The high pass energy filter is a spherical grid type. The transmission coefficient is 81% and its axis makes an angle of 117.5° with the primary beam (shown in Fig. 3). The detector is a scintillator light-pipe assembly. The energy resolution estimated is better than 100 eV for a 45 keV primary beam.

Diffracting conditions are determined by electron channeling patterns (ECP) recorded from a selected

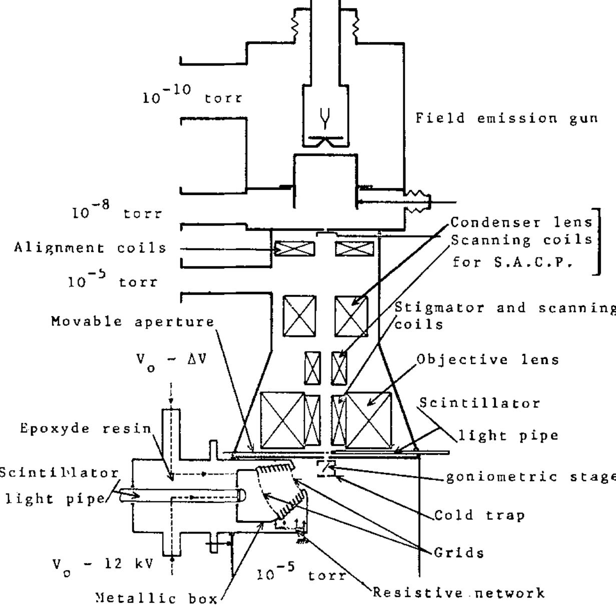

Fig. 3. Diagram of the scanning electron microscope

area (SACP) by the use of a rocking beam method. An extra set of coils near the cross-over of the gun, above the objective lens, allows the beam to be rocked around a point on the specimen surface.

The standard coils in the objective are not excited in this rocking mode. The objective diaphragm is removed in order to allow a $\pm 6°$ deflection angle. The area analyzed in SACP has a diameter of at least 10 μm.

A goniometer stage of an EM Philips transmission electron microscope has been adapted to the specimen chamber. The mechanical shift associated with tilt adjustments of the goniometer is less than 0.5 μm.

In order to avoid contamination, which occurs during long-time observation on the same area, the specimen is surrounded by copper walls cooled with liquid nitrogen.

Experimental

(100) silicon was deposited from the vapor phase at 980° by the pyrolysis of silane in H_2 on $(\bar{1}012)$ CZ single crystal sapphire substrate. A growth rate of 2 μm/min was used and silicon film thicknesses in the range 0.1-1 μm were investigated. Silicon quality was checked by double crystal x-ray rocking curves. The SEM was operated at 45 keV and the backscattered electrons were filtered with an energy filter window of 200 eV.

Results and Discussion

Figure 4 shows an electron channeling pattern obtained for an 8000Å thick silicon film. In all cases the flatness of the samples was sufficient to avoid a topographic contrast as evidenced by the good definition of the ECP.

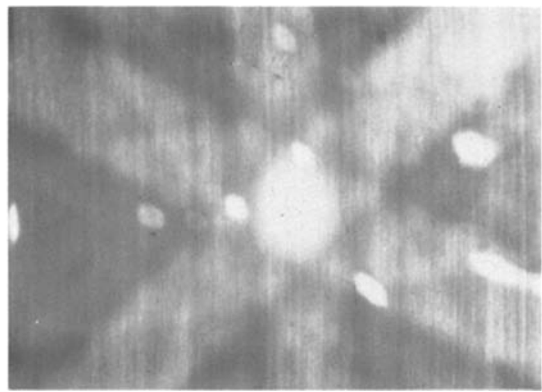

Fig. 4. ECP for 8000Å thick silicon film, showing [111] pole

Figure 5 shows the electron channeling image (ECI) obtained for three specimens with different silicon film thicknesses. These pictures were taken with the [111] silicon direction parallel to the incident beam. We can see a crystallographic contrast formed by two mutually perpendicular sets of black lines.

The contrast observed can be interpreted as the intersection of the microtwinning silicon planes {111} with (100) surface plane, that is along <110> directions.

We find that the density of microtwins increases for lower silicon film thickness. This result agrees with previous TEM observations (7). However for silicon film of thickness higher than 6000Å the density of defects is nearly constant, about $10^9/cm^2$. These results are comparable to those published by Inamura (8) for 1 μm silicon film thickness observed after chemical etching.

For silicon film thicknesses lower than 4000Å, counting of the defects is very difficult. Because of the small dimensions and the high density of defects we approach the limit of resolution of the method. The full width at half maximum (FWHM) of x-ray rocking-curves

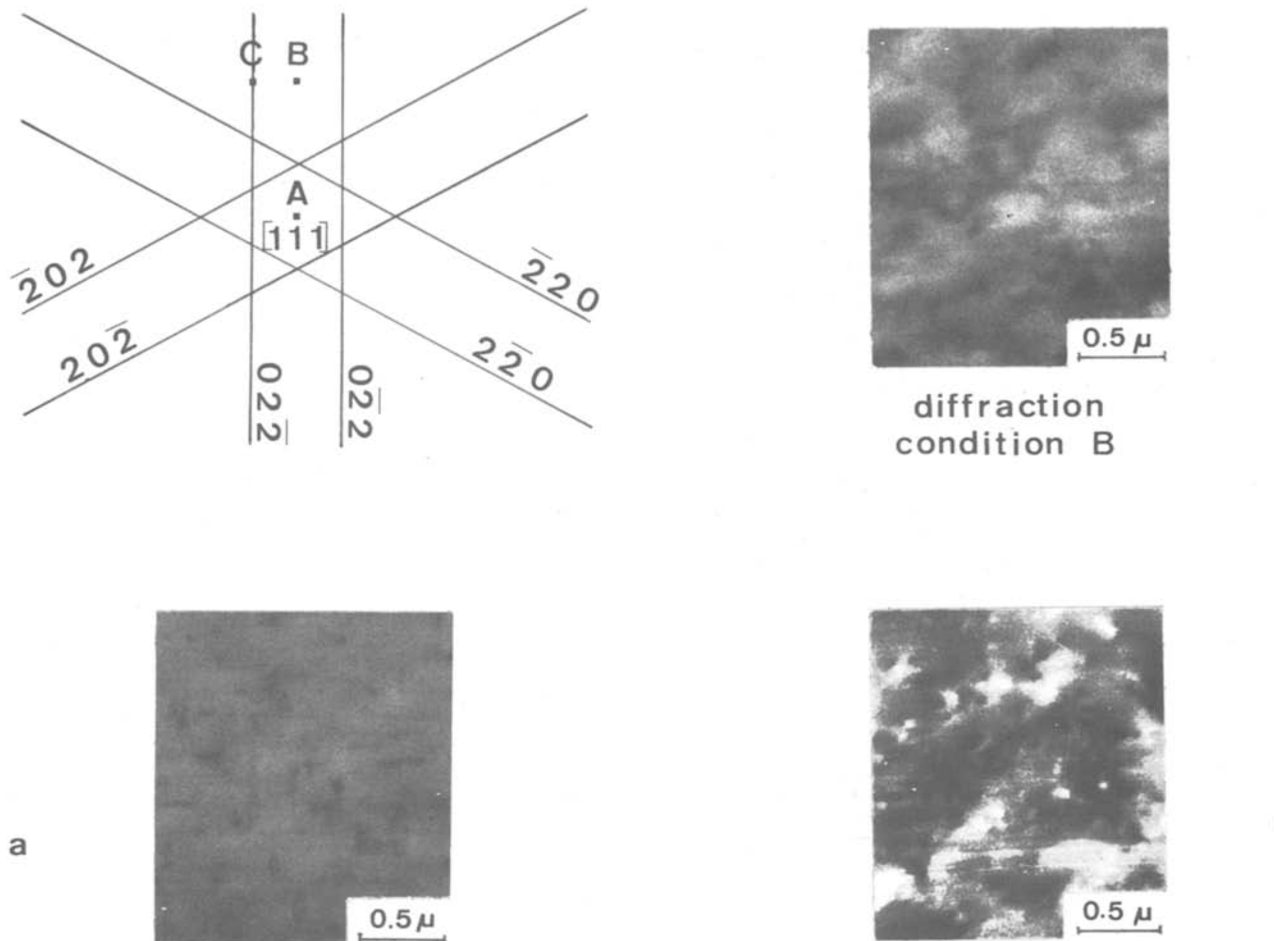

Fig. 7. ECI photographs of the same area of a 8000Å thick silicon film for different diffraction conditions

vs. silicon film thickness for these samples are plotted in Fig 6. These values, proportional to the defect density in the epitaxial silicon volume, show the same decrease in defect density as ECI. Nevertheless the main interest of the ECI technique is that it affords the possibility of observing weak and strong lattice stresses.

There is a high dependence between the diffraction condition and the image contrast. Figure 7 shows the contrast obtained for the same region of the sample when different diffraction conditions are used. These results are for a silicon layer of 8000Å.

When the incident beam is oriented in A or B position (see Fig. 7) for an SACP mode there is little change in intensity when the incident angle varies (see Fig. 1b). Consequently if a contrast is seen, it is due to a strong stress or a disruption of the lattice [see Fig. 7 (a), (b)]. For incidence of the electrons corresponding to the diffraction condition C, that is very near to the Bragg condition, our method is very sensitive to weak lattice stresses; our crystal has been highly stressed and microtwinning is not seen any more as shown in Fig. 7 (c), for which a strong contrast is observed. We suppose that the black pits are due to the stress field of emerging dislocations.

Conclusion

We have presented a new method for SOS characterization. We believe that it can yield much information on crystal defects and stress field in silicon on sapphire epitaxial layers. This technique presents several advantages over others. No special sample preparation is needed either by chemical etch or by difficult ion milling as is necessary for TEM.

Electron channeling is complementary to the x-ray rocking curve technique as it reveals the nature of crystal defects which can be identified by observation of the surface layer (~1000Å).

Pre- and Postepitaxial Gettering of Oxidation and Epitaxial Stacking Faults in Silicon

M. C. Chen[1] and V. J. Silvestri*

IBM T. J. Watson Research Center, Yorktown Heights, New York 10598

ABSTRACT

Certain gettering treatments on the back sides of wafers have been found to be effective in reducing stacking faults in Si bulk wafers. In this study results are reported for various back side, front side, and combined gettering processes on wafers used to receive epitaxial films. Focus in this investigation was on the effectiveness of gettering measures in removing defects in epitaxial films. Results of $POCl_3$ diffusion, Ar ion implantation (I/I), abrasion, and Si_3N_4 deposition as back-side treatments are reported as well as As I/I and boron diffusion front-side gettering effects. These treatments were employed either in the pre- or postepitaxial deposition mode. When used in the pre-epitaxial mode all of the back-side gettering techniques were found effective in reducing oxidation stacking faults (OSF) in epi films to levels of $\leq 10\ cm^{-2}$ as compared to nongettered levels of 100-1000 cm^{-2}. In the post-epi application, Ar I/I was found to give moderate reduction of CSF defects. The back-side gettering techniques combined with front-side gettering used in a pre-epitaxial mode reduces epitaxial type stacking faults (SFepi) significantly and eliminates oxidation stacking faults (OSF) in the epitaxial films. Counts of SFepi were not reduced using the back-side gettering alone. The two front-side procedures were, however, found to reduce both the OSF and SFepi types. The epitaxial films deposited on the As I/I surfaces showed a factor of ten reduction in SFepi defects and OSF types were reduced even more drastically. Boron diffusions in Si reduced OSF counts to nearly zero and SFepi faults by a factor of four over nongettered samples. Some effects of pre-epitaxial and postepitaxial oxidation treatments on stacking fault counts were also investigated. Results are also reported for effectiveness of stacking fault gettering relative to initial cleaning procedures used and stacking fault counts originating from substrates.

Good quality epitaxial films deposited on silicon are essential to achieve high yields in semiconductor device and integrated circuit fabrication. In practical applications, most often the epitaxial layer is grown at a point in the device processing sequence after a significant amount of high temperature treatment has occurred. This processing prior to epitaxy often includes an oxidation of the substrate with removal of the oxide just prior to the epitaxial deposition. Following film deposition, further high temperature treatment is often required before the final completion of devices or integrated circuits. All of this temperature cycling can result in increased density of defects in the epitaxial layer.

The defects which contribute to yield loss and anomalous device characteristics are classified as electrically active defects. Stacking faults and dislocation slip lines are two types of defects commonly included among the electrically active group. Their presence has been tied to excessively anomalous leakage in diodes (1), and they have been studied in relation to "pipes" in bipolar circuits (2-5). Two important kinds of stacking faults identified and studied in silicon epitaxial layers are the epitaxial stacking fault (SFepi) (6-8) and the oxidation-induced stacking fault (OSF) (1, 9, 10, 11). Since they are highly undesirable, various gettering techniques have been developed to help eliminate and suppress their densities in the starting silicon substrate material (6, 7, 12). The present work was specifically directed to studying the effects of gettering before and after epitaxial depositions and evaluate the effectiveness of the gettering procedures in reducing defects in the epitaxial films. Several decoration techniques were employed to detect the presence of SFepi and OSF type stacking faults and assess the effectiveness of the gettering procedures in films. In addition, observations are reported for epitaxial films deposited on arsenic ion implanted surfaces and epitaxial films which had experienced heavy boron diffusions.

Experimental

The substrates used for the epitaxial depositions were polished (100) oriented 5.7 cm diam n-type and p-type silicon wafers. The wafers were 0.38 cm in thickness. The n-type wafers were generally phosphorus-doped ranging from 0.5 to 0.05 Ω-cm in resistivity. The p-type wafers, unless otherwise specified, were boron-doped with a nominal resistivity of 10 Ω-cm. In most cases, when bulk n-type substrates were employed, they were first oxidized at 1000°C employing dry oxygen-water vapor-dry oxygen gases sequentially introduced which is referred to below as a dry-wet-dry (DWD) sequence. Generally the time involved 5 min for the dry oxygen steps. Most of the oxide, however, was grown during the steam cycle for a thickness of 6500Å (about 1 hr total oxidation time at 1100°C, or 2.5 hr at 1000°C). This oxide was then removed prior to epitaxial deposition. HCl gas was introduced during some oxidations. These cases will be specifically noted.

The epitaxial films were deposited by the hydrogen reduction of silicon tetrachloride ($SiCl_4$) at 1050°C using an AMC-1200 reactor. The epitaxial layers were deposited in blanket fashion to thicknesses of 8 μm on the n-type substrates and to 1.5 μm thicknesses on the n^+ subcollector patterned p-type wafers, respectively. The deposition rates for both thicknesses were 0.1 μm/min. Only n-type epitaxial films were deposited. AsH_3 was used as a dopant source. The film resistivities ranged from 0.1 to 1 Ω-cm. A standard cleaning employing NH_4OH and HCl in combination with H_2O_2 was generally used along with a final 50:50 HF:H_2O exposure just prior to epitaxy.

The epitaxial film defects were decorated using Wright etch (16) and examined using a Nomarski-interference microscope. Decoration and detection of the electrically active defects was accomplished using

an anodic etching technique (13) in which the n-type epitaxial film surface is exposed to a dilute HF solution (used as the electrolyte) while a voltage is applied to the substrate wafer which acts as the anode. A platinum wire in the solution acts as the cathode. Conditions used for anodic etching varied. In general, an HF concentration of 5% was employed. An applied voltage of 2V was generally used for the 1.5 μm epi films and 10V for the 8 μm epi films; 10-60 sec were typical times employed for anodic exposure.

Gettering measures were introduced both before (pre-epi) and after (post-epi) epitaxial depositions. Four back-side gettering measures specified below were evaluated. All these measures, whether used in a pre-epi or post-epi gettering mode, were restricted to one-half of the back side of the substrate wafers to allow for easy comparison. The back-side gettering techniques employed were: (*i*) Ar ion implant: Ar 350 keV, 5×10^{15} cm^{-2} dose, anneal 20 min 1000°C in N_2; (*ii*) $POCl_3$-diffusion: 870°C 15′ deposition, 20′ O_2-3 hr 40′ N_2, 1000°C drive-in; (*iii*) Si_3N_4 process: CVD Si_3N_4 ~5000Å on back side, 1100°C 2 hr Ar anneal; (*iv*) abrasion gettering. Although better gettering has been reported for Si substrates using higher temperature-time $POCl_3$ treatments, we chose to evaluate a 1000°C drive-in, since this was a more compatible process for our epitaxial films. The flow chart describing experimental pre-epitaxial gettering sequences is given in Fig. 1. Following back-side gettering, samples could either be given a pre-epitaxial oxidation or go directly in for epitaxial film deposition. For each gettering experiment a number of wafers were included which received a blanket front-side As I/I in addition to the back-side gettering. Following film deposition, defects were decorated using Wright etch and anodic etching for revealing SFepi type defects. A postepitaxial oxidation of the films was used to induce OSF type defects prior to decorating. The postepitaxial gettering process employed the following sequence: (*i*) epitaxial deposition, (*ii*) back-side gettering (either $POCl_3$ or Ar I/I), (*iii*) postepitaxial oxidation and Wright etch. Only OSF type defects were evaluated for the postepitaxial case. In addition to evaluating the above back-side gettering techniques in a postepitaxial mode, epitaxial films were deposited directly on surfaces which had received As I/I, or subsequent to deposition, were diffused with boron. These "front-side gettering" procedure details are as follows: As I/I (50 keV, 1.5×10^{16} cm^{-2} dose) followed by a drive-in oxidation from 1000° to 1100°C. The oxide formed was stripped just prior to epitaxial growth. The boron diffusions into the epi films used BN source wafers. The diffusion was performed through oxide openings into the n-type epitaxial film at a temperature of 1050°C for 65 min.

In order to facilitate observations and data gathering on the gettered *vs.* nongettered surface sectors, just prior to defect decoration, wafer surfaces were patterned using a metal mask. The mask consisted of circular holes (32 mils in diameter) on 100 mil centers. These holes were arranged in rectangular patterns which defined and covered five basic areas of the wafer surface. The areas covered on wafers are shown schematically in subsequent data description as rectangular shapes in Fig. 5, 6, and 7 and represent areas where defect counts were taken. To decorate the wafer, Al was evaporated through this mask to form an Al dot pattern on the Si surface. With the Al acting as a mask the exposed Si surfaces were then etched using reactive ion etching (RIE) to a depth of 600-1000Å. Other RIE masking techniques were also employed to produce surface steps in some cases. The steps formed in the Si from RIE etching were found to be retained during Wright etching and anodization. The mapped surfaces enabled us to (*i*) trace accurately particular etch figure changes through Wright etching and anodization, (*ii*) examine defect counts in boron diffused areas, and (*iii*) reduce the microscopic counting of defects necessary to determine a good statistical density for wafer areas.

Results and Discussion

Epitaxial Stacking Faults (SFepi) and Pre-epi gettering

The epitaxial stacking fault defect is believed to originate at the substrate-epi interface and propagate from this site during the epitaxial deposition. A typical SFepi as delineated by 20 sec Wright etch is shown in Fig. 2. The epitaxial film in Fig. 2 is 8 μm thick and the SFepi measures 13 μm on a side.

On epitaxial layers typically deposited on 0.05-0.5 Ω-cm n-type substrates which are nongettered, SFepi defects range in density from 30 to 60 cm^{-2} (Table I). The various gettering measures listed in the table when performed on the back side of substrate wafers in the pre-epi mode seemed to have little effect on the subsequent formation of SFepi faults. The numbers shown in the table give the typical SFepi densities observed on a number of wafers for each gettering procedure. For the Si_3N_4 case a definite increase was

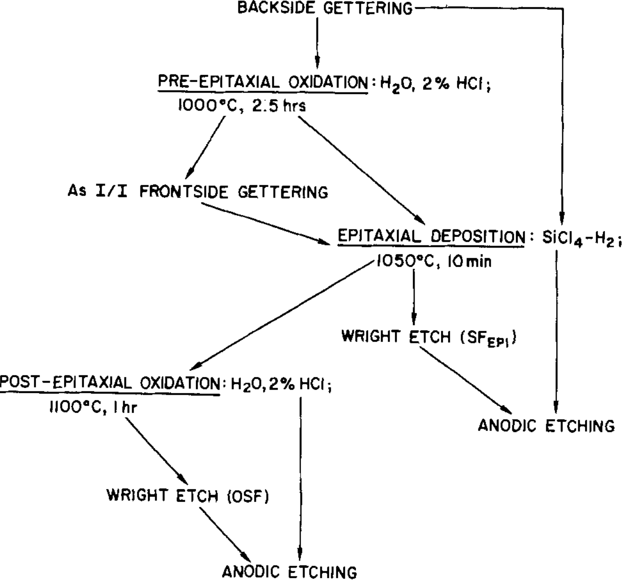

Fig. 1. Pre-epitaxial gettering process

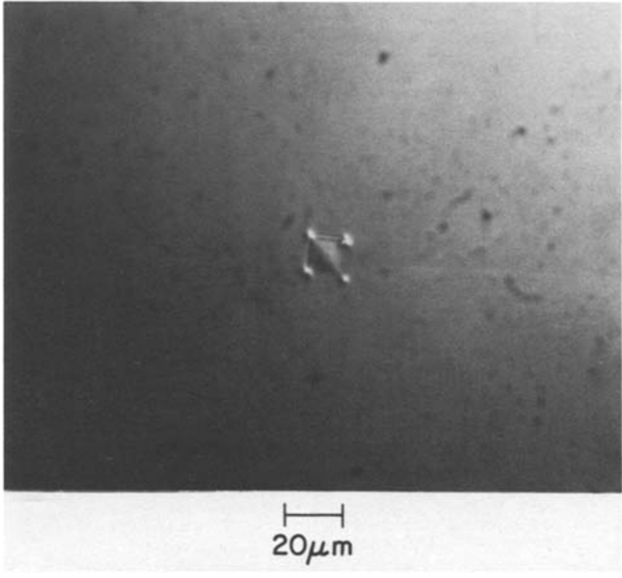

Fig. 2. Typical SFepi after 20 sec Wright etch

Table I. Pre-epitaxial gettering (SFepi)

Gettering	SFepi density (cm^{-2}) (back side only)	SFepi density (cm^{-2}) (back side + As I/I front side)
Nongettered	30-60	
$POCl_3$	46	4
Ar I/I	49	4
Si_3N_4	87	35

noted overall. Since this gettering procedure caused significant wafer warpage, the higher SFepi counts may have been induced because of the substrate distortion.

The samples which had received both the back-side gettering plus the As I/I front-side gettering showed an outstanding decrease in SFepi (Table I). The only exception to the very low counts in SFepi for the front and back treated samples can again be noted for the Si_3N_4 sample. Even here, however, a moderate improvement is noted.

The SFepi are electrically active defects. If an anodic etch exposure of 10V for 30 sec in 5% HF was applied to an 8 μm epi-film a typical decoration as is shown in Fig. 3 is obtained. The large etch artifact indicates that intensive anodic etching occurs at SFepi sites. Generally, about 90% of the SFepi sites initially indicated using Wright etch were further decorated anodically using similar anodic etching conditions. Presumably this 90% of SFepi defects contain precipitates along the partial dislocations making them electrically active and result in artifact formation with anodic etching.

Oxidation-Induced Stacking Faults (OSF) and Gettering Measures

Oxidation-induced stacking faults (OSF) are produced on the surface of epitaxial layers when an epilayer receives a high temperature steam oxidation treatment. Typical OSF structures are shown in Fig. 4. These OSF's occur even when the epitaxial films are deposited on substrates which in themselves do not exhibit OSF formation for similar oxidation treatments. The OSF densities can vary over the deposited epitaxial films. Typical densities ranged from 100 to 1000 cm^{-2} for an oxidation of 1100°C for 1 hr with 2% HCl.

The various back-side gettering measures included in the OSF studies were Ar ion implantation, $POCl_3$ diffusion, Si_3N_4 application, and abrasion. With respect to the wafer processing sequence, the back-side get-

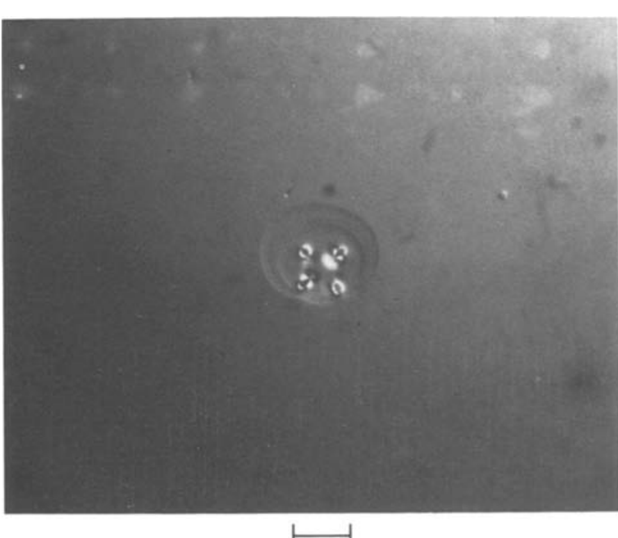

Fig. 3. Typical SFepi artifact after anodic etch, 10V, 30 sec, 5% HF.

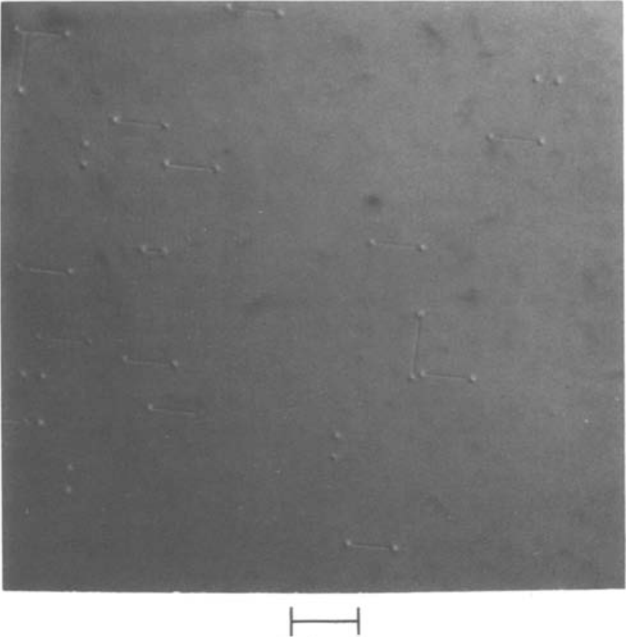

Fig. 4. Typical OSF revealed with 1 min Wright etch in epitaxial films.

tering measures were applied in both modes: pre-epi and post-epi. Dependent on the experiment, the processing could include a high temperature pre-epi oxidation treatment just prior to epitaxial growth. Following epitaxial growth all films were post-epi oxidized and etched for the OSF inspection. In all cases, except for the abrasion gettering experiment and otherwise specifically noted, the pre-epi and the post-epi oxidation conditions were [1000°C, DWD, 2.5 hr, 2% HCl] and [1100°C, DWD, 1 hr, 2% HCl], respectively. The pre-epi and post-epi gettering results for OSF defects follow below.

Pre-epi gettering of OSF.—With the Ar I/I, $POCl_3$, Si_3N_4, or abrasion gettering OSF's counts were observed to show reduced counts over the entire surface of the epitaxial layers even though the gettering had been applied to only one-half of the wafer back side. With the exception of abrasion gettering the OSF stacking fault densities found were very low ($\leq$ 10 cm^{-2}) as compared to separate wafers with no gettering (100-1000 cm^{-2}) in Table II. In combination with As I/I on the front side the above back-side gettering reduced defects to nearly zero. In view of the higher OSF densities observed on the nongettered epi-wafers, coupled with an estimated 1-2 cm total diffusion length of the interstitial sites, it is probable that all the gettering measures are working to some extent over the whole wafer even when applied to only half. On wafer edges where defect counts are always higher, careful inspections were made (approximately within 0.37 cm from the edge). For these higher count areas, clear demarcations between gettered and nongettered halves of the wafers were more easily observed. This is shown most clearly for the Ar I/I

Table II. Pre-epitaxial gettering (OSF)

Gettering	OSF density (cm^{-2})
Nongettered	100-1000
Argon I/I	$\leq$10 c
$POCl_3$	$\leq$10 c
Si_3N_4	$\leq$10 c
Abrasion	$\leq$30 c
Back side + As I/I front side	~0

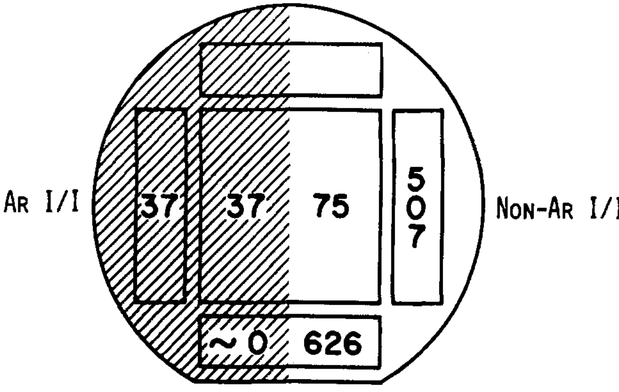

Fig. 5. Typical pre-epi Ar I/I gettering wafer count

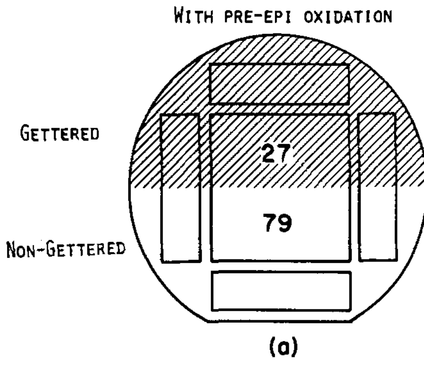
case in Fig. 5. The $POCl_3$ and Si_3N_4 gettered wafers did not show as clear a demarcation between gettered and nongettered halves even in these edge regions.

The abrasion gettered samples in the OSF studies received a somewhat different process treatment. The treatment eliminated the normal pre-epi cleaning and employed only the final HF etch prior to epitaxy. In addition some wafers received a pre-epitaxial oxidation while others did not. These modified procedures were expected to introduce higher OSF densities in the samples. Figure 6 shows the results for two abrasion gettered epi-wafers. Epi-wafer 6(a) had received a pre-epi oxidation treatment, while 6(b) had not. Gettering is obvious for both cases with a slightly higher overall density of OSF's occurring in the sample having pre-epi oxidation. It should be noted in Fig. 1 (process sequence) that the back-side gettering precedes the pre-epitaxial oxidations. It is believed that during this oxidation-heating step the effectiveness of the gettering region was diminished making it less effective during the subsequent epitaxial deposition. Substrate gettering would be expected to occur during the pre-epi oxidation. The defect count in Fig. 6(b) shows more effective gettering without pre-epi oxidation consistent with the above. This suggests that gettering in the pre-epitaxial mode should be introduced just before the epitaxial deposition.

Post-epi gettering of OSF.—Back-side post-epi gettering by Ar I/I and $POCl_3$ diffusion of substrates with deposited epitaxial films in place was investigated. In both cases, a pre-epi oxidation was performed on the substrates, *i.e.*, 1000°C DWD 2.5 hr, 2% HCl, prior to epi. The post-epi oxidation following back-side gettering was at 1100°C for 2 hr in steam with no HCl. In addition, the substrate wafers received only a final HF cleaning just prior to epitaxial deposition. Following the post-epi oxidation to induce OSF's in the epi the oxide was stripped and the wafers Wright etched to reveal the stacking faults. As might be expected, a much higher OSF count was generally observed (Fig. 7). In the post-epi gettering (Ar I/I), wafers having very high OSF defect densities ($> 10^5$ cm^{-2}) displayed no obvious distinction between the gettered and nongettered halves in so far as defect counts. This was probably due to our inability to see distinctions and count at the very highest densities. However, a moderate gettering effect was readily observed on wafers where "poor" cleaning had introduced a medium-high OSF density ($\sim$ 3000 cm^{-2}) as shown in the Fig. 7. The very low local OSF density of 10 cm^{-2} appearing in Fig. 7 on the gettered side is not attributed necessarily to the Ar I/I since this local area was found to contain many slip dislocation lines which can absorb OSF's locally. The post-epi $POCl_3$ back-side diffusion gettering procedure did not seem effective in reducing OSF defect counts for the conditions employed.



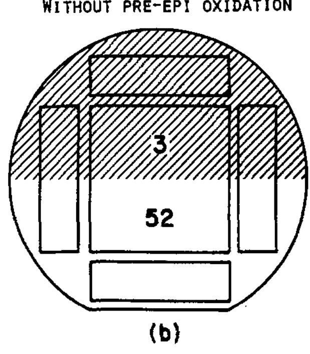


Fig. 6. Typical pre-epi abrasion gettered wafer defect count: (a) with pre-epi oxidation, (b) with no pre-epi oxidation.

Front-side Gettering

Arsenic I/I gettering.—The front-side As I/I procedure described earlier virtually eliminates oxidation stacking faults in epitaxial films deposited over the implanted regions. An example of such deposits over an n^+ As I/I region in a p^- substrate is shown in Fig. 8. The application of anodic etch to such epi surfaces shows greatly reduced decoration and etch artifacts over the n^+ implanted regions when compared to the p^- region.

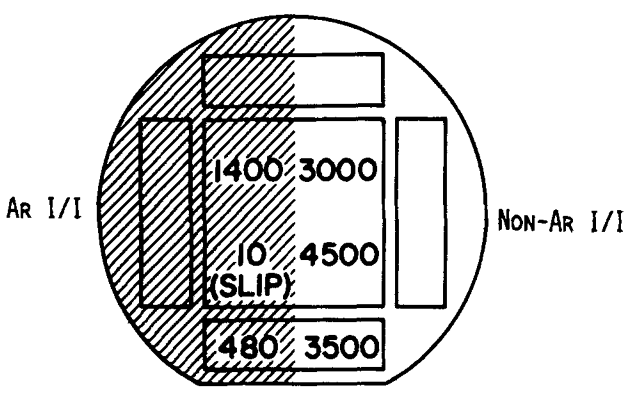

Fig. 7. Typical wafer defect counts for post-epi Ar I/I gettered samples.

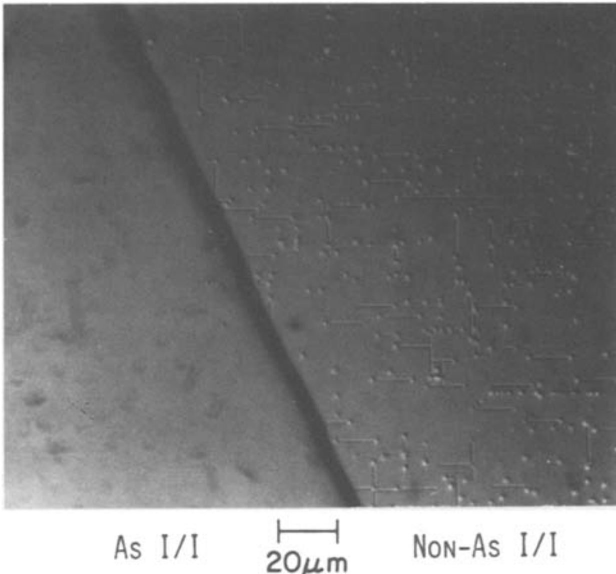

Fig. 8. Wright etch OSF decoration of epi surfaces having n^+ As I/I implanted regions.

Hillock-type defects, which will be discussed in greater detail further below, were found in both n^+ and p^- regions at similar densities [Fig. 9(a)]. These surface features appeared following Wright etching. Figure 9(b) shows the identical region in 9(a) photographed after it had been anodized. It is obvious that only some of the surface hillock features decorate anodically. Those that decorate appear as paired structures orthogonally oriented which can be seen with close examination of Fig. 9(a) in the p^- region.

Stacking fault reduction by boron diffusion.—Boron was diffused into 8 μm n-type epitaxial layers through an oxide mask as described in the experimental section in forming p-n junction diodes. The diffusions resulted in p-n junction depths of 1.4 μm with very sharp concentration profiles at the junction. Prior to boron diffusion, the epitaxial films had been steam oxidized at 1100°C to generate 13 μm long oxidation stacking faults. The characteristic leakage current of the diodes at 15V reverse bias was in the order of 10^{-12}A for a 35 mils dot size diode. This is several orders of magnitude lower than reported values on diodes known to contain OSF's (1). Reactive ion etching, with the Al contacts in place as a mask, was used to mark the diode regions. They could then be readily located and examined for defects after the aluminum contacts were removed. A 1 min Wright etch was performed on the wafers such that approximately 0.6 μm of the silicon was removed from the surfaces. This etch depth exposed surfaces both within and outside the diode area about halfway into the diode volume from the p-n junction. Oxidation stacking faults were observed in large numbers on the surface outside the boron-diffused diode areas, but no stacking faults were observed within the boron-diffused region [Fig. 10(a)]. Following this the wafer was further Wright etched for an additional 2 min to remove a total of 1.8 μm of the original surface. This procedure exposed regions below the junction. Oxidation stacking faults at this etch level were found both within and outside of the diode area [Fig. 10(b)]. The absence of OSF defects in the p-region in Fig. 10(a) shows that the presence of heavy boron acts as an effective getterer in the annihilation of electrically active stacking faults in silicon. It has been reported that stress introduced by the high concentration boron diffusion $> 10^{20}$ and solute lattice contraction results in some defect reduction (14). Observations of our leakage data also support these conclusions. In comparing decorated defect counts inside the individual diode areas after Wright etch (at the 1.8 μm etch level) with the leakage data associated with the particular diode no definitive correlation was found. This lack of sensitivity would support the conclusion that electrically active stacking faults were eliminated at least down to the junction

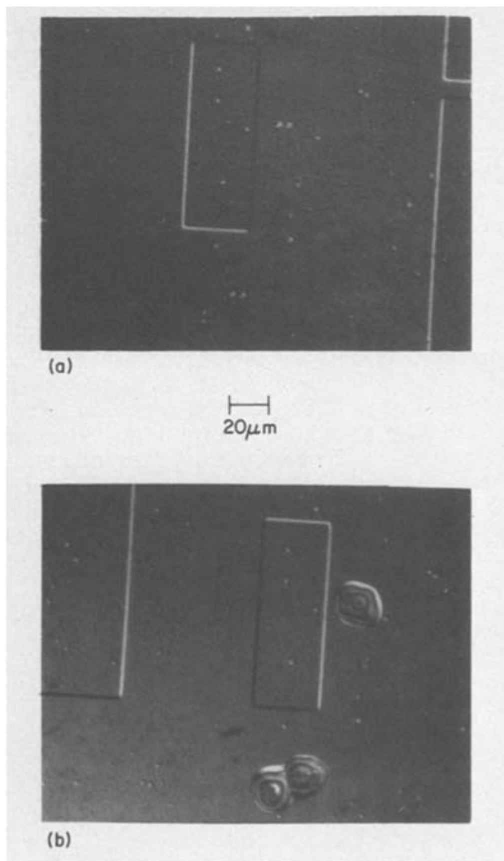

Fig. 9. Decorated hillock and OSF defects on As I/I subcollector structures: (a) after Wright etch, (b) after anodic decoration.

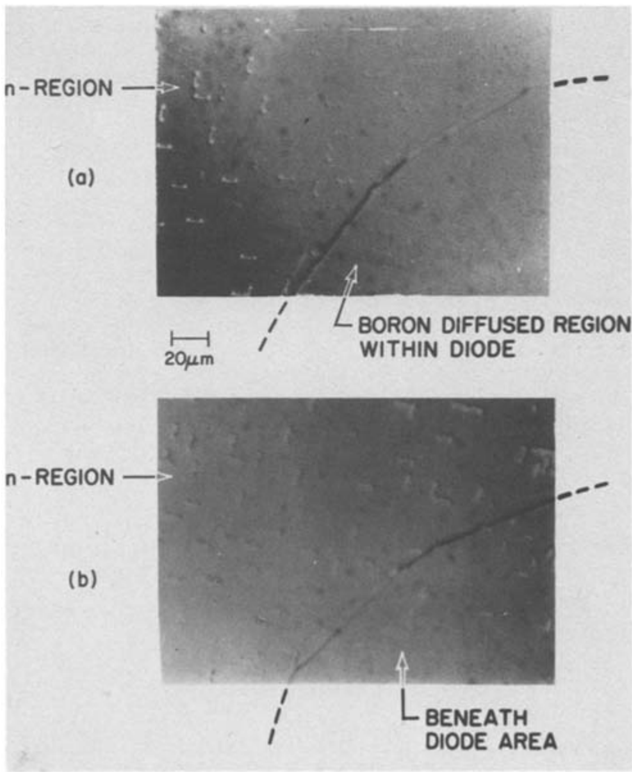

Fig. 10. Defect decoration in boron-diffused diodes: (a) within diodes, (b) beneath diode junction.

depth and probably gettered for some distance into the n-type regions surrounding the diode junction as well.

An experiment was also performed to investigate the influence of boron diffusion relative to the epitaxial-type stacking faults (SFepi). A similar boron diffusion at 1050°C was carried out for 2 hr to form 2 μm junction depth p-n diodes in a number of n-type epitaxial films. Following this a 1 min Wright etch was made on the structures removing 0.6 μm of silicon from the surfaces. Epitaxial stacking faults were exposed on the surface both inside and outside the boron-diffused diode areas. The SFepi densities inside the diode area were found to be a factor of 3-4 lower than those found in the nondiffused regions (Table III). In addition, the SFepi type artifacts found inside and outside the diode areas decorated differently with Wright etch, *i.e.*, the SFepi within the diode area were found to be less sharply defined and difficult to see microscopically. Similar to the OSF type defect observation, there appears to be no correlation between the occurrence of the epitaxial stacking fault artifacts in the diode region and the diode leakage. The data in Table III show that a good part of SFepi were eliminated by boron diffusion, and the excellent diode characteristics would suggest that those which had not been eliminated were essentially "electrically deactivated."

Hillock-type Defects

There have been correlations made between the epitaxial hillock occurrence and the surface nucleated oxidation-induced stacking faults (OSF) (9, 10). A half minute Wright etch performed on an epitaxial wafer, in addition to revealing OSF and SFepi, usually also reveals small etch hillocks. The density of the hillocks vary from wafer to wafer and even from point to point on the same wafer. Densities in the range of from 10^2 to 10^7 cm^{-2} have been observed. High temperature steam oxidation causes some of these hillock-type defects to produce OSF's, however, it has been noted above that not all the etch hillocks decorate as oxidation stacking faults (Fig. 9). With anodic exposure, sometimes single hillocks on wafers not experiencing oxidation may develop etch pits. Such unpaired hillocks have been found to decorate less intensely with anodic etching as compared to that of the SFepi or the OSF type defects. They appear as circular structures with a central pit associated with them. In Fig. 11 a scanning electron microscope photo of such a pit is shown. A cleavage was made through the anodically etched pit to reveal its saucerlike shape. The scale shown is for 50 μm. Only about 10-20% of the hillock defects were observed to be electrically active anodically in these studies compared to 90% decoration for the epitaxial stacking fault types. It is believed that the impurity precipitation which is the critical factor in the nucleation of OSF (10, 15) must also play a decisive role in whether a hillock-type defect is or is not electrically active. It is believed that those hillocks which develop anodic etch pits on non-oxidized substrates by anodic exposure would probably nucleate to form OSF if they had been subjected to oxidation processing.

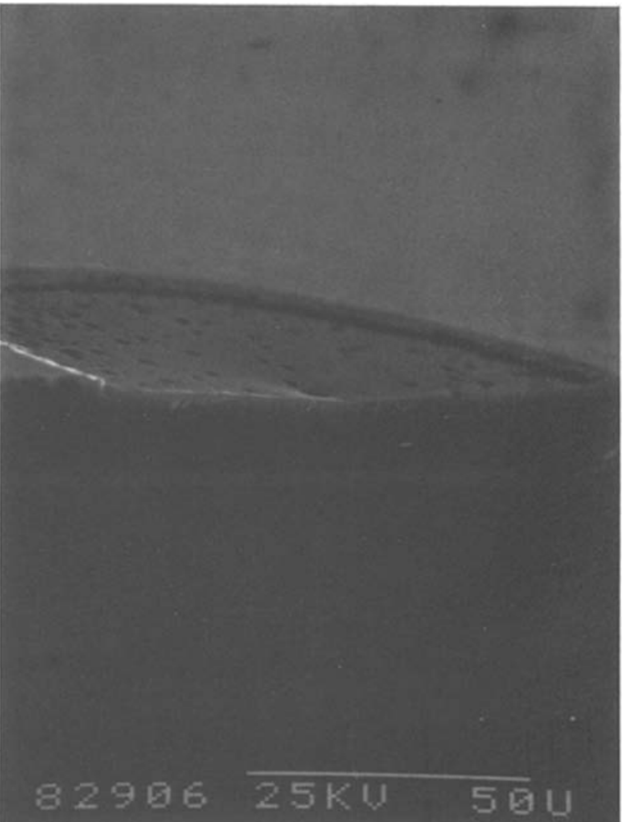

Fig. 11. Decorated unpaired hillock using anodic etch

Summary and Conclusions

For the pre-epitaxial and postepitaxial gettering of epitaxial films the following observations were made: the pre-epitaxial gettering, when back-side gettering alone was used, caused little reduction in SFepi. If the back-side gettering was used along with As I/I front-side treatment SFepi defects were significantly reduced.

The pre-epitaxial gettering on back sides of wafers reduce OSF counts to ≤ 10 cm^{-2}. When used in conjunction with As I/I on the front-side gettering of OSF defects in the epitaxial films is nearly 100% effective.

For the postepitaxial gettering case, of the two techniques tested ($POCl_3$ and Ar I/I), the Ar I/I method gave moderate OSF reduction in the films.

Both front-side gettering procedures were effective in significantly reducing OSF and SFepi-type defect counts.

Microdefect Elimination in Reduced Pressure Epitaxy on Silicon Wafer by Back Damage-Si_3N_4 Film Technique

Kohetsu Tanno, Fumio Shimura, and Tsutomu Kawamura

Central Research Laboratories, Nippon Electric Company, Limited, 4-1-1 Miyazaki, Takatsu-ku, Kawasaki, Japan

ABSTRACT

A gettering technique which prevents microdefect formation during oxidation processes after the growth of reduced pressure Si epitaxial layer for bipolar devices is described. A gettering process which consists of protection of the back damage layer with Si_3N_4 film is proposed. A microdefect density in epi-layers of $\sim 10^2$ cm^{-2} is obtained by back damage with the Si_3N_4 film coating technique, on the contrary, the microdefect density reaches $\sim 10^6$ cm^{-2} without the Si_3N_4 film. The critical thickness of Si_3N_4 film to elminate microdefects in epi-layers is obtained 2500 and 200Å for substrates without and with back damage, respectively. It is found that the gettering action is closely correlated with induced defects in the back surface (OSF, dislocation, damage line, etc.) by sandblast-damaging and/or Si_3N_4 film.

Reduced pressure (RP) silicon epitaxy is an especially important technique for bipolar devices with buried layer containing high concentration of As or Sb. The advantage of RP epitaxy has attracted special interest for shallow junction devices. It has been reported that RP silicon epitaxy has more advantage in characteristics of layer [autodoping, pattern shift, and uniformity of epitaxial layer, etc. (1-5)], than those of atmospheric silicon epitaxy.

In general, a variety of defects such as stacking faults, slip dislocations (6, 7), and microdefects correlated with impurities (8, 9) is introduced in epilayer during epi-processing. The stacking fault density can be obtained less than ~ 10 cm^{-2} by gas etching prior to epitaxy and slip dislocations can be decreased to negligible extent by a radiant heating technique. However, the existence of microdefects in the epitaxial surface has become one of the most serious problems (*e.g.*, collector-emitter leakage) for device characteristics.

In order to suppress nucleation sites for microdefects in epi-layer, a variety of gettering techniques has been proposed. These gettering techniques are based on mechanical damage (10, 11), deposition of Si_3N_4 film on back surface (12), and intrinsic gettering (13-17), etc. (18-21). Although a number of workers have shown that stacking faults are produced in the atmospheric silicon epitaxial layer during thermal oxidation (22-26), none has reported the oxidation-induced stacking faults and gettering of microdefects in RP epi-layers.

Key words: gettering, tensile stress, bow of wafer, oxidation-induced stacking fault.

In RP epitaxy applying the microdefect gettering with a back-side damage technique, the gettering effect was found to be decreased by the reasons as follows (27): (*i*) the back damage layer is removed by HCl gas etching prior to epitaxial growth and by HCl gas produced from the SiH_2Cl_2 source during epitaxial growth; (*ii*) gas etching on the back surface is accelerated by a reduced pressure; and (*iii*) the back damage layer is annealed-out during a high temperature epitaxial process. Therefore, a protection of damage layer with Si_3N_4 films is proposed for a more effective gettering.

In the present paper, we describe the reduction of microdefects in RP epitaxial layer by sandblast-Si_3N_4 gettering technique and discuss the gettering mechanism on the basis of preferential etching and x-ray diffraction topography (XRT) data. In addition, we refer to the bow of substrates with Si_3N_4 film on the back surface.

Experimental Procedures

The p-type Si substrates used in this study were taken from a CZ-grown crystal with the resistivity of 10 $\sim$ 20 Ω-cm. The wafers were 75 mm diam and 0.4 mm thick with the surface oriented approximately 3° from the (111) plane along the <110> direction. The front surfaces were mechanically-chemically polished and the back with and without sandblast-damage.

The Si_3N_4 films were deposited on the back surface of silicon wafers prior to epitaxial growth by chemical vapor deposition using the system SiH_4-NH_3-N_2 at 770°C.

The silicon epi-layer was deposited in a commercial "AMC-7800-RP" cylindrical epi-reactor. The epi-layer was grown to the thickness of 2 ~ 3 μm at a rate of 0.3 μm/min at 1080°C in a reduced pressure of 80 Torr.

Finally, epitaxial substrates were annealed at 1140°C for 1 hr in wet O_2 for the evaluation of microdefects in epi-layers. Microdefects in an epi-layer were revealed using the Sirtl etchant for 15 ~ 30 sec and the XRT Lang method was also used to characterize the defects in an epi-layer and back surface.

The Si_3N_4 film thickness and bow were measured by an ellipsometer and a microsensor.

Results and Discussions

The sandblast gettering technique is commonly applied to reduce the microdefects in a substrate surface or epi-surface for MOS and bipolar devices. In the case of RP epitaxy, an annihilation of damage layer was confirmed by the decrease of oxidation-induced stacking fault (OSF) density in the back surface after gas etching and/or heat-treatment the same as the epi-process.

In general, a wafer surface is vulnerable to adsorbed oxygen or other impurities from the carbon susceptor. Metallic contamination is apt to take place as a result of the reaction between an SUS component and HCl gas or Cl gas dissociated from SiH_2Cl_2 source. Therefore, gettering processes are important for the suppression of microdefects caused by heavy metal contamination in the RP epitaxial layer. The damage layer can be protected by the deposited Si_3N_4 film which is an acid- and heat-stable material.

Gettering effect by Si_3N_4 film without back damage.—Figure 1 shows the correlation between the microdefect density in epi-layers and the Si_3N_4 film thickness.

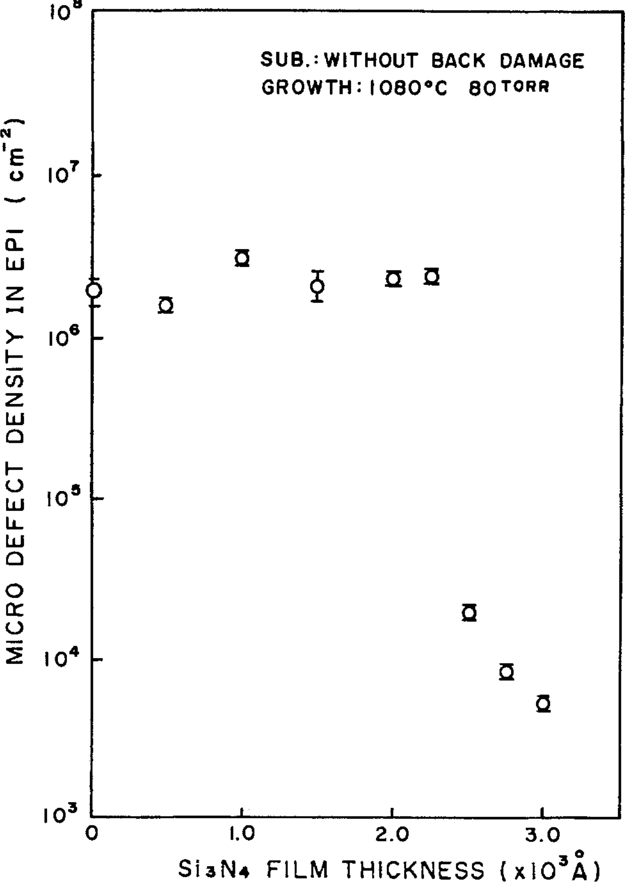

Fig. 1. Correlation between Si_3N_4 film thickness and microdefect density in epi-layer.

In the Si_3N_4 gettering process, Petroff *et al.* (12) reported the elimination of nucleation centers and impurities which occur during oxide growth involved in the formation of SF by the preoxidation process prior to epitaxial growth. In the paper mentioned above, the Si_3N_4 film was deposited to 4000Å thick to eliminate microdefects in the substrate surface. In the deposition of a 4000Å thick Si_3N_4 film, we speculate that the bow of the substrate increases and many slip dislocations are introduced in the wafers.

As shown in Fig. 1, the microdefect density in an epi-layer drastically decreases from $\sim 10^6$ cm^{-2} to $\sim 10^3$ cm^{-2} when the 2500Å-Si_3N_4 film was deposited. Epitaxial defects were evaluated by Sirtl etching after a heat-treatment at 1140°C for 1 hr in wet O_2. Sirtl-etched figures of epi-layers and back surfaces after removing Si_3N_4 films by hot H_3PO_4 solution are shown in Fig. 2(a) and (b), respectively.

Typical epitaxial microdefects, triangular shaped etch pits in the ungettered region observed by an optical microscope are shown in Fig. 3.

Damage line and dislocation pits, as shown in the bottom of Fig. 2(b), are observable in the back surface of gettered epi-wafer with an Si_3N_4 film of more than 2000Å thickness. These damage lines and dislocations are considered to be due to the stresses by an Si_3N_4 film.

Figure 4 shows that the microdefects in epi-layers are gettered when the Si_3N_4 film more than 2250Å thick is deposited. The Sirtl-etched epi-layer and back surface with an Si_3N_4 film are shown in Fig. 4(a) and (b), respectively. These damage lines have the tendency to run toward a definite direction as shown in Fig. 4(b). The remarkable correlation between the gettered region in epi-layer and the damage lines in back surface was observed in Fig. 4.

Figure 5 represents XRT of slip dislocations and damage lines in the substrate with a 3000Å-thick Si_3N_4 film. It is apparent from the topography that disloca-

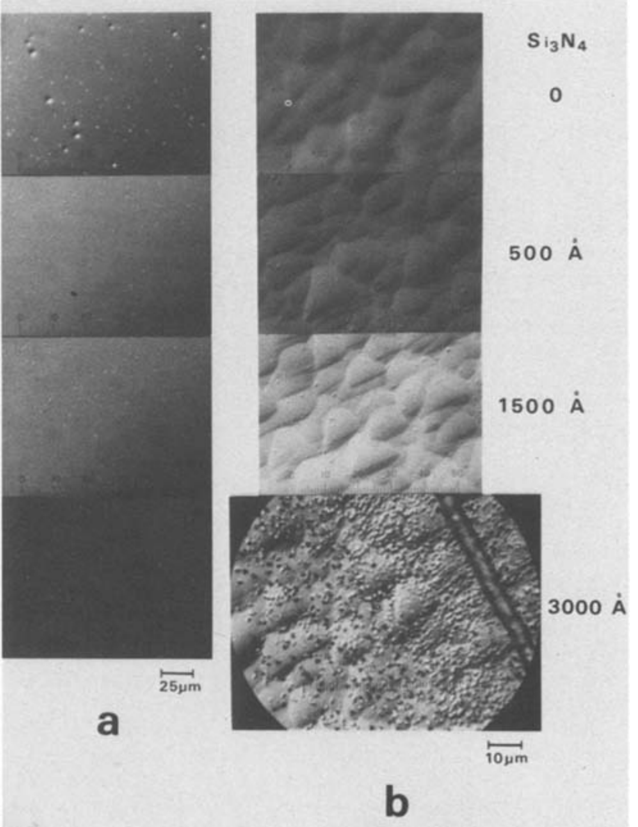

Fig. 2. Optical micrographs of defects in (a) epi-layer and (b) back surface removed Si_3N_4 film.

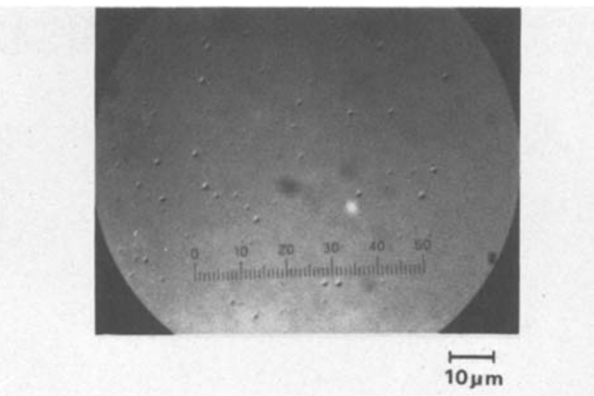

Fig. 3. Microdefects in RP epitaxial layer revealed by Sirtl etching.

tions are introduced around the damage lines, in accord with Fig. 2(b) (bottom).

The thick Si_3N_4 film is necessary to getter microdefects in an epi-layer with an Si_3N_4 film. That is, microdefects in epi-layer were reduced with Si_3N_4 films of 2500Å, 3000Å-thick without back damage, however the bow of the wafer becomes large in proportion to the Si_3N_4 film thickness as shown later and slip dislocations were introduced into the active layer as shown in Fig. 5. Consequently, the Si_3N_4 gettering technique without back damage has a problem which cannot be ignored for device processing.

Gettering effect by back damage with Si_3N_4 film.—In Fig. 6, the microdefect density in epi-layer is plotted as a function of the OSF density due to back damage by a sandblast technique prior to the deposition of a 1000Å-thick Si_3N_4 film. The microdefect density in an epi-layer is closely related to the density of OSF with back damage. It became evident that more than 5×10^5 cm^{-2} OSF's of density in the back-side damage is necessary to reduce epi-microdefects less than 10^3 cm^{-2} as shown in Fig. 6. Gettering experiments were

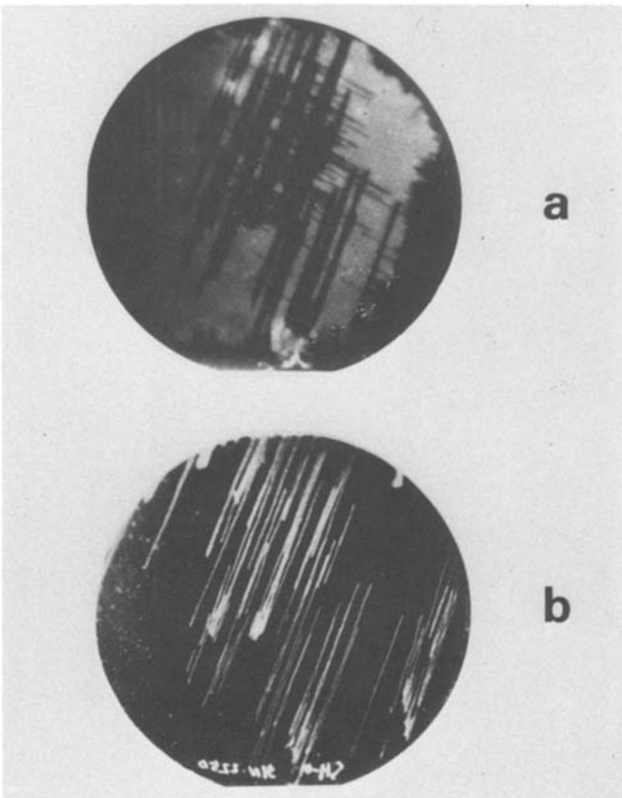

Fig. 4. (a) Sirtl-etched epi-surface and (b) its substrate back surface with 2250Å-thick Si_3N_4 film.

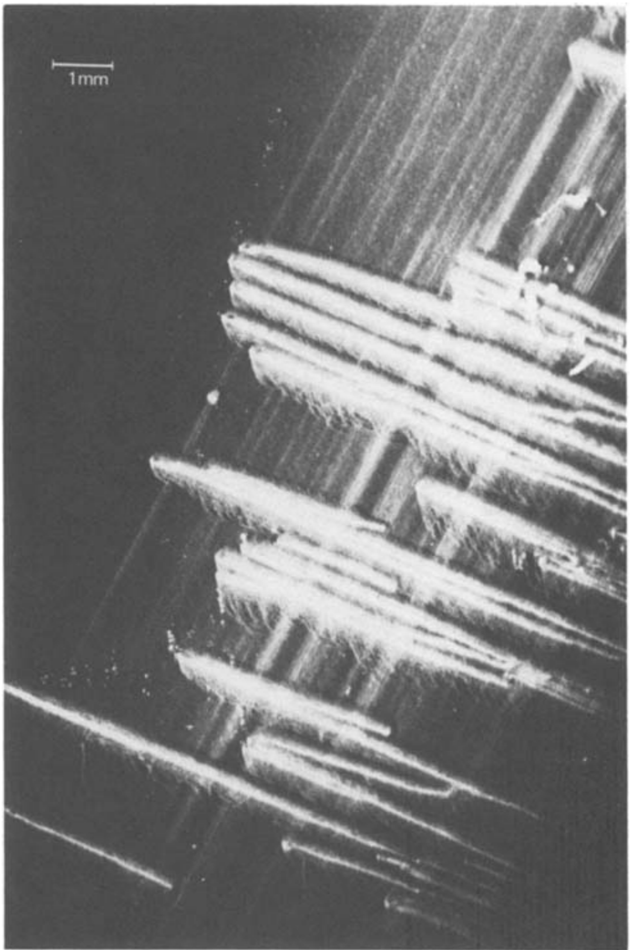

Fig. 5. X-ray diffraction topograph of epi-wafer with 3000Å-thick Si_3N_4 film. g = [2$\bar{2}$0].

carried out using back-damaged wafers with OSF's more than 5×10^5 cm^{-2} in the same wafer lots.

Figure 7 shows the dependence of epi-microdefect density on the Si_3N_4 film thickness. The epi-microdefect density decreased remarkably from 10^6 cm^{-2} to 10^3 cm^{-2} with the 200Å-thick film. When the Si_3N_4 film of 1000Å thickness was deposited, the microdefects in the epi-layer were reduced to the density of 5×10^2 cm^{-2}.

Figure 8 shows etched figures of the epi-layer and back surfaces with sandblast damage. The Si_3N_4 film was removed by hot H_3PO_4 solution before Sirtl etching. The defects in the back surface (Fig. 8b) remarkably differ from those on the back surface shown in Fig. 2(b). OSF's due to sandblasting are observed in the back surface with Si_3N_4 films of more than 200Å thick as shown in Fig. 8(b). That is, the defect density in a back surface was kept with more than 10^5 cm^{-2} even after epitxial growth. This shows that the extent of back damage with sandblasting remained at the same level before epitaxy, even though wafers were annealed in epitaxy and oxidation processes. It is suggested that the gettering action by back damage occurred effectively by covering with a thin Si_3N_4 film.

Bow of substrate with Si_3N_4 film.—A tensile stress of 10^{10} dynes cm^{-2} has been reported for chemically vapor deposited (CVD) Si_3N_4 films on an Si wafer (28, 29). It is well known that Si substrates bend (30) with the stress of the Si_3N_4 film being vulnerable to cracks (31) with increasing Si_3N_4 film thickness and the process temperature. As a result of cracking due to Si_3N_4 film, dislocations are introduced into the wafers.

Figure 9 shows the bow dependence on the Si_3N_4 film thickness after the oxidation of the epi-layer at

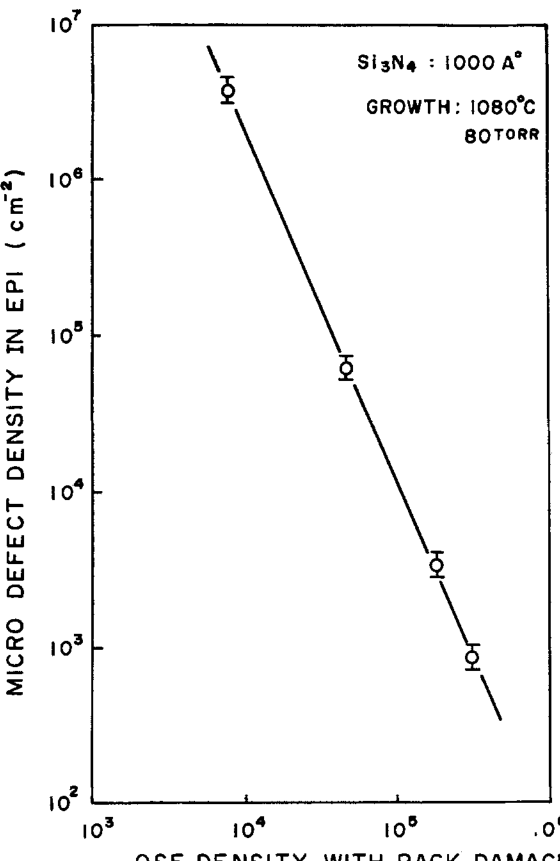

Fig. 6. Correlation between microdefect density in epi-layer and OSF density by back damage.

1140°C for 1 hr wet O_2. The cracks in Si_3N_4 films are observed after epitaxial growth and they accelerate, introducing dislocations into a substrate after an oxidation process. The minimum bow was found with the Si_3N_4 film of the thickness between 500 and 1000Å as shown in Fig. 9. In addition, the bow of wafers shows a tendency to approach a constant value with the Si_3N_4 film thickness above 2000Å which is the thickness of introducing cracks into a wafer. In the Si_3N_4 gettering without back damage, the constant bow region corresponds to the Si_3N_4 film thickness region with effective gettering in an epi-layer.

Since the bow of wafers becomes a serious problem in a photolithographic process after epitaxial growth, we may conclude that the effective thickness of an Si_3N_4 film with back damage is 500-1000Å for minimizing the bow of wafer and eliminating microdefects in an epi-layer.

Summary and Conclusion

The effective gettering of microdefects in an RP epitaxial layer has been shown in sandblast-wafers covering the back surface with a thin Si_3N_4 film. In both the gettering cases of applying Si_3N_4 film with and without back damage, it becomes clear that the elimination of the microdefects in an epi-layer is closely related to the induced defects in the back surface with sandblast-damage and Si_3N_4 film.

The conclusions reached are as follows.

1. The gettering of microdefects in an epi-layer occurs at the critical Si_3N_4 film thickness of 2500Å without back damage; however the bow of the wafer becomes large and many dislocations are introduced in the epi-layer.

2. The microdefect density in epi-layers shows a reciprocal correlaton with the density of OSF in the back surface and good linearity in log-log plotting.

3. The gettering of the microdefects in an epi-layer occurs with more than 200Å-thick Si_3N_4 film with back damage. The minimum microdefect density in an epilayer obtained was 5×10^2 cm^{-2} with the 1000Å-thick Si_3N_4 film.

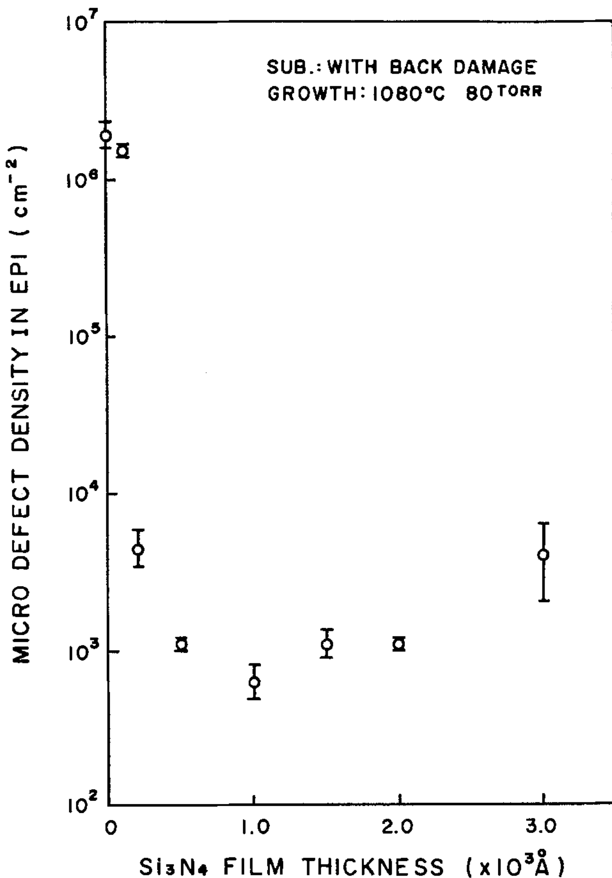

Fig. 7. Correlation between microdefect density in epi-layer and Si_3N_4 film thickness.

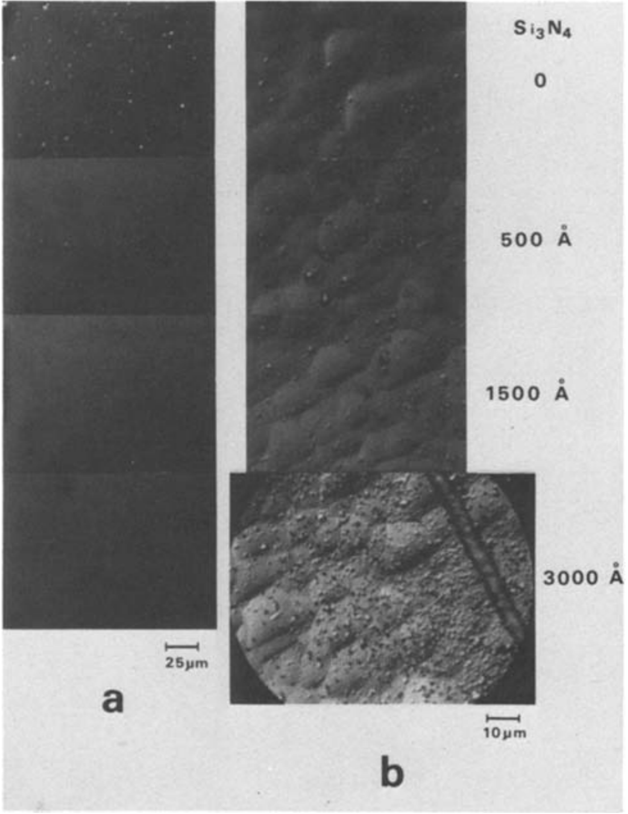

Fig. 8. Optical micrographs of defects in (a) epi-layer and (b) back surface removed Si_3N_4 film.

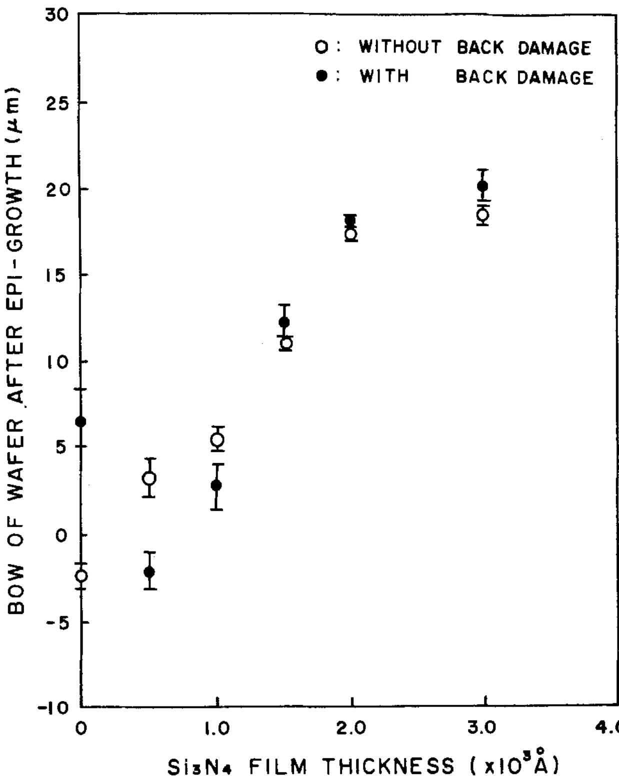

Fig. 9. Correlation between bow of wafer after epitaxial growth and Si_3N_4 film thickness.

4. The minimum bow of an epi-wafer with Si_3N_4-sandblast treatment after an epi-oxidation was found in the range of 500-1000Å in Si_3N_4 film thickness The bow was saturated at the Si_3N_4 film thickness more than 2000Å. This coincides with the Si_3N_4 film thickness which introduces cracks for effective gettering.

The Use of Si and Be Impurities for Novel Periodic Doping Structures in GaAs Grown by Molecular Beam Epitaxy

K. Ploog, A. Fischer, and H. Künzel

Max-Planck-Institut für Festkörperforschung, D-7000 Stuttgart 80, Germany

ABSTRACT

A new type of superlattice in GaAs consisting of a periodic sequence of ultrathin p- and n-doped GaAs layers (also called "nipi" crystal) has been achieved by molecular beam epitaxy (MBE). The individual p- and n-type GaAs layers of which the structure is composed were doped with beryllium as acceptor and silicon as donor impurities, respectively. Low temperature photoluminescence studies and transport measurements were performed first to attest a superior quality of the intentionally p- and n-doped constituent GaAs layers and of the characteristics of the individual p-n junctions prepared by MBE. The existence of a novel superlattice effect in the periodic p-n doping multilayer structures in GaAs was then established by studying the optical absorption tails which extend far into the gap of the unmodulated semiconductor ($\hbar\omega < E_g^{GaAs}$) depending on the constituent doping levels and on the artificially introduced periodicity of the crystal.

Doping structures in epitaxial GaAs thin films exhibiting abrupt variations of carrier concentration and/or carrier type in the submicron range have recently attracted great attention with respect to the optimization of standard-device performance as well as considering the exploration of novel device structures. Improved device operation of a number of GaAs microwave devices including mixer diodes (1), IMPATT diodes (2), and hyperabrupt varactor diodes (3) requires exactly tailored profiles of donor concentrations. In the field of improving the spatial resolution of GaAs doping profiles of only one carrier type (4) rapid progress has been made in recent years by applying the new growth technique of molecular beam epitaxy (MBE) (5). The superior characteristics of MBE are the ability to achieve reproducible ultrathin layers of extreme smoothness and tailoring doping profiles and/or composition on an atomic scale normal to the growth surface exactly to the desired function (6).

According to extensive theoretical calculations (7, 8), a novel type of a doping multilayer structure consisting of a periodic sequence of thin (200Å $\leq D \leq$ 1500Å) p- and n-doped GaAs layers, possibly with intrinsic (*i*-) layers in between, (also called "nipi" crystals) should exhibit intriguing peculiarities because the bandgap and carrier concentration can be tuned within wide limits in these crystals. Although the first GaAs films with a periodic variation of carrier type (p- to n-type) produced by MBE have been reported in 1971 (9), only very limited progress has been made since. Also recent attempts to grow periodic p-n multilayer structures in GaAs by using a single dopant source containing the amphoteric element Ge and changing the As to Ga ratio on the growth surface have been succesful only to some extent, because of the growth instabilities during Ga-stabilized (4 $\times$ 2) surface reconstruction (8, 10).

In the present paper we report now for the first time the preparation of a novel man-made superlattice in GaAs by MBE consisting of alternating p- and n-type layers with uniform dopant concentration within each individual layer and controlled thickness with constant periodicity by using Be as acceptor and Si as donor impurities. For an optimum performance of this new GaAs superlattice [*e.g.*, electroluminescence application (7)], a high quality with respect to majority as well as minority carrier properties has primarily to be assured to the constituent p- and n-doped layers and p-n junctions. First we present, therefore, experimental results indicating excellent uniformity of doping concentration, high carrier mobilities, and superior photoluminescence response of the individual Be- and Si-doped GaAs layers composing the periodic p-n multilayer structure. In some cases comparison is made with Sn- and Ge-doped layers grown in our laboratory in a previous study. We examine, furthermore, profiles of one carrier type in GaAs:Si and GaAs:Be layers and we discuss the abruptness of p-n junctions using (Be, Si)-doped GaAs layers. Finally, we provide convincing experimental evidence for the existence of a novel superlattice effect in the p-n multilayer structure from optical transmission measurements.

Key words: semiconductor thin films, molecular beam epitaxy (MBE), gallium arsenide, impurity incorporation, photoluminescence.

Experimental

At the present time the most important requirements for any significant advances in the quality of MBE grown III-V compound semiconductor structures and devices are (*i*) a careful selection of materials used for building the effusion cells as well as for the cell charges, (*ii*) the addition of a sample exchange load-lock system to the MBE growth chamber in order to eliminate the atmospheric contamination of the molecular beam sources during substrate introduction and removal, and (*iii*) a highly reproducible procedure for substrate preparation prior to epitaxial growth in order to avoid any effect of the substrate-active layer interface on the film properties.

