured and compared with that obtained for LiCl-KCl eutectic.

The experimental procedure and cell construction were similar to that reported earlier (1). The principal difference was that LiF-LiCl-LiBr (22.1-30.9-47.0 mol %) was used as the electrolyte. The FeS electrode contained a mixture of 3.0 g FeS, 2.0 g Li_2FeS_2, and 0.5 g Fe powders. The Li_2FeS_2 was prepared by heating an equimolar mixture of FeS and Li_2S at ∿800°C in a graphite crucible for several weeks. X-ray diffraction analysis verified that the product was Li_2FeS_2. Most of the emf measurements for the FeS → Li_2FeS_2 transition were made without cycling the cell before making measurements; however, some measurements were made after the cell had been discharged once and then charged. All of the Li_2FeS_2 → Li_2S measurements were made after a complete discharge and then partial charge (∿30% of the theoretical capacity). A Keithley model 191 digital multimeter (input impedance $>10^9 \Omega$) was used for the measurements. As a check on the reproducibility of the results data were obtained for both increasing and decreasing temperatures.

The experimental results are shown in Fig. 1. A linear regression analysis of the data indicated that the FeS → Li_2FeS_2 data could be fit by

$$E(\text{in mV}) = 1338.9 + 0.0133T\ (K) \qquad [1]$$

and the Li_2FeS_2 → Li_2S data by

$$E(\text{in mV}) = 1432.11 - 0.147T\ (K) \qquad [2]$$

Equations [1] and [2] were combined to yield the FeS → Li_2S transition

$$E(\text{in mV}) = 1385.8 - 0.067T\ (K) \qquad [3]$$

The slopes of these three equations are slightly more positive than those reported for measurements in LiCl-KCl eutectic electrolyte. However, the emf's computed from equations [1]-[3] agree with those for LiCl-KCl eutectic electrolyte (see Table 1). This agreement supports our earlier conclusion (1) that the calculated values for the FeS → Li_2FeS_2 and FeS → Li_2S transitions in LiCl-KCl were within several millivolts of the correct values.

The free energy of formation of Li_2S at cell operating temperatures was computed from Equation [3] and the thermodynamic data for LiAl (2) and FeS (3). The computed value is -100.22 kcal/mol at 700 K. The free energy of formation of Li_2FeS_2 was then computed using the derived value for Li_2S and Equation [2]. The resulting value is -125.45 kcal/mol at 700 K. The free energy change for the chemical formation of Li_2FeS_2 from FeS and Li_2S was computed using Equation [1] and [3]. The computed value is -0.45 kcal/mol at 700 K, a value which is in agreement with that computed earlier (1).

Evaluation of Organic Acids as Fuel Cell Electrolytes

J. Ahmad,* T. H. Nguyen,* and R. T. Foley*

Department of Chemistry, The American University, Washington, D.C. 20016

ABSTRACT

The electrochemical behavior of methanesulfonic acid, ethanesulfonic acid, and sulfoacetic acid as fuel cell electrolytes was studied in a half-cell at various temperatures. The rate of the electro-oxidation of hydrogen at 115°C was very high in methanesulfonic acid. The rate of the electro-oxidation of propane in all three acids was low even at 135°C. Further, there is evidence for adsorption of these acids on the platinum electrode. It was concluded that anhydrous sulfonic acids are not good electrolytes; water solutions are required. Sulfonic acids containing unprotected carbon-hydrogen bonds are adsorbed on platinum and probably decompose during electrolysis. A completely substituted (fluorinated) sulfonic acid would be the preferred electrolyte.

This research was directed toward the investigation of improved fuel cell electrolytes suitable for the low temperature (under 200°C) fuel cell. A comprehensive review of the fuel cell electrolyte problem has been made (1). All of the inorganic acids, phosphoric, sulfuric, hydrochloric, perchloric, and hydrofluoric, as well as the "super acids," are deficient in one or more physical, chemical, or electrochemical property when evaluated in terms of the established characteristics of the "ideal" electrolyte (2). The desired properties of a fuel cell electrolyte are: (*i*) good ionic conduction; (*ii*) proper vapor pressure and viscosity characteristics; (*iii*) a good medium for the oxidation of the fuel; (*iv*) a good solvent for the active materials and for material transport; (*v*) chemically and electrochemically stable over the operating temperature range; (*vi*) noncorrosive to fuel cell container materials; (*vii*) proper surface tension characteristics (should not wet Teflon bonded electrodes or foam excessively when bubbled with gases).

The shortcomings of inorganic systems have suggested organic acids as alternatives, mainly because it was felt that the ability to alter the structure of an organic molecule allowed for a flexibility not available with inorganic systems. One important property, lacking, for example, in phosphoric acid, was the ability to support the electro-oxidation of propane. For future advancement in the fuel cell field, the development of a direct hydrocarbon-air fuel cell has a high priority.

The first organic acid studied in any depth and also giving promising results was trifluoromethanesulfonic acid used as its monohydrate (3-6). The important finding in this work was to demonstrate convincingly that the development of new improved electrolytes was a route, alternative to electrocatalysis, which could lead to improved fuel cell performance.

A review of the literature and an examination of the physical and chemical properties of certain organic sulfonic acids, namely, methanesulfonic, ethanesulfonic, and sulfoacetic, indicated that these acids warranted further investigation. The specific objective of the present research was to evaluate these acids electrochemically, particularly their ability as electrolytes to support the electro-oxidation of hydrogen and propane.

Experimental

Preparation, purification, and analysis of electrolytes.—Methanesulfonic acid, ethanesulfonic acid, and sulfoacetic acid, were evaluated as fuel cell electrolytes, and sulfuric acid and trifluoromethanesulfonic acid monohydrate were used as "reference" electrolytes. Some physical properties of the three acids compared to those of phosphoric acid, sulfuric acid, and trifluoromethanesulfonic acid monohydrate are given in Table I.

The methanesulfonic acid was Eastman 95% practical grade distilled twice under vacuum. The double-distilled acid was further cleaned by maintaining a fuel cell electrode at 0.5V for about 15 hr in the three-compartment cell in which the experiment was to be performed. The methanesulfonic acid was analyzed at three stages to follow the possible oxidation or reduction of the compound: (*i*) the as-supplied, 95% practical grade; (*ii*) the double-distilled material; and (*iii*) the 80% (water) solution of the double-distilled acid which was electrolyzed at 0.9V and 100°C for 20 hr. The analyses were conducted by obtaining nuclear magnetic resonance spectra and gas chromatograms. Analysis by infrared absorption was found to lack sufficient sensitivity. A Varian Associates A60 analytical NMR spectrometer was used for the proton analysis and a Bruker WP-80, ^{13}C NMR spectrometer, for the carbon analysis. Deuterium oxide (D_2O) was used as a solvent and tetramethylsilane as an external standard. The tetramethylsilane peak was set at 0.00 ppm after properly phasing and maximizing the resolution and the spectra were run over a 1000 Hz range using a 250 sec sweep time. The gas chromatograms were obtained with a Hewlett-Packard 5830A Gas Chromatograph with a 18850A recorder. A 1% solution of the acid in ether was injected into the column (a 3% OV-225 column). A flame ionization detector was used to obtain a chromatogram of the acid. The experiment was programmed from 50° to 150°C with a 10% per min heating rate.

Table I. Physical properties of fuel cell electrolytes

Compound	Melting point	Boiling point	Solubility in water	Specific conductance at 40°C (Ω^{-1} cm^{-1})		Contact angle on Teflon (degrees)
Methanesulfonic acid, CH_3SO_3H	19-20	167/10 mm	Miscible in all proportions	0.019	(98 w/o)	93.59 (100%)
Ethanesulfonic acid, CH_3-CH_2-SO_3H	−17	123/1 mm	Very soluble	0.009 at 25°C	(98 w/o)	
Sulfoacetic acid, HO_3S-CH_2-COOH	84-86	245d	Very soluble	0.464	(58% H_2O solution)	90.15° (58% H_2O solution)
Phosphoric acid, H_3PO_4	42.35	½ H_2O, 213	Very soluble	0.1381	(85% H_2O solution)	>90 (58% H_2O solution)
Sulfuric acid, H_2SO_4	10.36	338 (98.3%)	Miscible in all proportions	0.790	(50% H_2O solution)	>90 (50% H_2O solution)
Trifluoromethanesulfonic acid, monohydrate $CF_3SO_3H \cdot H_2O$	33.8	217-219	Miscible in all proportions	0.01122 0.5750	(100% (40% H_2O solution)	72.83 (100%)

The ethanesulfonic acid was supplied by Aldrich and Company, vacuum distilled to remove impurities, and further cleaned in the cell by electrolyzing at 0.5V with a cleaning electrode for about 15 hr.

The sulfoacetic acid was supplied by Eastman as black crystals in semi-solid form and 98% purity. The acid could be further purified by forming the Pb salt with $PbCO_3$ and freeing the acid by precipitating PbS. However, the traces of sulfide that remained in solution poisoned the Pt electrode during the electrochemical experiments. The sulfoacetic acid of 98% purity was used in the electrochemical experiments described below.

Electrochemical techniques.—Two types of experiments were performed: (*i*) polarization studies with argon, hydrogen, and propane in the three electrolytes. The electrical apparatus, the three-compartment cell, the reference system, and the method of pretreatment of the gases have been described in previous publications (2). All potentials reported are *vs.* the dynamic hydrogen electrode (7); (*ii*) cyclic voltammetry experiments with apparatus and techniques previously described (6).

Results and Discussion

Methanesulfonic acid.—In preliminary experiments the systems were calibrated with polarization curves obtained by the electro-oxidation of H_2 in trifluoromethanesulfonic acid monohydrate over the temperature range of 80°-135°C and cyclic voltammetric scans in 4*N* sulfuric acid and in trifluoromethanesulfonic acid monohydrate. The results obtained from experiments with the monohydrate were similar to those previously reported in this laboratory (3) and the voltammetric sweeps in sulfuric acid were identical to those reported in the literature (8).

The polarization curves for argon, propane, and hydrogen in an 80% CH_3SO_3H solution at 115° and 135°C are given in Fig. 1. For hydrogen oxidation clear-cut limiting currents were observed, 78.8 and 108 μA/cm^2 at 115° and 135°C, respectively. There was no definite Tafel region in the hydrogen polarization curve. The oxidation currents for argon and propane increased with overvoltage. At an overvoltage of 0.3V the currents for Ar were 0.64 and 1.6 μA cm^{-2} at 115° and 135°C, respectively, while for propane values of 5.5 and 7.5 μA cm^{-2} were obtained. Above 0.65V the current density for Ar and propane increased rapidly and reached peak currents, or limiting currents at about 0.90V *vs.* DHE. At 135°C the peak currents were almost the same for both Ar and propane, suggesting that the oxidation current of the electrolyte, per se, exceeded that due to the electro-oxidation of propane.

The inspection of the cyclic voltammograms of the acid taken over a range of temperatures revealed some significant characteristics. At room temperature and up to 80°C, the hydrogen, double layer, and oxygen film regions were well defined and separated in the positive going part of the curve. At 90°C a strong oxidizing peak at 1200 mV and a shoulder-like peak at 760 mV started to appear; at higher temperature (115° and 135°C) those peaks increased and the hydrogen structure began to lose its fine structure. But the most dramatic change was that, in the cathodic scan, the current crossed into the anodic current domain directly following the reduction of the Pt oxide. This must be characteristic of the presence of an electroactive species. Cyclic voltammograms at 26° and 115°C in Fig. 2 illustrate this behavior. To further study this phenomena, a background voltammogram with 4*N* H_2SO was run and then a few drops of methanesulfonic acid was added to the cell. A typical cyclic voltammogram for 4*N* H_2SO was obtained at 80°C (Fig. 3). After addition of a few drops of methanesulfonic acid it was observed that there was no change in the background

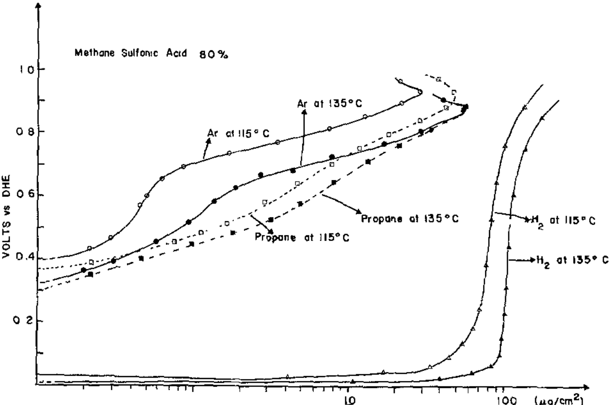

Fig. 1. Polarization curves for argon, propane, and hydrogen in an 80% CH_3SO_3H solution at 115° and 135°C.

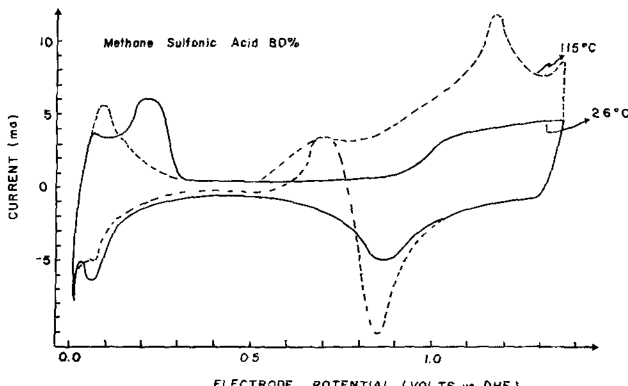

Fig. 2. Cyclic voltammograms in 80% solution of methanesulfonic acid at 26° and 115°C.

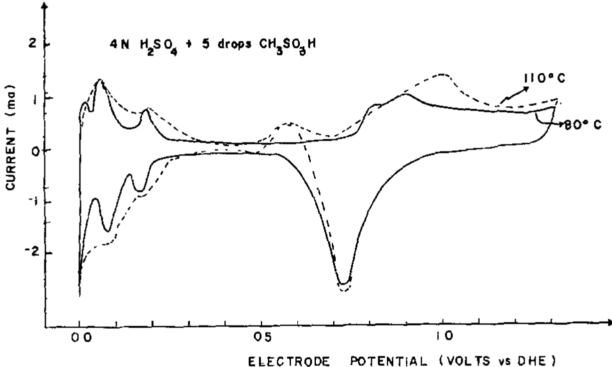

Fig. 3. Cyclic voltammogram in $4N$ H_2SO_4 to which was added a few drops of CH_3SO_3H.

curve. However, when the solution was heated up to 110°C, the effect of methanesulfonic acid became apparent. A strong oxidizing peak at 1.02V was then observed and in the reverse scan to the cathodic side, the current crossed over to the anodic area after the reduction of the platinum oxide.

From these observations, it is then concluded that methanesulfonic acid is dissociatively adsorbed

$$R—H \rightarrow R(ads.) + H(ads.)$$

At sufficiently large potential, the radical is desorbed and contributes to the high oxidation current. Then, in the reverse scan, after the reduction of the oxide layer on Pt, a product of the higher potential electrolysis reaction is oxidized on the oxide-free platinum surface.