MBE growth of the GaAs layer structures for this study was performed in a bakeable UHV system schematically shown in Fig. 1. The MBE system is of the vertical evaporation type, and it was designed for a growth process providing abrupt variation of dopants (p- to n-type) and/or of composition (GaAs to AlAs) without interruption of growth. Five effusion cells are installed in the growth chamber containing elemental arsenic, gallium, aluminum (not used in the present investigation), and the two dopant elements Be for p-type and Si for n-type doping. For cell materials, pyrolytic boron nitride (PBN) has been used for the high temperature evaporants (Ga, Al, and Si) and reactor-grade graphite for the As_4 and Be effusion cells. Each cell has its own mechanical shutter operated by a rotary feedthrough. The capacity of the

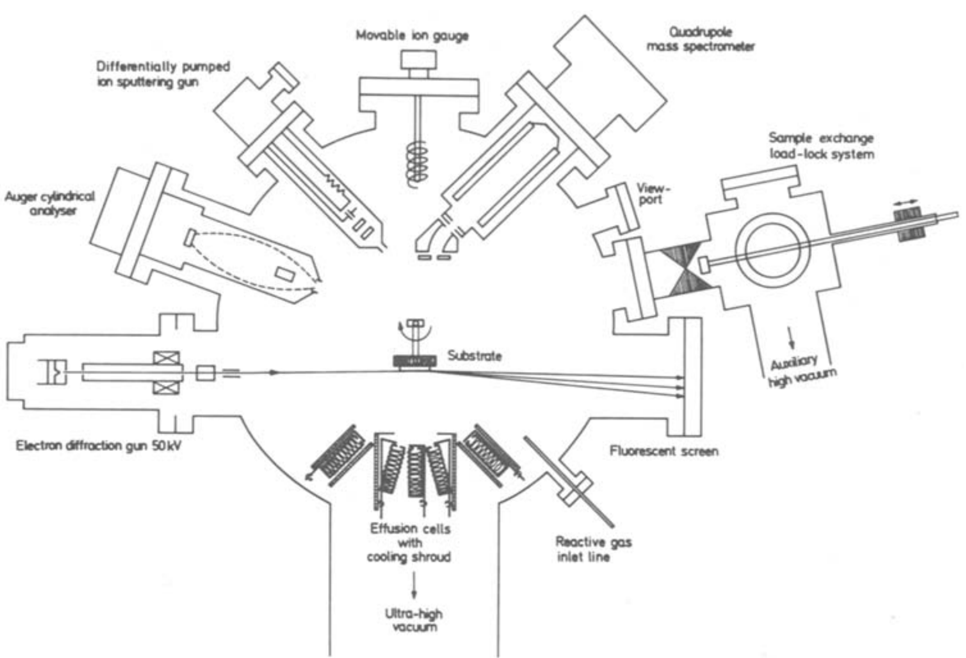

Fig. 1. Schematic cross section of the UHV system designed for molecular beam epitaxy of doped GaAs and $Al_xGa_{1-x}As$ films (vertical evaporation type).

crucible containing As_4 is sufficient for deposition of an equivalent of more than 100 μm thick GaAs films before refilling is required. The complete multiple effusion cell assembly is surrounded by liquid-nitrogen cooled shrouds for cryopumping of condensible species in order to minimize outgassing into the reaction chamber. A more extended use of cryopanels completely surrounding the substrate was not used for this study.

The temperatures of the individual effusion cells and of the substrate heater block were measured with tungsten-rhenium (3% Re *vs.* 25% Re) thermocouples, and they were monitored by a computer-controlled temperature regulation system (11). In addition to the components used directly for the epitaxial growth process, the growth chamber shown in Fig. 1 contains several components of surface analytical techniques, the application of which during MBE growth has been described earlier (12).

The (100) oriented GaAs substrates were either Cr-doped (semi-insulating) for Hall effect and low temperature photoluminescence (PL) measurements or Si-doped ($n > 1 \times 10^{18}$ cm^{-3})[1] for Schottky barrier or p-n junction current-voltage and capacitance-voltage characteristics of the grown films. Typically, a wafer was first polished with diamond paste to remove the initial saw-cut damage and etch-polished on an abrasive-free lens paper soaked with sodium hypochlorite solution leaving a mirrorlike finish. The slice was then successively rinsed in trichloroethylene, methanol, and double distilled water. After boiling in hydrochloric acid twice, the substrate was free-etched in a stagnant solution of $H_2SO_4:H_2O_2:H_2O = 3:1:1$ at 48°C for 1 min. Finally, the wafer was flooded with double distilled water to stop the etchant, rinsed in water, and blown dry with filtered nitrogen gas just before soldering it with liquid indium to a molybdenum plate under dust-free conditions.

Immediately after, the Mo mounting plate with the freshly prepared substrate was remotely exchanged with a plate holding the processed substrate from the previous growth run using an advanced sample exchange load-lock system[2] indicated in Fig. 1. The system was operated by a magnetically coupled transfer mechanism, and an all-metal isolation valve is utilized to separate the main growth chamber from the introduction chamber during epitaxy. The Mo mounting plate holding the substrate was fixed by a bayonet joint to the internally heated Mo block which remains always inside the growth chamber. During sample exchange the cryopanels in the growth chamber were held at liquid-nitrogen temperature, and the effusion cells were kept at temperatures not far below their usual operation temperatures. The entire sample exchange procedure was completed in 10 min and a new growth run could be started rapidly without any distortion of the growth conditions.

Prior to epitaxy the substrate was outgassed by heating to a temperature of 50°-80°C higher than the final operating temperature in a beam of As_4 ranging from 10^{14} to 10^{15} molecules/cm^2 sec for several minutes. This procedure produced a flat As-stabilized surface with a weak (2×4) reconstruction. Differently doped substrates required different time of heat-treatment.

During deposition the substrate temperature was maintained at 530°C for most of the Be- and Si-doped GaAs films yielding excellent majority carrier mobilities and PL efficiencies. The temperature was measured by a W-Re thermocouple and adjusted by the well-known oxygen desorption behavior of chemically etched (100) GaAs surfaces in a similar manner as described in Ref. (6). The temperatures of the Ga and As_4 effusion cells were kept constant throughout all growth runs resulting in a constant growth rate of 0.9 μm/hr and a constant As_4/Ga flux ratio of two. The temperatures of the Be and Si effusion cells were varied over wide ranges (*cf.* Fig. 2) according to the required dopant fluxes.

Most of the Be- and Si-doped GaAs films and of the doping structures used for this study were deposited without any buffer layer directly onto the appropriately doped substrate, and they had an overall thickness of not more than 2 μm.

An important aspect in the growth of highly refined GaAs layers doped with Be was the selection of the Be source material. Most of the commercially available Be metal which is at best 99.9% contains considerable amounts of Fe, Al, Cr, Cu, and Ni. These impurity elements can also be incorporated into the growing GaAs during evaporation of Be. We have found that the best source for Be is a tiny block of material carefully cleaved from a highly refined Be single crystal (99.999%) which has been purified by several cycles of zone refining.[3]

[1] GaAs substrate material was supplied by Laser Diode Laboratories, Incorporated, New Brunswick, New Jersey 08901.

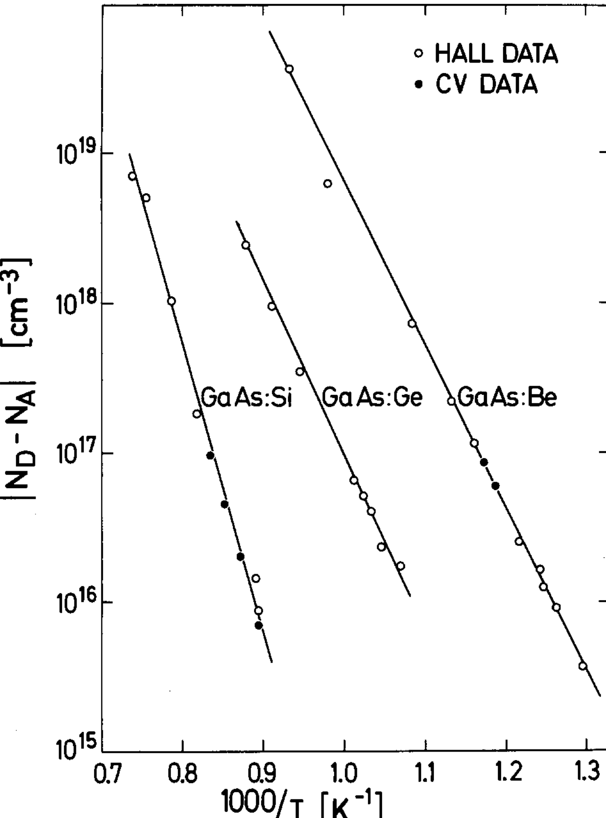

Fig. 2. Clausius-Clapeyron type plots of 300 K free-carrier concentrations of intentionally doped GaAs films as function of reciprocal dopant effusion cell temperatures for constant film growth rate, substrate temperature, and As_4 to Ga flux ratio.

The Ge-doped GaAs films which are in some cases cited for comparison with the Be- and Si-doped layers were grown in a separate growth system described earlier (13, 14), in order to prevent any Ge contamination of the system used for Be and Si doping.

Free-carrier concentrations and Hall mobilities of the 2 μm thick uniformly doped layers were measured in the temperature range of 77-300 K using the standard van der Pauw technique with contacts consisting of alloyed Sn (n-type samples) or Sn/Zn balls (p-type samples). Low current levels and a magnetic field of 5 kG were applied throughout these measurements. The ionized acceptor and donor concentrations were determined and separated by comparing the experimental 77 K data with the empirical curve of $\mu_{77\,K}$ *vs.* $[(N_D + N_A) \times$ (Brooks-Herring screening factor)$]$ derived by Stillman and Wolfe (15). No corrections were made for carrier depletion that occurs in epitaxial GaAs layers at their free surface and their interface with the semi-insulating substrate (16).

Free carrier profiles as a function of depth were derived from capacitance-voltage (*CV*) measurements of reverse-biased Schottky barriers or abrupt p-n junctions using the differential capacitance technique. The Schottky barriers on n-type films were formed by evaporating 0.2 μm Au through an Mo mask containing 0.5 mm diam holes in a separate vacuum system at 10^{-6} Torr and generally at room temperature. With p-n junctions the required contacts were obtained by successively depositing 0.02 μm Cr and 0.2 μm Au. Just prior to metallization, the surface of the GaAs film was carefully cleaned with hydrochloric acid for oxygen removal and rinsed in methanol for surface passivation. The ohmic contact on the back side of the heavily doped substrate wafer was formed by covering with liquid In/Ga = 4:1 alloy. Mesa diodes were obtained by removing the material between the metal dots to a depth of ~ 10 μm with a standard mesa etch ($CH_3OH/H_3PO_4/H_2O_2$ = 3:1:1). Further efforts to avoid any leakage currents such as diffusing a guard ring were not made.

Acceptor impurities incorporated in the MBE GaAs films intentionally doped with either Be, Si, or Ge were identified by high resolution photoluminescence (PL) measurements which were performed with the sample immersed in liquid helium pumped to temperatures below 2 K. The samples were excited by the 6471Å line of a Kr laser focused to a spot of area ~ 10^{-3} cm^2. The laser excitation power was varied between 10^2 and 10^{-2} mW using neutral density filters. The luminescence light was analyzed by a grating monochromator with a resolution better than 1Å and detected by a photon counting system attached to a cooled GaAs photocathode photomultiplier.

Optical transmission measurements on periodic p-n multilayer structures in GaAs at 1.6 K were made normal to the surface of the sample using a focused halogen lamp as light source and the same detection system as described before. Direct transmission was assured by placing the sample between two apertures with 4 mm diam holes. The transmitted light was focused onto the entrance slit of the monochromator.

Results and Discussion

Evaluation of Uniformly Doped GaAs:Si and GaAs:Be Layers

Electrical properties.—The elements Si and Be as well as Ge which have been used as dopants in the present study have unity sticking coefficients on (100) GaAs over a wide range of growth conditions, *i.e.*, substrate temperature up to 630°C, impurity flux 10^9-10^{14} atoms/cm^2 sec, As_4 to Ga flux ratio varied widely. This behavior is indicated by the Clausius-Clapeyron type plots of Fig. 2 which show the 300 K free-carrier concentration of a large number of intentionally doped GaAs films as a function of reciprocal temperature of the corresponding dopant effusion cells. The measured data fit well to an exponential $|N_D - N_A|$ *vs.* $1/T$ relation.

Ilegems (17), Wood *et al.* (18), and Shimanoe *et al.* (19) have pointed out that these log $|N_D - N_A|$ *vs.* $1/T$ plots have exactly the same slope as the vapor pressure curves of Si, Ge, and Be also plotted *vs.* $1/T$. This means that one incident dopant atom produces one ionized impurity species in the GaAs films, and the observed doping level is simply proportional to the dopant arrival rate. In addition we have found that the free-carrier concentration profiles of either Si-, Ge-, or Be-doped GaAs films of varying thickness are completely flat over that part of the film depth measurable by the *CV* profiling technique.

The important aspect of doping MBE GaAs with Ge is that it is strongly amphoteric and it can thus be incorporated on Ga as well as on As sites depending on growth conditions (10, 14, 18). The result that the slope of the vapor pressure curve agrees well with the $1/T$ dependence of the free-electron concentration (Fig. 2) is significant. This suggests that for n-type films grown at a constant substrate temperature and with a constant As_4 to Ga flux ratio the degree of autocompensation of Ge in GaAs does apparently not depend on the doping level.

In the present study we have achieved lower and upper limits of 300 K free-carrier concentrations of $(N_D - N_A) = 4.1 \times 10^{15}$ to 6.1×10^{18} cm^{-3} for GaAs:Si, $(N_D - N_A) = 1.7 \times 10^{16}$ to 3.5×10^{18} cm^{-3} for GaAs:Ge and $(N_A - N_D) = 3.7 \times 10^{15}$ to 3.7×10^{19} cm^{-3} for GaAs:Be. For the group IV dopants Si and Ge the upper limit of $(N_D - N_A)$ is given by the autocompensation at high impurity concentrations. The lower limit of the Si- and Be-doped films depends on the total background doping level due to carbon species (~ 5×10^{15} cm^{-3} without cryopanel), whereas the relatively "high" lower level of Ge-doped films

is caused by the strong memory effect of as yet undefined Ge species during MBE.

In Fig. 3(a) and (b) Hall mobilities measured at 300 and 77 K are plotted as functions of free-electron concentration for various n-type GaAs films doped with either Si or Ge. For comparison, the results obtained from Sn-doped GaAs films of a previous study (20) and the theoretical curves calculated by Rode and Knight (21) for different levels of compensation $(N_A + N_D)/n$ are also included in Fig. 3(a).

For all three dopants, the deviation of experimental 300 K mobilities from the theoretical curve for zero compensation is significant at rather low $[(N_D - N_A) < 3 \times 10^{16}\ cm^{-3}]$ and at high $[(N_D - N_A) > 1 \times 10^{18}\ cm^{-3}]$ carrier concentrations thus indicating an increasing compensation ratio. When $(N_D - N_A)$ is below $3 \times 10^{16}\ cm^{-3}$, the nearly constant acceptor concentration of between 5×10^{15} and $1 \times 10^{16}\ cm^{-3}$ imposes a rather high degree of compensation and therefore has a significant influence on the majority carrier mobility. In the limit of large free-electron concentrations $[(N_D - N_A) \geqq 1 \times 10^{18}\ cm^{-3}]$, on the other hand, the semiconductor becomes degenerate and the Born approximation used by Rode and Knight (21) probably becomes inadequate. In addition, the observed larger decrease of μ for Ge and Si doped films compared to the Sn-doped films must be attributed to the increasing autocompensation effect of these dopants in this region. In the range $5 \times 10^{16} \leqq (N_D - N_A) \leqq 1 \times 10^{18}\ cm^{-3}$, the slightly lower mobility values of n-GaAs:Ge are due to a persistent amount of Ge acceptors on As sites even at growth temperatures below 530°C in addition to the residual C acceptors (14). This effect is less pronounced for the obviously less amphoteric Si in n-GaAs: Si.

The 77 K Hall mobilitites of n-GaAs:Si and n-GaAs:Ge layers plotted in Fig. 3(b) fit well to an empirical "universal-value" curve introduced by Poth *et al.* (22). The authors compiled a large number of mobility data obtained from n-type GaAs films grown by LPE, MBE, and VPE with different dopants in various laboratories. All those experimental 77 K data were found to lie below the values predicted by Rode and Knight (21) for uncompensated material [dotted line in Fig. 3(b)]. The strongly amphoteric Ge in MBE-grown n-GaAs again causes a more pronounced deviation of $\mu_{77\ K}$ from the empirical curve.

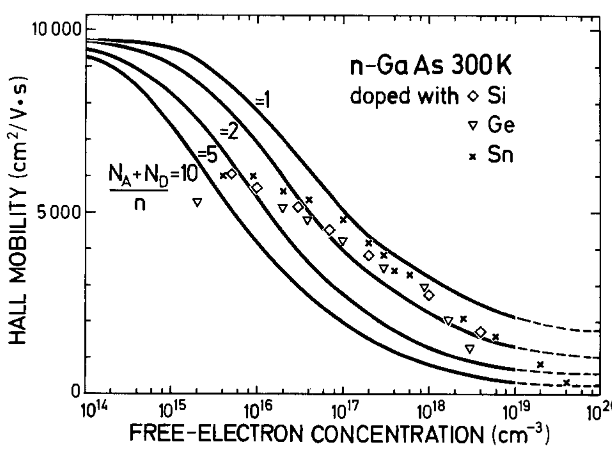
Using deep level transient capacitance spectroscopy (DLTS) (23), we have detected not more than three deep electron traps in Si-doped GaAs films grown at 530°C, corresponding to the activation energies 0.297 eV (M2), 0.583 eV (M5), and 0.620 eV (M6) according to the notation of Lang *et al.* (24). Typical trap concentrations N_T in an n-GaAs:Si sample with $(N_D - N_A) = 1.7 \times 10^{16}\ cm^{-3}$ were found to be $7.8 \times 10^{12}\ cm^{-3}$ at $E_T = 0.620$ eV, $9.4 \times 10^{12}\ cm^{-3}$ at $E_T = 0.583$ eV and $1.14 \times 10^{13}\ cm^{-3}$ at $E_T = 0.297$ eV, respectively (25). This result confirms overall trap concentrations as low as 10^{-3} of the doping level.

Figures 4(a) and (b) show the dependence of 300 and 77 K Hall mobilities on the hole concentration for several p-type MBE GaAs films doped with Be or Ge. Also included are the data of a few nominally "undoped" as-grown p-type GaAs films containing a considerable amount of residual C acceptors. The solid line depicted in Fig. 4(a) simply follows the general trend of experimental data obtained from the best p-type GaAs samples prepared by LPE and VPE (26). The 300 K mobilities extracted from Be- and C-doped GaAs films grown by MBE are in excellent agreement with this empirical curve. The strong amphoteric character of Ge is again indicated by the lower mobilities of p-GaAs: Ge films.

With respect to Fig. 4(b) it is obvious that the 77 K mobilitites of a number of Be-doped GaAs films prepared by MBE are higher in the range $(N_A - N_D) \geqq 6 \times 10^{15}\ cm^{-3}$ than the empirical curve derived by Wiley (26) does depict. This result demonstrates the superior quality of the MBE grown material prepared in the present study. The 77 K data of the Ge-doped p-type material, however, scatter considerably in the amount of carrier freeze out as well as in Hall mobility. The results obtained from C-doped p-type samples agree reasonably well with the empirical values.

Photoluminescence properties.—The results obtained from PL studies of the MBE-grown GaAs layers intentionally doped with either Si, Ge, or Be are displayed in Fig. 5 and 6. We restrict ourselves to the discussion of the high energy region of the PL spectra where recombination via shallow acceptors ($E_B \leqq 100$ meV) occurs which is significant to identify the dominant acceptor impurities in the material.

In PL spectra taken from Si-doped samples deposited at 530°C under standard As-stabilized growth conditions using an As_4 source, *i.e.*, As_4 to Ga ratio $\geqq 2:1$, only three broad emission lines can be clearly resolved [full line in Fig. 5(a)]. The peak labeled BE is assigned to the bound exciton recombination. This line is smeared out because of the relatively high level of ionized impurities present which lead to a broadening of the individual excitonic lines. For the same reason, the band-acceptor recombination line labeled C is also



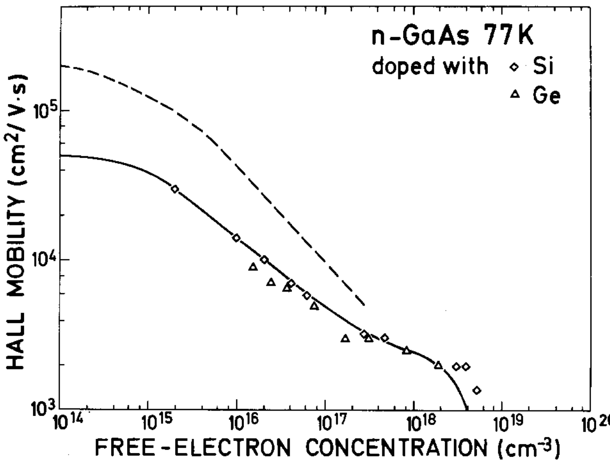


Fig. 3. Hall mobilities at (a, left) 300 K and (b, right) 77 K as a function of free-electron concentrations in MBE-grown 2 μm thick n-type GaAs films doped with either Si, Ge, or Sn. The solid lines in (a) and the dotted line in (b) follow the theoretical calculations of Rode and Knight (21) for different compensation ratios. The solid curve in (b) represents the empirical curve proposed by Poth *et al.* (22).

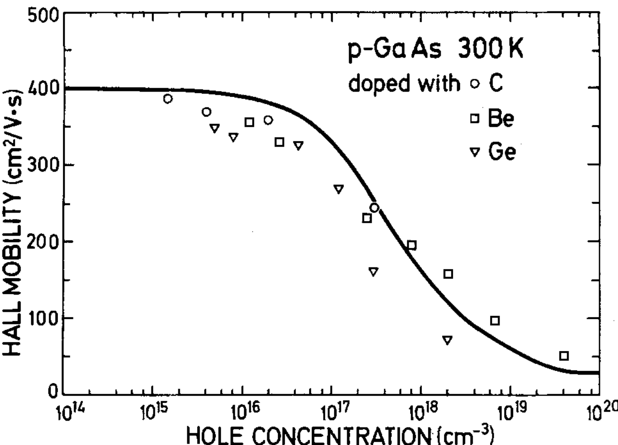

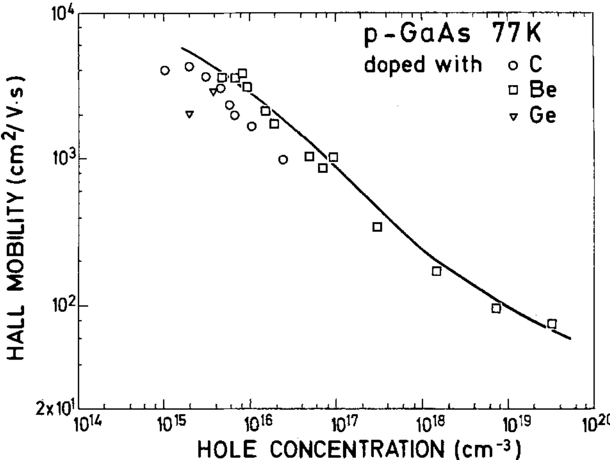

Fig. 4. Hall mobilities at (a, left) 300 K and (b, right) 77 K as a function of net-hole concentrations in MBE-grown 2 μm thick p-type GaAs films doped with either Be, C, or Ge. The solid lines represent the general trend of experimental data obtained from the best p-type GaAs samples prepared by LPE and VPE (26).

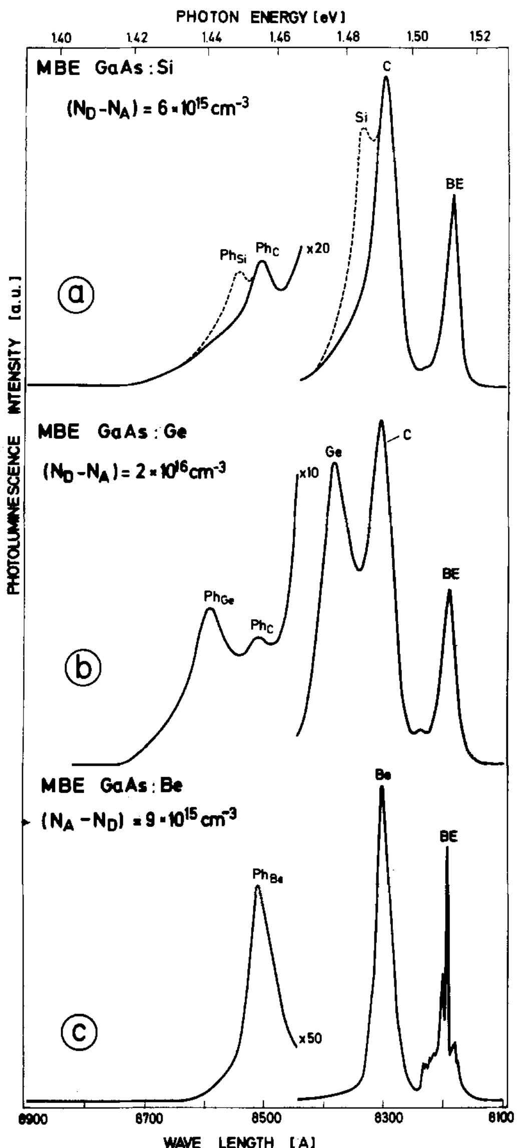

Fig. 5. Low temperature photoluminescence spectra taken at 1.6 K from intentionally doped GaAs films grown by MBE. (a) Si-doped, $(N_D - N_A) = 6.1 \times 10^{15}$ cm^{-3}; (b) Ge-doped, $(N_D - N_A) = 2.0 \times 10^{16}$ cm^{-3}; (c) Be-doped, $(N_A - N_D) = 8.9 \times 10^{15}$ cm^{-3}. Only the high energy regions of the spectra are shown. The various emission lines are labeled along their mechanisms (see text).

broadened and no evidence for the corresponding donor-acceptor transition is found. Ashen *et al.* (27) have shown in a fundamental study that this peak C may be attributed to carbon incorporated on arsenic sites. It is now generally accepted that carbon is the principal residual acceptor impurity associated with MBE growth of GaAs (28). We have hardly found any evidence for the BA recombination involving Si acceptors in MBE GaAs:Si layers of various doping levels when grown from an As_4 source with standard As-stabilized conditions. However, the peak at 1.485 eV corresponding to the BA emission due to Si incorporated on As sites does occur in samples grown (*i*) from an As_4 source and close to Ga-stabilized conditions, *i.e.*, substrate temperature >600°C or As_4 to Ga ratio <1, or (*ii*) from

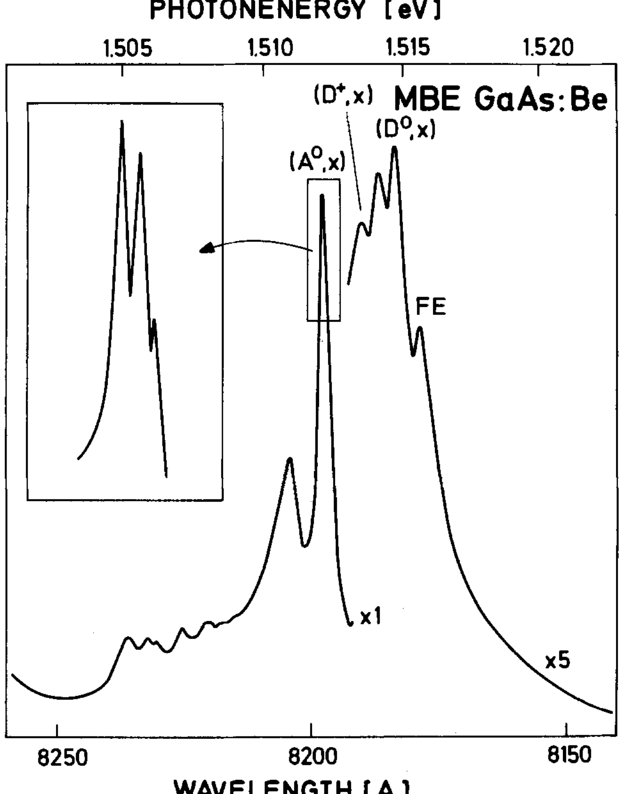

Fig. 6. 1.6 K photoluminescence spectrum of a Be-doped p-type GaAs layer of 2 μm thickness grown by MBE [$(N_A - N_D) = 8.9 \times 10^{15}$ cm^{-3}]. Only the excitonic region of the spectrum is shown. The various luminescence lines are labeled according to their recombination mechanisms (see text).

a GaAs source producing As_2 species. This additional peak is indicated by dotted lines in Fig. 5(a). The lines labeled $Ph_{C, Si, Ge, Be}$ are the phonon replicas of the corresponding BA transition ($\hbar\omega_{LO} = 36$ meV).

The typical PL spectra obtained from Ge-doped n-type GaAs films [Fig. 5(b)] are very similar to those taken from Si-doped samples with the important features that (*i*) the BA transition due to Ge (1.479 eV) is much easier to separate from the BA transition assigned to C, and (*ii*) the intensity of this peak is generally much higher and it is detected even in the best n-type GaAs: Ge samples ($N_D/N_A = 4$) grown at 500°C. This must be attributed to the relatively large amount of Ge being incorporated on As sites even under strongly As-stabilized growth conditions (14).

Finally, the PL spectra of Be-doped GaAs layers [Fig. 5(c)] are to some extent similar to those of Si-doped layers. Two BA transition lines due to C and Be acceptors which are definitely present in these samples would be expected. However, we were not able to resolve both BA transitions in any of the measured PL spectra because the values of the binding energies of the C acceptor (26.0 meV) and of the Be acceptor (28.0 meV) (27) lie too close together. We assume that the peak labeled Be in Fig. 5(c) reflects the Be acceptor, since this peak is slightly shifted towards lower energies compared to the C_{As} related BA transition found in GaAs: Si.

Considering the PL spectra of Be-doped GaAs layers, an excellent resolution with excitonic fine structure was obtained for free-carrier concentrations up to 1×10^{16} cm^{-3}. For the first time, all sharp features as yet only seen in the best quality intentionally doped p-type VPE or LPE samples were observed in these layers grown by MBE in our laboratory (Fig. 6). Referring to the fundamental study of Heim and Hiesinger (29), the several spectral features were identified as a well-separated free-exciton (FE) recombination line at 1.5156 eV, a sharp line at 1.5140 eV due to excitons bound to neutral donors (D^o, x) as well as a peak due to the corresponding excited states at 1.5144 eV (not labeled), and a line at 1.5134 eV due to the recombination of ionized donors-bound excitons (D^+, x). The entire PL spectrum of this p-type GaAs: Be layer is dominated by the neutral acceptor-bound exciton (A^o, x) recombination line. The insert in Fig. 6 shows that this line is further split into a triplet at 1.5123, 1.5122, and 1.5120 eV. This splitting is caused by j-j coupling of the two holes and one electron resulting in $J = 1/2, 3/2, 5/2$ states (29).

Several additional lines in the energy range 1.511-1.504 eV (Fig. 6) are only found in GaAs layers grown by MBE using As_4 molecular beams. An interpretation of these new spectral features specific to MBE material is referred to a subsequent paper (30). As a result, the PL measurements on intentionally doped GaAs layers presented here attest an excellent quality of the MBE grown material thus well suited as a component of highly refined III-V structures.

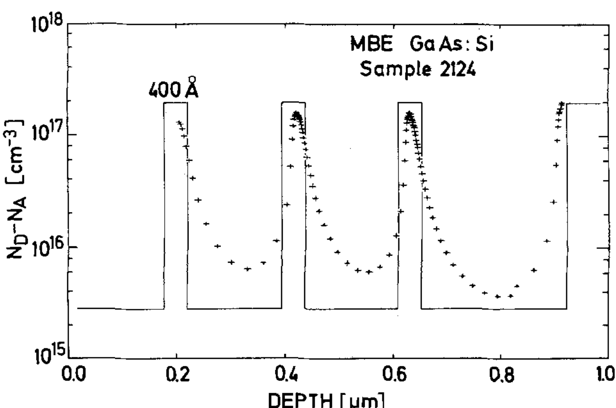
Dopant and Carrier Concentration Profiles

The incorporation behavior of the dopant elements Si, Ge, and Be in MBE GaAs was further studied by producing a number of structures consisting of stepwise changes in dopant beam intensity. For the case of doping with Si and Ge, the actual carrier profiles measured by the differential capacitance technique were compared with the corresponding dopant beam intensity *vs.* time profiles in Fig. 7. In these structures a 0.9 μm thick n^+ (2×10^{18} cm^{-3}) buffer layer was grown on the heavily Si-doped ($n = 2 \times 10^{18}$ cm^{-3}) substrate first. Then the 1 μm thick "active" n-GaAs layer was deposited which consisted of three narrow pulses of Si or Ge atoms, respectively, superimposed on a uniform doping background. Each pulse had a duration of time equivalent to the growth of 400Å GaAs. The width of the individual pulses was accurately controlled by opening and closing the mechanical shutters in front of the corresponding effusion cells.

The square traces in Fig. 7 reflect ideal profiles calculated from the dopant beam intensity which was modulated by the setting of the shutter. The ideal doping levels were extracted from the effusion cell temperatures related to the data of Fig. 2. The rectangular curves of Fig. 7 were calculated assuming a unity sticking coefficient of the dopants and neglecting surface segregation, bulk diffusion, and majority carrier diffusion.

The measured free-carrier profiles of the Si- and Ge-doped structures indicated by crosses in Fig. 7 differ significantly from one another. Using Si as dopant in GaAs, extremely abrupt profiles and a peak to background free-carrier ratio of nearly two orders of magnitude can easily be achieved, whereas in the case of the dopant Ge the actual carrier concentration decreases more slowly after the dopant beam has been cut off. Therefore, only less steep carrier profiles can be obtained with Ge doping. Note that in addition the background carrier concentration is one order of magnitude higher for Ge than for Si doping. The behavior of Ge must be attributed to its memory effect which gives rise to rather a high amount of Ge containing species remaining in the MBE growth chamber even after shuttering the Ge effusion cell and/or rapidly lowering the cell temperature.

The results obtained with Si doping have been used to verify doping profiles which are specifically designed for achieving Schottky barrier diodes with low diode noise temperature at cryogenic temperatures. Such diodes are required for cryogenically cooled millimeter wave mixers (1). The GaAs wafer consists of a heavily Si-doped substrate ($n = 2 \times 10^{18}$ cm^{-3}), a 1 μm thick n^+ buffer layer ($n = 2 \times 10^{18}$ cm^{-3}), and a 0.1-0.2 μm thick active layer having a carrier concen-



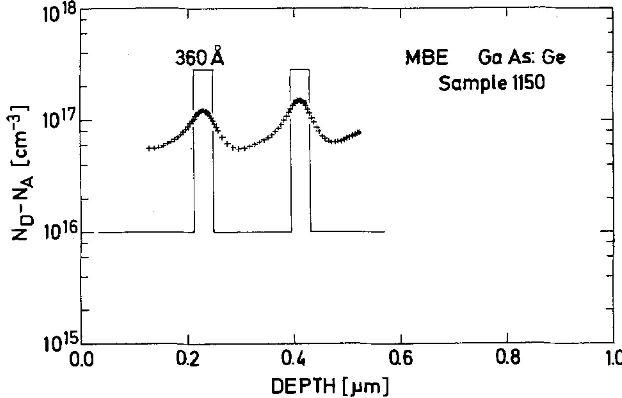


Fig. 7. Comparison of measured periodic doping profiles (indicated by crosses) of MBE-grown n-type GaAs layers doped with a pulsed beam of (a, left) Si and (b, right) Ge, respectively. The square traces are ideal profiles calculated from the dopant beam intensities.

tration of $n \simeq 1 \times 10^{16}$ cm^{-3}. The donor concentration profile of the n$^+$- to active layer interface must be as abrupt as possible. In order to determine the actual profile as a function of depth from the surface by the CV technique, thicker active n-type layers were grown in separate runs to account for the zero bias depletion layer. The resulting doping profile measured on a representative sample is shown in Fig. 9 (indicated by crosses), demonstrating an extremely abrupt transition from high to low carrier concentration. It should be noted that the actual profile is even more abrupt than the trace shown, because of the limited resolution of the profiling technique (*cf.* below).

In the doping profiles shown in Fig. 7 and 8 the actual free-carrier concentrations differ by several Debye-lengths [$\lambda_{Debye} \sim 450$Å for $(N_D - N_A) = 1 \times 10^{16}$ cm^{-3} (31)] from the dopant concentrations due to majority-carrier diffusion. For this reason, the ultimate step sharpness of free-carrier profiles measured by the CV technique is limited. Moreover, Johnson and Panousis (32) have pointed out that there exist even small differences between the theoretical free-carrier profile (31) corresponding to the given dopant profile and the measured free-carrier profile, because the metal contacts necessary for CV measurements are not infinitely far away from one another. Using computer simulations for a stepwise change in doping concentration by, for instance, two orders of magnitude, these authors demonstrated that different carrier profiles are measured depending on the rectifying contact being placed on the high- or low-doped side. Slightly asymmetric free-carrier profiles as shown in Fig. 7 and 8 are, therefore, expected to be measured for rectangular dopant pulses.

For similar profiling measurements of Be-doped p-type GaAs layers, a number of n$^+$ (substrate)-n$^+$-p-p$^+$ (contact) diode structures were produced. The n$^+$-side of the p-n$^+$ junction was doped with Si ($n = 2 \times 10^{18}$ cm^{-3}). The p-layer consisted of three sharp Be doping pulses in time duration equivalent to the growth of 335Å GaAs. A typical free-carrier profile obtained from measurements of mesa diodes fabricated on these structures is shown in Fig. 8. The solid line represents the rectangular profile calculated for the arriving dopant species. Note that also with Be extremely abrupt profiles in MBE GaAs with a peak-to-background free-carrier ratio of nearly two orders of magnitude have been obtained in this study. This outcome is an improvement of the actual carrier profile by one order of magnitude compared to the results of Ilegems (17). This improvement is simply a consequence of the superior quality of the Be doping material used in the present study.

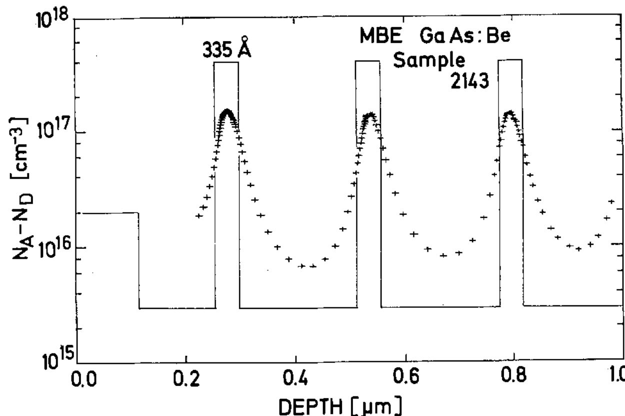

Fig. 8. Measured periodic doping profile (indicated by crosses) in a reverse-biased n$^+$-p junction with pulsed Be dopant beam modulation in the p-region. The calculated ideal dopant profile is indicated by the solid line.

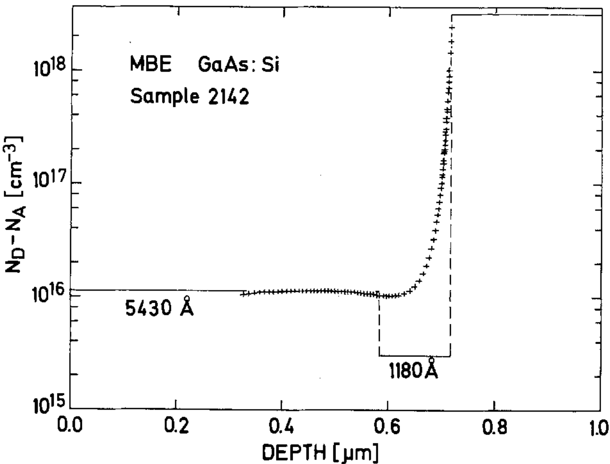

Fig. 9. Typical doping profile of a GaAs Schottky barrier diode designed for low diode noise temperature at cryogenic temperatures. In the actual mixer diodes the thickness of the active n-type layer is only 0.1-0.2 μm. The solid lines represent the ideal dopant beam intensity calculated from the cell temperature and shutter setting.

p-n Junction Behavior

The results obtained from n-GaAs:Si [Fig. 7(a)] and p-GaAs:Be (Fig. 8) periodic doping structures can be combined in order to simulate the expected free-carrier profile of a step p-n junction in GaAs taking into account the two dopant cells Be and Si. The profile of the junction extracted in this way is shown in Fig. 10. The Si dopant cell is closed by the mechanical shutter during growth of the Be-doped GaAs layer and opened just when the Be dopant cell is mechanically shuttered (indicated by the dotted line). The expected free-carrier profile (solid line) can then be computed by a point by point subtraction of the two individual carrier profiles actually measured and shown in Fig. 7(a) and 8. With a final free-carrier concentration of 1.45×10^{17} cm^{-3} on both sides of the p-n junction, the width necessary to change the free-carrier concentration from n-type 1×10^{17} cm^{-3} to the same level p-type is found to be less than 200Å. In this simulation procedure attention has been paid to all problems arising from CV profiling measurements discussed before. Therefore, the value of 200Å demonstrates that hyperabrupt p-n junctions in GaAs with excellent characteristics can be grown by MBE using Be and Si as p- and n-type dopants, respectively.

Based on the before-mentioned considerations one-sided abrupt p-n$^+$ junctions in GaAs were prepared using growth parameters established for periodic carrier profile growth. The diode structures consisted of an initial 1 μm thick Si-doped n$^+$-layer ($n = 2 \times 10^{18}$ cm^{-3}) on the heavily Si-doped ($n = 2 \times 10^{18}$ cm^{-3}) substrate followed by a 1 μm thick Be-doped p-layer [$1.7 \times 10^{16} \leq (N_A - N_D) \leq 2.4 \times 10^{17}$ cm^{-3}] and a final 0.5 μm thick highly Be-doped p$^+$-layer ($p = 2 \times 10^{18}$ cm^{-3}) for low resistance ohmic contacts. The constant free-hole level in the p-layer was systematically varied from sample to sample. The dopant type was selected by actuating the mechanical shutters in front of the Si and Be dopant cells. The abrupt increase of hole concentration at the p/p$^+$ transition was achieved by a step change of the Be cell temperature.

The properties of the (Be, Si)-doped GaAs p-n junctions were derived from IV and CV measurements on isolated mesa diodes. The results obtained for different doping levels of the p-region are summarized in Table I and in Fig. 11. In all diodes studied neither the forward nor the reverse characteristic showed evidence of leakage current. The current flow in the forward direction increases exponentially as $I = I_o \exp(qV/nkT)$. The diode-n-value extracted from the slope of the linear fit to the measured ln I vs. V curve for $V \geq 3kT/q$ was found to be 1.8 ± 0.2 for all diodes.

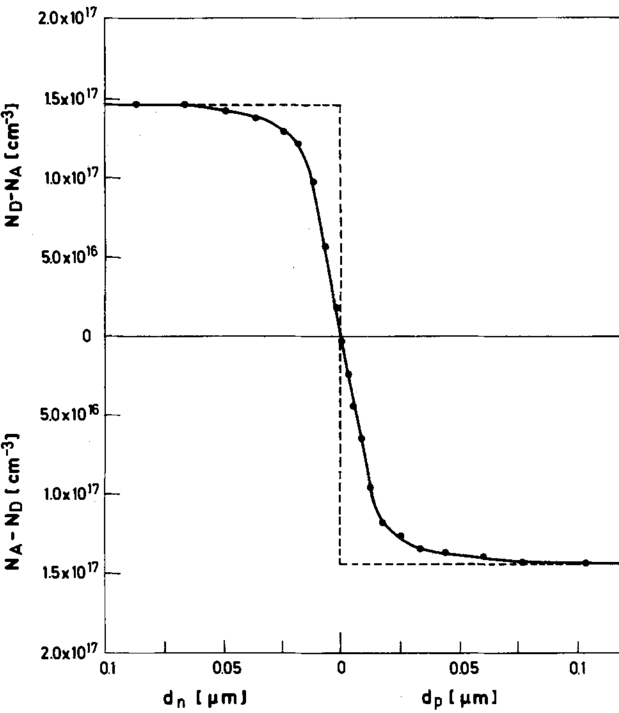

Fig. 10. Expected free-carrier profile (solid line) of a step p-n junction in (Be,Si)-doped GaAs grown by MBE computed by a point by point subtraction of the two individual measured carrier profiles shown in Fig. 7(a) and 8. The dotted line indicates the ideal profile extracted from the dopant beam intensities of Be and Si, respectively.

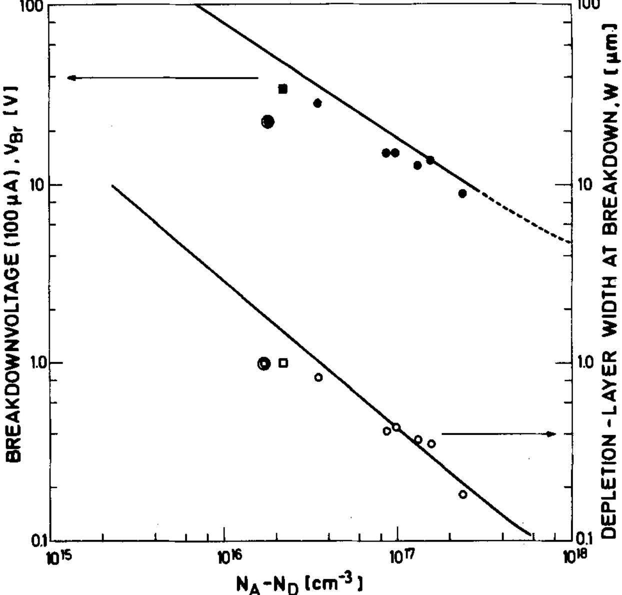

Fig. 11. Characteristics of one-sided abrupt p-n$^+$ junctions in (Be,Si)-doped GaAs layers having different doping levels in the p-region as derived from *IV* and *CV* measurements (indicated by circles). The solid lines represent the theoretical values of breakdown voltage and depletion layer width, resp., as a function of carrier concentration in the p-region calculated by Sze and Gibbons (34). In the sample labeled by double circles, the 1 µm thick p-type side of the junction is already totally depleted at 16V. The squares denote the results obtained from a p-n$^+$ junction in GaAs doped with the amphoteric Ge only (10).

This value indicates that the current flow across these p-n junctions is dominated by recombination-generation processes ($n_{rec} = 2.0$) as opposed to diffusion mechanisms (33) ($n_{dif} = 1.0$). Minor deviations from the linear ln I *vs.* V behavior which may sometimes occur at higher current levels are caused by series resistance effects.

The current flow in the reverse direction is characterized by the junction breakdown voltage V_{Br} which increases exponentially with decreasing carrier concentration. The measured values for V_{Br} (associated with that voltage at which the current in the reverse direction reaches 10^{-4}A) are compiled in Table I and Fig. 11. The data points are in excellent agreement with the theoretical curve derived by Sze and Gibbons (34) for one-sided abrupt junctions assuming that avalanche multiplication dominates the breakdown characteristics. Small differences between observed and calculated V_{Br} values can be attributed to the nonguarded diode structure as well as to minor imperfections of the crystal (35) both of which reduce the actual breakdown voltage. This effect was not further studied throughout the present work.

Only the results obtained from sample 2162 (*cf.* Table I) seem to indicate severe discrepancies. The p-layer of this sample, however, having also a thickness of only 1 µm, is almost totally depleted at 16V, thus yielding the limited value of V_{Br}. For comparison, the results extracted from a p-n$^+$ junction in GaAs doped with the amphoteric Ge only are also included in Table I and in Fig. 11. This sample exhibited excellent characteristics, although the Ge-doped p-n junctions are certainly not quite as steep as are the (Be, Si)-doped ones (10, 14).

Additional detailed insight in the p-n$^+$ junction behavior was deduced from *CV* profiling measurements. Outside the depletion region at $V = 0$, the measured doping profiles of the p-region as a function of depth were extremely flat, and the observed doping levels were in excellent agreement with the concentrations estimated from the Clausius-Clapeyron type plots of Fig. 2. The depletion layer width at breakdown voltage was derived and also compared with the theoretical width given for one-sided abrupt junctions in Ref. (34). As indicated in Fig. 11, there is a strict coincidence between measured and calculated depletion layer width for different doping levels. Finally, an extrapolation of the $1/C^2$ *vs.* V curve to $1/C^2 \to 0$ yields the built-in voltage V_{Bi} across the junction which was found to be 1.35 ± 0.15V for the samples studied here.

Table I. Characteristics of one-sided abrupt p-n$^+$ junctions in MBE grown GaAs layers having different doping levels in the p-region as derived from current-voltage and capacitance-voltage measurements

Sample	Dopants	Carrier concentration in the p-region (cm^{-3})	Breakdown voltage (V)	Diode-n-value	Depletion layer width (µm)	Built-in voltage (V)
2164	Be, Si	2.35×10^{17}	8.8	1.89	0.18	1.31
2184	Be, Si	1.55×10^{17}	13.6	1.69	0.35	1.49
2163	Be, Si	1.30×10^{17}	12.7	1.70	0.37	1.23
2106	Be, Si	9.80×10^{16}	15.0	1.94	0.43	—
2114	Be, Si	8.60×10^{16}	15.0	—	0.41	1.48
2183	Be, Si	3.50×10^{16}	28.4	1.82	0.82	1.30
2162	Be, Si	1.70×10^{16}	16.0*	1.86	>1.0	1.21

* 1 µm thick p-layer totally depleted at 16V.

Periodic p-n Multilayer Structures

Based on the foregoing experience, we have finally combined several p-n junctions in (Be, Si)-doped GaAs to build up a novel periodic multilayer structure in GaAs which is schematically depicted in Fig. 12. The structure is composed of a periodic sequence of thin p- and n-type GaAs layers with intrinsic (i-) layers in between. It is also called "nipi" structure (7, 8). The intrinsic layer denotes that region of the crystal in which the acceptor as well as the donor concentrations are as low as possible, *i.e.*, both the Si and the Be shutter are closed for a controlled duration of time. This region may have a thickness close to zero without substantially modifying the electronic properties of a nipi crystal [*cf.* Fig. 12(b)].

Figure 13 displays a scanning electron micrograph of the (110) cleavage plane of one of these periodic p-n multilayer structures in GaAs which has recently been grown by MBE when actuating the shutters in front of the dopant cells in the appropriate manner. A total of 20 individual alternating p- and n-doped GaAs layers corresponding to 10 periods are clearly resolved. The structure was deposited on a 1 μm thick n^+ buffer layer (2×10^{18} cm^{-3}) which was first grown on a heavily Si-doped GaAs substrate ($n = 2 \times 10^{18}$ cm^{-3}) in order to facilitate light transmission measurements. Each doping layer has a thickness of 0.10 μm and was doped to a level of $(N_D - N_A) = 7.5 \times 10^{17}$ cm^{-3} and $(N_A - N_D) = 2 \times 10^{18}$ cm^{-3}, respectively. The thickness of the intrinsic layer in the example shown was chosen to be close to zero by opening the Si shutter immediately after the Be shutter has been closed and vice versa. Using Be as acceptor and Si as donor impurities a uniform dopant concentration within each individual GaAs layer and a controlled thickness with constant periodicity has been successfully achieved. The interfaces between the individual GaAs layers remain extremely smooth down to atomic steps also for a large number of layers in sequence. We have varied the layer thicknesses d_n, d_p, and d_i ($0 \leq d_i \leq 0.1$ μm) and thereby the periodicity d as well as the individual doping levels over wide ranges according to the theoretical considerations of Döhler *et al.* (7, 8).

The 10 periods indicated in Fig. 13 are sufficient to bring about novel superlattice effects in these doping multilayer structures. The conduction and valence bandedges of a nipi multilayer structure in GaAs are periodically modulated by the space charge field of the ionized impurity atoms per individual layer as depicted in Fig. 12(b). The important parameters which characterize the electronic structure of a nipi crystal are the period d and the concentrations of donors and acceptors per doping layer, *i.e.*, $n_D \cdot d_n$ and $n_A \cdot d_p$, respectively. If the doping concentrations n_D and n_A are the same in the respectively doped layers and if, in addition, the number of dopants in the n- and p-type layers is equal, the amplitude of the space charge potential V_o may be calculated as follows

$$V_o \cong |\rho| \frac{d_n}{8 \cdot \epsilon \cdot \epsilon_o} \quad [1]$$

with ϵ = static dielectric constant [$\epsilon = 13.1$ for GaAs (36)], ϵ_o = permittivity of free space, and ρ = charge

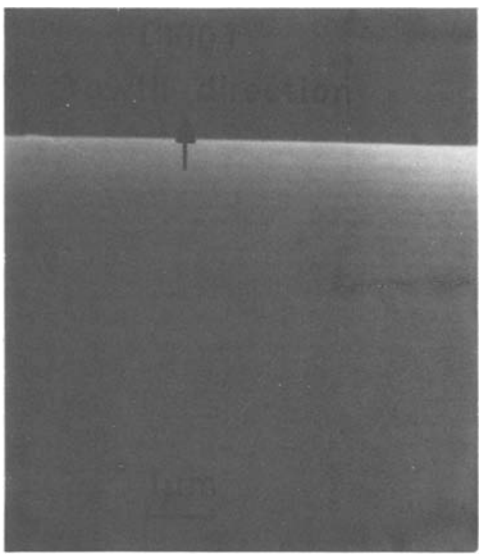

Fig. 13. Scanning electron micrograph of the (110) cleavage plane of a periodic p-n doping multilayer structure in GaAs consisting of 10 periods with a periodicity $d = 0.2$ μm. Each 0.1 μm thick individual layer was doped to a level of $(N_D - N_A) = 7.5 \times 10^{17}$ cm^{-3} and $(N_A - N_D) = 2 \times 10^{18}$ cm^{-3}, respectively.

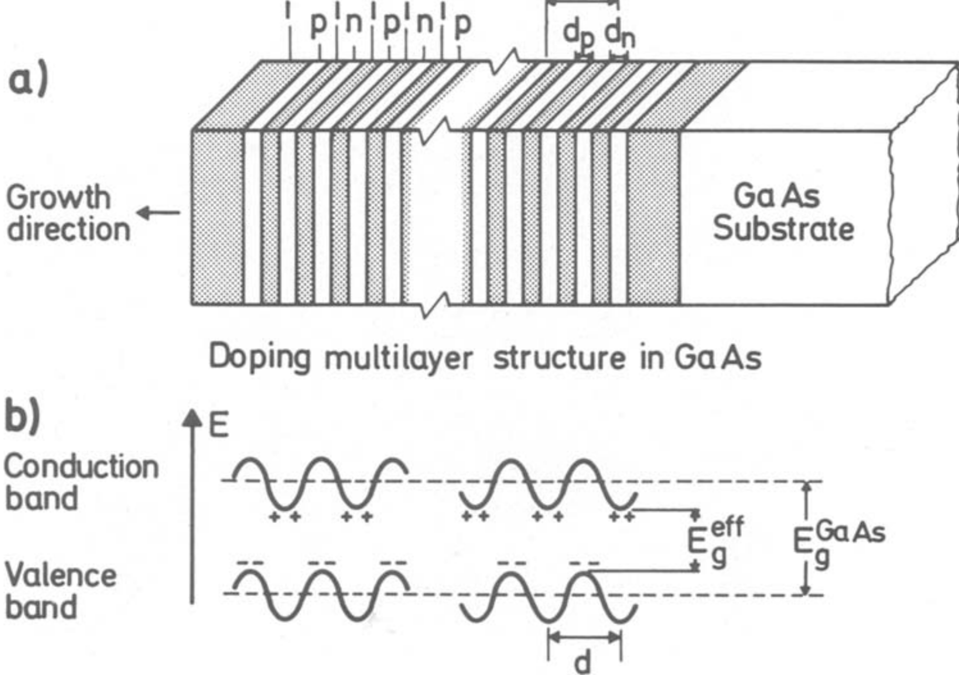

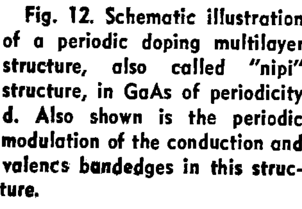

Fig. 12. Schematic illustration of a periodic doping multilayer structure, also called "nipi" structure, in GaAs of periodicity d. Also shown is the periodic modulation of the conduction and valencs bandedges in this structure.

density per layer ($\rho \leq \text{Min}\ (|e|n_D d_n,\ |e|n_A d_p)$. The effective bandgap E_g^{eff} of a nipi crystal defined as the energy difference between the lowest conduction subband and the uppermost valence subband is

$$E_g^{eff} = E_g^{GaAs} - 2V_o \quad [2]$$

As a result of the reduction of the effective energy gap in GaAs nipi crystals, the absorption of photons of energy

$$\hbar\omega > E_g^{eff} = E_g^{GaAs} - 2V_o \quad [3]$$

is energetically allowed. Döhler (7) has proposed that the absorption coefficient $\alpha(\omega)$ should become large for photon energies well below the gap E_g^{GaAs} of the unmodulated semiconductor due to the overlap between conduction and valence subband wavefunctions. This absorption tail for $\hbar\omega < E_g^{GaAs}$ may be understood in some respect as a Franz-Keldysh effect due to the internal space charge fields in nipi crystals.

The effect of these internal fields on the absorption or transmission behavior, respectively, of GaAs nipi crystals with varying doping periods d is shown for two different samples in Fig. 14. In both samples the individual p- and n-doped GaAs layers composing the structure are doped to a rather high free-carrier concentration of 1×10^{18} cm^{-3}, whereas the thickness of the individual layers is varied from 0.02 μm in sample 2227 ($d = 0.04$ μm) to 0.04 μm in sample 2228 ($d = 0.08$ μm). No intrinsic layers were interspersed between the alternating intentionally doped layers. These parameters yield a space charge potential V_o of about 0.069 eV for sample 2227 and 0.276 eV for sample 2228.

In Fig. 14 the two transmission spectra of the periodic doping structures are compared with two spectra of a heavily Si-doped substrate wafer used for MBE growth and of a slightly Si-doped epitaxial layer deposited on n^+-substrate. The strong shift of the absorption edge observed in the four layers is mainly due to the shift of the Fermi level at high carrier concentrations into the conduction band. In addition, the important feature in the optical transmission behavior of the p-n multilayer structures is the strong absorption tail observed particularly below the energy gap of the unmodulated material (indicated by an arrow in Fig. 14). These absorption tails are the result of the internal electrical field arising from the modulation of the bandedges [*cf.* Fig. 12(b)]. The differences between the two transmission spectra obtained from the p-n multilayer structures 2227 and 2228 are caused by the quantitative variation of the bandedge modulation. The values of

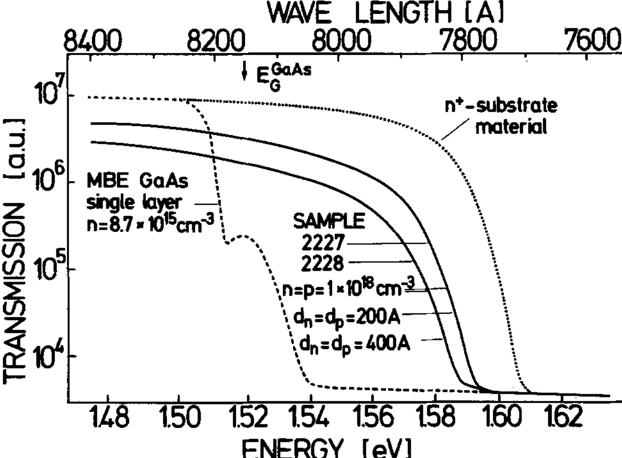

Fig. 14. 1.6 K optical transmission spectra of two representative periodic p-n doping multilayer structures in GaAs indicating the considerable absorpton tails for $\hbar\omega < E_g^{GaAs}$ extending far into the gap of the unmodulated semiconductor (marked by an arrow). For comparison, also the optical transmission of the n^+-substrate used and of a slightly n-doped GaAs layer are shown.

the maximum internal field strength as well as the layer thickness, in which a pronounced field strength exists, differ strongly and explain the remarkably lower transmission of sample 2228 compared to sample 2227.

As a result, the absorption tails observed for these periodic p-n doping multilayer structures extending far into the gap of the pure material can clearly be interpreted as internal Franz-Keldysh effect. The optical absorption at energies well below the gap of the unmodulated semiconductor is only one of the striking properties of this novel superlattice in GaAs first proposed by Döhler (7). A more extensive study of the effect of reduced effective bandgap and of the strongly anisotropic transport properties in these periodic p-n doping multilayer structures in GaAs is underway in this laboratory and detailed results are referred to in a subsequent paper (37).

Conclusion

The high degree of growth control during molecular beam epitaxy normal to the surface on an atomic scale, which was first established for MBE growth of GaAs/$Al_xGa_{1-x}As$ superlattices (38), has now been extended to the growth of a novel man-made superlattice in GaAs, also called "nipi" structure, consisting of a periodic sequence of ultrathin p- and n-type GaAs layers, possibly with intrinsic (i-) layers in between. The most stringent requirements for a successful growth of these periodic p-n multilayer structures are the superior electrical and optical quality of the individual p- and n-type GaAs layers composing the structures.

Using Be as acceptor and Si as donor impurities, respectively, for MBE grown GaAs, an excellent uniformity of doping concentration and high majority-carrier mobilities have been obtained. Low temperature photoluminescence measurements on GaAs:Be and GaAs:Si layers yielded highly resolved PL response with excitonic fine structure, thus attesting superior minority-carrier properties of these intentionally Be-doped MBE GaAs films never reported before. The measured periodic doping profiles normal to the surface in p-type GaAs:Be and in n-type GaAs:Si presented here exhibited peak to background free-carrier ratios which were a factor of two higher than those reported earlier. These results made feasible the MBE growth of extremely abrupt carrier profiles for p-n junctions in (Be, Si)-doped GaAs with a width of only 200Å necessary to change the carrier concentration from p-type 1×10^{17} cm^{-3} to the same level n-type on the other side of the junction.

Based on this encouraging outcome, the MBE technique has then been further exploited to the successful growth of highly sophisticated periodic p-n doping multilayer structures in GaAs. The doping levels of the individual layers and the periodicity of these nipi structures have been varied over wide ranges according to the theoretical calculations of Döhler *et al.* (7, 8), in order to modify the resulting effective bandgap of the crystals.

Finally, the key features of this novel superlattice in GaAs, which are also evident for device applications, may be summarized as follows: (i) the effective bandgap E_g^{eff} in nipi crystals can have any value between the energy gap E_g^{GaAs} of the unmodulated bulk and zero, depending on the choice of layer thickness and doping concentration; (ii) nipi crystals are extremely anisotropic with respect to their transport properties; (iii) electrons and holes are spatially separated from each other which prevents direct electron hole recombination. As a consequence the carrier concentration and the effective bandgap of nipi crystals may be modulated within wide limits by external bias or absorption of light (7, 8).

Interfacial Arsenic Growth in Anodic Oxide/GaAs Structures

G. P. Schwartz,* G. J. Gualtieri, J. E. Griffiths, and B. Schwartz*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Raman scattering has been employed to monitor both the structure and growth of elemental arsenic deposits thermally generated during the interfacial reaction which occurs between GaAs and the As_2O_3 component of its electrochemically anodized oxide. The band shape of the Raman scattering intensity is consistent with the formation of amorphous arsenic during the initial stages of reaction within the temperature interval 300°-366°C. The time and temperature dependence of a-arsenic growth can be approximated by

$$N(t,T) = 10^{28} \cdot t \cdot \exp(-2.3 \times 10^4/T) \text{ atoms/cm}^2$$

in the region where the Raman signal is linearly increasing with time and $300°C \leq T \leq 366°C$. Intensity variations due to multilayer interference were not observed during growth and have been neglected. The data suggest that more than one structural form of a-arsenic may evolve during the course of reaction.

Recent device-related applications utilizing native oxides on GaAs generated via thermal (1), anodic (2), or plasma (3) techniques suggest that progress is being made in circumventing some of the obstacles previously encountered with such films. Nevertheless, the electrical and chemical properties of these films still present

* Electrochemical Society Active Member.

Key words: Raman scattering, oxides, anodization.

a major obstacle to applications in device technology. Recent studies of the equilibrium Ga-As-O phase diagram (4) have disclosed that the stable interfacial phase should consist of Ga_2O_3 and elemental As. As a result, native oxides containing As_2O_3 are subject to an interfacial reaction given by $As_2O_3 + 2GaAs \rightarrow Ga_2O_3 + 4As$ at sufficiently high temperatures where the diffusion and reaction barriers can be overcome. Experimental confirmation of this reaction has already been obtained in electrochemically anodized (5) plasma (rf and d.c.) oxidized (6), and thermally oxidized (7, 8) films.

Although the role interfacial arsenic deposits play in affecting the electrical properties at the oxide/substrate interface remains open to question, it seems reasonably certain from a device viewpoint that such compositional variations are an undersirable complication. Since crystalline arsenic is a semi-metal and the amorphous form is a small bandgap (1.1 eV) semiconductor, it was important to know more about its structure in the interfacial region. Therefore, the present study was undertaken to monitor both the growth rate and the structural form of elemenal arsenic produced during the initial stages of interfacial reaction.

Experimental

Sample preparation and heating cell.—Bromine-methanol-polished Sn-doped ($n \sim 1\text{-}2 \times 10^{18}$ cm^{-3}) GaAs wafers of (100) orientation were electrochemically anodized at constant current (1 mA/cm^2) up to 50V in a saturated aqueous solution of As_2O_3 buffered to pH 4.0 with dibasic ammonium phosphate. The resulting oxide films were approximately 1000Å thick and consisted of nearly equimolar mixtures of As_2O_3 and Ga_2O_3.

The heating cell (Fig. 1) consisted of a ceramic insulation sleeve surrounding a beveled copper block into which a 400W cartridge heater was press fitted. Incident light entered the cell through a small hole and Raman scattered radiation passed through the quartz window to the collection optics. The cell was purged with argon in order to eliminate Raman scattering from the rotational bands of O_2 and N_2.

Anodized samples were mounted onto the beveled face of the copper block and secured with two Be-Cu spring clips. A Chromel-Alumel thermocouple was also screwed down onto the beveled surface. Separate oil bath/thermometer calibrations of this thermocouple were found to agree within ±3°C with tabulated (9) emf values over the range 20°-300°C.

Raman spectra.—Spectra were collected on an Instruments S.A. Raman spectrometer (Model HG-2S) which was coupled to standard pulse counting electronics with analog recorder readout. Laser excitation at 5145Å was polarized in the plane of incidence and struck the sample surfaces at Brewster's angle. The polarization of the Raman scattered light was not analyzed. The spectra slit width, count rate meter time constant, laser power, and monochromator scan rate were held constant at values of 8 cm^{-1}, 10 sec, 700 mW, and 10 cm^{-1}/min, respectively. Analog spectra were subsequently digitized at 2 cm^{-1} intervals. Spectral intensities for the as-anodized (prior to thermal reaction) wafers were normalized to the peak intensity of the GaAs LO phonon at 291 cm^{-1}.

Methodology.—An "interrupted reaction" scheme was employed which involved sequential steps of sample heating, cooling to room temperature, and data acquisition. The samples were never physically moved during repetitive sequences of these steps in order to avoid realignment errors. In addition, the laser excitation was kept off the sample during the heating and cooling parts of the cycle since arsenic growth and its crystallization could potentially be affected by the local heating associated with absorption of laser light during continuous monitoring of the reaction. At room temperature, the reaction rates were sufficiently slow that the local heating created during data acquisition was not observed to effect any changes. Further obstacles to making measurements at elevated temperatures during the reaction stemmed from background cell fluorescence and strongly enhanced plasma line scattering from the cell walls.

The adoption of an "interrupted reaction" sequence involves cumulative errors in defining the reaction time. With the small heat capacity of the copper block however, we were able to obtain the desired reaction temperature within 3-4 min. After a specified reaction time, the cartridge heater power was abruptly discontinued. The total cooldown times depended on the initial cell temperature, but in all cases the copper block had dropped to 300°C or less within the first 3 min following power discontinuation. Compared to a typical reaction time scale of hours, the error introduced by the response time of the heating block was considered to be acceptably small.

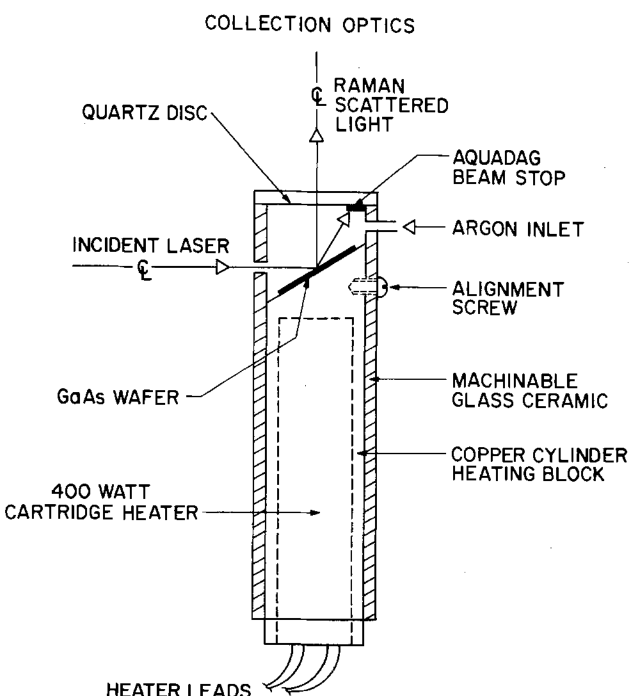

Fig. 1. Top view of the heating cell

Results and Discussion

Spectral data and structural aspects.—All data were initially acquired in analog form under fixed instrumental conditions (see "Experimental" for details). A typical analog spectrum for as-anodized (100) GaAs wafer is shown in Fig. 2. In addition to the prominent first-order longitudinal and transverse optic mode (LO, TO) scattering from GaAs, weaker two-phonon

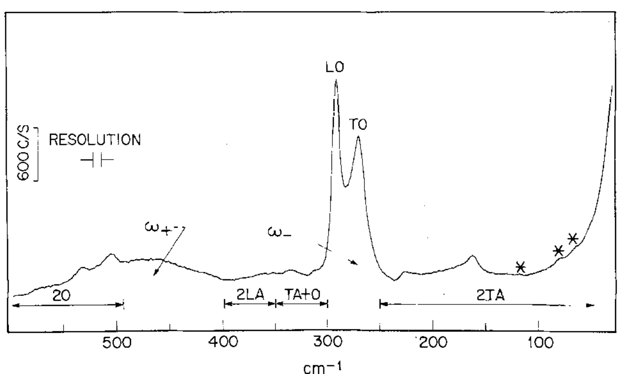

Fig. 2. Analog Raman spectrum of an as-anodized GaAs (100) wafer prior to thermal treatment. Data taken with 8 cm^{-1} slits at a scan rate of 10 cm^{-1}/min with a 10 sec time constant. Power at the sample was approximately 400 mW; asterisks denote laser plasma lines.

features associated with the substrate are also observed. The two-phonon bands (10) are designated as overtone (2O), longitudinal and transverse acoustic (LA, TA), and combination (TA + O) modes where (O) refers to the optic modes. Coupled LO-plasmon (11, 12) modes are denoted by ω_+ and ω_-. Asterisks identify laser plasma lines. No bands explicitly associated with the amorphous oxide (13) film (~1000Å) are readily apparent. The Raman spectrum of amorphous arsenic (14, 15) is dominated by a relatively featureless broad band which extends from 180 to 280 cm^{-1}. Rhombohedral arsenic shows Raman peaks (16, 17) at 195 and 257 cm^{-1}, whereas orthorhomic arsenic (18) has its most intense modes located at ~222 and 254 cm^{-1}.

In order to separate the arsenic signal from the GaAs substrate background, the following analysis procedure was employed. The analog spectra were digitized at 2 cm^{-1} intervals and the Rayleigh wing and background components were fitted to a damped Lorentzian function plus a constant term. The low frequency plasma lines were removed in the initial digitization in order to avoid distorting the fit to the Rayleigh wing. The digitized version of the analog spectrum seen in Fig. 2 is shown in Fig. 3 along with the Rayleigh wing and background (solid line). Subtraction of the latter yields the digital data of Fig. 4. The substrate LO, TO, and ω_- modes were then fitted

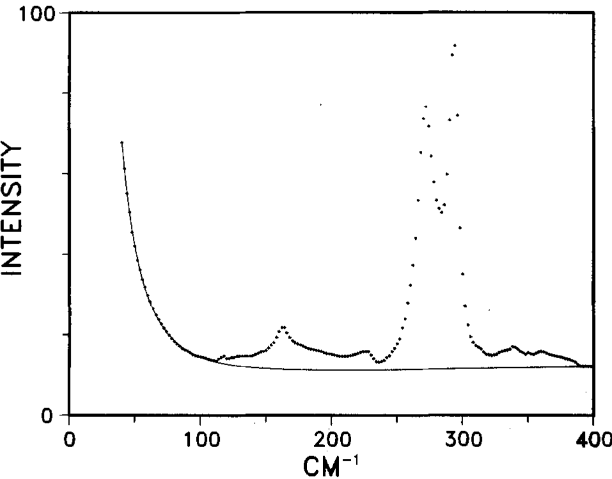

Fig. 3. Digitized (2 cm^{-1} intervals) version of Fig. 2 after removal of the 66 and 77 cm^{-1} plasma lines. The solid curve represents the nonlinear least-squares fit used to remove the Rayleigh wing and background between 30 and 400 cm^{-1}.

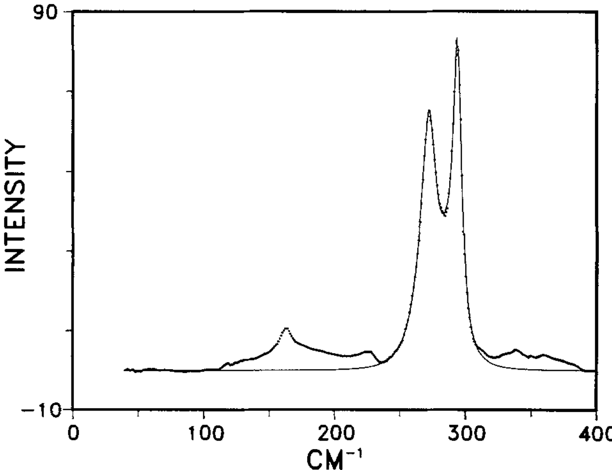

Fig. 4. Digital spectrum with the Rayleigh wing and background removed. The number of data points have been doubled using linear interpolation. The solid curve is the fit to the substrate LO and TO mode structure.

by an analytical function consisting of three damped Lorentzian using a nonlinear least squares routine. Prior to the fit, a linear interpolation routine was exercised in order to double the number of data points. This aided the fit to the wing which extends into the phonon combination (TA + O) mode region beyond ~300 cm^{-1}. Removal of the Rayleigh wing, constant background, and LO, TO, and ω_- structures yielded the shape of the substrate two-phonon spectrum for the as-anodized wafer. This is shown in Fig. 5. The small oscillations observed between 240-280 cm^{-1} originate from curve-fitting errors and were subsequently smoothed. The resulting spectrum represents an intrinsic structured background due to the substrate (Fig. 6A). Figure 6(B-D) shows the resulting spectra in the 100-280 cm^{-1} region of an anodized GaAs sample after heating at 330°C for (B) 7.5, (C) 20, and (D) 29 hr respectively. These spectra represent the two phonon background of 6(A) plus the Raman scattering from any amorphous arsenic formed during heating.

Spectra for the arsenic generated during the reactions were obtained after subtraction of the as-anodized substrate two-phonon structure. Representative data for reaction at 330°C are presened in Fig. 7. A spectrum for bulk amorphous arsenic grown by thermally decomposing GaAs and condensing the evolved arsenic onto a 77 K coldfinger is also included (bottom) for comparison.

The systematic occurrence of a relatively sharp peak imposed on all the a-arsenic spectra (Fig. 7, A, B, C) is noted at ~233 cm^{-1}. The intensity of this feature is essentially independent of either the reaction time or temperature. Its origin is believed to be associated with a slight broadening and shift of the substrate two-phonon background which accompanies the heating process and is not properly accounted for by using the as-anodized (unheated) spectra for base line subtraction.

A second peak at ~200 cm^{-1} is also obvious on the a-arsenic band shape after 29 hr of reaction at 330°C (Fig. 7C). The development of this feature in the reacted sample data was observed to be time and temperature dependent and was not observed in the 300 and 315°C data sets. Raman scattering data on a-arsenic by Lannin (14) and Nemanich *et al.* (15) clearly evidence a peak in this region in their samples which were prepared by prolytic decomposition of arsine. Lannin's (14) data for sputter deposited films do not show it, nor do ours for deposits prepared via thermal decomposition of GaAs (see Fig. 8A).

An unambiguous explanation of the evolution of the 200 cm^{-1} feature observed in Fig. 7C is complicated by at least two distinct types of structural considerations. The first of these deals with the implicit short-range order present in amorphous arsenic. Breitling (19) has

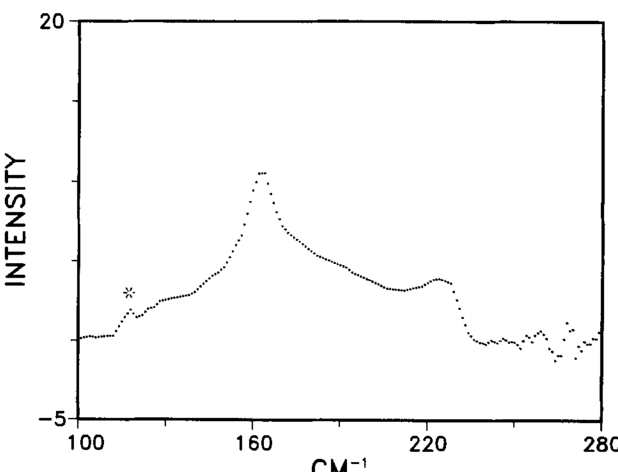

Fig. 5. Structure of the substrate two-phonon background in the region between 100 to 280 cm^{-1}. The asterisk denotes a laser plasma line.