To explain some of these electrochemical results, the methanesulfonic acid was analyzed using ^1H NMR, ^{13}C NMR, and gas chromatography techniques, the last being most informative.

The ^1H NMR spectra were recorded employing as-supplied, double-distilled, and electrolyzed samples. In these spectra two peaks were obtained: peak I, attributed to the $—CH_3$ group and peak II, attributed to the combined effect of the sulfonic group and solvent. The position of peak II changes from sample to sample and the shift is tabulated in Table II. The presence of H_2O in the sample tends to shift the spectrum to a lower ppm value so the shift of peak II to 5.2 ppm is interpreted as the presence of a new structure.

The ^{13}C NMR spectra were not particularly informative but seemed to indicate an impurity in all three samples.

These NMR spectra were run at 60°C (proton) and at room temperature (carbon). The gas chromatography analyzed the acid samples at elevated temperature (up to 150°C). The chromatograms obtained from the double-distilled sample of methanesulfonic acid and the acid that had been electrolyzed at 0.9V and 100°C for 20 hr are displayed in Fig. 4 and 5, respectively. It is apparent that the electrolysis at 100°C was effective in producing several fragments or new compounds. These analyses suggest that methanesulfonic acid is unstable at 100°C and 0.9V.

Table II. The positions of the absorption peaks in the ^1H NMR spectra of methanesulfonic acid samples

Spectrum	*Position of peak I (ppm)	*Position of peak II (ppm)
As-supplied sample	1.5	4.8
Double-distilled sample	1.5	4.55
Electrolyzed sample	1.5	5.2

* These positions are over a 1000 Hz range using a 250 sec sweep time.

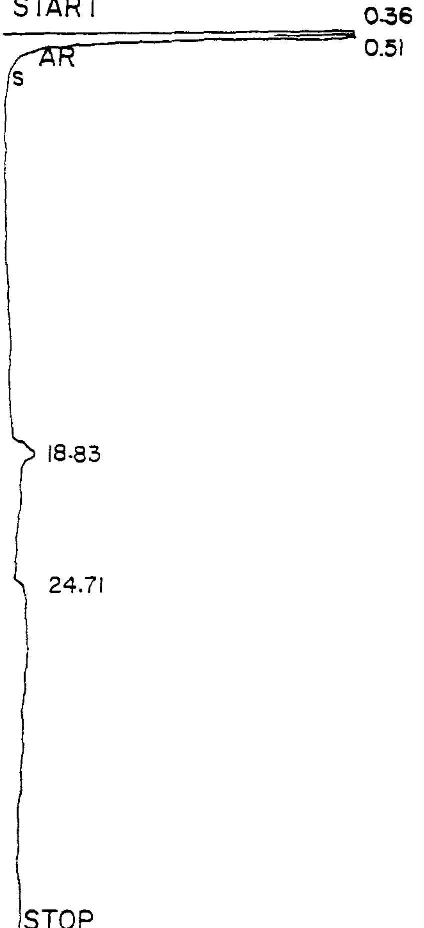

Fig. 4. Chromatogram obtained with a double-distilled sample of methanesulfonic acid.

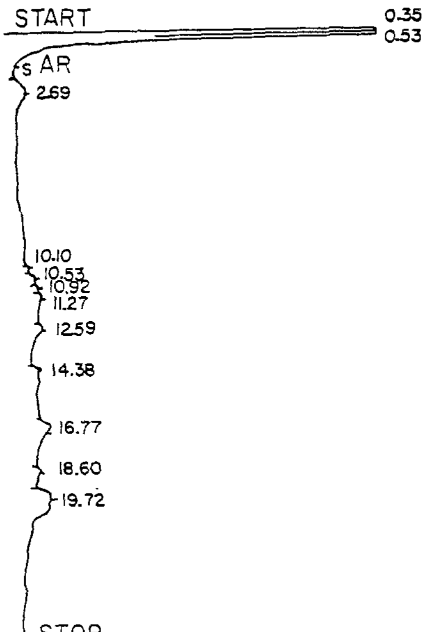

Fig. 5. Chromatograms obtained with a sample of methanesulfonic acid that had been electrolyzed at 0.9V for 20 hr at 100°C.

Ethanesulfonic acid.—Polarization curves were obtained with Ar, propane, and H_2 in a 50% acid-H_2O solution of ethanesulfonic acid. At 115°C, the limiting-current for hydrogen was 27.6 $\mu A/cm^2$, about half of the current obtained with methanesulfonic acid. Also, the polarization curve did not show a distinct Tafel region (Fig. 6). For propane and Ar, there were no

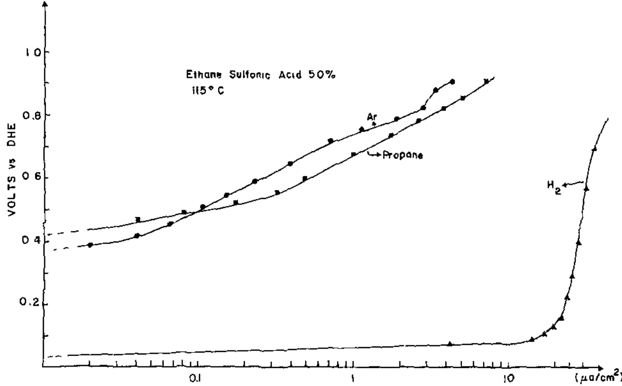

Fig. 6. Polarization curves for argon, propane, and H_2 in 50% solution of ethanesulfonic acid at 115°C.

clear-cut limiting currents but the current density for propane was slightly higher than for Ar. At an overvoltage of 0.3V the current density for propane was 1.2 μA-cm^{-2} compared to 0.65 μA cm^{-2} for Ar.

The cyclic voltammogram of the 50% acid solution at different temperature is shown in Fig. 7. It is interesting to note that at room temperature, ethanesulfonic acid exhibited electrochemical behavior similar to that of methanesulfonic acid at higher temperatures. This suggests that ethanesulfonic acid is strongly adsorbed on the platinum electrode surface. As we increased the temperature, it is observed that: (*i*) the oxidation peak-current increases; (*ii*) the Pt-oxide reduction current slightly decreases; (*iii*) the electro-oxidation current of the electroactive species increased; and (*iv*) the definition of the hydrogen peaks decreases and almost completely disappears above 85°C. From those observations, it is concluded that ethanesulfonic acid is strongly adsorbed on the Pt surface and at sufficiently high temperature, inhibits the hydrogen and oxidation reactions. This behavior appears to be characteristic of a platinum electrode in strong concentrated acidic electrolytes.

Sulfoacetic acid.—The polarization curves for argon, propane, and hydrogen in a 50% acid solution are shown in Fig. 8. The current density for hydrogen oxidation at an overvoltage of 0.3V was 38 μA/cm^2 at 115°C. The polarization curves for argon and propane did not exhibit a limiting current density but it can be remarked that the current obtained with propane was almost the same as with argon. The voltammogram for the acid shown in Fig. 9 did not show any special behavior. It did not appear that sulfoacetic acid is adsorbed on the Pt electrode from the study of the

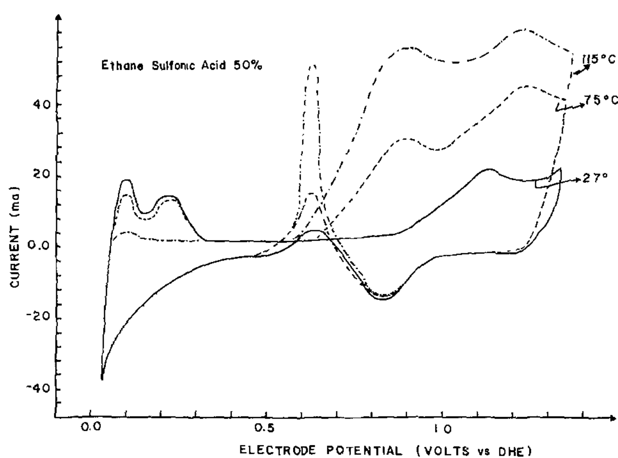

Fig. 7. Cyclic voltammogram in 50% solution of ethanesulfonic acid at 27°, 75°, and 115°C.

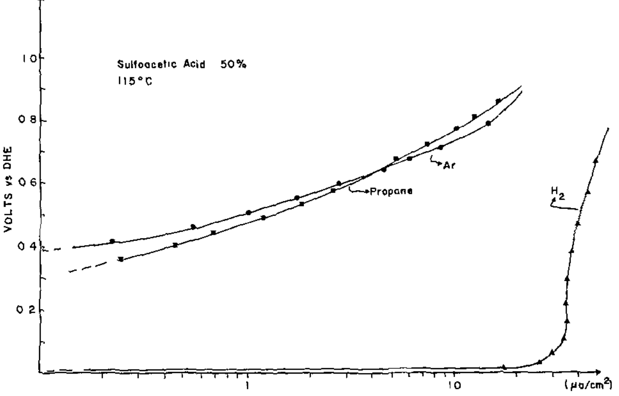

Fig. 8. Polarization curves for argon, propane, and H_2 in 50% sulfoacetic acid solution at 115°C.

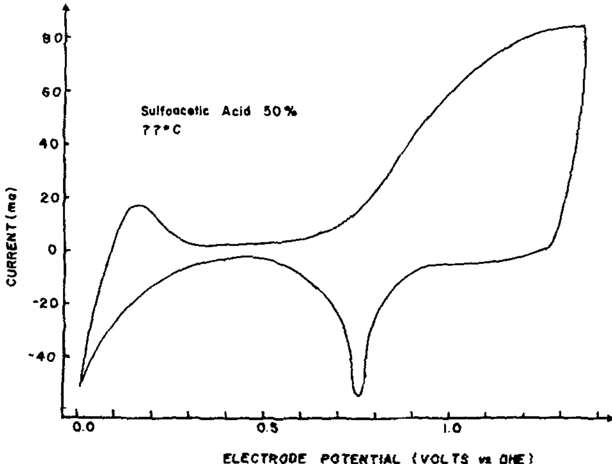

Fig. 9. Cyclic voltammogram in 50% solution of sulfoacetic acid at 77°C.

cyclic voltammogram at different temperature. However, it must be remarked that the commercially available sulfoacetic acid appears to be of uncertain quality to use as an electrolyte and no suitable method of purification has been worked out despite considerable effect to recrystallize the compound using conventional organic chemistry methods.

Conclusions

The three electrolytes are compared by tabulating the current densities achieved with hydrogen, argon, and propane in Table III.

Certain conclusions may be drawn with regard to the three sulfonic acids. The polarization studies indicate that an electrolytic solution, 80% in methanesulfonic acid and 20% in H_2O supports high current densities with H_2, but shows little promise with propane. The results obtained with H_2 agree with results obtained by Rebert *et al.* (9) in a study with platin-

Table III. Summary of current density values obtained in different electrolytes

Electrolyte	Current densities (μA/cm^2) at 0.3V over potential					
	Hydrogen		Propane		Argon	
	115°C	135°C	115°C	135°C	115°C	135°C

Trifluoromethanesulfonic acid, monohydrate $CF_3SO_3H \cdot H_2O$	122	296				

ized-platinum rotating disk electrodes. They found that at the same potential and comparable rotation speeds, methanesulfonic acid supports currents that are more than an order of magnitude higher than those obtainable in phosphoric acid. They did not study propane. The practical grade (95%) methanesulfonic acid darkens during electrolysis probably due to further decomposition. The cyclic voltammetry studies indicate that methanesulfonic acid is decomposed at elevated temperatures and high potentials. Analysis of this acid by NMR and gas chromatography also indicates that this acid decomposes into different fragments or forms new compounds during electrolysis, particularly at temperatures 100°C or above.

The polarization studies with ethanesulfonic acid indicate that this acid as an electrolyte does not support high current densities either with H_2 or propane. Ethanesulfonic acid is also completely adsorbed on the Pt electrode. For these reasons this compound does not appear to be a promising fuel cell electrolyte.

From these results it is concluded that sulfonic acids, such as CH_3SO_3H or $CH_3—CH_2—SO_3H$, containing terminal methyl groups unprotected by fluorination, are strongly adsorbed on the platinum surface and decompose relatively easily during electrolysis. It now appears necessary that the sulfonic acid electrolytes to be evaluated in future studies should be properly substituted to protect the molecule against electrolytic oxidation or reduction.

During the course of the investigation it became apparent that it would be necessary to work with aqueous solutions rather than the anhydrous acids. The anhydrous acids are poor ionic conductors—the conduction process is achieved with hydrated protons. Further, there is evidence that many of these compounds are thermally unstable at temperatures over 100°C.

The commercially available sulfoacetic acid appears to be of uncertain quality to use as an electrolyte and no suitable method of purification has been worked out. Furthermore, the acid is chemically unstable in the 80°-115°C range.

Electrochemical Reactivity of Strong Sulfuric Acid: Some Unusual Behavior at Pt Electrodes

B. E. Conway* and D. M. Novak*[,1]

Chemistry Department, University of Ottawa, Ottawa, Ontario, Canada K1N 6N5

ABSTRACT

In very strong, 98%, sulfuric acid cyclic-voltammetry experiments at Pt reveal unusual reduction and oxidation processes as distinct from those associated with electrodeposition and ionization of atomic H, and surface oxide formation and reduction, which are familiar in dilute aqueous solutions of H_2SO_4 at Pt. No reduction processes are observed on a less electrocatalytic metal, Au, under the same conditions. Holding the potential of a Pt electrode near the H^+/H_2 potential (E_H) in 98% H_2SO_4 gives rise to reduction of the acid, producing a species that is immediately chemisorbed and becomes oxidized in the adsorbed state in a following anodic potential sweep over the "surface oxide formation" potential region. In the succeeding cathodic sweep, a large cathodic current peak follows surface oxide reduction. By means of chemical simulation experiments, it is shown that the reduction behavior is accounted for first by formation of SO_2 or HSO_3^- at potentials near E_H, followed by oxidation to a species, possibly adsorbed dithionate ($S_2O_6^{2-}$), or some other chemisorbed sulfur-oxygen species, in a following anodic sweep. This oxidation process cannot be from SO_2 or HSO_3^- back to H_2SO_4 or HSO_4^- since, in the next cathodic sweep, a re-reduction occurs in a well-defined peak, a little positive to E_H. Experiments at a rotated Pt disk electrode enable distinctions to be made between processes associated with strongly bound chemisorbed species and other species that can be spun off into solution, giving diminished currents in successive cyclic voltammograms. Additions of small quantities of water diminish the reduction reaction observed in 98% H_2SO_4.

In the course of experiments (1) on the surface oxidation of Pt in nonaqueous media containing traces of water, we investigated the behavior of Pt electrodes in very strong 98% sulfuric acid. Some unusual and interesting bulk and surface electrochemical processes are found which are not observed in ordinary aqueous solutions of H_2SO_4. At the 98% level of concentration of H_2SO_4, the medium is essentially a nonaqueous solution with H_3O^+ and HSO_4^- ions as the electrolyte at about 1.1M concentration. Some higher, condensed sulfuric acid species, *e.g.*, $H_2S_2O_7$, are also present in traces (2).

Studies in very strong acid media are of interest in fuel-cell technology where acids such as H_3PO_4 and CF_3SO_3H are used at *ca.* 85% concentrations, often at elevated temperatures.