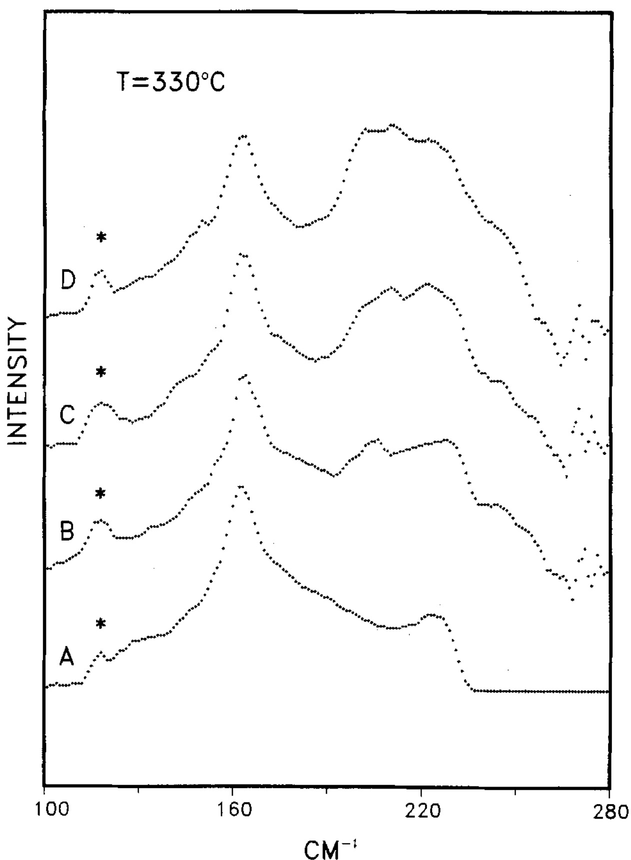

Fig. 6. Raman scattering intensity in the 100-280 cm^{-1} region for interfacial reaction at 330°C. Reactions times in hours are (A) 0, (B) 7.5, (C) 20.0, and (D) 29.0. Oscillations in (A) between 235 and 280 cm^{-1} have been smoothed. Asterisks denote laser plasma lines.

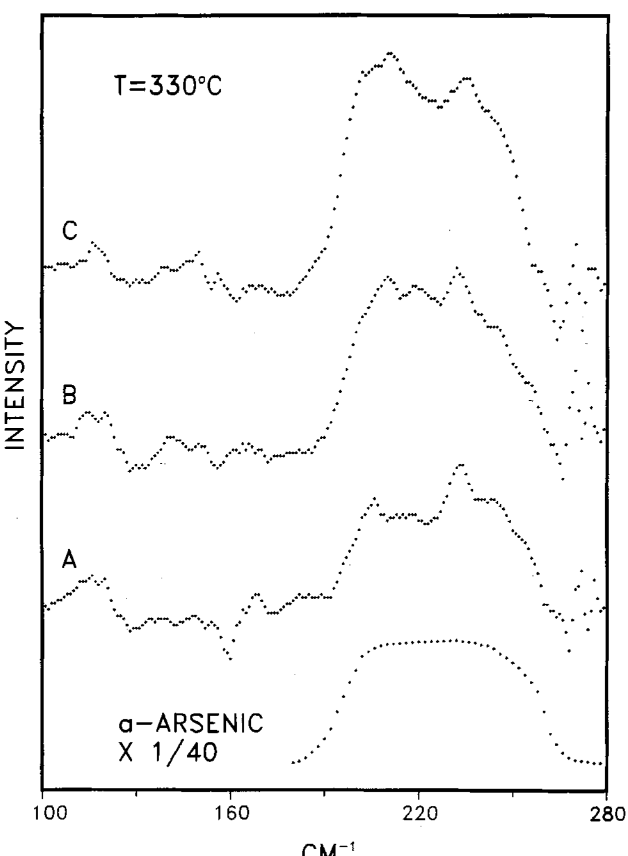

Fig. 7. The net Raman spectra for 330°C reaction after times of (A) 7.5, (B) 20.0, and (C) 29.0 hr following removal of the substrate two-phonon structure. The bottom panel shows the band contour obtained from a bulk sample of a-arsenic using a simple linear background subtraction as shown in Fig. 8.

observed that the radial distribution functions obtained from evaporated and precipitated films of a-arsenic evidence distinctly different values for the shortest interlayer separations of 3.66 and 4.05Å, respectively. The growth of the 200 cm^{-1} peak could be indicative of a transformation from one distinct interlayer separation to the other. Alternatively, crystallization may be occurring to yield microcrystallites whose dimensions are small compared to the wavelength of the phonon modes. This process is expected to lead to a breakdown of the momentum selection rules in Raman scattering (20) and modify the bulk crystalline band shapes. Documentation on such phenomena on well-defined samples is quite limited. The work of Keramidas and White (21) on ZrO_2 suggests that crystallites of very small dimensions (~ 30Å) can be detected by Raman scattering in the form of bands significantly broader than those expected for macroscopic crystals. As crystallization progresses, the bands sharpen and their peak intensities increase (21). More recently, Nemanich *et al.* (22, 23) reported Raman scattering from thin films (50-60Å) of polycrystalline Te and Ti. Broadening of the E_g mode of hexagonal Ti was observed. In the Te films, both the A_1 and E-type bands were slightly broadened compared with those observed for bulk material. Thus, crystallites of Ti and Te in which at least one dimension is not greater than 60Å give rise to Raman spectra characteristic of macroscopic crystals. For each situation described above, the particles are not isolated and strong intermolecular interactions may produce results that differ significantly from those expected for systems of small structurally and chemically separated scatterers. Ruppin (24) has reported that, for such systems, well-defined surface modes may be detectable and in fact the intensity of such modes are particle size dependent.

Returning to the case of arsenic, the growth of a broad band near 200 cm^{-1} during annealing without observing the parallel growth of an A_1-type band of crystalline arsenic suggests that the changes occurring do not involve a crystallization process. Instead, a change in the interlayer separation is favored. To test this interpretation, bulk films of amorphous arsenic were examined. The as-deposited film (Fig. 8A) was essentially featureless except for the laser plasma line artifact at 266 cm^{-1}. Annealing this sample at a copper block temperature of 220°C for 30 and 60 min yielded the spectra shown in Fig. 8B and 8C, respectively. One notes the growth of the 200 cm^{-1} spectral feature with essentially no evidence for the development of a corresponding band near 257 cm^{-1}. On the contrary, there appears to be a systematic decrease in intensity in the higher frequency region of the band envelope with increasing annealing time. Although our conclusions at the present time are quite speculative, we feel that the bulk of the evidence favors a structural interlayer separation change rather than crystalline size effects.

Reaction rates for interfacial arsenic formation.—To obtain an estimate of the interfacial arsenic growth rate, graphical integration of the a-arsenic intensity was performed for each sample and plotted *vs.* reaction time. The results are seen in Fig. 9. In extracting the integrated intensities the following two constraints were employed: (*i*) the a-arsenic band shape was assumed to be featureless, and (*ii*) the integration limits were taken at 180 and 270 cm^{-1}. The error introduced by neglecting the presence of the 200 cm^{-1} feature was approximately 10-15% in the worst case.

The heterogeneous nature of the interfacial reaction is further complicated by the presence of both diffusion and reaction barriers. In the following description of the interfacial a-arsenic growth we will assume that the time and temperature dependence are separable and of the empirical form

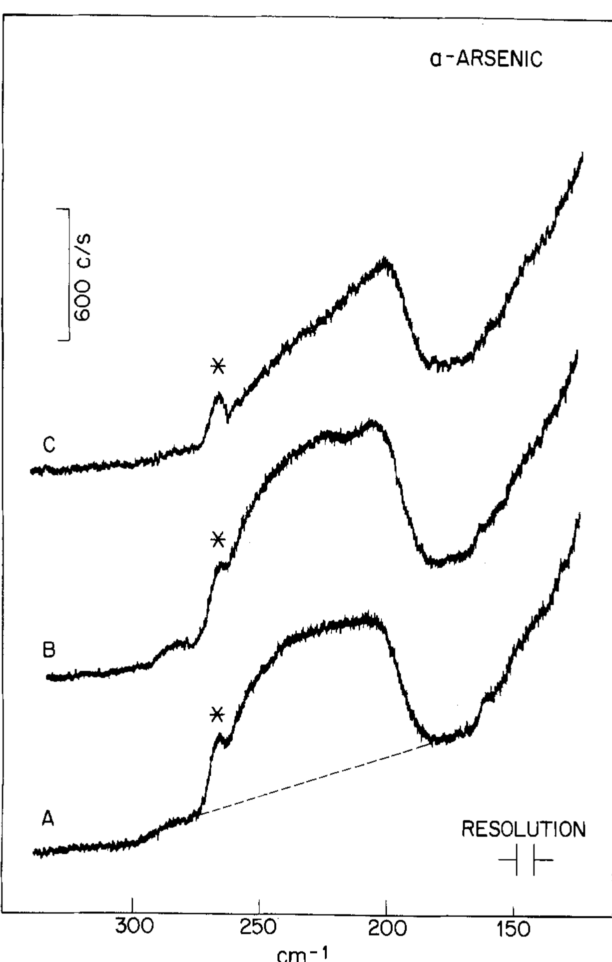

Fig. 8. Spectral lineshape changes observed in bulk a-arsenic after thermal annealing at 220°C. (A) as-deposited, (B) 30 min annealing, and (C) 60 min annealing.

$$N_{As}(t, T) = N_0 \cdot f(t) \cdot \exp(-E/kT) \quad [1]$$

An attempt was made to obtain a nonlinear least-squares fit to the functional form $N_0 \cdot t^m \cdot \exp(-E/kT)$, but the fits obtained via this procedure always displayed a high degree of correlation between the parameters N_0, m, and E. Consequently we have chosen to utilize only the initial regions of the growth curves in which $f(t)$ is well described as a linear function of time. Assuming the separability of the time and temperature variables appropriate to Eq. [1], one obtains the effective barrier energy E from the slope of a plot of $\log_e$ (rate) *vs.* $1/T$, where the rate is the time derivative of the growth curves presented in Fig. 9. This plot is shown in Fig. 10 along with error bars constructed from estimated errors in the integrated intensities and reaction temperatures. The maximum possible deviations in slope constrained by the requirement that the lines intersect the error bars of all data points were also constructed in order to obtain upper and lower limits to the barrier energy E. In the limited temperature interval between 300°-366°C, we obtain a barrier energy $E = 46 \pm 9/14$ kcal per mole of arsenic atoms. Extension of the interfacial reaction data to higher temperatures is complicated by the onset of rapid crystallization and concomitant change in arsenic lineshapes. At lower temperatures the interfacial reaction is prohibitively slow.

In order to complete the description of interfacial arsenic growth via Eq. [1], it is necessary to convert the integrated intensities into some measure of equivalent thickness of amorphous arsenic. An estimate of this thickness is provided by monitoring the progressive attenuation of the GaAs LO intensity by an absorbing layer of thickness t and absorption coefficient α. Two implicit assumptions limit the accuracy of this technique. First of all, the a-arsenic layer is assumed to be continuous and of uniform thickness with an absorption coefficient α equal to that found in bulk (25) amorphous films. Secondly, reflectivity losses incurred at the oxide/a-arsenic interface are difficult to assess and have been neglected. With the constraints of these assumptions, analysis of the data suggests that a uniform 8Å layer is equivalent to ~25 intensity units in Fig. 9. The uncertainty in this conversion is high however; we conservatively estimate that the absolute value of the 8Å figure may be in error by 100%.

Assuming a density of 4.7 g/cm^3 for a-arsenic, an 8Å × 1 cm^2 volume would contain ~3×10^{15} arsenic atoms. Since the laser beam spot size is not accurately known, we have chosen to express $N_{As}(t, T)$ in units of atoms/cm^2 implying a finite depth of accrued arsenic. Within the temperature range 300°-366°C and for times sufficiently short that only a-arsenic is observed, we obtain an interfacial growth function given by

$$N_{As}(t, T) = 10^{28} \cdot t \cdot \exp(-2.3 \times 10^4/T) \text{ atoms/cm}^2 \quad [2]$$

It should also be noted that this growth function is

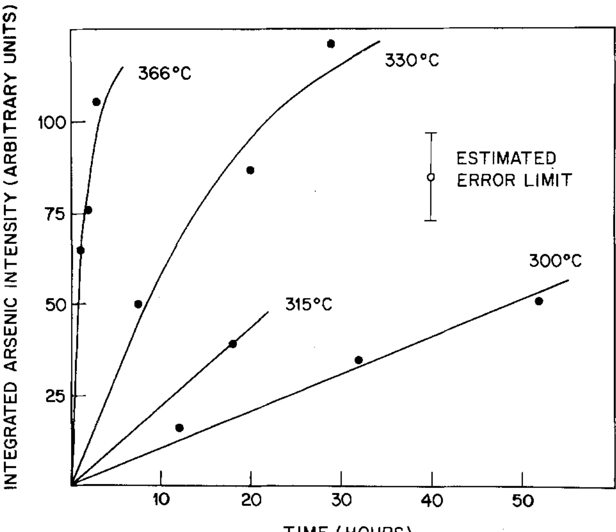

Fig. 9. Plot of the integrated a-arsenic intensity as a function of temperature and time.

probably specific to anodic oxide/GaAs interfaces and may be different for films produced by rf or d-c plasma anodization.

Summary

Structural and growth rate aspects of interfacial arsenic accumulation have been studied in thermally treated anodic films on GaAs. The initial stages of the interfacial reaction between As_2O_3 and the substrate yield deposits of amorphous arsenic in the reaction temperature range 300°-366°C. There is some evidence that more than one amorphous structure is observed. The growth of this amorphous arsenic is characterized by the equation

$$N_{As}(t, T) = 10^{28} \cdot t \cdot \exp(-2.3 \times 10^4/T) \text{ atoms/cm}^2$$

where t is in seconds and T in degrees Kelvin.

An AES/XPS Study of the Chemistry of Palladium on Hydrogenated Amorphous Silicon Schottky Barrier Solar Cells

J. H. Thomas III* and D. E. Carlson

RCA Laboratories, David Sarnoff Research Center, Princeton, New Jersey 08540

ABSTRACT

Thin layers of palladium (~100Å thick) on hydrogenated amorphous silicon have been used as diodes and photovoltaic devices (solar cells). Auger electron spectroscopy (AES) and x-ray photoelectron spectroscopy (XPS) in conjunction with ion-milling were used to characterize the interface region. At the interface, a thin oxide layer is observed along with possible palladium silicides. Palladium and palladium silicides extend well into the silicon substrate. Palladium silicide is due in part to ion-mixing. Heating device structures in D_2O caused considerable electrical degradation. Data indicate that the degradation is due to oxide formation at the Pd/a-Si:H interface.

Both Pt and Pd contacts have been used to form Schottky barriers on hydrogenated amorphous silicon (a-Si:H) (1). A recent study has shown that Pt/a-Si:H Schottky barriers exhibit degradation when exposed to water vapor (2). In the present investigation Auger electron and x-ray photoelectron spectroscopy were used to study Pd/a-Si:H junctions as formed and also after heat-treatments at 80°C for three weeks either in vacuum or in D_2O vapor. The junctions stored at 80°C in D_2O vapor exhibited significant degradation compared to unaged junctions or those heat-treated in vacuum (1, 3). The goal of this study was to determine the junction chemistry and to see if any measurable difference is observed for samples treated in different ambients.

* Electrochemical Society Active Member.
Key words: ESCA, Auger, Schottky diodes, interfaces.

Experimental

Three samples of palladium (~100Å thick) evaporated on glow-discharge-deposited a-Si:H were fabricated. The a-Si:H was deposited in a d-c proximity glow discharge in SiH_4 at a substrate temperature of ~300°C. The discharge pressure was ~0.7 Torr and the

flow rate was ~90 sccm. The hydrogen concentration in the a-SiH was ~20 atomic percent (a/o) (3). One device was aged at 80°C in a rough vacuum of ~10 milliTorr. A second device was stored at 80°C in saturated D_2O vapor at approximately atmospheric pressure. The third device was an unaged control sample. The samples were subsequently electrically tested and subjected to surface analysis.

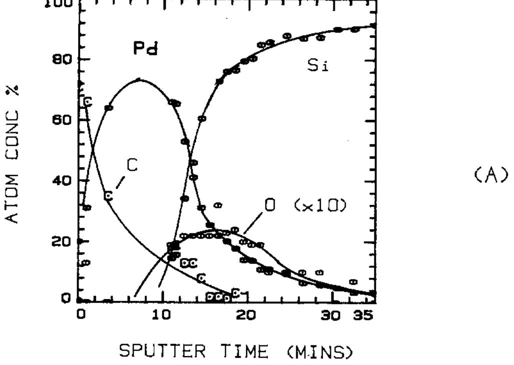
Elemental/chemical analysis was performed in a Physical Electronics Industries ESCA/Auger system. Auger electron spectra were excited with an electron beam energy of 3 keV at 10 μA. A 3V peak-to-peak modulation was applied to the double pass cylindrical mirror analyzer (DPCMA) operating in a nonretarding mode. The narrow slit was used in obtaining the Auger spectra. X-ray photoelectron (or ESCA) spectra were excited with an achromatic magnesium Kα x-ray source operated at 10 keV and 30 mA (300W). The DPCMA was operated in a retarding potential mode with the large slit. Survey and high resolution spectra were obtained at pass energies of 200 and 25 eV, respectively. Photoelectron pulse currents from the electron multiplier were detected and amplified with a Princeton Applied Research Model 1120 amplifier/discriminator. Data acquisition, display, and replotting were accomplished through the use of a computer-controlled data-acquisition system based on a Hewlett-Packard Model 1000 minicomputer and appropriate software.[1] Binding energies were internally referenced to the silicon 2p core photoelectron line due to elemental silicon at 99.40 eV (4). Curve deconvolution was accomplished with a gaussian curve-fitting program. Depth profiling for AES and XPS measurements was done with a Physical Electronics Industries ion gun (Model 20-045) operated at 1 keV at 20 mA, defocused slightly, in 5×10^{-5} Torr of xenon. The sputter rate for SiO_2 was ~2 Å/min. Xenon was used because of its small penetration depth (range) at 1 keV (~7Å) (5).

AES Results

The three samples were depth profiled. Auger spectra were measured in sputter time increments of ~2 min. The palladium MNN, carbon KLL, oxygen KLL, and silicon LVV Auger lines were tracked through the palladium film and well into the amorphous silicon substrate. Electrons emitted in the energy range below 500 eV, which includes all the transitions measured, have escape depths of less than 10Å (6). Elemental concentrations were obtained from the peak-to-peak derivative signal amplitudes using the sensitivity factors from Davis *et al.* (7). The concentrations at each point were normalized to 100%. The elemental depth profile for the unaged sample was identical to the profile of the 80°C vacuum-aged sample and is not shown for brevity.

Figure 1A and B show the depth profiles for the vacuum- and D_2O-aged Pd/a-Si:H samples. A significant amount of carbon is observed in the evaporated palladium layers of the vacuum-aged sample. Carbon on the immediate surface is contamination, probably from the ambient of the vacuum oven. Oxygen is observed at the Pd-Si interface of both samples. This is partly a native oxide that grew on the a-Si:H surface prior to metallization. The peak oxygen concentration in the vacuum-aged sample (~2 a/o) is less than in the D_2O-aged sample (~10 a/o). Palladium is observed in a-Si:H to a depth of greater than 50Å in both samples. The concentration is estimated as 4 a/o at this depth, in agreement with SIMS studies of similar films (2). The interface region is diffused in the three samples which may be in part due to ion mixing effects and crater formation during sputtering. An accurate measure of the interface width cannot be obtained from these data since the sputter rate of palladium is ~5× that of silicon. Qualitatively, the interface region of the three samples is similar.

[1] The basic data acquisition system was designed by J. R. Woolston and S. H. McFarlane.



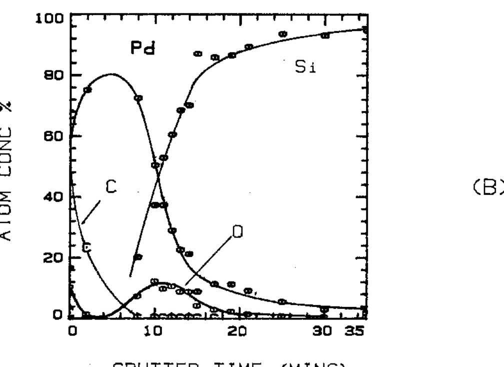


Fig. 1. (A) AES depth profile for the vacuum-aged Pd/a-Si:H device (80°C/3 weeks). (B) AES depth profile for the D_2O-aged Pd/a-Si:H device (80°C/3 weeks). The sputter rate of Si ≅ 2 Å/min and Pd ≅ 10 Å/min. Surface O on (A) is ~10% (not shown).

XPS Results

Survey spectra (Fig. 2) were measured at most of the sputter times for which the Auger depth profile was measured. Elemental concentrations as a function of sputter time (depth) were calculated from the core photoelectron peak amplitudes and theoretical photoionization cross sections for Mg Kα radiation (1253.6 eV) (8, 9). The general features of the AES depth profile are also observed in the XPS depth profiles for palladium, carbon, and silicon. The elemental concentration in each sample is quantitatively close to the concentration computed in the Auger depth profile and will be used later in computing bond concentrations.

High resolution spectra of the palladium $3d_{3/2,5/2}$ and silicon 2p photoelectron lines were obtained at a few points near the surface and in the interfacial region. Figure 2 shows a typical survey spectrum with insets of the Pd $3d_{3/2,5/2}$ and Si 2p lines. The high resolution spectra were obtained in an MCS (multichannel scaling) mode: 1 second/channel, and 30 scans. The secondary electron background was subtracted from the Si 2p and Pd 3d spectra, using Shirley's iterative method (10).

Structure, as indicated by the arrows, is observed on the high binding energy side of the Pd 3d and Si 2p lines (shown in the insets). The O 1s line is obscured by the palladium $3p_{3/2}$ line. An approximation of the oxygen line amplitude can be obtained by subtracting the estimated $3p_{3/2}$ amplitude from the total measured amplitude at 530 eV since the ratio of the Pd $3p_{1/2}$ to $3p_{3/2}$ intensity is constant. Separation of the Pd $3p_{3/2}$ and O $1s_{1/2}$ using the gaussian curve-fitting procedure was not attempted.

The Pd 3d and Si 2p lines were fitted with gaussian curves at sputter times of 3, 10, 13, 21, 25, and 30 min. The silicon 2p spectrum was fitted with a minimum of three peaks to adequately fit the spectra. Elemental silicon referenced to the Au $4f_{7/2}$ line occurs at 99.4 eV with an FWHM of 1.45 eV in this XPS system. Therefore, the binding energy scale has been shifted slightly

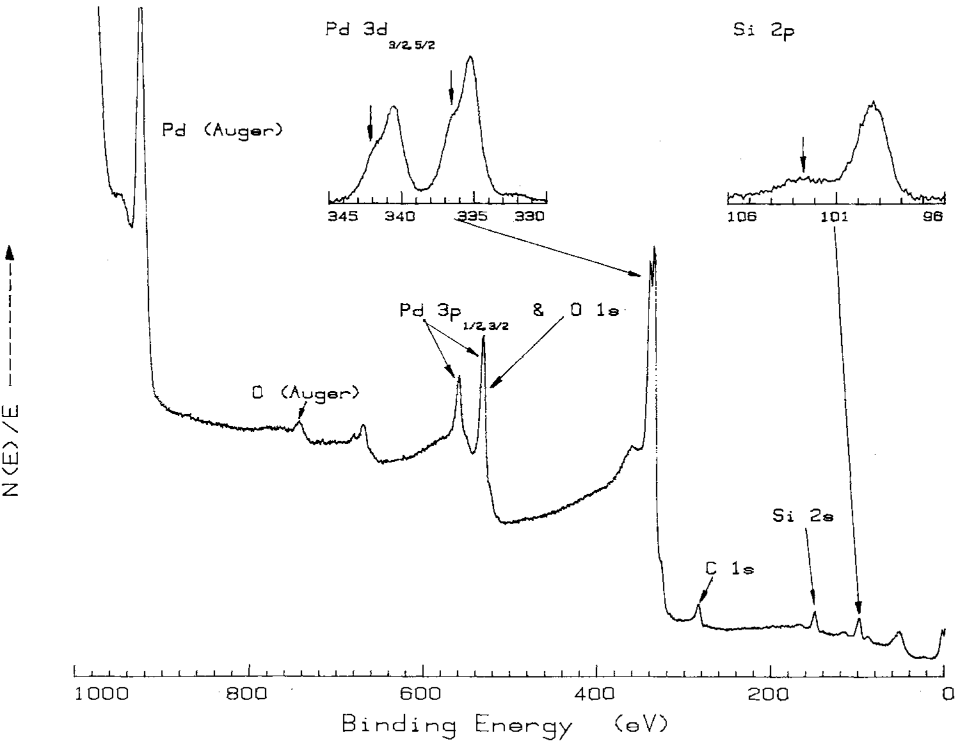

Fig. 2. Survey spectrum for vacuum-aged Pd/a-Si:H sputtered 11 min.

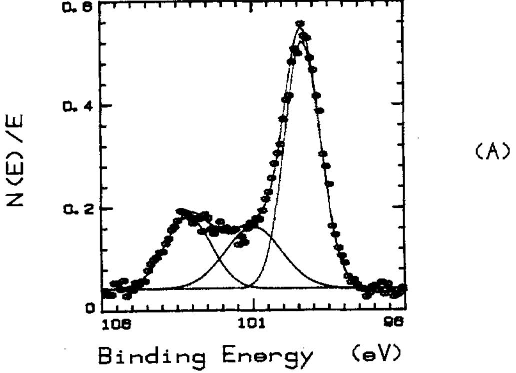
(±0.1 eV) to account for minor instrumental changes. The other two gaussian peaks are centered at 103.0 ± 0.1 eV and 100.6 ± 0.2 eV and have FWHM's of 1.8 and 2.2 eV, respectively. A typical gaussian fitted spectrum is shown in Fig. 3A for silicon.

The gaussian fit to the Pd 3d lines was poor due to line asymmetry (11). This asymmetry which is about 10% of the 3d line area requires an additional gaussian peak on the high energy side of the $3d_{3/2,5/2}$ lines which can be subsequently "subtracted" from the spectrum. The Pd $3d_{5/2}$ line consists of two gaussian components at 335.4 ± 0.1 eV and 336.8 ± 0.1 eV which vary in amplitude with sputter time. Their full widths at half maximum (FWHM) are 1.35 and 1.5 ± 0.05 eV, respectively. A typical gaussian fitted spectrum is shown in Fig. 3B.



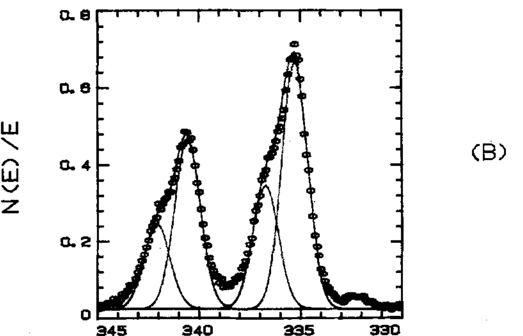


Fig. 3. (A) High resolution spectrum of the Si 2p region for the D_2O-aged sample sputtered 11 min. The gaussian fitted components are shown. (B) The same as Fig. 3(A) for the Pd $3d_{3/2,5/2}$ region.

The vacuum-aged sample is not significantly different from the D_2O-aged sample. However, the contribution of the 100.6 and 103.0 eV peaks relative to the 99.4 eV peak are somewhat greater in the D_2O-aged sample. Figures 4A and 4B show the Pd $3d_{3/2,5/2}$ and Si 2p spectra for the vacuum-aged samples as a function of sputter time (or depth). As the sputter time is increased, the contribution of the 103.0 eV peak decreases while elemental silicon increases. The contribution of the Pd 336.8 eV peak, relative to the 335.4 eV peak, increases with depth into the silicon substrate. Only a few of the Si and Pd spectra were plotted to demonstrate the trends observed. All the spectra plotted are shown with the secondary electron background removed. The vertical scale ($N(E)/E$) of the silicon spectra is 1/4 that of the palladium.

Interpretation of XPS Peak Positions

The palladium $3d_{5/2}$ consists of two component gaussian peaks, 335.4 and 336.8 eV. A similar set of peaks are observed at the 3/2 spin doublet but will not be discussed. The peak at 335.4 eV is due to elemental palladium (Pd^E) and is in good agreement with Barr's results (12). The peak at 336.8 eV is close to 336.9 eV for Pd in PdO (12). However, from the AES results, <10 a/o of oxygen is present in the interface region. At the interface, (~10 min sputter time) both samples consist of about 50 a/o Pd of which equal amounts are at 335.4 and 336.8 eV. Therefore, the 336.8 eV peak cannot be attributed only to PdO. Some valence effects are observed in UPS studies of PdH_x (13). However, it is unlikely that the 3d state of Pd would be shifted by 1.4 eV due to the presence of hydrogen bonding. Therefore, we can conclude that the 336.8 eV peak is due to Pd in silicide form (Pd^B) and PdO.

The silicon 2p spectrum is resolved into three component gaussian peaks at 99.4, 100.6, and 103.0 eV. The 99.4 eV peak has been attributed to elemental silicon (Si^E) (4, 14). The 100.6 eV peak and a portion of the 103.0 eV peak appear to be associated with silicon in

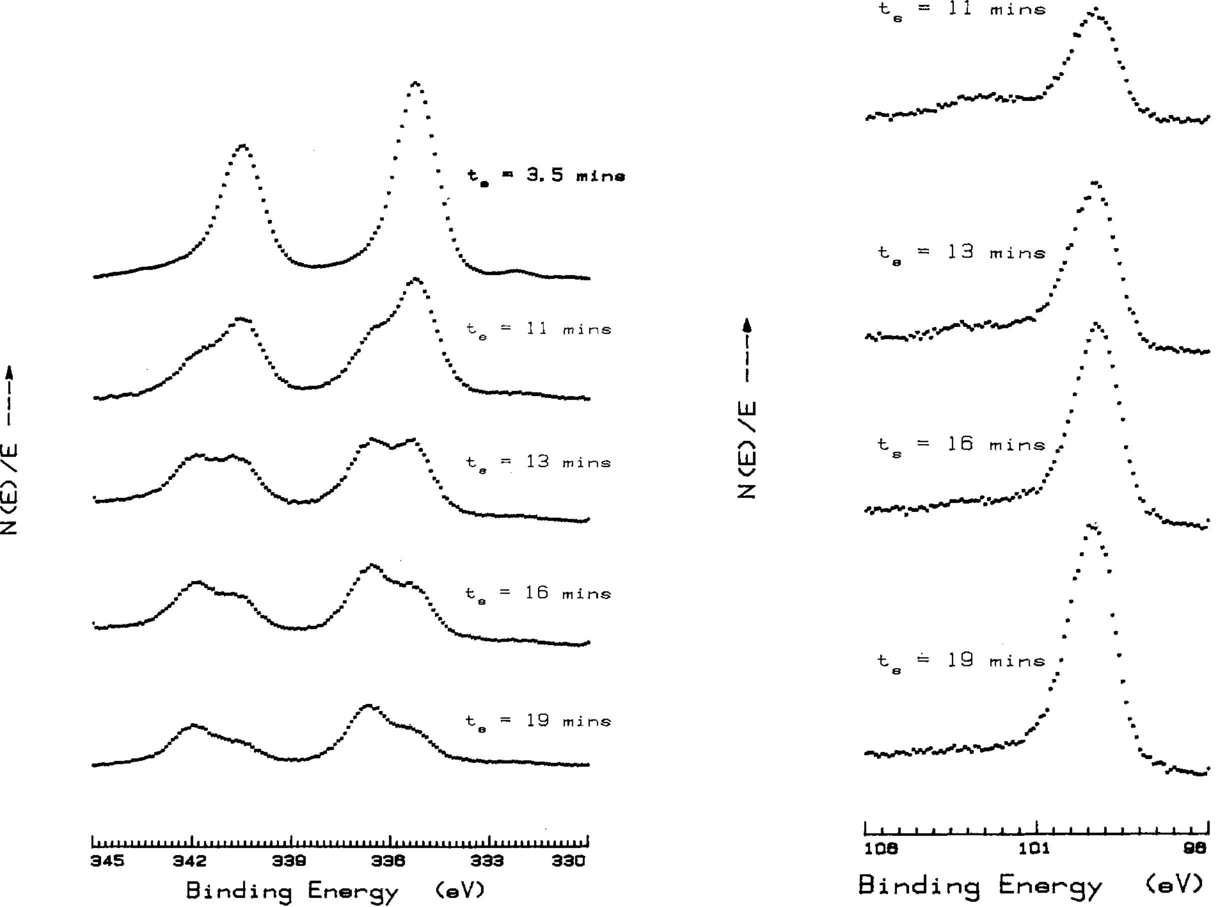

Fig. 4. (A, left) Palladium $3d_{3/2,5/2}$ spectrum as a function of sputter time for the vacuum-aged sample. (B, right) Silicon 2p spectrum as a function of sputter time for the vacuum-aged sample. The sputter rate is 2 Å/min Si and 10 Å/min Pd.

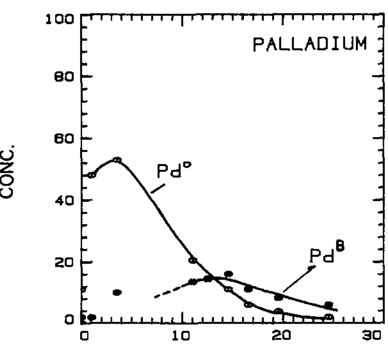
silicide form (15). Since oxygen is observed at the interface, these peaks are also related to nonstoichiometric silicon oxides which correspond to Si_2O_3 and Si_2O, respectively, in Raider and Flitsch's analysis (16). The broadened Si 2p line (FWHM = 1.45 eV) may indicate the presence of substantial hydrogen bonding in the material. For simplicity, it is assumed that the 103 eV Si 2p peak is Si^B and the 336.8 eV Pd $3d_{5/2}$ peak is Pd^B. The remaining Si 2p peak at 100.6 eV is termed intermediate (Si^I).

Integrating the gaussian components of the palladium and silicon spectra, the relative percentages of palladium and silicon in elemental and bound states are determined. Applying these percentages to the actual total palladium and silicon atom concentration as a function of sputter time (or depth), depth profiles of the bond state concentration of Si and Pd are obtained. These data are plotted in Fig. 5 and 6 for both samples as a function of sputter time. It is interesting to note that the curves due to the Pd^B and Si^B appear to track with depth between 10 and 20 min sputter time. The Si^I concentration is observed well into the silicon substrate material as is the Pd^B. Pd^E is also observed well into the substrate (as also observed by SIMS). The Si^B peak at 103 eV is not observed at these depths. The ratio of Pd^E to Pd^B remains ~1:4 to a sputter time of 35 min. Obviously, a stoichiometric palladium silicide is not formed. The silicide stoichiometry appears to continuously change with depth through the interface into the hydrogenated amorphous silicon substrate. The oxygen concentration after a sputter time of 35 min is ~0.2 a/o and appears to be chemically associated with the silicon (the Pd^B at that depth is associated with a silicide).

It has been implicitly implied that silicide is formed during the device fabrication or thermal aging process. However, the depth profiles were obtained by ion sputtering using 1 keV Xe^+. Ion mixing effects are severe for Pd on Si and silicides of palladium are readily formed at low ion doses and energies (17, 18). Therefore, the observed palladium in silicide form (Pd^B) may have formed as a result of sputtering and



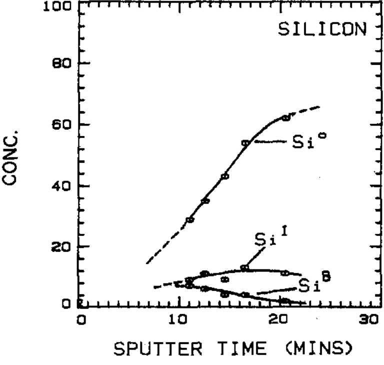


Fig. 5. Bond concentration profile of elemental and bound (A) Pd and (B) Si for the vacuum-aged sample.

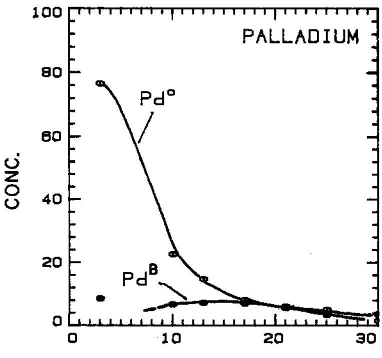

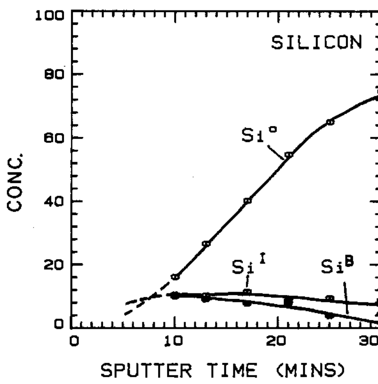

Fig. 6. Bond concentration profile of elemental and bound (A) Pd and (B) Si for the D_2O-aged sample.

subsequent ion-mixing. Using a simple model (see Appendix) which incorporates ion-mixing phenomena, a constant ratio, Pd^E/Pd^B, is predicted for long sputter times. SIMS data show a linear palladium gradient on log-linear coordinates (3, 19) that is, an exponential gradient. From the gradient of these data, the ratio, Pd^E/Pd^B, is found to be near 1:4. Therefore, the silicide observed away from the interface is created by ion-mixing and all the observed palladium is qualitatively elemental palladium.

Conclusions

This study has shown that palladium interdiffuses with hydrogenated silicon at relatively low temperatures to form a diffuse junction containing both oxides and possible silicides. Auger depth profiles show palladium and oxygen extending into the silicon substrate and are in good qualitative agreement with SIMS analysis of similar samples (3). Low temperature diffusion of palladium into single crystal silicon has been reported by Thomas and Terry (20), and the formation of Pd_2Si has been reported by Köster *et al.* (21) for Pd in contact with evaporated amorphous silicon at room temperature. The oxygen concentration is observed to broadly peak in the interface region between Pd and Si and is similar to the results of Pd on crystalline silicon (22). The shape of the peak oxygen distribution may be qualitatively explained by ion-mixing phenomena and a considerably larger oxygen peak content may be present (24). However, the tail into the silicon appears to be real and not an ion-mixing artifact. This is in agreement with SIMS results (3). Thermal aging of Pd/a-Si:H samples in D_2O vapor causes an increase in oxygen concentration ($\sim 5\times$) at the interface between the palladium and silicon relative to that observed in the vacuum-heated sample. Therefore, oxygen or D_2O diffuses through the palladium layer to the interface. SIMS (3) also indicates that deuterium (probably as D_2O) (2) diffuses through Pd.

XPS bond concentration profiles reveal that a transition region (interface), of about 30Å thick, exists. In this region, the palladium is observed to change from a predominately elemental to the bound state. The bound palladium has tentatively been associated with oxide and ion-induced silicide. Also, in the transition region, silicon is observed in two bonding states believed to be associated in part with the existence of silicides (15). However, due to the small but measurable amount of oxygen extending well into the substrate, these states are also associated with suboxides of silicon (16).

Both the vacuum- and D_2O-aged Pd/a-Si:H samples have an interfacial layer of what appears to be in part a silicide intermixed with silicon suboxides, between 20 and 100Å in extent, depending upon the sputter rate used in the computation. Bound palladium and silicon are observed to peak in this region (Fig. 5 and 6). In comparing the vacuum-aged sample with the D_2O-aged sample, approximately $2\times$ more palladium is associated with silicide in the former. The bond concentration of the Si 103 eV peak is greater in the D_2O-aged sample due to the increased number of Si-O bonds and is in agreement with the Auger results of this study. The bond concentration of the Si 100.6 eV peak (intermediate) is about the same in each sample due to Si-O and Pd-Si bonding. The only significant difference as measured by XPS between the two samples is the Si-O bond concentration.

Diodes fabricated with palladium on a-Si:H exhibit good electrical characteristics (1) with an oxide layer at the interface. However, storing Pd/a-Si:H junctions at 80°C in D_2O causes the photovoltaic conversion efficiency to fall by a factor of ~ 5 as compared to vacuum-aged devices (3). This degradation is probably caused by the presence of $\sim 5\times$ more oxygen at the interface of the D_2O-aged sample.

APPENDIX

Using SIMS depth profile data which indicates that palladium in a-Si:H varies exponentially with depth, x, into the a-Si:H layer and that ion-mixing creates a uniform concentration Pd_xSi region in the ion depth range, w, a simple expression for the XPS peak area ratio can be obtained. The usual expression for peak area which is given by (23)

$$dI_i = n_i \sigma_i K(E_k) \exp(-x/\lambda)\, dx$$

where I_i = intensity, n_i = atom density of i, σ_i = photoionization cross section, λ = electron escape depth, E_k = kinetic energy of electrons, and $K(E_k)$ = spectrometer transmission $\times$ geometry $\times$ detector efficiency.

To compute the intensity ratio of unbound to bound palladium over the sample depth range, it is assumed that $n_i \propto \exp(-x/x_o)$ at $x > w$ and $n_i = 0$ at $0 \leq x \leq w$. The amount of bound palladium is assumed constant at $0 \leq x \leq w$ and zero at $x > w$. x_o is assumed as a parameter and will not be defined now. Two equations can be written for unbound and bound palladium, that is

$$I_{Pd^E} = \int_w^\infty n_{Pd^o} \sigma_{Pd} K \exp(-x/\lambda) \exp(-x/x_o)\, dx$$

and

$$I_{Pd^B} = \int_0^w x_o N_{Pd^o} \sigma_{Pd} K \exp(-x/\lambda) [1 - \exp(-w/x_o)]\, dx/w$$

where the average palladium concentration in $0 \leq x \leq w$ is given by $(1 - \exp(-w/x_o)) \times N^o{}_{Pd} x_o/w$. The above expressions are easily evaluated and the ratio $I_{Pd^E}/I_{Pd^B} = F$.

$$F^{-1} = \left\{ \exp\left[\frac{x_o + \lambda}{x_o \lambda} w \right] \right\} \{[1 - \exp(-w/x_o)] [1 - \exp(-w/\lambda)]\} (x_o + \lambda)/w$$

F was evaluated on an HP-1000 using a simple Fortran IV program as a function of w/λ for various values of x_o and w. These data are not shown for brevity. However, if real numbers are substituted for λ, x_o, and w (25, 500, and 15Å, respectively), F is found to be near 1/4. This calculation is very "model sensitive" and is intended to show, semi-quantitatively, how ion-mixing affects the measured XPS spectra. More detailed investigations are being performed in our laboratory.

A New Technique for Antimony Diffusion into Silicon

M. Nanba

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

A new technique using auxiliary silicon wafers lapped with Al_2O_3 powder has been developed for Sb diffusion into silicon. Diffusion wafers are set face to face with those wafers in an open-tube system with Sb_2O_3 as the dopant source. This technique can easily attain a carrier concentration as high as the solid solubility of Sb in silicon without surface defects such as surface erosion. Carrier concentration is controlled by changing the distance between the diffusion and auxiliary wafers. In addition, it is confirmed that higher diffused areas on the diffusion wafers correspond to the lapped areas of the auxiliary wafers.

In bipolar IC fabrication technology, Sb buried layers are more effective than As buried layers for lowering the autodoping from the buried layer during epitaxial growth (1). However, two problems remain in conventional Sb diffusion with Sb_2O_3 source. One is surface defects such as surface erosion (2, 3), which hinders normal epitaxial growth. The other is the difficulty in obtaining high carrier concentrations at the surface of the diffused layer (4). Although $SbCl_3$ and $Sb(C_2H_5O)_3$ have been proposed as dopant sources to avoid the former problem, the latter problem has not been resolved (5, 6).

This work presents a new Sb diffusion technique which avoids both the problems described above. This new diffusion system consists of an open-tube furnace for use with Sb_2O_3 and auxiliary silicon wafers lapped with Al_2O_3 powder which are set face to face with the diffusion silicon wafers. The strong point of this technique is its utilization of auxiliary silicon wafers.

The diffusion silicon wafers employed in this study were CZ, (100) oriented, p-type, and 10-30 Ω-cm wafers. The front surface of the diffusion wafer was damage-free mirror polished, and the back was chemically etched. Both surfaces of the auxiliary silicon wafers were polished with No. 1200-1500 grit Al_2O_3 powder. Before setting in a holder, these auxiliary wafers were thermally oxidized in wet oxygen atmosphere (O_2 bubbled through 90°C H_2O) to prevent the diffusion wafers from outdiffusion of Al_2O_3. Since the sheet resistance (ρs) of the diffusion wafer depended on the number of uses of the auxiliary wafer, the wafer was changed every experiment.

Figure 1 shows a schematic representation of the present diffusion system. Dry nitrogen was used as the carrier gas. In the first zone of the furnace shown in this figure, the Sb_2O_3 source was held in a platinum boat and heated to 750°C. In the second zone, the diffusion and auxiliary wafers were held on a fused silica holder at 1200°C. The front surface of the diffusion wafer (s) was set face to face with the auxiliary wafer. The distance between the diffusion and auxiliary wafers (d) was varied from 2 to 24 mm to investigate the influence of this distance on concentration profile. Concentration profiles of Sb were obtained by the

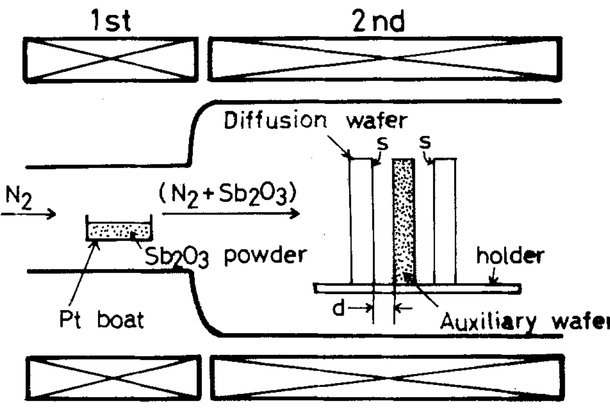

Fig. 1. Schematic design of the experimental apparatus. The marks *s* and *d* denote the front surface of the diffusion wafer and the distance between the diffusion and auxiliary wafers, respectively.

differential conductivity method (7) as well as Rutherford backscattering method. Surface erosion density was evaluated from optical microscopy. The sheet resistance (ρs) homogeneity map on a diffusion wafer was measured by a fully automated four-point probe.

The carrier concentration profiles obtained by the present and conventional techniques are shown in Fig. 2. Although the diffusion conditions of the present technique are quite similar to those of the conventional one, the concentration obtained by our technique is about 3 times as high as that by the conventional technique. Moreover, it should be noted that the surface concentration obtained by our technique is equal to the solid solubility (6×10^{19} cm^{-3}) (8), which is the highest concentration in the reported values at 1200°C (4, 9, 10).

In this figure, a plot of the error function complement (erfc) is also shown for comparison with the experimental data. Since the profile obtained by the conventional technique roughly fits the erfc, it is possible to estimate the effective diffusion coefficient (2.6×10^{-13} cm^2/sec), which agrees with that reported by Fuller *et al.* (9). On the other hand, the profile obtained by the present technique differs from the erfc. This suggests that the Sb diffusion coefficient depends on the surface concentration, as do phosphorus and boron (7, 11, 12).

When the ρs of the diffusion layer was 40 Ω/□, the surface defect density in the wafer diffused by our technique was about 1 cm^{-2}, while that by the conventional one was about 10 cm^{-2}. Therefore, this technique is more useful than the conventional one in practical use.

Figure 3 shows the dependence of the carrier concentration on the distance (*d*). The surface concentrations are 6.0, 5.0, 4.0, 2.7, and 2.2×10^{19} cm^{-3} for *d* of 2, 4, 8, 16, and 24 mm, respectively. It is evident that the surface concentration can be controlled by changing the *d*. The effect of the auxiliary wafer becomes weak as the *d* increases. Then the carrier profile at the *d* of 24 mm is equal to that obtained by the conventional technique as known in Fig. 2. These results indicate that the auxiliary wafers play an important role on the Sb diffusion.

The reciprocal of the sheet resistance ($1/\rho s$), *i.e.*, sheet conductance (σs), corresponds to the net carrier distribution in the diffusion wafer. The σs of the profiles shown in Fig. 3 are 42.5, 33.3, 24.2 16.5, and 12.1 mV for *d* of 2, 4, 8, 16, and 24 mm, respectively.

Here we will define $\sigma_s{}^p$ and $\sigma_s{}^c$ as the sheet conductance obtained by the present and conventional techniques, respectively. Therefore, the value ($\sigma_s{}^p - \sigma_s{}^c$) can be considered to reveal the effect on the Sb diffusion obtained by the present technique. The ($\sigma_s{}^p - \sigma_s{}^c$) are 30.4, 21.2, 12.1 and 4.4 mV for *d* of 2, 4, 8, and 16 mm, respectively.

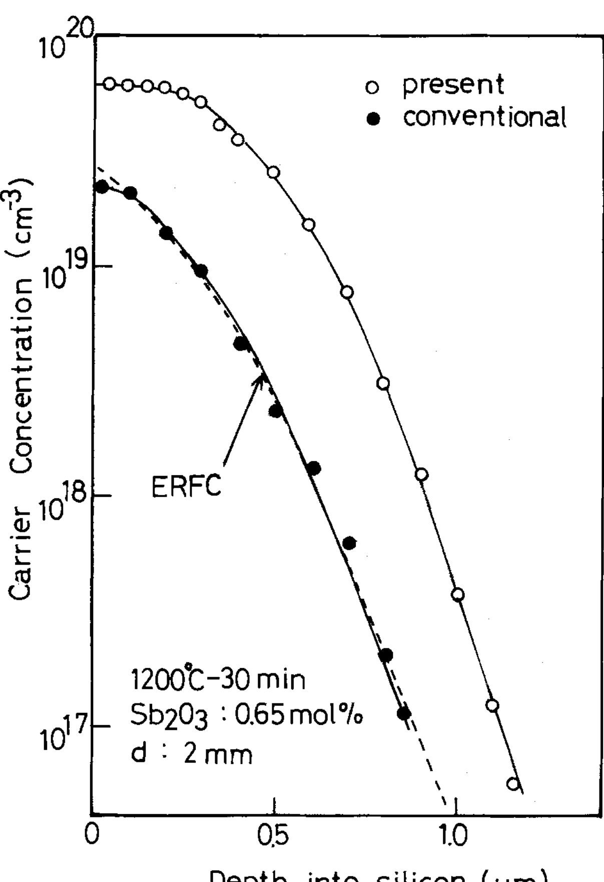

Fig. 2. Carrier concentration profiles obtained by the present (○) and conventional techniques (●).

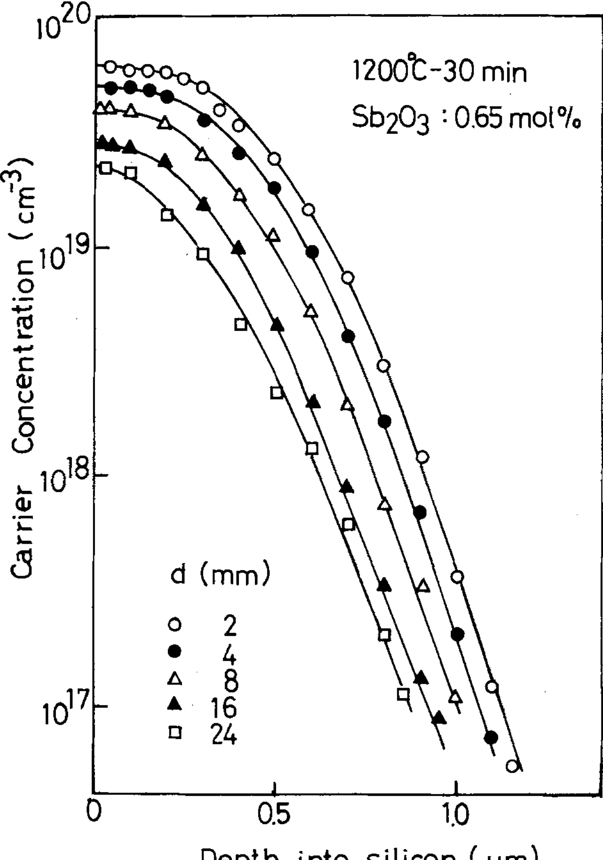

Fig. 3. Dependence of the carrier concentration on the distance between the diffusion and auxiliary wafers (*d*).

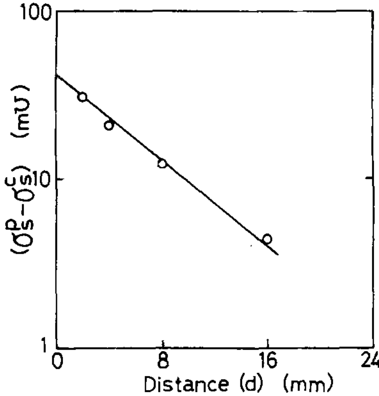

Fig. 4. The ($\sigma_s^p - \sigma_s^c$) vs. the distance between the diffusion and auxiliary wafers (*d*). The σ_s^p and σ_s^c show the sheet conductance obtained by the present and conventional techniques.

Figure 4 shows the relation between the ($\sigma_s^p - \sigma_s^c$) and the *d*. This relation is represented by

$$(\sigma_s^p - \sigma_s^c) = \sigma so \exp\left(-\frac{d}{\lambda}\right) \qquad [1]$$

where σso is 43 mV and λ is 6.8 mm. From Eq. [1], it is easily seen that the smaller distance (*d*) is, the larger ($\sigma_s^p - \sigma_s^c$) is.

Figures 5 (a)-(c) are surface photographs of the auxiliary wafers. Areas marked by M and L denote the mirror and lapped surfaces, respectively. Figures 5 (d)-(f) are the ρs homogeneity maps of the diffusion wafers obtained after Sb diffusion using the auxiliary wafers shown in Fig. 5(a)-(c), respectively. This result shows that the areas of the lower ρs on the diffusion wafers agree with the lapped areas of the auxiliary wafers.

These results look as if some diffusant is emitted from the surface of the auxiliary wafers. The diffusant is estimated to be the dopant source (Sb_2O_3) or the abrasives (Al_2O_3). Therefore the Sb and Al contents in the Sb glass layer grown on the diffusion wafer should be analyzed. Further investigation is needed.

Figures 6(a) and (b) show 330 keV $^4He^+$ Rutherford backscattering spectra for the diffusion wafer with and without glass layer, respectively. The yield of Sb in a glass layer obtained by the present technique is about 10% that by the conventional one. On the other hand, the yield of Sb in silicon obtained by the former technique is higher than that by the latter. This result is curious.

However, it should be noted that the spectrum in glass layer measured by Rutherford backscattering is mainly due to Sb_2O_3, which is the main component in the layer (9). Since it is implausible that Sb_2O_3 diffuses into silicon (9), the contributory diffusant is not Sb_2O_3, but elemental Sb. Thus, it is concluded that the Sb diffusion is not simply governed by the Sb_2O_3 concentration in the glass layer. If one allows the above interpretation, the results of Rutherford backscattering is not contrary to the carrier concentration profiles in Fig. 2 and 3.

From the point of view described above, it can be considered that the carrier concentration in silicon depends strongly on the diffusant concentration at the glass-silicon interface. In this case, it is reasonable to consider that the concentration of elemental Sb obtained with the present technique is higher than that obtained with the conventional one at the interface because the carrier concentration in silicon obtained with the former technique is higher than that with the latter one, as seen in Fig. 2 and 3.

Although this increase in the concentration of elemental Sb at the interface is clearly ascribable to the auxiliary wafer, it is not easy to explain this mechanism, nor the role of the auxiliary wafer, at present. Further investigation is necessary.

Planarization of Phosphorus-Doped Silicon Dioxide

A. C. Adams* and C. D. Capio

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

A process has been developed for smoothing surfaces of phosphorus-doped silicon dioxide (P-glass). Samples are coated with a positive photoresist which flows during application to form a relatively smooth surface. The photoresist is etched in a CF_4-O_2 plasma using conditions that etch the photoresist and the P-glass at nearly the same rates. Since the surface profile of the photoresist is preserved during etching, the P-glass is left with a relatively smooth surface. This process reduces step heights, usually by at least 50%, and decreases the angles at abrupt steps to 5°-30°. In contrast to the flowed P-glass process, planarization does not require high temperatures and is independent of phosphorus concentration.

A primary cause of metallization failures in integrated circuit devices is incomplete metal coverage over oxide steps (1-3). Several techniques have been developed to improve the metal coverage by providing smaller or less abrupt steps. These techniques include: P-glass flow (3, 4), tapered etching (3, 5-9), and localized oxidation (3, 10-16). Recently another technique, surface leveling or planarization, which is shown schematically in Fig. 1, has been described (17, 18). In Fig. 1, an abrupt step in phosphorus-doped silicon dioxide (P-glass) is covered with a sacrificial organic coating. Since the organic material has a low viscosity, flow occurs during application or during a low temperature bake to give a relatively smooth surface with small, gentle steps. By etching the organic material using conditions that etch the sacrificial coating and the P-glass at nearly the same rates, the original profile of the coating material is maintained, leaving the P-glass surface with only small, gentle steps. This technique has been described for smoothing surfaces by sputter etching (17). The present paper describes a process for planarizing phosphorus-doped silicon dioxide films deposited over steps in polycrystalline silicon. The factors that affect the planarization are described, and the planarization technique is compared with the flowed glass process.

Experimental Procedure

The samples are etched in a parallel-plate, radial-flow reactor that has been described previously (19, 20). The etcher has an electrode spacing of 3.1 cm and an electrode area of 1250 cm^2. Ten 75 mm silicon wafers can be etched at one time. The phosphorus-doped silicon dioxide is deposited at 450°C using the reaction between silane, phosphine, and oxygen at atmospheric pressure. The phosphorus concentrations are determined by measuring sheet resistivities of the silicon substrates (on p-type monitor wafers) after a 20 min, 1100°C diffusion, and have been checked by infrared measurements and etch rate determinations (21). Unless stated otherwise, the phosphorus concentrations are approximately 6 weight percent (w/o).

* Electrochemical Society Active Member.
Key words: dielectrics, etching, integrated circuits.

Stylus measurements of the surface profiles are made with a Taylor-Hobson Talystep using a fine stylus, with a truncated pyramidal shape and a tip dimension of 0.1 × 2.5 μm. Most experiments use test structures containing 0.4 μm thick polycrystalline silicon, anisotropically etched in a Cl_2-C_2F_6 plasma to give vertical walls (20, 22), and covered with 1.0-1.5 μm of 6% P-glass. An alternate structure contains 1.2 μm of thermally grown silicon dioxide, etched to give a 45°C taper (7), and covered with 1.0 μm of 6% P-glass. The sacrificial coatings are all applied by standard photolithographic spinning techniques.

Planarization

Coatings.—Three organic resists have been examined as sacrificial coatings: HPR-204, a positive photoresist from Philip A. Hunt Chemical Corporation; AZ-111, a positive photoresist from Shipley Company, Incorporated; and PIQ, a polyimide resist from Hitachi Chemical Company. Surface profiles after P-glass deposition, after application of the organic coating, and after etching are given in Fig. 2. The profile of the P-glass after deposition shows cusps at the top of the step and crevices or thinning at the bottom. The maximum step height, from the top of the cusp to the bottom of the crevice, is 1.5 μm. After coating, the profiles are smoother; the steps become much less abrupt and the maximum step height decreases to 0.6-0.8 μm because the coating materials tend to flow and fill-in at the bottom of the steps (curves marked A). The profile of the P-glass after etching the sacrificial layer tends to follow the original profile when the coating material is HPR-204 or PIQ (curves marked B). In both cases, the step heights increase by only 0.1 μm during etching to give final heights of 0.8-0.9 μm (compared to 1.5 μm in the original P-glass). The AZ-111 occasionally cracks during etching, possibly because of very strong adhesion between the resist and the P-glass, and leaves a crazed surface with little smoothing (as shown in Fig. 2). Of the three materials examined, the HPR-204 is preferred. It flows at a low temperature, produces a smooth surface, and etches at a rate similar to that of P-glass (discussed later).

The amount of smoothing depends on the thickness of the coating material, as illustrated in Fig. 3 which shows the surface profiles obtained with different thicknesses of HPR-204 (1.0, 1.4, and 1.8 μm). After deposition, the P-glass has the characteristic cusps and crevices with a maximum step height of 0.61 μm. Application of the HPR-204 provides a large reduction in step height and the formation of a very gentle topography. After etching, the step heights increase slightly but are still much less than the original height after deposition. The cusps and crevices are completely removed during planarization. In addition, the angles made by the P-glass going over the steps are reduced from about 90° after deposition to less than 20° after planarization. As the resist thickness increases, the surfaces become smoother. However, the thicker resists require longer etch times and cause a decrease in the reproducibility in the P-glass thickness after etching. Consequently, the 1.0 μm thickness is preferred.

The effect of baking the HPR-204 is shown in Fig. 4. At bake temperatures above about 150°C, the resist softens and flows providing a large decrease in step height (the solid circles) which is also observed in the P-glass surface after planarization (the open circles). The etch rate of the HPR-204 in a CF_4-O_2 plasma, measured in Å/min and shown by the squares, is independent of the bake temperature. The thickness of the HPR-204 is affected by the bake temperature, decreasing linearly from 1.10 μm after a 90°C bake to 0.82 μm after the 215°C treatment. Baking above 150°C is recommended because of the improved topography and because of decreased defects (discussed later).

The decrease in step height depends on the width of the line or space being covered. Relevant data using three thicknesses of HPR-204, all baked at 90°C, are given in Fig. 5. After P-glass deposition the maximum step height is about 0.60 μm and is independent of the feature size. After coating with the HPR-204, the step height is reduced to less than 0.25 μm. As the

feature size decreases the step height decreases further, and steps of less than 0.1 μm are observed for very narrow lines or spaces. The reduction in step height is greater for the thicker coatings, as previously shown. Flowing the resist at temperatures above 150°C gives step heights that are less than 0.1 μm and are nearly independent of feature size over the range measured. The P-glass surfaces after planarization show a similar behavior to Fig. 5 but with the step heights increased by about 0.1 μm. The angles made by the P-glass after planarization are about 13° and are nearly independent of the feature size and the resist thickness.

Etching.—The etch rates of HPR-204, PIQ, and P-glass in CF_4-O_2 plasmas are shown in Fig. 6-8. The etch rates increase in the order, P-glass < HPR-204 < PIQ for each of the variables investigated (gas composition, rf power, and sample temperature). Although the etch rates are affected by changes in these variables, the ratio of the HPR-204 etch rate to the P-glass etch rate remains nearly constant, and conditions giving equal etch rates have not been found. This

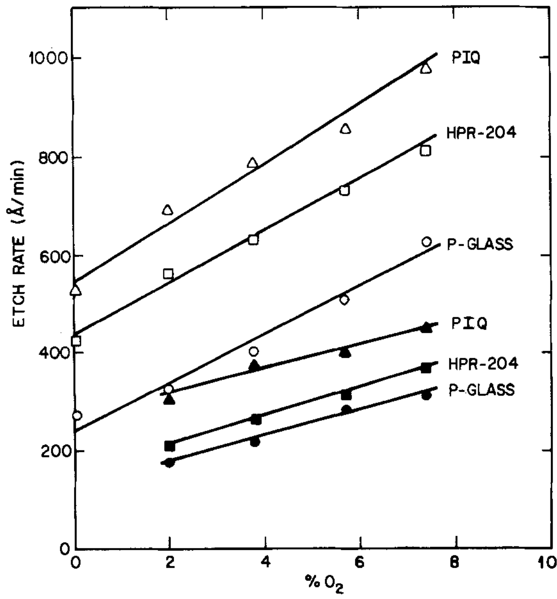

Fig. 6. Etch rate vs. gas composition for CF_4-O_2 mixtures at 0.4 Torr and 28°C: open points, 700W; closed points, 130W.

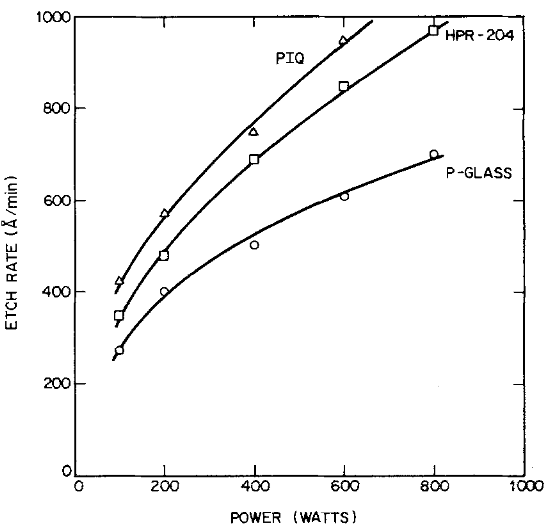

Fig. 7. Etch rate vs. power for CF_4-8% O_2 at 0.4 Torr and 28°C

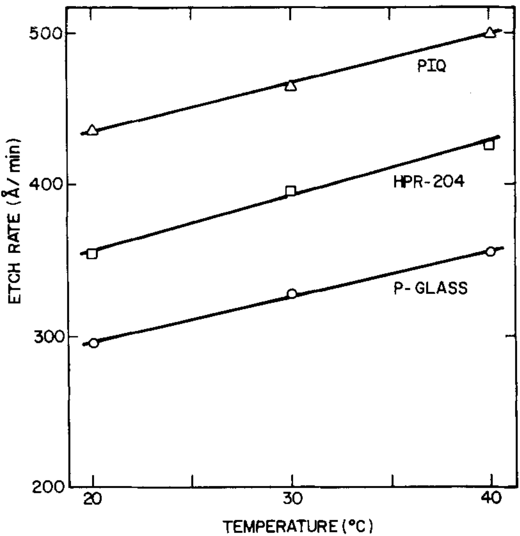

Fig. 8. Etch rate vs. sample temperature for CF_4-8% O_2 at 0.4 Torr and 130W.

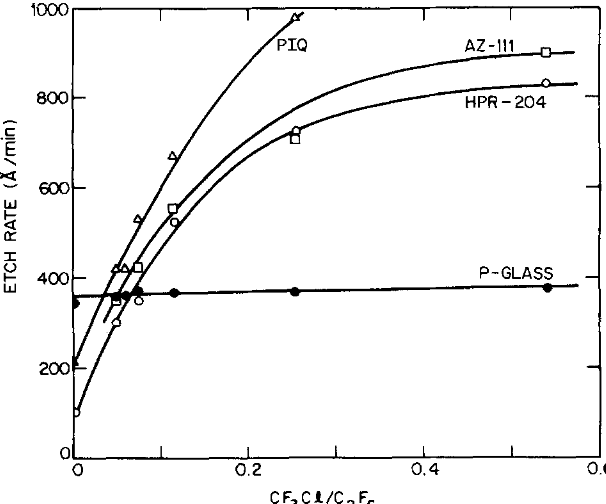

Fig. 9. Etch rate vs. gas composition for CF_3Cl-C_2F_6 mixtures at 0.4 Torr, 800W, and 28°C.

difference in etch rates causes the slight increase in step height as samples coated with HPR-204 are planarized (Fig. 2-4).

Etch rates in a CF_3-C_2F_6 plasma are shown in Fig. 9 as a function of the gas composition. The etch rates of the organic materials increase in the order: HPR-204 < AZ-111 < PIQ, and all increase as the CF_3Cl/C_2F_6 ratio increases. In contrast, the etch rate of the P-glass is nearly constant. Equal etch rates for the HPR-204 and the P-glass are obtained at a CF_3Cl/C_2F_6 ratio of about 0.07. Unfortunately, P-glass samples planarized with a CF_3Cl-C_2F_6 plasma are left with a very rough surface that consists of long nodules or fingers that increase in length as the etching time increases. This rough surface occurs with all three coating materials, and with CO_2-C_2F_6 plasmas and with C_2F_6 alone. The rough surface appears to be characteristic of P-glass planarization with C_2F_6 but has not been investigated further. The rough surface is not observed when samples are planarized with CF_4-O_2.

The etch rate of silicon in a CF_4-O_2 plasma depends on the quantity of material being etched (the loading effect) (23). This effect also occurs when P-glass and resist are etched during planarization. The loading effect during planarization shown by the data in Fig. 10 is smaller than that observed for silicon (23). The small loading effect is a disadvantage of the CF_4-O_2 plasma etching, but it has not caused serious problems during the planarization of devices.

Planarization process.—The recommmended processing sequence for planarization is as follows. The phosphorus-doped silicon dioxide (4-6 w/o P) is deposited to give a thickness of 1.5 μm. After deposition the samples are scrubbed to remove particles and then baked at 180°C for 45 min. The HPR-204 resist is applied (1.0 μm thick). The samples are given a final bake at 180°C for 20 min and then planarized using CF_4-8% O_2 at 100W and 0.4 Torr. The thickness of P-glass after planarization is approximately 0.8 μm.

Surfaces and cross sections of samples after P-glass deposition and after planarization using the above process are shown in the SEM photographs in Fig. 11. It is evident that planarization completely removes the cusps and crevices and decreases the step height and the angle made by the P-glass. For most topographies, planarization reduces step heights by at least 50% and reduces the angles to less than 30°.

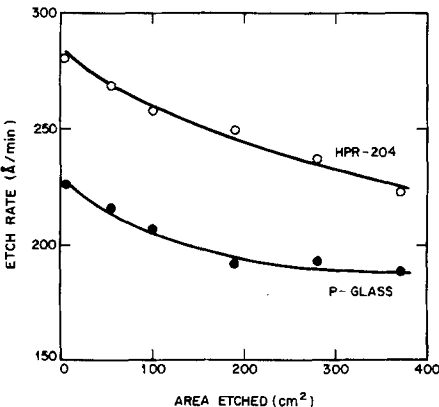

Fig. 10. The loading effect for HPR-204 and P-glass in CF_4-8% O_2 at 0.4 Torr and 100W.

Defects.—Several types of defects associated with the planarization process have been observed. Pinholes or cracks in the P-glass lead to large holes in the silicon substrates since the etch rate of silicon in the CF_4-O_2 plasma, about 1000 Å/min, is much larger than the etch rate of P-glass. The holes in the silicon have been observed only on samples etched for very long times. Craters etched in the P-glass, usually 0.1-0.5 μm deep and about 10 μm in diameter, are occasionally observed. The craters are probably caused by moisture on the P-glass surface or solvent in the resist coating. The water or solvent vaporizes in the vacuum chamber to form a bubble in the HPR-204, thus allowing the P-glass to etch prematurely. These craters can be eliminated by baking the HPR-204 above 150°C. Mounds, approximately 10-20 μm in diameter and 0.5-1.0 μm high, have also been observed after planarization. These mounds, which are probably caused by particles on the original P-glass surface, are eliminated by scrubbing the P-glass after deposition. Striations are occasionally present in the HPR-204 and are transferred to the P-glass during planarization. The striations do not appear to cause serious problems since the thickness variations across the striations are only 0.05-0.10 μm.

Comparison with P-glass Flow

Plasma planarization provides a smooth surface by altering the topography of the P-glass. Flowing the P-glass by heating to high temperatures also changes the P-glass topography. It is interesting to compare the two processes. The SEM photographs in Fig. 12 show a polycrystalline silicon line crossing an oxide step with the entire surface covered with P-glass (4.6 w/o P). The samples have been treated in steam at 1100°C for different times. Flow is indicated by the progressive loss of detail. As shown in Fig. 12, flow is normally a kinetic or rate phenomenon with the amount of flow strongly dependent on the time. Samples usually do not reach an equilibrium state during flow.

Flow is shown as a function of the phosphorus concentration in the SEM cross sections in Fig. 13. As deposited, the P-glass has a concave or retrograde angle with a cusp at the top of the step and a thin region at the bottom. As the phosphorus concentration increases, flow increases giving a decrease in the angle made by the P-glass going over the step.

Quantitative measurements of flow can be obtained from the SEM cross sections by measuring the angle made by the P-glass. The data in Fig. 14 show the angles for samples annealed in steam, nitrogen, or oxygen at 1100°C and in steam at 1050°C. Also shown are angles for planarized samples (the dashed line). The trends observed in Fig. 14 are in good agreement with those previously reported (14). Flow is similar in oxygen or nitrogen but increases significantly in steam. If flow occurs by the breaking and reforming of chemical bonds, then the increased flow in steam probably results from the rapid, reversible hydrolysis of the P-O bonds. The angle made by 6.5% P-glass after flowing at 1100°C for 20 min is 45°-65°. This is much greater than the angles observed on similar structures after planarization (28°, independent of the phosphorus concentration).

An additional comparison of planarization and P-glass flow is provided by the SEM photographs in Fig. 15. The cross sections show 1.5 μm of 7.2% P-glass covering 1.0 μm steps of polycrystalline silicon. Samples are shown after P-glass deposition, after flow in nitrogen at 1100°C for 20 min, and after planarization in a CF_4-O_2 plasma for 60 min. The sample showing the P-glass after deposition has been etched in dilute hydrofluoric acid to make the polycrystalline silicon easier to see. The step heights and angles for the three samples are: 1.60 μm and 122° after deposition; 1.32 μm and 42° after P-glass flow; and, 0.56 μm and 10° after planarization. It is obvious that planarization provides a greater reduction in step height and a much greater decrease in the angle made by the P-glass going over the step.

The viscosity of phosphorus-doped silicon dioxide can be calculated by assuming fourfold bonding and using known values for the viscosities and activation energies of SiO_2 and P_2O_5 (24). Calculated values are shown in Fig. 16 for three flow temperatures. Although the detailed relationship between viscosity and flow is not known, Fig. 16 can still provide useful information. Assuming that a sample containing 6.5% phosphorus has adequate flow at 1100°C, then decreasing the flow temperature to 1050°C requires an increase in phosphorus concentration to 9.5% (to obtain the same viscosity). Such a high phosphorus concentration is not compatible with aluminum metallization. Similarly, a decrease in phosphorus concentration to 3.5% P requires an increase in the flow temperature to 1150°C, which would have deleterious effects on diffused junctions in semiconductor devices. This illustrates the severe restrictions on the phosphorus concentration and on the flow temperature for the flowed glass process. These restrictions do not apply to the planarization process where the maximum temperature is less than 200°C and where phosphorus concentrations of 0-8% P have been used with nearly equal results.

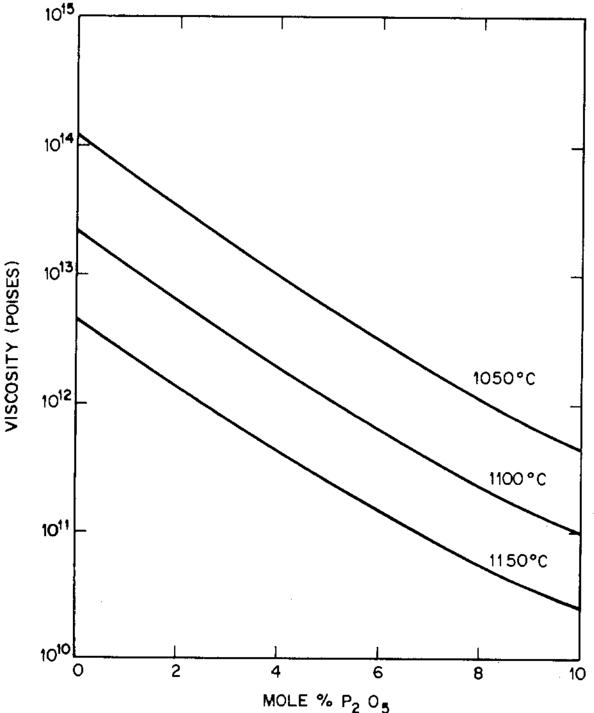

Fig. 16. Calculated viscosity of P-glass vs. composition

Summary and Conclusions

A process for smoothing or planarizing surfaces of phosphorus-doped silicon dioxide has been described. Planarization is achieved by coating the P-glass with a sacrificial coating and then plasma etching using conditions that etch the coating and the P-glass at nearly equal rates. The preferred material for the sacrificial layer is HPR-204. Other materials etch too rapidly or crack during etching. The preferred etching gas is CF_4-8% O_2. Gas mixtures containing C_2F_6 provide a better etch rate ratio, but leave a very rough surface. The planarization process typically reduces step heights by about 60% and reduces the angles made by the P-glass going over steps to less than 30°. However, the final surface depends strongly on the original topography and on the sacrificial layer. Surfaces become smoother for small feature sizes, and are made smoother by using thick resist and by flowing the resist before planarization.

Methods have been found for eliminating or minimizing the defects that are caused by planarization. These defects are: mounds, caused by particles on the P-glass; craters, caused by moisture on the surface or solvent in the resist; holes etched in the silicon substrate, caused by pinholes or cracks in the P-glass; and, striations in the P-glass caused by the striations in the resist.

The planarization process has been compared to the flowed glass process. Planarization reduces step heights and leaves angles of 5°-30°. The flowed glass process gives very little reduction in step height and leaves surface angles of 45°-65°. The flowed glass process requires temperatures of 1050°-1100°C and phosphorus concentrations of 6-7%. Planarization is a low temperature process, less than 200°C, and is nearly independent of the phosphorus concentration. These features make planarization a very attractive process for fabricating devices with small dimensions.