As far as we are aware, no previous studies of the electrochemical surface reactivity of pure H_2SO_4 to give chemisorbed decomposition products at electrode interfaces have been reported except in the work of Arvia *et al.* (3) who investigated electrochemical surface processes at Ir in 96% H_2SO_4. In this work, however, only the usual surface reactions of Ir are revealed with H adsorption and surface oxide formation regions being observed in the normal way, but with displacement of these two processes to more negative and more positive potentials, respectively, due to HSO_4^- ion adsorption, as is known in more dilute solutions at Pt with SO_4^{2-} (4) and HSO_4^- ion (5), depending on concentration and *p*H.

An interesting study was also made by Arvia *et al.* (6) on the electrochemistry of fuming sulfuric acid containing various concentrations of SO_3 and small quantities of SO_2, and comparatively on 97.4% H_2SO_4 in the same paper. Most of this work was concerned with the steady-state current-potential behavior arising from reduction of SO_3 at stationary and rotated Pt electrodes, which gives rise to SO_2 and some S. Also, the cathodic evolution of H_2 and the anodic decomposition to O_2 and persulfuric acid was investigated. The question of adsorbed species that might be involved in the reactions was not treated in this work. In work by Lal *et al.* (7-10) and by Loučka (11-13), however, adsorbed species from SO_2 solutions and S layers formed from H_2S and SO_2 were recognized and investigated. As we discuss later, some of these results are relevant to the interpretation of the experiments in the present work.

Arvia *et al.*, in a series of papers (14), have also reported underpotential deposition of H and surface oxidation of Pt and Ir in $KHSO_4$ and $NaHSO_4/KHSO_4$ melts.

In the present paper, we report some unusual reduction and oxidation processes at Pt in 98% H_2SO_4 at ordinary temperatures, studied by means of the linear potentiodynamic sweep method and related procedures. Attempts to identify the principal intermediates involved were made by means of chemical simulation experiments using likely species such as SO_2, dithionite, and dithionate.

Experimental

Method.—A conventional system for applying single and repetitive linear potential sweeps to an electrode was used, employing the equipment and procedure referred to in previous publications (5, 15, 16). In the cyclic-voltammetry mode, the system enables a series of sweeps in an anodic or cathodic direction to be made to successively more positive or more negative potentials, respectively, using the triggering capability for sweep reversal at a constant sweep rate which is provided by a Servomex LF 141 function generator operating on a Wenking potentiostat. This system also allows the potential to be held conveniently at a controlled fixed value (potential "holding" experiment) for recorded times before a following anodic or cathodic sweep is initiated. This type of apparatus enabled current-density (i) *vs.* potential (V) profiles to be recorded, as described previously by us

* Electrochemical Society Active Member.
[1] Present address: Research Laboratories, Eldorado Nuclear Limited, Tunney's Pasture, Ottawa, Canada.

(1, 5, 16) and by other authors, *e.g.*, Ref. (15). Most experiments were conducted at 298 K at a Pt disk electrode (Pine Instrument Company) that could be rotated when desired. Some comparative experiments were made at a high purity grade Au wire.

H_2SO_4 electrolyte.—B.D.H. Aristar pure (98%) H_2SO_4 was used as the electrolyte, initially without dilution. This is the acid which gives, at ordinary concentrations (0.5 ~ 1M), the best clean aqueous solution of H_2SO_4 for cyclic-voltammetry experiments at Pt, as we have described in earlier papers (5, 16). In some experiments, where controlled small additions of water are made, pyrodistilled water (16) was used.

Cell.—A small 3-compartment cell capable of being fitted to a rotating disk electrode system was used, as described previously (1). It was provided with a compartment in which either a reversible H_2/H^+ electrode or an $(\alpha + \beta)$PdH electrode was situated.

Reference electrodes.—A platinized-Pt hydrogen electrode was employed as the reference electrode directly in the strong H_2SO_4. In the 98% H_2SO_4, the potentials are not true reversible potentials but rather steady mixed potentials due to the slow electrocatalytic reduction reaction involving H_2SO_4 which is the subject of this paper. Very satisfactorily steady potentials ($\pm < 1$ mV) could, however, be maintained over an hour or so. In some experiments the $(\alpha + \beta)$PdH reference electrode was used. Potentials on all graphs to be shown below are on the scale of the H_2/H^+ electrode in the same solution as that in which the working Pt or Au (see below) electrodes were studied. This scale is designated for convenience by E_H.

Potential programs.—The potential-time programs shown in Fig. 1 were applied to the working Pt electrode in 98% H_2SO_4 in order to investigate the nature of the observed electrochemical reactivity of H_2SO_4 and to distinguish the currents from those arising in the normal way [cf. (5, 15, 16)] from underpotential deposition of H, or OH and O species; the potentials employed were adjusted on the function generator and the potentiostat and read with an accuracy of 1 mV on a high impedance digital millivoltmeter. At all times, the latter instrument was used to monitor numerically the various potentials involved at sweep reversal and in constant potential holding experiments (see below).

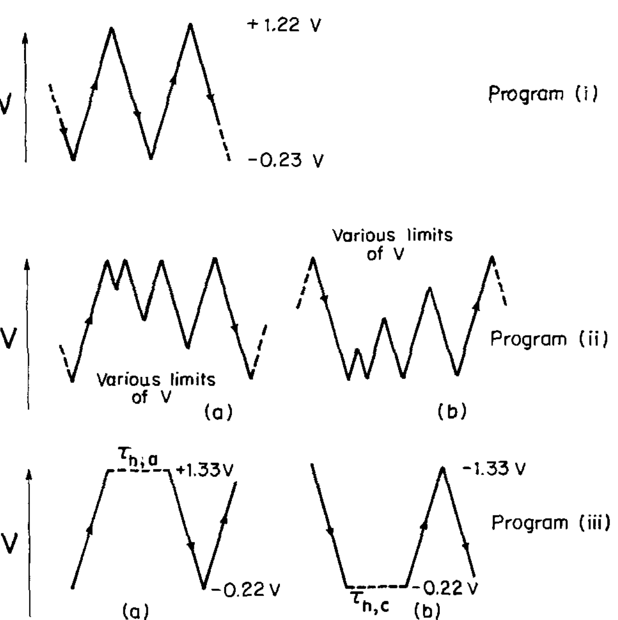

Fig. 1. Potential programs

(i) Cyclic-voltammetry at 70 mV sec^{-1}.—Cyclic-voltammetry experiments were first made by means of a repetitive symmetrical triangular sweep, referred to as program (i) (Fig. 1). Several potential limits to the cathodic and anodic sweeps were employed and are defined on the experimental *i vs. V* profiles shown in Fig. 2a and b and Fig. 3a and b. Experiments in this mode established the normal *i vs. V* profiles for the surface processes at Pt in 98% H_2SO_4, as shown in Fig. 2 and 3.

(ii) Cyclic-voltammetry experiments over progressively decreasing ranges of potential.—These were made by reversing the sweep at successively increas-

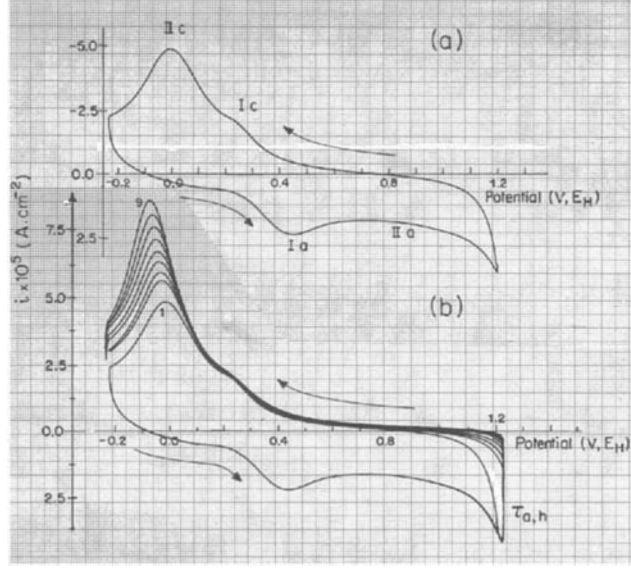

Fig. 2. (a) Cyclic-voltammetry *i vs. V* profiles for Pt in 98% H_2SO_4 at 70 mV sec^{-1} at 298 K, [program (i)]. Designations of principal anodic and cathodic processes are shown. (b) As in Fig. 2 (a) but with holding the potential constant at the positive end of the anodic sweep giving rise to growth of the surface oxide at Pt (70 mV sec^{-1}, 298 K). Curves 1 to 9 for $\tau_{h,a}$ = 0, 5, 10, 15, 20, 60, 120, 240, and 360 sec.

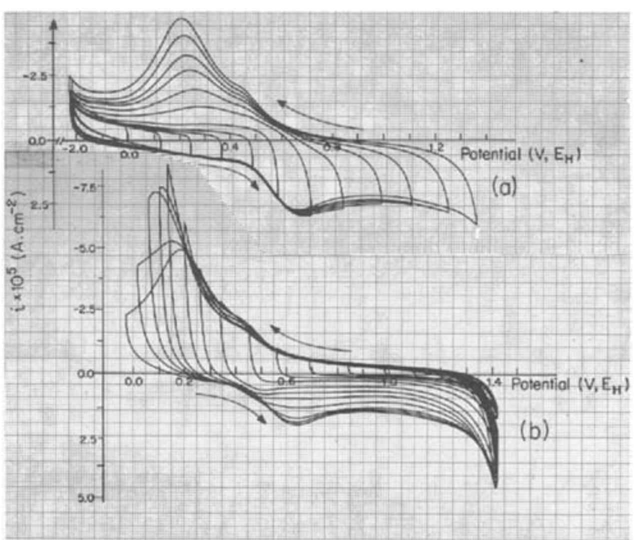

Fig. 3. (a) Cyclic-voltammetry *i vs. V* profiles for Pt in 98% H_2SO_4 at 70 mV sec^{-1} at 298 K showing the effects of reversing the direction of potential sweep at successively more positive potentials in the anodic sweep direction [program (iib)]. (b) As in Fig. 3 (a), but showing the effects of reversing the direction of potential sweep at successively less positive potentials in the cathodic sweep direction [program (iia)].

ing potentials in the anodic or successively decreasing potentials in the cathodic sweep directions. These procedures are illustrated in Fig. 1 and are referred to as programs (iib) and (iia), respectively. These procedures give information on what processes observed in, *e.g.*, a cathodic sweep (where a current peak arises) are conjugate to processes in the prior anodic sweep, or vice-versa, as shown in Fig. 3a and b. The changing potential limits in the programs (iia) and (iib) are evident from the potentials of reversal of the series of curves shown in Fig. 3a, b.

(iii) Potential holding experiments.—Holding the potential at either the end of an anodic sweep for a time $\tau_{h,a}$ [program (iiia)] or at the end of a cathodic sweep for a time, $\tau_{h,c}$ [program (iiib)] followed by initiation of a further cathodic or anodic sweep, respectively, enabled the formation and reactivity of products of slow processes to be followed. It was in these experiments, with cathodic holding of the potential near ($-0.2V$ E_H) the steady-state hydrogen electrode potential (see above), that the unusual reactivity of H_2SO_4 was observed. The potentials at which cathodic or anodic holding for times τ_h was maintained are shown later in the respective figures.

After each change of conditions, *e.g.*, potential holding, the electrode was allowed to return to the reproducible state generated initially as in section (*i*) above by repetitive anodic/cathodic cycling [program (i)] until the initial *i vs. V* curve, corresponding to the cyclic-voltammetry profile shown in Fig. 2, was recovered. This *i vs. V* profile, under continuous cycling, was exactly reproducible from one experiment to another and between different Pt electrodes with normalization to the same real area. It was also virtually identical with the initial anodic and cathodic *i vs. V* profile observed when an electrode, precycled in 1M aq H_2SO_4, was transferred to the 98% H_2SO_4.

Real electrode area.—The real area of the disk Pt electrode used in most of the experiments was determined, in the usual way, from the charge for desorption of the underpotential deposited H layer measured separately in 0.05m aq H_2SO_4, using the figure 2.10 C m^{-2} for the H monolayer at Pt [cf. (17)]. After several days' experiments in the 98% H_2SO_4, the real area of the electrode determined by the H accommodation remained unchanged within 0.5%.

Experiments at Au.—In order to establish how specific the observed H_2SO_4 reduction was to Pt, comparative experiments were carried out on a noble metal less electrocatalytic than Pt, *viz.*, Au.

Reflectance experiments.—In order to see if chemisorbed intermediate species which arise, as shown later, in the reduction of H_2SO_4 can be distinguished from other, *e.g.*, surface oxide, species on the electrode, relative reflectivities $(\Delta R/R)_{\parallel}$ were measured in the cyclic-voltammetry experiments using the apparatus and procedures previously described (18).

Results and Discussion

Phenomenology of the effects.—Cyclic-voltammetry and potential-holding experiments: programs (i) and (iii).—The unusual electrochemical reactivity of H_2SO_4 at Pt arises in the cathodic holding experiments, (iiib). However, it is first necessary to show the normal behavior of a Pt electrode in 98% H_2SO_4 under conditions where the unusual reactions either do not take place significantly in the time scale of an anodic/cathodic sweep at 25 mV sec^{-1} or at all, if the potential range in the sweep is adjusted appropriately.

Figure 2a shows the *i vs. V* profiles for a Pt electrode in 98% H_2SO_4 over the potential range -0.244 to $+$ 1.210V E_H and with cycling over successively diminished ranges of potential in the anodic (Fig. 3a) or cathodic (Fig. 3b) sweeps. These figures define the general behavior of Pt in the 98% H_2SO_4 without any further added water. Characteristic regions of the *i vs. V* profile are designated by Ia, IIa, Ic, IIc, etc., where "a" and "c" denote anodic and cathodic processes, respectively.

Under the above conditions, the observed currents are predominantly for surface processes since the reduced current densities, *i/s*, (*viz.*, the apparent pseudocapacitance per unit area) are almost constant with changing sweep rate, *s*, after a given holding period, $\tau_{h,c}$.

The *i vs. V* profiles for Pt in 98% H_2SO_4 under the conditions of Fig. 2 and 3 differ substantially from those well known (5, 15, 16) for Pt in dilute (~0.05M) aqueous H_2SO_4. Principally, no region of underpotential deposition of H is seen, *i.e.*, before H_2 is evolved at the most negative end of a cathodic potential sweep. This is presumably due to strong adsorption of H_2SO_4 molecules and HSO_4^- ions and to the changed nature of the solvent. The regions Ia, IIa (Fig. 2a) of the anodic sweep, which are presumably attributable in the usual way to surface oxidation (since, *e.g.*, the charge in the reduction peak increases logarithmically with time of holding at the positive end of the anodic sweep and the hysteresis between formation and reduction regions increases with time of anodic holding), are broad and almost structureless, showing less well-resolved states than are observed in a dilute aqueous solution (15, 16) of H_2SO_4.

An oxide reduction region, which appears to be conjugate with the broad surface oxidation region, Ia, IIa, shows a peak (IIc) and a shoulder (Ic). A similar behavior is only resolved in more dilute H_2SO_4 solutions under special low temperature conditions (19) or with weakly adsorbed anions, *e.g.*, ClO_4^-. That the currents in the region Ia,c and IIa,c correspond to surface processes is indicated by approximate constancy (to 5%) of the charges under the curves in experiments conducted at various sweep rates.

Application of the potential holding program (iiia) at the positive end of an anodic sweep gives the results shown in Fig. 2b. Only growth of the surface oxide occurs, as indicated by the increasing reduction charges with time, $\tau_{h,a}$, in the cathodic sweep which increase logarithmically in $\tau_{h,a}$. This is the normal kind of behavior, *e.g.*, as observed (20, 21) in dilute solutions at Pt.

It is under the cathodic holding program (iiib) that the unusual behavior of H_2SO_4 is observed. When the potential is held at the negative end of a cathodic sweep at $-0.244V$, E_H for various times, $\tau_{h,c}$, an increasing anodic current appears initially over the surface oxide region in a following anodic sweep (Fig. 4). With increasing $\tau_{h,c}$, the currents in following anodic sweeps after the holding period: (*a*) initially increase but eventually reach a saturation limit; (*b*) are independent of solution mass-transfer rate at a rotated electrode [see the following section]; also, (*c*) a component of anodic current in these anodic sweeps appears at a lower than usual (Fig. 2) anodic potential, giving a shoulder. IIIa, (Fig. 4), on the anodic *i vs. V* profiles after holding for more than 20 sec.

As this shoulder current appears and increases with increasing $\tau_{h,c}$, the oxide reduction current profile (Ic, IIc) diminishes and a new cathodic current peak (IIIc) appears and progressively increases with increasing $\tau_{h,c}$, eventually reaching saturation. This behavior is illustrated in the succession of *i vs. V* profiles shown in Fig. 4 for various times of holding.

The dependence of the extra anodic currents which appear over the oxide formation region and of the new cathodic currents which appear in the cathodic sweep, and also of the oxide reduction charges, on time of cathodic holding, $\tau_{h,c}$, is shown as integrated charges in

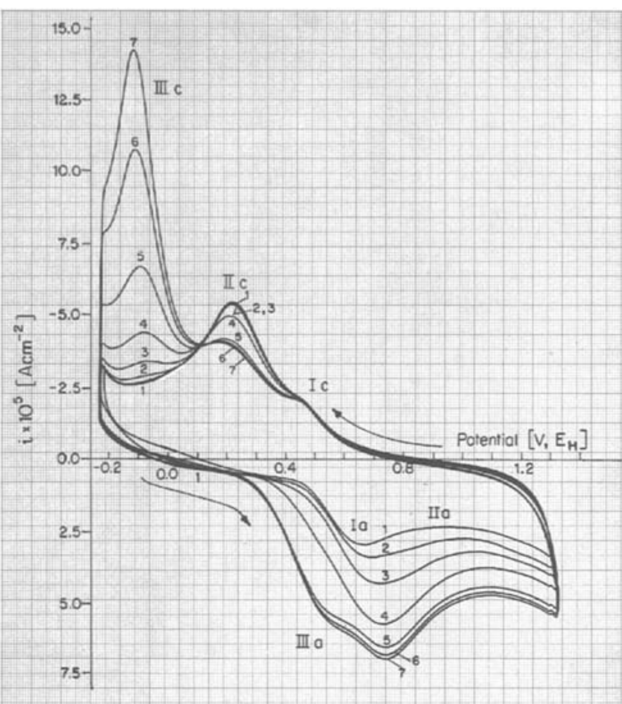

Fig. 4. A series of anodic followed by cathodic cyclic-voltammetry curves for Pt in 98% H_2SO_4 at 298 K after various times $\tau_{h,c}$ of holding the potential constant at $-0.244E$. Sweep rate 70 mV sec^{-1}; times $\tau_{h,c}$: curve 1, 0; curve 2, 5; curve 3, 10; curve 4, 15; curve 5, 20; curve 6, 40; and curve 7, 80 sec.

Fig. 5. There appears to be some induction period in the formation of whatever species (see later) that gives rise to the extra cathodic peak in the cathodic sweep which follows the first anodic sweep after holding. All the charges derived from integration of the currents over various regions of the i vs. V profiles correspond, in order of magnitude (see Fig. 5), to values

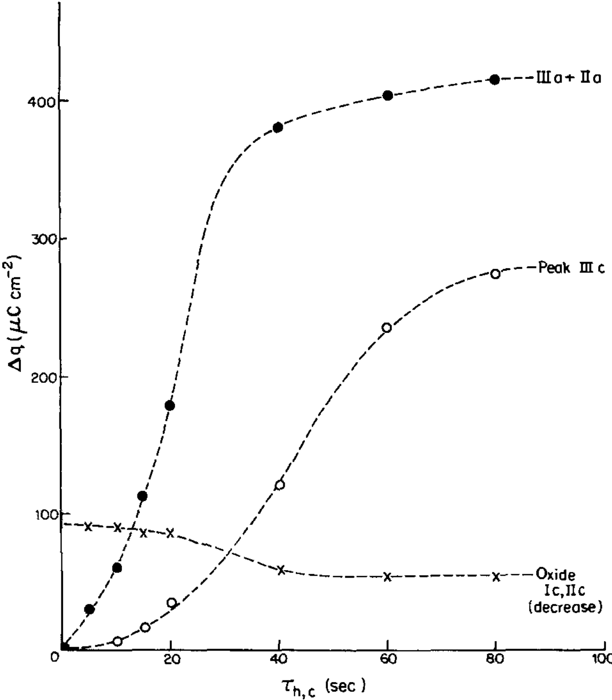

Fig. 5. Charges in $\mu C\ cm^{-2}$ for the three principal time-dependent processes in the curves of Fig. 4 as a function of cathodic holding time $\tau_{h,c}$ sec. ⊙ Charges for process IIIc; ● charges for processes in the region IIIa + IIa; and × charges in the surface oxide reduction region Ic, IIc.

for monolayer processes, suggesting the role of chemisorption in the reactions involved.

If, after the experiment at a series of successively increasing cathodic holding times, the electrode is allowed to be freely cycled [cyclic-voltammetry mode (i)], the new cathodic peak IIIc gradually diminishes, the currents over the surface oxidation region diminish, and the surface oxide reduction region eventually recovers to its initial charge and peak currents. As this recovery takes place (slowly, as shown in Fig. 6), an isopotential point (22) is observed between the series of decreasing current peaks at 0.05V for process IIIc and the series of increasing surface oxide reduction currents Ic and IIc. This suggests that there is a coupling between the processes, Ic, IIc, and the reduction process, IIIc, probably through adsorption and occupancy of surface sites on the Pt electrode by two species.

Behavior at the rotated Pt electrode.—If the experiments corresponding to the results shown in Fig. 4 and 6 are performed at a rotating Pt disk electrode (1000 ~ 3000 rpm), the initial ($\tau_{h,c} = 0$) i vs. V profile shown in Fig. 2a remains unchanged. If, however, the cathodic holding experiment is carried out under rotation conditions, the development of the enhanced anodic and new cathodic currents in following sweeps (as shown in Fig. 4) is retarded, but eventually, as $\tau_{h,c} \rightarrow 90$ sec (Fig. 7) the same (saturation) anodic current profiles are attained as in the static solution with $\tau_{h,c} \simeq 45$ sec (curve for IIa + IIIa in Fig. 5). This result suggests that (a) the immediate product of reduction becomes spun-off into solution, but (see below) may become re-adsorbed after its formation; and (b) the primary reduction process involves H_2SO_4 rather than another species such as $H_2S_2O_7$ (2) at low concentration, since electrode rotation retards rather than enhances the reduction process; thus, if the reduction effects observed in 98% H_2SO_4 were, in fact, due to a small concentration of electroactive $H_2S_2O_7$, rotation would tend to enhance rather than diminish the observed reduction effects, due to the expected facilitation of mass transfer of $H_2S_2O_7$ molecular to the electrode surface under rotation conditions.

An experiment in which the cathodic holding is conducted at a stationary Pt disk electrode, but the

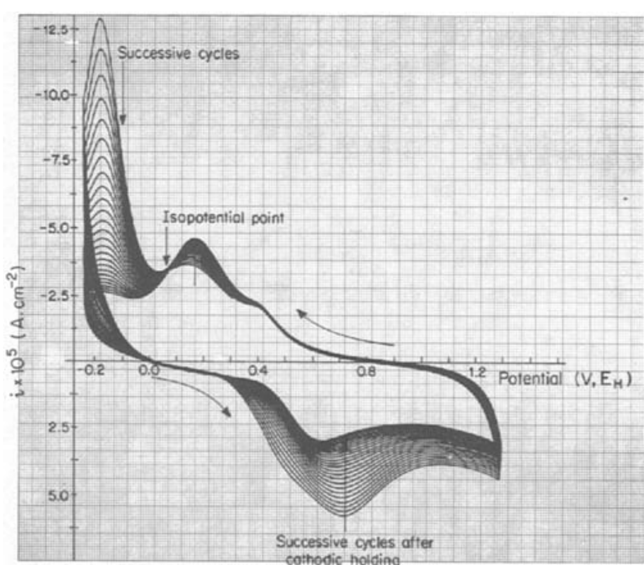

Fig. 6. "Recovery" of initial cyclic-voltammetry i vs. V profile [Fig. 3(a)] after a series of 25 repetitive potential sweeps at 70 mV sec^{-1}, following a period $\tau_{h,c}$ of holding the potential at $-0.244V\ E_H$. Time scale of the succession of the 25 curves is determined by the sweep rate of 70 mV sec^{-1} and the potential range of 1.54V.

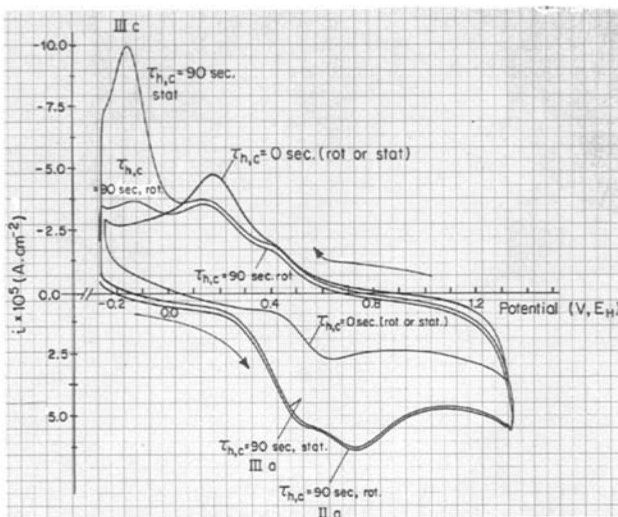

Fig. 7. Cyclic-voltammetry *i* vs. *V* profiles for a Pt disk electrode in 98% H_2SO_4 at 70 mV sec^{-1} after 0 and 90 sec cathodic holding, with ("rot") and without ("stat") electrode rotation at 3000 rpm. Current-density profiles in regions IIIa, IIa are independent of electrode rotation.

following anodic sweep is taken with or without rotation at 3000 rpm, shows (Fig. 7) that the profiles of the extra anodic currents that pass at the rotated electrode on the anodic sweep immediately following the reduction during the time $\tau_{h,c}$, are identical with those observed at the stationary electrode under otherwise the same conditions. This suggests that, although the immediate product (say "X") of reduction in the cathodic holding experiment may be a species weakly adsorbed and hence able to be spun away into solution (as indicated by the result referred to in the previous paragraph), eventually a strongly bound species (say "Y") becomes, and remains, chemisorbed up to a saturation limit (Fig. 4 and 5) at the Pt electrode during the subsequent anodic sweep.

If, however, after cathodic holding for 80 sec without rotation, free potential cycling is allowed to occur as in Fig. 6, but now with electrode rotation, the cathodic peak currents marked IIIc and the extra anodic currents (marked IIIa and IIa) which overlap with the original surface oxide formation region Ia + IIa, rapidly decay (as shown in Fig. 7) almost to the level of currents in the initial *i vs. V* profile (cf. Fig. 1a) without holding. This shows that while the species (Y, say) which originates from the species X produced in the cathodic holding treatment is a chemisorbed species, it can, however, following oxidation on the surface in processes Ia + IIa + IIIa (Fig. 4), be spun away into the bulk solution after reduction and slow desorption in the next cathodic sweep, so that currents in subsequent cathodic and anodic sweeps progressively diminish; Y itself and its products of oxidation in IIIa and IIa are bound species unaffected by mass-transfer conditions (Fig. 7).

The reduction process in IIIc appears to be associated with a species that arises from IIc and is loosely bound on the surface since electrode rotation eliminates most of the reduction current in this region almost from its commencement in the IIIc region (Fig. 7), yet the remainder of the anodic and cathodic *i vs. V* profile is independent of rotation, *e.g.*, after $\tau_{h,c}$ = 90 sec. However, under successive cycling conditions (Fig. 6) after $\tau_{h,c}$ = 90 sec with no rotation, it then takes *ca.* 20 cycles (*ca.* 400 sec) for the peak current at IIIc to decay to the level in Fig. 7 after 1 cycle with rotation, so that the species being reduced at the surface in IIIc remains in some loose attachment to the Pt sufficient for reoxidation immediately in the following anodic sweep with little loss of the level of currents over the regions IIIa, and Ia (Fig. 4). (Possibly a polymeric form of S or a polysulfide is involved.) The latter result indicates clearly that the species generated at the end of the cathodic sweep through the IIIc region (*e.g.*, the top curve, Fig. 6) is the same as that formed in the initial holding period for $\tau_{h,c}$ sec.

Possible mechanism of the effects: elucidation by chemical simulation experiments.—The results of Fig. 4, 5, and 6 suggest that a product, X, derived from the sulfuric acid is first formed by reduction near the H_2/H^+ steady potential. Some of X, probably in a further reduced chemisorbed state Y (see below), then becomes oxidized to a species Y_o in the following anodic sweep. The reduction of H_2SO_4 to form detectable X and Y, as indicated by its subsequent oxidation to Y_o and the following reduction of Y_o in the next cathodic sweep, is quite slow, requiring *ca.* 20 sec for formation of a detectable adsorbed intermediate at 298 K.

In the next cathodic sweep, following formation of Y_o by oxidation of Y derived from X, Y_o is reduced to a species "Z", giving (Fig. 4) the substantial peak IIIc on the cathodic *i vs. V* profile near the H_2/H^+ potential. The reduction current giving Z depends on how much X, and hence Y (and thus Y_o from Y), were produced in the cathodic holding.