Convective Interference and "Effective" Diffusion-Controlled Segregation during Directional Solidification under Stabilizing Vertical Thermal Gradients; Ge

Douglas E. Holmes[1] and Harry C. Gatos*

Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

Convection and segregation phenomena during vertical directional solidification of Ga-doped Ge under stabilizing vertical thermal gradients were investigated. Microscopic growth rates were determined by interface demarcation, compositional profiles by single point spreading resistance measurements, and thermal characterization of the melt by direct thermal probing. It was found that destabilizing horizontal temperature gradients, even in melts with a diameter as small as 3 mm, led to convection with pronounced effects on solidification. Turbulent convection resulted in microscopic growth rate-controlled dopant inhomogeneities similar to those observed for solidification under destabilizing vertical gradients. Under laminar convection dopant inhomogeneities were caused by perturbations in boundary layer thickness. Macrosegregation under both turbulent and laminar convection was controlled by the boundary layer thickness. A model based on diffusive and convective fluxes was developed describing laminar fluid flow and segregation; an experimental correlation between segregation and the Rayleigh number, consistent with the model, was obtained. Indirect evidence for diametrically antisymmetric fluid flow in the melt was obtained from lateral microsegregation across the interface. Theoretical and experimental results showed that complete elimination of convective interference is virtually impossible; however, "effective" diffusion-controlled segregation was achieved at relatively high growth rates and low Rayleigh numbers.

An understanding of the effects of convective heat and mass transport on the solidification process is of fundamental importance in assessing and/or defining the parameters which control the liquid-solid phase transformation. In addition, convective effects often preclude the extrapolation of macroscopic solidification parameters to segregation on a microscale, thereby preventing quantitative evaluation of cause-effect relationships between solidification parameters and materials properties.

Convection-related segregation effects have been recognized for many crystal growth configurations including the Czochralski (1), horizontal Bridgman (2), and destabilizing vertical thermal gradient (3) geometries. Directional solidification under stabilizing vertical thermal gradients, on the other hand, has been employed for the purpose of minimizing convective interference (4). However, virtually no quantitative characterization of the effect of destabilizing horizontal temperature gradients in the melt, which are virtually unavoidable, has been carried out. Such gradients, although they may be reduced to very small values, invariably lead to convective flow. Recently, techniques have become available for the direct determination of solidification parameters on a macro- and microscale for dilute binary alloy semiconductor systems (3).

The present investigation was undertaken to study segregation in a vertical directional configuration with

stabilizing vertical thermal gradients employing recently developed techniques. Emphasis was placed on the correlation of convection and segregation processes, and on the identification of practical limitations associated with minimizing convective interference in high temperature systems in the light of horizontal thermal gradients.

Apparatus and Procedures

A diagram of the crystal growth apparatus employed in this investigation is shown in Fig. 1. A precast polycrystalline germanium charge doped with gallium to the desired level was brought into contact with a <100> germanium seed contained in a cylindrical ampul. The outer quartz tube positioned between two water-cooled brass-plates permitted control of the ambient atmosphere. Melting of the charge was carried out in two stages. First, with the outer heater the temperature of the system was raised to 800°C and was maintained constant throughout the experiment. Then, the inner heater was employed for melting the charge from top to bottom until the melt touched the seed. The system was then allowed to reach thermal equilibrium. Melting and equilibration were monitored visually through the gold-coated heat reflector and a window in the outer heater ceramic mandrel.

Solidification was initiated and allowed to proceed by controlled power reduction in the inner heater. Vertical temperature gradients in the melt during thermal equilibration ranged from 28° to 75°C/cm. Control of radial heat losses through the sample-ampul wall was achieved by adjusting the relative position of the inner and outer heaters and the ampul, and by independently controlling the power in each heater. The microscopic solidification rate would be varied up to 42 μm/sec.

Interface demarcation (5) was employed to determine the microscopic growth rates and interface morphology; pulses of 18 A/cm^2, of 50-80 msec duration, and at frequencies between 0.1-1 Hz were applied across the growth interface.

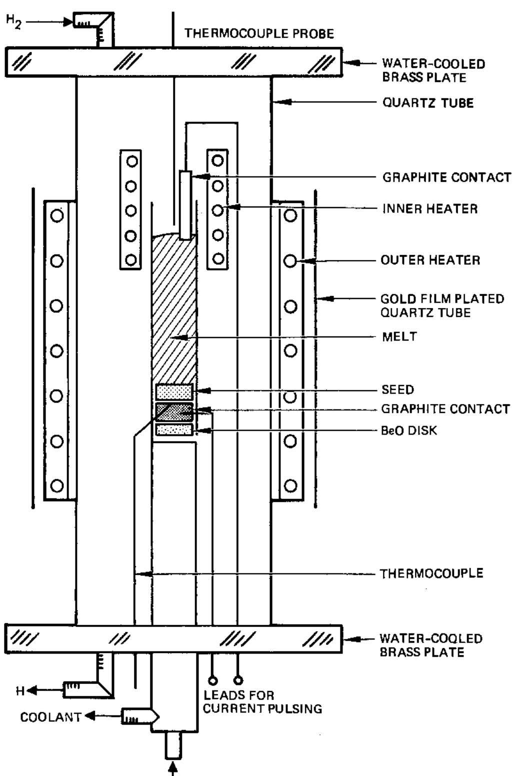

Fig. 1. Schematic arrangement of the apparatus used for the study of crystal growth under stabilizing vertical temperature gradients.

Growth and segregation analyses were performed on crystal segments cut along the growth axis, the segments were polished and etched (1 HF + 1 CH_3COOH + 1 H_2O_2) to reveal segregation effects and interface demarcation lines by interference contrast microscopy.

Carrier concentrations were determined with a single point spreading resistance probe (6) with a spacial resolution of about 5 μm. Spreading resistance data were converted directly to carrier concentration employing a calibration curve constructed from the average spreading resistance of 6 standard samples with carrier concentrations ranging from 9×10^{16} cm^{-3} to 1.2×10^{20} cm^{-3}, as determined by Hall effect measurements.

Thermal characterization of the melt was carried out with a movable thermal probe (inserted through the top of the furnace) which could be positioned at any desired melt height. The most sensitive and durable probe was constructed of a 0.030 in. Omega Chromel-Alumel sheath thermocouple with a thin ceramic coating to prevent chemical attack and to provide electrical insulation. The time assistant was 0.38 sec. A similarly constructed thermocouple was positioned just below the seed.

Temperature gradients in the liquid at the interface, during solidification, were determined by measuring the temperature at one position in the melt (typically 1.5 cm from the initial interface). The interface demarcation current pulses were inductively sensed by the thermal probe and were registered as instantaneous pen deflections on the temperature recorder. Thus, a direct time correspondence between the temperature at the probe tip and the interface demarcation lines (solidification behavior) could be made (3). Since the interface temperature is known, the gradient was calculated assuming a linear profile. The temperature gradient in the solid near the interface during solidification was obtained from the temperature registered by the thermocouple below the seed and the distance from the thermocouple to the advancing growth interface as determined from the interface demarcation lines in the crystal.

The temperature gradient in the liquid near the interface, G_L, was also determined by a second approach, *i.e.*, it was calculated from the boundary condition for unidirectional heat flow at the solid-liquid interface, *i.e.*

$$G_L = \frac{k_s G_s - \rho H R}{k_L} \qquad [1]$$

where k_s and k_L are the thermal conductivities of the solid and liquid, respectively, G_s is the temperature gradient in the solid, ρ is the density, H is the heat of fusion per gram, and R is the solidification rate. Agreement between the two types of determinations of G_L was generally within 20%.

A series of experiments were carried out in which the following geometrical, thermal, and growth parameters were studied: (*i*) the inside ampul diameter was varied from 3 to 9 mm, (*ii*) graphite and quartz ampuls were used which have relatively high and low thermal conductivity, respectively, (*iii*) the average vertical temperature gradient in the melt during solidification was varied from 15°C/cm to 60°C/cm, (*iv*) the average microscopic growth rate was varied from 8 to 21 μm/sec, (*v*) the amount and type of concentric thermal insulation was varied, and (*vi*) an ambient atmosphere of hydrogen and of argon were employed.

Results and Discussion

Thermal characterization of the melt.—In order to determine the temperature gradient as a function of melt height, continuous temperature recordings were obtained at various positions in the melt as the Ge charge was melted. Continuous recordings obtained from a 5.5 cm high melt in a 9 mm diam cylinder as

shown in Fig. 2, exhibited random temperature fluctuations throughout the melt with amplitudes of up to 7°C, indicating turbulent convective behavior.

The vertical temperature gradient in the central portion of this melt ($\partial T/\partial X$) was smaller than in the upper and lower regions ($\partial T'/\partial X$). This behavior is characterized by the Nusselt (7) number, Nu, defined as the ratio of the total longitudinal heat flux in the melt and the conductive heat flux. In the present case, Nu can be expressed as

$$\mathrm{Nu} = (\partial T'/\partial X)/(\partial T/\partial X) \quad [2]$$

and it was found to be > 1.

It has been shown (8-10) that Nu exceeds 1 at the onset of turbulent convection. It is, thus, confirmed that turbulent convection prevailed in the above solidification configuration. Since the vertical gradient was stabilizing, the turbulent behavior resulted from unavoidable horizontal gradients. In all other experiments, in which the ampul diameter was 5 mm or less, the temperature fluctuations exhibited periods of 1.5 to 3.5 min and amplitudes between 0.1° and 0.7°C. Representative values of Nu measured in these melts equaled 1. These characteristics are indicative of laminar convection, although the presence of near-oscillatory convection (11) cannot be ruled out.

Microsegregation.—Microsegregation characteristics in the crystals grown were determined from high resolution etching in conjunction with phase contract microscopy, compositional profiles, and microscopic growth rate measurements. Crystals grown in 9 mm diam ampuls generally exhibited pronounced dopant inhomogeneities over the 5 mm segment first to solidify, as shown in Fig. 3A. The inhomogeneities are identified as remelt striations which intersect each other at various angles and indicate a complex pattern of transient-backmelting occurring alternately on the right- and on the left-hand side of the crystals. The spacing of the striations corresponded to about 10 sec intervals. During this stage of solidification, the nature of the thermal field underwent a transition from static

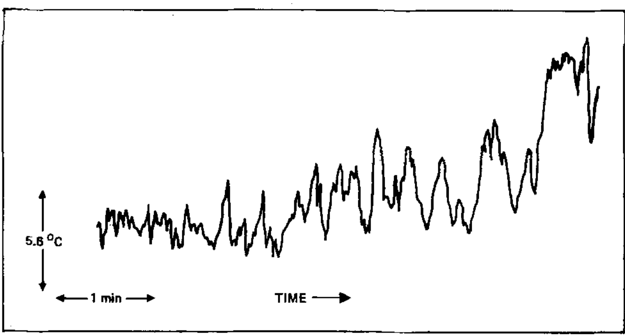

Fig. 2. Continuous temperature recording obtained during melt equilibration from a 9 mm diam, 55 mm high melt at a position 3 mm above the solid-liquid interface.

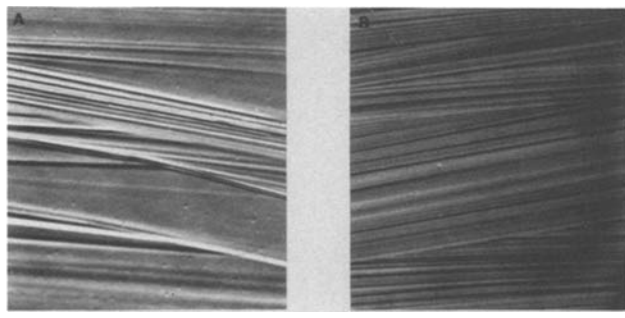

Fig. 3. Comparison of etched longitudinal segments of Ga-doped Ge crystals grown under turbulent convection resulting from destabilizing horizontal (A) and destabilizing vertical (B) thermal gradients. ~200×.

(melt equilibration) to dynamic (programmed cooling) and the interface shape changed from convex (with respect to the solid) to wavy ("S"-shaped).

A one-to-one correlation between temperature fluctuations in the liquid adjacent to the solid-liquid interface during growth and remelt striations could not be made. However, the period of remelt striations was similar to the period of temperature fluctuations during melt equilibration (5-10 sec). Thus, it can be concluded that turbulent convection prevailed during the first stage of solidification. The virtual disappearance of the dopant inhomogeneities (as deduced from chemical etching) as growth proceeded, indicates a significant reduction in amplitude of the temperature fluctuations.

The segregation characteristics described above bear a striking similarity to those observed in an earlier study (Fig. 3B) on solidification under turbulent convection arising from destabilizing vertical gradients (3). In this earlier investigation an inverted Bridgman configuration was employed. With continued growth downward (decreasing melt height), the melt experienced successively turbulent, oscillatory, and laminar convection with correspondingly different growth and segregation behavior. Under conditions of turbulent convection, the frequency of remelt striations (shown in the figure) was found to correlate directly with the measured temperature fluctuations. By analysis of the measured microscopic growth rate and dopant concentration, the BPS relationship (12) was found to be applicable

$$C_s = \frac{k_o C_L}{k_o + (1 - k_o)\exp(-R\delta/D)} \quad [3]$$

where C_s is the dopant concentration in the solid, C_L is the dopant concentration in the bulk melt, k_o is the equilibrium distribution coefficient, R is the microscopic growth rate, δ is the diffusion boundary layer thickness, and D is the diffusion coefficient of the dopant in the melt. It has been concluded that dopant inhomogeneities incorporated under turbulent convection were induced by changes in the microscopic growth rate and that boundary layer fluctuations were secondary.

A direct segregation analysis was not possible in the present investigation in view of the limited resolution of interface demarcation lines under pronounced backmelting. However, the similarity between segregation characteristics in the present and earlier studies and the correlation of remelt striations and temperature fluctuations in both cases can be taken as evidence that, in the present case also, microsegregation was controlled primarily by the microscopic growth rate under turbulent convection. This cause and effect relationship is apparently independent of the orientation of the destabilizing thermal gradient with respect to the gravitational field.

Pronounced dopant inhomogeneities were virtually eliminated under laminar convection. However, broadly spaced inhomogeneities were occasionally observed, as shown in Fig. 4A. These inhomogeneities were observed in regions grown under enhanced radial heat flow, as indicated by the pronounced concave shape of the demarcation lines.

The dopant concentration and microscopic growth rate along the spreading resistance impact traces visible in Fig. 4A are shown in Fig. 4B. It is seen that dopant concentration maxima do not coincide with growth rate maxima. Since the distribution coefficient of Ga in Ge is less than one, these results clearly indicate that in this case microsegregation is not controlled by the microscopic growth rate, but apparently by the boundary layer thickness.

Macrosegregation.—Longitudinal and radial macrosegregation profiles were obtained with spreading resistance by scanning at 50-250 μm intervals. The radial

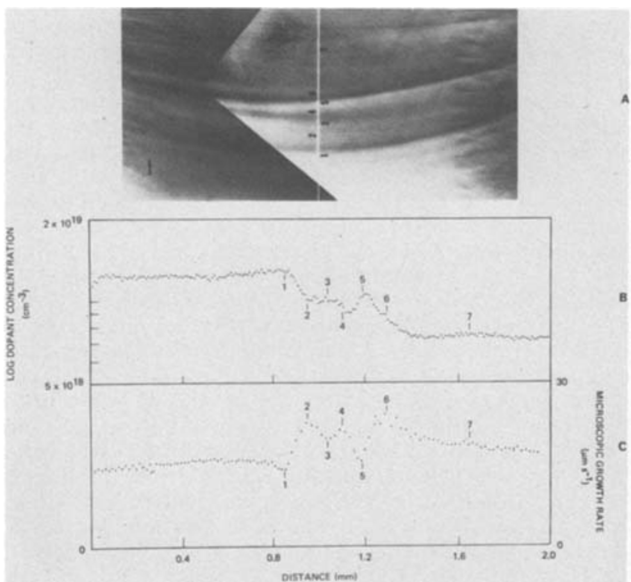

Fig. 4. Microsegregation analysis of Ge crystal grown under laminar convection: (A) micrograph of dopant inhomogeneities ("banding") across the crystal, (B) compositional analysis, (C) growth rate analysis. The increased concavity of the interface shape in this region suggests a transitory period of enhanced radial heat flow. Note that concentration maxima do not coincide with growth rate maxima.

scans were adjusted for interface curvature in order to represent the dopant concentration along the solid-liquid interface at a given time during growth.

The longitudinal macro-compositional profile of a 9 mm diam crystal is shown in Fig. 5 where the ratio of the dopant concentration at the growth interface (C_s) and the initial bulk liquid concentration (C_o) is plotted as a function of solidification distance (x). The experimental profile is shown together with the theoretical profile for diffusion-controlled segregation (13), given by

$$\frac{C_s}{C_o} = \{k_o + (1 - k_o)\ [1 - \exp\ (-Rk_ox/D)]\} \quad [4]$$

and the normal freeze (complete stirring) profile (14) given by

$$\frac{C_s}{C_o} = k_o(1 - f_s)^{k_o - 1} \quad [5]$$

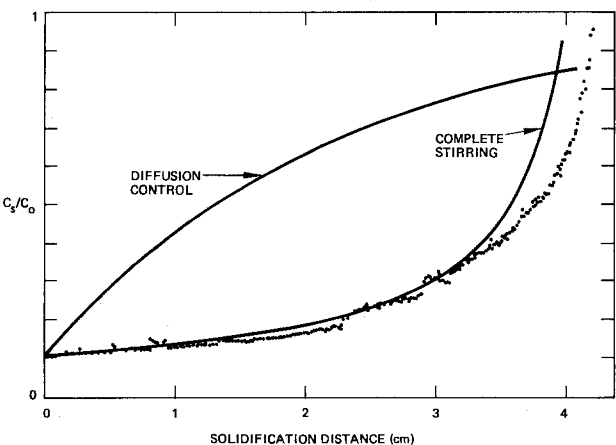

Fig. 5. Comparison of experimental longitudinal macrocompositional profile with theoretical curves for diffusion control and complete stirring (normal freeze). The experimentally determined average microscopic growth rate and bulk melt composition were 8 μm sec^{-1} and 1.1 $\times$ 10^{19} cm^{-3}, respectively. For the calculations we took $D = 1.5 \times 10^{-4}$ cm^2 sec^{-1} and $k_o = 0.087$.

where R is the average microscopic growth rate and f_s is the fraction solidified.

It is seen that the experimental profile is in good agreement with Eq. [5] indicating that high convective stirring reduces the diffusion boundary layer thickness to very small values. Thus, it is concluded that macrosegregation under turbulent convection is controlled by the boundary layer thickness. It is of interest to note that longitudinal compositional profiles of some 3 mm and 5 mm diam crystals grown under conditions of laminar convection indicated significant deviations from diffusion-controlled dopant segregation.

A characteristic value of the effective distribution coefficient (12), k_{eff}, defined as C_s/C_L in Eq. [3], was determined for each sample. For crystals grown under complete mixing conditions, $k_{eff} \rightarrow k_o$. For crystals in which the dopant concentration macro profiles were between the theoretical normal freeze and diffusion-controlled profiles, k_{eff} was determined iteratively by dividing the solid concentration by the bulk liquid concentration estimated for that fraction solidified consistent with the chosen value of k_{eff}. The measured values varied from k_o to 0.8; the highest value was found in a 5 mm diam crystal. The results are presented and discussed below.

A series of radial concentration profiles of a 5 mm diam crystal together with the central longitudinal profile are shown in Fig. 6. The concentration maximum in the first scan was correlated experimentally with the lateral variation in microscopic growth rate as the initially concave growth front flattened out during the first 3 mm of solidification. However, subsequent changes in the asymmetry of the profiles were found to be unrelated to microscopic growth rate variations. Therefore, the concentration variation along an individual profile reflects a variation in the boundary layer thickness; variations between successive profiles indicate time variations in the boundary layer thickness. The implications with respect to the fluid flow pattern are discussed further below.

Model for segregation under laminar convection.— A model for laminar fluid flow and segregation was developed in order to analyze the experimental results on macrosegregation in terms of relevant growth parameters. The growth configuration is modeled in two dimensions. The fluid flow pattern ahead of the solid-liquid interface is assumed to be an axis-antisymmetric

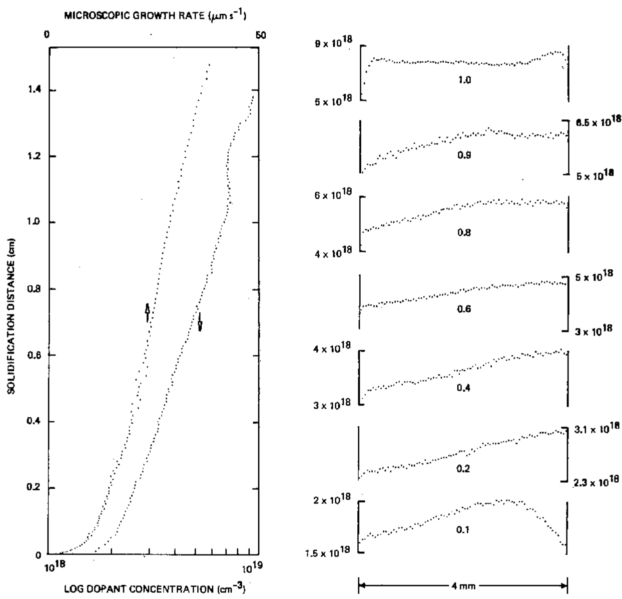

Fig. 6. Longitudinal (left) and lateral (right) concentration profiles of a 5 mm diam crystal. The lateral scans are plotted on a linear concentration scale. The number designating each lateral scan gives the respective solidification distance in centimeters.

cell with an aspect ratio of unity (circular flow pattern with fluid ascending and descending at opposite walls). Only the horizontal heat flow between the two vertical walls (held at different temperatures) is taken into account. Steady-state conditions are assumed.

Modeling of the segregation process was based on the establishment of a diffusion boundary layer thickness, δ_m, outside of which transport is convection-controlled. Here, δ_m was taken as the distance at which the diffusion flux equals 10% of the convection flux under steady-state conditions as suggested in a previous analysis of horizontal solidification (2). The diffusion flux was calculated from the dopant concentration gradient normal to the interface according to the approximation

$$\partial C/\partial x \approx C_o/\delta_m \left(\frac{k_{eff}}{k_o} - 1\right) \quad [6]$$

The convective flux was calculated from the horizontal component of the laminar fluid flow velocity, v_y, across the solid-liquid interface, given by

$$v_y = \left(\frac{\kappa}{d}\right)\frac{\partial\psi}{\partial x} = \frac{-2}{3}\,\frac{\kappa}{d}\,y^2(1-y)^2 \; x(1-x)(1-2x) \quad [7]$$

where ψ is the dimensionless stream function for a fluid of unity aspect ratio confined between two vertical plates held at different temperatures (15), x and y are dimensionless lengths in units of the melt diameter and denote the vertical and horizontal directions, respectively, κ is the thermal diffusivity and d is the distance between the vertical plates; ψ is given by

$$\psi = \frac{1}{3} N_R\, x^2 (1-x)^2 y^2 (1-y)^2 \quad [8]$$

where N_R is the horizontal thermal Rayleigh number. N_R is given by

$$N_R = \frac{g\alpha}{\nu\kappa}\, d^3\, \Delta T \quad [9]$$

where g is the acceleration due to gravity, α is the thermal expansion coefficient, ν is the kinematic viscosity, and ΔT is the temperature difference between the plates.

The values of v_y above the midpoint of the interface ($y = 0.5$) are shown in Fig. 7 as a function of distance from the interface for a 5 mm diam cylinder and various Rayleigh numbers. The magnitude of v_y increases from zero at the interface to a maximum value at about 1000 μm from the interface and decreases to zero at about 2500 μm since the flow pattern reverses direction at the upper portion of the convection cell.

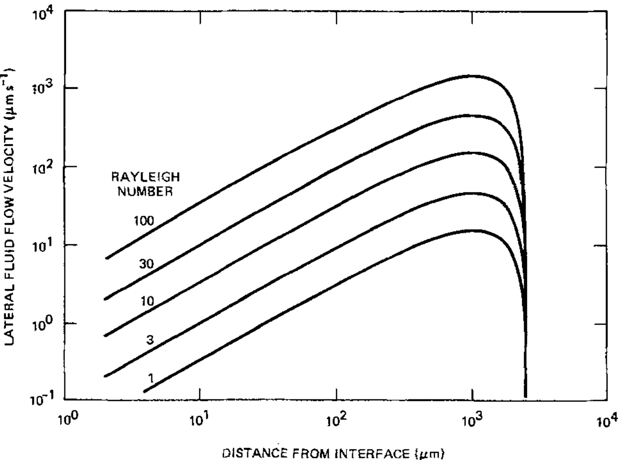

Fig. 7. Lateral fluid flow velocity in the center of a 5 mm diam cylinder as a function of distance from the solid-liquid interface over a range of Rayleigh numbers.

Equating the diffusion flux to 10% of the convective flux[2] and inserting the expression for v_y one obtains

$$\delta_m\, x(1-x)(1-2x) = \frac{15d}{\kappa N_R}\left[\frac{k_{eff}}{k_o} - 1\right] \Big/ \left[y^2(1-y)^2\right] \quad [10]$$

In Fig. 8, δ_m is plotted as a function of N_R for a 5 mm diam cylinder and various values of k_{eff}. It is seen that δ_m increases with decreasing N_R (for constant d and k_{eff}) because the fluid velocity decreases with decreasing N_R and the boundary layer thickness can extend further into the melt before convection dominates.

The final parameter to be introduced into the model is the microscopic growth rate, R. The growth rate corresponding to the conditions specified in Fig. 8 was estimated from Eq. [10] employing the BPS relation [3]. Equation [3] gives a convenient theoretical expression for k_{eff} as a function of R and δ_m. Accordingly, the growth rate is plotted as a function of boundary layer thickness in Fig. 9 for various Rayleigh numbers and a cylinder diameter of 5 mm; δ_m increases with increasing R for constant N_R and decreases with increasing N_R for constant R.

As indicated in Fig. 9, as the growth rate increases, a point is reached where δ_m can no longer have a meaningful value because the diffusive flux is always greater than 10% of the convective flux. This condition is chosen as one criterion for diffusion-controlled

[2] The equation of fluxes normal and parallel to the interface seems justifiable when considering diffusive and convective flux distributions ahead of the interface. The present calculation does not apply away from the center of the cylinder where the component of fluid flow normal to the interface is not negligible.

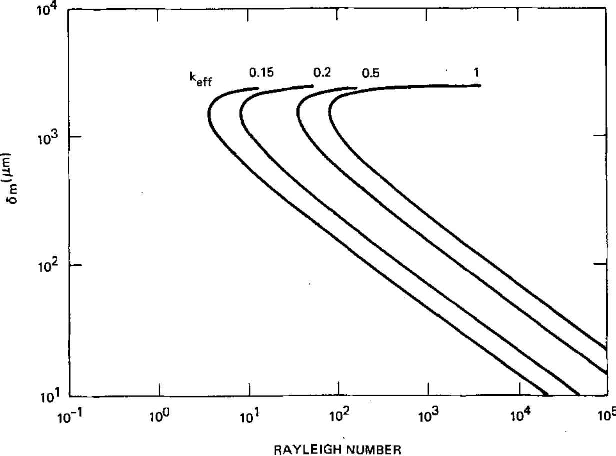

Fig. 8. Boundary layer thickness, δ_m, as a function of Rayleigh number in a 5 mm diam cylinder over a range of values of k_{eff}.

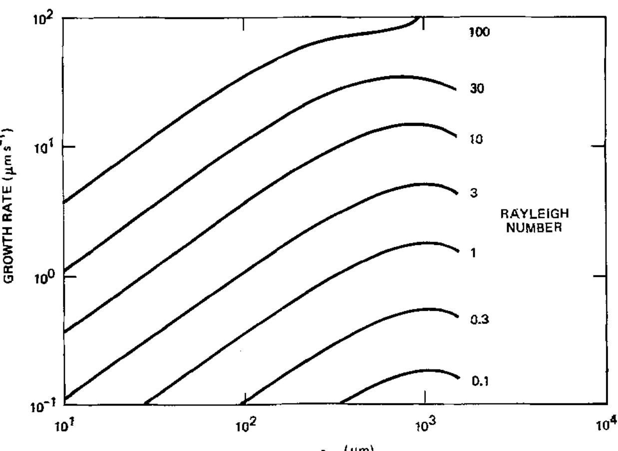

Fig. 9. Growth rate, R, as a function of boundary layer thickness, δ_m, in a 5 mm diam cylinder over a range of Rayleigh numbers.

segregation where the limit of k_{eff} becomes 1. A second criterion for diffusion control is

$$\delta_m > D/R \quad [11]$$

where D/R is the characteristic boundary layer thickness for diffusion-controlled segregation (13).

In order to present these calculations in a convenient graphical form representative of solidification under a wide range of conditions, Eq. [3], [10], and [11] were combined to determine k_{eff} as a function of growth rate for various hydrodynamic conditions. The results are shown in Fig. 10; they indicate a discontinuous rise in k_{eff} with increasing growth rate at constant Rayleigh number. The discontinuity results from the assumptions concerning the transition point from convection to diffusion control. The parameters used in the model can be readily modified to give a more realistic rise in k_{eff} as a function of growth rate. However, the essential features will remain the same: under a constant set of hydrodynamic conditions, diffusion-controlled segregation is predicted above a critical growth rate; the critical growth rate increases with increasing Rayleigh number. Thus, diffusion-controlled segregation is expected at sufficiently high growth rates and sufficiently low Rayleigh numbers.

Comparison of theory and experiment.—In order to analyze the experimental results on macrosegregation on the basis of the above, the magnitude of the destabilizing horizontal temperature gradients and the characteristic Rayleigh numbers during solidification were determined. The interface shape was revealed by demarcation lines and was found to be concave during the growth of all but the 9 mm diam crystals; thus, the horizontal gradients could be obtained from the vertical gradient and the experimental curvature parameters defined in Fig. 11 (taking the interface as isothermal). Both (near) symmetric and asymmetric interfaces were observed, as shown in the figure. The Rayleigh number for the symmetric (R_s) and asymmetric (R_a) interfaces are given by

$$R_s = \frac{1}{8}\,\frac{g\alpha}{\nu\kappa}\,Gd^3\,\Delta Z \quad [12]$$

$$R_a = \frac{g\alpha}{\nu\kappa}\,G\Delta Z\left\{d\left(\frac{1}{2} + CP\right)\right\}^3 \quad [13]$$

$$R_a = \frac{g\alpha}{\nu\kappa}\,d^3\,G\Delta A \text{ (the larger value)} \quad [14]$$

The geometric, hydrodynamic, and growth parameters obtained from seven crystals solidified under a wide range of growth conditions are shown in Table I. The analysis of the growth of the 9 mm crystals with

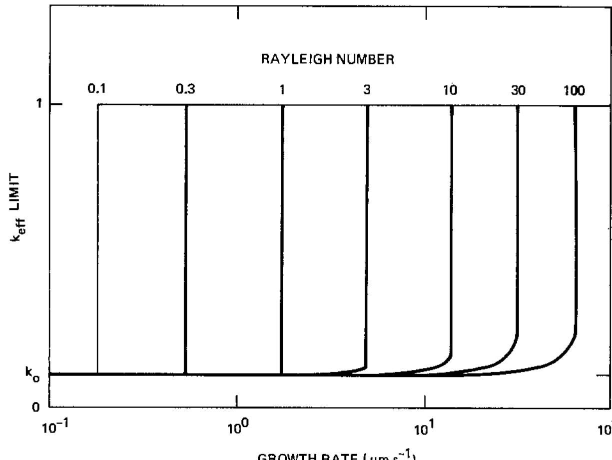

Fig. 10. The limit of k_{eff} as a function of growth rate in a 5 mm diam cylinder over a range of Rayleigh numbers.

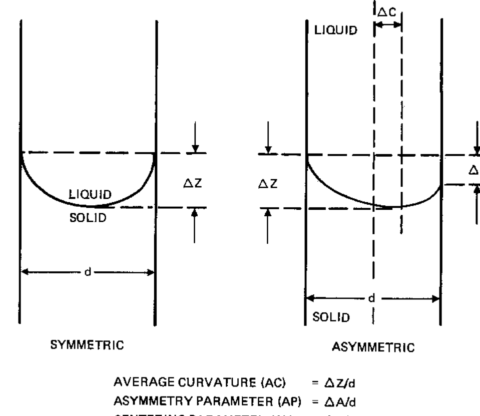

Fig. 11. Curvature parameters used to determine the Rayleigh number.

convex or "S"-shaped interfaces was also carried out on the same basis. By comparing experimental values of k_{eff} and growth rate, shown in the table, with the theoretical curves (such as those shown in Fig. 10) for 3, 4, 5, and 9 mm diam cylinders, it is found that theory and experiment are in good agreement.

In order to simplify the presentation of this analysis the theoretical curves for the 3-5 mm crystals were reduced to a plot of k_{eff} as a function of the ratio of Rayleigh number and growth rate at the transition of convection to diffusion control. Thus, a range of theoretical transition ratios is obtained and shown as a cross-hatched region in Fig. 12. This range was not extended to include 9 mm cylinders because macrosegregation was always convection controlled and the transition point was never approached. The experimental results are also shown in the figure. It is seen that the theoretical transition range is in good agreement with experimental data. Thus, diffusion-controlled segregation can be approached at sufficiently high growth rates and sufficiently low Rayleigh numbers. A representative Rayleigh number-to-growth rate ratio for the transition is 1 sec/μm. However, approaching effective diffusion control, $k_{eff} > 0.9$, requires rigorous control of the radial heat losses and the shape of the solidification front.

The present model, which applies to macrosegregation behavior, cannot be successfully extended to transient microsegregation because steady-state laminar convection is assumed. However, the apparent suppression of turbulent convection and associated dopant inhomogeneities during growth in the small diameter

ampuls (3-5 mm) as compared to growth in the larger diameter ampuls (9 mm) is consistent with established thermohydrodynamic criteria for the heating of a confined fluid from the side, on which the present model is based. It has been shown (15) that, in general, the transition from laminar to turbulent convection occurs at a critical Rayleigh number $N_R{}^C$. The value of $N_R{}^C$ decreases with decreasing cylinder diameter for small aspect ratios (the ratio of the melt height and diameter), and is independent of diameter for large aspect ratios (keeping the melt height constant). Therefore, the critical aspect ratio for a 3 mm diam crystal growth ampul is actually smaller than for a 9 mm diam ampul. However, enhanced hydrodynamic stability was achieved in the present experiments by reducing the ampul diameter because the actual Rayleigh numbers could be controlled below the critical levels more effectively.

A theory applicable to the present solidification configuration which predicts the critical Rayleigh number as a function of aspect ratio for low Prandtl number fluids, such as Ge, heated from the side is not available. In order to consider the present experimental results in this light, the procedure outlined in Ref. (15) to determine the theoretical relationship between $N_R{}^C$ and aspect ratio for air was used to obtain a similar curve for Ge. This was accomplished by substituting the appropriate materials constants for Ge, and by fitting the curve to an experimentally determined Rayleigh number of 2000 for the onset of turbulent convection in a 9 mm diam ampul. The result is shown in Fig. 13. It is seen that, as solidification progresses upward in a vertical direction solidification configuration, the critical Rayleigh number increases and the melt becomes progressively more stable. The experimental aspect ratios in this investigation ranged from zero (at the end of solidification) to a maximum value of 18 (at the beginning of solidification in the 3 mm diam ampul. The Rayleigh numbers measured for growth under laminar convection all lie below the curve at the corresponding aspect ratio, as shown in Fig. 13, indicating that the curve can serve as a guide-

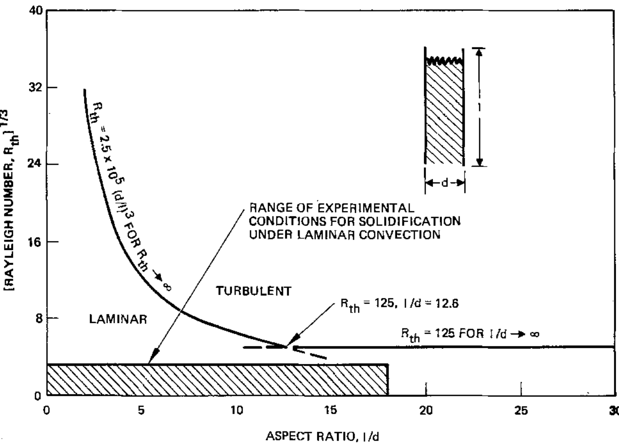

Fig. 13. Semi-empirical laminar-to-turbulent demarcation for directionally solidified Ge under stabilizing vertical thermal gradients.

line for laminar and turbulent convection regions for Ge growth in the present configuration. It is emphasized, however, that the curve is semi-empirical in nature and further theoretical work is needed.

The assumption in the present model of axis-antisymmetric flow is supported by the analysis of lateral segregation (Fig. 6) in which it was shown that the asymmetry of lateral compositional profiles reflects variations in boundary layer thickness. Thus, fluid descended on one side of the ampul, decreasing δ_m and k_{eff}, and ascended on the opposite side, increasing δ_m and k_{eff}. This conclusion is based on the consideration of the fluid flow velocity component normal to the growth interface as described in the BPS (12) analysis, which was not taken into account in the present model. However, if this indirect "sampling" of the fluid flow pattern is valid, then variations in the characteristics of successive lateral profiles indicate variations in the flow pattern. Thus, referring to the lateral scans in Fig. 6, the shift of the concentration maxima from the center of the crystal to the right, and then back toward the left, indicates an additional rotational component of the flow pattern about the axis along the direction of solidification; the flow pattern on one side of the ampul alternately shifts from ascending to descending with each half period of the rotational cycle. Therefore, a concentration minima becomes a maxima within the same time frame.

Three additional experimental observations support the presence of rotational displacement. First, analysis of broad dopant inhomogeneities which occurred under laminar convection (Fig. 4) revealed that the striations intersected successive demarcation lines continuously from one side of the crystal to the other. From the relative position of striations and demarcation lines, the apparent "lateral velocity" of the perturbation across the crystal could be measured; thus, for the striations shown in Fig. 4, it is about 1 mm/sec. (It should be pointed out that the actual three-dimensional nature of the striations was not determined, and it must certainly be much more complex.) It was observed that, while the first striation apparently travelled in one direction, successive striations travelled alternately in opposite directions. Although the precise mechanism of the formation of the striations has not been worked out, this result is consistent with the occurrence of rotational displacement in the melt during solidification.

The second observation, which is indicative of a rotational flow pattern, is the morphology of intersecting melt striations which occurred under turbulent convection (Fig. 3). Here, rotation of the hot fluid caused remelt on alternate sides of the crystal and the slope of the growth front shifted correspondingly from positive to negative with respect to a flat reference line.

Third, if alternate striations are formed as a result of flow reversal (due to rotation), then the spacing of successive striations must be related to the rotational period. Accordingly, the period of striations, ω, occurring under a wide range of hydrodynamic conditions was measured as a function of the local Rayleigh number with the aid of interface demarcation lines. The results, shown in Fig. 14, indicate that ω

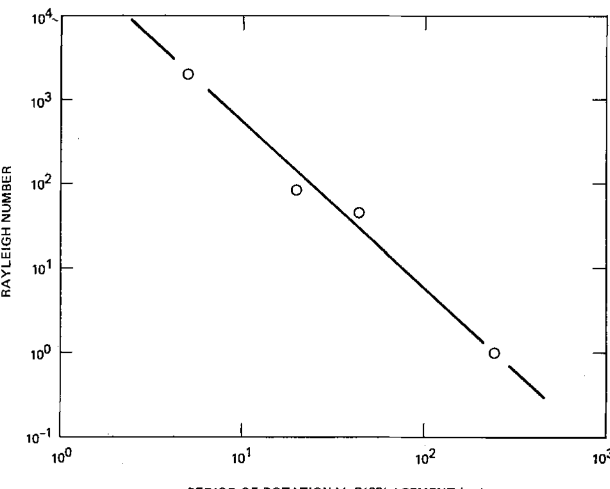

Fig. 14. Experimentally determined relationship between the Rayleigh number and period of fluid rotational displacement (deduced from the spacing of successive striations).

varies linearly with N_R. This trend agrees qualitatively with previous measurements of a confined fluid heated from the side (8, 11) and supports further the existence of fluid rotation.

Although the above segregation analysis represents a qualitative account of the fluid flow pattern adjacent to the solid-liquid interface, the three-dimensional flow behavior in the bulk of the melt cannot be ascertained. However, on the basis of the present results and existing theoretical analyses of similar configurations, such as a differentially heated inclined box (16) and a vertical tube with a square cross section heated from the side (17), it can be concluded that the flow pattern consisted of a single steady unicell under laminar convection and a series of cells, one above the other and with aspect ratios of 1, under turbulent convection. Further theoretical evaluation is necessary. Also, both the horizontal and vertical components of fluid flow must be taken into account to describe lateral segregation, although average longitudinal macrosegregation behavior predicted by the present model is in agreement with experiment.

To this point, only thermally driven convection has been considered. However, since the density of liquid Ge decreases with increasing Ga content, the contribution to the total vertical density gradient of the Ga concentration profile within the diffusion boundary layer is destabilizing. These conditions can lead to composition-driven, or solutal convection. The problem of fluid stability with simultaneous gradients of temperature and composition is complex and has received relatively little attention theoretically and experimentally; the potential influence of solutal convection in the present investigation can be evaluated semi-quantitatively at best. Calculated values of the total density gradient in the melt near the growth front were always positive (stabilizing); the density gradient due to the temperature was generally a factor of 5-10 times greater than that due to composition (18). Thus, the solutal effect would seem insignificant. On the other hand, theoretical calculations (19) predict that under certain conditions fluid instability can occur in spite of an overall stable density gradient when the thermal component is stabilizing and the compositional component is destabilizing. Although this theory is based on a thin film of infinite extent with stationary boundaries, and does not directly apply to the present experimental configuration, it indicates the possible significance of the solutal effect. The present experimental results, including thermal characterization, and macro- and microsegregation behavior, are consistent with convection driven by thermal density gradients.

Achievement of effective diffusion-controlled segregation.—It was one of the objectives of this study to determine the optimum vertical solidification configuration for minimal convective interference. As was shown above, the parameters leading to diffusion control are high growth rates, low vertical temperature gradients, small ampul diameter, and low interface curvature. The present apparatus allowed independent control of horizontal and vertical temperature gradients. However, the interface curvature and growth rate were found to be interdependent. As shown in Fig. 15, the curvature increased with increasing growth rate. In experiments carried out in quartz ampuls the curvature ($\Delta Z/d$) was found to be smaller and less sensitive to growth rate changes, $\left(\frac{\partial \Delta Z/d}{\partial R}\right)$, than in those carried out in graphite ampuls. Thus, the curvature parameter, $\Delta Z/d$, represents the balance of longitudinal and radial heat flows, since radial heat losses decrease with decreasing ampul thermal conductivity and with increasing growth rate.

On the basis of these findings, three modifications of the growth configuration were made: (*i*) programmed cooling was introduced to the cooling shaft to enhance longitudinal heat flow and render the solid-liquid interface shape less concave; (*ii*) a 5 mm ID × 8 mm OD quartz ampul was employed with concentric lava insulation to reduce heat losses; and (*iii*) the inner heater was positioned above the top of the melt to reduce radial heat flow in that region of the melt. With these modifications, it was found that the Rayleigh number was maintained below 0.9 and the curvature parameter at about 0.01.

A longitudinal macrocompositional profile of a crystal grown in this configuration is shown in Fig. 16. The microscopic growth rate was accelerated to 36 μm/sec and the composition steadily increased to within 15% of the steady-state value as solidification progressed. Since no theories were available to analyze segregation under conditions of nonconstant growth rate, the data were compared with theoretical curves for diffusion control, expressed in (4), using the measured average microscopic growth rate of 18 μm/sec. In view of the uncertainty in the values of D and k_o, a theoretical range was obtained by varying both parameters over the range of the published data, as shown in Fig. 16, bounded by curves calculated using values of D and k_o of 2×10^{-4} cm²/sec and 0.087, respectively, and of 1×10^{-4} cm²/sec and 0.11. The experimental data lie within the theoretical range, indicating that within a margin of uncertainty, effective diffusion-controlled segregation prevailed. Furthermore, the ex-

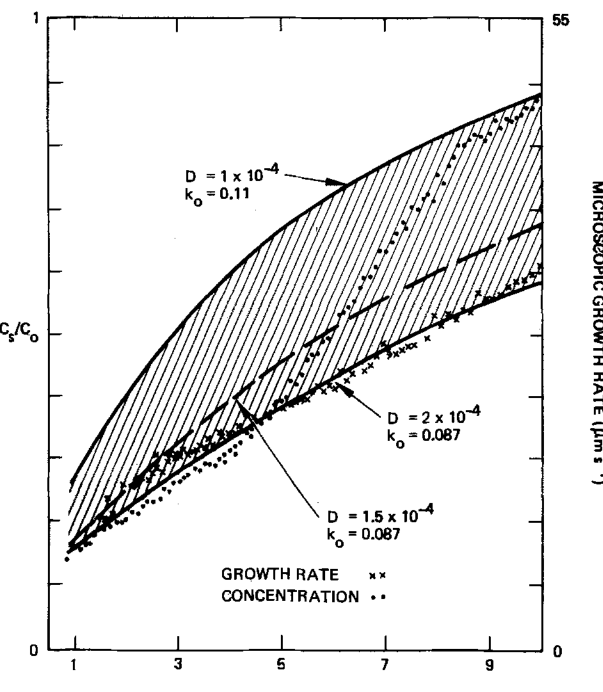

Fig. 16. Compositional and growth rate analysis of crystal grown under the highest achieved hydrodynamically stable conditions. The experimental concentration profile is compared with a range of theoretical curves for diffusion-controlled segregation (shaded area) corresponding to the uncertainty in the values of D and k_0. The theoretical curve calculated with the commonly accepted values of D (1.5×10^{-4} cm²/sec) and k_0 (0.087) is also shown (dashed curve).

perimental curve first lags and then leads the theoretical curve calculated with the most commonly accepted value of D, 1.5×10^{-4} cm²/sec, and k_0, 0.087. This behavior is expected for a diffusion-controlled growth under conditions of increasing growth rate and supports further that effective diffusion control was achieved.

Summary and Conclusion

Convection and convection-related segregation phenomena are dominant processes during directional solidification under stabilizing vertical thermal gradients due to the presence of unavoidable destabilizing horizontal thermal gradients. Under turbulent conditions the solidification rate is coupled to temperature fluctuations in the melt which leads to material with pronounced and random dopant inhomogeneities. This behavior is virtually eliminated under laminar convection. However dopant inhomogeneities broadly spaced are present due to perturbations in boundary layer thickness resulting from transient thermal conditions in the melt. Macrosegregation in both convective regimes is controlled by the boundary layer thickness. Effective diffusion-controlled segregation is achieved at sufficiently high growth rates and sufficiently low Rayleigh numbers. Thus, the generally made assumption that diffusion control or minimal convective interference prevails during vertical directional solidification is not valid without experimental verification: direct thermal characterization of the melt, micro- and macrocompositional profiling, and the determination of horizontal temperature gradients and interface curvature are essential in the evaluation of convection and its effects on segregation.

Partial Pressures over HgTe-CdTe Solid Solutions

I. Calibration Experiments and Results for 41.6 Mole Percent CdTe

J. P. Schwartz, Tse Tung, and R. F. Brebrick*

Metallurgy and Materials Science, Marquette University, Milwaukee, Wisconsin 53233

ABSTRACT

Calibration experiments are reported that enable the partial pressures of Hg, Te_2, and Cd to be calculated from measurements of the optical absorbance between 220 and 700 nm of the vapor phase. In particular, the self-broadening and Hg-broadening coefficients of the 228.7 and 325.7 Cd lines are established. The pressure ranges are between 10^{-2} and 32 atm for Hg, 10^{-4} and 10^{-2} atm for Te_2, and 10^{-7} and 10^{-5} atm for Cd. These calibrations are used in a study of the HgTe-CdTe solid solution containing 41.6 mole percent CdTe to determine all three partial pressures along the three-phase curve, the chemical potentials of HgTe and CdTe components, and the Gibbs free enthalpy of formation. Density and lattice parameter as a function of CdTe content are also reported.

HgTe and CdTe form a continuous range of solid solutions with the zinc blende structure in which the Hg and Cd atoms are distributed at random over the sites of one sublattice. The material is a semiconductor with a forbidden energy gap varying from about 2 eV for CdTe to a small negative value for the semimetallic HgTe, and various HgTe-rich compositions are used as infrared detectors. Some values exist for the densities and lattice parameters of the solid solutions (1, 2). The pseudobinary phase diagram has been determined by thermal analysis (1, 3) and by chemical analysis of the first crystals to freeze from large volumes of melt (4). Total pressure measurements have been made by a reflux method for pseudobinary melts containing up to 60 mole percent (m/o) CdTe and these also furnish a few liquidus points (5). However, neither the partial pressures over the pseudobinary solid solutions have been reported nor has the Gibbs free enthalpy of formation for the various solid solutions.

It is observed that the concentration of electronic carriers in these materials for a given Hg to Cd ratio can be varied by equilibration at temperatures above 200°C under various mercury pressures (6-10). In accordance with the simple defect chemistry of solids, it is inferred that this implies a varying concentration of native atomic point defects, which can act as donors or acceptors, and consequently a small range of stability around an atomic fraction of one-half for Te. Statistical thermodynamic arguments show (11) that if the value of y in the formula $(Hg_{1-x}Cd_x)_yTe_{1-y}(c)$ is restricted to values close to 1/2, then the sum of the chemical potentials of Hg and Te and that of Cd and Te are to a good approximation independent of y and functions of T and x (and weak functions of the total pressure, characteristic of condensed phases). Thus, for a given x and T, only one partial pressure need be fixed to fix all of the intensive variables, including the electronic carrier concentrations. For such purposes it is valuable to know the partial pressure of the predominant vapor species for both the metal-saturated and the tellurium-saturated solid solutions.

In the present paper we report measurements of the optical absorbance between 220 and 700 nm of the vapor coexisting with a solid solution of $x = 0.416$ between about 300° and 800°C. From these it is possible to obtain (*i*) the solidus temperature for this composition, (*ii*) the partial pressure of Hg along the three-phase curve, where the solid solution coexists with the vapor and another condensed phase, (*iii*) all three partial pressures in certain ranges of T and y, and (*iv*) the Gibbs free enthalpy of formation. (Moreover, direct evidence of the narrow composition range of stability about $y = ½$ is obtained.) Extensive calibrations experiments are required to convert the measured optical absorbances into partial pressures. This is particularly true in the case of Cd(g), which occurs at low partial pressures and shows an absorption line which varies from one that is narrower than our monochromator bandpass to one extensively broadened by mercury.

Measurements of the density and lattice parameter for various x-values were carried out to check the composition of the crystals and are also reported here.

Experimental

Materials.—The ternary solid solutions were furnished as large grain size samples by Mr. J. Schmit of Honeywell Corporate Research Laboratory in Bloomington, Minnesota. They were prepared by combining the weighed, spectroscopically-pure elements in sealed silica tubes with extra Hg to compensate for loss to a small volume of vapor phase, melting, cooling rapidly to below the solidus temperature, and annealing for long periods. The samples were slices cut from portions of the ingot where scanning electron microprobe analysis showed the Hg/Cd ratio typically to be the most uniform. The bottom one-third of each slice was discarded to further minimize any variation in Hg/Cd ratio following Mr. Schmit's experience. The remainder of each slice was then lightly lapped with 12 μm grit alumina and rinsed with methyl alcohol. The density of roughly 5g samples was determined by weighing in air and in distilled water of measured temperature using an analytical balance with a sensitivity of 0.1 mg. The slices were then ground in an agate mortar and pestle and roughly 2g was further ground to pass a standard 44 μm stainless steel sieve. Diffraction patterns were obtained with a Norelco diffractometer using CuKα radiation, a graphite monochromator in the diffracted beam, a ¼° divergence slit, and a 4° scattering slit. Values of 2θ between 23° and 133° were scanned at ¼°/min and a chart speed corresponding to 5.0 cm/° in 2θ. Thus angles could be read to 0.01°. The instrumental bandpass with this arrangement was 0.14°. The goniometer readings were corrected using ZnTe ($a_o = 6.1027$Å) as an external standard (12, 13).

In the instances in which it was necessary to add one or more of the elements to the slices, 6 nines pure elements from Cominco American, Spokane, Washington, were used.

Key words: mercury-cadmium telluride, partial pressures, three-phase curve, free enthalpy, chemical potentials.

Optical cells.—The T-shaped optical cells were made of fused silica and consisted of a cylindrical cell-proper with roughly plane, parallel windows through which light passed and a 50 cm long sidearm attached at right angles to the cylindrical axis at its midpoint. The cells were ultimately sealed off under vacuum at the sidearm, leaving it 20 cm long. The extra length made it possible to attach the cell to a vacuum system and outgas the cell-proper and entire final 20 cm length of sidearm. The length of the cell-proper, exclusive of window thickness, ranged between 1 and 10 cm and was measured to the nearest 0.01 cm before attachment of the windows. For low pressure runs the cell-proper was 1.7 cm ID with a 0.15 cm wall and 0.2 cm thick windows. For runs in which the pressure exceeded 15 atm, the cell-proper was 0.8 cm ID with a 0.3 cm wall and 0.3 cm thick windows. Also for the high pressure cells, 15 cm of the sidearm length closest to the cell-proper was 0.16 cm ID capillary to minimize the vapor volume, only the 5 cm length furthest from the cell-proper being enlarged to 0.7 cm ID to hold the sample. High purity silica windows with a transmission exceeding 90% at 200 nm were used for all cells. The volume of the optical cell-proper and that of the sidearm as a function of length were determined by adding water from a burette with 0.05 ml divisions. That of the high pressure cells was determined by adding mercury and weighing. The cells were cleaned using a 15 sec rinse with 37 weight percent (w/o) HF, several distilled water rinses, and then drained dry. They were then outgassed for 16 hr at 1000°C and $3(10^{-7})$ Torr. Upon cooling the cells were ready for loading.

A weighed amount of solid solution passing a 125 μm sieve and being retained by a 44 μm sieve was loaded via a long funnel along with a weighed amount of Hg or Te into the optical cell-proper. The cell was then put on vacuum again and after 5-10 min sealed off with an H_2-O_2 torch to leave a 20 cm long sidearm. This was a sufficiently long period that the pressure was in the 10^{-7} Torr range for samples with added Te and about 10^{-6} Torr for those with added Hg. After seal-off the sample was shaken into the end of the sidearm. The small amount of fine material remaining in the cell-proper and upper portions of the sidearm was sublimed toward the bulk of the sample by imposing a temperature of 600°C over all the cell except the lower 6 cm of the sidearm, which was surrounded by a water-cooled copper cylinder. The sample was then homogenized by an isothermal anneal at about 500°C for 20 hr, the cell-proper and upper portions of the sidearm being held at higher temperature.

In order to determine the relation between optical absorbance and partial pressure a number of cells were prepared which contained pure Te, pure Hg, pure Cd, or weighed amounts of Hg and Cd.

Experimental arrangement.—Figure 1 is a schematic of the optical system which is a GCA McPherson RS10, 1m focal length, 12,000 grooves/cm grating monochromator arranged with reverse optics, and an open sample area large enough to accept a 30 cm long furnace. Light from a 75W high-pressure xenon lamp is sent through a chopper wheel and split into two beams. These are alternately sent into the entrance slit of a prism disperser (incorporated to eliminate higher orders and minimize stray light) by a flipper mirror that oscillates at 6.66 Hz between two stable positions, spending 50 msec in each. A small lamp and silicon diode mounted on opposite sides of the chopper wheel provide the synchronizing signal for a lock-in amplifier. Most of the measurements were taken with 200 μm settings for the entrance and exit slits of the monochromator giving a spectral bandpass of 0.17 nm. A recorder displayed the common logarithm of the ratio of reference beam to sample beam intensity, *i.e.*, the optical absorbance. Measurements of the Cd line were also taken in transmission, with the flipper mirror stationary and sending the sample beam into the monochromator. Then the intensity of the transmitted sample beam was recorded and various slit widths between 20 and 100 μm were used. In operation a furnace containing an optical cell was placed in the sample beam so that the cylindrical axes of the cell-proper lay along the beam direction.

Figure 2 is a schematic of the split-T, 6-zone electrical resistance furnace with an optical cell in place. The furnace consists of two halves, each similar to that shown, that are hinged together along the upper edge of the upper leg of the T. Each zone is made of two heating elements connected in series, one in the lower half of the split-T, the other in the upper half, so that the two elements form a cylinder when the furnace is closed. The center zone of the upper leg of the T, Z2, is controlled electronically using a Platinel II thermocouple located near the middle of the cell-proper and between the heating element and the steel liner. Slave controls furnish an adjustable percentage of the power sent to the center zone and to the adjacent end zones, Z1 and Z3. Power to the center sidearm zone, Z5, surrounding the sample, is also directly controlled and the end zone, Z6, is under slave control. The power to Z4 is controlled manually using an autotransformer and ammeter. The liners serve to position the optical cell, to hold some of the measuring thermocouples in position, to provide additional thermal mass to smooth out short-time temperature fluctuations, and, especially in the case of the silver liner, to minimize the temperature gradients in the cell-proper and around the sample. The eleven thermocouples used for temperature measurement were all $5(10^{-2})$ cm diam thermocouple grade Pt; Pt, 10% Rh wire from Englehard In-

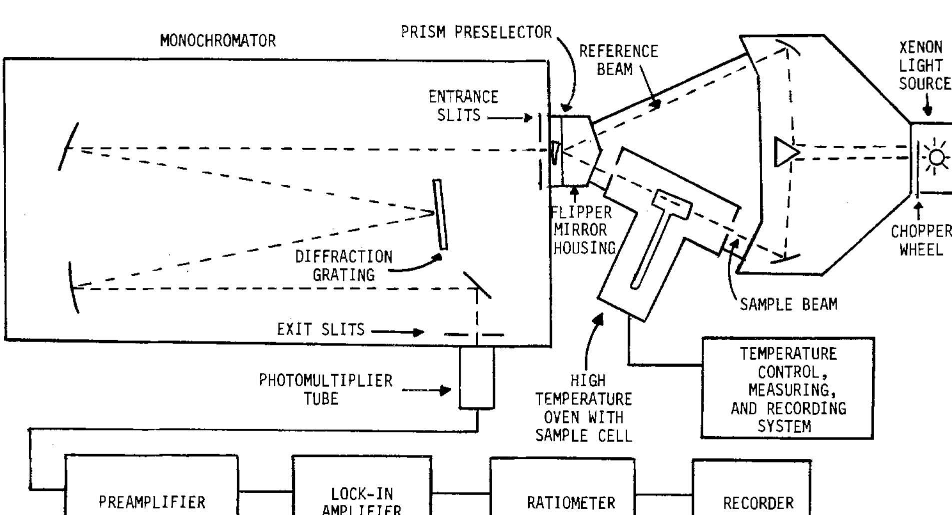

Fig. 1. Schematic of spectrophotometer with optical cell and furnace in place.

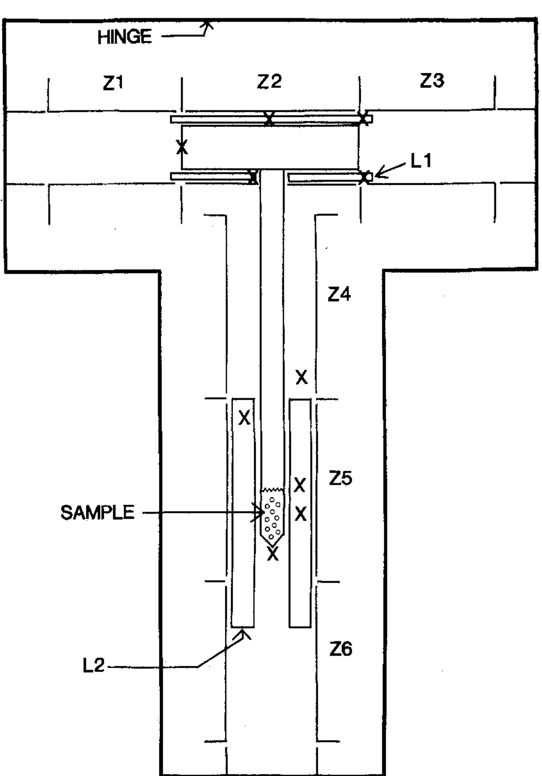

Fig. 2. Schematic cross section of hinged, split-T optical-cell furnace with cell in place. L1 is a 1.0 cm wall thickness, 10.2 cm long, split cylinder made of a high Ni-Cr steel (RA330; Rolled Alloy Products, Chicago, Il.). L2 is a 0.89 cm wall, 12.5 cm long cylinder of silver. The walls of both liners contain thermocouple holes. Thermocouple positions are indicated by an X. There are two thermocouples at the end of the cell near the boundary of zones Z1 and Z2. One is at the bottom of the cell, the other near the top.

dustries, New Jersey. A certificate of calibration showed that thermocouples made from sample sections of this wire gave emf's matching the NBS tables to within −0.6° to −1.3°C between 400° and 1100°C. The temperatures of the six thermocouples distributed around the cell-proper were read to 0.75°C using a Multipoint Honeywell Potentiometric recorder. Those of four of the five thermocouples placed along the sidearm were read to the nearest 0.1°C using a Fluke, Model 2000, Digital Thermometer. The fifth thermocouple placed against the sidearm near the middle of the sample had a cold junction in an automatic ice bath and its emf was measured to the nearest 0.1 μV using a Leeds and Northrup, Model 7564, differential potentiometer. Temperatures were obtained using the National Bureau of Standards Thermocouple Reference Tables. Consistency of the temperature readings from the three instruments was checked in separate experiments in which the thermocouple hot junctions were held as close together as possible in the middle of the silver liner. Readings from the digital thermometer and differential potentiometer agreed to within 1°C over the 400°-800°C range while those of the Multipoint recorder agreed with these to within 5°C.

Experimental procedure.—In a set of measurements the temperature of the optical cell-proper was held fixed at 755°C with a variation of 3°C or less across the cell. For a few high sample temperature measurements with metal-saturated solid solutions, the optical cell temperature was held at 800°C. With the sample temperature near 200°C, and insufficient vapor present to give a measurable signal, the optical absorbance was measured between 200 and 700 nm. This measurement was repeated 2-5 times to furnish an average base line characterizing losses in the sample beam

$$D(\lambda) = \log_{10}\left(\frac{I_{RO}}{I_{SO}}\right) \quad [1]$$

where I_{RO} and I_{SO} are the initial intensities in the reference beam and sample beam, respectively. The sample temperature was then increased so absorption became measurable, measurements made, and the sample temperature increased again by 5°-20°C. At a given sample temperature setting, the sample temperatures and the absorbance at some strongly adsorbing wavelength were recorded as a function of time. When both were steady the optical absorbance was measured as a function of wavelength. When Cd was present the transmission of the 228.7 and 325.7 nm lines was also recorded. Temperatures were recorded for the various positions along the cell-proper and sidearm. The net optical absorbance at a given wavelength was calculated by subtracting that of the base line from the total measured, $\log_{10}(I_R/I_{S,t})$, to give

$$D(\lambda, \text{net}) = \log(I_R/I_{S,t}) - \log(I_{RO}/I_{SO}) \quad [2]$$

where $I_{S,t}$ is the intensity of the light within the spectral bandpass at λ that is transmitted by the vapor-containing optical cell. Assuming (*i*) that no change occurs in the optical characteristics of the sample-beam path except that due to the changing vapor state and (*ii*) that any change in lamp output effects both beams equally so the $I_R = fI_{RO}$ and $I_{S,i} = fI_{SO}$, then the net optical density calculated from Eq. [2] can be written as

$$D(\lambda, \text{net}) = \log(I_{S,i}/I_{S,t}) \quad [3]$$

where $I_{S,i}$ is the intensity of the sample beam incident on the optical cell. The net optical absorbance is then a measure of the vapor absorbance alone. The assumed constancy of the base line with time was monitored at nonabsorbing wavelengths and occasionally was also checked after a run by cooling the sample to near 200°C and measuring the optical absorbance. The net optical densities at various wavelengths were plotted on a log scale against the reciprocal absolute sample temperature. Abrupt and significant base line shifts, which would appear as discontinuities, were not detected.

Accuracy of measurements.—The monochromator wavelength indicator was checked by locating the absorption maxima of Zn at 213.8 and 305.7 nm, of Cd at 228.7 nm, and Hg at 253.7 nm, with the vapors at a pressure of about 10^{-5} atm in each case. This showed the indicator was low by 0.4 nm at these wavelengths and so all wavelengths quoted here have been corrected by adding 0.4 nm to the reading. Wavelengths could be reproduced to within a few hundredths of a nanometer. Total optical absorbances were measured between 0.01 and 2.7. Reproducibility and noise were worse at 220 nm than at 300-700 nm. Typical noise amplitudes at 220 nm were ± 0.02 at optical absorbances between 0.01 and 1.0 and ± 0.1 at 2.0. One might then expect the partial pressures given in this paper to be accurate within 2% to 10%. In most cases, except for the partial pressure of Cd(g) and that of Hg(g) below 0.01 atm, several values for a partial pressure were obtained by using the optical absorbance at several different wavelengths and the average taken. These average values and the associated standard deviation are given in the tables that follow.

Photometric accuracy was checked by measuring the optical absorbance of Zn vapor in a 1000°C optical cell between 220 and 270 nm as a function of the temperature of the liquid Zn. Plots of the logarithm of the net optical absorbance *vs.* reciprocal absolute sample temperature could be well represented at all wavelengths as parallel straight lines with a slope twice that of the vapor pressure of zinc. Moreover the relative optical densities at different wavelengths agreed closely with those obtained elsewhere with a different monochromator and furnace (11, 14).

The response time for a full scale deflection from near zero absorbance to 3 was about 2.5 sec. Consequently when rapid changes in absorbance as a function of wavelength occurred the scanning rate was appropriately decreased, sometimes to zero.

The sample temperature was taken as the average of those recorded from the three thermocouples placed near either end of the sample and near the middle after adding a correction of + 1.0°C. The maximum temperature variation across the sample was about 3°C. We estimate our corrected average sample temperatures are accurate to ± 1.5°C. The temperature of the optical cell-proper is estimated to be correct to ± 3°-5°C. For fixed partial pressures, the concentrations of the vapor species in the light path depend on the reciprocal absolute temperature of the optical cell. The uncertainty in the optical cell temperature therefore contributed an error of less than 1% to the measured optical absorbances.

Density and Lattice Parameter

Densities were determined at 20°C to within 0.1%. Lattice parameters were determined with a standard deviation of one part in 10^4 from a least squares fit to the corrected values of 2θ. Since the unit cell contains four formula units, $Hg_{1-x}Cd_xTe$, the value of x is given in terms of the density, d, in g/cm^3 and the lattice parameter, a_o, in angstroms as

$$x = \frac{328.19 - (0.15056)da_o^3}{88.19} \quad [4]$$

The variation in lattice parameter from $x = 0$ to 1 is only 1/3% and if this is a linear variation, then Eq. [4] is a linear relation between x and d to an accuracy of 0.05% in d. In fact, the experimental values of x and d are well fit by a least squares straight line that goes through the densities of pure HgTe and CdTe

$$d = 8.077 - 2.225X \quad [5]$$

The experimental values obtained for x, d, and a_o are given in Table I along with the standard deviation between measured and calculated values of 2θ. It is apparent the percentage variation of density with x is much larger than that in a_o and so density measurements afford the more sensitive means of determining x. The use of Eq. [4] assumes the density samples are homogeneous and free of voids. The former was evidenced by the fact the half-width of the diffraction line was essentially equal to the instrumental bandpass of 0.14 even at the highest values of 2θ near 133°. Figure 3 shows a_o as a function of x.

Our values and all but one of those from Blair and Newnham (1) fall close to straight line through the values for HgTe and CdTe. Those of Wooley and Ray (2) form a bow and are somewhat lower.

Calibration Measurements

Tellurium.—From a number of closely agreeing studies (15-18) the vapor pressure of Te above its melting point is given to within 2% by

$$\log P_{Te_2}{}^{\circ} \text{ (atm)} = -5960.2/T + 4.7191 \quad [6]$$

Table I. Experimental values at 20°C for $Hg_{1-x}Cd_xTe$

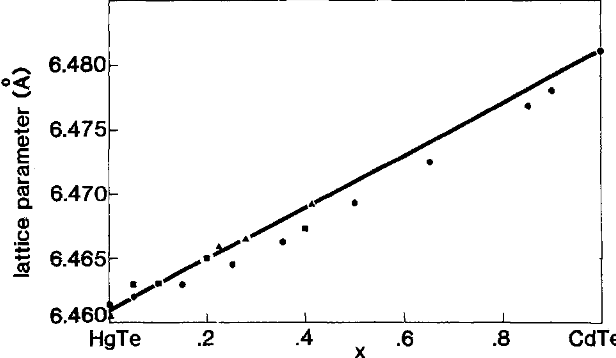

Fig. 3. Lattice parameter at 20°C as a function of the mole fraction of CdTe in HgTe-CdTe solid solutions. Triangles: this study. Circles: Wooley and Ray (2). Squares: Blair and Newnham (1).

Selected values by Hultgren *et al.* (19), however, favor the data of Machol and Westrum (20), which show a decrease from values calculated from Eq. [6] that starts at about 620°C and amounts to about 20% at the 449.5°C melting point. The experimental points are relatively few in number between 450° and 500°C and the values are near the experimental limits of precision. In contrast, the optical absorbance of the strong Te_2 peaks in the 199.5-206.0 nm region indicate that Eq. [6] is followed down to the melting point (18). The present absorbance measurements in the visible also indicate that this is so to within ± 5%, the optical absorbance of a number of wavelengths being well represented by parallel straight lines with a slope of −5960 on a plot of log D *vs.* $10^3/T$ as shown in Fig. 4. We therefore choose Eq. [6] as the best representation for the vapor pressure of Te above its melting point. We should note that the tellurium calibration runs were made somewhat after the rest of those described here. The diameter of the sidearm section of the furnace was enlarged and a 20 cm long, 4.0 cm ID heat pipe inserted; one end being within 4.6 cm of the optical cell-proper and insulated from it except for a hole through which the optical cell sidearm passed. A 12.5 cm long sidearm cell was used. A close-fitting 12.5 cm long Ag liner was inserted inside the heat pipe and symmetrically around the part of the cell sidearm containing the Te(l). Temperatures within the Ag liner and adjacent to the cell sidearm were constant to within 0.3°C over the 2 cm length of the sample and those measured by the digital voltmeter and differential potentiometer agreed to within ± 0.2°C. For an optical path at 755°C the net optical density for 200 μm slits is written as

$$P_{Te_2} \text{ (atm)} \equiv P_2 = 9.78 a_\lambda D_\lambda / L \quad [7]$$

where L is the optical path in centimeters and the values of a_λ are listed in Table II. The wavelengths listed include a number that were not tabulated in a previous study (21) using different instruments. For other wavelengths, the agreement with older values of a_λ is within 3%. The vibronic spectrum of Te_2(g) in the visible has been described previously (22). In particular, the vibronic peaks strongly overlap so that the difference in adjacent maxima and minima are only about 10% of the optical absorbance at the maximum. Moreover the latter values are independent of spectral bandpass between 0.08 and 0.17 nm (21). Finally, Lamberts law is followed and D varies linearly with path length.

Mercury.—It has been known for some time that the 5^1S_0-6^3P_1 absorption line of Hg at 253.7 nm broadens extensively toward the visible for pressures greater than 1 atm. (The absorption lines of Zn(g) and Cd(g) associated with the ground states of these atoms behave similarly.) Consistent with the statistical theory

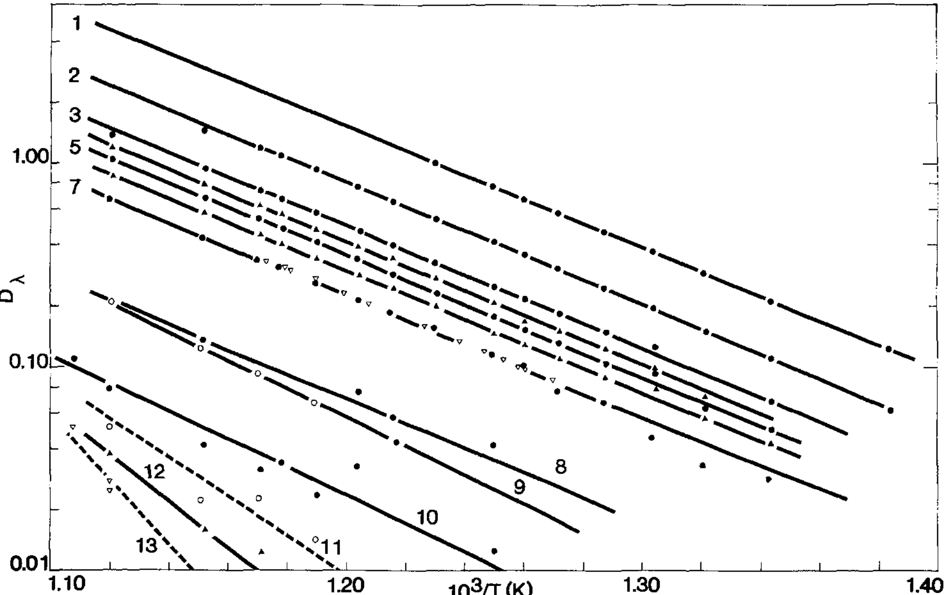

Fig. 4. Optical absorbance of $Te_2(g)$ at various wavelengths plotted on a log scale vs. 1000 times the reciprocal absolute temperature of a liquid Te sample. Data taken with a 0.17 nm spectral bandpass and a 9.78 cm optical path at 755°C. The seven uppermost lines have the same slope as the vapor pressure of Te. The inverted triangles along the line for 500.4 nm are from Ref. (21). 1, 431.5 nm; 2, 464.0; 3, 481.8; 4, 485.6; 5, 490.2; 6, 496.8; 7, 500.4; 8, 340.4; 9, 255.4; 10, 330.4; 11, 280.4; 12, 320.4; 13, 310.4 and 300.4.

of broadening, the optical absorbance on the visible side of the line center depends on the square of the mercury concentration. The proportionality constants between optical absorbance and the square of the mercury pressure have already been determined (21) for a 755°C optical cell for wavelengths between 255 and 330 nm and for pressures between about 1 and 20 atm. The purpose of the present measurements was to redetermine these constants, to extend the measurements to 30 atm, to obtain a vapor pressure point in that vicinity, and to obtain a relation between absorbance and Hg pressures for pressures below 1 atm. These results are given below, but first it is necessary to discuss the vapor pressure of Hg(l) and the equation of state for Hg(g).

The vapor pressure of Hg(l) can be adequately represented between 0.1 and 38 atm by the equation

$$\log_{10} P_{Hg}^\circ \text{ (atm)} = -3099/T + 4.920 \quad [8a]$$

Equation [8a] agrees with tabulated selected values (19) to 1% at 0.5 atm and to within 0.5% at 1 and 10 atm. Between 10 and 38.5 atm it agrees to within 1% with the measured values of Sugawara and Sato (23), who used a six term equation to fit their points to about 0.5%. These authors also developed an equation of state for Hg(g), based in part on their vapor pressure measurements. For the saturated vapor, the difference between PV/RT and unity is -4.7% at 28.3 atm, -3.8% at 19.6 atm, -2.4% at 10 atm, and -0.44% at 1 atm. Another equation of state (24) based on vapor pressure data only up to 6 atm gives values for this difference that are in fair agreement and are, respectively, -4.0%, -3.1%, -2.1%, and -0.40%. Between 10^{-3} and 10^{-1} atm the selected values (19) of P_{Hg}° are given to within 1% by

$$\log P_{Hg}^\circ \text{ (atm)} = -3157/T + 5.028 \quad [8b]$$

Figure 5 shows the optical absorbance at four wavelengths for a 755°C optical cell as a function of the Hg(l) sample temperature. The total Hg content of the cell was 0.2940 ± 0.005g. At 631°C ($10^3/T = 1.106$) and above the optical absorbance no longer increases with increasing temperature, indicating complete vaporization of the Hg(l). Knowing the volume of the cell and sidearm, assuming the temperature varied linearly along the sidearm between the values measured at four positions, and using Sugawara and Sato's equation of state, one calculates that $P_{Hg} = 31.4$ atm. At 631°C Eq. [8a] gives 31.1 atm in good agreement. Below the complete vaporization temperature in Fig. 5, the data at each wavelength can be well represented by straight lines of log D vs. $1/T$ with a slope that is

* b_λ for a 9.83 cm optical path at 1028 K as obtained with a 0.17 nm spectral bandpass. L path length in cm. r_λ values from Ref. (21) are for wavelengths 0.4 nm shorter than listed and are increased by 1% to make them compatible with the Hg vapor pressure equation used here.

twice that in Eq. [8a]. Similar behavior is shown at lower pressures and shorter wavelengths and the results are in good agreement with those from a study (21) of HgTe(c) as can be seen in Table III. The range of pressures over which the constants in Table III were determined for each wavelength can be inferred from the path length and the fact that the measured net optical absorbances were in the 0.05-2.6 range. For wavelengths greater than 300 nm the measurements were made using a 2.92 cm path cell and the optical absorbances were normalized by multiplying by 9.83/2.92.

In contrast to the measurements of $Te_2(g)$, those on Hg(g) discussed above were made with the monochromator wavelength scan-drive off. Thus the somewhat slow response time of the measuring electronics was not a factor when the optical absorbance changed rapidly with wavelength near 253.7 nm.