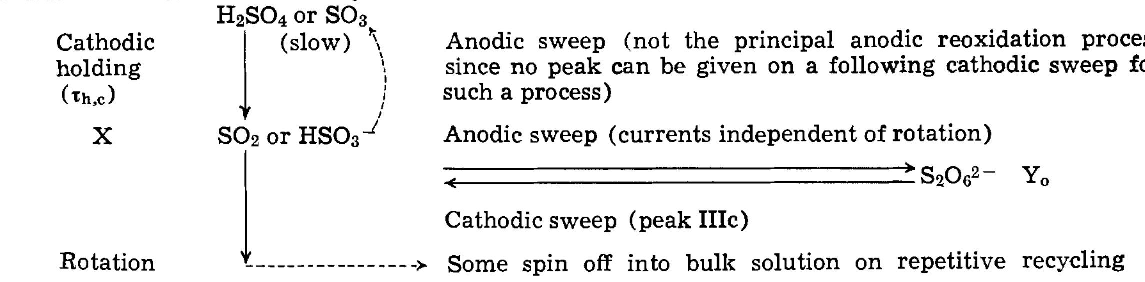
The observation of the reduction peak IIIc producing Z, after oxidation of X and Y to Y_o species in the previous anodic sweep, means that the process of oxidation of X or Y is not re-formation of H_2SO_4 or $H_2SO_4^-$ ion (*i.e.*, Y_o is not one of these species) since H_2SO_4 (or HSO_4^-) itself is not rapidly reduced in a single cathodic sweep, as follows from the behavior in Fig. 2, and from the fact that the primary reduction process which takes place during cathodic holding is quite slow.

Consideration of the chemistry of 98% H_2SO_4 suggests that the first reduction product X is likely to be SO_2 or HSO_3^- produced either from H_2SO_4 molecules or any dissolved SO_3 present [cf. Ref. (6)]. However, the latter possibility is quite unlikely since the concentration of SO_3 in 98% H_2SO_4 (*ca.* 1M in H_2O) is known to be vanishingly small (2). The effects are unlikely to be due to other adventitious impurities since we have found previously (16) with this B.D.H. acid, and in the present work, that its solutions in pyrodistilled water give excellent cyclic voltammograms for Pt without any impurity problems. This is also indicated by the behavior of Au (see later) in this acid.

Since only monolayer magnitudes of intermediates in the H_2SO_4 reduction are produced in the experiments (*e.g.*, see Fig. 5), direct chemical analyses and characterizations were not feasible, especially in excess of 98% H_2SO_4. However, chemical simulations of the behavior of several likely intermediates, by addition of known sulfur compounds in trace amounts, were found to be profitable for the purpose of indicating some of the initial processes that take place.

First, in order to test the possibility that X is SO_2 (or HSO_3^-), a small amount of SO_2 was added (as SO_3^{2-} in a crystal of Na_2SO_3) to the 98% H_2SO_4 in which the potential of the Pt electrode was being cycled as in Fig. 2a (full potential range). Immediately the characteristics of Fig. 4 were developed, including quantitatively the finer details. Therefore, the initial reduction of H_2SO_4 is evidently to SO_2 or HSO_3^-. However, it is known [*e.g.*, Ref. (7)] that SO_2 itself can be reduced at Pt to sulfur species in lower oxidation states, *e.g.*, H_2S or S. This could explain the initial effects of electrode rotation in the cathodic holding experiment; thus, SO_2 (X) is first produced and some can be spun away, but some more strongly bound reduced species Y, such as one-site

and two-site chemisorbed S and corresponding SO species (7, 8) are eventually built up on the surface from the SO_2 and give rise the anodic saturation



currents for partial reoxidation of these species in regions IIa + IIIa (Fig. 4, 5, and 7) when $\tau_{h,c}$ is sufficiently long (90 sec). The subsequent oxidation of these strongly bound species, or of the SO_2 initially produced, in the anodic sweep following the time $\tau_{h,c}$ cannot be back to H_2SO_4 or SO_3, otherwise no further facile reduction of Y_o to Z in the next cathodic sweep would be observed, as we mentioned earlier.

There is some induction time in the development of the species (Y) that is oxidized in the anodic sweeps after cathodic holding and after this induction time an extra anodic current shoulder (IIIa) appears on the anodic sweep. It is when this shoulder is developed that the re-reduction peak, IIIc, on the subsequent cathodic sweep is developed (Fig. 4). The efficiency of the production of Y and Y_o from X depends on the mass-transport conditions and these determine the induction time.

The chemistry of the oxy- and thio-oxy-acids of sulfur is very complex (23) and a number of possibilities exists for the identity of the species Y and Y_o. Generally speaking, there are two types of species that may be involved: (*a*) thio-oxy-acid or anion species that may be produced in an adsorbed state on the electrode, but correspond stoichiometrically to known molecules or ions; or (*b*) chemisorbed species, not necessarily known molecules, derived from reduction of SO_2 (produced initially from the H_2SO_4) and from the reoxidation of these species on the electrode surface, *e.g.*, Ref. (7, 8). First, we shall deal with possibilities of type (*a*).

The experiment with added SO_2 as SO_3^{2-} gives the unambiguous conclusion that the initial product (X) of electrochemical reduction of H_2SO_4 at Pt is SO_2 or HSO_3^-. Products of further reduction could be dithionite (X′, see below), and of subsequent reoxidation in the following anodic sweep, they could be SO_2 (or HSO_3^-) or dithionate ($S_2O_6^{2-}$), or the corresponding acids or acid anions. Sulfoxylate or sulfoxylic acid, $S(OH)_2$, is unlikely to be the species Y_o as the S in this compound is in a lower valence state than that of S in SO_2 or HSO_3^- and is very unstable (23).

A first possibility for consideration is that, initially, after short periods of cathodic holding, SO_2 can, in fact, be to some extent reoxidized back to H_2SO_4 (or SO_3) in an anodic sweep, but, during longer times of reduction, $\tau_{h,c}$, SO_2 can be reduced further to dithionite ion, $S_2O_4^{2-}$. This could be then reoxidized on the following anodic sweep to the species Y_o that can be re-reduced in the cathodic peak IIIc. Thus Y_o would be SO_2 and Z $S_2O_4^{2-}$ again.

A chemical simulation experiment with addition of dithionite (as $Na_2S_2O_4$) was unproductive as the $S_2O_4^{2-}$, or the corresponding acid, is immediately decomposed by 98% H_2SO_4 to SO_2, and some H_2S and colloidal S. Only the characteristics of added SO_2 are observed. $S_2O_4^{2-}$ appears therefore to be too unstable to be a likely intermediate giving rise to Y as SO_2.

The electrolytic oxidation of SO_2 or SO_3^{2-} to dithionate, however, is reported in the early literature (23): $2SO_3^{2-} \rightarrow S_2O_6^{2-} + 2e$. This suggests an alternative pathway for the reduction and reoxidation processes observed in 98% H_2SO_4 at Pt, as follows:

Here it is supposed that the species Y_o (which cannot be H_2SO_4 or SO_3) is $S_2O_6^{2-}$, formed in the anodic sweep over regions Ia and IIa from X (SO_2 or HSO_3^-), and that $S_2O_6^{2-}$ can be reduced with facility back to SO_2 or HSO_3^- in the cathodic sweep (peak IIIc), following its formation from SO_2 or HSO_3^-.

A further simulation experiment was performed in which $S_2O_6^{2-}$ (as the Na^+ salt) was added at the beginning of the surface oxidation region (Ia) in an anodic sweep. No enhancement of anodic currents is observed under these conditions, but on the following cathodic sweep, the cathodic current peak IIIc near the H_2 reference potential is observed, as in the experiments with slow reduction of the H_2SO_4 (Fig. 4) in the absence of an added compound. A subsequent anodic/cathodic cycle gave a substantial increase in this cathodic peak; the behavior of added $S_2O_6^{2-}$ is illustrated in Fig. 8.

These observations are consistent with Y_o being an adsorbed form of $S_2O_6^{2-}$ (or $HS_2O_6^-$ or dithionic acid) since if Y_o is $S_2O_6^{2-}$ and it is added at the beginning of the surface oxidation region, no extra anodic currents should be observed; this is as found. Moreover, if Y_o is $S_2O_6^{2-}$ formed from the SO_2 or HSO_3^- produced in the reduction experiments in H_2SO_4, then it could be reduced back to SO_2 or HSO_3^- (or some other species such as H_2S) in the cathodic peak sweep (peak IIIc); this is observed in the simulation experiment (Fig. 8).

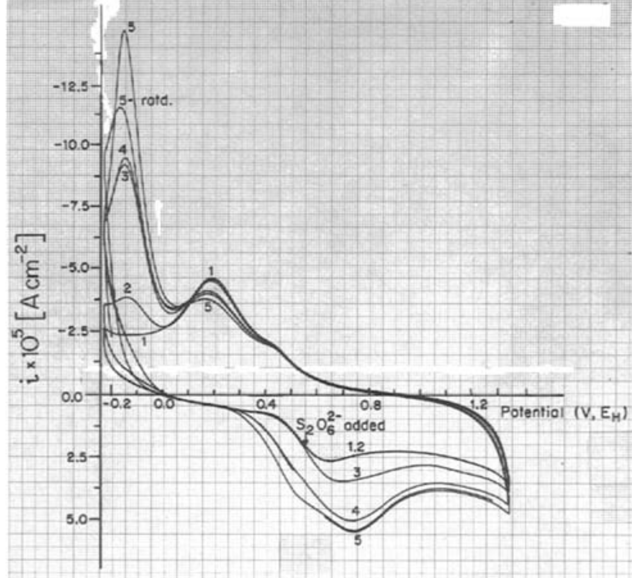


Fig. 8. Cyclic-voltammograms at 70 mV sec^{-1} for Pt in 98% H_2SO_4 with dithionate added on the anodic sweep at 0.48V E_H. Curve 1, initial anodic sweep *i vs. V* profile without holding and without addition of $S_2O_6^{2-}$. Curve 2 (beyond 0.48V), after addition of 10^{-4} mol $S_2O_6^{2-}$ (no change). Curves 3, 4, 5 *i vs. V* profiles for successive potential sweeps after completion of 1, 2 following addition of the dithionate.

It should be noted that most of the thio-oxy-acids of S, and their anions, are unstable in acid medium but $S_2O_6^{2-}$ is known to be the least unstable (23). It does, however, decompose in H_2SO_4 with evolution of SO_2, as was observed in the present experiments. Since this SO_2 could form Y_o on the anodic sweep, whatever Y_o is, another simulation experiment was carried out by cycling the electrode only over the potential range up to the onset of surface oxidation (0.48V) (Fig. 8), *i.e.*, over the range where Y_o could be reduced on a following cathodic sweep, but where no oxidation peaks for any species such as SO_2 formed from some decomposition of added $S_2O_6^{2-}$ would be observed. $S_2O_6^{2-}$ was added and again gave, under these conditions, a reduction peak on the cathodic cycle, similar to that observed in the experiments on reduction of H_2SO_4 or with added SO_2 or HSO_3^-.

These results suggest that the intermediate Y_o could be $S_2O_6^{2-}$ (or $HS_2O_6^-$ or dithionic acid) or, more likely, $S_2O_6^{2-}$ in an adsorbed state. We next consider (*b*), chemisorbed species.

Possible chemisorbed species.—Not all the features of the reduction behavior of H_2SO_4 can be accounted for simply in terms of plausible, "stable" chemical intermediates such as dithionite or dithionate species, even if they are chemisorbed. It has already been mentioned that the lack of an effect of electrode rotation rate on the anodic *i vs. V* profile observed after reduction of the H_2SO_4 to SO_2 for times $\tau_{h,c}$ indicates that a species in a chemisorbed state is derived from SO_2 (X) and saturation coverage can be attained as measured by the subsequent oxidation current profile (IIIa + IIa). This opens up a number of possibilities for the identity of species Y_o, or Z, other than in terms of known chemical intermediates of the kind considered above.

Some insight into the nature of the chemisorbed species that evidently might be involved in the reduction of H_2SO_4 can be gained from the work of Lal *et al.* (7-10) and of Loučka (11-13) who studied chemisorbed S-containing species at Pt, derived from H_2S and SO_2 in aqueous medium. Both Loucka (11, 13) and Lal *et al.* (7, 8) concluded that an oxygenated S species arose in chemisorption from either SO_2 or H_2S solutions (9) at Pt when the Pt surface was subjected to an anodic sweep. Bridged and linear "Pt-S-O" species (valencies and bonding not defined) were proposed, based on cyclic-voltammetry experiments on 0.5M aq H_2SO_4 solutions containing SO_2 and H_2S. Doubly and singly bound S and S_2 species produced in successive reduction stages from SO_2 were also postulated. Species such as "Pt-S-O" would be qualitatively consistent with the observation that the reduction peaks in the "surface oxide" region, observed in the present work, are related in some coupled way to the reduction process IIIc nearer the H region, as indicated by the isopotential point (Fig. 6). When the species X and some derived oxidized form Y_o is produced on the electrode, the bound surface oxide reduction charge on the following cathodic sweep is diminished, but the charge associated with the "re-reduction" process at IIIc is increased. The process IIIc can evidently produce a product which is desorbed as indicated by the experiments at a rotated electrode (Fig. 7). This product is unlikely to be regenerated SO_2 since the results show that at potentials near the cathodic side of the peak IIIc, SO_2 is strongly adsorbed. Possibly the step IIIc involves reduction of the previously adsorbed species to H_2S. At the moment the nature of the various chemisorbed species remains speculative.

An attempt was made by means of relative reflectivity measurements to distinguish qualitatively between the surface oxide species generated in the regions Ia, IIa, and the species associated with the extra currents observed in this region and IIIa (Fig. 4) after cathodic holding. Thus the surface oxide monolayer formed at Pt normally gives an increasingly negative $(\Delta R/R)_{\parallel}$ signal with increasing positive potential. Figure 9 shows how $(\Delta R/R)_{\parallel}$ varies with potential in anodic and cathodic sweeps following cathodic holding. The potential range is the same as that in Fig. 4, so that both the regions where extra anodic currents pass in IIIa, + Ia + IIa, and the region where the cathodic peak IIIc arises are covered in this diagram.

Figure 9 shows that the general shape of the $(\Delta R/R)_{\parallel}$ *vs. V* relations remains the same while the chemisorbed reactive species produced on cathodic holding is removed by successive anodic/cathodic cycling, but the intensity of the $(\Delta R/R)_{\parallel}$ signal falls as less of the species remains on the electrode. In the anodic direction, the reflectivity features of surface oxidation are not lost despite the development of extra oxidation charge (~ 4.20 C m^{-2}, Fig. 5) over the surface oxide formation region. This suggests [*cf.* Ref. (7, 8, 11, 13)] that the adsorbed species generated by cathodic holding and oxidized in the following sweep, is in a state intimately connected with the development of the surface oxide film as we have implied earlier in discussing the cyclic voltammograms and the isopotential point observed therein.

Relation to surface oxide formation and reduction.—The diminution of the surface oxide reduction peak as larger extents of reduction of H_2SO_4 are allowed to take place (Fig. 4) during cathodic holding, probably arises because the surface oxide participates, during the anodic sweep after holding, in the oxidation of SO_2 or of a reduced and/or chemisorbed (7-13, 24) form, to $S_2O_6^{2-}$ or to other adsorbed species such as -S-O (9), so that less oxide is formed during the time of that anodic sweep. The experiment where cathodic holding was carried out at the stationary and

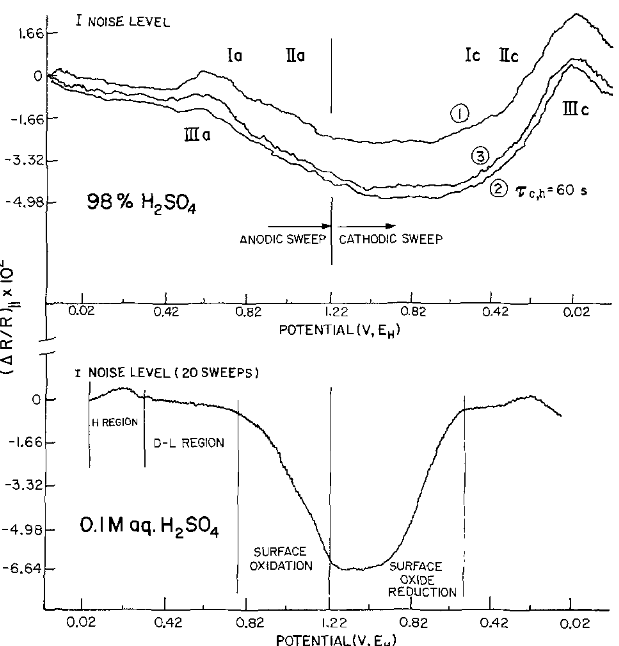

Fig. 9. Relative reflectivity $(\Delta R/R)_{\parallel}$ profiles for Pt in 98% H_2SO_4 as a function of potential (sweep rate 70 mV sec^{-1}, 298 K) at Pt in the presence of the adsorbed species generated by cathodic holding for 60 sec and in its absence during a repetitive sweep or during its decline after holding. Designations as in Fig. 2(a). Curve 1, behavior on repetitive cycling, as in Fig. 2(a); curve 2, after 60 sec holding at cathodic end of sweep, one cycle; curve 3, third cycle after the 60 sec cathodic holding; lower curve for 0.1M aq H_2SO_4 for comparison.

rotated electrode, showing that rotation had no effect on anodic currents observed on the subsequent anodic sweep, implies that $S_2O_6^{2-}$ or S-O-species are being formed in an adsorbed state, thus competing with formation of some of the surface oxide that would otherwise have been produced on the anodic sweep as in Fig. 2 without any reduction of H_2SO_4. The complete absence of an observable upd region for H at Pt (Fig. 2a) indicates that strong adsorption of H_2SO_4 molecules and/or HSO_4^- ions is occurring as well.

The conclusions concerning $S_2O_6^{2-}$ or S-O-adsorption are supported by the behavior observed when the potential is held constant for some time at the end of the anodic sweep, following slow reduction of H_2SO_4 during cathodic holding: then a normal quantity (cf. Fig. 2) of surface oxide becomes again observable. It was also concluded by Geronov *et al.* (25), that reduction of SO_2 at Pt, in this case in CH_3CN, leads to formation of an adsorbed species that rapidly transforms into a passivating film of dithionate (*sic;* probably dithionite in their case).

Role of water.—Following the work described above in "98%" H_2SO_4, some experiments were performed with controlled additions of water to give concentrations of 0.275, 0.55, and 1.10M of added H_2O in the 98% H_2SO_4. As shown in the series of *i vs. V* profiles in Fig. 10, addition of water allows some upd of H to arise before significant H_2 evolution currents appear. Also, in the presence of added water, cathodic holding, followed by an anodic cathodic sweep, produces less of the reduced and reoxidizable species as the water content is increased. Eventually normal behavior of an aqueous H_2SO_4 solution is recognized where reduction effects are insignificant.

Since, with relatively small additions of water, the reduction reaction is considerably diminished, yet the concentration of H_2SO_4 is still *ca.* 17M, this behavior suggests that the reduction to SO_2 and another intermediate does not take place from molecular H_2SO_4 but possibly from the small concentration[2] of $H_2S_2O_7$ that is present at equilibrium with H_2SO_4 molecules (2). The added water of course, even at the highest concentration of 1.1M could only produce 1.1M of extra H_3O^+ and HSO_4^- ions, *i.e., ca.* 5.8 mol percent, so that most of the H_2SO_4 remains as un-ionized molecules.

Behavior at Au.—In order to examine if the reduction of H_2SO_4, or $H_2S_2O_7$ contained in it, is a simple electron-transfer process or one requiring chemisorption and electrocatalysis, the behavior of a gold electrode in 98% H_2SO_4 was examined comparatively. An excellent cyclic-voltammetry profile is obtained at Au, with no evidence of impurity effects [cf. Ref. (5, 16)], confirming the high degree of purity of B.D.H. Aristar H_2SO_4. The general features of this curve for Au are similar to those for Au in aqueous H_2SO_4. Cathodic holding for up to 2 min at the same potential as at Pt revealed absolutely no indication of any reduction of the H_2SO_4. The subsequent anodic and cathodic sweeps were identical with those under repetitive cycling conditions. Under the same conditions as at Pt, addition of SO_2 (as SO_3^{2-}) also gave no reaction currents, either in anodic or cathodic sweeps. This is contrary to what has been found in aqueous solutions (24) and the absence of such an effect here must be attributed presumably to the strong adsorption of H_2SO_4 [cf. Ref. (5)] at Au and the different effective cathodic range of potentials therefore involved. Adsorption and reactivity of S (as S^{2-}) at Au are also known (26).

It is therefore to be concluded that the reaction of H_2SO_4 reduction observed at Pt is associated with the catalytic and adsorptive properties of this metal and that H_2SO_4, or $H_2S_2O_7$, is not easily reduced in an electron-transfer process not involving chemisorption and electrocatalysis.

[2] However, the rotation experiments mentioned on p. 2265 on behavior at the rotated Pt electrode would not support this conclusion unless the rotation effect is more conneced with spin-off of SO_2, restricting further reduction and/or chemisorption to Y.

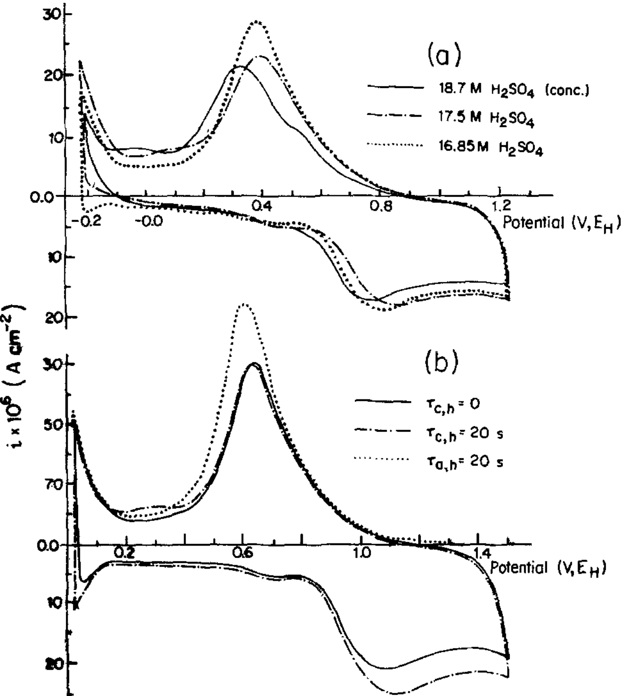

Fig. 10. Cyclic-voltammetry *i vs. V* profiles for Pt in 98% H_2SO_4 with small additions of extra water. Sweep rate 58 mV sec^{-1}; 298 K. (a) Anodic/cathodic cyclic-voltammograms without cathodic holding. (b) Behavior after cathodic holding for 20 sec or, separately, anodic holding for 20 sec. Concentrations of H_2SO_4, after additions of water, as indicated.

Conclusions

98% H_2SO_4 can be reduced at Pt electrodes near the steady potential of a hydrogen electrode in the same solution. Chemical simulation experiments demonstrate that the identity of the initial product of the observed slow reduction of H_2SO_4 is SO_2 or HSO_3^-. A chemisorbed species derived from SO_2 is oxidized in a following anodic sweep not back to H_2SO_4 or SO_3 but to an adsorbed intermediate Y_o that is reduced back to a species that is relatively easily desorbed into solution at the end of a subsequent sweep near the H_2/H^+ steady potential. Simulation experiments show that it is possible that the species (Y_o) derived from SO_2 is dithionate or dithionic acid, probably stabilized in some state by adsorption at the Pt electrode. It is most likely that chemisorbed intermediates, derived from SO_2, or from the added $S_2O_6^{2-}$, which are not normal stable compounds, are involved.

No reduction of 98% H_2SO_4 or electroactivity of SO_2 (or HSO_3^-) is observed at Au under the same conditions as at Pt. By comparison, therefore, the observation of reactions which take place at Pt indicate that an electrode surface, where electrosorption and electrocatalysis can occur, is required for the initial stage of reduction of H_2SO_4 to SO_2.

Reactions of Scratched Copper Electrodes in Aqueous Solutions

G. T. Burstein* and R. C. Newman[1]

Department of Metallurgy and Materials Science, University of Cambridge, Cambridge CB2 3QZ, England

ABSTRACT

The behavior of copper electrodes scratched under potential control in aqueous electrolytes is presented. In alkaline solution the metal surface shows the presence of two distinct types of oxidized monolayer, ascribed to CuOH and Cu_2O, each formed over a unique potential range well below the reversible potential for bulk Cu_2O formation. The Cu_2O monolayer is a necessary precursor to passivation of the metal, and in sulfuric acid solution only the CuOH monolayer is observed. This monolayer acts as an intermediate layer in both the dissolution and passivation processes and probably also exists during steady-state hydrogen evolution. Addition of ammonia to alkaline electrolytes modifies the CuOH monolayer, probably by incorporation of NH_3, rendering formation of Cu_2O more difficult.

Determination of the kinetics of reaction between scratched metal electrodes and aqueous electrolytes gives quantitative information on fast electron transfer steps (1-6). The scratched iron electrode (1) reacts very rapidly to form an Fe(I) species adsorbed to complete coverage to the metal surface. Given the nominal composition of FeOH, this monolayer is affected by some anions in the electrolyte such as Cl^- and $H_2PO_4^-$ (2). Silver has been shown to react anodically with the formation of single adsorbed monolayers of AgOH and Ag_2O (3, 4). These monolayers are formed at potentials well below the reversible potential for bulk Ag_2O formation and the behavior is in complete accord with results obtained from fast potential sweeping and potential pulsing experiments on polished silver surfaces (3). Thus, at least in the case of silver, these underpotential reactions are not uniquely a property of the heavily cold-worked scratch surface. Further, at *p*H 14, scratched silver shows a small potential range in which no oxidation reaction occurs: Under these conditions it is possible to determine the zero charge potential of the unreacted metal surface (3, 7).

The fast electron transfer reactions that occur from scratched surfaces have been used to interpret the rate of stress-corrosion cracking in some systems (5, 6, 8). The relevance of bare surface reaction kinetics

to mechanically assisted corrosion processes such as stress-corrosion cracking and corrosion fatigue has prompted investigation of dissolution and passivation processes on dynamically strained wire electrodes (9); however, the ill-defined rate of bare surface generation in this type of experiment renders difficult the quantification of this type of result.

The ohmic potential drop to potentiostatically controlled scratched electrodes in relatively resistive solutions has been calculated (10): This type of calculation is necessary because of the very large current densities that flow from the freshly generated metal surface. It is worthy of note that when pure copper is scratched in solutions containing NO_2^- in open circuit, reduction of the anion to NH_3 occurs (11, 12).

In the present paper we examine the behavior of potentiostatically controlled scratched copper electrodes and describe the effects of ammonia on the reactions that occur.

Experimental

Rotating disk electrodes (8 mm diam) were prepared from pure Cu (Johnson-Matthey, 99.999%) by mounting into Perspex and sealing with Araldite. The technique used to scratch potentiostatically controlled rotating disk electrode was described previously (1-6). The diamond stylus tracked with a weight of ~2g, creating a shallow scratch ~3 μm deep and 40 μm wide at a rotation rate of 100 Hz and a linear scratching velocity of ~2 $msec^{-1}$. The contact times of the stylus varied from 0.2 to ~1 msec. By using the slope of the rising current transient during the actual scratching process to calculate the bare surface current density i_s the resulting value is independent of the contact time of the stylus and also independent of any small irregularities occurring in the scratch width. Thus

$$i_s = \frac{1}{2\pi r\omega y}\frac{dI}{dt}$$

where dI is the change in current on the electrode in time dt due to scratching, r is the distance of the scratch from the center of rotation, ω is the rotation rate of the disk, and y the scratch width. The maximum scratch depth is small compared with its width and is thus ignored. The total charge density q_s required to bring the scratch back to a steady state was also measured; this was calculated from the total area under the current transient, and is given by

$$q_s = \frac{1}{2\pi r\omega y t_c}\int_0^\infty I dt$$

where t_c is the contact time of the stylus. The quantity $2\pi r\omega y t_c$ is the area of the scratch surface. Where re-equilibration of the scratch surface took longer than 5 msec, the q_s values quoted are for 5 msec after initial contact of the stylus.

The potential of the working electrode was measured relative to a saturated calomel electrode via a Luggin capillary probe positioned ~40 mm below the working electrode. All potentials are presented relative to the normal hydrogen electrode and have been corrected for the liquid junction potential between the working and reference electrolytes. Corrections have also been made for the ohmic potential drop in the electrolyte due to the current from the scratch using calculations and measurements of the resistance to flow of current to narrow strip electrodes (10).

The counterelectrode was a circular platinum foil, 30 mm diam, containing a small concentric hole through which the Luggin capillary probe emerged. Electrolytes were prepared from analytical grade reagents and doubly distilled water and were purged with deoxygenated nitrogen before and during experiments. Ammoniacal electrolytes were made up to a constant concentration of (NH_3 + NH_4^+) at 1.0M, the latter being added as $(NH_4)_2SO_4$. Where necessary Na_2SO_4 was added as supporting electrolyte to give approximately constant ionic strength. Measurements were made at a temperature of 293 ± 2 K. Potentials were controlled with a Wenking potentiostat (Type OPA 69). Current transients were recorded in a transient recorder (Datalab Type DL 905) and displayed on an oscilloscope or chart recorder.

Results

Bare surface polarization curves and charge density curves for copper in 1.0M KOH are shown in Fig. 1. The anodic reaction is accelerated by orders of magnitude at all potentials above −900 mV (NHE) when compared with the steady-state current densities i_b (also shown in Fig. 1). At potentials more negative than −900 mV (NHE) the cathodic reaction, representing the evolution of hydrogen, is also greatly accelerated. Both anodic and cathodic branches of the bare surface polarization curves do indeed represent electron transfer reactions and are not accounted for by non-faradaic double layer charging processes, since the bare surface charge densities, q_s, are too large at all potentials to represent the latter process. Only in the region of the bare surface mixed potential E_{ms}, at E_{ms} ± 25 mV, does q_s fall below 100 μC cm^{-2}, accounted for quite clearly by the fact that the anodic and cathodic reactions occur at comparable rates over this small range.