At low values of P_{Hg} the optical absorbance of the 253.7 nm line was scanned as a function of wavelength and the area of the line computed. The results are shown in Fig. 6. For values of $10^3/T$ less than about 2.4, where $P_{Hg}{}^\circ = 3.7(10^{-3})$ atm, the measured full line width at half-intensity is greater than the spectral bandpass of 0.017 nm and the absorbance area has a slope close to that of the vapor pressure on the log (area)-$10^3/T$ plot. Obtaining a least squares straight line to the high temperature portion of Fig. 6 and using Eq. [8b] to eliminate $10^3/T$ in favor of P_{Hg}, one obtains

$$\log P_{Hg}\ (\text{atm}) = 0.9382 \log A - 1.763 \qquad [9]$$

where the area of the absorbance curve, A, has the units of optical absorbance-angstroms. This equation is used here to establish P_{Hg} in the 0.001-0.20 atm range.

Cadmium.—The true area of an atomic absorption line on a plot of optical absorbance *vs.* λ is proportional to the number of atoms in the light beam that are in the initial state of the optical transition. In the experiments to be discussed, the partial pressure of Cd

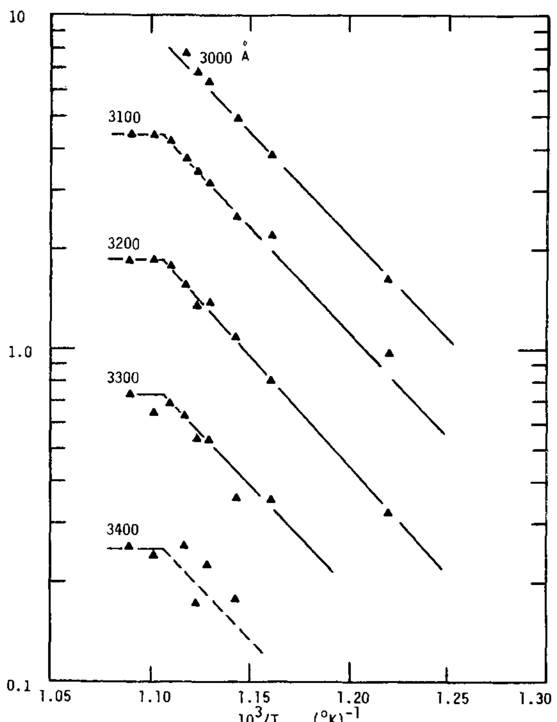

Fig. 5. Normalized optical absorbance on a long scale as a function of the reciprocal temperature of a liquid Hg sample. Absorbance is measured with a 0.17 nm spectral bandpass and a 2.92 cm optical path at 755°C. Measured values are normalized to a 9.83 cm path by multiplication by the factor 9.83/2.92. Labels give the wavelength in angstroms.

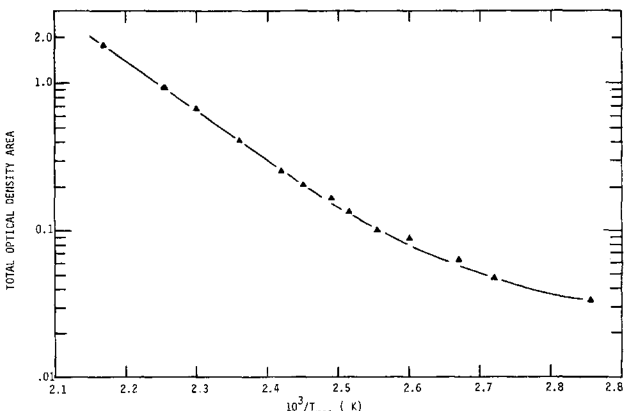

Fig. 6. Area of the 253.7 nm Hg line in units of optical absorbance-angstroms as a function of the reciprocal temperature of a liquid Hg sample. Data taken with a 0.017 nm spectral bandpass and a 9.83 cm optical path at 755°C.

varied over a range of low values while that of Hg was simultaneously in the 1-30 atm range. Correspondingly the true half-width of the Cd lines varied from values less than our smallest spectral bandpass of about 0.01 nm to values that were comparable or somewhat larger because of broadening by Hg. In such a case it is not possible to obtain reliable values of the partial pressure of Cd, P_{Cd}, from optical absorbance measurements unless extensive calibration measurements are made over a range of known P_{Cd} values for a set of known values of P_{Hg}. Moreover, the calibration results are unique to the slit settings and even to the particular monochromator used (25). We chose to shorten the labor somewhat, at the necessity of relying on the theory of lineshape, by making transmission measurements and obtaining the area in the transmission minima of the Cd lines. This is a common procedure when dealing with atomic lines and relies on the fact that although the transmission curve is distorted when the spectral bandpass is comparable to or larger than the true line half-width, the true area of the transmission curve is obtained to a first approximation. However, a knowledge of the absorption lineshape is necessary to extract the partial pressure of the absorber atom from the transmission area. The necessary results from lineshape theory are now summarized (26). If the intensities of the incident and transmitted beams at some frequency ν are I_0 and I_ν, respectively, then these are related by

$$I_\nu = I_0 \exp(-k_\nu L) \qquad [10]$$

where L is the optical path length and k_ν is a frequency-dependent absorption coefficient. Comparison with Eq. [4] shows the net optical absorbance used here and k_ν are related by

$$D(\lambda, \text{net}) = k_\nu L/2.303 \qquad [11]$$

It is assumed that at sufficiently low P_{Cd} that the lineshape is the Voigt profile given by

$$k_\nu = \frac{k_0 a'}{\pi} \int_{-\infty}^{\infty} \frac{\exp(-z^2)\,dz}{(a')^2 + (\omega - z)^2} \qquad [12]$$

where the reduced frequency ω is given in terms of the frequency of the line center, ν_0, and the Doppler half-width $\Delta\nu_D$ by

$$\omega = 2(\nu - \nu_0)(\ln 2)^{1/2}/\Delta\nu_D \qquad [13]$$

The parameter k_0 is proportional to the number of atoms, N, in the optical path that are in the initial state for the particular transition in question and to the oscillator strength of the transition, f, as given by

$$k_0 = 9.40(10^{-2})(\ln 2)^{1/2} N f/\pi\Delta\nu_D \qquad [14]$$

The initial state for the optical transitions giving rise to the 228.7 and 325.7 nm lines observed here is the ground state of Cd(g). At the low temperatures and light intensities used, all of the Cd atoms are in the ground state and N is the concentration of Cd atoms. The Doppler half-width is given by

$$\Delta\nu_D = (2\nu_0/c)(2[\ln 2]RT/M)^{1/2} \quad [15]$$

where R is the gas constant, T is the optical cell temperature, and M is the gram-atomic weight of Cd. The width of the Voigt line is determined by the broadening parameter, a', given by

$$a' = (\Delta\nu_N + \Delta\nu_S + \Delta\nu_F)(\ln 2)^{1/2}/\Delta\nu_D = a_N + a_S + a_F \quad [16]$$

where the natural half-width is determined by the lifetime of the excited state, τ

$$\Delta\nu_N = 1/(2\pi\tau) \quad [17]$$

and where the self-broadening contribution, a_S, is assumed to be proportional to the partial pressure of the absorber while the foreign gas contribution a_F is in general a sum of terms, one for each foreign gas that is proportional to the partial pressure of that foreign gas. It is necessary to experimentally determine a_S and a_F. The lifetimes τ, and equivalently, the oscillator strengths, of the 228.7 and 325.7 nm lines are known so that the natural half-width and the parameter k_0 in Eq. [14] can be calculated. Equation [12] predicts a lineshape that is symmetrical about ν_0 and the equation is valid sufficiently close to ν_0 and at low pressures. At frequencies sufficiently far from the line center and at high pressures the statistical theory of broadening holds and the Cd lines broaden extensively toward the visible. The proportionality between optical absorbance and the square of P_{Cd} has already been utilized (14) in determining the partial pressures along the three-phase curve for CdTe(c). In this study the Voigt lineshape was assumed to hold as long as the transmission curves were symmetrical. Finally, the total absorption as obtained in a transmission measurement is defined as

$$y' = \frac{(\ln 2)^{1/2}}{\Delta\nu_D}\int_0^\infty [1 - \exp(-k_\nu L)]d\nu \quad [18]$$

For a given value of a', y' can be calculated as a function x' where

$$x' = 10.6k_0L = NfL(\ln 2)^{1/2}/\pi\Delta\nu_D \quad [19]$$

Curves of y' as a function of x' are known as curves of growth and are given for a few values of a' by Mitchell and Zemansky (26) and by Penner (27). The measured transmission areas correspond to the integral factor of Eq. [18] with $d\nu$ replaced by $d\lambda$ and the wavelength in angstroms. They are converted to the integral factor by multiplication by $\nu_0^2/3(10^{18})$, where ν_0 is the frequency at the line center. Values of x' were calculated from Eq. [19] using published values of the oscillator strength and assuming that Cd(g) is an ideal gas whose pressure can be calculated from the Cd sample temperature and the vapor pressure equation given by

$$\log P_{Cd}^{\circ}\ (\text{atm}) = -5808/T + 5.956 \quad T < 594\ \text{K}$$
$$= -5317/T + 5.119 \quad T > 594\ \text{K} \quad [20]$$

Equations [20] match the tabulated values [19] to within 2% between 10^{-8} and 1 atm.

Figure 7 shows a few curves of growth along with the experimental points for the 228.7 Cd line. At low Cd pressures the experimental points follow closely the curve of growth for $a' = 0.023$, corresponding to natural and Doppler broadening. At higher pressures, the points cross the curves of growth indicating the onset of significant self-broadening. The 325.7 nm line shows a similar behavior except that at the lowest pressures the experimental points are somewhat above the theoretical curve for $a' = 2.69(10^{-5})$. If the self-broadening parameter, $a_S = a' - a_N$ is plotted against P_{Cd}, Fig. 8 results. The best straight lines of unit slope through the points are given by

$$a_S(228.7\ \text{nm}) = 108P_{Cd}(\text{atm}) \quad [21]$$

$$a_S(325.7\ \text{nm}) = 1.50P_{Cd}(\text{atm}) \quad [22]$$

In terms of the full frequency width at half-intensity, Eq. [21] and [22] correspond to

$$\Delta\nu_{HW}(228.7) = 2.75(10^{11})P_{Cd} \quad [23]$$

$$\Delta\nu_{HW}(325.7) = 2.74(10^{9})P_{Cd} \quad [24]$$

Theoretical calculation (28, 29) of this half-width for resonance broadening is most accurate for lines with oscillator strengths near unity, such as the 228.7 line, and are of the form

$$\Delta\nu_{HW} = ke^2fN/8m\nu_0 \quad [25]$$

with k of the order of unity and equal to 1.45 for

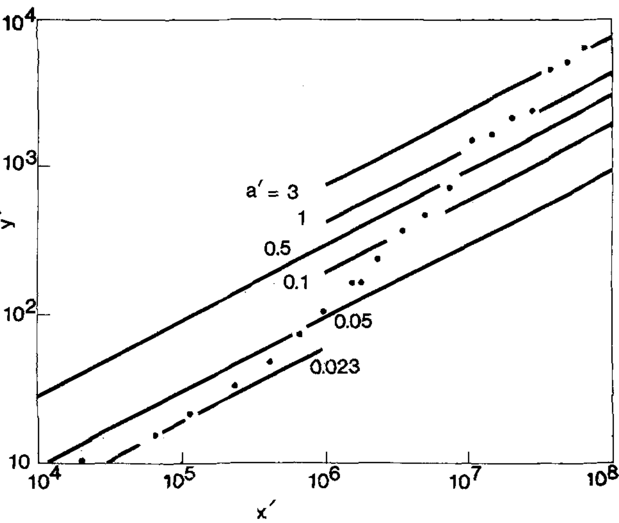

Fig. 7. Parameter y' of Eq. [18], which is proportional to the transmission area, plotted against x' of Eq. [19] for the 228.7 nm Cd line on a log-log scale. A few curves of growth are shown for labeled values of a'. Data taken with a 9.40 cm optical path at 755°C. $x' = 7.57(10^9)\ P_{Cd}(\text{atm})$.

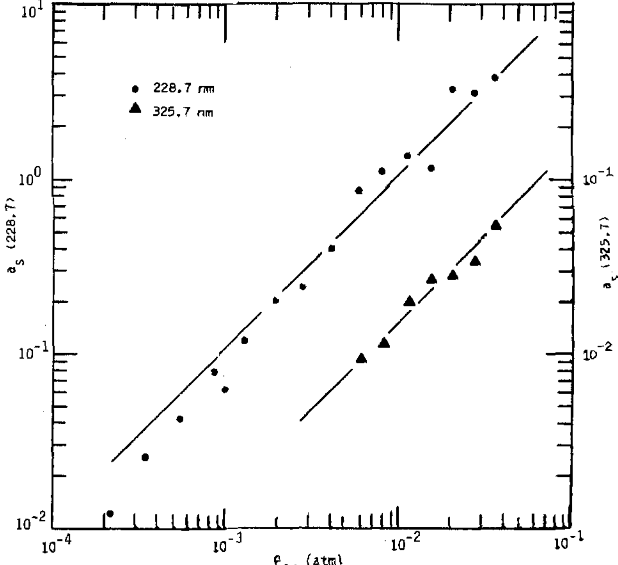

Fig. 8. Self-broadening parameters for the 228.7 and 325.7 nm Cd lines as a function of the pressure of Cd(g) in atmospheres.

$^1P_1$-$^1S_0$ and $^3P_1$-$^1S_0$ transitions. The proportionality constant between half-width and Cd pressure calculated from Eq. [25] is $2.77(10^{11})$ sec^{-1} for the 228.7 line and $6.3(10^8)$ sec^{-1} for the 325.7 line. As can be seen the agreement with experiment is excellent in the former case and somewhat less so, as expected, in the latter case.

Mercury-cadmium.—The foreign gas broadening parameters representing the effect of Hg(g) on the Cd absorption lines were determined by measuring these lines in transmission for the vapor over Hg-Cd liquids for which P_{Hg} and P_{Cd} were known as a function of sample temperature. The area in the transmission minimum of a given line was converted to the van der Held parameter, y', using Eq. [18] and the experimental points superimposed on a plot of the curves of growth. At each value of x' given by Eq. [19], the broadening parameter was determined. Subtracting the natural half-width contribution given by Eq. [16] and [17] and the self-broadening contribution given by Eq. [21] and [22] gave the Hg contribution, a_F, for each line.

Two slightly different techniques were used to obtain known values of P_{Hg} and P_{Cd}. In one, Hg-Cd solutions were prepared by weighing and successive dilution. Exposure of these solutions to the air was minimized by covering them with kerosene for the short time required for weighing and storing them in evacuated, sealed, silica tubes. For the experiments reported here the mercury surface remained clean and showed no sign of dark cadmium oxide even after heating in the optical cells. Sufficiently small, known weights of these solutions were sealed into optical cells so that the sample would completely vaporize at some sample temperature below the optical cell temperature of 755°C. An approximate temperature of complete vaporization was calculated assuming the Hg-Cd liquid was ideal. Measurements were then made for a few sample temperatures higher than this. Complete vaporization was confirmed by the fact that the transmission at the line center was only weakly dependent on sample temperature. The values of P_{Hg} and P_{Cd} were calculated from the known weight and atom fraction of the initial sample and the volume temperature profile in the cell and sidearm assuming the vapor was a mixture of ideal Cd(g) and imperfect Hg(g). The value of P_{Hg} could be independently obtained from the optical absorbance in the 255.0-340.0 nm interval using the results given in the section on Calibration Measurements, Mercury. The two values of P_{Hg} so obtained agreed to within a few percent. In the second technique, larger, known, sample weights were used so that dilution was not necessary, but the samples were never completely vaporized. For each sample temperature, P_{Hg} was obtained from the optical absorbance in the 255.0-340.0 nm interval and the composition of the liquid sample calculated assuming the vapor was essentially all Hg(g). A calculated value for P_{Cd} was then obtained for the known sample temperature and composition assuming the partial molar enthalpy and entropy for both Cd and Hg at 600 K are temperature independent. The equation used was

$$\ln P_{Cd} = \ln P_{Cd}^\circ + (\bar{h}_{Cd} - T\bar{s}_{Cd})/RT \qquad [26]$$

where the vapor pressure P_{Cd}° is given by Eq. [20] and the relative partial molar enthalpy, $\bar{h}_{Cd}$, and entropy, $\bar{s}_{Cd}$, were interpolated between the values given by Hultgren *et al.* (30) at intervals of 0.1 in atom fraction.

The values of a_F are shown plotted *vs.* P_{Hg} in Fig. 9 and 10 along with the least squares straight lines obtained under the constraint of unit slope on the log-log plot. As indicated in the figure captions certain points corresponding to longer times at temperature were weighted more heavily in the fit. From these results and those given in the section on Calibration Measurements, Cadmium, the broadening parameters given in general by Eq. [16] can be written for a 755°C optical path as

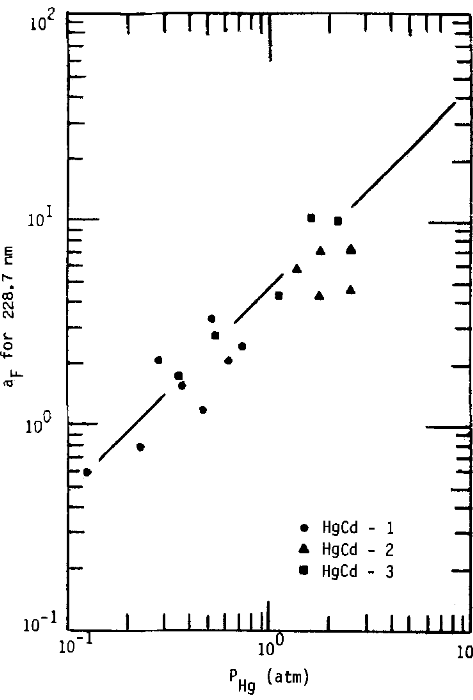

Fig. 9. Foreign gas broadening parameter for the 228.7 nm Cd line as a function of Hg(g) pressure. Data shown as squares represent 15-18 hr at sample temperature and are favored in determining the least squares line shown.

$$a'(228.7) = 0.0236 + 108P_{Cd} + 4.60P_{Hg} \qquad [27]$$

$$a'(235.7) = 2.69(10^{-5}) + 1.50P_{Cd} + 1.18P_{Hg} \qquad [28]$$

where the pressures are in atmospheres.

The 228.7 line becomes slightly asymmetric and broadened toward the visible for P_{Hg} greater than about 0.5 atm. Table IV lists the literature values used and a few of the derived quantities used.

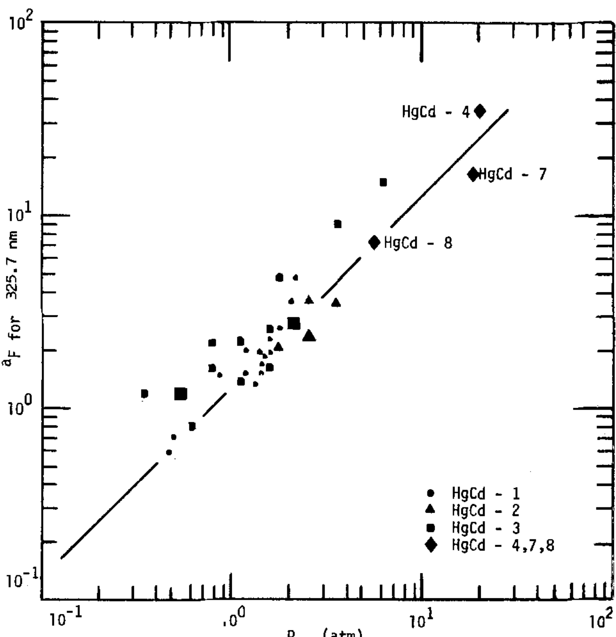

Fig. 10. Foreign gas broadening parameter for the 325.7 nm Cd line as a function of Hg pressure. Oversized squares, triangles, and diamonds represent 15-18 hr at sample temperature and are favored in determining the least squares line shown.

Calculation of Partial Pressures

Four optical cells containing $Hg_{1-x}Cd_xTe$ with $x = 0.416$ were prepared. One contained a known weight of Te in addition, three contained known weights of Hg. Of these last three, one was a high pressure cell described in the section Experimental, Optical cells. Except for this cell, whose optical path length was 2.92 cm, the cells had path lengths near 9.8 cm.

The partial pressure of $Te_2(g)$ was calculated from the measured net optical absorbances between 363.4 and 550.4 nm where Hg(g) and Cd(g) do not absorb at the partial pressures encountered here. The partial pressure of $Te_2(g)$ was calculated using Eq. [7]. Except at the lowest values of P_2 below 10^{-4} atm, at least three or four wavelengths gave values of D between 0.1 and 2.5 and corresponding values for P_2. This procedure assumes no effect of the high mercury pressures on the $Te_2(g)$ spectrum. The vibronic spectrum of Te_2 appeared qualitatively unchanged, although the maxima are broad and flat enough to obscure possible wavelength shifts of 0.1-0.4 nm. However, consistent with the above assumption, the relative optical densities in the visible remained the same as for pure $Te_2(g)$ within experimental error, *i.e.*, the values of P_2 calculated using Eq. [7] for the various wavelengths generally agreed within the expected accuracy (Experimental, Accuracy of measurements) of the optical absorbance values.

Except at values of 10^{-2} atm and below, the mercury pressure was also obtained as the average of generally closely agreeing values calculated from the absorbance at different wavelengths. First the $Te_2(g)$ contribution to the net absorbance in the 255-340 nm region was calculated from the net absorbance due to $Te_2(g)$ in the visible and the assumption that the relative values shown for D in Fig. 4 for pure $Te_2(g)$ are unchanged in the presence of Hg(g). This, generally small, contribution was then subtracted from the net optical absorbance to give the contribution, $D(\lambda,Hg)$, of Hg. The contribution of Hg(g) to absorption in the long wavelength tail of the 253.7 nm line is given by

$$D(\lambda,Hg) = LR^2C^2/t_\lambda^2 \quad [29]$$

where R is the gas constant, L is the optical path length, C is the concentration of Hg(g), and $1/t_\lambda^2$ is the product of the fraction of Hg atoms in the initial state of the transition (which is the ground state) and a transition probability. The linear dependence on L has been verified for the spectral band pass of 0.17 nm used here (21). Approximating Hg(g) as an ideal gas, Eq. [29] can be rewritten as

$$P_{Hg}(atm) = t_\lambda T_o D_\lambda^{1/2}/L^{1/2} = b_\lambda D_\lambda^{1/2} \quad [30]$$

where T_o is the temperature in the optical path and where b_λ is given in Table III for $L = 9.83$ cm and $T_o = 755$°C. Since the fraction of Hg(g) atoms in the ground state is essentially unity up to much higher temperatures than used here, t_λ is a constant for a given wavelength if the transition probability is independent of T_o. Theoretical analysis of resonance broadening predicts such an independence (28). Moreover, runs on pure Hg with $T_o = 860$°C give $b_\lambda(755)/b_\lambda(860)$ close to 0.90 for the same path length (31) and in close agreement with the value of $1028/1133 = 0.91$ expected from Eq. [30] and the assumed constancy of t_λ. [In Ref. (31) the theoretical dependence of b_λ on T_o is stated incorrectly.] The necessary values of b_λ for different path lengths and optical cell temperatures were calculated from those in Table III using the result of Eq. [30] *i.e.*

$$b_\lambda(L,T_o) = \left(\frac{T_o}{1028}\right)\left(\frac{9.83}{L}\right)^{1/2} b_\lambda(9.83, 755) \quad [31]$$

For values of P_{Hg} below about 0.2 atm, the partial pressures of Te_2 and Cd were below the detectable limits of, respectively, 10^{-4} and 10^{-7} atm. The contribution of foreign gas broadening to the 253.7 Hg line was therefore assumed negligible. The area obtained from a trace of optical absorbance *vs.* λ across the line was multiplied by $9.83/L$ to give a normalized area. Equation [9] was then used to calculate P_{Hg}.

Once P_{Hg} was known, the broadening parameters, a', for the Cd lines were calculated using Eq. [27] and [28] with $a_S = 0$. A first approximation for P_{Cd} could then be calculated from the observed area in the transmission minima using the curves of growth. A computer program was written that numerically evaluated the van der Held parameter, y', of Eq. [18] for given values of the broadening parameter, a', and the parameter, x', of Eq. [19]. A trial and error search was used to find the value of x' giving a value of y' in agreement with the value from experiment. This allowed an evaluation of the self-broadening parameter, a_S, according to Eq. [21] and [22] and a second approximation for a' for each wavelength. The values of P_{Hg} were so much larger than those of P_{Cd} that the first and second approximations for a' were close enough to lead to the same values of P_{Cd} within 1%. A small but clear asymmetry developed in the 228.7 line for P_{Hg} greater than about 0.5 atm, the long wavelength tail broadening. In this case the value of P_{Cd} was then calculated from the area of the 325.7 line in transmission.

The partial pressure of Hg was greater than that of either Cd or Te_2 in all of the measurements reported. Consequently the solid samples became progressively poorer in Hg with increasing sample temperature. From the partial pressures at a given sample temperature and the volume and temperature distribution along the optical cell and sidearm, the composition of the sample could be calculated assuming the vapor phase to consist of ideal $Te_2(g)$ and Cd(g) and imperfect Hg(g). Writing the composition of the solid solution as $(Hg_{1-x}Cd_x)_yTe_{1-y}$, data for which $x = 0.416 \pm 0.01$ are grouped together here and taken as characteristic of the solid solution with $x = 0.416$.

Results for 41.6 m/o CdTe, HgTe-CdTe

The partial pressure of $Te_2(g)$ over the Te-saturated solid solution is shown in Fig. 11 which also shows the vapor pressure of pure Te adopted here (see section on Calibration Measurements, Tellurium). Those partial pressures obtained with cell 38-TE1, to which excess Te was added, are given in Tables V and VI.

Figure 12 shows P_{Hg} for a cell to which Hg was added. At low temperatures the sample is metal saturated and P_{Hg} is very close to the vapor pressure of pure Hg. At 367°C ($10^3/T = 1.562$), $P_{Hg} = 1.2$ atm, the mercury pressure becomes nearly independent of temperature for a long interval. Complete vaporization of the added Hg would provide a vapor at 1.19 atm at 367°C, agreeing with the observed value within experimental error. Therefore we conclude that the solid solution sample used in this cell is essentially free of either Hg-rich or a Te-rich second phase. Upon heating above 367°C the small loss of Hg to the vapor phase causes the composition variable y in the formula $(Hg_{1-x}Cd_x)_yTe_{1-y}$ to move from its value at metal saturation to that at Te saturation, indicated by the sudden strong dependence of P_{Hg} on T. The point of Te saturation is $T = 624$°C ($10^3/T = 1.115$), $P_{Hg} = 1.29$ atm; $P_2 = 5.0$ (10^{-3}) and $P_{Cd} = 5.4$ (10^{-7}) atm. On log P *vs.* $10^3/T$ plots, P_2 and P_{Cd} show discontinui-

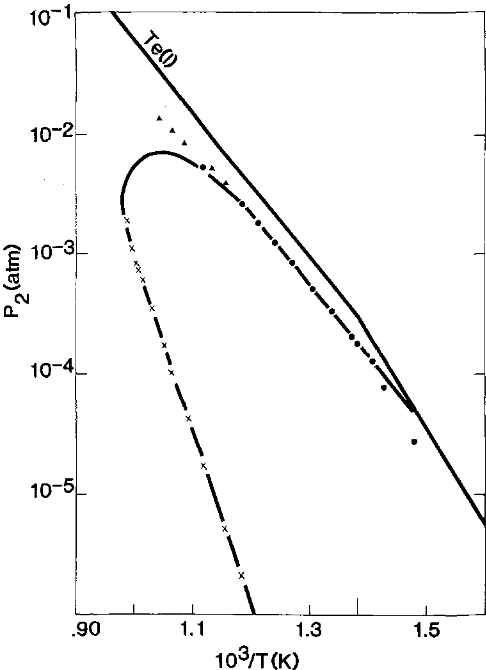

Fig. 11. Partial pressure of $Te_2(g)$ along the three-phase curve for 41.6 ± 1 m/o CdTe, HgTe-CdTe solid solution. ties in slope at close to the same temperature as does P_{Hg}. Chronologically this cell was the first one used and it became apparent that, although P_{Hg} reached a steady-state value in a few hours, 15-18 hr were required for P_2 and P_{Cd} to do so with the particle size used here (see Experimental, Materials). Table VII summarizes the data for the runs of June 1977 for which the samples were 15-18 hr at temperature.

Table V. Partial pressures in atmospheres over a condensed phase of gross composition $(Hg_{1-x}Cd_x)_yTe_{1-y}$ obtained from cell 38-TE1 with a 9.40 cm optical path at 1028 K*

* In general a partial pressure is obtained as the average of values calculated from the optical absorbance at several wavelengths. The uncertainties listed are the standard deviation of these values. For T up through 729.6 K, P_{Hg} is obtained using Eq. [9]. At higher T in this table and in Table VI, six values from D at λ between 255.0 and 270.0 nm are averaged. Two to six values from readings at λ between 421.5 and 500.4 nm are averaged to obtain P_2, the partial pressure of $Te_2(g)$.

Table VI. Partial pressures in atmospheres from cell 38-TE1 at high temperatures. Cadmium pressures are obtained from 228.7 nm line except for the value at 959.5 K in brackets which is obtained from the 325.7 nm line.

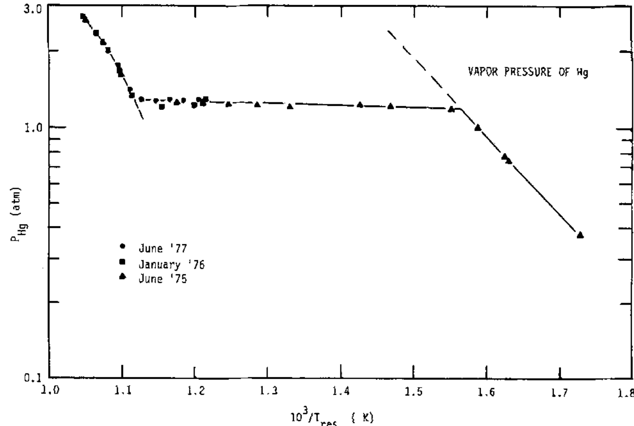

Fig. 12. Partial pressure of Hg on a log scale vs. reciprocal sample temperature for cell 38-HG1. The dashed line at upper right shows the vapor pressure of Hg. The data show the sample leaving the metal-saturated condition at low temperatures, crossing the homogeneity range, and attaining Te saturation.

The value of P_{Hg} along the three-phase curve for $x = 0.416$ is shown in Fig. 13. The lowest values are from the Te-saturated sample described earlier. One cell contained sufficient extra Hg to cross the stability field of the solid solution with P_{Hg} near 5 atm. This run furnished one metal-saturated point and one Te-saturated point in addition to a number of points within the stability field which can be used to calculate the chemical potentials of HgTe and CdTe and the standard Gibbs free enthalpy of formation from the elemental gases. The long-time points are given in Table VIII. From the data obtained with this cell the metal saturation point is at $10^3/T = 1.315$ and $P_{Hg} = 5.6$ atm. The Te-saturation point is at $10^3/T = 1.046$ and $P_{Hg} = 5.84$ atm. The highest mercury pressures were obtained using a high pressure cell. As shown in Fig. 13, P_{Hg}

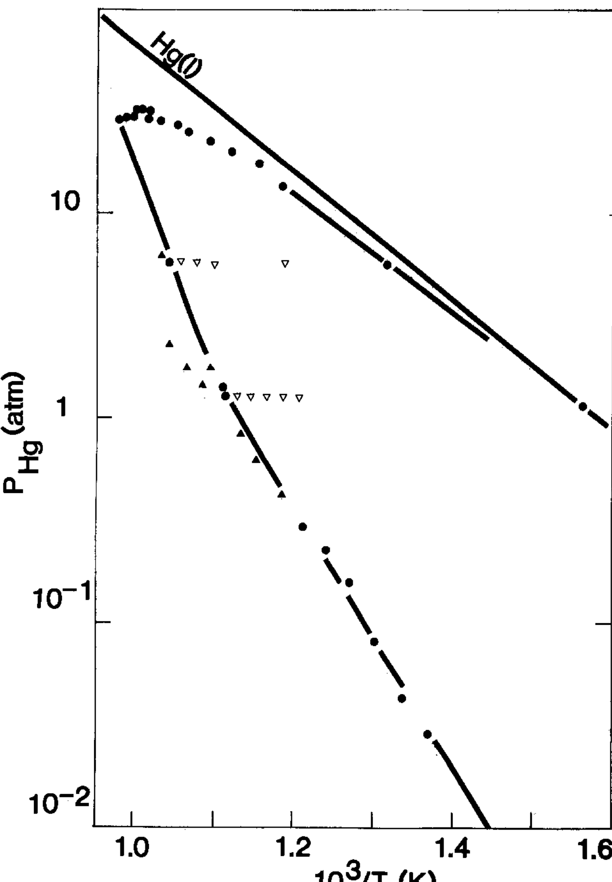

Fig. 13. Vapor pressure of Hg shown as uppermost line and partial pressure of Hg(g) along the three-phase curve for 41.6 ± 1 m/o CdTe, HgTe-CdTe solid solution. ● Saturation point or point on three-phase curve, ▽ inside field of stability, ▲ outside field of stability.

reaches at maximum of 32.0 atm near 723°C. The sample used to obtain these high pressures leaves the three-phase curve at 745° ± 2°C, P_{Hg} = 28.0 atm, and the data undergo a reversal in slope. This is shown in more detail in Fig. 14 in which the optical absorbance is plotted. The temperature of 745° ± 2°C is interpreted as the solidus point for $Hg_{0.584}Cd_{0.416}Te$(c). It agrees with the published data (4) within their scatter. The published data are from chemical analysis of the

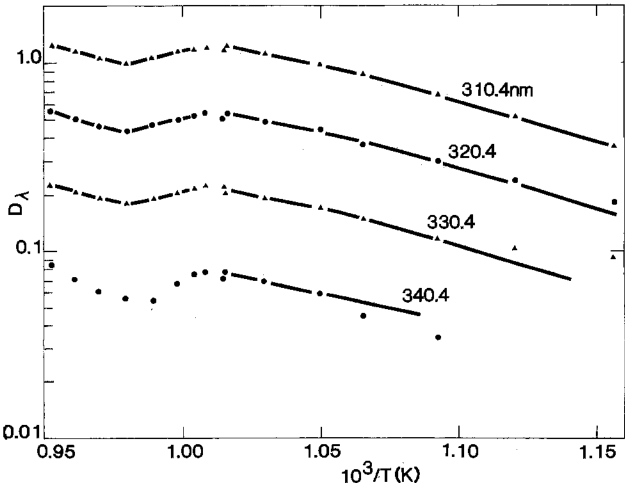

Fig. 14. Optical absorbance on a log scale and for different wavelengths as a function of reciprocal sample temperature for metal-saturated solid solution containing 41.6 ± 1 m/o CdTe. Data from cell 40-HG2 with a 2.92 cm optical path at 755° or 800°C. Pressures given in Table IX.

first crystals to freeze from a large volume of melt and furnish directly the compositions of coexisting liquid and solid solution phases. The corresponding temperature was taken from the smoothed liquidus line as determined by thermal analysis (1). The static technique used here to determine the solidus point is quite different and it is encouraging to obtain agreement. Steininger (5) has measured P_{Hg} over the pseudobinary melts by a reflux method. He found the unusual result that for several mole percents of CdTe between 0 and 60%, that the points all fell on the same straight line on a plot of log P_{Hg} *vs.* $10^3/T$. At 745°C he finds P_{Hg} = 24 atm in fair agreement with our value of 28 atm. The values of P_{Hg} from the measurements with the high pressure cell are summarized in Table IX. In order to minimize the time at high temperature and pressure the measurements necessary to obtain P_2 and P_{Cd} were omitted.

Discussion

For the experiments described here, in which the samples changed from a metal-saturated condition at low temperature to one of Te saturation at higher temperature, the calculated atomic percent of Te remained equal to 50% within an estimated experimental error of ± 0.2%. Hall measurements (6) on solid solution samples with x = 0.40 that were either metal saturated or Te saturated at high temperatures show an excess of holes over electrons for saturation temperatures above 350°C. At 600°C the excess of holes over electrons is about 10^{17} cm^{-3} for metal saturation and $2(10^{17})$ cm^{-3} for Te saturation. The data have been combined with the values of P_{Hg} reported here in a defect chemistry analysis (32). Assuming no significant concentration of native point defects that are inactive as donors or acceptors, $(Hg_{0.584}Cd_{0.416})_yTe_{1-y}$(c) is always Te-rich, *i.e.*, $y < 1/2$, above about 350°C and the range of y for a stable phase is restricted to values within $5(10^{-4})$ of 1/2. Thus it is to be expected that the standard Gibbs free enthalpy of formation is independent of y to a good approximation. In fact, for such a narrow homogeneity range, statistical thermodynamic argument shows (11) that the chemical potentials of the thermodynamic components HgTe and CdTe are also independent of y to a good approximation. This theoretical prediction affords a check on the internal consistency of the measurements reported here which is discussed below. First, however, it should be noted that the independence of the chemical potentials of HgTe and CdTe from y implies a similar independence for the difference in the chemical potentials of Hg and Cd. Second, the discussion of HgTe and CdTe as thermodynamic components of the solid solution of course does not imply the existence of either HgTe or CdTe as structural units.

* N = number of data points.
** σ = standard deviation between measured and calculated values of μ/RT or $\Delta G°_f/RT$.
† σ_2 = corresponding standard deviation for μ or $\Delta G°_f$.
‡ 1/<1/T> = reciprocal of average 1/T value for experimental points.
§ The uncertainties in the enthalpies and entropies are at the 95% confidence level as calculated using the Student t-distribution with N − 2 degrees of freedom.

Assuming the vapor phase is ideal the chemical potentials relative to those of Hg(g), Te_2(g), and Cd(g), each at 1 atm are

$$\bar{\mu}_{HgTe} = RT \ln P_{Hg}P_{Te_2}{}^{1/2} \quad [32]$$

$$\bar{\mu}_{CdTe} = RT \ln P_{Cd}P_{Te_2}{}^{1/2} \quad [33]$$

$$\bar{\mu}_{Hg} - \bar{\mu}_{Cd} = \bar{\mu}_{HgTe} - \bar{\mu}_{CdTe} = RT \ln P_{Hg}/P_{Cd} \quad [34]$$

The standard Gibbs free enthalpy of formation for the reaction

$$0.584Hg(g) + 0.416Cd(g) + \tfrac{1}{2}Te_2(g) \rightarrow Hg_{0.584}Cd_{0.416}Te(c) \quad [35]$$

is given by

$$\Delta G°_f = 0.584\,\bar{\mu}_{HgTe} + 0.416\,\bar{\mu}_{CdTe} \quad [36]$$

These quantities can be calculated from the entries in Tables V-VIII. Alternatively, the nonideal behavior of Hg(g) could be taken into account using the equation of state of Sugawara and Sato (23) to calculate the fugacity. The largest corrections occur for the data given in Table VIII and amount to −10 to −15 cal for the chemical potential of Hg. Since these prove to be considerably less than the precision to which the chemical potential of HgTe can be fit, these corrections are neglected here. The negative of the chemical potential of HgTe is plotted as a function of T in Fig. 15. For completeness the figure includes some points outside the range $x = 0.416 \pm 0.01$. There are the three highest temperature points for 38-TE1 and the two highest temperature points for 38-HG1. These out of range points, as well as that at 830 K and the lowest point at 935.4 K are excluded from a least squares fit of $\bar{\mu}_{HgTe}/RT$ to a straight line as a function of $1/T$

$$\bar{\mu}_{HgTe}/RT = \bar{h}/RT - \bar{s}/R \quad [37]$$

where the partial molar quantities are assumed to be independent of T. The result is shown as the solid line in Fig. 15 and in the first entry of Table X. It should be noted that the partial enthalpy and entropy of HgTe are highly correlated. The most probable values fall essentially along a line segment in the $\bar{h}$-$\bar{s}$ plane which passes through the best fit point, which has a slope of 871.8 K, and which is terminated with 95% confidence at values of $\bar{h}_{Te}$ that are ± 1201 cal away from −41,470. cal (33). Mathematically, the most probable values are related by the equation

$$\bar{h} = -41{,}470. + 871.8\,(\bar{s} + 41.491);$$
$$-44.05 \leq \bar{s} \leq -38.93 \text{ at 95\% confidence} \quad [38]$$

Analogous comments are valid for the fits to $\bar{\mu}_{CdTe}$ and $\Delta G°_f$. Figure 16 shows the chemical potential of CdTe and the least squares line. The two points for 38-TE1 are shown for completeness only. They correspond to x-values greater than 0.426 and were not included in the least squares analysis. A similar out of range point is the 914.7 K point for 38-HG1. The two lowest temperature points for 38-HG1 were excluded from the analysis because they were far from the least squares line obtained by including them. These same two points were also excluded from the analysis of $\Delta G°_f$. A plot of the $\Delta G°_f$-T points is shown in Fig. 17. Figure 18 shows a plot of the difference in the chemical potentials of Hg and Cd *vs.* T. Using Eq. [34] and

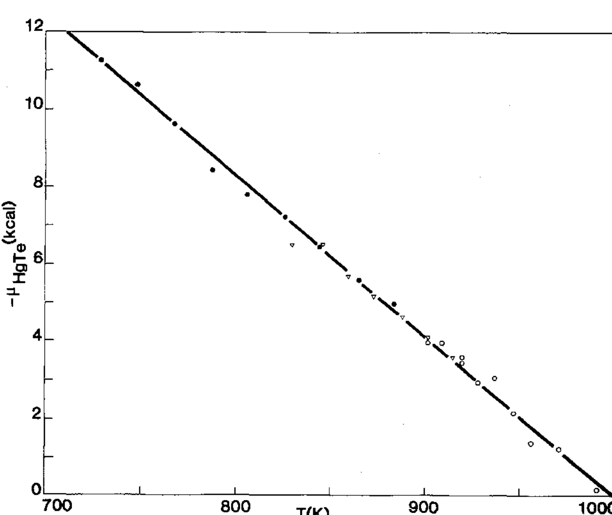

Fig. 15. The negative of the chemical potential of HgTe for a solid solution containing 41.6 ± 1 m/o CdTe as a function of absolute temperature. Solid line is from a least squares fit. ● 38-TE1, ▽ 38-HG1, ○ 40-HG3.

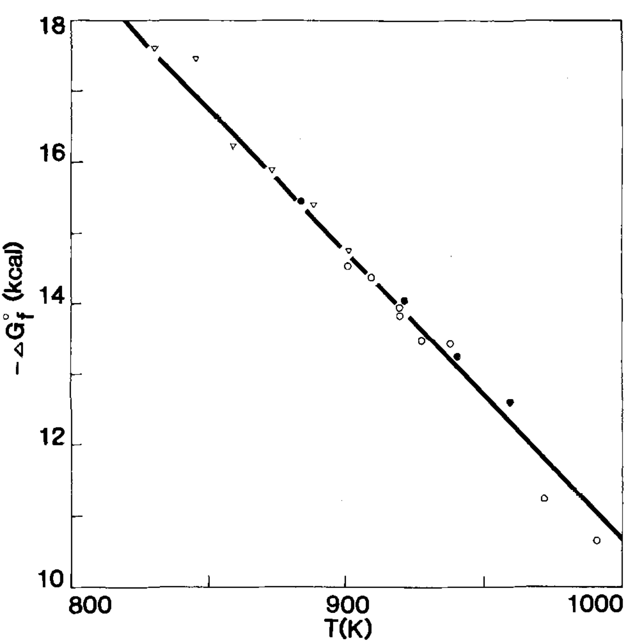

Fig. 17. Negative of the Gibbs free enthalpy of formation from $Te_2(g)$, Hg(g), and Cd(g) of a solid solution containing 41.6 ± 1 m/o CdTe as a function of absolute temperature. Solid line is from a least squares fit. Symbols denote data from different cells as given for Fig. 15.

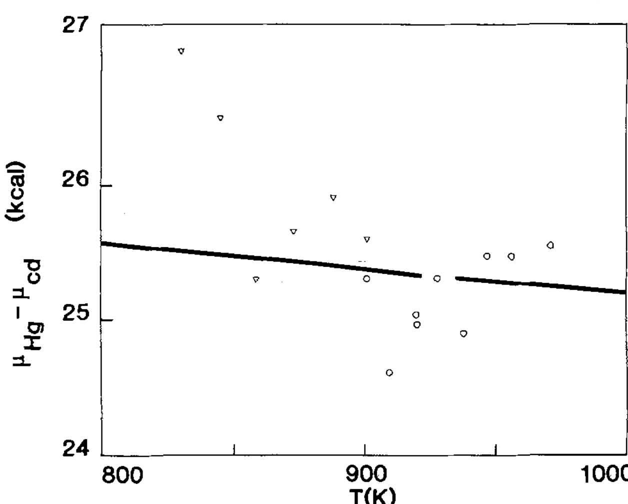

Fig. 18. Difference between the chemical potentials of Hg and Cd in a solid solution containing 41.6 ± 1 m/o CdTe as a function of absolute temperature. Solid line is from a least squares fit. Symbols retain same meaning as for Fig. 15.

Table X and not expressing the uncertainties, one obtains

$$\bar{\mu}_{Hg} - \bar{\mu}_{Cd} = 27{,}063. - 1.856T \quad [39]$$

Values for the partial pressures of $Te_2(g)$ and Cd(g) along the three-phase curve can be calculated where they were not measured using the measured values of P_{Hg}, Eq. [32] and [33], and the entries in Table X. These are shown by the symbol, x, in Fig. 11 for P_2 and in Fig. 19 for P_{Cd}. The calculated points agree well with those measured directly. The utility of Eq. [32] and [33], which give two of the partial pressures if the third is known, is, of course, not limited to points along the three-phase curve. The equations are applicable for the entire composition stability field of $x = 0.416$.

The standard Gibbs free enthalpies of formation of HgTe(c) and CdTe(c) from $Te_2(g)$ and the monoatomic metallic atoms have been determined from optical absorbance measurements at high temperatures

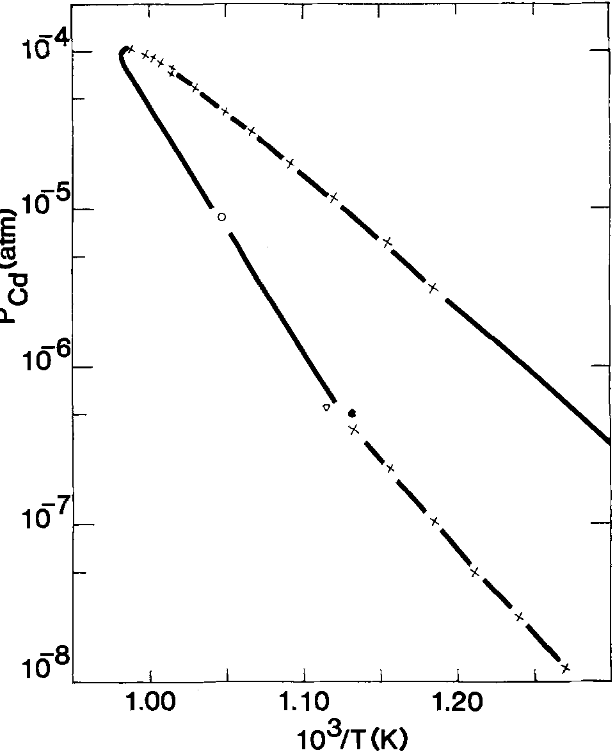

Fig. 19. Partial pressure of Cd(g) along the three-phase curve for a solid solution with 41.6 ± 1 m/o CdTe as a function of reciprocal absolute temperature. ● 38-TE1; ▽ 38-HG1; ○ 40-HG3; × calculated from P_{Hg} in Table IX and Eq. [39] or, along bottom leg, from P_{Hg} in Table V and Eq. [39].

(21, 14) and are given, respectively, by

$$\Delta G^\circ_f(\text{cal/mole HgTe}) = -41{,}660. + 42.71T \quad [40]$$

$$\Delta G^\circ_f(\text{cal/mole CdTe}) = -68{,}640. + 44.94T \quad [41]$$

Combining these equations with the data in Table X, the ΔG°_f for the reaction

$$0.584\,\text{HgTe(c)} + 0.416\,\text{CdTe(c)} \rightarrow Hg_{0.584}Cd_{0.416}Te\text{(c)} \quad [42]$$

is

$$\Delta G^\circ_f = 1888. - 3.32T \quad [43]$$

If instead of starting with the last entry of Table X, one starts with the best fits to the chemical potentials of HgTe and CdTe individually and Eq. [36], one obtains for the reaction given by Eq. [42]

$$\Delta G^\circ_f = -155. - 1.37T \quad [44]$$

In either case, within the uncertainty limits inferred from Table X the enthalpy of formation from HgTe(c) and CdTe(c) is zero and the entropy of formation agrees with the value of 1.35 cal/K-formula weight for the random mixing of Cd and Hg on the metal sublattice.

Partial Pressures over HgTe-CdTe Solid Solutions

II. Results for 10, 20, and 58 Mole Percent CdTe

Tse Tung, Leszek Golonka,[1] and R. F. Brebrick*

Metallurgy and Materials Science, Marquette University, Milwaukee, Wisconsin 53233

ABSTRACT

The partial pressures of Hg, Cd, and Te_2 are obtained along the three-phase curves for 10, 20, and 58 mole percent CdTe, HgTe-CdTe solid solutions by measuring the optical absorbance of the coexisting vapor between 220 and 700 nm. The pressure ranges covered are 10^{-2}-32 atm for Hg, 10^{-8}-10^{-5} atm for Cd, and 10^{-5}-10^{-2} atm for Te_2, and Hg is always the predominant vapor species. The data allow the calculation of the chemical potentials of HgTe and CdTe and the Gibbs free enthalpy of formation for the solid solutions. In addition, the solidus temperatures are obtained directly from the optical absorbance measurements.

In a previous paper (1), the calibration experiments required to obtain the partial pressures of Hg, Cd, and Te_2 and the results for an HgTe-CdTe solid solution containing 41.6 mole percent (m/o) CdTe were reported. Here we report similar experiments on 10, 20, and 58 m/o CdTe solid solutions. These experiments establish for each mole percent CdTe (*i*) the solidus temperature, (*ii*) all three partial pressures along the three-phase curve, (*iii*) the chemical potentials of HgTe and CdTe components in the solid solution, and (*iv*) the Gibbs free enthalpy of formation. To the best of our knowledge, this is the first determination of items *ii*, *iii*, and *iv*. The predominant vapor species for both the metal-saturated and the Te-saturated solid solutions is Hg(g).

* Electrochemical Society Active Member.

Key words: mercury-cadmium-telluride, partial pressures, three-phase curve, free enthalpy, chemical potentials.

Experimental

The experimental details are the same as those described in Part I (1) with some important exceptions that are noted below. The mole percent of CdTe in the solid solution samples was determined as before from density measurements. The weight of solid solution and its particle size are noted in the table headings for each cell as well as the weight of any elements added. The experiments fell into two general classes. In the first, sufficient Hg was added along with the solid solution to provide a pressure of about 20 atm. In the sec-

ond, the results of which are given in Tables IV, V, and VI, either excess Te or a small amount of Hg was added so that Te saturation was achieved at fairly low sample temperatures. For this second type of experiment, both sidearm portion of the furnace and the optical cells were modified. The modification of the furnace and the use of a heat pipe around the sample end of the sidearm are described in Calibration Measurements, Tellurium in Part I (1). Because of the heat pipe and its inner silver liner, the temperature variation over the roughly 5 cm length of the sidearm containing the sample was a few tenths of a degree centigrade or less. The sidearm of the cell consisted of two sections. The section attached to the cell-proper was 1.1 cm OD and 9 cm long. The section which was the end of the sidearm after seal-off was 2.0 cm OD and 3 cm long. Thus the overall sidearm length was about 12 cm, rather than 20, and approximately 5g samples could be spread out to provide a geometric surface area of about 3 cm^2. For the cells used in Part I (1), this area was about 0.5 cm^2. We believe this increased surface area was useful in minimizing equilibration times at high temperatures where the original particle size distribution tended to disappear because of sintering. It should be noted that, although there was sintering, there was no evidence of gross vapor transport along the sample section, attesting to the uniformity of temperature there.

As in Part I (1), the transmission over the Cd lines was measured rather than the optical absorbance. However, here the measurements were repeated at least three times and the integrated areas averaged.

Results

The optical absorbance measurements and the integrated area in the transmission valley for the Cd lines were converted to partial pressures as described in the section Calculation of Partial Pressures, in Part I (1).

As in Part I, it was found that the partial pressure of Hg, P_{Hg}, attained steady-state values within a few hours after a steady sample temperature was reached. In contrast the partial pressures of $Te_2(g)$, P_2, and of Cd(g), P_{Cd}, required 4-15 hr or more depending on the temperature. A decrease in maximum particle size to 63 μm, see Table VI, seemed to reduce the time required for the attainment of a steady state.

Tables I through VI, with the exception of Table III, list the partial pressures measured. In all of these tables, the second column gives the number of hours the sample was at temperature before measurement. The measurement of optical absorbance and transmission (for the Cd lines) itself required an additional 40-60 min. The third column gives $10^3/T$, where T is the sample temperature in K. The last two columns titled x and y, respectively, are calculated values for the overall composition of the condensed phase or phases as expressed by the formula $(Hg_{1-x}Cd_x)_yTe_{1-y}$. These were obtained from the known weights of solid solution and added elements, the known volume of the cell and sidearm, the temperature distribution along the cell and sidearm, and the assumptions: (*i*) y = 0.500 for the solid solution added to the cell, (*ii*) Cd(g) and $Te_2(g)$ are ideal gases, and (*iii*) Hg(g) is a slightly imperfect gas with an equation of state given by Sugawara and Sato (see the section on Calibration Measurements, Mercury in Part I).

Tables I and II give P_{Hg} and P_2 for metal-saturated solid solution with x of, respectively, 0.108 and 0.198. These mercury pressures are also shown along the upper branches of the three-phase curves shown in Fig. 1. For comparison the data for HgTe (2) and for x = 0.416 from Part I (1) are also shown. The maximum values of P_{Hg} for x = 0.108 is 21 atm and occurs at 673°C. That for x = 0.198 is 24 atm and occurs at 683°C. Solidus temperatures were obtained from measurements with these cells and are given in Table III along with those for x = 0 and 0.416. The determination of the solidus temperature depends on the fact that the optical absorbance D, in the 254.0-340 nm region where Hg(g) absorbs, increases with increasing temperature, attains a maximum value, decreases, and then increases linearly on a log D *vs.* $10^3/T$ plot. The behavior is similar to that shown in Fig. 14 of Part I (1). The high temperature, linear portion is characteristic of a liquid-solid solution equilibrium and its intersection with the decreasing segment of the log D *vs.* $10^3/T$ curve is taken as the solidus temperature. The evaluation of the solidus temperature for each x-value was made using D at a number of wavelengths and is independent of the accuracy with which P_{Hg} was established. Near the solidus temperature for x = 0.108 the optical absorbance for four wavelengths between 290.4 and 320.4 nm was in the reliable measurement range of 0.1-2.0 in D and all gave the same solidus temperature within ± 1°C. For x = 0.198 the solidus temperature was established to within ± 1°C from the same type of reversal in the sign of the slope of a log D *vs.* $10^3/T$ plot for four wavelengths between 300.4 and 330.4 nm. The solidus temperatures given in Table III are obtained by an essentially static technique and so it is gratifying that they agree well with those obtained from chemical analysis of the first crystals to grow from large volumes of melt (3) combined with liquidus temperatures obtained by thermal analysis (4) (given only in the form of graph). The values of P_2 in Table I are the average of those calculated from the optical absorbance at 2-6 wavelengths between 400 and 500 nm.

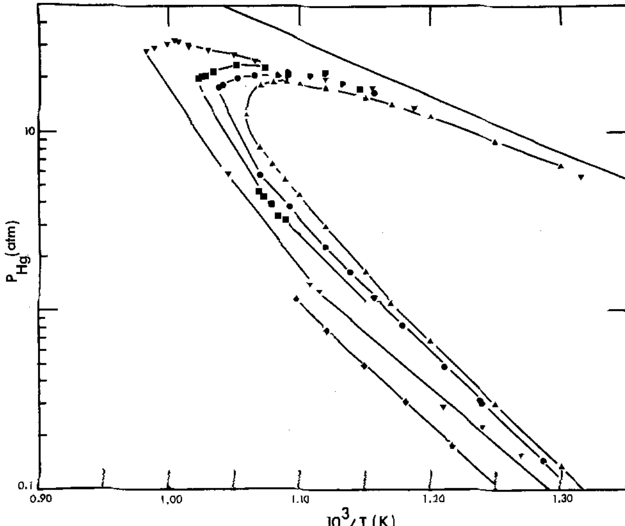

Fig. 1. Vapor pressure of Hg, shown as the uppermost line, and the partial pressure of Hg along the three-phase curves for various x-values of $Hg_{1-x}Cd_xTe(c)$ as a function of $10^3/T$. ▲, $x = 0.0$ [Ref. (2)]; ●, $x = 0.094$, 0.108; ■, $x = 0.196$; ▼, $x = 0.416$; ◆, $x = 0.581$.

Table III also gives P_{Hg} at the solidus temperature as obtained here and as established by a reflux method (5). In the latter study, P_{Hg} falls along a common straight line on a log P_{Hg}-$1/T$ plot for pseudobinary melts containing between 0 and 60 m/o CdTe. Therefore, the value of P_{Hg} at the solidus temperature for a given mole percent CdTe solid solution can be calculated knowing only the solidus temperature. As shown in Fig. 1 for $x = 0$, P_{Hg} along the three-phase curve has in principle an infinite slope at the solidus temperature, so that it can be difficult to establish its exact value. Data along the Te-rich leg and close to the solidus temperature, which we do not have, would serve to bracket this pressure. As it is, our values in Table III are upper limits and the agreement with Ref. (5) is satisfactory.

Table IV lists the partial pressures obtained for a Te-saturated solid solution with $x = 0.094 \pm 0.010$. For the last entry the loss of Hg to the vapor phase is large enough that the x-value differs by more than 0.01 from the nominal value. The values of P_{Hg} are shown in Fig. 1 along the lower leg of the three-phase curve for $x = 0.094$.

Table V gives the partial pressures for $x = 0.196$. The cell had only a small amount of added Hg and so left the metal-saturated condition and entered the solid solution single-phase field at 427°C with $P_{Hg} = 2.96$ atm. With increasing temperature the value of y increases by a small amount within the precision of our measurements, P_{Hg} remaining almost constant, and then finally attains Te saturation. Upon further increase in temperature, P_{Hg} starts to increase. From the discontinuities in the slopes of the optical absorbance at different wavelengths, Te saturation is attained at 646°C where $P_{Hg} = 3.2$ atm, $P_2 = 4.23 \times 10^{-3}$ atm, and $P_{Cd} = 1.92 \times 10^{-6}$ atm.

It is to be noted that the calculated values of x and y are constant to three significant figures up to $10^3/T = 1.0837$. Assuming the major errors are a 2% uncertainty in P_{Hg} and a 5% uncertainty in the volume of the optical cell implies approximate uncertainties of 0.5% in x and 0.25% in y. The maximum variation for the values in Table V are close to these estimates, being 0.4% in x and 0.1% in y.

Table VI lists the partial pressures for an x-value of 0.58. The partial pressures of $Te_2(g)$ along the three-phase curves for the various x-values are shown in Fig. 2 along with the vapor pressure of tellurium and a portion of the Te-rich leg for CdTe from Ref. (6). As can be seen there are not enough data points to define the maximum value of P_2 for $x = 0.416$.

A number of cells were prepared with added elemental Hg. As discussed above in connection with Table V, these left the metal-saturated condition with increasing T and entered the homogeneity range, where P_{Hg} was almost constant with increasing T. The values of $10^3/T$ and P_{Hg} at the metal-saturation points are given in Table VII since Fig. 1 does not extend to low enough T to include them all.

Discussion

For a narrow homogeneity range solid solution, $(Hg_{1-x}Cd_x)_yTe_{1-y}$, in which the solid is a stable phase only for a narrow range of y-values near 1/2, say less than 0.01 wide, certain chemical potentials are theoretically independent of y to a good approximation, *i.e.*, they are stoichiometric invariants (7).

Assuming Cd and Te_2 behave ideally in the vapor phase and f_{Hg} is the fugacity of Hg(g), these are

$$\bar{\mu}_{HgTe} = RT \ln f_{Hg}P_2^{1/2} = \bar{h}_{HgTe} - T\bar{s}_{HgTe} \quad [1]$$

Table V. Partial pressures in atmospheres over 19.7 m/o CdTe, HgTe-CdTe

Cell I, 9.775 cm optical path at 755°C. Cell loaded with 4.8230g of solid solution of $x = 0.196$ and particle size between 44 and 125 μm plus 0.2060g Hg. Volume in cubic centimeters of cell-proper, upper part of sidearm, and sample end of sidearm minus sample volume are, respectively, 17.63, 2.8, and 6.97. Sidearm divided into six zones in calculation of x and y.

* Entries marked with an asterisk are omitted from the least squares fits to the chemical potentials of either HgTe or CdTe.

$$\bar{\mu}_{CdTe} = RT \ln P_{Cd}P_2^{1/2} = \bar{h}_{CdTe} - T\bar{s}_{CdTe} \quad [2]$$

$$\bar{\mu}_{Hg} - \bar{\mu}_{Cd} = RT \ln f_{Hg}/P_{Cd} \quad [3]$$

Finally the standard Gibbs free enthalpy of formation of the solid solution according to the reaction

$$(1 - x)\,Hg(g) + xCd(g) + 1/2\,Te_2(g) \rightarrow Hg_{1-x}Cd_xTe(c) \quad [4]$$

is given by

$$\Delta G^\circ_f = (1 - x)\,\bar{\mu}_{HgTe} + x\,\bar{\mu}_{CdTe} = \Delta H^\circ_f - T\Delta S^\circ_f \quad [5]$$

The chemical potentials were calculated from the partial pressures given in the tables. Using the equation of state for Hg(g) given by Sugawara and Sato (8), one obtains

$$\bar{\mu}_{Hg} = RT \ln f_{Hg} = RT \ln P_{Hg} + 4857.6P_{Hg}\,(-1.793/T + 251/T^2 + 0.001071) \quad [6]$$

For the cases where both P_{Hg} and P_2 were measured, the correction term ranges from near zero to −70 cal/mole. Since the chemical potentials of HgTe and CdTe are independent of y, the solid solution can be described as effectively being a binary solution containing two thermodynamic components, HgTe and CdTe, for some purposes. In particular, the Gibbs-Duhem relation holds between $\bar{\mu}_{HgTe}$ and $\bar{\mu}_{CdTe}$. The experimental data obey the Gibbs-Duhem relation at least qualitatively in that $\bar{\mu}_{HgTe}$ increases at a given T with decreasing x while $\bar{\mu}_{CdTe}$ increases with increasing x.

Least squares straight lines were determined from the experimental values of $\bar{\mu}_{HgTe}/RT$ and $\bar{\mu}_{CdTe}/RT$, assuming that these quantities vary linearly with $1/T$. The temperature dependence of the corresponding enthalpies and entropies is thereby neglected and the values obtained are for a temperature near the midpoint of the temperature range. The results are summarized in Table VIII. Column 3 lists the standard deviation, σ^*, between measured and calculated values of $\bar{\mu}_{HgTe}$ etc., rather than of $\bar{\mu}_{HgTe}/RT$ etc., because the former seem to us to have a more immediately recognizable significance. Certain entries in Tables I, II, IV, V, and VI, indicated by an asterisk superscript, were excluded from these fits either because the value of x deviated by more than ±0.01 from the nominal value or because the corresponding points fell too far from the least squares straight lines obtained by including them.

Table VII. Points on metal-saturated three-phase curves for various x-values. Vapor pressure of Hg, $P_{Hg}°$ given for comparison. Cells 162, J1 used only to establish these points and not at high temperatures.

Cell	x	$10^3/T$ (K)	P_{Hg} (atm)	$P_{Hg}°$ (atm)

0.416	52858	42.397
0.581	57140	43.041

The data for $x = 0.416$ reported in Part I (1) and the original data points for HgTe (2) were reanalyzed including the correction for the nonideality of Hg(g). For completeness these results are also listed in Table VIII, as well as the published (6, 9) standard enthalpy and entropy of formation of CdTe(s) from Cd(g) and $1/2\,Te_2$(g). The chemical potential of HgTe can also be calculated for metal-saturated, $x = 0.108$, solid solution from the data in Table I. Except for the first four entries in Table I, and except for temperatures above the 691°C solidus, these fall very close to the least squares straight line determined from the data in Table IV for Te-saturated, $x = 0.094$, solid solution. The least squares line for $\bar{\mu}_{CdTe}$, $x = 0.196$, intersects that for $x = 0.094$ near 527°C. This of course cannot be correct. The error stems from the fact that the six data points cover only a 40°C range.

The enthalpy and entropy values shown in Table VIII are highly correlated in each case and their most probable values fall within an extremely elongated ellipse, which for practical purposes can be approximated by a thin rectangle in the enthalpy-entropy plane (10). The bisector of this rectangle is a line segment that goes through the best fit value for the enthalpy and entropy, has a slope given by the reciprocal of the mean value of $1/T$ listed in the next-to-last column of Table VIII, and is terminated at the 95% confidence limits by the uncertainty quoted for the enthalpy, or equivalently, that quoted for the entropy. Thus, for the first entry in Table VIII, the most probable values of $\bar{h}$ and $\bar{s}$ are related by

$$\bar{h} = -42{,}169 + 870.18(\bar{s} + 43.256) \pm w \qquad [7]$$

$$-42.86 > \bar{s} > -43.66 \text{ for 95\% confidence limit}$$

where $2w$ is the width of the 95% probability ellipse at the best fit value of -43.256 for $\bar{s}$ and is given in the last column of Table VIII for all of the fits. The value of w is the product of the uncertainty in $\bar{h}$ and a factor $(1 - \rho^2)^{1/2}$. The correlation coefficient, ρ, in turn is given as the ratio of the average reciprocal temperature of the experimental points, $<1/T>$, to that of the square root of the average squared reciprocal temperature, $<(1/T)^2>$

$$\bar{\rho} = -<1/T>/<(1/T)^2>^{1/2} \qquad [8]$$

It can be seen that the inclusion of the w term in Eq. [7] does not increase the uncertainty in $\bar{h}$ significantly above the uncertainty associated with $\bar{s}$. Its presence is significant, however, in determining the uncertainty in the chemical potentials, which are much more precisely established than the corresponding individual values of $\bar{h}$ and $\bar{s}$. Expressing the chemical potential in terms of its partial molar enthalpy and entropy, and using Eq. [7] to eliminate $\bar{h}$, for the first entry in Table VIII one obtains

$$\bar{\mu}_{HgTe} = -4528 + (870.2 - T)\,\bar{s} \pm w \qquad [9]$$

Thus the uncertainty in the chemical potential depends on that in $\bar{s}$, but at 870.2 K reduces to a minimum value of $\pm\, w$ or $\pm$ 60 cal. At temperatures increasing removed from 870.2 K, the uncertainty in $\bar{s}$ enters and increases that in the chemical potential above $\pm$ 60 cal.

The difference between the chemical potentials of Hg and Cd can be obtained as a function of T for a given value of x by using Eq. [1], [2], [3], and Table VIII.

Knowing the chemical potentials of HgTe and CdTe for the x-values listed, it is possible to calculate any two of the partial pressures, P_{Hg}, P_{Cd}, or P_2, over the solid solution, given the third. The calculated points along the three-phase curves of Fig. 1 and 2 and the calculated values for P_{Cd} along the three-phase curves shown in Fig. 3 were obtained using the expressions for $\bar{\mu}_{HgTe}$ and $\bar{\mu}_{CdTe}$ established in Table VIII, Eq. [1], [2], [3], and the measured values of P_{Hg} given in Tables I

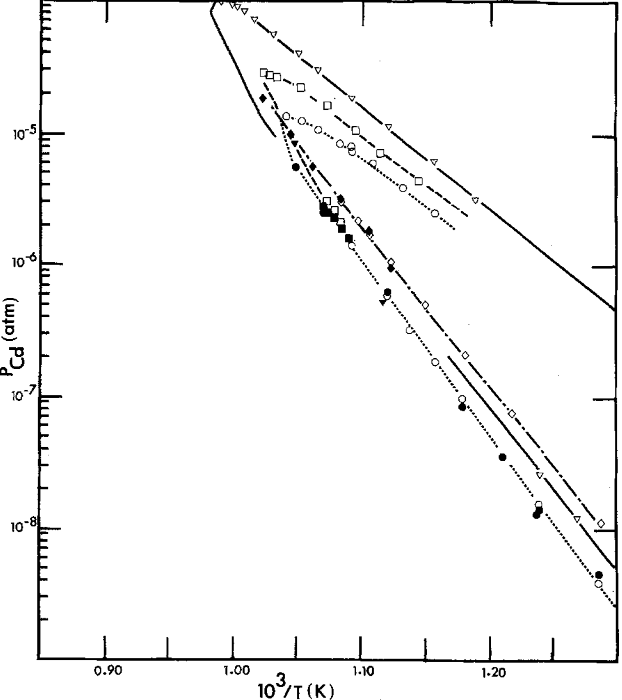

Fig. 3. The partial pressure of Cd along the three-phase curves for various x-values as a function of $10^3/T$. Closed symbols have the same meaning as indicated in the caption for Fig. 1. Open symbols are calculated values.

through VI. In contrast to the P_{Hg} and P_2 three-phase curves, those for P_{Cd} show that, at a given temperature, P_{Cd} is generally higher the larger x for both metal-saturated and Te-saturated solid solutions.

The standard enthalpies and entropies corresponding to the reaction given by Eq. [4] are given in the last section of Table VIII as calculated using the quantities for CdTe from Ref. (6). These were obtained using Eq. [5] and the individual fits to $\bar{\mu}_{HgTe}$ and $\bar{\mu}_{CdTe}$, rather than by a fit to the $\Delta G°_f$ points directly. Since the cadmium pressures were generally not measured over as wide a temperature range as the other two, the latter procedure would not include all the values of $\bar{\mu}_{HgTe}$ that were measured.

The standard enthalpy and entropy for the reaction

$$(1-x)\ \mathrm{HgTe(c)} + x\mathrm{CdTe(c)} \rightarrow \mathrm{Hg}_{1-x}\mathrm{Cd}_x\mathrm{Te(c)} \qquad [10]$$

can be calculated using the data in Table VIII. The results are given in Table IX without the uncertainties attached.

Both $\Delta H°_f$ and $\Delta S°_f$ are small and at the 95% confidence limit are consistent with the interpretation that the solid solution is ideal with an entropy of mixing corresponding to the random mixing of Hg and Cd. Although the partial pressure measurements are fairly precise, as demonstrated by the fairly low values of w in Table VIII, the $\Delta G°_f$ values corresponding to Eq. [10] and Table IX are relatively small differences of large quantities. In spite of the above, one can attempt to gain further insight into the thermodynamics-of-mixing for the solid solution by considering the chemical potentials. Since the solid solution appears to be close to ideal, it seems reasonable to assume that it is a

Table IX. Standard enthalpy and entropy for the reaction, $(1-x)\ \mathrm{HgTe(c)} + x\ \mathrm{CdTe(c)} \rightarrow \mathrm{Hg}_{1-x}\mathrm{Cd}_x\mathrm{Te(c)}$

x	$\Delta H°_f$ (cal/ formula wt)	$\Delta S°_f$ (cal/ K-formula wt)
0.094	−1492	1.46
0.197	−533	0.12
0.416	323	1.56

simple solution, *i.e.*

$$\bar{\mu}_{HgTe} - \bar{\mu}^\circ_{HgTe} = \Omega x^2 + RT \ln(1 - x) \quad [11]$$

$$\bar{\mu}_{CdTe} - \bar{\mu}^\circ_{CdTe} = \Omega(1 - x)^2 + RT \ln(x) \quad [12]$$

where Ω is a function of T and $\bar{\mu}^\circ_{HgTe}$ and $\bar{\mu}^\circ_{CdTe}$ are the chemical potentials (or Gibbs free enthalpies of formation) of pure HgTe(c) and CdTe(c), respectively. Accordingly, the left-hand sides of Eq. [11] and [12] were calculated at 880 K, the average of the $1/\langle 1/T \rangle$ values in Table VII, and Ω evaluated for each x-value. Ideally, plots of Ωx^2 *vs.* x^2 and of $\Omega(1 - x)^2$ *vs.* $(1 - x)^2$ should yield two straight lines through the origin with the same slope, Ω. A superposition of the two plots should show points clustered around a common straight line. Actually, the chemical potentials of CdTe lead to points much higher than those derived from the chemical potentials of HgTe. If the former are all corrected by subtracting 720 cal, then Fig. 4 results. Two CdTe points are not shown. That for $x = 0.416$ occurs at $(1 - x)^2 = 0.341$ and is at -481 cal. That for $x = 0.094$ occurs at 0.821 and is at 1378 cal. The presence of scatter in the points derived from $\bar{\mu}_{HgTe}$ is not surprising because the calculated values of Ωx^2 are not much larger than the 20-70 cal maximum precision with which the chemical potentials have been determined. Nevertheless they indicate a positive, nonzero value for Ω. In contrast, with the exception of $x = 0.416$, the values of $\Omega(1 - x)^2$ derived from $\bar{\mu}_{CdTe}$ range from 800 to 2100 cal, large compared to the maximum precision of 100-200 cal in $\bar{\mu}_{CdTe}$ (see last column of Table VIII). We conclude that the value of $\bar{\mu}_{CdTe} - \bar{\mu}^\circ_{CdTe}$ for $x = 0.416$ is inconsistent with its values for

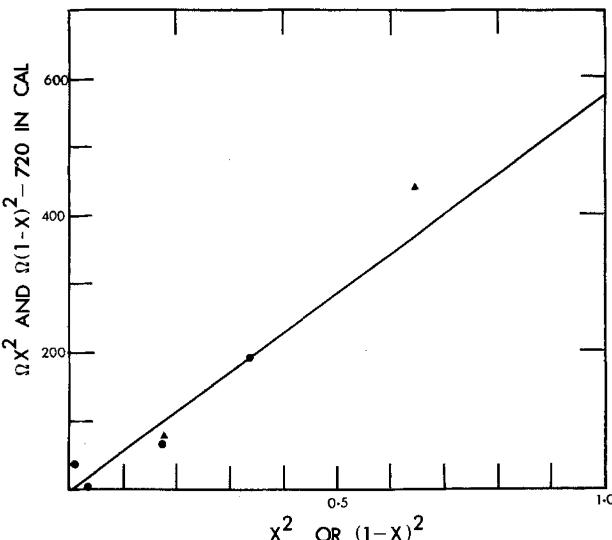

Fig. 4. The excess relative chemical potential of HgTe in $Hg_{1-x}Cd_xTe(c)$, Ωx^2, plotted against x^2 and the analogous quantity for CdTe, $\Omega(1 - x)^2$, plotted against $(1 - x)^2$. ● Ωx^2, ▲ $\Omega(1 - x)^2$.

other x's and should be ignored. Moreover, all the values for $\bar{\mu}_{CdTe} - \bar{\mu}^\circ_{CdTe}$ are most likely subject to a systematic error of about -720 cal/mole. A possible source for this error lies in the Gibbs free enthalpy of formation of CdTe(c) itself. The value of ΔG°_f for CdTe at 880 K calculated from Ref. (9) is 324 cal less negative than that from Ref. (6) and used here (see Table VIII). Another value (11), determined in the same high temperature range, is about 1 kcal less negative. The postulated error is therefore not unreasonable. This still leaves unexplained the high value of $\bar{\mu}_{CdTe} - \bar{\mu}^\circ_{CdTe}$ for $x = 0.094$. A true value of P_{Cd} only 0.6 of that measured would be required to reduce the corrected value of $\Omega(1 - x)^2$ to 470 cal and put it on the line shown in Fig. 4. The above discussion of errors is speculative. However, we feel the values of Ωx^2 in Fig. 4, derived from the HgTe chemical potentials, do indicate a positive value for Ω that is roughly 600 cal at 880 K.

Estimated Thermodynamic Properties of the Solid Zirconium Iodides

Robert H. Lamoreaux and Daniel Cubicciotti*

SRI International, Menlo Park, California 94025

ABSTRACT

Literature values of ZrI_4 pressures in equilibrium with solids of the zirconium-iodine system have been used to calculate Zr and ZrI_4 activities as functions of composition at 700 K. These activities, along with estimated heat capacities and free energy functions, were used to derive values of the activity of iodine and of the enthalpies of formation of solid stoichiometric ZrI, ZrI_2, and ZrI_3. The estimated enthalpies of formation were: $\Delta H^\circ_{298}(ZrI,s) = -34.0 \pm 2.5$ kcal/mole; $\Delta H^\circ_{298}(ZrI_2,s) = -66.4 \pm 2.5$ kcal/mole; $\Delta H^\circ_{298}(ZrI_3,s) = -93.6 \pm 3.5$ kcal/mole.

The solid-state chemistry of the zirconium-iodine system, which must be known to understand the iodine-induced stress corrosion cracking of zirconium alloys, is complex and to a large extent undetermined. The earlier literature contains little thermodynamic information and is inconsistent about the compositions of solid phases. Recent torsion-effusion studies (1-3) of the pressure of ZrI_4 in equilibrium with solid zirconium iodides have established solid solution regions corresponding approximately to tetra-, tri-, di-, and mono-iodide.