Anodic current density plateaus occur between −800 and −550 mV (NHE) and between −500 and −350 mV (NHE). These correspond to plateaus in charge density q_s, at 145 ± 26 and 378 ± 58 μC cm^{-2}, respectively; although the latter is rather poorly defined it is in quantitative agreement with that found for the

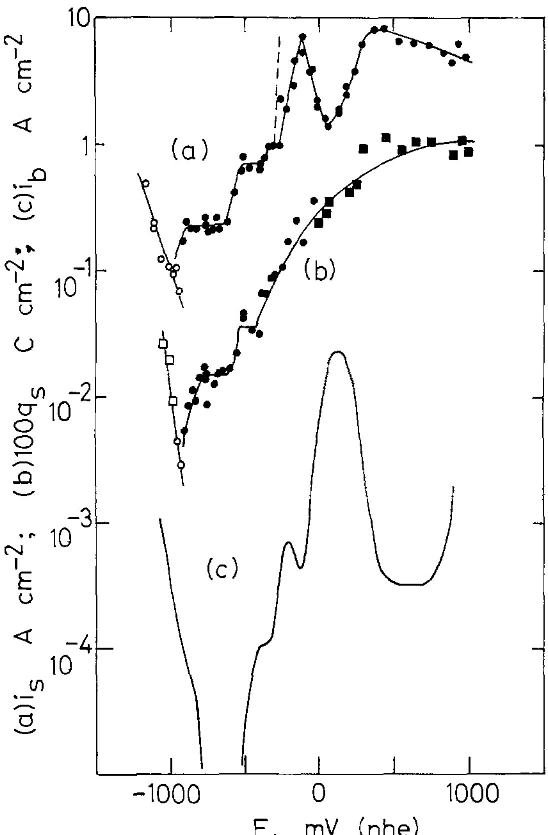

Fig. 1. Bare surface electrochemistry of copper in 1.0M KOH. (a) i_s. (b) q_s after complete re-equilibration (●), or 5 msec after first stylus contact (■). silver electrode in the same electrolyte (3) (see below). Between −120 and +80 mV (NHE) i_s decreases with increase in E. This potential range corresponds to a rise in the steady-state current density i_b, where copper dissolves anodically to give CuO_2^{2-} in solution prior to passivation of the metal by CuO. It should be noted that during this process q_s increases continuously. The maximum anodic current density observed on the scratch surface is 8 A cm^{-2}. Typical current transients obtained at different potentials in 1.0M KOH are shown in Fig. 2.

Further bare surface polarization curves measured in nonammoniacal electrolytes are shown in Fig. 3-5. In 1.0M H_2SO_4 the maximum anodic current density, i_s, is 1 A cm^{-2}, and q_s shows a maximum at 208 ± 58 $\mu C\ cm^{-2}$ covering the long potential range −250 to +250 mV (NHE). The second plateau in i_s and q_s does not occur in this electrolyte. Figures 4 and 5 also show plateau anodic charge densities in borate solutions.

Results obtained for ammoniacal electrolytes at three pH values are shown in Fig. 6-8. The diagrams show regions in which both i_s and q_s are independent of E. Regions of potential are also shown where i_s decreases with increase in E, although there is no parallel decrease in q_s. The potential range over which the latter effect occurs commences with the onset of anodic activity of the electrode as a whole, as can be seen by inspecting the appropriate values of i_b in Fig. 6-8. These features of the bare surface polarization curves are discussed below.

The bare surface mixed potentials E_{ms} are plotted in Fig. 9 as a function of pH, together with the reversible potentials for stable equilibrium reactions given by Pourbaix (13) for copper in noncomplexing solutions. Solution species are plotted at a concentration of 10^{-6}M. The values of E_{ms}, which represent potentials at which the rates of oxidation of copper and reduction of hydrogen on the scratch are equal, all lie well below the thermodynamic equilibrium potentials. The anodic reactions on the scratch are thus

occurring at an underpotential compared with the equilibrium potentials for bulk reactions. In the nonammoniacal electrolytes two regions of pH dependence occur: For $pH < 8$, $\partial E_{ms}/\partial pH = -57$ mV, while for $pH > 11$ the bare surface mixed potential is indepen-

dent of pH. In ammoniacal electrolytes the values of E_{ms} are more positive and give for pH < 10, $\partial E_{ms}/\partial pH$ = 137 mV, but this also tends toward pH independence at high pH.

Also shown are the following equilibrium lines from Pourbaix (13): (a) $Cu = Cu^{2+} + 2e^-$ with $(Cu^{2+}) = 10^{-6}$M, (b) $2Cu + H_2O = Cu_2O + 2H^+ + 2e^-$.

Discussion

Nonammoniacal electrolytes.—In a previous paper we showed that the current and charge densities passed on scratched silver surfaces in 1.0M KOH were not significantly different from those obtained by potential pulsing or rapid potential sweeping experiments on unscratched silver surfaces. Two different adsorbed oxidized monolayers, designated AgOH and Ag_2O, were proposed to account for anodic charge densities of ~150 and ~300 $\mu C\ cm^{-2}$, respectively, obtained by all three techniques; these monolayers were shown to exist over two consecutive potential ranges, both well below the potentials at which anodic activity of the metal is expected (13). The fact that all three techniques showed similar behavior indicates that these observations are not influenced significantly by the highly defective nature of the surface produced by scratching. Figure 1 shows that copper behaves in a very similar way when scratched in 1.0M KOH, with two distinguishable plateaus in the anodic q_s *vs.* E curve (145 and 378 $\mu C\ cm^{-2}$, respectively) at low potentials. It is not possible to compare these results obtained on scratched copper directly with those obtained from rapid potential sweeping or potential pulsing experiments owing to interference from the hydrogen electrode reaction. Thus no zero charge potential is observed for scratched copper [as was obtained for silver (3)] owing either to formation of adsorbed hydrogen or oxidation of Cu, or both, at all potentials around the bare surface mixed potential. The two plateau charge densities in the anodic region are ascribed to formation of single adsorbed monolayers of CuOH and Cu_2O, respectively. One would expect a monolayer of Cu_2O to contain approximately twice as many Cu^+ ions per unit area as CuOH, in line with comparisons of other oxide-hydroxide molar density ratios. Both of these monolayers occur at potentials well below the equilibrium potentials required for multilayer oxide formation (13).

The full sequence of reactions exhibited by the scratched Cu electrode in 1.0M KOH is given in Table I. At −350 mV (NHE) q_s rises above 378 $\mu C\ cm^{-2}$, representing growth of a multilayer film of Cu_2O, in full agreement with the value of $E_o = -356$ mV (NHE) (13). Dissolution as CuO_2^{2-} also occurs and this contributes to the rise in i_b. Formation of Cu_2O and CuO on the bare surface in Table I is described in terms of the net reactions, and the mechanisms are unknown. Thus for example the underpotential monolayer of Cu_2O may occur in one step

$$2Cu + OH^- \rightarrow Cu_2O_{ads} + H^+ + 2e^-$$

or may form from the previously formed CuOH monolayer

$$Cu + CuOH_{ads} \rightarrow Cu_2O_{ads} + H^+ + e^-$$

The effects of scratching on the oxygen evolution reaction ($E_o = +400$ mV (NHE)] are also unknown because of interference from the copper oxidation reactions.

The results obtained in 1.0M H_2SO_4 (Fig. 3) differ from those shown in Fig. 2 in that q_s is almost constant at 208 $\mu C\ cm^{-2}$ over a large potential range. This charge density is consistent with, although slightly greater than that assigned to formation of a monolayer of CuOH in the alkaline solution, and the monolayer of Cu_2O is not formed. In the borate electrolytes (Fig. 4 and 5) the higher charge density plateau, at 300 to 400 $\mu C\ cm^{-2}$, is observed although plateaus at around 150 $\mu C\ cm^{-2}$ are obscure. The full analyses of these charges are given in Table II, together with those obtained from the ammoniacal electrolytes.

It is important to realize that in 1.0M H_2SO_4 only the CuOH monolayer is formed. The monolayer of adsorbed Cu_2O, which is apparent at potentials below the Cu/bulk Cu_2O reversible potential in neutral and alkaline solutions, was not found in acid solution. Inspection of the i_b *vs.* E curve for the acid electrolyte (Fig. 3) shows that there is no tendency for the metal to passivate. Clearly, the first monolayer of Cu_2O is a necessary precursor for passivation, whereas the adsorbed CuOH monolayer acts as an intermediate layer in both the dissolution and passivation processes. Indeed, the CuOH layer probably participates in the hydrogen evolution reaction as well, since Fig. 1-5 indicate that the layer is present at potentials where hydrogen evolution occurs in the steady state. It is for this reason, of course, that the hydrogen evolution reaction is accelerated on scratching. In the regions where i_s is cathodic in Fig. 1-5 values of q_s show that more than a monolayer of hydrogen is reduced on the scratch surface before a steady state is reestablished.

Ammoniacal electrolytes.—The introduction of 1.0M $(NH_3 + NH_4^+)$ into neutral electrolytes (Fig. 6) profoundly affects the behavior of the scratched copper electrode. Values of q_s in the potential range −150 to +50 mV (NHE) were 62 $\mu C\ cm^{-2}$, compared with 388 $\mu C\ cm^{-2}$ in the absence of ammonia (see Table II). The Cu_2O monolayer is thus not formed in the ammoniacal solution. Indeed, the values of q_s are even smaller than that expected for a monolayer of CuOH, and it is clear that NH_3 must be incorporated into the monolayer lattice, so that the number of copper atoms required to form the oxidized monolayer is decreased. The proposed monolayer for ammoniacal electrolytes is $Cu(NH_3)OH$, in which the cation is now $Cu(NH_3)^+$, occupying a greater surface area per cation than Cu^+ for nonammoniacal electrolytes. The formation of the ammonia-containing monolayer might be expected to hinder further reaction to produce the Cu_2O monolayer and thus impede passivation of the metal at higher po-

Table I. Reactions of scratched copper in 1.0M KOH and steady-state surface composition as a function of E

E, mV (NHE)	Bare surface reactions	Steady-state surface composition
< -900	$H_2O + e^- \rightarrow H_{ads} + OH^-$	$\theta_H << 1$ θ_{CuOH}
-900 to -550	$Cu + OH^- \rightarrow CuOH_{ads} + e^-$	$\theta_{CuOH} = 1$
-550 to -500	$Cu + OH^- \rightarrow CuOH_{ads} + e^-$ $2Cu + OH^- \rightarrow Cu_2O_{ads} + H^+ + 2e^-$	$\theta_{CuOH} + \theta_{Cu_2O} = 1$
-500 to -350	$2Cu + OH^- \rightarrow Cu_2O_{ads} + H^+ + 2e^-$	$\theta_{Cu_2O} = 1$
-350 to -150	$2Cu + OH^- \rightarrow Cu_2O_s + H^+ + 2e^-$	Cu_2O (multilayer)
> -150	$Cu + OH^- \rightarrow CuO_s + H^+ + 2e^-$	CuO (multilayer)

Table II. Analysis of plateau charge densities passed on a bare copper surface in several electrolytes. Error limits are standard deviations over the number of points given. The adsorbed surface monolayers give the proposed stoichiometries, each at complete monolayer coverage.

Electrolyte	pH	E, mV (NHE)	q_s (μC cm^{-2})	Number of points	Adsorbed surface monolayer
1.0M KOH	14	-800 to -600	145 ± 26	9	CuOH
1.0M KOH	14	-500 to -400	378 ± 58	4	Cu_2O
0.5M $K_2B_4O_7$	9.8	-250 to -200	352 ± 25	2	Cu_2O
0.5M Na_2SO_4 + 0.05M (H_3BO_3 + $Na_2B_4O_7$)	7.3	-450 to -50	388 ± 55	5	Cu_2O
1.0M H_2SO_4	-0.16	-250 to $+275$	208 ± 58	26	CuOH
1.0M NH_3 + 0.5M Na_2SO_4	11.6	-490 to -350	233 ± 33	6	CuOH
1.0M (NH_3 + NH_4^+) + SO_4^{2-}	9.5	-390 to -170	133 ± 32	10	CuOH + $Cu(NH_3)OH$
1.0M (NH_3 + NH_4^+) + SO_4^{2-}	7.25	-150 to $+50$	62 ± 15	12	$Cu(NH_3)OH$

tentials, since the process

$$Cu + Cu(NH_3)OH_{ads} \rightarrow Cu_2O_{ads} + NH_4^+ + e^-$$

requires removal of NH_4^+ rather than H^+, as in the reaction

$$Cu + CuOH_{ads} \rightarrow Cu_2O_{ads} + H^+ + e^-$$

This is reflected in the far higher steady-state dissolution current densities i_b shown for ammoniacal electrolytes (compare Fig. 6-8 with Fig. 1, 4, and 5). In this respect it is noteworthy that the main product of steady-state anodic dissolution of Cu in these ammoniacal electrolytes is $Cu(NH_3)_2^+$, which is soluble to the extent of 0.05M in equilibrium with Cu_2O (14).

For higher pH, on the other hand, the values of q_s shown in Table II for ammoniacal electrolytes are higher; this is probably due to reversion of the monolayer to CuOH with increase in hydroxide concentration. This is also reflected in the E_{ms} *vs.* pH curve (Fig. 9): at high pH E_{ms} approaches the same constant value for both types of electrolytes. Values of the dissolution current density i_b, however, are not a direct consequence of whether the initial monolayer is CuOH or $Cu(NH_3)OH$, since formation of the monolayer is not the rate-determining step in the total dissolution process. Subsequent steps also clearly involve complexing ligands. This has already been described for the scratched iron electrode in chloride and bicarbonate electrolytes (2). Both Cl^- and HCO_3^- cause pitting of iron, but only Cl^- enters the formation of the initial monolayer.

Effects of electrolyte resistance.—Many of the bare surface polarization curves shown in Fig. 1 and 3-8 exhibit regions in which i_s decreases as E becomes more positive. The feature is shown most dramatically in Fig. 1 and 6-8 and is invariably associated with a rise in i_b, representing an increasing rate of anodic dissolution of Cu from the unscratched surface. It is not seen in electrolytes in which Cu is passive (Fig. 4 and 5); nor is it seen in the sulfuric acid system. The effect is associated invariably with ohmic potential drops (10) which occur on and near the scratched surfaces owing to a combination of high electrolyte resistance and high anodic scratch current densities. The consequence of this is to superimpose on the anodic current transient emanating from the scratch, a cathodic current transient resulting from a lowering of the electrode potential on an area surrounding the scratch when the electrode as a whole is dissolving or carries a readily reducible film. The effect may include two components: a decrease in the rate of steady-state anodic dissolution of the area surrounding the scratch, or electrochemical reduction of surface oxidized species. Thus for example, in Fig. 1 in the potential region in which steady-state dissolution as Cu(II) (in the form of CuO_2^{2-}) occurs from the electrode as a whole, scratching the electrode causes a transient reduction in the rate of steady-state dissolution on an area surrounding the scratch, giving an apparent lowering of the value of i_s with increasing E. The further possible effect of the ohmic potential drop is to reduce oxidized ions on the surface, for example by the following reactions:

on the scratch

$$Cu + H_2O \rightarrow CuOH_{ads} + H^+ + e^-$$

on the surrounding surface

$$2CuO + H^+ + 2e^- \rightarrow Cu_2O + OH^-$$

Either or both mechanisms may explain the effect as it is observed in 1.0M KOH (Fig. 1) since it occurs in a potential region [commencing at -150 mV (NHE)] where both CuO_2^{2-} and CuO can form (13). The effect has also been observed for the scratched silver electrode (3) at potentials where AgO is reduced transiently to Ag_2O on the area surrounding the scratch.