Vaporization measurements on solid zirconium iodides determine the equilibrium pressure of ZrI_4 according to the generalized equation

$$\left(\frac{x+y}{y}\right) ZrI_{4-x}(s) = \left(\frac{x}{y}\right) ZrI_{4-x-y}(s) + ZrI_4(g) \qquad [1]$$

Zirconium tetraiodide is the predominant gaseous metal iodide species in equilibrium with any condensed phase in the zirconium-iodine system below about 1000 K (2).

The equilibrium behavior of the condensed phases must conform to the phase rule. A two-component system with a gas phase is univariant when there are two condensed phases (*i.e.*, two immiscible solids) and bivariant when there is only one condensed phase (*i.e.*, one solid solution of variable composition). The number of condensed phases and their compositions can be deduced from the behavior of the pressure of ZrI_4 in the system as the composition of the solid changes during vaporization. As ZrI_4 is removed by vaporization from a solid by Eq. [1], the overall composition of the condensed phase becomes poorer in iodine. If the condensed phase consists of two solids, then the system is univariant and the equilibrium pressure of ZrI_4 depends only on the temperature of the system; in this case, removal of ZrI_4 by vaporization will not change the pressure, but will change only the amounts of the two solids present. If only one solid phase is present (a solid solution), then the system is bivariant and the pressure of ZrI_4 depends on the composition of the solid solution as well as on the temperature; in this case, removal of ZrI_4 will cause the composition of the solid solution to change and the equilibrium pressure to decrease at constant temperature.

The composition limits of zirconium iodide solid phases are listed in Table I (see also Fig. 1). These limits should vary somewhat with temperature, but the variation might be small, as found by Daake and Corbett (4) for the triiodide. The tetraiodide has been characterized, but there is no information about the range of composition over which it is stable. For this phase to be in equilibrium with triiodide, it must extend to $ZrI_{4-\gamma}$, since stoichiometric $ZrI_4(s)$ vaporizes congruently (1). The ZrI solid solution composition limits were established by x-ray and chemical analysis of equilibrated samples (4), whereas those of the ZrI_2 and ZrI phases were established by observation of one- and two-solid-phase vaporization behavior (2, 3, 5). Two-solid-phase behavior was observed (3) between $ZrI_{1.05}$ and Zr. The two equilibrium solids in that region were determined from x-ray analysis of a sample of composition $ZrI_{0.1}$, which indicated that the only phases present were Zr and the monoiodide (3).

Table I. Composition limits of solid phases of the zirconium-iodine system

Nominal phase	Composition range	Ref.
Zr	$Zr\text{-}ZrI_{\delta}$	—
ZrI	$ZrI_{1.05 \pm 0.1}\text{-}ZrI_{1.30 \pm 0.1}$	(2)
ZrI_2	$ZrI_{1.9 \pm 0.1}\text{-}ZrI_{2.1 \pm 0.1}$	(2)
ZrI_3	$ZrI_{2.83 \pm 0.05}\text{-}ZrI_{3.43 \pm 0.05}$	(4)
ZrI_4	$ZrI_{4-\gamma}\text{-}ZrI_{4+\epsilon}$	—

Heats of formation and free energy functions of solid zirconium monoiodide, diiodide, and triiodide are needed to assess their chemical reactivities with other materials. Since there are no measured values, we have estimated the free energy functions and utilized the limited amount of vaporization data to estimate the heats of formation. Thermodynamic functions used in

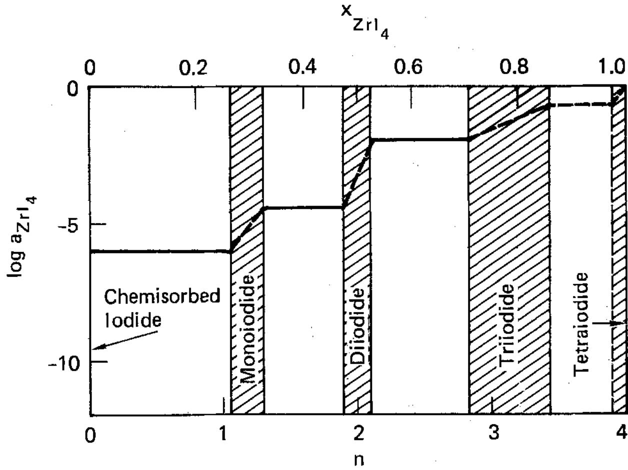

Fig. 1. Activity of ZrI_4 in solid phases of the Zr-I system at 700 K. The lower abscissa is the coefficient n in the formula ZrI_n. Dashed lines represent unknown values. Clear areas are 2 solid phase regions; diagonally ruled areas are 1 solid phase (solid solution) regions.

the calculations were taken from sources summarized in the Appendix.

Calculational Procedures and Results

Activities of Zr and ZrI_4.—Zirconium (component 1) and ZrI_4 (component 2) were taken to be the components of the Zr-I system. The pure solid at the temperature in question was used as the standard state for each component. The activity of ZrI_4 in a two-solid-phase region at a given temperature was calculated as $a_2 = p_2/p°_2$, where p_2 was derived from the data of Table II, and $p°_2$ was the pressure of ZrI_4 over pure, congruently vaporizing ZrI_4(s), calculated from the relationship given in Ref. (1)

$$\log p°_2(\text{atm}) = -\frac{1}{4.575}[31880T^{-1} - 49.7 + 6.68 \times 10^{-3}T - 1.131 \times 10^{-6}T^2 + 8.06 \times 10^4 T^{-2}] \quad [2]$$

(450-670 K)

Existing ZrI_4 activity data for the Zr-I solid phase system are indicated in Fig. 1 by solid horizontal lines. The few pressure values reported in the literature for compositions in one-solid-phase regions of this system were considered unreliable because of the probable lack of equilibrium in effusion cells containing a solid phase whose composition changed as ZrI_4 was removed.

The procedure used was to (*i*) calculate the activities of ZrI_4 and Zr in the two-solid-phase regions, (*ii*) calculate these activities at compositions (ZrI_2, ZrI_3) within one-solid-phase (solid solution) regions, and (*iii*) use these activities and estimated free energy function to derive values of the enthalpy of formation for the solid iodides. The lack of experimental data for the triiodide-tetraiodide two-solid-phase region precludes exact calculation of activities within the ZrI_3 phase, but it will be shown that the enthalpy of formation of ZrI_3(s) may nevertheless be fixed within the stated uncertainties.

The activity of Zr was found by integrating the Gibbs-Duhem equation

$$d \ln a_1 = -\frac{x_2}{x_1} d \ln a_2 \quad [3]$$

Over a sufficiently narrow solid phase region it can be shown[1] that

$$\Delta \ln a_1 = -\left(\frac{x_2}{x_1}\right)_{\text{average}} \Delta \ln a_2 \quad [4]$$

or, in terms of n

$$\Delta \ln a_1 = -\left(\frac{n}{4-n}\right)_{\text{average}} \Delta \ln a_2 \quad [5]$$

This simple expression gave results for $\Delta \ln a_1$ in the mono- and di-iodide phases which were identical, at all values of n to results obtained by a more complex technique involving 3-term Margules expressions for the activity coefficients. The activities for stoichiometric ZrI_2 were thus obtained by interpolation. For ZrI, the activities were those of the Zr-$ZrI_{1.05}$ two-solid-phase region; this procedure was justified by the uncertainty in the phase boundaries.

[1] The function $f(\ln a_2) = (x_2/x_1)$ expanded as a Taylor's series about $\ln a_2'$ is truncated to $f(\ln a_2' + h) = f(\ln a_2') + h f'(\ln a_2')$, then substituted on Eq. [3] for integration.

Because data are lacking for the $ZrI_{3.43}$-$ZrI_{4-\gamma}$ region, activities for $ZrI_{3.0}$ were calculated for the two limiting cases: (*i*) activities unchanged between $ZrI_{2.83}$ and $ZrI_{3.0}$, and (*ii*) the activity of ZrI_4 reaches unity at $ZrI_{3.0}$. As shown below, both cases lead to closely agreeing values of the enthalpy of formation of ZrI_3(s).

The activities of Zr and ZrI_4 calculated at 700 K from the data of Tables I and II are shown in Table III. At this temperature, chosen to minimize extrapolation of ZrI_4 pressure relationships outside their experimental regions, $p_2° = 0.937$ atm. The activity of Zr in the two-solid-phase region ZrI_5-$ZrI_{1.05}$ was taken as unity because of the negligible solubility of iodine in metallic zirconium.

Thermodynamic functions for the solid zirconium iodides.—No experimental values of heat capacities, C_p, entropies, $S°$, or free energy functions, $\Phi°_{298} = -(G° - H°_{298})/T$ were found for solid ZrI, ZrI_2, or ZrI_3. They were estimated by the method used by the authors of the JANAF Table (8) for $ZrCl_2$ and $ZrCl_3$ as follows. For the solid compound ZrI_n for which $n = 1$, 2, or 3, or solid solution for which n is nonintegral, the quantity Q ($Q = C°_p$, $S°_T$, or $\Phi°_{298}$) was estimated by subtracting (4-n) iodine-gram-atomic contributions from the molal quantity for ZrI_4(s) according to the relationship

$$Q(ZrI_n,s) = Q(ZrI_4,s) - \frac{4-n}{4}[Q(ZrI_4,s) - Q(Zr,s)] \quad [6]$$

We estimate the uncertainties introduced by this procedure are ±1 cal/mole degree for C_p and ±2 cal/mole degree for both $S°$ and Φ_{298}. Table IV presents the thermal data used in Eq. [8] to evaluate the estimated quantities for the solids. Values for the nonstoichiometric solid solutions can be estimated by this procedure as well as for the stoichiometric compounds because the method assumes simply that the thermal quantities (Q) are arithmetic averages of the known values for the two components. The quantity of interest in the present work was the tempered Gibbs energy function, $\Phi°_{298}$. That function for the zirconium iodide solid solutions can be represented in one equation as follows

$$\Phi°_{298}(ZrI_n,s) = 7.53 + 0.0051T + n(10.91 + 0.00487T) \quad [7]$$

That equation is assumed to be applicable for n including nonintegral values, from 1 to 4 and over the temperature range 400-800 K.

Activity of $I_2(g)$ and $I(g)$.—In applications in which zirconium is exposed to attack by gaseous iodine, values of the activity of I(g) and I_2(g) over zirconium iodide solids are needed to understand the resulting chemical behavior. When ZrI_4 and Zr activities were known, the activity of I_2(g) with reference to the 1 atm perfect-gas standard state was calculated from the equilibrium

$$ZrI_4(s) = 2I_2(g) + Zr(s) \quad [8]$$

for which

$$\Delta G° = -RT \ln K = -R \ln \frac{a_{Zr}\, a^2_{I_2}}{a_{ZrI_4}} \quad [9]$$

and

$$a_{I_2} = \left(\frac{K\, a_{ZrI_4}}{a_{Zr}}\right)^{1/2} \quad [10]$$

The standard Gibbs energy change for reaction [8] was calculated using tabulated values of $\Phi°_{298}$ and $\Delta H°_{298}$ (1, 8). At 700 K

$$K = 1.02 \times 10^{-30}$$

The activity of monatomic iodine was calculated from the equilibrium constant K_I for the reaction

$$I_2(g) = 2I(g) \quad [11]$$

Table II. Pressures of ZrI_4 over two-solid phase regions of the zirconium-iodine system

	$\text{Log}_{10}P(\text{atm}) = -AT^{-1} + B$			
Two-solid-phase region	A	B	T range, K	Ref.

$$K_I = a_I^2/a_{I_2} \quad [12]$$

at 700 K, $K_I = 1.13 \times 10^{-6}$.

Activities of I_2 and I obtained in this way are given in Table III.

Enthalpies of formation of solid ZrI, ZrI_2, and ZrI_3.—The standard Gibbs energy changes, $\Delta G°$, for formation of solid ZrI_n (n = 1, 2, 3, or 4) from solid Zr and ZrI_4 by the reactions of the type

$$\frac{4-n}{4}\,\mathrm{Zr(s)} + \frac{n}{4}\,\mathrm{ZrI_4(s)} = \mathrm{ZrI_n(s)} \quad [13]$$

were obtained from the activities of Zr and ZrI_4 at the composition ZrI_n (where $x_2 = n/4$); through the relationship

$$\Delta G° = -RT \ln [a_{ZrI_n}/(a_{Zr})^{(4-n)/4}(a_{ZrI_4})^{n/4}] \quad [14]$$

or, since the ZrI_n activity of pure ZrI_n(s) is unity

$$\Delta G° = RT \ln (a_{Zr})^{(4-n)/4}(a_{ZrI_4})^{n/4} \quad [15]$$

Since the method used (*i.e.*, Eq. [6]) for estimating heat capacities, entropies, and free energy functions of the solid zirconium iodides implies that $\Delta C°_p$ and $\Delta S°$ for Reaction [13] are zero at all temperatures, then $\Delta G°_T = \Delta H°_T = \Delta G°_{298} = \Delta H°_{298}$ for Reaction [13] so that

$$\Delta H_f(\mathrm{ZrI_n}) = \Delta H_{13} + \frac{n}{4}\,\Delta H_f(\mathrm{ZrI_4}) \quad [16]$$

and $\Delta H_{13} = \Delta G°_{13}$ obtained in Eq. [15].

Activities of ZrI_4 and Zr at 700° from Table III were used to evaluate the enthalpies of formation. The values obtained for the stoichiometric compounds were $\Delta H°_{298}$(ZrI,s) = −34.0 ± 2.5 kcal/mole, $\Delta H°_{298}$(ZrI_2,s) = −66.4 ± 2.5 kcal/mole, and ΔH_{298}(ZrI_3,s) = −93.6 ± 4.5 kcal/mole. For purposes of comparison, for ZrI_4(s), $\Delta H°_{298}$ + −116.8 ± 1.5 kcal/mole (1). The uncertainties in $\Delta H°_{298}$ for ZrI(s) and ZrI_2(s) are essentially due to uncertainties in $Φ°_{298}$. The difference in $\Delta G°$ between the two limiting activity cases for ZrI_3 was 0.5 kcal/mole, but the cumulative uncertainties in a_{Zr} increase the uncertainty in the value of $\Delta H°_{298}$ for ZrI_3(s). The same procedure was used to obtain the enthalpies of formation of the nonstoichiometric solid solutions. The results are presented graphically in Fig. 2. The lower curve gives the enthalpy of formation of the solid per gram atom of zirconium which is also the value per mole of solid ZrI_n. The upper curve gives the values per gram atom of iodide. The segments of that upper curve, which represent the approximate ranges of solid solution, fall on a straight line within experimental error. Thus, the enthalpies of formation of the solids per gram atom of iodide can be expressed by the rather simple equation

$$\Delta H_{298}(f, \mathrm{ZrI_n}, \mathrm{s}), \text{kcal/g atom } I = -35.6 + 1.6\,n \quad [17]$$

The enthalpy of formation per gram atom of iodine chemisorbed iodide was taken from Ref. (8) and represents a value obtained for a surface coverage of the order of a fraction of a monolayer. That value fits into Eq. [17] within experimental error. Therefore the range of values of n in Eq. [17] includes the value zero.

The enthalpies of formation of the gaseous iodide of zirconium can be combined with the enthalpies of formation of the solid stoichiometric iodides, given above, to derive enthalpies of sublimation for the four iodides. These values are given in Table V. These enthalpy changes correspond to the four reactions

$$\mathrm{ZrI_n(s)} = \mathrm{ZrI_n(g)} \quad [18]$$

It should be recognized that the equilibrium sublimations of all the iodides except the tetraiodide correspond to incongruent vaporization. That is, in general the major vapor species in gaseous ZrI_4 so that reaction [18] represents the equilibrium vaporization process. Nevertheless, reaction[2] can be considered per se. The values are in keeping with the relative pressures of species calculated for the equilibrium with zirconium at temperatures below about 1200 K in Ref. (7). That is, in the gas the monoiodide was the least important while the tetraiodide was the most important with the di- and

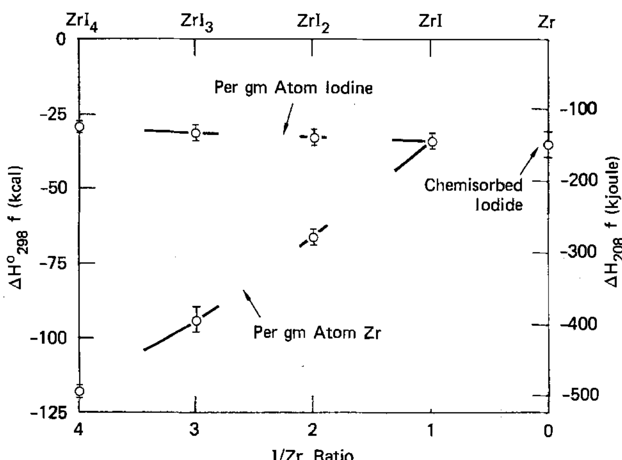

Fig. 2. Enthalpies of formation of the solid zirconium iodides. Values are presented per gram atom of zirconium (lower curve) or per gram atom of iodide in the solid (upper curve). The data points are the values for the stoichiometric solids. The curve segments represent values for the solid solution ranges.

Table V. Enthalpies of sublimation of zirconium iodides*

	ΔH_{298} (subl) kcal/mol
ZrI	130
ZrI_2	99
ZrI_3	63
ZrI_4	31.9

* Values are hypothetical because all the iodides, except ZrI_4, vaporize incongruently to $ZrI_4(g)$, see text.

tri-iodides intermediate, in keeping with the relative values of their sublimation enthalpies, which dominates the entropy at those lower temperatures.

ABSTRACT

A generalized treatment of the parabolic oxidation of pure metals forming electronically semiconducting oxides containing different kinds of defects is developed by extending the Kröger approach to Wagner's theory of oxidation based on the analysis of the diffusion of lattice defects. Only oxides with defects in the cation sublattice are considered for simplicity. It is shown how the generally used expressions for the dependence of the parabolic rate constant and the self-diffusion coefficient of the metal as functions of the oxygen activity through the scale are modified by the presence of more than one type of lattice defect. This treatment is then applied to the oxidation of cobalt in oxygen at 1000°C taking into account the actual defect structure of CoO, obtaining a reasonable agreement with the experimental results.

The oxidation of pure metals forming semiconducting oxides of p- or n-type is usually interpreted in terms of Wagner's theory of parabolic oxidation (1-4), assuming that only one kind of lattice defect predominates over the whole range of oxygen activities between the value of equilibrium metal/oxide and that prevailing in the gas phase. In some cases this assumption has led to a reasonably good agreement between the experimental values of the parabolic rate constant and those calculated by means of the diffusion coefficients of the migrating species obtained from independent measurements (5-14) and also in the reverse calculation (15-17). Frequently, however, the parameters giving the oxygen pressure dependence of the diffusion coefficient and the parabolic rate constant have not the exact integer values predicted by the theory for a single species of defects (1-4, 18). A pos-

Key words: parabolic oxidation, pure metals, theory.

sible reason for this discrepancy is the presence of interactions between defects, not accounted for by the theory, as pointed out recently by C. Wagner (19), but this may also depend on the simultaneous presence of different types of defects in the growing oxide. This situation has been recently discovered for oxides like CoO and NiO, since it has been found that at high temperatures their solid solutions contain a substantial concentration of metal interstitials in addition to the metal vacancies (20). It has also been found for CoO that the concentration of defects obtained from measurements of deviations from stoichiometry is smaller than the overall concentration, suggesting the presence of metal interstitials (Frenkel defects) (17, 21). In addition, the same type of lattice defect may present different electric charges, with the ratio between the concentrations of the differently charged defects depending on the actual value of the oxygen activity.

It seems therefore appropriate to examine the problem of the growth of pure and doped oxides on a metal in more detail than is usually done, considering the actual complexity of the defect structure of the oxides, even for those usually considered simple, like NiO and CoO, to see the effects that this may have on their oxidation behavior. An extension of Wagner's theory taking into account the participation of different kinds of defects to the mass transport during the metal oxidation has already been presented and applied to the oxidation of nickel and cobalt (12). This treatment is extended and generalized here to include the presence of any kind of defects in the cation sublattice.

Throughout the following analysis the Wagner theory of parabolic oxidation will be used as a basis, considering the diffusion of lattice and electronic defects according to the treatment developed by Kröger (22). Even if this approach to the metal oxidation is not exempt from criticism (23, 24), it represents a sufficiently approximate theory for the present purposes and at the same time has the advantage of being essentially simple. This procedure is also partly justified by the proof given by C. Wagner (25) that deviations from local equilibrium in a growing oxide are not likely to affect the final result appreciably. In addition, the many approximations involved in dealing with practical systems, as mentioned below, would prevent a completely rigorous treatment anyway.

Only electronically conducting oxides are considered here, and any kind of interaction between defects as well as defect aggregation will be neglected. This is undoubtedly a major approximation since defects, being generally electrically charged, will usually interact, so that the concept of free defects is a crude assumption when their concentration exceeds 10^{-3}-10^{-4} in mole fraction (19, 26). Therefore, a correct treatment should make use of activities of defects instead of concentrations. The thermodynamic theory of lattice defects along these lines, however, is not yet completely developed (19, 26-27). In addition, the diffusion coefficients of the different defects are assumed to be equal and independent of their concentration, even if the theory does not require this limitation, since apparently there are no experimental results in this field. Furthermore it will be assumed that oxygen diffusion is negligible with respect to that of the metal.

In view of the many limitations mentioned above, the present treatment is considered only approximate, although it represents an improvement of the single-defect model generally used so far. Therefore, when applied to actual cases it is not expected to lead to a complete agreement with the experimental results. In fact, in addition to the improvements indicated above, this would also require a consideration of other frequently important factors such as the short-circuit diffusion, the presence of porosity and of mechanical stresses in the scale, the lack of scale adherence, and many others, many of which cannot be accounted for quantitatively and whose consideration would make the theory extremely complex and not general.

This paper examines the oxidation behavior of pure metals: a following paper will discuss within the same framework the effect of the presence of a uniform concentration of aliovalent impurities on the growth of the scale on dilute alloys for oxides with simple or complex defect structure (28).

Theory

The most general model for the defect structure of a pure oxide should include all kinds of defects, also because under appropriate conditions even minority defects may play an important role. Therefore, we will consider the possibility of formation of both cation vacancies and metal interstitials, neglecting only for simplicity the presence of defects in the anion sublattice. This possibility may, however, be easily considered in this type of treatment. In addition, and in agreement with the above simplification, we assume that the contribution to the oxide growth by the oxygen diffusion is negligible.

The quasi-chemical equations for the formation of the different kinds of cation lattice defects in an oxide MO are

$$\tfrac{1}{2}\,O_2 = O^x + V^x \qquad [1]$$

$$V^x = V' + h^\cdot \qquad [2]$$

$$V' = V'' + h^\cdot \qquad [3]$$

$$M^x = M_i^x + V^x \qquad [4]$$

$$M_i^x = M_i^\cdot + e' \qquad [5]$$

$$M_i^\cdot = M_i^{\cdot\cdot} + e' \qquad [6]$$

and for the electronic defects

$$O = e' + h^\cdot \qquad [7]$$

where a simplified Kröger-Vink notation is used (22) since only metal vacancies are considered here. Each of the previous equations gives rise to a corresponding equilibrium constant K_i, where i represents the number of the equation in the scheme above. The concentrations of the different species so considered (expressed here as mole fractions) are therefore given by

$$[V^x] = K_1\,P_{O_2}{}^{1/2} \qquad [8]$$

$$[V'] = \frac{K_1K_2}{p}\,P_{O_2}{}^{1/2} \qquad [9]$$

$$[V''] = \frac{K_1K_2K_3}{p^2}\,P_{O_2}{}^{1/2} \qquad [10]$$

$$[M_i^x] = \frac{K_4}{K_1P_{O_2}{}^{1/2}} \qquad [11]$$

$$[M_i^\cdot] = \frac{K_4K_5}{nK_1P_{O_2}{}^{1/2}} \qquad [12]$$

$$[M_i^{\cdot\cdot}] = \frac{K_4K_5K_6}{n^2K_1P_{O_2}{}^{1/2}} \qquad [13]$$

$$n = K_7/p \qquad [14]$$

where n is the concentration of electrons and p that of the electron holes. By means of Eq. [14] the concentration of $M_i^\cdot$ and $M_i^{\cdot\cdot}$ may also be given as a function of p. The previous equations show that the concentration of the lattice defects depends on the local oxygen activity.

A condition which must be fulfilled during the oxide growth is that of local electroneutrality, which in our case takes the form

$$p + [M_i^\cdot] + 2[M_i^{\cdot\cdot}] = n + [V'] + 2[V''] \qquad [15]$$

Substituting in Eq. [15] the concentrations of the various defects as given by Eq. [8]-[14] and making

use of the oxygen activity defined as $a_O = P_{O_2}^{1/2}$ gives

$$2\frac{K_4K_5K_6}{K_1K_7a_O}p^4 + \left(1+\frac{K_4K_5}{K_1a_O}\right)p^3 - (K_7 + K_1K_2a_O)p - 2K_1K_2K_3a_O = 0 \quad [16]$$

For any value of a_O, Eq. [16] gives the corresponding concentration of the electron holes and then Eq. [8]-[14] those of all the defects.

During the metal oxidation an oxygen activity gradient is built up between the inner and outer scale interfaces, producing therefore corresponding gradients in the concentrations of the different defects and thereby a flux of matter through the scale. For each kind of defect the diffusion flux is proportional to the corresponding gradient of the electrochemical potential (29) in the form

$$J_{def} = \frac{N_A d_{ox}}{M_{ox}}\left(-D_{def}\frac{d[\text{def}]}{dx} \pm v_{def}[\text{def}]\frac{d\phi}{dx}\right) \quad [17]$$

where x is the distance from the metal/scale interface, D_{def} the diffusion coefficient of the defect, v_{def} its mobility, and $-d\phi/dx$ the built-in electric field set up by the diffusion of charged species having a different mobility. The sign before the second term on the right-hand side of Eq. [17] is positive for a species with a negative effective charge and vice versa, while the factor $R = N_A d_{ox}/M_{ox}$ (where N_A is the Avogadro number, d_{ox} the oxide density, and M_{ox} its molar weight) is required to convert the concentrations of the defects from mole fractions to number of defects/cm^3, which is also a common way of expressing the defect concentrations. The diffusion coefficient of each defect D_{def} is related to the mobility or to the transport number t_{def} of the same species by the relationships (29, 30)

$$D_{def} = v_{def}\frac{kT}{|z_i|\,q} \quad [18a]$$

and

$$D_{def} = t_{def}\frac{kT\sigma}{z_i^2q^2c_{def}} \quad [18b]$$

where c_{def} is the concentration of defects (number of defects/cm^3), k the Boltzmann constant, q the electron charge, z_i the charge of the defect, T the absolute temperature, and σ the electrical conductivity.

During the growth of the oxide, the condition of local electroneutrality requires also that the various fluxes of defects are related by the restriction

$$J(h^\cdot) + J(M_i^\cdot) + 2J(M_i^{\cdot\cdot}) = J(e') + J(V') + 2J(V'') \quad [19]$$

which is also called the "coupled current condition" (31). The previous equation may be used to obtain an expression for the diffusion electric field to substitute in Eq. [17]. This procedure may be simplified by considering only the motion of the electronic defects which are by far the most mobile species in the electronic conductors. It is easy to show that this is equivalent to putting equal to one the transport number of the electrons and the electron holes in the final expression for the overall flux of matter through the scale, as is usually done in the derivation of the expression of the parabolic rate constant according to Wagner's treatment (1-4, 22). A more thorough justification of this procedure has been given by Fromhold (32) with the introduction of the concept of "virtual current equilibrium" of the species giving the most important contribution to the electrical conductivity. For an oxide with prevailing electronic conduction the so-called "kinetic potential" or the actual electrostatic potential set up across the oxide by the diffusion of charged species may be deduced by setting equal to zero the flux of the prevailing electronic defect or also by imposing the condition that the sum of the fluxes of electrons and electron holes is zero, taking into account the equilibrium for the intrinsic ionization of the oxide, as used here. Equating, therefore, the fluxes of electrons and electron holes as given by Eq. [17] yields then

$$E(x) = -\frac{d\phi}{dx} = \frac{kT}{q}\frac{d\ln p}{dx} \quad [20]$$

Upon introduction of Eq. [20] and [18a] and [18b] into Eq. [17], the fluxes of the lattice defects are obtained in the form

$$J(V^x) = -D_{V^x}\frac{d[V^x]}{dx}R \quad [21]$$

$$J(V') = -D_{V'}\left(\frac{d[V']}{dx} + [V']\frac{d\ln p}{dx}\right)R \quad [22]$$

$$J(V'') = -D_{V''}\left(\frac{d[V'']}{dx} + 2[V'']\frac{d\ln p}{dx}\right)R \quad [23]$$

$$J(M_i^x) = -D_{M_i^x}\frac{d[M_i^x]}{dx}R \quad [24]$$

$$J(M_i^\cdot) = -D_{M_i^\cdot}\left(\frac{d[M_i^\cdot]}{dx} - [M_i^\cdot]\frac{d\ln p}{dx}\right)R \quad [25]$$

$$J(M_i^{\cdot\cdot}) = -D_{M_i^{\cdot\cdot}}\left(\frac{d[M_i^{\cdot\cdot}]}{dx} - 2[M_i^{\cdot\cdot}]\frac{d\ln p}{dx}\right)R \quad [26]$$

where D_i is the diffusion coefficient of the defect i. The overall flux of matter through the oxide is then given by

$$J_{ox} = -J(V^x) - J(V') - J(V'') + J(M_i^x) + J(M_i^\cdot) + J(M_i^{\cdot\cdot}) \quad [27]$$

For simplicity sake the diffusion coefficients of the vacancies will be considered to be independent of their charge and have a common value D_V and in the same way a common value D_I is assumed for the interstitials: apparently there is no *a priori* theoretical reason for this, even though in some cases this condition has been found approximately true (12).

Introduction of Eq. [21]-[26] into Eq. [28] and use of the previous assumption gives then for the overall flux

$$J_{ov} = R\left[D_V\left(\frac{d[V^x]}{dx} + \frac{d[V']}{dx} + \frac{d[V'']}{dx}\right) + D_V([V'] + 2[V''])\frac{d\ln p}{dx} - D_I\left(\frac{d[M_i^x]}{dx} + \frac{d[M_i^\cdot]}{dx} + \frac{d[M_i^{\cdot\cdot}]}{dx}\right) + D_I([M_i^\cdot] + 2[M_i^{\cdot\cdot}])\frac{d\ln p}{dx}\right] \quad [28]$$

Differentiation of Eq. [8]-[13] with respect to x and substitution into Eq. [28] gives finally

$$J_{ov} = \left[D_V([V^x] + [V'] + [V''])\frac{d\ln a_O}{dx} + D_I([M_i^x] + [M_i^\cdot] + [M_i^{\cdot\cdot}])\frac{d\ln a_O}{dx}\right]R = RF(a_O)\frac{d\ln a_O}{dx} \quad [29]$$

(where $F(a_O) = \Sigma D_{def}\,[\text{def}]$ is a function of a_O) for the overall flux which is now expressed as a function

of the concentrations of all the defects and the gradient of the oxygen activity through the scale.

For a fixed time and scale thickness, the overall flux of matter remains constant through the scale, neglecting the usually small changes in stoichiometry of the oxide. This assumption is essentially correct if the oxide has small deviations from the ideal composition: for large deviations it does not hold strictly, but it is still a reasonable approximation in view of the fact that in these cases other factors, such as interactions between defects, come into play. This point has been examined with particular care by Hirth (33) and Fromhold (34). Therefore, multiplication of both sides of Eq. [29] by dx and integration from $x = 0$ (corresponding to the metal/scale interface, with $a_O = a_O'$) to $x = x_S$ (where x_S is the position of the scale/gas interface, with $a_O = a_O''$) gives

$$J_{ov}\, x_S = k_t = R \int_{a_O'}^{a_O''} F(a_O)\, d \ln a_O \qquad [30a]$$

where k_t is the parabolic rate constant expressed in molecules of oxide formed per unit surface per unit time (35).

An alternative expression for the parabolic rate constant k_t may be obtained by defining a dimensionless distance parameter $y = x/x_S$, which upon differentiation gives $dx = x_S dy$. Introduction of this expression for dx into Eq. [29] and use of the definition of k_t as in Eq. [30] yields

$$J_{ov} x_S = k_t = RF(a_O) \frac{d \ln a_O}{dy} \qquad [30b]$$

Integration of Eq. [29] between $x = 0$ and $x = x$ (with $x \leq x_S$) gives instead

$$J_{ov} x = R \int_{a_O'}^{a_O} F(a_O)\, d \ln a_O \qquad [31]$$

Division of Eq. [31] by Eq. [30a] yields then

$$x/x_S = y = \frac{R}{k_t} \int_{a_O'}^{a_O} F(a_O)\, d \ln a_O \qquad [32]$$

which defines the relationship between a_O and the corresponding relative position within the scale y.

Using the rate constant k_x expressed as a function of the scale thickness by the relationship

$$x_S^2 = k_x t \qquad [33]$$

and related to k_t by (35)

$$k_x = 2 \frac{M_{ox}}{N_A d_{ox}} k_t = 2k_t/R \qquad [34]$$

Eq. [32] becomes

$$y = \frac{2}{k_x} \int_{a_O'}^{a_O} F(a_O)\, d \ln a_O \qquad [35]$$

For a fixed value of the oxygen activity in the gas phase a_O'' the rate constant k_x may be computed by means of Eq. [30a] and [34] and the profile of the oxygen activity through the scale by means of Eq. [35] once that the corresponding value of k_x has been obtained, using Eq. [8]-[13] and Eq. [16] to calculate the concentrations of all the defects as functions of a_O. In addition, it is also possible to obtain the fractional flux of each kind of defects, *i.e.*, the ratio between the flux of a defect and the overall flux, as a function of y, to detect the contribution of the different defects to the overall growth of the oxide at various positions in the scale. In fact, using the same procedure as before for the overall flux, the partial flux for any kind of defects is given by

$$J_{def} = RD_{def}[\text{def}] \frac{d \ln a_O}{dx} \qquad [36]$$

and, dividing Eq. [36] by Eq. [29]

$$\frac{J_{def}}{J_{ov}} = \frac{D_{def}[\text{def}]}{F(a_O)} \qquad [37]$$

where the ratio of the fluxes is a function of a_O and/or y.

Equation [37] implies that the fractional flux of each defect changes with x even if J_{ov} remains constant, under a fixed x_S. In fact, in the simplest case where all the defects have the same diffusion coefficient, the fractional flux of each defect is simply proportional to its fractional concentration which is a function of the local value of the oxygen activity since the concentrations of the various defects have a different kind of dependence on a_O, as shown by Eq. [8]-[13]. Therefore at any point in the scale the largest contributions to the matter transport come from the species having the largest concentrations. If the mobilities of the defects are different, then also this factor must be considered, as implied by Eq. [37].

A final subject to be considered is the expression of the electrical potential due to the migration of charged species in the oxide and of the electric field connected with it. The latter is given by Eq. [20] and is in general a function of x (or y) and x_S. For an oxide with several kinds of defects it can be computed by a numerical evaluation of $d \ln p/dx$. However, it is more convenient to compute the quantity $F(y) = x_S E(x)$ which is only a function of y and does not depend on x_S. This may be found by expressing dx as $x_S dy$ in Eq. [20] giving

$$x_S E(x) = F(y) = \frac{kT}{q} \frac{d \ln p}{dy} \qquad [38]$$

In fact, since p is a function of a_O and a_O of y, $d \ln a_O/dy$ will depend only on y and not on x_S.

The expression of the electrostatic potential is obtained in a straightforward way by integration of Eq. [20] as

$$V(x) - V(0) = -\frac{kT}{q} \int_0^x d \ln p = \frac{kT}{q} \ln \frac{p(0)}{p(x)} = V(x) \qquad [39]$$

(where $p(0)$ and $p(x)$ are the concentrations of electron holes at $x = 0$ and $x = x$, respectively), putting as usual the integration constant $V(0) = 0$. If the upper limit in the above integration is x_S, then we obtain

$$V(x_S) = \frac{kT}{q} \ln \frac{p(0)}{p(x_S)} \qquad [40]$$

Equations [39] and [40] show that the electrostatic potential V is a function of the distance from the metal/scale interface x. However, since p is also a single-valued function of the relative position within the scale y through the local oxygen activity a_O, the potential is also a function of y. Therefore, the potential at a point y in the scale is

$$V(y) = \frac{kT}{q} \ln \frac{p(a_O')}{p(a_O)} \qquad [41]$$

where a_O' is the oxygen activity at $y = 0$ and a_O that at $y = y$, while the potential across the scale is

$$V(1) = \frac{kT}{q} \ln \frac{p(a_O')}{p(a_O'')} \qquad [42]$$

and does not depend on the actual value of the scale thickness x_S, but only on a_O' and a_O''. Examples of calculation of $F(y)$ and $V(y)$ are given in the next section.

Oxides with a Simple Defect Structure

The previous equations for k_x as a function of a_O and for a_O as a function of y are reduced to the simple

expressions generally used if only one kind of defect is present in the oxide in the whole range of oxygen activities. In fact in this case the overall flux of matter through the scale is the same as that of the unique kind of defect to be considered and is given by

$$J_{ov} = \pm J_{def} = RD_{def}\,[\text{def}]\,\frac{d\ln a_O}{dx} \qquad [43]$$

where the minus is for vacancies and the plus for interstitials. Using the same procedure described previously, one may easily obtain the expressions for k_x and a_O for these simple situations as shown below.

Oxides containing only one kind of metal vacancies.—If the oxide contains only vacancies with an effective charge r, the reaction for their formation becomes

$$\tfrac{1}{2}\,O_2 = O^x + V^{r'} + rh^{\circ} \qquad [44]$$

with an equilibrium constant

$$K_V = \frac{[V^{r'}]\,p^r}{a_O} \qquad [45]$$

and a neutrality condition (for $r \neq 0$) $p = r\,[V^{r'}]$. Substitution of this relationship into Eq. [45] gives the concentration of the vacancies in the form

$$[V^{r'}] = \left(\frac{K_V}{r^r}\right)^{1/m} a_O^{1/m} = [V^{r'}]^{\circ}\, a_O^{1/m} \qquad [46]$$

where $m = r + 1$ and $[V^{r'}]^{\circ}$ is the concentration of vacancies when $a_O = 1$. Substitution of Eq. [46] into Eq. [43] yields

$$J_{ov} = -J_V = RD_V\,[V^{r'}]^{\circ}\, a_O^{1/m}\,\frac{d\ln a_O}{dx} \qquad [47]$$

Integration of Eq. [47] between $x = 0$ and $x = x_S$ yields then

$$k_x = 2mD_V\,[V^{r'}]^{\circ}\,[(a_O'')^{1/m} - (a_O')^{1/m}] \qquad [48]$$

or, using Eq. [46] and indicating with $[V^{r'}]'$ and $[V^{r'}]''$ the concentrations of the metal vacancies at $x = 0$ and $x = x_S$, respectively

$$k_x = 2mD_V\,\{[V^{r'}]'' - [V^{r'}]'\} \simeq 2mD_V[V^{r'}]'' \qquad [49]$$

since usually $[V^{r'}]'' >> [V^{r'}]'$. The parabolic rate constant k_x can be put in a different form frequently used by means of the relationship (37)

$$D_M = D_V\,[V^{r'}] \qquad [50]$$

where D_M is the self-diffusion coefficient of the metal in the oxide. When $a_O = 1$ Eq. [50] becomes

$$D_M^{\circ} = D_V\,[V^{r'}]^{\circ} \qquad [51]$$

which, upon introduction into Eq. [48] gives finally

$$k_x = 2m\,[(a_O'')^{1/m} - (a_O')^{1/m}]\,D_M^{\circ} \qquad [52]$$

where the dependence of k_x on the oxygen activity in the gas phase a_O'' is given more clearly.

Integrating again Eq. [47] between $x = 0$ and $x = x$, corresponding to an oxygen activity, a_O, dividing by Eq. [48] and regrouping gives finally, using Eq. [30b] and [34]

$$a_O^{1/m} = (a_O')^{1/m} + [(a_O'')^{1/m} - (a_O')^{1/m}]\,y \qquad [53]$$

for the profile of a_O through the scale.

For these oxides, in view of the relationship between p and a_O as given by Eq. [46] and the appropriate electroneutrality condition, the electric field becomes

$$E(x) = \frac{kT}{qx_S}\,\frac{d\ln p}{dy} = \frac{kT}{qx_S}\,\frac{1}{m}\,\frac{d\ln a_O}{dy} \qquad [54]$$

and, according to Eq. [53]

$$E(x) = \frac{kT}{qx_S}\,\frac{(a_O'')^{1/m} - (a_O')^{1/m}}{a_O^{1/m}} \qquad [55]$$

showing that E is a function of y through a_O and of x_S as well: the product $x_S E$ however depends only on y.

Proceeding as for the general case, the electrostatic potential in the oxide will be

$$V(y) = \frac{kT}{q}\ln\left(\frac{p(0)}{p(y)}\right) = \frac{kT}{qm}\ln\left(\frac{a_O'}{a_O}\right) \qquad [56]$$

and the potential across the whole scale

$$V(1) = \frac{kT}{qm}\ln\left(\frac{a_O'}{a_O''}\right) \qquad [57]$$

showing again the independence of $V(1)$ of the actual scale thickness x_S.

Equation [55] shows that the electric field within the oxide is not constant for a fixed x_S and therefore $V(x)$ is not a linear function of x. Actually, the condition of a constant electric field is not consistent with the condition of a constant flux of defects through the scale for a fixed oxide thickness. In fact, according to Eq. [54], a constant field requires a constant value of $d\ln p/dy$ and $d\ln a_O/dy$. However, since the flux of vacancies is given by Eq. [36], their concentration should be independent of y to produce a constant flux under a constant gradient of $\ln a_O$. This condition is, however, contradictory since the concentration of vacancies is related to the oxygen activity by Eq. [46] and must therefore change with a_O.

Oxides containing only one kind of metal interstitials.—The reaction for the formation of metal interstitials with an effective charge s is

$$M^x + O^x = M_i^{s\cdot} + se' + \tfrac{1}{2}\,O_2 \qquad [58]$$

with an equilibrium constant

$$K_I = [M_i^{s\cdot}]\,n^s a_O \qquad [59]$$

and a neutrality condition (for $s \neq 0$)

$$n = s\,[M_i^{s\cdot}] \qquad [60]$$

Upon introduction of Eq. [60] into Eq. [59] the concentration of interstitials becomes

$$[M_i^{s\cdot}] = \left(\frac{K_I}{s^s}\right)^{1/t} a_O^{-1/t} = [M_i^{s\cdot}]^{\circ}\, a_O^{-1/t} \qquad [61]$$

where $t = s + 1$ and $[M_i^{s\cdot}]^{\circ}$ is the concentration of $M_i^{s\cdot}$ when $a_O = 1$. Substituting Eq. [61] into Eq. [43] gives then

$$J_{ov} = J_I = RD_I\,[M_i^{s\cdot}]^{\circ}\, a_O^{-1/t}\,\frac{d\ln a_O}{dx} \qquad [62]$$

Proceeding as before we get

$$k_x = 2tD_I\,[M_i^{s\cdot}]^{\circ}\,[(a_O')^{-1/t} - (a_O'')^{-1/t}] \qquad [63]$$

for k_x, or also, using Eq. [61] and indicating with $[M_i^{s\cdot}]'$ and $[M_i^{s\cdot}]''$ the concentrations of metal interstitials at $x = 0$ and $x = x_S$, respectively

$$k_x = 2tD_I\,([M_i^{s\cdot}]' - [M_i^{s\cdot}]'') \simeq 2tD_I\,[M_i^{s\cdot}]' \qquad [64]$$

since usually $[M_i^{s\cdot}]' >> [M_i^{s\cdot}]''$. The parabolic rate constant k_x may again be put in a different form by means of the self-diffusion coefficient of the metal D_M, which is related to the concentration of the interstitials by (37)

$$D_M = D_I\,[M_i^{s\cdot}] \qquad [65]$$

or, when $a_O = 1$, by

$$D_M^{\circ} = D_I\,[M_i^{s\cdot}]^{\circ} \qquad [66]$$

Introduction of Eq. [66] into Eq. [63] yields

$$k_x = 2tD_M^{\circ}\,[(a_O')^{-1/t} - (a_O'')^{-1/t}] \qquad [67]$$

Proceeding as for the metal vacancies, the profile of a_O through the scale is obtained as

$$a_O^{-1/t} = (a_O')^{-1/t} - [(a_O')^{-1/t} - (a_O'')^{-1/t}]\,y \qquad [68]$$

For these oxides, using the relationship between a_O and p obtained by means of Eq. [14], [59], and [60], the electric field becomes

$$E = \frac{kT}{qx_S}\frac{d\ln p}{dy} = \frac{kT}{qx_S}\frac{1}{t}\frac{d\ln a_O}{dy} \quad [69]$$

and, using Eq. [68]

$$E = \frac{kT}{qx_S}\frac{(a_O')^{-1/t} - (a_O'')^{-1/t}}{a_O^{-1/t}} \quad [70]$$

so that E depends on y through $a_O^{-1/t}$ as given by Eq. [68]. The electrostatic potential across the scale is given by

$$V(y) = \frac{kT}{q}\ln\left(\frac{p(0)}{p(y)}\right) = \frac{kT}{qt}\ln\left(\frac{a_O'}{a_O}\right) \quad [71]$$

and the overall potential across the scale

$$V(1) = \frac{kT}{qt}\ln\left(\frac{a_O'}{a_O''}\right) \quad [72]$$

Equation [70] shows again that the electric field is a function of the position inside the scale, as discussed previously.

It is finally possible to show that the assumption of the existence of a single type of defect in an oxide leads necessarily to the consequence of the presence of a linear gradient of the concentration of the defect through the oxide as a result of the constancy of the flux of defects with respect to x for a constant x_S. In fact, if the oxide contains only metal vacancies with an effective charge r, their flux is given by Eq. [47] while their concentration is related to the local oxygen activity by Eq. [46]. Taking the logarithm of Eq. [46], differentiating with respect to x and substituting into Eq. [47] gives then

$$J_V = -RD_V m\frac{d[V^{r'}]}{dx} \quad [73]$$

which, since J_V must be independent of x, requires a linear change of the concentration of the vacancies with x. In the same way, if the oxide contains only metal interstitials with an effective charge s, the flux of interstitials is given by Eq. [62], while their concentration depends on a_O through Eq. [61]. Proceeding as before we get then

$$J_I = -RD_I t\frac{d[M_i^{s\cdot}]}{dx} \quad [74]$$

showing again that the concentration of interstitials is a linear function of x. This situation is of course no longer true for oxides containing more than one kind of defect, since in this case the concentrations of defects are not related to the oxygen activity simply by equations of the form of Eq. [46] of Eq. [61].

The previous simplified expressions for k_x and a_O are strictly valid only if a single kind of defect predominates over the whole range of oxygen activities from a_O' to a_O''. In particular, Eq. [53] represents the equation derived by Pettit for the oxygen activity profile through the scale in case of p-type semiconducting oxides (38). This expression, however, is strictly correct only for special values of m, *i.e.*, $m = 1$, 2, or 3. Otherwise the complete expressions for J_{ov}, k_x, and a_O should be used, dropping at most from them the terms corresponding to defects having only a negligible concentration everywhere.

Numerical Results

Since well-known analytical expressions are available for the different parameters examined above as functions of a_O or y for oxides containing a single kind of defect, no particular discussion is required for these simple systems. On the contrary, we present here calculations for an oxide like CoO which has a more complex defect structure and for which approximate values of the different parameters required for the application of the theory are available. This oxide is selected as an example of the effect that the complex nature of the defects in the oxide may have on the oxidation behavior of the pure metal.

The high temperature oxidation of cobalt has been studied frequently so far (9-12, 39-46), like the defect structure (12, 16, 20, 21, 47-52) and the diffusion properties of CoO (9, 12, 16, 21, 50-60). There is a general agreement that Co oxidizes according to a parabolic rate law at high temperatures, the process being controlled by the diffusion of metal vacancies in the p-type semiconducting oxide (39-46). Neutral, singly, and doubly charged metal vacancies are present in CoO, their concentration being a function of the prevailing oxygen activity under a constant temperature. Around 1000°C and at high oxygen activities the vacancies are prevailingly singly charged (12, 16, 21, 47-52), in agreement with the value of the oxygen pressure exponent in the dependence of the parabolic rate constant, the deviations from stoichiometry, and the self-diffusion coefficient of Co on $P(O_2)$ (16, 21, 39-60). Diffusion of oxygen is instead unimportant in this oxide (56).

In addition to metal vacancies, Co interstitials have been proposed as minority defects to explain the effect of Li doping on the electrical properties of CoO (61) and the difference between the concentration of defects deduced from the deviations from stoichiometry and that obtained from measurements of the oxidation rate of cobalt (21, 52). Metal interstitials have also been found by x-ray diffraction in solid solutions CoO-NiO (20) at high temperatures.

Recently, the presence of interstitials in CoO has been questioned on the basis of a comparison between the experimental dependence of the Co self-diffusion coefficient on a_O and that predicted semi-quantitatively for different ratios between the diffusion coefficients of vacancies and interstitials (60). However, a more precise calculation of D_{Co} as a function of a_O at 1000°C shows that the presence of a low concentration of Co interstitials is not inconsistent with the experimental findings, as shown below. Therefore, the following calculations are performed for both situations, *i.e.*, for the presence of vacancies only (case 1) and of vacancies plus interstitials (case 2). In fact, even if for pure Co the presence of a low concentration of interstitials affects the oxidation behavior slightly, particularly under high oxygen activities, this may have a profound effect in case of doping, as shown elsewhere (28).

Experimental data.—To apply the calculations developed above to the cobalt oxidation we need the values of the equilibrium constants for the formation of the different defects. These have been measured by different authors in the high temperature range (12, 60, 61): we make use here of those calculated by Dieckmann (60) for the three kinds of metal vacancies, which at 1000°C take the values: $K_1 = 1.37 \times 10^{-3}$, $K_2 = 1.94 \times 10^{-2}$, and $K_3 = 1.89 \times 10^{-4}$, respectively. In the case of the presence of interstitials, three other constants would also be required: however, following Dieckmann (60), we adopt the simplification of considering only the presence of doubly charged interstitials according to the reaction

$$Co^x = V_{Co}'' + Co_i^{\cdot\cdot} \quad [75]$$

The corresponding equilibrium constant K_I is obtained assuming that at $a_O = a_O'$ (Co/CoO equilibrium) the concentration of V_{Co}'' is equal to that of $Co_i^{\cdot\cdot}$, which represents an upper limit to the concentration of interstitials, since higher values would affect appreciably the self-diffusion coefficient of Co at low oxygen activities. In this way we get for K_I

$$K_I = 1.05 \times 10^{-10}$$

The equilibrium constant for the intrinsic ionization of

CoO is in the range 10^{-8}-10^{-12} at 1000°C (61) and in the calculation we adopt the value $K_7 = 10^{-9}$.

The parabolic rate constant for the oxidation of cobalt at 1000°C and 1 atm O_2 ranges between 3.2 × 10^{-8} and 1.57 × 10^{-8} g^2 cm^{-4} sec^{-1} (9-12, 39-46), the lowest value being that measured by Mrowec *et al.* (46), which has been obtained by taking into account appropriate correction factors to the experimental value. Conversion of the latter value to the rate constant expressed in terms of scale thickness as used here yields at 1000°C

$$k_x = 1.07 \times 10^{-8} \text{ cm}^2 \text{ sec}^{-1}$$

Finally, the diffusion coefficient of vacancies in CoO has been measured many times with a sufficient agreement (12, 16, 54, 57, 60). For internal consistency, we make use of the value measured by Dieckmann (60), assuming that all the vacancies have the same diffusion coefficient which, at 1000°C, takes the value

$$D_V = 2.957 \times 10^{-7} \text{ cm}^2 \text{ sec}^{-1}$$

Using the previous values of the equilibrium constants for the formation of vacancies and of $Co_i^{\cdot\cdot}$ and the diffusion coefficient for vacancies reported above, the self-diffusion coefficient of Co in CoO at 1000°C is easily obtained as a function of a_O by means of the relationship (60)

$$D_{Co} = D_V \Sigma [V_{Co}] + D_I [Co_i^{\cdot\cdot}] \quad [76]$$

putting $D_I = \alpha D_V$. The results are reported in Fig. 1 for case 1 (absence of interstitials) and case 2 (presence of interstitials) with different values of α. Comparison of these curves with the experimental results reported by Dieckmann (60) shows that the condition $[Co_i^{\cdot\cdot}] = [V_{Co}'']$ at a_O' with $\alpha \leq 1$ is not contradictory with the data about D_{Co}. Therefore in the following the calculations for case 2 will be performed with the previous value of K_I and with $D_I = D_V$.

The oxygen pressure for the equilibrium Co/CoO at 1000°C is obtained from the standard free energy of formation of CoO as $P'(O_2) = 2.77 \times 10^{-12}$ atm, corresponding to $a_O' = 1.66 \times 10^{-6}$ (62).

Calculated properties.—The concentrations of the lattice and electronic defects in CoO at 1000°C calculated with the previous values of the different parameters are shown in Fig. 2 as functions of a_O'' for cases 1 and 2, respectively. As expected, the difference between the two cases is rather small and limited to the region of low oxygen activities. Doubly charged vacancies are the prevailing defects from a_O' to about $a_O = 4 \times 10^{-4}$, while above this value singly charged vacancies predominate. Neutral vacancies are instead minority defects everywhere, even if their concentration is larger than that of V'' above $a_O = 0.12$. The presence of $Co_i^{\cdot\cdot}$ produces a decrease of p and a simultaneous increase of the concentration of the species with a negative effective charge, *i.e.*, V', V'', and electrons, which is detectable however only close to a_O', where the concentration of $Co_i^{\cdot\cdot}$ is larger. The oxide is of p-type everywhere, but close to a_O' it shows p $\simeq$ n, especially in presence of the interstitials. This is a consequence of the value selected for K_7: a lower value would give a smaller concentration of electrons, but in lack of more precise information these plots are considered sufficiently accurate. Figure 3 shows the concentrations of the defects as functions of the normalized coordinate y for case 2 only, since those for case 1 are very similar. Comparison with Fig. 2 shows that the largest changes in the concentrations of all species occur for small values of y, *i.e.*, close to the metal/scale interface.

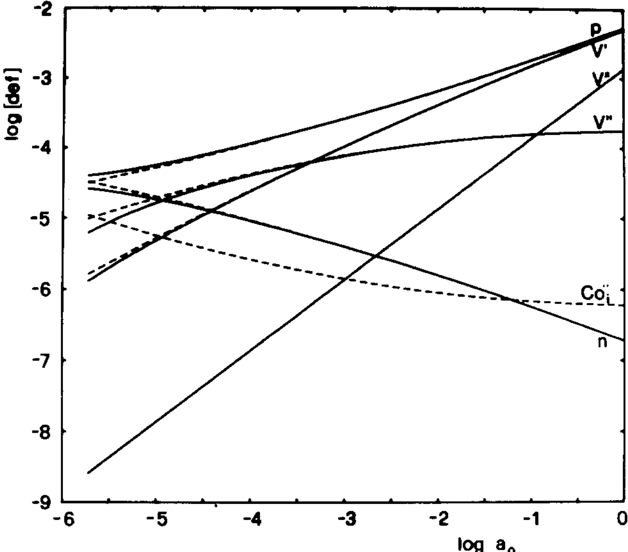

Fig. 2. Concentrations of the different defects in CoO at 1000°C as functions of the oxygen activity. Case 1, continuous lines; case 2, dotted lines.

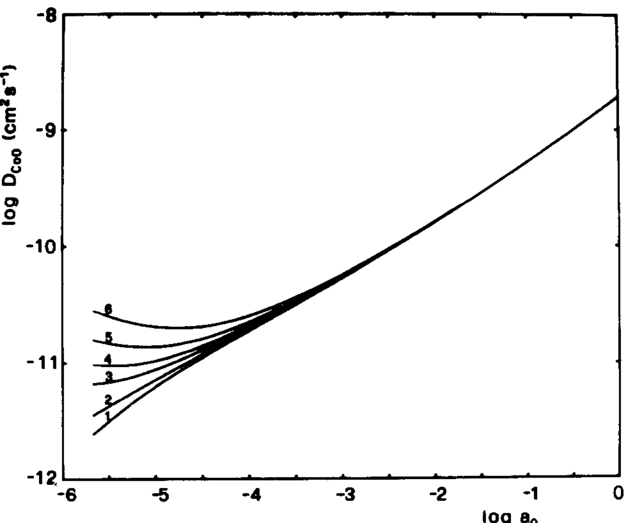

Fig. 1. Self-diffusion coefficient of cobalt in CoO at 1000°C as a function of the oxygen activity for several values of $\alpha = D_I/D_V$. Curve 1: case 1. Curves 2-6: case 2 for different values of α (curve 2, $\alpha = 0$; curve 3, $\alpha = 1$; curve 4, $\alpha = 2$, curve 5, $\alpha = 4$, curve 6, $\alpha = 8$).

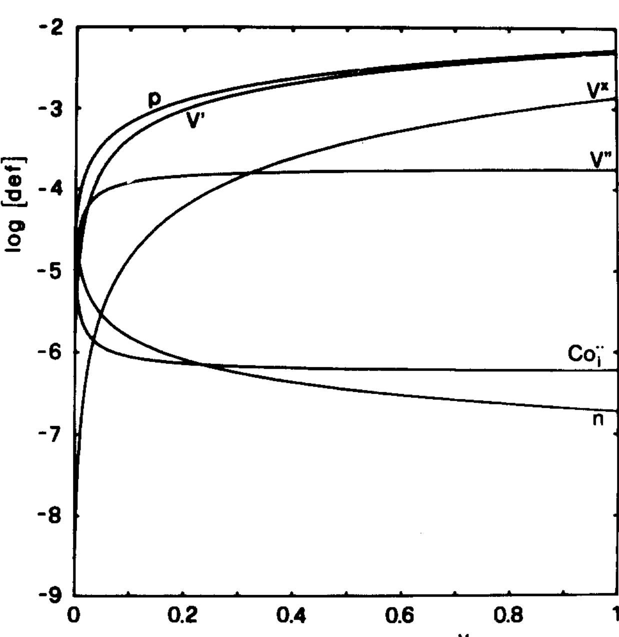

Fig. 3. Concentrations of the different defects in CoO at 1000°C as functions of the normalized distance $y = x/x_S$ for case 2.

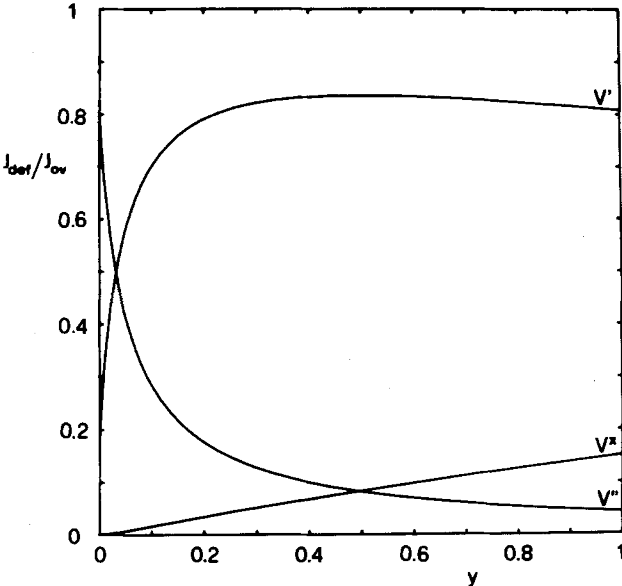

Fig. 4a. Fractional fluxes of the different defects in CoO at 1000°C as functions of the normalized distance $y = x/x_S$ for case 1.

The fractional fluxes of the different lattice defects as functions of y are reported in Fig. 4a and 4b for the two cases. Comparison of Fig. 4b with Fig. 3 shows that the transport through the scale is mainly by means of the doubly charged vacancies close to $y = 0$ where these vacancies prevail, while for the remainder of the scale thickness Co diffuses mainly by means of V': the contribution of V^x is however significant particularly close to $y = 1$. Comparison of Fig. 4a with Fig. 4b shows instead that the presence of interstitials reduces the flux of V'' close to $y = 0$, so that this shows a sharp maximum at very small values of y. The contribution of the cobalt interstitials is significant only close to $y = 0$, in agreement with the rapid fall of their concentration with y.

The next parameter to be considered is the parabolic rate constant k_x: the plot of k_x as a function of a_O'', calculated by means of Eq. [30a] and [34] is given in Fig. 5 for both cases. The consistent curvature of the plots at low oxygen activities is a consequence of the fact that in this range a_O'' is not negligible in com-

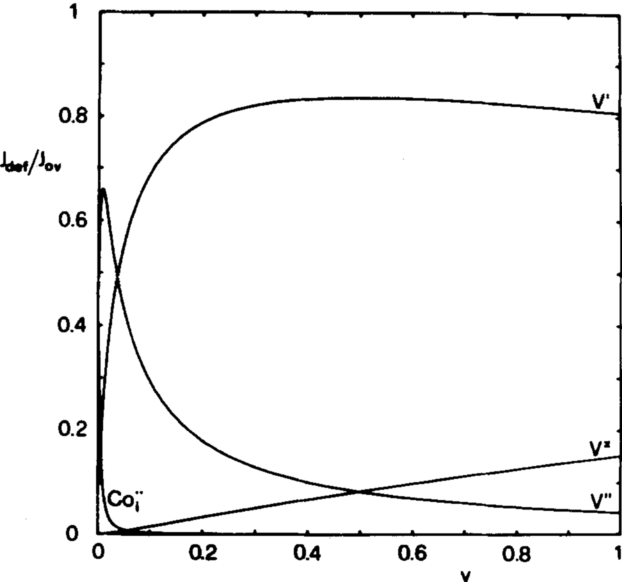

Fig. 4b. Fractional fluxes of the different defects in CoO at 1000°C as functions of the normalized distance $y = x/x_S$ for case 2.

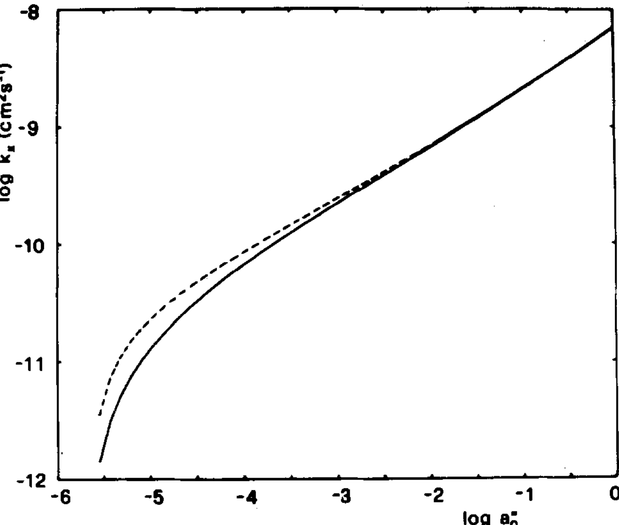

Fig. 5. Parabolic rate constant for the oxidation of pure Co at 1000°C as a function of the gas-phase oxygen activity a_O''. Case 1 continuous line; case 2, dotted line.

parison with a_O' in the expression of k_x, so that the rate constant becomes a function of both a_O' and a_O'' and tends to zero as a_O'' approaches a_O'. The difference between the two curves is related, however, to the different defect structure assumed in the two cases and above $a_O = 10^{-3}$ approximately is no longer affected by a_O'. In the region of high oxygen activities the two curves tend to coincide, so that it may be concluded that the presence of low concentrations of $Co_i^{\cdot\cdot}$ does not affect appreciably the oxidation kinetics of Co at 1000°C under sufficiently high oxygen activities in the gas phase. In presence of impurities, however, the presence of metal interstitials may play an important role, as will be shown elsewhere (28).

The numerical values obtained for k_x by the previous calculation with $a_O'' = 1$ amount to 7.015×10^{-9} cm^2 sec^{-1} for case 1 and 7.045×10^{-9} cm^2 sec^{-1} for case 2, very close together. These values are about 30% lower than the experimental value obtained by Mrowec (46), as reported above. The agreement is not good therefore, but is considered acceptable in view of the fact that the diffusion coefficient of the cobalt vacancies used here to obtain k_x (60) is smaller than the values reported by other authors (12, 57). No attempt is made here to improve the agreement between the calculated and experimental values of k_x by changing the diffusion coefficient of the metal vacancies also on account of the purpose of exemplification of the present calculations.

The dependence of the parabolic rate constant of oxidation of a metal and of the self-diffusion coefficient of the metal ions in its oxide D_M on a_O'' is usually expressed in the form

$$k_x \propto (a_O'')^{1/m} \quad \text{and} \quad D_M \propto (a_O'')^{1/m'} \qquad [77]$$

According to the previous discussion, the above relationships are not correct for oxides with a complex defect structure, but they may still be used to express in a simple way the dependence of these parameters on a_O''. In these cases, however, m and m' will no longer be constant, but will change as functions of a_O''. From Eq. [77] m and m' may be defined as

$$m = \frac{d \ln a_O''}{d \ln k_x} \quad \text{and} \quad m' = \frac{d \ln a_O''}{d \ln D_M} \qquad [78]$$

and may be calculated directly by a numerical differentiation procedure from the known dependence of k_x and D_M on a_O. Plots of m and m' are reported in Fig. 6 for cases 1 and 2: they show that m and m' are indeed rather sensitive functions of a_O and more-

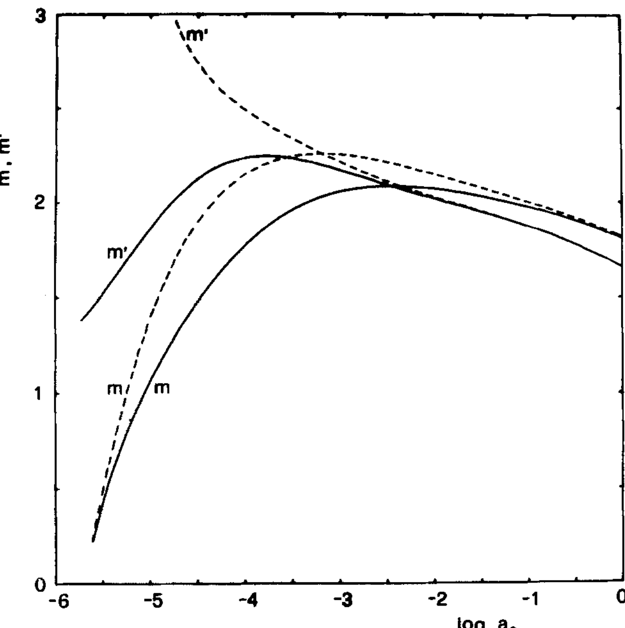

Fig. 6. Oxygen activity exponents of the parabolic rate constant for the Co oxidation (m) and the cobalt self-diffusion coefficient in CoO (m') at 1000°C as functions of the oxygen activity, a_O. Case 1, continuous lines; case 2, dotted lines.

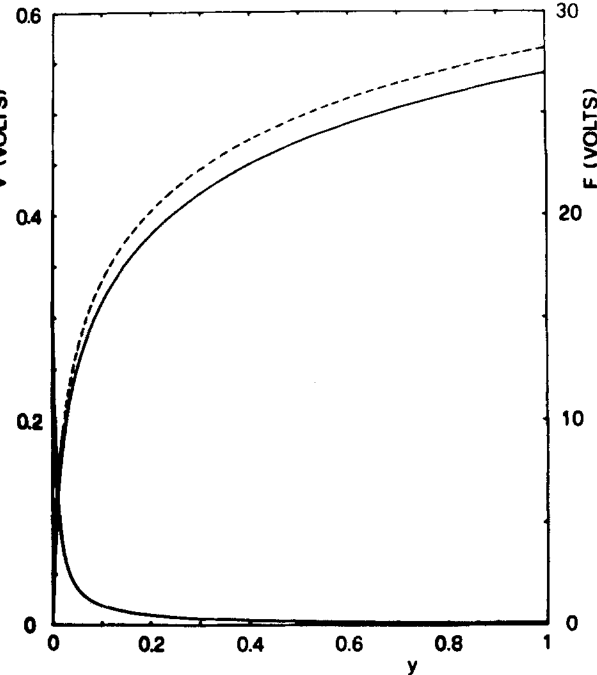

Fig. 7. Electrostatic potential V and product of the electric field by the scale thickness $F = x_S E$ as functions of the normalized distance $y = x/x_S$ for the oxidation of cobalt at 1000°C. Case 1, continuous lines; case 2, dotted lines. The plot of F for case 2 is practically coincident with that for case 1.

over that they are different even for the same model of defect structure of the oxide. While the anomalous values of m for low oxygen activities are a consequence of the fact that Eq. [77] does not hold for small values of a_O'', the change of m with a_O at high a_O values and that of m' in the whole range are an effect of the complex defect nature of the oxide. Both curves are affected by the presence of the interstitials in the region of low a_O values, but this is particularly true for m' which shows a maximum in case 1, but is a continuously decreasing function of a_O in case 2 with $D_I = D_V$. At $a_O = 1$ we get for both cases $m = 1.812$ and $m' = 1.662$ to be compared with the experimental values $m = 1.725$ (46) and $m' = 1.7$ (45): the agreement seems rather satisfactory.

Finally, the product $x_S E = F(y)$ and $V(y)$ as defined by Eq. [38] and [41] are reported as functions of y in Fig. 7 for the two cases. The presence of interstitials affects the curves at some extent. In both cases, however, the potential is not a linear function of y, as has been found also for simple oxides, but shows a continuously changing gradient which is largest close to $y = 0$. It seems, therefore, that the conclusion that the presence of a potential which is a linear function of y is incompatible with a constant flux of matter through the scale applies also to oxides with a complex defect structure. Correspondingly the diffusion electric field is maximum close to the metal/scale interface and then decreases rather rapidly with y tending to a small value as y approaches 1.

In view of the many simplifications introduced into the present treatment and the uncertainty in the values of many parameters, the agreement between the calculated and experimental values of the various parameters examined here is considered satisfactory.

Conclusions

The previous calculations performed for the specific case of the oxidation of pure cobalt in oxygen at 1000°C show that the different parameters involved and relevant for the kinetics of oxidation of a pure metal are significantly affected by the actual structure of the defects of the oxide, and particularly even by minority defects. This applies even to oxides usually considered simple and seems to be a rather general rule since thermodynamics predict the presence of more than one kind of defect in any compound. Therefore a complete account of all the aspects connected with the oxidation of metals requires a careful consideration of the actual defect structure of their oxides. The theory presented here allows the calculation of all the quantities involved in the parabolic growth of a scale on a metal independently of the complexity of the oxide properties, overcoming even the difficulty connected in dealing with oxides showing a transition from n- to p-type semiconductivity with a change in the oxygen activity.

Unfortunately, the application of the present approach to the interpretation of the metal oxidation is generally prevented by the lack of sufficient knowledge of the relevant parameters involved. In addition, when the concentration of defects is rather large, interactions between defects become increasingly larger and should also be taken into account. It is hoped that in the future more fundamental research on the nature of defects and other basic properties of the oxides, mainly those of metals relevant for high temperature application, both pure and doped, will be developed, so that the interpretation of their oxidation behavior at high temperatures may be founded on a more solid basis and lead to a deeper understanding of the complex processes involved. In this connection we notice that the treatment developed here does not consider the effect of factors such as the contribution of short-circuit diffusion to the transport through the scale, which is of some importance at intermediate temperatures (13), or the presence of porosity and other possible complications. This represents obviously a limitation of the present approach which should be appreciated when it is applied to actual systems.

ABSTRACT

The theory of parabolic oxidation of metals forming oxides with a complex defect structure developed in a previous paper is applied here to the oxidation of dilute alloys with incorporation of aliovalent impurities in the scale. The treatment is limited, however, to the simple case of a uniform distribution of the dopant. First, the effect of the dopant on the oxidation rate is examined quantitatively for oxides containing a single kind of defect, obtaining simple analytical expressions for the relevant parameters for limiting situations. Then the growth of CoO on dilute cobalt alloys at 1000°C is analyzed by means of numerical calculations both in the case of the presence and of the absence of metal interstitials, allowing for the presence of metal vacancies of different electric charge. This case is examined as an example of the oxidation behavior of metals forming oxides with a complex defect structure in the presence of dopants. The treatment shows that in some cases even minority defects may change deeply the effect of impurities on the oxidation rate of the pure metal, even reversing the behavior predicted on the basis of a simpler defect model.

In a previous paper [Part I (1)] we have examined the oxidation behavior of pure metals forming electronically semiconducting oxides with a complex defect structure, extending Kröger's approach (2) to Wagner's theory of parabolic oxidation (3) and considering oxides in which only metal diffusion is important. We extend here the same analysis to the growth of doped oxides on dilute alloys, so that only the base oxide is formed in the process.

The rate constant for the parabolic oxidation of a metal is usually changed various extents by the addition of a second component forming a solid solution scale. Doping by foreign ions having the same valency as those of the matrix also affects the concentration of defects and the diffusion of matter through the scale (4-8), but this case will not be considered here. Doping by ions of different valency has, however, a stronger effect, since it produces a new kind of defect with an effective charge different from zero, the impurity itself. This is usually known as the Wagner-Hauffe effect (9-11) and is interpreted on the basis of the change of the concentration profiles of the lattice defects through the scale with respect to the pure oxide due to the incorporation of the aliovalent impurities. The change in the oxidation kinetics is usually analyzed assuming the presence of a single kind of defect even in the doped oxide. The thermodynamic theory of lattice defects shows, however, that the presence of impurities is able to change the concentrations of all the defects as well as their ratios, under a constant oxygen activity, since it affects the concentration of the electronic defects (12). In this way defects which may be neglected in the pure oxide may play an important role in the doped oxide. In some cases this may even lead to a change in the defect structure of the oxide, as found for example in Li-doped CoO (13). Therefore it is particularly important to take into account the actual defect structure of the base oxide when examining the effect of doping on the oxidation rate of a metal.

Key words: parabolic oxidation, dilute alloys, doping effects.

In this paper the effect of a dopant on the kinetics of oxidation of a metal is analyzed considering the particular but unlikely case of a uniform distribution of the dopant in the scale, such as has been considered in the derivation of the Wagner-Hauffe rules (9, 10). This simple treatment is, however, extended here to include the case of oxides having a complex defect structure, as has been done in a previous paper (1). The more complete problem of the growth of a doped oxide with a simple or complex defect structure and a nonuniform distribution of the dopant will be dealt with elsewhere (14).

Theory

The presence of aliovalent impurities in the oxide growing on a dilute alloy produces an unbalance of the electric charge, which must be compensated for by a change in the local concentration of the charged defects with respect to the pure oxide under the same oxygen activity. The concentrations of these species will then depend not only on the oxygen activity but also on the local dopant concentration. From the point of view of the parabolic growth of the scale this situation will affect in principle all the parameters involved, namely, the profile of the oxygen activity, the electric field within the scale, the partial and overall fluxes of the defects, and finally the parabolic rate constant itself.

A primary factor for all these changes is clearly the profile of the concentration of the dopant in the scale, which in general will not be flat, but will show a preferential accumulation of the dopant either close to the metal/scale or to the scale/gas interface. The average concentration and the actual distribution of the dopant in the oxide will obviously depend on many factors, such as the bulk alloy composition, the difference between the affinity for oxygen of the two alloy components, the tendency of the impurity to oxidize internally if forming the most stable oxide, the solubility of the dopant in the matrix, and, above all, the relative diffusivities of the two kinds of cations in the scale. From this last point of view the ion moving

faster will clearly tend to accumulate close to the scale/gas interface.

The effect of all these factors on the overall scaling behavior of a binary alloy has already been thoroughly investigated in case of alloys producing a solid solution scale for any alloy composition (4-8) and will not be considered here. Even for aliovalent impurities a complete theory would involve the solution of the coupled equations for the diffusion of both the base metal and the impurity in the scale, as has been done by C. Wagner *et al.* for the oxidation of Ni-Cr alloys (15). However, this treatment introduces some parameters which are usually unknown, so that it may only be used as a qualitative criterion. The case of a uniform distribution is analyzed here with the purpose of obtaining indications of general character about the effects of doping, which require only a correct knowledge of the defect structure of the oxide. Actual cases of nonuiform distribution of the impurity in real systems must instead be solved individually taking specifically into account the different rates of diffusion of the two metal species and, while retaining their specific interest for the special system investigated, would lose any generality.

In the following it will be assumed that the dopant assumes only substitutional positions in the lattice of MO. Furthermore, only the case of monovalent and trivalent impurities will be considered: the extension to the case of impurities of higher valency is however obvious. In addition, the concentration of the impurity is considered sufficiently small so that the oxygen activity at the alloy/scale interface remains substantially unchanged with respect to the pure metal. It is finally assumed that the impurity is present in its normal charged state in the matrix: if this is not true, as has been found for Cr and Ti in CoO (16), the equilibrium between the states with a different electric charge of the impurity should also be considered. The same restrictions as used in Part I (1) are also assumed to apply here: in particular only defects in the cation sublattice are considered. The cases of presence of lower valent or higher valent impurities are examined in turn separately.