In 1.0M H_2SO_4 (Fig. 3) the ohmic potential drop effect is not observed, despite overall dissolution of the electrode, since the ohmic resistance of the electrolyte is small, and the values of i_s are themselves lower. In the ammoniacal environments, however, where the electrolyte resistance is high, the effect is clearly observed where the entire electrode is dissolving as $Cu(NH_3)_2^+$.

Previous work on scratched and rapidly strained brass electrodes in ammoniacal electrolytes (8, 15) has overlooked these effects and thus obtained values of i_s which are too low. While the effect has not yet been fully quantified, it is clear that the electrode surface

area over which it extends is large compared with the scratch area since i_s is large compared with i_b. It follows that an increase in the ratio of the scratch area to the total electrode area would decrease the ohmic potential effect, and this has indeed been demonstrated by the use of lacquered and partially lacquered electrodes. Appropriate positioning of the Luggin capillary probe would also be of some benefit, but this is impracticable because (*i*) the proximity of the scratching stylus and (*ii*) the diameter of the probe tip which would have to be small compared with the scratch size.

Conclusions

1. Scratching of Cu electrodes at constant potential results in greatly accelerated anodic oxidation and cathodic reduction current densities. Up to 8 A cm^{-2} of anodic reaction have been recorded.

2. Copper carries two surface oxidized monolayers at potentials very much more negative than the Cu/Cu_2O reversible potential. These underpotential monolayers are designated as CuOH and Cu_2O and account for anodic charge densities of ~150 and 300-400 μC cm^{-2} on the scratch surface, each occurring to complete coverage. The former exists at the lowest accessible anodic potentials on the scratch and probably even into the region where hydrogen evolution is the dominant electrode reaction.

3. The Cu_2O monolayer occurs only in neutral and alkaline solutions and is a necessary precursor to passivation of the metal at higher potentials by a thicker film of Cu_2O.

4. The steady-state anodic dissolution of Cu occurs through an adsorbed monolayer of CuOH at complete coverage. The steady-state evolution of hydrogen on Cu also occurs through this monolayer, at least at low cathodic overpotentials.

5. The presence of 1.0*M* ($NH_3 + NH_4^+$) in the electrolyte results in formation of an adsorbed monolayer of $Cu(NH_3)OH$ in the neutral *p*H range at potentials very much more negative than the Cu/Cu_2O reversible potential. This monolayer is not readily converted to a Cu_2O monolayer, and results in dissolution of the metal as $Cu(NH_3)_2^+$ at higher anodic potentials.

6. The scratched copper electrode does not yield a potential of zero charge since electron transfer occurs at all potentials for all *p*H.

Protective Coatings by Anodic Coupling Polymerization of o-Allylphenol

Giuliano Mengoli, Paolo Bianco, Sergio Daolio, and Maria Teresa Munari

Istituto di Polarografia ed Elettrochimica Preparativa del C.N.R., Corso Stati Uniti 4, 35100 Padova, Italy

ABSTRACT

The anodization of Fe sheets in hydroalcoholic solutions of o-allylphenol containing allylamine leads to *in situ* formation of coherent coatings. These coatings consist of thermosetting polyoxyphenylenes which after thermal curing have good adhesion and impart corrosion protection to the substrate. The anodization time and electric power consumption are comparable with those typical of a conventional electrophoretic coating.

A route for achieving the *in situ* formation of thick (10-20 μm) polyoxyphenylene coatings, having possible applications for metal protection, has been recently outlined (1, 2). The process may be realized by anodizing, at the metal surface to be coated, hydroalcoholic solutions of phenol containing a suitable amine [allylamine gave the best performances (2)]. However, the data so far reported have shown that the process is not yet competitive with other conventional "painting" techniques. In comparison with the electrophoretic deposition (3) of preformed polymers, the major handicaps were: extended electrolysis times; limited corrosion resistance of the coatings (from salt fog tests), and poor adhesion under stress (from conical mandrel and drawing tests).

The fact that the electrolysis time was too long was mainly related to the low useful electrolysis current

Key words: film, corrosion, organic, electrolysis.

(<10 mA/cm²). *In situ* phenol polymerization, in fact, did not tolerate high applied voltages,[1] because either passivation of the substrate occurred especially when Fe sheet anodes were coated, or rupture of the film being formed took place. The limited corrosion resistance and poor adhesion were likely related to the structure of the polymer. The polymer probably was, *ab initio*, exceedingly branched and cross-linked and thus could neither take appreciable advantage from thermal curing nor have elasticity enough to tolerate stresses and deformations. Through the utilization of o-allylphenol instead of phenol we now have overcome such handicaps.

The aim of this paper is to describe both the features of o-allylphenol/allylamine *in situ* polymerization onto Fe sheet anodes and the protective performances of the resulting coatings.

Experimental

Apparatus and procedure.—The coating runs were performed in a single compartment cell described previously (1, 4) by applying a constant voltage between the sample of Fe sheet (anode) and a Pt coil (cathode) facing the sheet. Physical properties of the coated specimens were determined according to ASTM methods. The composition of the polymeric material, once recovered from the substrate, was investigated by instrumental analytical techniques, including pyrolysis coupled to mass spectroscopy (5) and thermogravimetry. Information on the molecular weights and their distribution was obtained by vapor pressure osmometry and gel permeation chromatography. Other experimental details are reported in either the tables or the captions of the figures.

Chemicals.—All compounds used in this study were commercially available reagent grade chemicals. The reaction medium consisted of water/alcohol mixtures. The preferred standard composition was: o-allylphenol 6 ml, allylamine 6 ml, cellosolve 2 ml, KOH 0.5g, all dissolved in a standard 100 ml of H_2O/CH_3OH (equal volumes). The Fe sheets [23.5 × 2.5 × 0.05 cm (1, 2)] were dipped in alkaline cleaning bath prior to coating.

Results

Characteristics of the electrolytic process.—The formation of coatings on Fe sheet anodes from the o-allylphenol/allylamine system bears many similarities to systems based on phenol as described in preceding papers (1, 2). Thus, the coating material is produced by a yield not far from 2**F**/mol of monomer consumed. An oxidative coupling process is therefore strongly supported, whereas the engagement of the allyl group in an electrolytic polymerization must be discarded.

The formation of a coherent and homogeneous coating is indicated, during electrolysis, by a smooth continuous current decrease. Such current transients are qualitatively affected by experimental variables such as monomer and amine concentration, temperature, composition of the medium, and applied voltage.

However, it must be noted that the high voltages applied here (≧ 15V) do not cause the dramatic passivation phenomena observed elsewhere (1, 2). This behavior is illustrated in Fig. 1 and 2. Figure 1 shows the current transients obtained during the coating process for various applied voltages. In each case the sheets were uniformly coated: The high residual current tested at the highest voltage is due to the relatively low electrical resistance of the wet film. Figure 2 shows the current-potential curves obtained potentiodynamically on a rotating Fe microdisk. Anode insulation by filming is evident here only for very

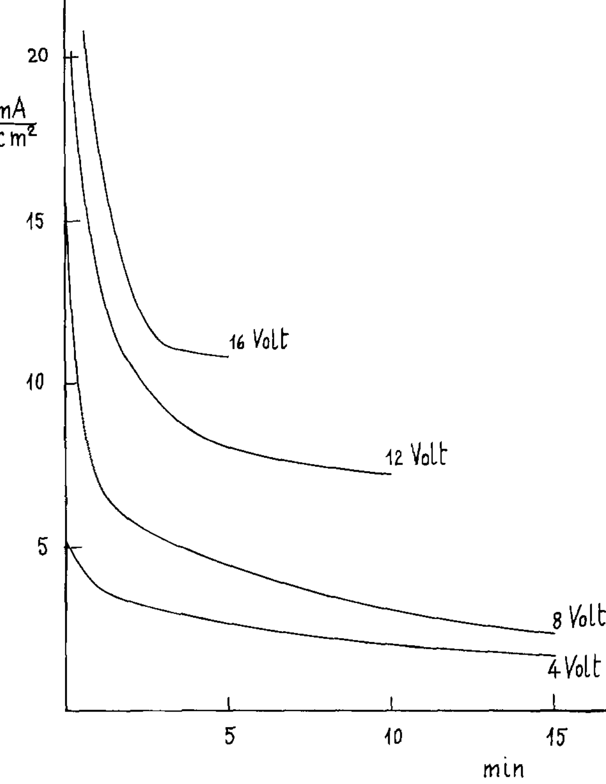

Fig. 1. Current transients during the anodization of Fe sheets in the standard composition (o-allylphenol 0.456 mol liter^{-1}, allylamine 0.800 mol liter^{-1}, cellosolve 0.200 mol liter^{-1}, KOH 0.09 mol liter^{-1}, in H_2O/CH_3OH at t = 25°C) for increasing applied voltages.

low potential sweep rates (*i.e.*, long electrolysis times).

As mentioned before, the fact that the o-allylphenol/allylamine system tolerates far higher voltages than phenol-based systems is very important from a practical point of view, as faster coating operations are achieved. This may be deduced from the data of Table I. The decrease of coulombic yield taking place as the voltage is increased to 16V is quite acceptable considering that both coating thickness (mg/cm²) and deposition time become typical of a conventional electrophoretic process.[2]

Molecular weights.—In previous work, the coating material obtained from phenol, when dried, partially dissolved only in trifluoracetic acid. By contrast the (uncured) products from allylphenol consist of a major fraction soluble in common organic solvents (acetone) and a minor insoluble fraction. The latter, which constitutes the inner layer in contact with the metal, may become important in some experimental conditions.

Table II shows how the experimental variables influence both $\overline{M}_n$ and the ratio of soluble to insoluble fractions. Constancy (in the range 2000-3000) of $\overline{M}_n$ obtained for different conditions indicates that the termination step is mainly determined by insolubility of the chains, which cannot thus undergo further anode oxidation. The higher $\overline{M}_n$ resulting either at a high percentage of methanol (runs 8-9) or with ethanol and propanol instead of methanol (runs 20-21), therefore takes into account the increased solubility of the polymer in the medium, whereby chain precipitation takes place for higher degrees of polymerization. The inverse dependence of M_n on monomer concentration which seems indicated by runs 1

[1] Not more than 3-5V could be generally applied to an electrolyzer having a cell constant ∼20 cm, and for solutions having χ = 3-8 msec (1).

[2] The current passed is about ten times higher here than in electrophoresis, but power consumption ($i \times t \times v$) is of the same order.

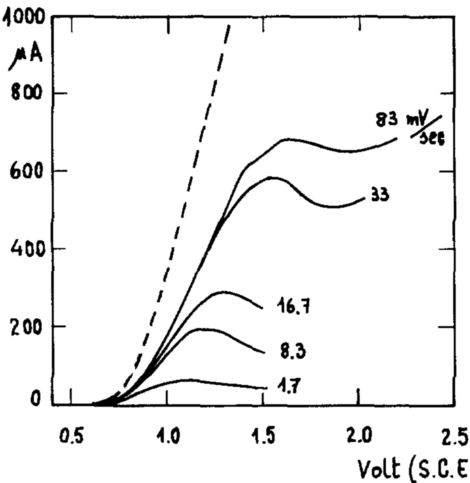

Fig. 2. Current-potential (vs. SCE) curves obtained from the standard composition by a rotating (1000 r/min) Fe microanode (area 0.03 cm^2). The dashed line refers to the oxidation of the background system alone; the other curves refer to increasing sweep rates (mV sec^{-1}).

and 5-7 is not surprising when considering that polymer chains are built up step by step at the anode and that the probability of oxidizing and coupling the same chains again increases with monomer dilution. The formation of the insoluble fraction seems to be favored by the highest temperatures, methanol concentrations, and electrolysis times, but depends inversely on the amine concentration (runs 17-19). Neither applied voltage nor charge transferred has any influence.

Molecular weight distributions were estimated, using polystyrene as a standard, by gel permeation chromatography, as shown in Fig. 3.

Table I. Features of electrolytic coating process for various voltages applied*

Applied voltage (V)	Time (min)	Charge (C)	I initial (mA/cm^2)	I final (mA/cm^2)	Current yield (mg/C)
3.0	50	81	2.78	0.59	0.577
5.0	15	78	8.52	1.89	0.564
10.0	8	86	23.33	5.00	0.477
16.0	3	74	31.48	10.55	0.400

* Conditions: o-allylphenol 0.456 mol $liter^{-1}$; allylamine 0.800 mol $liter^{-1}$; cellosolve 0.200 mol $liter^{-1}$; H_2O/CH_3OH 50% by volume; t = 25°C. The coating yield (mg/cm^2) ranged from 1.7 (3V) to 1.3 (16V).

Reproducibility of coating performances.—Figure 3 refers to samples selected from a series of 50 sheets, all coated one after the other, with the same 100 ml of standard solution. The good independence of molecular weights on the progressive number of the sheets constitutes a first test of reproducibility for the system.

Confirmation is provided by the constancy of the coulombic yield (mg/C $\approx$ 0.55) observed during the coating process for all these 50 sheets. However, in a limited volume of solution, repeated coating runs lead to a kinetic decline. This is shown in Fig. 4 where the coating yield (mg/cm^2) obtained on each sheet after 30 min of electrolysis (*i.e.*, average coating rate) is plotted *vs.* the progressive number of sheets. This behavior is determined by progressive impoverishment of the monomer from the solution (compare dashed curves a and b of Fig. 4). For the same voltage and electrolysis time, a concentration decrease in effect results in a reduced transfer of current. However, since from a practical point of view it is very easy to achieve automatic control of both monomer concentration in solution and thickness of coatings formed (by the coulombs passed), it may be concluded that system features[3] are such as to allow application in continuous processes.

Protective features of the coatings.—When withdrawn from the anodization bath, the coated sheets appear homogeneous and coherent, their color varying from pale yellow to brown yellow.

Wet film adhesion to the substrate is good enough to allow rinsing in running water before drying. When the samples are cured in an oven at 150°-155°C for 20-30 min a fine gloss is obtained. Thermal treatment further improves resistance toward chemicals and organic solvents as well as any other protective feature.

Table III shows the properties of samples obtained on varying either o-allylphenol/allylamine concentrations or electrolysis voltages. Each sample was prepared with the same current passed. The very good results of the conical mandrel and drawing tests, evidencing strong adhesion coupled to elasticity, are to be noted. Remarkable improvements are furthermore shown in the salt fog tests: The time scale of resistance to salt corrosion, especially for samples prepared by fast electrolysis (high voltages), is now more than an order of magnitude higher than the data

[3] The gas chromatographic analysis of the solutions after repeated coating operations performed on different days showed only dimers as by-products; however, these are easily engaged in the anodic coupling.

Table II. Features of the coating and molecular weight of the product for various experimental conditions

Run No.	Temp (°C)	Alcohol (%)	o-Allylphenol (mol/liter)	Allylamine (mol/liter)	Voltage (V)	Electr. time (min)	Coulombs	Yield (mg/C)	Insoluble (%)	$\overline{M}_n$*