Lower valent impurities.—Since the oxide is assumed to have the composition MO, the lower valent impurity can only be monovalent. Li will be taken as an example of this class of dopants. In the presence of Li in substitutional positions in MO, in addition to the usual equations for the formation of the different lattice defects (1), the mechanism of incorporation of the impurity in a normal lattice site according to the reaction (17)

$$\tfrac{1}{2}\,O_2 + Li_2O = 2Li' + 2h^{\cdot} + 2\,O^{x} \qquad [1]$$

must also be considered. Equation [1] shows that the introduction of Li in MO produces an increase in the concentration of the electron holes: this in turn will lower the concentration of the charged metal vacancies or raise that of the charged metal interstitials in oxides containing only one kind of defect, but will affect simultaneously both concentrations in the case of oxides having both kinds of defects, according to Eq. [9]-[10] and [12]-[13] of Part I (1).

In the presence of Li as the impurity, the neutrality condition becomes

$$p + [M_i^{\cdot}] + 2[M_i^{\cdot\cdot}] = n + [V'] + 2[V''] + [Li'] \qquad [2]$$

so that, expressing the concentrations of the charged defects by means of Eq. [9]-[14] of Part I (1) and rearranging, Eq. [2] becomes

$$2\,\frac{K_4K_5K_6}{K_1K_7a_O}\,p^4 + \left(1 + \frac{K_4K_5}{K_1a_O}\right)p^3 - [Li']p^2 - (K_7 + K_1K_2a_O)p - 2K_1K_2K_3a_O = 0 \qquad [3]$$

as a final expression of p as a function of both a_O and [Li']. For any given value of a_O and [Li'] the previous equation may be solved for p and then the concentrations of all the defects may be calculated. Then the partial fluxes of the various kinds of defects, the overall flux, the parabolic rate constant, and the oxygen activity profile may be calculated as for the pure oxide (1), using only Eq. [3] rather than Eq. [15] of Part I (1) to compute p. For a nonuniform distribution of the dopant the solution of Eq. [3] requires a knowledge of [Li'] as a function of a_O, which has to be obtained by some indirect procedure to be discussed elsewhere (14). The solution is instead much simpler if [Li'] is uniform since in this case p will be only a function of a_O, but all the parameters must still be computed numerically for each specific case. Only in the case of the existence of a single kind of defect is it possible to obtain simplified expressions which, even though of limited use because based on excessively drastic approximations, may still be used to make a qualitative prediction of the effect of the dopant. These simplified expressions are given below for the different possible cases.

Neutral vacancies or neutral interstitials.—Since the presence of Li in substitutional positions with an effective charge -1 does not affect the concentration of the neutral lattice defects, J_{ov} and k_x are still given by Eq. [47] and [48] of Part I (1) with $r = 0$ for neutral vacancies, or by Eq. [62] and [63] of Part I (1) with $s = 0$ for neutral interstitials, so that no change of k_x or of the profile of a_O is expected in this case. It is however to be noticed that this situation is very unlikely, particularly for high levels of doping, because in presence of high concentrations of electrons or electron holes the concentration of charged lattice defects may become important even in oxides in which they are usually insignificant. In fact, the assumption that a compound contains only neutral defects is only a simplifying approximation, since the equilibria between the differently charged states of the same kind of defect must always exist. In these cases, therefore, the complete treatment discussed above must be used.

Charged vacancies.—If a single kind of charged vacancy predominates in the doped oxide, then the electroneutrality condition becomes (r being the effective charge of the vacancies)

$$p = n + r\,[V^{r'}] + [Li'] \qquad [4]$$

or, since $p >> n$ for these oxides, particularly when Li doped

$$p \simeq r\,[V^{r'}] + [Li'] \qquad [5]$$

The previous equation may be used to compute p as a function of [Li'] and a_O, expressing the concentration of the vacancies by means of the relationship (1)

$$K_V = \frac{[V^{r'}]\,p^r}{a_O} \qquad [6]$$

where K_V is the constant of the equilibrium for the formation of the vacancies.

A special situation arises when the concentration of the dopant is so high that $[Li'] >> [V^{r'}]$, so that Eq. [5] becomes

$$p \simeq [Li'] \qquad [7]$$

and the concentration of the vacancies becomes, from Eq. [6]

$$[V^{r'}] = \frac{K_V a_O}{[Li']^r} \qquad [8]$$

The overall flux, which is given by J_V, becomes then (1)

$$J_{ov} = -J_V = RD_V\,[V^{r'}]\,\frac{d\ln a_O}{dx} = RD_V\,\frac{K_V}{[Li']^r}\,\frac{da_O}{dx} \qquad [9]$$

and, upon integration from $x = 0$ to $x = x_S$ (1)

$$k_x = 2D_V \frac{K_V}{[\mathrm{Li'}]^r} (a_O'' - a_O') \quad [10]$$

Alternatively, making use of the concentration of the metal vacancies in the pure oxide as obtained from Eq. [6] with the neutrality condition $p = r\,[V^{r'}]$

$$k_x = 2D_V \frac{r^r}{[\mathrm{Li'}]^r} \{([V^{r'}]_o'')^m - ([V^{r'}]_o')^m\} \simeq 2D_V \frac{r^r}{[\mathrm{Li'}]^r} ([V^{r'}]_o'')^m \quad [11]$$

where $[V^{r'}]_o'$ and $[V^{r'}]_o''$ are the concentrations of $V^{r'}$ in the pure oxide at the alloy scale interface and the scale/gas interface, respectively.

The ratio of the parabolic rate constant for the oxidation of the alloy k_x to that of the pure metal $k_x°$ as given by Eq. [49] of Part I (1) becomes then

$$\frac{k_x}{k_x°} = \frac{r^r}{m} \left\{ \frac{[V^{r'}]_o''}{[\mathrm{Li'}]} \right\}^r \quad [12]$$

Equation [12] shows that under the conditions used to obtain it, k_x is smaller than $k_x°$, so that the introduction of Li slows down the oxidation rate with respect to the pure metal. In fact, apart from the numerical factor r^r/m which is close to one, one has $[\mathrm{Li'}] >> [V^{r'}]_o''$ by hypothesis, so that $k_x << k_x°$.

The profile of the oxygen activity is obtained as for the pure oxides by integration of Eq. [9] from $x = 0$ to $x = x$ and division by Eq. [10] in the form

$$a_O = a_O' + (a_O'' - a_O')\,y \quad [13]$$

so that in this case a_O is simply a linear function of y.

Charged interstitials.—The electroneutrality condition for these oxides which are essentially n-type semiconductors is, assuming that they contain only metal interstitials with an effective charge s

$$p + s\,[\mathrm{M_i}^{s\cdot}] = n + [\mathrm{Li'}] \quad [14]$$

where the concentration of $\mathrm{M_i}^{s\cdot}$ depends on a_O through the relationship (1)

$$K_I = [\mathrm{M_i}^{s\cdot}]\,n^s a_O \quad [15]$$

where K_I is the equilibrium constant for the formation of the interstitials. Equations [14] and [15] allow the calculation of p as a function of a_O and [Li'].

A special situation is met also in this case in presence of high concentrations of Li, when $[\mathrm{Li'}] >> n$ and also $[\mathrm{M_i}^{s\cdot}] >> p$, so that Eq. [14] becomes

$$s\,[\mathrm{M_i}^{s\cdot}] \simeq [\mathrm{Li'}] \quad [16]$$

leading to an approximately constant concentration of interstitials through the scale. The flux of interstitials will be then (1)

$$J_{ov} = J_I = RD_I [\mathrm{M_i}^{s\cdot}] \frac{d \ln a_O}{dx} = RD_I \frac{[\mathrm{Li'}]}{s} \frac{d \ln a_O}{dx} \quad [17]$$

from which, by integration from $x = 0$ to $x = x_S$ we obtain

$$k_x = 2D_I \frac{[\mathrm{Li'}]}{s} \ln\left(\frac{a_O''}{a_O'}\right) \quad [18]$$

The ratio of the rate constant k_x to that of the pure metal $k_x°$ as given by Eq. [64] of Part I (1) will then be

$$\frac{k_x}{k_x°} = \frac{1}{s(s+1)} \frac{[\mathrm{Li'}]}{[\mathrm{M_i}^{s\cdot}]_o'} \ln\left(\frac{a_O''}{a_O'}\right) \quad [19]$$

where $[\mathrm{M_i}^{s\cdot}]_o'$ is the concentration of $\mathrm{M_i}^{s\cdot}$ in the pure oxide at $x = 0$, *i.e.*, at $a_O = a_O'$.

From Eq. [19] it follows that the introduction of Li produces an increase of the parabolic rate constant of oxidation in comparison with the pure metal under the same oxygen activity in the gas phase. In fact for the pure oxide $s\,[\mathrm{M_i}^{s\cdot}]_o' = n_o'$, where n_o' is the concentration of electrons in the pure oxide at $a_O = a_O'$, while for the doped oxide $s\,[\mathrm{M_i}^{s\cdot}]' \simeq [\mathrm{Li'}]$, but, because of reaction [1], one has also $[\mathrm{M_i}^{s\cdot}]' >> [\mathrm{M_i}^{s\cdot}]_o'$: in addition, also the factor $\ln(a_O''/a_O')$ is greater than one, so that $k_x >> k_x°$.

The profile of a_O through the scale is obtained by the usual procedure in the form

$$a_O = a_O' \cdot (a_O''/a_O')^y \quad [20]$$

Higher valent impurities.—Chromium will be taken as an example of higher valent impurity in an oxide MO. The incorporation of chromium in substitutional positions occurs according to the reaction (17)

$$\mathrm{Cr_2O_3} = 2\mathrm{Cr^\cdot} + 2\,\mathrm{O^x} + \tfrac{1}{2}\,\mathrm{O_2} + 2e' \quad [21]$$

and produces, therefore, an increase in the concentration of electrons. As a consequence, the concentration of metal vacancies will increase and that of metal interstitials decrease according to the equilibria expressed by Eq. [9]-[10] and Eq. [12]-[13] of Part I (1). The condition for electroneutrality becomes in this case

$$p + [\mathrm{M_i^\cdot}] + 2[\mathrm{M_i^{\cdot\cdot}}] + [\mathrm{Cr^\cdot}] = n + [V'] + 2[V''] \quad [22]$$

and, expressing the concentrations of the different defects as functions of a_O and p and regrouping, p is given by

$$2\frac{K_4K_5K_6}{K_1K_7a_O} p^4 + \left(1 + \frac{K_4K_5}{K_1a_O}\right) p^3 + [\mathrm{Cr^\cdot}]p^2 - (K_7 + K_1K_2a_O)\,p - 2K_1K_2K_3a_O = 0 \quad [23]$$

Equation [23] replaces Eq. [16] of Part I (1), which applies to the pure oxide, and allows the calculation of p when a_O and $[\mathrm{Cr^\cdot}]$ are known. As in the case of monovalent impurities, the calculation of the parabolic rate constant, the fluxes of the different defects, and the profile of a_O through the scale requires a complete solution of the relevant equations, obtaining p by solution of Eq. [23].

Simplified solutions may be obtained also in this case if it is assumed that essentially only one kind of defect is present in the whole range of stability of the oxide and that the impurity is uniformly distributed through the scale. As before, the different possibilities are examined in turn.

Neutral vacancies or neutral interstitials.—As for the case of the presence of monovalent impurities, no change in the rate constant or in the oxygen activity profile is expected in presence of these defects if it is assumed that the defect structure of the doped oxide remains the same as that of the pure oxide. However, as discussed above, this is only a crude approximation which is not expected to hold particularly for high doping levels.

Charged vacancies.—The electroneutrality condition in this case is

$$p + [\mathrm{Cr^\cdot}] = n + r\,[V^{r'}] \quad [24]$$

or, since $p >> n$ in these oxides

$$p + [\mathrm{Cr^\cdot}] \simeq r\,[V^{r'}] \quad [25]$$

which may be used to compute p as a function of $[\mathrm{Cr^\cdot}]$ and a_O using Eq. [6] to express $[V^{r'}]$ as a function of a_O.

A special situation is met when the concentration of the dopant is much higher than p and independent of a_O, since in this case Eq. [25] becomes simply

$$[\mathrm{Cr^\cdot}] = r\,[V^{r'}] \quad [26]$$

The overall flux of matter through the scale is equivalent to J_V and becomes

$$J_{ov} = -J_V = RD_V [V^{r'}] \frac{d \ln a_O}{dx} = RD_V \frac{[Cr^{\cdot}]}{r} \frac{d \ln a_O}{dx} \quad [27]$$

Integration of Eq. [27] from $x = 0$ to $x = x_S$ yields

$$k_x = 2D_V \frac{[Cr^{\cdot}]}{r} \ln \left(\frac{a_O''}{a_O'} \right) \quad [28]$$

In comparison with the oxidation of the pure metal we obtain, using Eq. [49] of Part I (1)

$$\frac{k_x}{k_x^{\circ}} = \frac{[Cr^{\cdot}]}{mr [V^{r'}]_o''} \ln \left(\frac{a_O''}{a_O'} \right) \quad [29]$$

or, expressing the concentration of charged vacancies $V^{r'}$ in the pure oxide as a function of a_O at $x = x_S$ by means of Eq. [46] of Part I (1)

$$\frac{k_x}{k_x^{\circ}} = \frac{[Cr^{\cdot}]}{mr [V^{r'}]_o^{\circ}} \frac{1}{(a_O'')^{1/m}} \ln \left(\frac{a_O''}{a_O'} \right) \quad [30]$$

where $[V^{r'}]_o^{\circ}$ is the concentration of $V^{r'}$ at $a_O = 1$ in the pure oxide.

The previous equation shows that the presence of a higher valent impurity produces an increase in the parabolic rate constant for oxidation in comparison with the pure metals under the same oxygen activity in the gas phase. In fact for the pure oxide $p_o'' \simeq r [V^{r'}]_o''$, while for the doped oxide $r [V^{r'}]'' \simeq [Cr^{\cdot}]$, but, as a consequence of reaction [21], $[V^{r'}]'' >> [V^{r'}]_o''$, so that $[Cr^{\cdot}]/[V^{r'}]_o'' > 1$: in addition, also the factor $\ln (a_O''/a_O')$ is larger than one, so that $k_x >> k_x^{\circ}$.

The profile of the oxygen activity is given in this case by the same equation as for the doping of MO by monovalent ions when the oxide contains only charged metal interstitials (Eq. [20]).

Charged interstitials.—The electroneutrality condition is now

$$p + s [M_i^{s\cdot}] + [Cr^{\cdot}] = n \quad [31]$$

or, since $n >> p$ in this case

$$s [M_i^{s\cdot}] + [Cr^{\cdot}] \simeq n \quad [32]$$

where the concentration of the interstitials depends on a_O by means of Eq. [15]. Equation [32] may be used in conjunction with Eq. [15] to compute p as a function of a_O if the concentration of chromium is known as a function of a_O too. The solution is obviously simpler if $[Cr^{\cdot}]$ is independent of a_O.

If the concentration of the dopant is constant within the scale and much greater than the concentration of the metal interstitials, Eq. [32] becomes

$$[Cr^{\cdot}] \simeq n \quad [33]$$

and the concentration of metal interstitials is given by

$$[M_i^{s\cdot}] = \frac{K_I}{[Cr^{\cdot}]^s a_O} \quad [34]$$

Under this situation the flux of metal interstitials, equivalent to J_{ov}, has the form (1)

$$J_I = J_{ov} = RD_I [M_i^{s\cdot}] \frac{d \ln a_O}{dx} = RD_I \frac{K_I}{[Cr^{\cdot}]^s a_O} \frac{d \ln a_O}{dx} \quad [35]$$

From Eq. [35] the parabolic rate constant is obtained by the usual procedure in the form

$$k_x = 2D_I \frac{K_I}{[Cr^{\cdot}]^s} \left(\frac{1}{a_O'} - \frac{1}{a_O''} \right) \quad [36]$$

or, using the concentration of interstitials in the pure oxide where the neutrality condition is $s[M_i^{s\cdot}] = n$, as given by (1)

$$[M_i^{s\cdot}] = [M_i^{s\cdot}]^{\circ} a_O^{-1/t} \quad [37]$$

even in the form

$$k_x = 2 \frac{D_I s^s}{[Cr^{\cdot}]^s} \{ ([M_i^{s\cdot}]'_o)^t - ([M_i^{s\cdot}]''_o)^t \} \simeq 2 \frac{D_I s^s}{[Cr^{\cdot}]^s} ([M_i^{s\cdot}]'_o)^t \quad [38]$$

where $[M_i^{s\cdot}]'_o$ and $[M_i^{s\cdot}]''_o$ are the concentrations of $M_i^{s\cdot}$ in the pure oxide at $a_O = a_O'$ and $a_O = a''_O$, respectively.

In comparison with pure oxide we obtain, using Eq. [64] of Part I (1)

$$\frac{k_x}{k_x^{\circ}} = \frac{s^s}{t} \left\{ \frac{[M_i^{s\cdot}]'_o}{[Cr^{\cdot}]} \right\}^s \quad [39]$$

Equation [39] shows that the introduction of chromium in an oxide containing metal interstitials produces a decrease of the parabolic rate constant for oxidation in comparison with the pure metal. In fact, a part from the numerical factor s^s/t, close to one, one has by assumption $[Cr^{\cdot}] >> [M_i^{s\cdot}]'_o$, so that $k_x << k_x^{\circ}$.

The profile of the oxygen activity is obtained as previously in the same form as holding for a pure oxide with prevailing neutral metal interstitials (Eq. [68] of Part I (1) with $t = 1$), or

$$a_O^{-1} = (a_O')^{-1} - ((a_O')^{-1} - (a_O'')^{-1}) y \quad [40]$$

Numerical Results

This section is divided into two parts: first, the effect of the dopants on the parabolic rate constant of oxidation is evaluated as a function of the dopant concentration for a fixed oxygen activity in the gas phase or as a function of a_O'' for fixed concentrations of the impurities for oxides having a single kind of defect. Then the effect of the presence of a constant concentration of impurities is evaluated for the growth of CoO on cobalt alloys at 1000°C both in the presence and in the absence of metal interstitials as an example of the behavior of oxides having a more complex defect structure.

Oxides containing a single kind of defect.—Oxides with metal vacancies.—As discussed above, the oxidation of metals forming oxides containing only neutral vacancies should not be affected by the addition of heterovalent impurities. but this case is not physically significant. We will therefore examine in detail the case of singly charged vacancies: oxides with doubly charged vacancies give similar results which are not reported here for brevity.

The numerical values of the various parameters required for the calculations are taken similar to those applying to the oxidation of cobalt at 1000°C. The diffusion coefficient of the metal vacancies is given the value $D_V = 10^{-7}$ cm^2 sec^{-1}; for the equilibrium constant K_V we take the value 10^{-4}, corresponding to a concentration of V' equal to 10^{-2} at $a_O = 1$. For the constant of the equilibrium for the intrinsic ionization K_7 we use two values, namely $K_7 = 10^{-9}$ and $K_7 = 10^{-12}$, to show the effect that it may have on the concentrations of the various defects in the presence of impurities. Finally the oxygen activity corresponding to the metal/oxide equilibrium is taken equal to that prevailing for the Co/CoO equilibrium at 1000°C ($a_O' = 1.66 \times 10^{-6}$) (1).

Figure 1 shows the change of the parabolic rate constant k_x with the gas-phase oxygen activity a_O'' for the pure oxide and for some selected values of the concentration of the dopants, both monovalent and

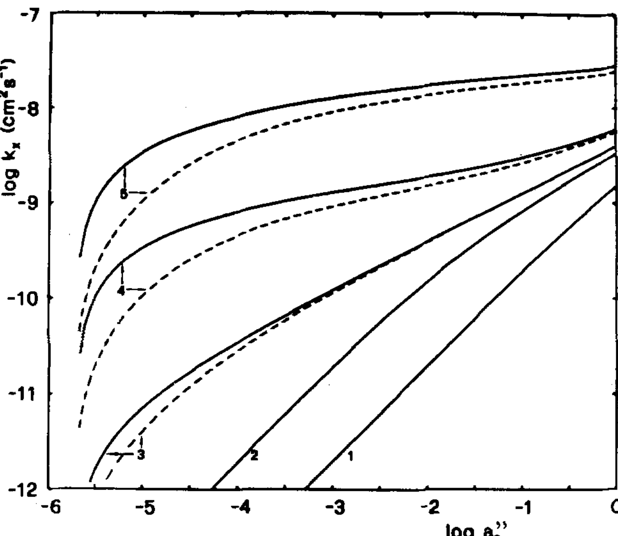

Fig. 1. Parabolic rate constant of oxidation of a metal as a function of the gas-phase oxygen activity a_O'' with formation of an oxide MO containing only metal vacancies V'. Continuous lines: $K_7 = 1 \times 10^{-1/2}$; dotted lines: $K_7 = 1 \times 10^{-9}$. Curves 1 and 2: oxide containing a monovalent impurity with a concentration 10^{-2} and 10^{-3}, respectively. Curves 3: pure oxide. Curves 4 and 5: oxide containing a trivalent impurity with a concentration 10^{-3} and 10^{-2}, respectively.

trivalent, and for the two values of K_7. The effect of monovalent impurities is to produce a decrease of k_x and that of the trivalent impurities an increase, as expected. The curves tend to approach each other in the range of high oxygen activities while they diverge for low a_O values. The curves corresponding to the same concentrations of monovalent impurities and the two values of K_7 are identical, while those for the trivalent impurities as well as for the pure oxide differ. This is an example of the importance of the value of the intrinsic ionization constant K_7 in establishing the concentrations of all the defects as functions of a_O. For the pure oxide the expression of k_x as given by Eq. [49] of Part I (1)

$$k_x = 2mD_V [V']''_o \qquad [41]$$

holds only if the condition $p = [V'] = (K_V a_O)^{1/2}$ is fulfilled in the whole range of a_O. Actually, however, the complete condition of neutrality is $p = n + [V']$, so that the equality between p and $[V']$ is only an approximation holding when $p >> n$ or $[V'] >> n$. Taking into account the two equilibria for the formation of vacancies, electrons and electron holes, the condition $p \simeq [V']$ requires that $K_V a_O >> K_7$, a situation which is less likely to hold at small oxygen activities and in particular at $a_O = a_O'$. In the present example, since $K_V = 10^{-4}$ and $a_O' = 1.66 \times 10^{-6}$, we obtain $K_7 << 1.66 \times 10^{-10}$ to have $p \simeq [V']$. This condition is fulfilled if $K_7 = 10^{-12}$, but not if $K_7 = 10^{-9}$, leading in the latter case to a $[V']$ smaller than p at low oxygen activities. The consequence is that for $K_7 = 10^{-9}$ the parabolic rate constant is smaller than for $K_7 = 10^{-12}$ in the region of low a_O, even if the effect tends to disappear at high a_O. In the presence of monovalent impurities the concentration of the electron holes is increased and that of the electrons decreased with respect to the pure oxide, so that the value of k_x is no longer affected by the value of K_7. On the contrary, the addition of trivalent impurities produces an increase in the concentration of the vacancies and electrons and a decrease in that of the electron holes so that, depending on the value of K_7 and the concentration of the impurity, the oxide may change from p- to n-type at least in the range of small oxygen activities. In addition, the concentration of electrons in the region of low a_O may become larger than that of V', so that the condition $[V'] \simeq [Cr^\cdot]$ does no longer hold, but one has instead $[V'] < [Cr^\cdot]$: for a fixed concentration of impurity these changes occur under an a_O value which is smaller the larger is K_7. This is shown in Fig. 2 where the concentrations of the different defects are plotted as functions of a_O for the two values of K_7 and a concentration of the trivalent impurity equal to 10^{-2}. The consequence of this situation is that the k_x curves corresponding to $K_7 = 10^{-12}$ are higher than for the larger value of K_7 due to the higher concentration of vacancies in the former case in the region of low a_O.

Figures 3a and 3b show the ratio between the parabolic rate constant for the formation of a doped oxide

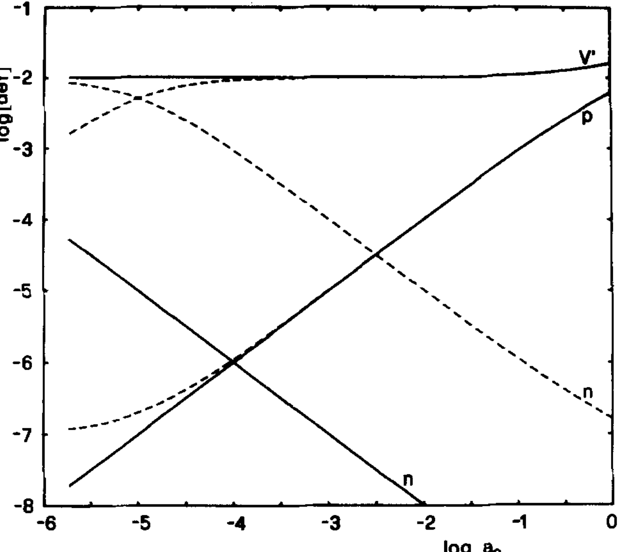

Fig. 2. Concentrations of the different defects as functions of the oxygen activity a_O in an oxide MO containing only metal vacancies V' and a concentration of a trivalent impurity 10^{-2}. Continuous lines: $K_7 = 10^{-12}$; dotted lines: $K_7 = 10^{-9}$.

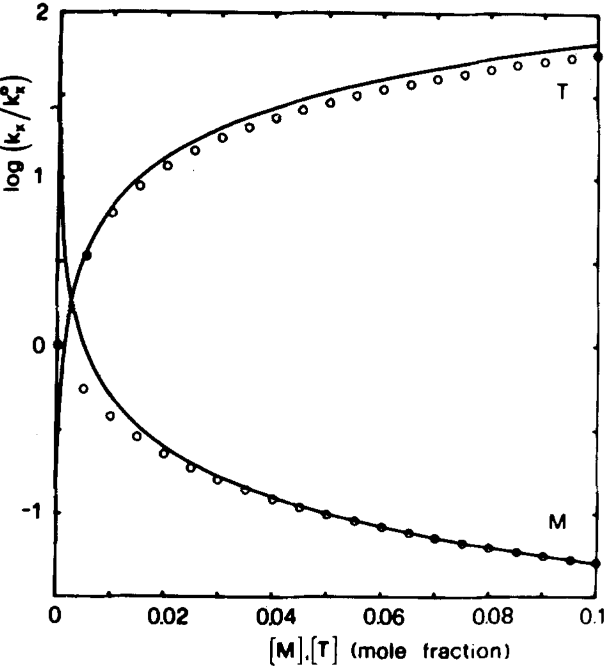

Fig. 3a. Ratio of the parabolic rate constant for the growth of a doped oxide k_x to that for the growth of the pure oxide k_x° under a gas-phase oxygen activity $a_O'' = 1$, as a function of the concentration of the dopant: M = monovalent impurity; T = trivalent impurity. Continuous lines obtained from Eq. [12] (M) and Eq. [29] (T), respectively. $K_7 = 10^{-9}$.

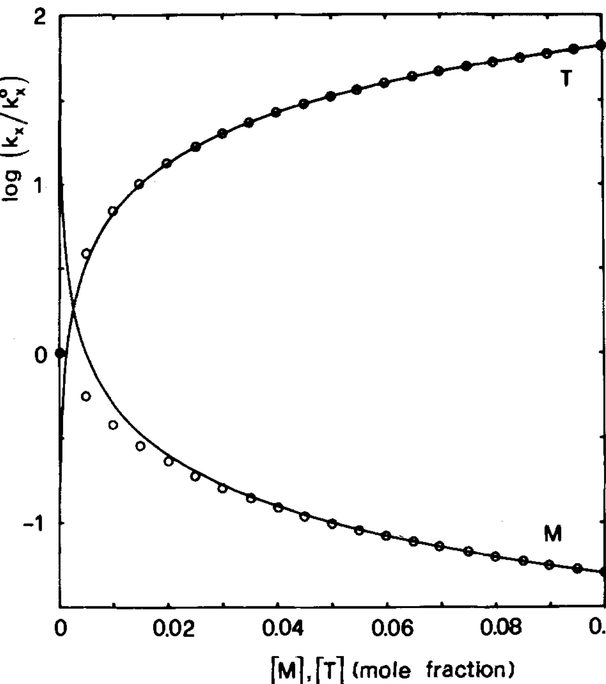

Fig. 3b. Ratio of the parabolic rate constant for the growth of a doped oxide k_x to that for the growth of the pure oxide k_x° under a gas-phase oxygen activity $a_O = 1$, as a function of the concentration of the dopant: M = monovalent impurity; T = trivalent impurity. Continuous lines obtained from Eq. [12] (M) and Eq. [29] (T), respectively. $K_7 = 10^{-12}$.

k_x and that for the corresponding pure oxide k_x°, calculated for a fixed value of the gas-phase oxygen activity $a_O'' = 1$, as a function of the concentration of the dopants, both monovalent and trivalent, along with the curves corresponding to the limiting expressions as given by Eq. [12] for Li doping and Eq. [30] for Cr doping. The values of k_x/k_x° are calculated up to a high concentration of the dopants (10^{-1}) to show more clearly the effect of doping, but the results in this region are only indicative in view of the high concentrations of defects prevailing under this condition, requiring appropriate corrections to the simple expressions used here. The continuous curves corresponding to the limiting expressions are clearly wrong for low doping levels, since these equations do not extrapolate to this region where the approximations used to obtain them do not hold. At high dopant concentrations the curves are superimposed to the points calculated by the complete numerical procedure in the case of the presence of monovalent impurities for both values of K_7, while this happens only for $K_7 = 10^{-12}$ in the case of trivalent impurities. In fact for the higher value $K_7 = 10^{-9}$ the calculated points lie below the simplified curve due to the reasons discussed above, i.e., to the fact that the condition $[V'] \simeq [Cr^\cdot]$ which has been used in the derivation of the analytical expression does not hold everywhere.

Regarding the effect of doping on the value of the parabolic rate constant for oxides containing only vacancies, substitution of $dx = x_S dy$ into Eq. [9] yields (1)

$$J_{ov}x_S = k_t = RD_V[V'] \frac{d \ln a_O}{dy} \quad [42]$$

where k_t is the parabolic rate constant expressed in molecules of oxide formed per unit surface area per unit time (18). Equation [42] shows that the value of k_t, and therefore also of k_x which is proportional to it (1), is related to two factors, namely, the concentration of defects and the gradient of ln (a_O) with respect to y. Using Eq. [42] to express k_t for the doped as well as for the pure oxide, the ratio k_x/k_x° can be expressed in the form

$$\frac{k_x}{k_x^\circ} = \frac{[V^{r'}]_{doped}}{[V^{r'}]_{pure}} \frac{\left(\frac{d \ln a_O}{dy}\right)_{doped}}{\left(\frac{d \ln a_O}{dy}\right)_{pure}} = R_1R_2 \quad [43]$$

with

$$R_1 = \frac{[V^{r'}]_{doped}}{[V^{r'}]_{pure}} \quad [44a]$$

and

$$R_2 = \frac{\left(\frac{d \ln a_O}{dy}\right)_{doped}}{\left(\frac{d \ln a_O}{dy}\right)_{pure}} \quad [44b]$$

Both factors R_1 and R_2 will in general contribute to fix the value of the ratio k_x/k_x° while for a fixed gas-phase oxygen activity a_O'' and a dopant concentration independent of x their product must remain constant through the scale, i.e., for any value of a_O between a_O' and a_O''. The individual values of R_1 and R_2 will, however, generally change with a_O, so that it seems useful to examine the contributions of these factors to k_x/k_x° separately as functions of a_O. This may be done easily by the usual numerical procedure by evaluating R_1 and R_2 as functions of a_O: the result is shown in Fig. 4 for the same values of the parameters used above and $K_7 = 10^{-12}$ with a fixed concentration of impurities (10^{-2}). For a monovalent impurity the ratio k_x/k_x° under the conditions specified above becomes 0.379: the change of R_1 and R_2 reported in Fig. 4 shows that in this case R_1 always gives a contribution to the decrease of k_x with respect to k_x°, since it is smaller than one everywhere, while R_2 is larger than one below a_O (1) = 0.211 approximately and smaller than one above a_O (1), so that the overall reduction of k_x with respect to k_x° has to be attributed to R_1 everywhere and to R_2 only above a_O (1). In the region below a_O (1) R_1 tends to produce a decrease of k_x while R_2 an increase, but the effect of R_1 is numerically prevailing. On the contrary for trivalent impurities, giving a

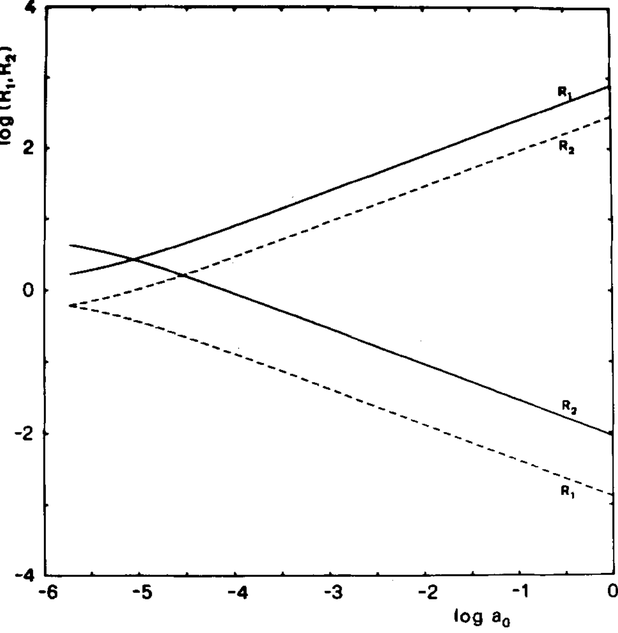

Fig. 4. R_1 and R_2 (defined in the text) as functions of the oxygen activity for the growth of an oxide MO containing only V' vacancies pure and doped with a concentration 10^{-2} of monovalent or trivalent impurities under a gas-phase oxygen activity $a_O'' = 1$. Continuous lines: monovalent impurity; dotted lines: trivalent impurity.

ratio $k_x/k_x° = 6.919$, R_1 is always greater than one while R_2 is larger than one only above a_O (1) = 2.24 × 10^{-2} so that the increase of k_x with respect to $k_x°$ is due mainly to R_1. It may be concluded that for a uniform distribution of the dopant the change of k_x is related principally to the change in the concentration of the vacancies produced by the impurities, even though this is not the only factor to produce the observed effect.

Finally, different values of the equilibrium constant for the formation of the vacancies K_V yield results similar to those reported above: the effect of the dopants, however, increases for smaller values of K_V, since these correspond to smaller concentrations of vacancies in the pure oxide, in agreement with the theoretical predictions according to Eq. [12] and [29].

Oxides with metal interstitials.—Only oxides containing singly charged interstitials will be considered in detail. The diffusion coefficient of the interstitial metal atoms is taken again as $D_I = 10^{-7}$ cm²/sec^{-1} while for the constant of equilibrium for the formation of interstitials we take the value $K_I = 1.664 \times 10^{-10}$, corresponding to a concentration of interstitials 10^{-2} at the M/MO interface, using for a_O' the value $a_O' = 1.66 \times 10^{-6}$ as previously. Two different values are used for the intrinsic ionization equilibrium constant K_7 ($K_7 = 10^{-9}$ and $K_7 = 10^{-12}$) as for the vacancies to examine the effect of K_7 on the different parameters.

The change of k_x as a function of a_O'' for some selected values of the concentration of the dopant, both monovalent and trivalent, is reported in Fig. 5 for the two values of K_7: the presence of monovalent impurities produces an increase and that of trivalent impurities a decrease of k_x with respect to the value for the pure metal $k_x°$, as expected. The curves show a fast increase of k_x at low oxygen activities and then tend to a constant value: this behavior is typical of oxides containing only metal interstitials. The curves corresponding to the presence of the same concentration of a trivalent impurity are coincident for the two K_7 values, while those for a monovalent impurity differ at high values of a_O, those for $K_7 = 10^{-12}$ being higher than those calculated for $K_7 = 10^{-9}$. This is again a result of the relatively large value of K_7 in the latter case. In fact, in the presence of monovalent impurities the concentration of interstitials and that of electron holes is increased with respect to the pure oxide and therefore that of electrons is decreased, so that the oxide tends to change from n- to p-type semiconductivity. Moreover, if K_7 is large and the concentration of the impurity great enough, the condition $[M_i^·] < [Li']$ takes the place of the condition $[M_i^·] \simeq [Li']$ holding for a lower K_7 value, as shown in Fig. 6 for a concentration of impurities equal to 10^{-2} and $K_7 = 10^{-9}$: this case yields, therefore, to a lower value of k_x.

The ratio $k_x/k_x°$ as a function of the concentration of the dopant under $a_O'' = 1$ for monovalent and trivalent impurities is reported in Fig. 7a and 7b for the two values of K_7 along with the curves obtained from

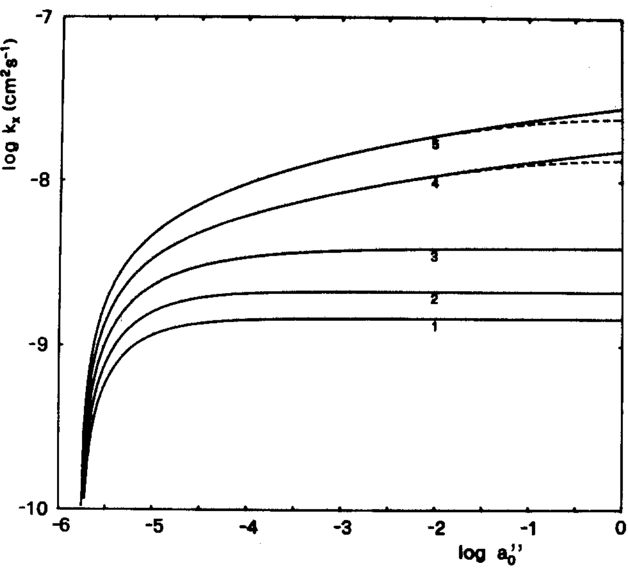

Fig. 5. Parabolic rate constant of oxidation of a metal as a function of the gas-phase oxygen activity a_O'' with formation of an oxide MO containing only metal interstitials $M_i^·$. Continuous lines: $K_7 = 10^{-12}$; dotted lines: $K_7 = 10^{-9}$. Curves 1 and 2: oxide containing a trivalent impurity with a concentration 10^{-2} and 5×10^{-3}, respectively. Curve 3: pure oxide. Curves 4 and 5: oxide containing a monovalent impurity with a concentration 5×10^{-3} and 10^{-2}, respectively.

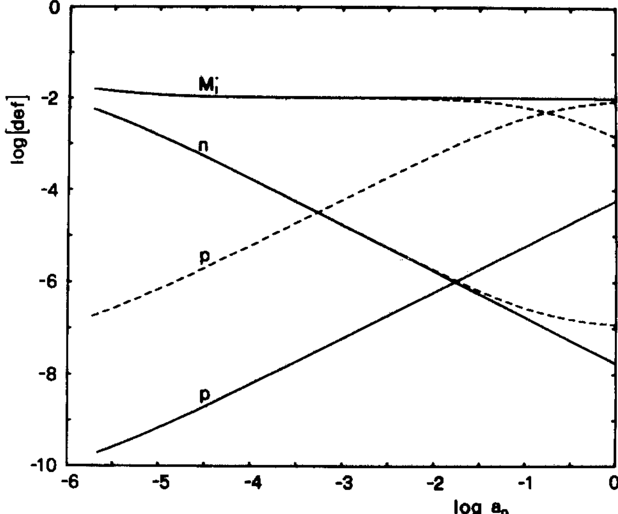

Fig. 6. Concentrations of the different defects as functions of the oxygen activity a_O in an oxide MO containing only metal interstitials $M_i^·$ and a concentration of a monovalent impurity 10^{-2}. Continuous lines: $K_7 = 10^{-12}$; dotted lines: $K_7 = 10^{-9}$.

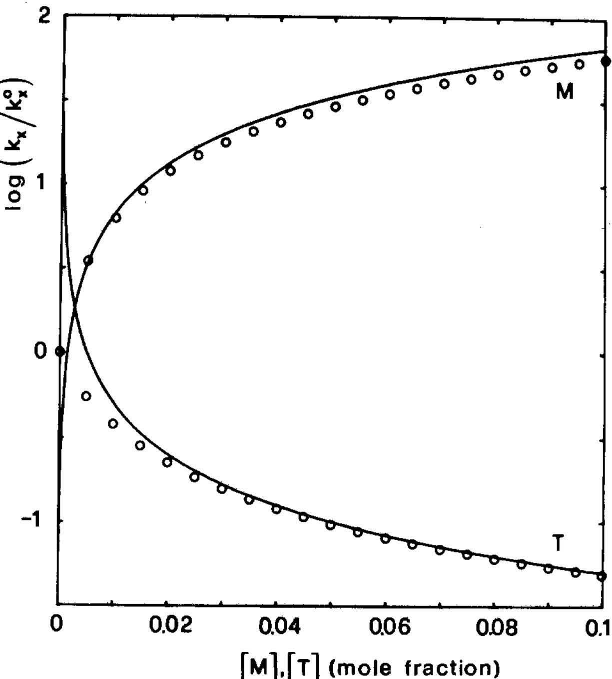

Fig. 7a. Ratio of the parabolic rate constant for the growth of a doped oxide k_x to that of the pure oxide $k_x°$ under a gas-phase oxygen activity $a_O'' = 1$ as a function of the dopant concentration: M = monovalent impurity; T = trivalent impurity. Continuous lines obtained from Eq. [19] (M) and Eq. [39] (T), respectively. $K_7 = 10^{-9}$.

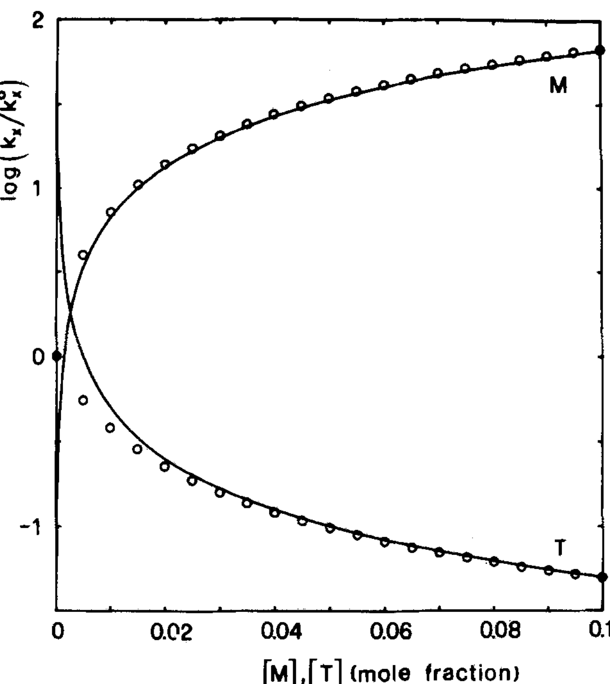

Fig. 7b. Ratio of the parabolic rate constant for the growth of a doped oxide k_x to that of the pure oxide k_x° under a gas-phase oxygen activity $a_O'' = 1$ as a function of the dopant concentration: M = monovalent impurity; T = trivalent impurity. Continuous lines obtained from Eq. [19] (M) and Eq. [39] (T), respectively. $K_7 = 10^{-12}$.

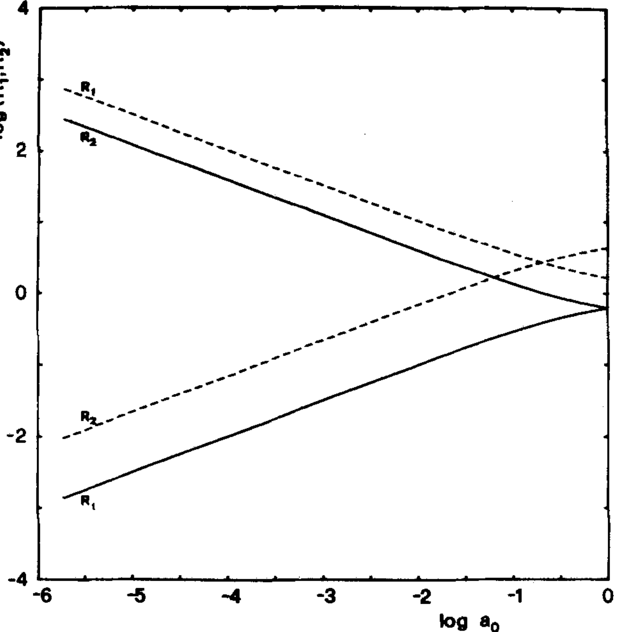

Fig. 8. R_1 and R_2 (defined in the text) as functions of the oxygen activity a_O for the growth of an oxide MO containing only metal interstitials $M_i^\cdot$ pure and doped with a concentration 10^{-2} of monovalent or trivalent impurities under a gas-phase oxygen activity $a_O = 1$. Continuous lines: monovalent impurities; dotted lines: trivalent impurities.

the simplified limiting equations (Eq. [19] and [39]). For the lower K_7 value the points obtained by the complete calculation agree well with the simplified curves at sufficiently high doping levels. On the contrary, for $K_7 = 10^{-9}$ the agreement is obtained only for the trivalent, but not for the monovalent impurities, for which the complete calculation leads to results lower than those obtained from Eq. [19]. This behavior depends again on the high value of K_7 and on the effect it has on the concentration of metal interstitials, as discussed above.

Proceeding as for the vacancies, the ratio k_x/k_x° may be expressed in the form

$$\frac{k_x}{k_x^\circ} = R_1 R_2 \qquad [45]$$

with

$$R_1 = \frac{[M_i^\cdot]_{\text{doped}}}{[M_i^\cdot]_{\text{pure}}} \qquad [46a]$$

and

$$R_2 = \frac{\left(\dfrac{d \ln a_O}{dy}\right)_{\text{doped}}}{\left(\dfrac{d \ln a_O}{dy}\right)_{\text{pure}}} \qquad [46b]$$

so that the ratio is affected by both factors R_1 and R_2. These may be calculated separately as functions of a_O and are reported in Fig. 8 for $K_7 = 10^{-12}$ and a concentration of impurity equal to 10^{-2} either monovalent or trivalent. In the case of the addition of a uniform concentration of a monovalent impurity the ratio k_x/k_x° takes the value 7.0: R_1 is always greater than one while R_2 is greater than one only below a_O (1) $= 7.94 \times 10^{-5}$ approximately and smaller than one above a_O (1). Therefore, below a_O (1) both R_1 and R_2 act in the same direction to increase k_x, even if at a different extent: above a_O (1) instead R_1 and R_2 act in the opposite way, but the effect of R_1 prevails over that of R_2. For the same concentration of a trivalent impurity one obtains instead $k_x/k_x^\circ = 0.367$ and R_1 is always smaller than one while R_2 is smaller below a_O (1) $= 10^{-5}$ and greater above it. The general conclusion is therefore the same as for the charged vacancies, *i.e.*, that the change of k_x is mainly due to the change in the concentration of the lattice defects produced by the incorporation of the impurity which is usually opposite and prevails over the change in the gradient of the logarithm of the oxygen activity through the scale.

Results similar to those reported here may be obtained for different values of the equilibrium constant K_I or also for oxides containing doubly charged interstitials. In the former case a decrease of K_I leads to a greater effect of the addition of the dopants on k_x, in agreement with the predictions based on Eq. [19] and [39].

Oxides with a complex defect structure: CoO.—The same values of the parameters as used for the calculation on pure CoO (1) are also used here. The calculation is performed for the case of the absence as well as for the presence of interstitial cobalt atoms, which are referred to as case 1 and case 2, respectively. In the latter case the concentration of interstitials is calculated assuming that at an oxygen activity corresponding to the Co/CoO equilibrium $[Co_i^{\cdot\cdot}] = [V'']$.

Figure 9a and 9b show the plots of k_x as functions of a_O'' for the oxide pure and doped with some selected concentrations of impurities either monovalent or trivalent for cases 1 and 2, respectively. In presence of trivalent impurities the curves corresponding to the two cases are exactly coincident. On the contrary, in the case of the presence of monovalent impurities the behavior of k_x is completely different in the two cases. In fact, while in absence of $Co_i^{\cdot\cdot}$ the parabolic rate constant is decreased by the addition of Li with respect to pure Co, in the presence of Co interstitials it is increased even if these are minority defects in the pure oxide. This situation is related to the fact that the addition of a monovalent impurity carrying a negative effective charge produces a large increase in the concentration of the metal interstitials, particularly close to the metal/scale interface, as is shown in Fig. 10 for $[Li'] = 10^{-2}$, and this in turn produces an increase in the value of k_x with respect to k_x° particularly at

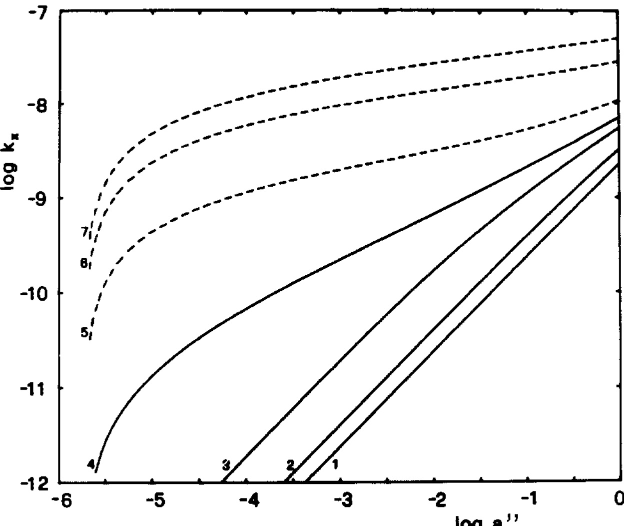

Fig. 9a. Parabolic rate constant for the growth of CoO at 1000°C pure or doped as a function of the gas-phase oxygen activity $a_O'' = 1$ for case 1 (absence of $Co_i^{\cdot\cdot}$). Continuous lines: pure oxide (curve 4) or oxide containing a monovalent impurity with a concentration 10^{-2} (curve 1), 5×10^{-3} (curve 2), and 10^{-3} (curve 3). Dotted lines: oxide containing a trivalent impurity with a concentration 10^{-3} (curve 5), 5×10^{-3} (curve 6), and 10^{-2} (curve 7).

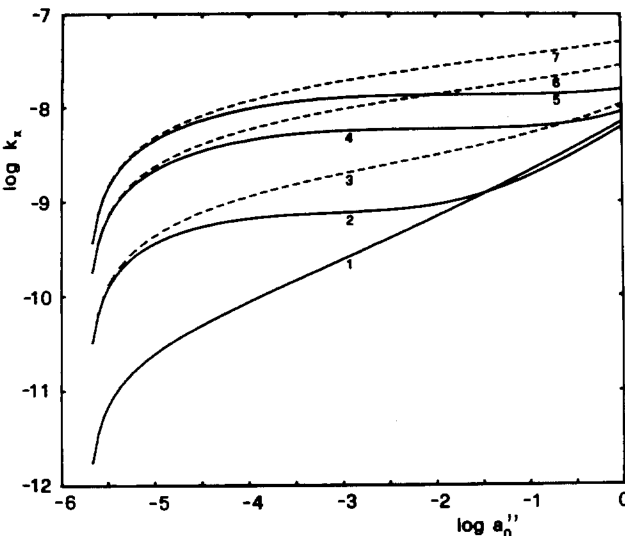

Fig. 9b. Parabolic rate constant for the growth of CoO at 1000°C pure or doped as a function of the gas-phase oxygen activity $a_O'' = 1$ for case 2 (presence of $Co_i^{\cdot\cdot}$). Continuous lines: pure oxide (curve 1) or oxide containing a monovalent impurity with a concentration 10^{-3} (curve 2), 5×10^{-3} (curve 4), and 10^{-2} (curve 5). low values of a_O''. On the contrary, the addition of a trivalent impurity with a positive effective charge leads to a decrease of the concentration of the $Co_i^{\cdot\cdot}$ with respect to the pure CoO, where their role is already very limited, so that their presence has no effect in this situation.

The effect of the concentration of the impurity on the parabolic rate constant as measured by the ratio $k_x/k_x°$ under a constant gas-phase oxygen activity $a_O'' = 1$ is presented in Fig. 11 for both cases 1 and 2. While the curve corresponding to the presence of trivalent impurities remains unaffected by the presence or the absence of $Co_i^{\cdot\cdot}$, that corresponding to the addition of monovalent impurities is completely reversed, unless for very small values of [Li'], which lead to a

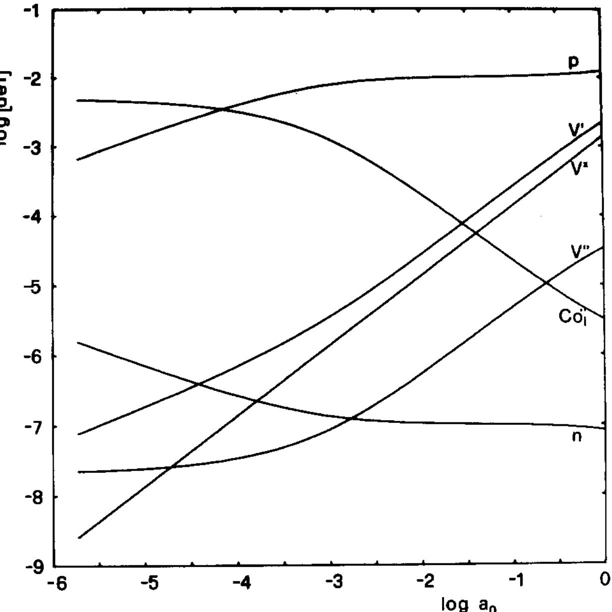

Fig. 10. Concentration of the different defects in CoO doped with a concentration 10^{-2} of a monovalent impurity as a function of the oxygen activity a_O at 1000°C for case 2.

small decrease of k_x with respect to $k_x°$ at low oxygen activities.

The previous conclusion about the effect of the addition of monovalent impurities on the oxidation rate of cobalt is supported by the results of the high temperature oxidation of a solid solution of copper in cobalt containing about 10 weight percent of Cu, which shows a small increase of the parabolic rate constant with respect to pure cobalt instead of a decrease as expected in the case of the absence of Co interstitials (19). This effect may be attributed to the presence of copper dissolved in CoO in the form of Cu^+ ions, at least in the region of low oxygen activities. A similar

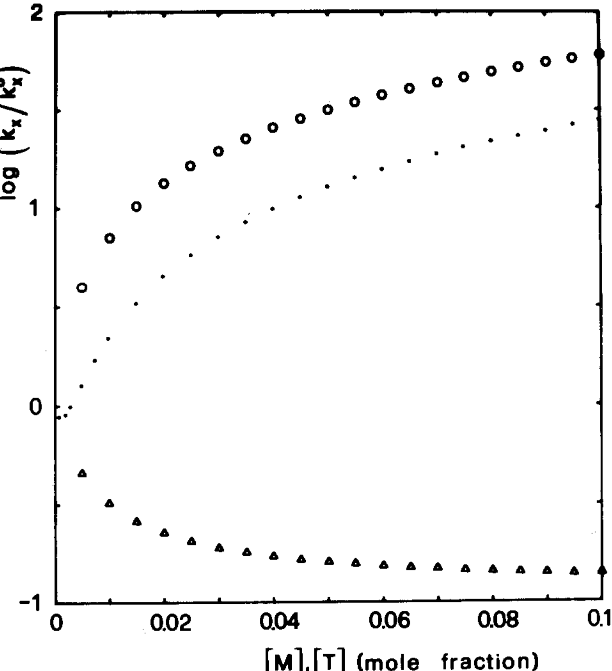

Fig. 11. Ratio of the parabolic rate constant for the growth of doped CoO to that of pure CoO at 1000°C and $a_O'' = 1$ as a function of the dopant concentration. △ points calculated for a monovalent impurity for case 1; ● calculated for a monovalent impurity for case 2; ○ calculated for a trivalent impurity for both cases 1 and 2.

effect has also been found in the oxidation of a copper-rich Cu-Ni alloy (20) and this could also have the same explanation.

The addition to cobalt or nickel of a second alloy component forming cations of valency higher than two has been found to produce an increase in the oxidation rate of the base metal, in agreement with the Wagner-Hauffe rules as given for a uniform concentration of the impurity (21-30). These impurities, however, show a tendency to accumulate preferentially close to the alloy/scale interface, thereby decreasing or even reversing the gradient of the concentration of the metal vacancies through the scale. In this situation the vacancies have to diffuse against their own concentration gradient in their motion inward from the scale/gas interface, a situation which at first sight seems physically unrealistic. The contradiction is, however, only apparent since the inward flux of charged vacancies is given by Eq. [22] or [23] of Part I (1) in the form

$$J_V = -RD_V\left(\frac{d[V^{r'}]}{dx} + r\,[V^{r'}]\frac{d\ln p}{dx}\right) \quad [47]$$

where the first term represents the flux due to the gradient of the concentration of the vacancies and the second that produced by the gradient of the electric potential due to the motion of the more mobile electronic species. It is therefore possible for the vacancies to move uphill with the help of an accelerating electric field which forces them to proceed inward.

It has been shown above that for oxides containing only one kind of metal vacancy and uniformly doped with a higher valent impurity the increase of k_x with respect to $k_x°$ depends on two factors related respectively to the change of the concentration of the vacancies and of the gradient of the logarithm of the oxygen activity with respect to the normalized distance from the alloy/scale interface y. For that case the observed increase of k_x is due mainly to the first factor. However, if the distribution of the dopant is not uniform, it seems not possible to state *a priori* even if the addition of the impurity will enhance or depress the oxidation rate. In fact this may only be assessed by means of the appropriate calculations taking into account the actual distribution of the dopant in the scale, as will be attempted in a next paper (19). The experimental results point out, however, that the net effect of doping is to increase the oxidation rate, suggesting that the increase in the concentration of the vacancies produced by the impurities is still the dominating factor in modifying the oxidation rate for these systems.

Conclusions

The application of a theory for the parabolic oxidation of metals developed previously (1) to the growth of oxides doped with heterovalent impurities forming on dilute alloys confirms the conclusions already known as the Wagner-Hauffe rules for oxides containing a single kind of defects and a uniform distribution of the dopant, allowing however a more complete calculation of all the parameters involved. For oxides containing different kinds of defects it is shown that under suitable conditions defects which are unimportant in the pure oxide may play a substantial role leading to an effect of the dopant which may be very different or even reversed with respect to that predicted on the basis of a simpler defect model. These results point out again that a correct and complete interpretation of the oxidation behavior of dilute alloys as well as of pure metals can only be carried out if the actual defect structure of the oxide is known with sufficient accuracy. For the time being a complete understanding of the high temperature oxidation behavior of pure metals and dilute alloys is generally prevented by the incomplete knowledge of this subject. Further progress should be possible, however, by a future development of the basic research in this field along with a consideration of all the other important factors also affecting the experimentally observed reaction rates.

Use of an Electron Beam to Separate Semiconductor Devices with Beam Leads

Irena Barycka, Bogusław Boratynski, Tomasz Ohly, Mirosław Szreter, and Helena Teterycz

Instytut Technologii Elektronoweoj, Politechniki Wrocławskiej, 50-372 Wrocław, Poland

and Olga Ikanowicz

The division of silicon wafers covered with diodes, transistors, or integrated circuits into single structures presents a major difficulty in the manufacture of silicon devices with beam leads. The commonly used technique for division is laborious, since it involves many processes.

The wafer to be divided is first thinned down to a thickness of about 100 μm, then is coated (vacuum or CVD) with an SiO_2 film and photoresist and the areas to be etched are uncovered by photolithographic techniques. These uncovered areas are then etched in an alkaline solution. The procedure of matching the photomask with the patterns being on the opposite side of the wafer is very difficult, and the thinning of the wafer reduces its mechanical strength (1-3).

The fact that single crystal damaged regions have much higher etch rates than undamaged areas (4, 5) has been used by us as the basis for the separation of semiconductor devices with beam leads.

In this paper the results of an investigation using a technique utilizing an electron beam are presented. The electron beam was used to generate damage on selected areas of the silicon wafer (6). The damaged regions, which now have an increased etching rate, would enable the division of the wafer without reduction of thickness and without lithographic processing. Etching in alkaline solution is particularly sensitive to the crystallographic orientation of silicon (7, 8) and thus the course of the etching process will depend significantly on the orientation of the wafers used.

Key words: electron beam, semiconductor devices, silicon, beam leads, alkaline etching.

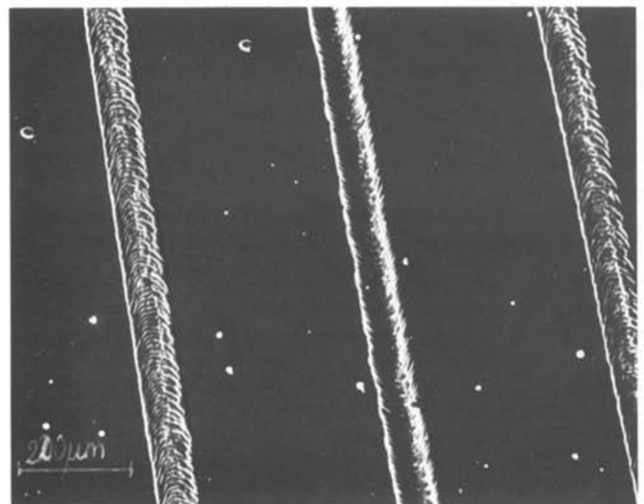
Experimental

The experiments have been conducted on typical polished single crystal silicon wafers 200 μm thick with (100) and (111) orientation. The resistivities of the samples were 10^{-3}-10^{-1} Ωm, p- and n-type, and the dislocation density was up to 10^3 cm^{-3}.

A number of lines, parallel and perpendicular to the basic cutting directions, were ruled on the wafer surface with an electron beam. The pulsed beam was focused on the wafer surface. During exposure the wafer was shifted at a speed of 2 mm/sec.

After a preliminary investigation, it was found that a change in etch rate appeared only when the electron beam interaction resulted in melting of the silicon material.

In further experiments, electron accelerating voltages were chosen in the 100 to 120 kV range, pulse frequency 200 and 1000 Hz, and pulse duration 10 and 20 μsec. The electron beam current varied between 1 and 7 mA. The lines formed on the wafer surface due to exposure to the electron beam are shown in Fig. 1.



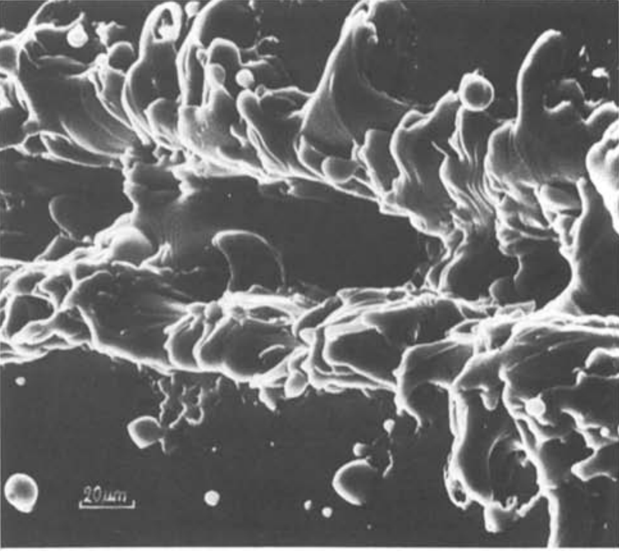


Fig. 1. Tracks formed on a (111) silicon wafer due to an electron beam, U_p = 120 kV, f = 200 Hz, τ = 10 μsec (SEM). a. General view, I = 4 mA; b. selected fragment, I = 7 mA.

After exposure to the electron beam the wafers were placed on a rotating disk (250 rpm) and etched in 10M NaOH solution at 353 K.

Results

Exposure of the silicon wafer to the electron beam produces damaged regions (in the form of lines). To evaluate the range of damage produced in the material, the wafers were cut perpendicular to the electron beam trace and then etched in Sirtl etch solution, commonly used for defect detection in single crystal silicon. An example of such a cross section is shown in Fig. 2. The depth of the region damaged depends mainly on the intensity of the beam current and to a smaller degree on other beam parameters. The depth of the damaged region *vs.* current intensity is shown in Fig. 3. No dependence on crystallographic orientation of the specimen was observed in this portion of the investigation.

Fig. 2. Cross section through the irradiated (111) wafer. Beam parameters the same as in Fig. 1b (SEM).

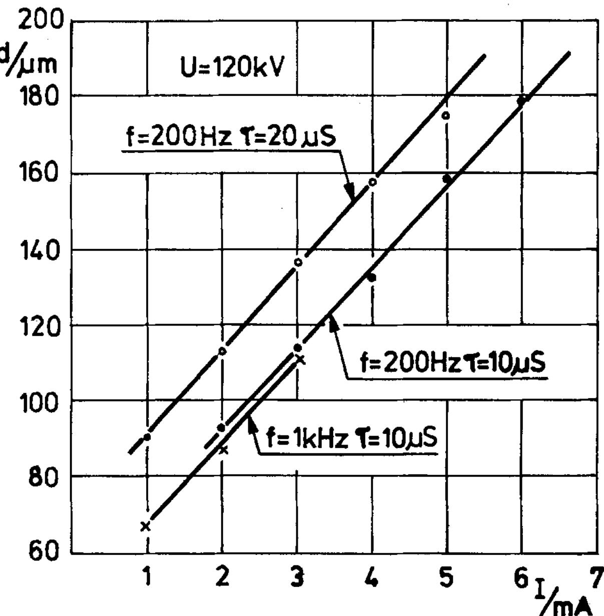

Fig. 3. The depth (d) of region damaged vs. beam parameters

To evaluate the effects of etching, the wafers were placed in an NaOH solution and etching was carried out as described previously. Under the conditions used (10M NaOH, 353 K, 250 rpm) the etching rates were:

orientation	(100)	(111)	damaged (100) and (111)
etching rate µm/min	1.16	0.168	2.3

The etch rates of the damaged regions were constant and were not dependent on the orientation. A series of grooves was formed as the result of the differences between the etch rates for damaged and undamaged silicon. The geometry of the grooves was examined by means of profilographs. Cross sections of the grooves were also made and their shape was observed using a scanning electron microscope (Fig. 4). The width and depth of the grooves obtained, as measured by both methods were in satisfactory agreement. There are some differences in groove formation between wafers oriented (111) and (100). Their dependence on the etching time and the exposure conditions as well as on the crystallographic orientation of the wafers is shown in Fig. 5 and 6.

After the damaged material had been removed from the (111) wafer, a flat bottom, terminated by the (111) plane was formed. This was then etched at the same rate as the undamaged wafer surface. Thus the depth of the groove remains constant during further etching, whereas its width increases rapidly. The inclination angle of the walls remains constant at 142°. This is shown schematically in Fig. 7a.

The deepening of grooves in the wafers with (100) orientation proceeds differently. After removal of the damaged material the etching proceeds perpendicularly to the (100) plane. The final shape of the groove is determined by the high etching rate of the lateral walls, as well as by the high etching rate of the (100) plane. That is why a flat bottom is formed on the

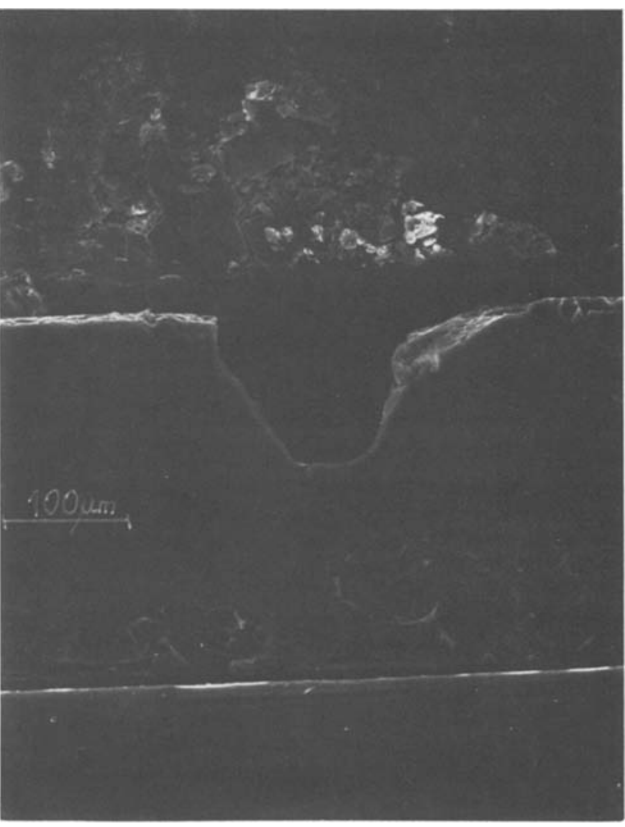

Fig. 4. Cross section of the groove after etching for 50 min, (111) wafer (SEM).

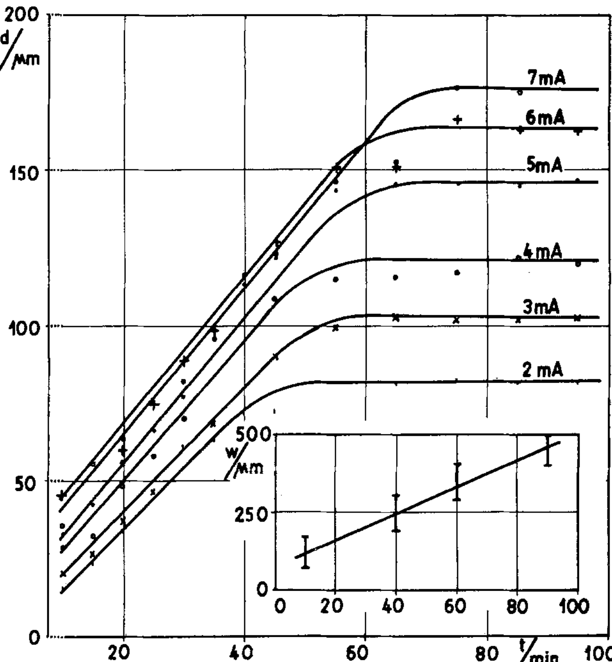

Fig. 5. Depth (*d*) and width (*w*) of groove *vs.* etching time (*t*) for silicon with (111) orientation, U_p = 120 kV, *f* = 200 Hz, τ = 10 μsec current *I* is given in the graph.

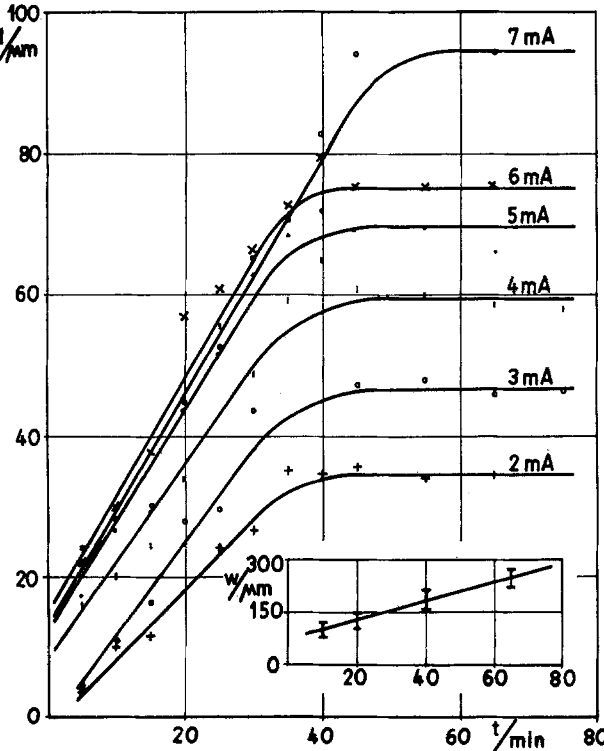

Fig. 6. Depth (*d*) and width (*w*) of the groove *vs.* etching time (*t*) for silicon with (100) orientation, U_p = 120 kV, *f* = 200 Hz, τ = 10 μsec, current *I* is given in the graph.

groove after a large quantity (approximately 100 μm) of silicon is removed (Fig. 7b).

The structures on the wafer with (100) orientation can be separated without masking and without preliminary reduction of the wafer thickness. The exposure conditions should be chosen so that the damaged region reaches a specific depth, depending on the plate thickness and on the geometry of the beam leads. For example, for a 200 μm thick wafer and for a 100 μm distance between the structures, the minimum required depth is 100 μm. Under these conditions the structures separated by the etching technique yield pyramids or truncated pyramids about 50 μm high. An example of a structure separated by this method is shown in Fig. 8.

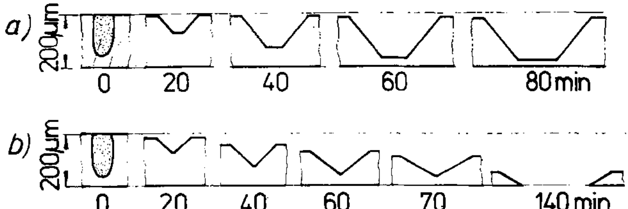

Fig. 7. Schematic representation of the etching process of electron beam exposed wafers. a, (111) and b, (100) orientation.

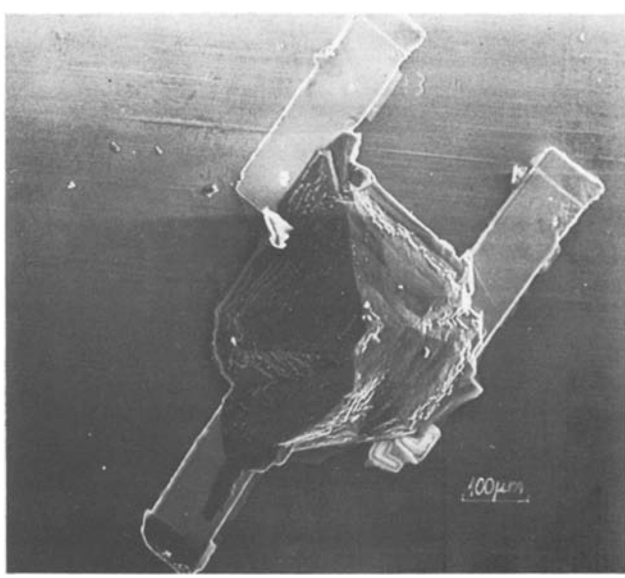

Fig. 8. Transistor with beam leads separated by means of an electron beam (SEM).

It is also possible to separate the structures with beam leads made on a (111) wafer. Note that groove widening on the (111) plane proceeds at a high rate. Thus, this method requires a suitable arrangement of structures on the wafer: the beam leads must not be linked, and they must be separated by a distance of about 100 μm. Here the exposure conditions should be chosen so that the defect region reaches the opposite side of the wafer. Etching should be continued until the defect region is completely removed and the beams are exposed along the length required. The structures obtained will have the shape of a truncated pyramid whose height is slightly less than that of the initial thickness of the wafer.

This method requires a certain decrease in packing density of the structures on the (111) surface. The effective packing density can be higher if the integration scale of each single chip is larger.

Mineralized Surfaces of the Dental Alloys

S. Yamaguchi*

2-72 Kotake-cho, Nerima-ku, Tokyo, 176, Japan

and T. Tsuchiya

2-15-4 Asakusa-bashi, Daito-ku, Tokyo, 111, Japan

It is of interest to study the dental gold/dental porcelain interface, as already reported by Sperner (1). In the present study, this problem has been treated in terms of RHEED (Reflection High Energy Electron Diffraction).

There are two types among the dental alloys of practical use. They are the solid solutions whose contents are given by Au(72)-Pt(13)-Pd(10)-Ag(3)-Rh(1)-Ir(0.5)-Sn(0.4)-Si(0.1) and by Au(72)-Pt(13)-Pd(10)-Ag(3.4)-Rh(1)-Ir(0.5)-Si(0.1), respectively. The former alloy contains Sn, whereas the latter is free from this element. These alloys are supposed to stick fast to the dental artificial porcelain that is composed of SiO_2(43), Al_2O_3(32), SnO_2(10), K_2O(9), Na_2O(5), and a small amount of MgO, CaO, Li_2O.

In order to mate the alloys with the porcelain, one preheats the former in the air at about 1000°C. Figure 1 is the RHEED pattern from the surface of the 0.4% Sn alloy treated thermally for 30 min. All the reflections in this figure belong to the SnO_2 crystallites. The result of the analysis of Fig. 1 is given in Table I. This verifies that a selective oxidation (2) has taken place at the specimen surface. This mineralized surface could stick fast to the dental porcelain containing SnO_2.

* Electrochemical Society Active Member.
Key words: RHEED, adhesion, dental alloys.

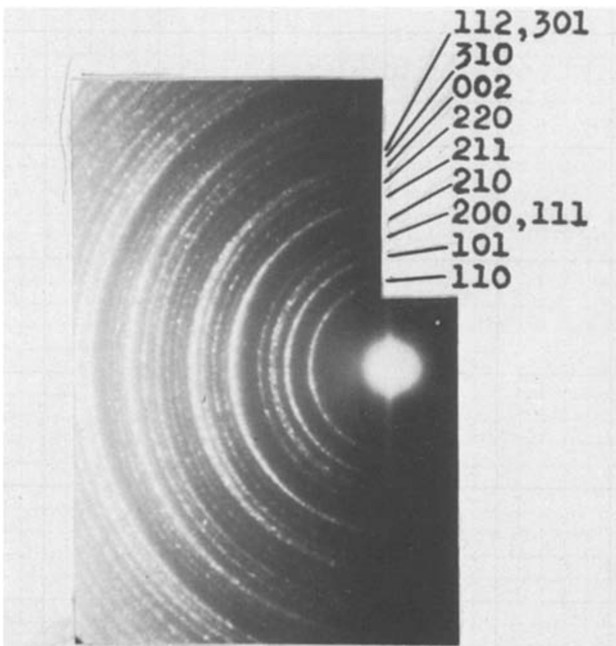

Fig. 1. RHEED pattern from the mineralized surface of the 0.4% Sn dental alloy. SnO_2 is formed as the result of selective oxidation. The Miller indexes corresponding to the space group P4/mnm are attributed to the reflections. Wavelength of the electrons: 0.0347Å. Distance between the object and the screen: 50 cm. Positive enlarged 2.3 times.

Table I. Result of the analysis of Fig. 1. *d*(Å): interplanar spacings measured on Fig. 1; *hkl:* Miller indexes corresponding to the reflections; *I*: reflection intensities estimated in arbitrary units from Fig. 1. The lattice constants $a_0 = 4.74$ and $c_0 = 3.19$Å calculated coincide with those of SnO_2 crystal (space group: P4/mnm) (3).

2.64	101	8
2.37	200	5
2.31	111	5
2.12	210	2
1.76	211	10
1.67	220	2
1.59	002	3
1.50	310	3
1.44	112	6
1.41	301	6

The surface layer corresponding to Fig. 1 behaved in a chemically active manner. It began to deteriorate when exposed to the air at room temperature for several hours, succumbing to the attack of H_2O, CO_2, and other gases in the air. In fact, the deteriorated specimen surface gave rise to an RHEED pattern different from Fig. 1. It was necessary to mate the alloy surface with the porcelain immediately after the former had been preheated in air. A strong adhesion was not obtained

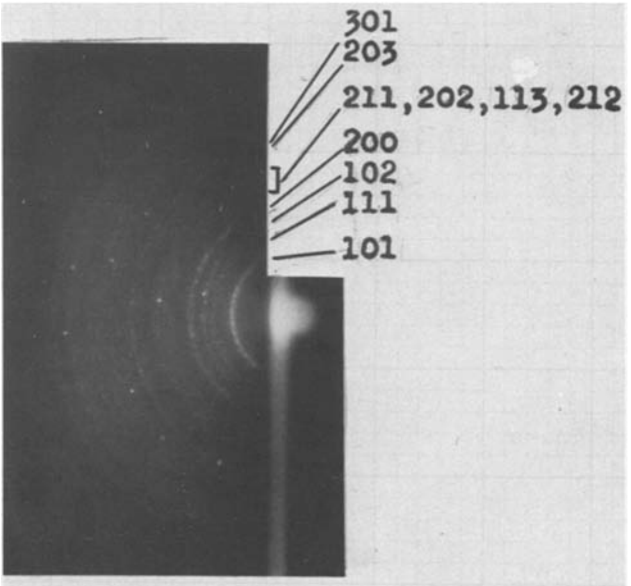

Fig. 2. RHEED pattern from the mineralized surface of the Sn-free 0.1% Si dental alloy. SiO_2 ($P4_12_12$) is formed as the result of selective oxidation. Wavelength of the electrons: 0.0329Å.

between these two dental materials if one delayed this operation.

The RHEED pattern reproduced in Fig. 2 was observed from the surface of the Sn-free 0.1% Si alloy which was preheated at 1000°C in air. All the reflections found in Fig. 2 are characteristic of tetragonal SiO_2. The result of the analysis of Fig. 2 is given in Table II. This demonstrates that a selective oxidation has taken place at the specimen surface. The SiO_2 layer formed on the alloy could cement together with the porcelain rich in SiO_2.

Table II. Result of the analysis of Fig. 2. d(Å): interplanar spacings measured on Fig. 2; hkl: Miller indexes corresponding to the reflections; I: reflection intensities estimated in arbitrary units from Fig. 2. The lattice constants calculated $a_0 = 4.94$ and $c_0 = 6.92$Å coincide with those of SiO_2 crystal ($P4_12_12$) (4).

d(Å)	hkl	I
4.05	101	10
3.18	111	3
2.87	102	4
2.47	200	6
2.11	211	3
2.02	202	3
1.97	113	3
1.90	212	3
1.69	203	2
1.61	301	5

It is empirically known that the 0.4% Sn alloy shows a stronger adhesion to the porcelain than the 0.1% Si. This is because the SnO_2 layer can adhere more firmly to the alloy substrate than the SiO_2.

A Mixed Rate Cathode for Lithium Batteries

M. Stanley Whittingham* and Allan J. Jacobson

Exxon Research and Engineering Company, Linden, New Jersey 07036

Many cathode materials for alkali metal anode batteries even though of high capacity are restricted in their application due to low rate characteristics, poor rechargeability and/or low electronic conductivity. Titanium disulfide, and some other dichalcogenides particularly those of vanadium, show high rate discharge and charge capabilities, essentially perfect reversibility and good electronic conductivity (1). The behavior of the former class of materials as shown in this paper can be improved by the addition of a minor amount of one of the dichalcogenides. The use of a good mixed, ionic and electronic, conductor such as TiS_2 should both assist in the transfer of ions between the active material particles, and minimize the need for the use of a non-electrochemically active conductive diluent such as carbon. In addition, the admixture of say TiS_2 with a higher energy density but lower rate cathode material should allow the retention of the latter's high capacity whilst permitting high current pulse discharging. This high rate capability will depend on the appropriate matching of the discharge voltage profiles of the two component materials.

In this paper this concept of a mixed rate cathode is tested using MoS_3 as the high energy component. This cathode as described previously (2) can react with up to 4 Li to give Li_4MoS_3 with a theoretical energy density of about 1.1 Whr/gm. However, at a continuous drain of 10 ma/cm^2 less than 30% of this capacity is attained (3). TiS_2 and VSe_2 were used as the high rate but lower capacity component; both exhibit almost 100% utilization at 10 ma/cm^2 (1) but have an energy density less than half that of MoS_3. Both TiS_2 and VSe_2 have at least a part of their discharge voltage profile below that of MoS_3 so that under a high rate discharge pulse when the MoS_3 becomes polarized the dichalcogenide will react with the lithium. Then, when the pulse is off the MoS_3 will recharge the high rate component readying it for the next pulse. The sloping discharge of TiS_2 which crosses that of MoS_3 should also permit pulse charging.

The electrochemical cells were constructed as described earlier (1) using teflon bonded electrodes and a lithium perchlorate dioxolane electrolyte. The mixed cathodes were prepared by the thermal decomposition of the thiomolybdate, $(NH_4)_2MoS_4$(2), mixed with 27 wt% of the dichalcogenide and 3 wt% teflon. The cells of area 2 cm^2 were then discharged at 20 ma, with the current on for 20 secs and then off for 20 secs. The same current cycle was used on charging but the rate was reduced to 4 ma. The first discharges of a mixed cathode and its components are shown in Fig. 1. The mixed cathode shows the highest capacity under these discharge conditions even though the pure MoS_3 cathode had a 20% greater theoretical capacity. This difference between the two cells increased continuously on subsequent cycling as shown in Fig. 2, and is even greater when the capacity is given in watt-hours rather than amp-hours due to a large polarization in the MoS_3 cell at 10 ma/cm^2. A cell constructed with VSe_2 in place of TiS_2 showed

*Electrochemical Society Active Member,
Present Exxon Address: P.O. Box 101, Florham Park, N.J. 07932

Key words: battery, cathode, titanium disulfide, vanadium diselenide

similar characteristics, indicating that the behavior is not unique to TiS_2. By the 7th cycle both the mixed cathodes showed more than double the capacity of the single component cathode.

The data of Fig. 1 and Fig. 2 shows that the addition of a conductive high rate cathode material can enhance the discharge behavior of molybdenum trisulfide. The same enhancement is expected for many other cathodes such as MoO_3, V_2S_5, V_2O_5 and V_6O_{13} which have inherently high capacities for lithium but which have poor electronic conductivities and/or a low rate capability. In addition the replacement of the conductive diluent in some primary cells, such as the Li/FeS_2 and Li/MnO_2 cells, should also lead to an enhanced storage capacity. Preliminary studies (4) on FeS_2 cells in which the carbon diluent was replaced by titanium disulfide showed a 36% greater utilization of the FeS_2 itself and a 60% overall greater coulombic capacity, i.e. capacity of TiS_2 + FeS_2 over C + FeS_2.

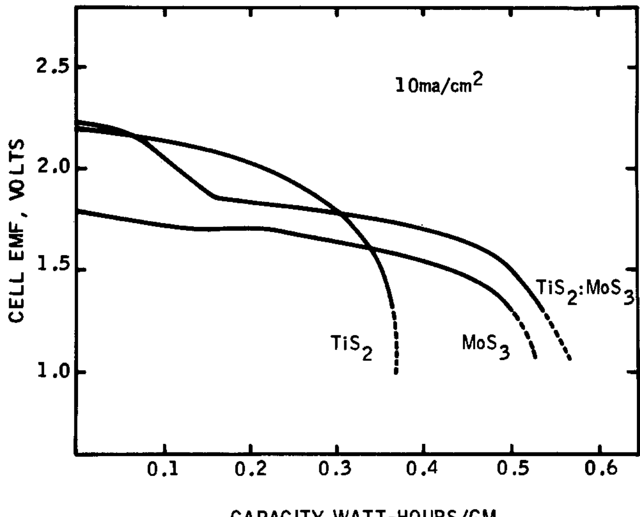

FIG 1 First discharge of TiS_2, MoS_3 and TiS_2:MoS_3 mixture in lithium cells (theoretical capacity/gm electrode: TiS_2 = 0.43; MoS_3 = 0.98; mixture = 0.82 (0.67 MoS_3, 0.15 TiS_2; wt MoS_3/TiS_2 = 1.92)).

Some Observations on the Oxidation of an Fe-12% Cr Alloy in Gaseous Chlorine

Z. A. Foroulis*

Exxon Research and Engineering Company, Florham Park, New Jersey 07932

Only a few metallic oxides, sulfides and nitrides are ionic at room temperature and it is doubtful whether any of these compounds can be regarded as entirely ionic at elevated temperatures. Nevertheless, the oxidation mechanism of metals and alloys that form ionic conducting protective layers is a subject of considerable fundamental interest(1-5). Metal halides are more likely to be purely ionic than other metallic compounds. Silver bromide and silver chloride are such compounds which have been studied experimentally in the temperature range 200-400°C by Wagner(2). This brief communication presents experimental data which show that the oxidation of an Fe-12% Cr alloy in chlorine gas exhibits kinetics which can be interpreted by postulating kinetic control by electronic conductivity (along electron defects) through an outer $CrCl_{3(s)}$ surface film formed during the chlorination reaction.

EXPERIMENTAL

The material used in this study was a commercial alloy with the following analysis (12% Cr, 0.6% Mn, 0.4% Si, 0.1% C and the balance iron). The oxidation kinetics were investigated by exposing alloy coupons in Cl_2-N_2 mixtures (chlorine partial pressure 0.5 to 3 x 10^{-2} atm.) and in the temperature range of 270-500°C. Rectangular coupons with a surface area of about 10 sq cm were placed in a horizontal quartz tubular reactor located inside a furnace capable of maintaining the reaction zone in the desired temperature. Mixtures of Cl_2 and N_2 were prepared by using conventional flow meters and a mixing coil. Steady-state reaction rates were determined by measuring the weight loss of test coupons before and after exposure. Coupons were polished with 6/0 emery paper and cleaned in acetone prior to weighing. After each experiment for weight loss determination, the reaction product surface films were removed by careful honing. Prior to each experiment, the test coupons were treated in situ at 497°C for at least one hour with pure hydrogen to reduce any surface oxide films. The kinetic data were supplemented with SEM, EDAX, X-ray diffraction and chemical analysis of the reaction product surface films.

RESULTS AND DISCUSSION

The reaction of the Fe-12% Cr alloy with low partial pressure chlorine gas was found to obey a parabolic kinetic law as shown schematically in Figure 1. This figure is a plot of the square of the alloy weight converted to reaction products per unit surface area as a function of exposure time at 500°C in a Cl_2-N_2 mixture with a 0.01 atm. chlorine partial pressure. The kinetics of the alloy-chlorine gas reaction is influenced by the nature and composition of the reaction product surface film produced.

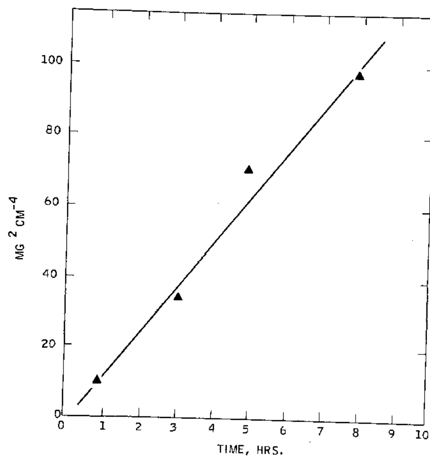

Figure 1. Variation of the Square of the Weight of the Alloy Converted to Reaction Products per Unit Surface Area Versus Exposure Time in a Cl_2-N_2 Mixture (0.01 Atm. Chlorine Partial Pressure) at 500°C.

* Electrochemical Society Active Member.
Key Words: Oxidation, Chlorination, Electronic Conductivity

The reaction product surface film formed with this alloy during the chlorination reaction is a well-adhering protective film consisting of two layers; an inner layer composed essentially of $FeCl_2$ and an outer layer consisting essentially of $CrCl_3$. The $FeCl_2$ and $CrCl_3$ produced as a result of this reaction are solids with negligible vapor pressure(6) in the temperature studied. The temperature dependence of the parabolic rate constant for this reaction in the temperature range studied corresponds to an apparent activation energy of about 11 kcal/mole.

To gain a better understanding of the mechanism of this reaction, a series of experiments was also carried out at different chlorine partial pressures at 500°C. The chlorine partial pressure dependence of this reaction shown in Figure 2 indicates that the parabolic rate constant for this reaction varies with the 1/2 power of the chlorine partial pressure. In addition, gas velocity was found to have no effect on the reaction rate.

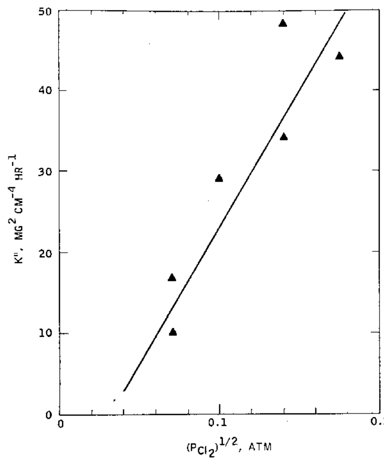

Figure 2. Dependence of the Parabolic Rate Constant for the Chlorination Reaction of a 12% Cr Alloy on the Chlorine Partial Pressure at 500°C.

The essential independence of this reaction on gas velocity and the parabolic law kinetics observed suggest that the reaction is limited by a solid-state migration process through the reaction product surface film. Diffusion through the inner $FeCl_2$ film is assumed not to be rate limiting, since for the iron-chlorine reaction (where the surface film consists only of $FeCl_2$) the overall kinetics have been shown to be controlled by migration of chlorine gas through the gas boundary layer or by the reaction of $FeCl_2$ with chlorine gas to form volatile $FeCl_3$(7,8). Reaction of $CrCl_3$ with gaseous chlorine to form volatile $CrCl_4$ species via the reaction $CrCl_3 + 1/2\ Cl_2 \rightarrow CrCl_4$ as a likely limiting reaction in the overall kinetics is not consistent with the observed parabolic kinetics and the insensitivity of the overall reaction on gas velocity. It is reasonable, therefore, to conclude that a migration process through the $CrCl_3$ surface film is the rate controlling process in the chlorination reaction of the Fe-12% Cr alloy.

The mechanism of the limiting solid-state migration process within the $CrCl_3$ outer surface film is not known. However, assuming that $CrCl_3$, like several other metallic halides (e.g., AgCl, AgBr, etc.) exhibits ionic conductivity, it is reasonable to postulate that the rate-limiting process may be migration of electronic defects through the $CrCl_3$ film. In analogy with AgBr and AgCl, which were studied extensively by Wagner(2,9), the following reaction can be written as representing formation of $CrCl_3$:

$$3/2\ Cl_{2(g)} = CrCl_{3(s)} + \square Cr^{3+} + 3\oplus \quad (1)$$

and the mass action equation:

$$[\oplus]^3\ [\square Cr^{3+}] = k\ [pCl_2]^{3/2} \quad (2)$$

where $\square Cr^{3+}$ are ionic defects (cation vacancies), $\oplus$ are positive holes, pCl_2 is the chlorine partial pressure, and k is the equilibrium constant.

In analogy with other metal halides which are predominantly ionic conductors, it is reasonable to assume that the normal concentration of $\square Cr^{3+}$ in $CrCl_3$ is likely to be relatively great so that it is not noticeably changed by the effect of chlorine. Hence, it follows from Eq. (2) that the concentration of positive holes ($[\oplus] \ll \square Cr^{3+}$) depends on chlorine partial pressure according to Eq. (3).

$$[\oplus] = \text{const.}\ [pCl_2]^{1/2} \quad (3)$$

where the quantity $\square Cr^{3+}$ is incorporated into the constant since it remains relatively unchanged. According to Eq. (3), the concentration of electronic defects and, therefore, the rate of chlorination reaction should be proportional to the square root of the chlorine partial pressure(10). This conclusion is consistent with the experimentally determined variation of the parabolic rate constant (Figure 2) according to the 1/2 power of the chlorine partial pressure. The postulated mechanism can, at present, be considered only as tentative. Additional work in this area is required, particularly

in the field of electronic properties of metal halides such as $CrCl_3$, to confirm the postulated mechanism.

Electrosynthesis of Chlorate in the Nineteenth Century

H. Vogt

Fachbereich Verfahrenstechnik der Technischen Fachhochschule Berlin, D-1000 Berlin 65, West Germany

ABSTRACT

A critical review is given of the origins of the electrosynthesis of chlorate in 1802 to the beginning of industrial chlorate manufacture toward the end of the century. The contemporary efforts to establish the fundamentals of a theory of electrochemical chlorate formation are also discussed.

The Origin of Chlorate Electrosynthesis

The first chlorate produced by electrosynthesis dates back to 1802, earlier than currently written in historical reviews. This fact gives rise to the need for a critical review of the origins of the electrosynthesis of chlorate and on the development of technology and theory in the first 100 years, at the same time correcting a number of misconceptions.

Volta's famous letter to the Royal Society in London in 1800 prompted scientists all over Europe to study the effect of the electric current on chemical reactions. It was this interest in the new matter that induced Wilhelm von Hisinger together with Jöns Jakob Berzelius to run "experiments relating to the effect of the electrical pile on salts and their bases" (1). Neither men were professionals: Hisinger was a mine owner and Berzelius had become doctor of medicine and was at that time an unpaid assistant to a professor of medicine and pharmacy at the School of Surgery in Stockholm (2). The studies on the electrolytic decomposition of salts, dissolved in water, took several months in the autumn and winter of 1802 and were more than only cursory hobby activities. Runs with several solutions and various electrode materials showed an amazingly systematic manner.

In one of the series, sodium chloride solution was electrolyzed between silver wires, serving as electrodes in a U-type cell. After the anolyte had been evaporated and cooled down, sodium chloride precipitated. The remaining clear solution was found to contain sodium chloride and silver chloride and "perhaps, hyperoxygenized muriatic sodium and a formerly unknown silver salt" (1d).[1] The latter one was immediately identified by Gehlen (1a) with the "hyperoxygenized muriatic silver" which Chevenix had obtained through a chemical way (3). In fact, the salts were sodium chlorate and silver chlorate. A definite proof of the formation of chlorate through electrolysis of chloride solutions was given much later by Kolbe in 1847 (4).

A report on the joint studies of Hisinger and Berzelius was written in Swedish by Berzelius and published in German in February 1803 (1a). It was further published in French two years later (1b), in Swedish (1806) (1c), and once more in German (1807) (1d). "This treatise contains the fundaments of those laws which the electrochemical theory later was based upon," Berzelius recapitulated with self-confidence many years later in his autobiography (5). However, "the unknown names of the authors attracted no special attention." Indeed, in the chlorate literature of our century, the first preparation by electrosynthesis is erroneously dated throughout as of 1808 and attributed to Berzelius only.

Hisinger and Berzelius were not the first to prepare chlorate, which had already been prepared by Glauber in 1657 by chemical means (6, 7) and rediscovered and identified by Berthollet (8) in 1786—nor were they the first who applied electrolysis to prepare it. It must be guessed that earlier electrolyses of chloride (9, 10) would have led to chlorate, but they were the first who recognized having prepared chlorate.

Industrial Chlorate Production

Few years after Kolbe's observation, in 1851, a remarkable attempt at industrial application is reported. The chemist Charles Watt in Kensington, London, received a patent for the electrochemical decomposition of salt and other substances and separation into their components (11), Fig. 1. It is surprising that some features of modern chlorate process are anticipated in this first chlorate cell patent: the omission of a diaphragm, the relevance of high temperature to favor the chlorate formation, the separation of chlorate by crystallization, and the recycling of the mother liquor and its electrolysis after resaturation. Some of these characteristics were not realized with the first

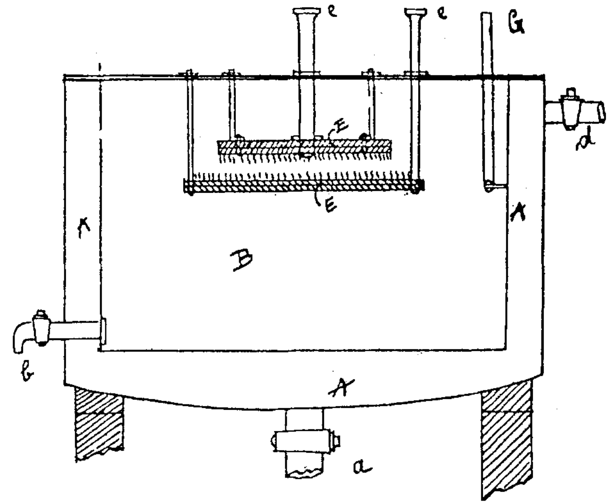

Fig. 1. Chlorate cell of the 1851 patent of C. Watt. The electrolyte vessel is surrounded by a steam-heated jacket.

Key words: electrosynthesis, electrochemical chlorate formation.

[1] The passage cited is given after (1d); the first edition (1a) uses the expression "oxygenirt-salzsaures Natron" instead of überoxygenirt-salzsaures Natron" (1d).

industrial chlorate cells coming on stream and had to be rediscovered gradually.

A practical use of the patent is not reported and cannot be expected owing to the absence of powerful energy sources at that time. The only method of manufacture was the chemical process developed by Liebig. Chlorine was introduced into solutions of caustic potash or calcium carbonate to make chlorate (12).

After the dynamo machine was invented and improved for industrial use, the prerequisite for industrial electrosynthesis of chlorate was given. But even in 1888, the conviction was declared that electrochemical processes would have no future in the alkali industry (13). That happened two years after H. Gall and A. de Montlaur had started in 1886 the first plant in Villers-St. Sépulcre in Switzerland, where chlorate was electrochemically produced under industrial conditions.[2] The cell cases were reported to be made of wood and equipped with a diaphragm (14). The cells were operated at elevated temperatures. Thc concentration of chlorate in cell liquid was raised until crystals precipitated which were removed manually using enameled iron scoops. Cell voltage was 5V and a current was used of 1000A. Energy consumption per kg of potassium chlorate is reported to 24 hp (14) or 17.7 kW-hr/kg $KClO_3$, corresponding to a total current efficiency of 37%. The plant served as a prototype and was shut down in 1891, when the new bigger factory in Vallorbe (Switzerland) was ready to start (15). In 1896, the Société d'électrochimie started a second factory in St. Michel de Maurienne (France) (14).

The company was not the only electrochemical chlorate producer for long. In Sweden, the Superfosfat Fabriks AB started the manufacture in 1894 in Mansboe and in 1899 at Alby fall in Ljungan using the process of O. Carlson (16).

A big factory was started in Chedde (France) in 1896, which used the process of Corbin and Lederlin with bipolar electrodes. A description in detail was given by Kershaw (14).

At nearly the same time, electrochemical chlorate manufacture started in the U.S.A. (14). In 1896 and, 1897, the Chemical Construction Company operated a chlorate factory at Niagara Falls, New York, using the process of Blumenberg. The cell was equipped with a diaphragm and differs from contemporary types by the fact that chlorine gas was transported through a special pipe into the cathode compartment to mix with the catholyte remote from the cathode, but inside the cathode compartment. Owing to the cathodic reduction losses the process was not successful and production was finished in 1898 or 1899. As early as in 1905 the opinion was uttered (14) that Blumenberg would have had better results if he had carried out the reaction between chlorine and alkali in a vessel completely separated from the cell, an important process feature which was much later patented (17) and has come into industrial use since about 1970.

In 1894, Franchot and Gibbs started a test plant in Buckingham, Quebec. After the foundation of the National Electric Company an industrial plant was constructed in 1897 and started in 1898 at Niagara Falls. The cells had no diaphragm and were equipped with some kind of bipolar electrodes with pre-electrode and an electrode distance of only 1.5 to 3.0 mm (14).

In 1898, the North American Chemical Company, a subsidiary of the United Alkali Company of Liverpool was founded. Production started a little later in Bay City, Michigan, using a process of Brock with cells arranged in terraces (18).

In 1899, Oldbury Electro-Chemical Company started manufacturing potassium chlorate at Niagara Falls. The chlorate manufacture in the United States and Canada from that time on was reported in detail by Wallace (19).

[2] The year 1866 is sometimes erroneously reported in literature.

At the turn of the century, chlorate factories were operated in Switzerland (Vallorbe and Turgi), in France (St. Michel de Maurienne and Chedde), in the U.S.A. (Niagara Falls and Bay City), and in Sweden (Mansboe and Alby) (14, 19). Chlorate was not manufactured by electrosynthesis in Germany where the commercial electrochemical chlorate production started not before 1915, after first attempts at industrial scale, executed in 1887 in Leopoldshall, had failed. This situation is surprising since Germany, at that time, was the center of chlorate research.

The Controversy on the Theory of Electrosynthesis of Chlorate

With the beginning of the electrochemical chlorate production on an industrial scale, an interest in the knowledge of the processes of chlorate formation developed. At that time, it was the general belief that the electrosynthesis of chlorate took place in complete agreement with the chemical formation. Thus, chlorine and hydroxide "primarily" generated at anode and cathode were thought to react with each other to form "secondarily" hypochlorite and chlorate (20, 21)

$$2KOH + Cl_2 \rightarrow KClO + KCl + H_2O$$

$$6KOH + 3Cl_2 \rightarrow KClO_3 + 5KCl + 3H_2O$$

Soon it became clear that these reactions did not comprehensively describe the processes in the cell.

In 1889, Fogh (22) had subjected a neutral solution of alkali chloride to electrolysis without diaphragm and had found from a gas analysis that oxygen was also evolved at the anode. One of the reasons for the loss of current efficiency was found, irrespective of the question whether oxygen is generated by decompostion of water or by any other way.

Oettel, in 1894 (23), interpreted the finding as follows. "Primarily" chloride is anodically oxidized to chlorine. Secondarily, hypochlorite forms at both sides of the diaphragm. In the cathode compartment the hypochlorite is reduced at the cathode. In the anode compartment, part of the hypochlorite is "tertiarily" oxidized to chlorate, while the rest, together with some "tertiarily" formed chlorate is electrolytically decomposed

$$2ClO^- + H_2O \rightarrow 2HClO + \tfrac{1}{2} O_2 + 2e^-$$

$$2ClO_3^- + H_2O \rightarrow 2HClO_3 + \tfrac{1}{2} O_2 + 2e^-$$

Additionally, an anodic discharge of hydroxyl is supposed. In any case, the formation of chlorate through anodic discharge of hypochlorite was unthinkable at that time. "The formation of oxygen compounds with chlorine is, therefore, attributed to purely chemical interaction between chlorine and potassium hydroxide," Oettel concluded (23).

The reaction scheme established by Oettel was questioned a few years later in connection with studies on the electrolysis of hydrochloric acid. In 1898, Haber and Grinberg (24) concluded that simultaneously with the secondary (chemical) formation of hypochlorite and chlorate a primary (anodic) formation takes place

$$Cl^- + 2\,OH^- \rightarrow ClO^- + H_2O + 2e^-$$

$$Cl^- + 6\,OH^- \rightarrow ClO_3^- + 3H_2O + 6e^-$$

With this interpretation, the old theory of an exclusively chemical formation of chlorate was fundamentally shaken, stimulating extensive research at various places. The activities resulted in a complete revision of the chlorate theory, accompanied by sometimes violent discussions. The results of these fertile years shortly before and after the turn of the century form the basis of a theory which nowadays is essentially considered valid.

Oettel (25) compared the conclusions of Haber and Grinberg with older considerations and gathered that in neutral electrolytes chlorate is preferably formed from hypochlorite partly by "secondary" reactions in bulk of the solution, partly "primarily" by oxidation at the anode. In alkaline electrolytes he surmised a formation of chlorate predominantly by direct combination of chlorine and oxygen set free at the anode.

In 1898, Wohlwill (26), stimulated by his teacher Nernst, carried out experiments on the subject. In agreement with the Haber-Grinberg hypothesis he also stated that chlorate is not exclusively formed "secondarily" (*i.e.,* by chemical reaction in bulk of the solution), but directly at the anode. From the observation that chlorate is never formed without the presence of hypochlorite he followed that chlorate is always generated from hypochlorite according to

$$2ClO^- + OH^- \rightarrow ClO_3^- + H^+ + Cl^- + 2e^-$$

while hypochlorite is formed "secondarily." From today's viewpoint the reaction cannot be considered valid since the concentration of OH^- in the bulk is usually small and its rate of diffusion toward the anode is negligible (27), but it is to Wohlwill's credit to have first given a formula for anodic discharge of hypochlorite to form chlorate and chloride.

This construction, possibly kindled by the rude style of the paper and the direct attacks on Oettel and Haber, prompted the arousal of controversy on the central question of whether chlorate is formed "primarily" or "secondarily." In his famous Göttingen lecture in 1899, Foerster (28) reported on his essential finding that the electrolyte has to be slightly acidic to give way to the autoxidation of hypochlorite (ClO^- + $HClO$) to chlorate (29) which was a real novelty and stood in marked contrast to theory and practice of that time. But at the same meeting he strictly denied that chlorate formation took place at the anode. He had found that always, even in alkaline electrolytes, the electrolyte in the vicinity of the anode was acidic, and so he excluded the possibility of any anion discharge.

In an answer, Wohlwill (31) defended his construction against Foerster and uttered the opinion that in neutral or slightly acidic solutions chlorate is generated by primary as well as by secondary reactions. The aggressive mode of his comment on Foerster's theory provoked Foerster himself to a sneering answer (32) in which he insisted on his old conviction. The way this controversy was carried out obstructed the general acceptance of Wohlwill's theory, and probably was part of the phenomenon that Wohlwill's contribution to the chlorate theory is widely underesteemed.

One year later, Foerster published a study on the anodic processes (33) containing the untenable statement that oxygen is set free only to a very small extent and that chlorate is formed "anodically not in any appreciable extent." It was also in 1900 when Brochet (34) concluded from experiments that in alkaline solutions a primary chlorate formation does not occur.

The same year, Lorenz and Wehrlin summarized the existing views and published their voluminous experimental results (35). The authors concluded that primarily hypochlorite is formed and that under certain conditions chlorate is formed at the anode, thus confirming Wohlwill.

Foerster continued to deny any anodic chlorate formation (36), but soon Foerster and Müller (37, 38) came to the definite conclusion that apart from autoxidation of hypochlorite requiring a slightly acidic region chlorate formation occurs by discharge of hypochlorite at the anode

$$3ClO^- + 1.5H_2O + ClO_3^- + 2Cl^- + 3H^+ + 0.75\,O_2 + 3e^-$$

They coined the expression of "anodic chlorate formation" which is still in use.

The Problem of Hypochlorite Reduction

The other relevant problem that occupied the science in the chlorate field was the question whether and how it was possible to prevent reduction of hypochlorite at the cathode. The formation of chlorate is favored by intensive mixing of anodic and cathodic products. But it was just this mixing that caused hypochlorite reduction to such an extent that current efficiency was held down and the economy of the whole process severely affected. To allow industrial operation, a diaphragm was generally used to separate anolyte and catholyte (20). "It is self-evident that the electrolysis of chlorides of potassium or sodium must be carried out with use of a membrane" (23).

When in 1894 Oettel (21) studied the conditions of electrochemical chlorate formation with the intention to check the assumed reaction equations, he concluded that the process should run best in the case where the diaphragm is omitted. In an extended test with a single compartment cell he was able to show that the current efficiency could be maintained at 80-82% without tendency of significant decrease (21). He soon obtained an efficiency of 87% when he operated such a cell with a strongly alkaline solution of calcium chloride (39). Oettel erroneously interpreted this current efficiency to be caused by the absence of hypochlorite during electrolysis. He was so enthusiastic that he called electrolysis without diaphragm "one of the most elegant processes that electrochemistry presents" (39), a statement which must be seen before the background of the enormous technical difficulties of making suitable diaphragms.

Independent of this realization, that same year the first industrial chlorate cell without diaphragm was started. As early as in 1890, Oscar Carlson had taken a Swedish patent (40) for a single-compartment cell. The process was used in the Mansboe factory. An advanced technology was used: "In a vessel alkali chloride is dissolved and the solution is then electrolyzed between an anode made of carbon or other convenient material and a cathode preferably made of iron under omission of a partition" (40). However, when discussing the question of priority of diaphragmless cells, Watt's patent of 1851 (11) has to be considered. Carlson was the first who used carbonates of alkaline earths as additive to the solution. The text of the patent (40) reveals that Carlson did not have a clear idea of the effect of this step. He was of the opinion that the hydroxides of alkaline earths react directly with the chlorine, thus playing an active role in the formation of chlorate. The disadvantageous side effect was that the layer of alkaline earth hydroxide attaching to the cathode continued to increase in thickness during electrolysis, causing a corresponding increase in voltage drop.

In 1898, Bischoff and Foerster (41) gave an interpretation of the way of action which also today is roughly valid: calcium hydroxide, being less soluble than alkali hydroxide, forms a diaphragm at the cathode surface thus obstructing the reduction of hypochlorite.

It was another Swede, J. Landin, who gave a definitely practicable solution of the problem (16, 42). In 1897, he proposed to use additives of compounds of those metals which occur in various valencies, particularly chromic acid. In 1898, Imhoff was granted a German and an American patent (43) (which was transferred to the United Alkali Company, Limited) for the addition of chromate.

Obviously without knowledge of Landin's and Imhoff's patents, Müller (44, 45) used potassium chromate additive with the intention of accelerating the conversion of hypochlorite to chlorate, but found that the additive was suitable to extensively suppress the cath-

odic reduction. "The electrolysis with chromate represents one of the most ideal diaphragm processes one can imagine" (46). Contemporary experiments showed that current efficiencies of 80-92% were attainable (33). A means thoroughly satisfying in industrial electrosynthesis of chlorate had been found. In 1905, world production of chlorate amounted to 15,000 tons per year, 65% of which were already made by electrosynthesis (14).

Mathematical Modeling of the Lithium-Aluminum, Iron Sulfide Battery

I. Galvanostatic Discharge Behavior

Richard Pollard*,[1] and John Newman*

Materials and Molecular Research Division, Lawrence Berkeley Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

A mathematical model of the LiAl/LiCl, KCl/FeS high temperature battery is presented. The model considers a whole prismatic cell which consists of negative electrode, separator, electrolyte reservoir, and positive electrode. Physical phenomena described are ohmic potential drop and diffusion potential in the electrolyte, changes in porosity and electrolyte composition due to electrochemical reactions, local reaction rates, and diffusion, convection, and migration of electrolyte. In addition, the analysis includes finite matrix conductivities, variable physical properties, and the possibility of specific simultaneous reactions in the positive electrode. The theoretical results show many of the trends in behavior observed experimentally. The effects of state of charge, initial electrolyte composition, cell temperature, and current density are presented, and factors that can limit cell performance are identified.

The LiAl/LiCl, KCl/FeS_x high temperature battery is a candidate for off-peak electrical energy storage and for electric vehicle propulsion. A mathematical model is needed to predict the operational characteristics of the system and to assess the influence of changes in design parameters on the cell performance.

Many models have been proposed to describe the behavior of flooded porous electrodes, and current and reaction distributions in a direction perpendicular to the separator have been considered in great detail (1). The electrode can be regarded as a homogeneous mixture of matrix and electrolyte (2) or as a single pore, provided that proper averages are taken over a cross section (3, 4).

The macrohomogeneous model has been applied to several specific battery electrodes. An analysis of the constant current discharge behavior of electrodes with sparingly soluble reactants, such as the Ag-AgCl and $Cd\text{-}Cd(OH)_2$ couples, has elucidated the relative importance of different failure modes in these systems (3). Transient and failure analyses have also been made of the zinc electrode (5) and the lead dioxide electrode (6, 7). An assessment of steady-state composition profiles in lithium/sulfur battery analogues has been made, but the results are restricted to nonporous systems (8).

Far less effort has been directed toward modeling complete cells and, up until now, only the lead acid cell has been considered in detail (9-12). In this paper, a one-dimensional model is presented for the LiAl/FeS system, which is currently being developed at the Argonne National Laboratory (13). A whole prismatic cell is considered, consisting of negative electrode, separator, electrolyte reservoir, and positive electrode (see Fig. 1). The model can be used to identify system limitations and to help guide experimental research.

Model Development

The analysis is based on the macroscopic theory of porous electrodes in which the solution and matrix phases are treated as superposed continua without regard for the actual geometric details of the pores (2). With this approach, one can obtain a consistent framework for the description of isothermal transport processes in the molten salt electrolyte (14).

A material balance for species i is given by

$$\frac{\partial(\epsilon c_i)}{\partial t} = aj_{in} - \nabla \cdot \mathbf{N}_i \quad [1]$$

where $\mathbf{N}_i$ is the flux of species i in the pore solution averaged over the cross-sectional area of the electrode and where aj_{in} represents the transfer rate of species i from the solid phases to the pore solution per unit electrode volume. In addition, the superficial current density in the pore solution is due to the movement of the charged species

$$\mathbf{i}_2 = \mathbf{F}\sum_i z_i \mathbf{N}_i \quad [2]$$

and, as a consequence of the condition of electrical neutrality, the divergence of the total current density is zero

$$\nabla \cdot \mathbf{i}_1 + \nabla \cdot \mathbf{i}_2 = 0 \quad [3]$$

For j simultaneous reactions of the form

$$\sum_i s_{ij} M_i^{z_i} \rightarrow n_j e^- \quad [4]$$

Key words: porous electrodes, molten salt electrolyte, cell performance.

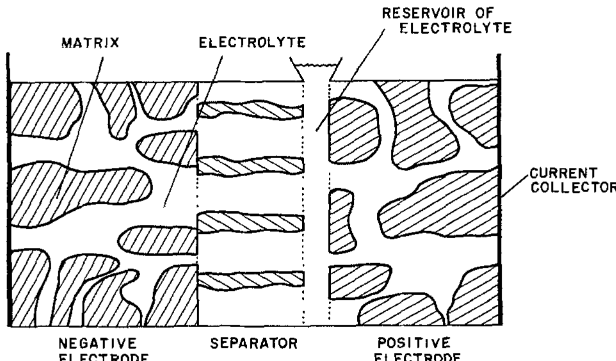

Fig. 1. Schematic diagram of LiAl/FeS cell

Faraday's law can be expressed as

$$aj_{in} = -\sum_j \frac{s_{ij}}{n_j\mathbf{F}} ai_{nj} - \frac{1}{\tilde{V}_k}\frac{\partial \epsilon_{pk}}{\partial t} \quad [5]$$

provided that double layer charging can be ignored. The last term on the right side of Eq. [5] represents the removal of species i from the electrolyte as a result of precipitation of salt k. The transfer current per unit electrode volume $\nabla \cdot \mathbf{i}_2$ is related to the individual average transfer current densities by

$$\nabla \cdot \mathbf{i}_2 = \sum_j (ai_n)_j \quad [6]$$

A material balance on the solid phases indicates how the electrode porosity changes with the extent of reaction at each location within the electrode

$$\frac{\partial(\epsilon + \epsilon_p)}{\partial t} = \sum_j \sum_{\substack{\text{solid}\\\text{phases}}} \frac{s_{ij}\tilde{V}_i}{n_j\mathbf{F}} (ai_n)_j \quad [7]$$

where $\epsilon_p = \sum_k \epsilon_{pk}$.

The flux of mobile species in the electrolyte can be attributed to the combined effects of diffusion, migration, and convection. For the LiCl-KCl electrolyte, the fluxes of lithium and potassium ions are given by (14)

$$\mathbf{N}_1 = -\frac{\epsilon D}{\tilde{V}}\nabla x_A + \frac{t^\star_1 \mathbf{i}_2}{\mathbf{F}} + x_A(c_A + c_B)v^\star \quad [8]$$

$$\mathbf{N}_2 = -\frac{\epsilon D}{\tilde{V}}\nabla x_B + \frac{t^\star_2 \mathbf{i}_2}{\mathbf{F}} + x_B(c_A + c_B)v^\star \quad [9]$$

These relationships can be substituted into Eq. [1] to give, respectively

$$\frac{\partial(\epsilon x_A/\tilde{V})}{\partial t} + \nabla \cdot \left[x_A\mathbf{g} + (x_B t^\star_1 - x_A t^\star_2)\frac{\mathbf{i}_2}{\mathbf{F}} - \frac{\epsilon D}{\tilde{V}}\nabla x_A\right] = aj_{1n} \quad [10]$$

$$\frac{\partial(\epsilon x_B/\tilde{V})}{\partial t} + \nabla \cdot \left[x_B\mathbf{g} + (x_A t^\star_2 - x_B t^\star_1)\frac{\mathbf{i}_2}{\mathbf{F}} - \frac{\epsilon D}{\tilde{V}}\nabla x_B\right] = aj_{2n} \quad [11]$$

where

$$\mathbf{g} = \frac{\mathbf{v}^\star}{\tilde{V}} + (t^\star_1 + t^\star_2)\frac{\mathbf{i}_2}{\mathbf{F}} \quad [12]$$

For the special case where $t^\star_1 = x_A/2$ and $t^\star_2 = x_B/2$, the direct dependence of Eq. [10] and [11] on current density is removed. The molar average velocity has been chosen as the reference frame because physical data for LiCl-KCl mixtures are often correlated with the mole fraction (see Appendix).

The movement of electrons in the matrix phase is governed by Ohm's law

$$\mathbf{i}_1 = -\sigma\nabla\phi_1 \quad [13]$$

where σ is the effective conductivity of the matrix. In the electrolyte, the variation in solution potential is given by (14)

$$\frac{\mathbf{i}_2}{\kappa} = -\nabla\Phi_2 - \frac{1}{\mathbf{F}}\left[\left(\frac{s_1}{n} + t^c_1\right)\frac{1}{x_B} - \frac{s_3 x_A}{n x_B}\right]\nabla\mu_A \quad [14]$$

where Φ_2 is measured with a reference electrode that has stoichiometric coefficients s_i and number n of electrons transferred, and μ_A is the chemical potential of LiCl (see Appendix). Equations [13] and [14] may be combined to obtain variations in the overpotential $\eta = \Phi_1 - \Phi_2$ directly.

Polarization equations are needed to express the dependence of the local rate of each reaction on the various concentrations and on the potential difference driving force at the reaction interface. Electrode kinetics do not follow fundamental laws that can be expressed as reliably as Ohm's law or the law of conservation of matter. Consequently, the polarization relationships will be subject to further refinement, as one tries to account not only for the mechanism of the charge transfer process but also for the morphology of the electrode, the formation of covering layers, and the transport of species to and from the reaction site.

It is common to begin with a polarization equation of the form

$$i_{nj} = i_{oj}\left[e^{\alpha_{aj}\mathbf{F}\eta_{sj}/RT} - e^{-\alpha_{cj}\mathbf{F}\eta_{sj}/RT}\right] \quad [15]$$

where η_{sj} is the local value of the surface overpotential, $\eta_{sj} = \eta - U_{j,o}$, and where the exchange current density can be written as

$$i_{oj} = i_{oj,\text{ref}}\prod_i\left(\frac{c_{i,o}}{c_{i,\text{ref}}}\right)^{\gamma_i}\prod_k a_k^{\gamma_k} \quad [16]$$

The theoretical open-circuit cell potential for reaction j is given by

$$U_{j,o} = U_j^\theta - U_{re}^\theta + \frac{RT}{n_{re}\mathbf{F}}\sum_i s_{i,re}\ln a_{i,re} - \frac{RT}{n_j\mathbf{F}}\sum_i s_{i,j}\ln a_{i,o} \quad [17]$$

The discharge reaction in the negative electrode is

$$\text{LiAl} \rightarrow \text{Li}^+ + \text{Al} + e^- \quad [\text{I}]$$

In the fully charged state, it is assumed that the negative matrix consists of nonporous, spherical particles of β-LiAl. On discharge, the outermost region of a particle reacts first and a layer of α-Al is established which thickens gradually, at the expense of β-LiAl, as the reaction proceeds. The Butler-Volmer Eq. [15] should be modified to include the diffusional overpotential for mass transport of lithium across the α-phase to the solid-electrolyte interface.

The parameter

$$S = \frac{3.87(1-\epsilon)I}{n\mathbf{F}\bar{c}_{Li^\beta}La^2D_\alpha} \quad [18]$$

can be used as a criterion to assess the importance of solid-state diffusion within an LiAl particle (16). Small values of S indicate that the time required for diffusion is much shorter than the time needed for complete utilization of the particle. Even though $S \sim 0(0.1)$ for this system, the influence of solid-state diffusion may be appreciable at high current densities or with low specific interfacial areas, particularly toward the end of discharge. However, for $S < 1$, it is reasonable to invoke the pseudo-steady state approximation to evaluate the composition profile within the α-phase. With this assumption, and with unit activity coefficients, the surface concentration of lithium can be written as (17)

$$\frac{(c_{Li^{\alpha}})_o}{(c_{Li^{\alpha}})_{sat}} = 1 - \frac{\nabla \cdot \mathbf{i}_2}{(\nabla \cdot \mathbf{i}_2)_{lim}} \quad [19]$$

The diffusion-limited transfer current is given by

$$(\nabla \cdot \mathbf{i}_2)_{lim} = \frac{4\pi N \mathbf{F} D_{\alpha} (c_{Li^{\alpha}})_{sat}}{(1 - \bar{x}_{Li^{\alpha}}) \left(\dfrac{1}{r_{\beta}} - \dfrac{1}{r_{\alpha}} \right)} \quad [20]$$

where r_{α} and r_{β} can be related to the state of charge (17). Combination of Eq. [6], [15], [19], and [20] gives

$$\nabla \cdot \mathbf{i}_2 = \frac{e^{\alpha_a \mathbf{F}\eta/RT} - e^{-\alpha_c \mathbf{F}\eta/RT}}{\dfrac{1}{4\pi N r_{\alpha}^2 i_{o,ref} \left(\dfrac{x_A}{x_{A,ref}} \right)^{\gamma_{Li^+}}} + \dfrac{e^{\alpha \mathbf{F}_a \eta/RT}}{(\nabla \cdot \mathbf{i}_2)_{lim}}} \quad [21]$$

where η is measured with a reference electrode of the same kind as the working electrode, but with a fixed lithium activity corresponding to saturated β-phase (see Table I). Implicit in Eq. [21] are the assumptions that there is no more reaction after the β-LiAl is completely transformed to α-Al and that there are no variations in electrolyte composition between the center of a pore and the ajdacent solid surface.

The complicated discharge processes in the positive electrode are represented by two simultaneous reactions

$$2FeS + 2Li^+ + 2e^- \rightarrow Li_2FeS_2 + Fe \quad [IIA]$$

$$Li_2FeS_2 + 2Li^+ + 2e^- \rightarrow 2Li_2S + Fe \quad [IIB]$$

Equation [15] is used to describe the rate of each reaction, and the reference electrode is taken to be the same kind as reaction [IIB] (see Table I). More sophisticated models for the positive electrode kinetics could include additional intermediate reactions, diffusion of reactants and products to and from reaction sites, and crystallization overpotentials for the formation of solid products. However, the detailed mechanism of the reactions and the juxtaposition of the different phases have not yet been formally established and are the subject of a separate study (18). At the high operating temperatures of the lithium/iron sulfide system, and with the relatively high concentration of lithium ions in the electrolyte, the rate of reaction is expected to be high and, therefore, the simplified kinetic analysis may be adequate.

The governing differential equations for the lithium-aluminum/iron sulfide system are subject to the following boundary conditions (see Fig. 1):

(*i*) at the current collectors

$$(a)\ \mathbf{N}_i = 0 \qquad (b)\ \mathbf{g} = 0 \qquad (c)\ \mathbf{i}_2 = 0 \quad [22]$$

(*ii*) at the negative electrode/separator interface

Table I. Kinetic parameters used in model

Negative electrode		Positive electrode	
Parameter	Value	Value	Parameter
$\alpha_a = \alpha_c$	0.5	1.0	$\alpha_{aj} = \alpha_{cj}$
n	1.0	2.0	n_j
s_1	−1.0	−2.0	$s_{1,j}$
s_3	0.0	0.0	$s_{3,j}$
$(x_A)_{ref}$	0.58	1.0	$(x_A)_{ref}$

D_a (cm²/sec) (30)	4.0×10^{-10}	0.0326	$U_{IIA,o}$ (V)
$\bar{x}_{Li^a}$	0.05	0.0	$U_{IIB,o}$ (V)

$$(a)\ \mathbf{i}_2 = I$$

$$(b)\ x_A,\ \mathbf{v}^{\star}\ \text{continuous} \quad [23]$$

$$(c)\ \left(\epsilon D \frac{\partial x_A}{\partial y} \right)_s = \left(\epsilon D \frac{\partial x_A}{\partial y} \right)_e$$

(*iii*) at the positive electrode/reservoir interface

$$(a)\ \mathbf{i}_2 = I$$

$$(b)\ x_A\ \text{continuous} \quad [24]$$

$$(c)\ \frac{V_R}{A}\frac{\partial x_{AR}}{\partial t} = \left(\epsilon D \frac{\partial x_A}{\partial y} \right)_e - \left(\epsilon D \frac{\partial x_A}{\partial y} \right)_s$$

where V_R/A can be estimated from

$$\frac{\partial (V_R/A)}{\partial t} = \mathbf{v}^{\star}_s - \mathbf{v}^{\star}_e + \frac{V_R}{A}\frac{d \ln \tilde{V}}{d x_A}\frac{\partial x_A}{\partial t} \quad [25]$$

The electrolyte composition is assumed to be uniform across the reservoir. It should also be noted that alternative formulations can be used for the boundary conditions at the front of the electrodes. These choose control volumes for the material balances that avoid the need for separate evaluation of the composition gradients at the interfaces (17). In the separator, the governing equations can be simplified in accordance with

$$(a)\ \mathbf{i}_2 = I \qquad (b)\ \nabla \cdot \mathbf{i}_2 = 0 \qquad (c)\ \epsilon = \epsilon_s \quad [26]$$

The initial conditions are taken as

(*i*) $x_A = x_A^o$

(*ii*) $\epsilon_e = \epsilon_e^o$ [27]

(*iii*) $$\nabla \cdot (\tilde{V}\mathbf{g}) = \bar{V}_A a j_{1n} + \bar{V}_B a j_{2n} - \frac{\partial \epsilon}{\partial t} + \frac{\epsilon}{\tilde{V}}\frac{\partial \tilde{V}}{\partial T}\frac{\partial T}{\partial t} + \tilde{V}\nabla \cdot \left(\frac{\epsilon D}{\bar{V}} \nabla x_A \right)$$

where Eq. [27(*iii*)] is derived from Eq. [10] and [11].

During discharge the temperature is assumed to be uniform throughout the cell sandwich, but it can change with time in response to reversible heat effects, Joule heating, overpotentials associated with electrode reactions, and precipitation or dissolution of electrolyte. The first law of thermodynamics gives

$$\frac{m\hat{C}_p}{2A}\frac{dT}{dt} = \left[U_o - V - T_o \frac{\partial \hat{U}_o}{\partial T} \right] I - h_o (T - T_A) + \sum_k \frac{L_k}{\bar{V}_k} \int_o^{L_T} \frac{\partial \epsilon_{pk}}{\partial t} dy \quad [28]$$

where the heat transfer coefficient h_o is based on estimated heat losses for a battery module. The total cell potential V is obtained by integration of local matrix and electrolyte potential gradients in the electrodes and separator, in accordance with Eq. [13] and [14], respectively. Kirchhoff's voltage law requires inclusion of the surface overpotentials (with appropriate signs) at the front of each electrode as well as the difference in potential between the two types of reference electrode at one location. Resistances of the electrolyte reservoir and current-collector grid can also be included.

The LiAl/LiCl, KCl/FeS system can be described by the local variables x_A, ϵ, $\mathbf{i}_2$, $\mathbf{g}$, and η, and by the governing Eq. [7], [10], [11], [14], and [15], subject to the specified boundary conditions. These relationships constitute a set of coupled, ordinary, nonlinear differential equations at each time step which are cast into finite

difference form accurate to $0(h^2)$, and solved simultaneously by a numerical technique (19). Each nonlinear equation is linearized properly to assure convergence, and each time-dependent equation is programmed symmetrically between the old time step and the present one, in order to attain stability.

Results and Discussion

Electrolyte composition.—Figure 2 shows composition profiles across the cell sandwich for several times during a constant current discharge of 41.6 mA/cm². A lithium-rich electrolyte is used, and the dimensions and capacities of the fully charged electrodes correspond to those of the Argonne National Laboratory, Mark 1A cell (13). When the discharge is started, lithium ions are introduced into the electrolyte at the negative electrode and transported across the porous separator to the positive electrode, where they can react cathodically to form Fe and Li_2FeS_2 or Li_2S. Since the transference number of Li^+ is not unity, a concentration profile develops, and diffusion aids migration in the transport of lithium ions. An almost constant composition gradient is established across the separator that corresponds to the flux of lithium ions needed for the specified current density. The presence of the reservoir attenuates composition changes at the front of the positive but, within the electrode, the composition variations are accentuated by local porosity changes.

The details of the composition variations can be attributed to the combined effects of diffusion, migration, convection, and electrochemical reaction. The contribution of convection, which arises primarily from the influx or squeezing out of electrolyte as the porosity alters, is expected to be small for this system ($v^\star \sim 0(10^{-5})$ cm/sec). However, convection is included in the analysis to ensure that the accuracy of the electrolyte material balances is retained.

The importance of $v^\star$ was tested by repeating the simulation in Fig. 2, with the temperature dependence of the electrolyte molar volume included in a manner that caused oscillation in $v^\star$, without adversely affecting the material balances. The results differed by less than 0.2%, except in the region with KCl precipitation, where the largest error in ϵ_p was 5%. The sensitivity of precipitation to temperature and composition indicates that a significant proportion of this error should be associated with changes in $\tilde{V}$, rather than $v^\star$.

If the cell temperature remains constant, the model predicts that the electrolyte composition in the negative electrode would cross the solubility limit for LiCl (indicated by the dashed line) after 1.5 hr. However, the average temperature rises by approximately 15°C during this period, and therefore precipitation of LiCl is avoided. Nevertheless, at about 54% depth of discharge, the composition has fallen markedly in the positive electrode and precipitation of KCl is predicted. This is illustrated in Fig. 3, which shows the variations in maximum and minimum electrolyte concentrations during the discharge, in comparison with the saturation compositions. The prediction of large variations in electrolyte composition during discharge emphasizes the need for inclusion of variable physical properties in the theoretical analysis.

The fraction of active material utilized within the negative electrode is shown in Fig. 4, at several discharge times. The large electrode surface area and the high operating temperature help to create fast reaction kinetics. As a result, a highly nonuniform reaction distribution, dominated by ohmic effects, is obtained. Initially, the sharp reaction front is restricted to the electrode/separator interface because an infinite matrix conductivity has been assumed for the simulation (2, 20). This reaction zone gradually moves through the electrode as active material is consumed and the potential required for the reaction becomes more positive. At the back of the electrode, the transfer current rises gradually in response to the composition-dependent term in the Ohm's law relationship for the electrolyte. This effect is more pronounced at high current densities and, as a result, the reaction front at a given state of charge is less sharp at higher discharge rates.

The complementary reaction distributions for the positive electrode are presented in Fig. 5. Reaction [IIA] starts first, and after 2 hr it has proceeded about two-thirds of the way through the electrode. The FeS is fully converted to Li_2FeS_2 behind this reaction front, which is itself relatively narrow. Subsequently, a front for reaction [IIB] begins to move through the electrode, and its influence on the composition can be seen in Fig. 2 at 2.5 hr.

The distance that the first reaction penetrates the electrode before onset of the second front is dependent on the operating conditions. Table II indicates that the

distance between the fronts is smaller, and hence the reactions are less distinct, with higher current densities or with lower initial electrolyte compositions.

The microstructure in the positive shortly after the second reaction has begun is shown in Fig. 6. In this example, the initial composition is that of the eutectic, 58 mole percent LiCl, and precipitation of KCl occurs at a relatively low depth of discharge. Precipitation is responsible for the extremely small value of the porosity ϵ at a distance of about 0.075 cm which effectively blocks off the back portion of the electrode. In this isolated region, self-discharge reactions can take place as a result of composition variations in the electrolyte and potential gradients in the matrix. The diagram shows that, in the depth of the electrode, reaction [IIA] has occurred to some extent, producing a certain volume fraction ϵ_X of Li_2FeS_2 and slightly decreasing the porosity from its initial value of 0.5. Behind the central reaction front, there is a plateau for the values of ϵ_X, ϵ, and ϵ_{Fe} that corresponds to completion of reaction [IIA]. At distances less than 0.01 cm from the reservoir, the consequence of reaction [IIB] can be seen; Li_2FeS_2 is consumed, Li_2S is produced, and the porosity drops to a small value.

As the first reaction front moves back through the positive electrode, the precipitated region does so also, and it remains as a sharp spike located in the region of highest transfer current. The progression of the second reaction is accelerated by the isolation of the back of the electrode, and the region of precipitation can spread rapidly to affect a larger part of the electrode. The local reductions in porosity that result from the large molar volume of the Li_2S and the precipitation

of KCl lead to a reduction in local electrolyte conductivity in accordance with Eq. [A-2]. Consequently, a significant potential drop can develop across the low porosity region, and this may severely limit utilization of the electrode. The plugging of porous electrodes has been cited as a possible cause of failure in other electrodes (5, 21). In the zinc electrode, for example, a large volume fraction of ZnO can be produced at the front face early in a discharge, particularly if the reaction distribution is highly nonuniform.

Initial electrolyte composition.—An important consideration in the development of the LiAl/LiCl, KCl/FeS battery is the choice of initial electrolyte composition, $x_A{}^o$. The dependence of composition changes on $x_A{}^o$ is illustrated in Fig. 7, at two different depths of discharge. The difference between the maximum and minimum electrolyte compositions is larger for smaller $x_A{}^o$, and this effect becomes magnified as the discharge proceeds. The composition changes have a direct influence on the extent of precipitation and on the Nernst relationship for the cell potential.

With pure LiCl, there is no concentration polarization, but the minimum operating temperature would be 609°C. For molten salt mixtures with Li^+ as a common ion, the composition changes in the Li/FeS cell are expected to be small. The transport theory developed in Ref. (14) can be applied directly to binary electrolytes such as LiCl-LiF. It also applies to more complicated mixtures, such as LiCl-LiF-LiBr, provided that it is reasonable to assume that, from a mass transport standpoint, the anions can be lumped together to give only a single independent composition variable.

If the anions do not participate in the electrode reactions, the production term in the material balance equation is given by (14)

$$R_A = \tilde{V}aj_{3n}\left(\frac{c_2t_1{}^r}{\nu_2{}^B\nu_3{}^A} - \frac{c_1t_2{}^r}{\nu_1{}^A\nu_3{}^B}\right) \qquad [29]$$

For electrolytes with unit stoichiometric coefficients, and for transference numbers that are directly proportional to concentration, Eq. [29] reduces to $R_A = 0$ and, therefore, the electrolyte composition is constant.

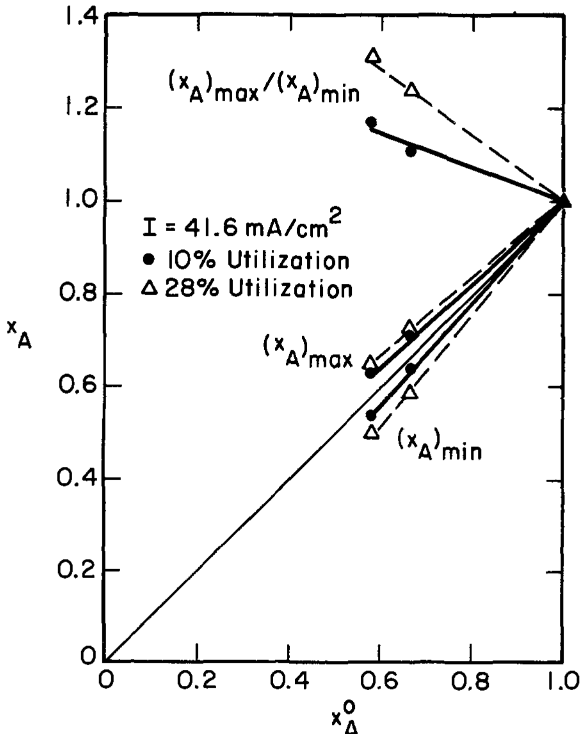

Fig. 7. Dependence of composition variables on initial electrolyte concentration. Parameters as in Fig. 2, except as indicated.

In practice, R_A is still expected to be small even with transference numbers not exactly proportional to concentration, and successful cell operation may be possible at temperatures much closer to the melting point than are permissible with the LiCl-KCl electrolyte.

Discharge curves.—An important capability of the model is to predict the dependence of total cell voltage on state of charge. Discharge curves for the Argonne Mark 1A cells are presented in Fig. 8 for several different operating conditions. The upper curves are for a current density of 41.6 mA/cm², and the highest of these is for a lithium-rich electrolyte, which has a larger bulk electrolyte conductivity than the eutectic mixture. Two curves are shown for the eutectic, which is the composition actually used in the Mark 1A cell design. Curve A takes account of precipitation of either component of the electrolyte, whereas curve B does not. For all three curves, the sharp reduction in cell voltage can be attributed to the localized porosity reductions in the fully reacted region of the positive electrode. Precipitation reduces the porosity still further, and the decline in voltage is correspondingly more acute. In practice, the porosity changes may not be quite so dramatic because it is possible for the electrodes to swell. Expansion may occur by compaction of the separator and displacement of the can walls during the formation cycles of the cell, or by motion of the electrodes relative to one another during a particular charge or discharge. The extent to which swelling can take place will depend on the stresses generated within the cell and the physical restraints on the container.

At the high current density, the initial cell voltage is considerably reduced as a result of the finite grid resistance (see Appendix). Also, the cell voltage declines more rapidly since there is less time available for diffusional processes to take place, and because the reaction distribution in the positive electrode is less uniform (see Table II).

The triangles in Fig. 8 indicate the onset of precipitation of KCl. They show that, at lower I or higher $x_A{}^o$, precipitation is delayed. The exact time when precipitation begins is largely dependent on the details of the heat balance used to estimate the average cell temperature, Eq. [28]. Small changes in the rate of heat loss from the battery module, or slight differences in initial cell temperature, could have a significant impact on the extent of precipitation and, possibly, on the cell performance. In the examples shown, precipitation of LiCl is not predicted, even though the maximum composition is close to the solubility limit (see Fig. 3).

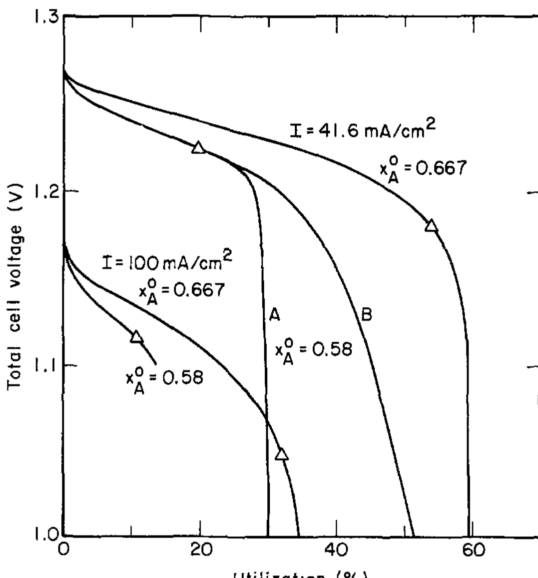

Fig. 8. Theoretical discharge curves for Argonne National Laboratory Mark 1A cells. Parameters as in Fig. 2, except as indicated.

Careful consideration of precipitation is needed for several additional reasons. The rate of mass transport from the electrolyte in the bulk of the pores to the matrix surface may influence the rate at which precipitation takes place. This has been included in previous studies of electrodes with sparingly soluble reactants (22-24), but the effects may not be so important in molten salt systems because the salt concentrations are generally much higher. The morphology of the precipitate may be important, particularly if it forms as a passivating layer over the active material. Furthermore, local thermal effects may influence the extent and nature of precipitation; heat generated as precipitate forms will tend to retard the precipitation process.

In Fig. 9, an experimental discharge curve is compared with theoretical predictions obtained at a similar current density. The experiment was done with a bicell (2 negative electrodes with a central positive plate) that was built with electrodes designed for the Mark 1A battery program (25). The computer simulation is based on the electrode capacities specified in Fig. 8, but it is assumed that the positive and negative electrodes have expanded 12.5% and 23%, respectively. It is also assumed that the heat transfer coefficient h_o is twice as large as the value assumed for the Mark 1A battery model. The ambient temperature used in the model remains at 25°C, whereas it may be closer to 450°C in the experiments.

Theoretical curves A and B in Fig. 9 indicate the influence of initial cell temperature on the predicted system behavior. The cell temperatures rise by 18° and 26°C during the discharge, for low and high T_o, respectively. Even with high operating temperatures and swollen electrodes, the maximum predicted utilization is still considerably below the experimental observations. Two possible reasons for this discrepancy are: (*a*) Larger local porosities in the positive electrode at a given stage of charge due to: (*i*) additional expansion, (*ii*) solid phase intermediates with relatively low molar volumes that are not included in the present model, and (*iii*) more uniform distribution of reactions. (*b*) Reduction in amount of KCl precipitation due to: (*i*) smaller composition variations as a result of larger porosities or free convection, (*ii*) high local temperatures, (*iii*) mass transport limitations, and (*iv*) modification of the equilibrium solubility limit by the presence of sparingly soluble species in the electrolyte or due to supersaturation.

Curve C in Fig. 9 represents the same simulation as curve B, except that precipitation of electrolyte is not taken into account. The relatively good agreement with the experimental data, although possibly fortuitous, gives some support to the reduced precipitation concept and provides an incentive for a more detailed examination of the possible causes enumerated above. In particular, a force balance on the electrolyte in a direction parallel to the separator, together with Darcy's law, indicates that free convection is even less important than forced convection in vertical LiAl/FeS cells.

In addition, at the end of the simulation depicted by curve C in Fig. 9, $(x_A)_{min} = 0.220$, whereas $(x_A)_{sat} = 0.437$. If local temperature effects dominated, the temperature in the positive electrode would need to be 155 K above the average cell temperature; temperature differentials of this magnitude are not expected to be observed in these cells because the electrodes are thin and the materials have relatively high thermal conductivities. Furthermore, large degrees of supersaturation would not be expected in the heterogeneous electrode medium. A separate study may be needed to monitor cell temperature and to investigate local variations in electrolyte composition, under closely controlled experimental conditions.

One can also speculate on the reasons for the differences between experiment and theory shown in Fig. 9, at low utilizations. The experimental curve rises more sharply than the model predictions at depths of discharge below approximately 25%. This can be attributed, at least in part, to the presence of about 15% Cu_2S in the positive electrode. Copper sulfide was added to the Mark 1A electrodes to minimize the formation of an intermediate sulfide, $LiK_6Fe_{24}S_{26}Cl$ (J-phase), which can adversely affect cell performance (26). There is now evidence to suggest that J-phase can also be suppressed by the use of lithium-rich electrolytes and increased operating temperatures (27). Elimination of Cu_2S from the positive would be advantageous because gross movement of Cu_2S to the separator, with subsequent cell shorting, can take place (28).

Small quantities of lithium are sometimes added to the negative to augment the electrode capacity. As with Cu_2S, addition of lithium tends to raise the total cell voltage. However, the lithium activity is increased, and this may cause operational difficulties, such as displacement of potassium from the electrolyte, reaction with the separator material, dendrite formation, shift of charge range in cycling, or failure to achieve full charge.

An alternative explanation for the differences at low utilizations resides in the higher potentials present during the preceding charge half-cycle, which persist for a while after discharge is begun. These would not be present in the computer simulation.

The small discrepancy between experiment and theory at approximately 30% utilization could result, among other reasons, from uncertainty in the estimation of the current collector and terminal resistance (see Appendix). The finite conductance of the grid will also lead to nonuniform current and potential distributions across the face of an electrode, which are not included explicitly in the one-dimensional cell model. A separate study has been made of ohmic drop in current collectors in order to help provide a rational basis for scale-up of cells (29).

An analysis of local variations in potential across the cell sandwich can provide additional insight into the behavior of the individual electrodes. Figure 10 shows potentials at different positions across the cell described in Fig. 9, relative to a saturated β-LiAl/LiCl, KCl reference electrode placed at the front face of the negative. The separator potential Φ_s is almost unchanged throughout the discharge, in keeping with the constancy of the composition profile across the separator (see Fig. 2). The open-circuit potential difference $(\Phi_s)_{I=0}$, that would be measured by a reference electrode at the front face of the positive electrode, indicates the influence of concentration polarization, which

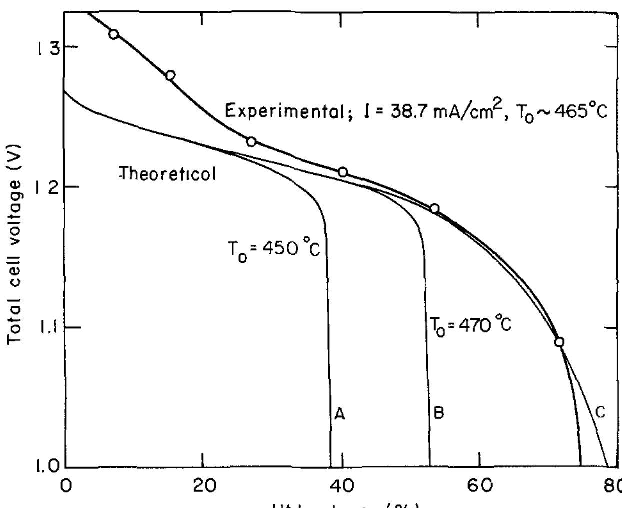

Fig. 9. Comparison of theoretical and experimental (25) discharge curves. Simulation parameters: $Q_- = 2800$ C/cm^3, $Q_+ = 4630$ C/cm^3, $L_- = 0.32$ cm, $L_s = 0.16$ cm, $L_+ = 0.18$ cm, $\epsilon_-^\circ = 0.39$, $\epsilon_s^\circ = 0.75$, $\epsilon_+^\circ = 0.555$, $x_A^\circ = 0.58$, $I = 41.6$ mA/cm^2, $N = 5.5 \times 10^7$ cm^{-3}, $h_o = 8.25 \times 10^{-2}$ W/m^2 · K.

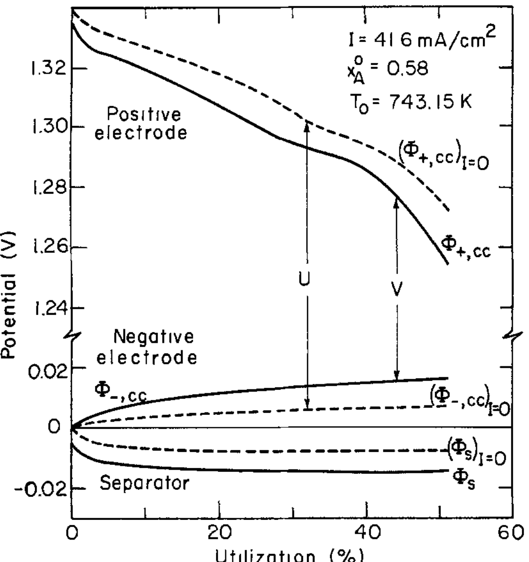

Fig. 10. Theoretical potential variations at different locations across the cell sandwich. Parameters as in Fig. 9. Dashed lines represent open-circuit potentials.

is characterized by the composition dependent term in Ohm's law, Eq. [14]. The curves marked $\Phi_{+,cc}$ and $\Phi_{-,cc}$ represent the potentials of the positive and negative current collectors, respectively. The difference between these potentials and their open-circuit counterparts can be regarded as the resistances of the individual electrodes. In the negative electrode, there is assumed to be no potential difference in the matrix phase, and, in the positive electrode, the matrix potential difference is too small to be discernable in Fig. 10 because the effective matrix conductivity calculated with Eq. [A-10] is large [$\sigma \sim 0(10^4)$ Ω^{-1} cm^{-1}], throughout the discharge.

The components of the potential for the experimental cell depicted in Fig. 9 are presented in Fig. 11 (25). Both experimental and theoretical results indicate that changes in total cell voltage are largely dependent on the variations in apparent open-circuit cell potential U, and that changes in electrode resistances are relatively small. The experimental results show that the positive is polarized more strongly than the negative electrode, but that the negative electrode potential rises more sharply toward the end of discharge. This could be interpreted as a negative electrode "limitation," although this term has not been carefully defined. In this context, it is not possible to distinguish between limitations caused by inherent electrochemical factors or by changes in the usable capacity of an electrode over a number of cycles. It might be expected that, with a sufficient increase in excess capacity in the negative electrode, the positive would limit cell performance on both charge and discharge.

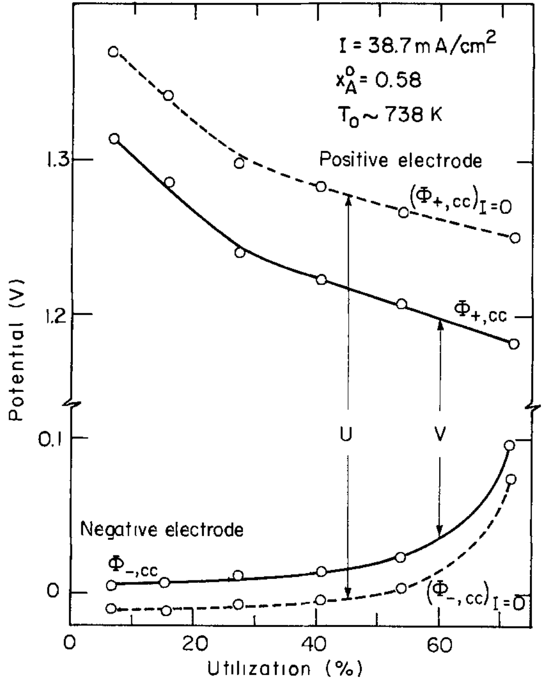

Fig. 11. Potentials at different locations across a cell sandwich measured with a reference electrode placed at the edge of the separator (25). Dashed lines represent open-circuit potentials, 15 sec after current interruption.

For both electrodes, the model predicts resistances that are smaller than the observed values. This could be caused by overestimation of electrochemically active interfacial areas, exchange current densities, or matrix conductivities. Contact resistance or partial loss of electrical connectivity between electrode particles can lead to conductivities below those calculated from Eq. [A-10], which is based on the concept of parallel conduction paths. Separate experiments may be needed to establish the conductivity of each electrode matrix as a function of stage of charge. Contact resistances are not expected to be significant in the positive electrode during discharge because the large volume of solid products tends to increase the internal electrode pressure. Furthermore, the presence of Li_2S at the front of the positive electrode may not influence cell behavior markedly, since all the current will be carried in the electrolyte across the fully reacted region. However, the formation of a poorly conducting layer adjacent to the current collector could have a more profound effect on the predicted potential distribution.

Despite the underestimates for the electrode resistances, the model still gives voltages that lie below the experimental results in Fig. 9. This is directly associated with the estimated value of the current collector resistance R_g, which is included in the model only to improve the accuracy of the heat balance. The estimate of R_g could be refined with more precise experimental data for the polarization conductance Y of a cell element. This parameter (Y) could be obtained directly in a small, open test cell with current collectors large enough to ensure insignificant current and potential variations across the face of a plate and with voltage taps placed in direct contact with the current collectors.

Additional experiments may also be needed to elucidate the reasons for the observed rise in potential of the negative electrode toward the end of discharge (see Fig. 11). The theoretical calculations indicate that the increase in porosity as the discharge proceeds more than compensates for the additional distance the current must penetrate the electrode and that the current collector potential approaches a constant (see Fig. 10). The discrepancy between theory and experiment may result from: (*a*) reduction in negative electrode porosity caused by expansion of the positive, (*b*) gross morphology changes in the negative electrode, (*c*) reduction in the available electrode capacity and uncertainty in the state of charge caused by (*i*) segregation of active material from the bulk and (*ii*) cumulative coulombic losses, and (*d*) nonuniform initial distribution of reactants.

Agglomeration would reduce the electrochemically active interfacial area and increase the diffusion overpotential for transport of lithium atoms across the α-Al. A computer simulation with the initial particle size r_0^o increased by a factor of 4.5 shows an increased electrode resistance at a particular depth of discharge but, contrary to observations, the open-circuit potential $(\Phi_{-,cc})_{I=0}$ does not alter appreciably. The influence of the initial variation in state of charge across the negative electrode could be investigated by comparing potential distributions obtained

during two experiments; one where a considerable time interval was introduced between the discharge of interest and the previous charge, and the other where the discharge followed the charge immediately, but the overall initial state of charge matched the first experiment.

It should also be noted that a considerable quantity of lithium can be retained in the α-Al after the β-phase has been completely utilized. For the example B in Fig. 9, the characteristics of particles at the front of the electrode when the cutoff voltage is reached are: $r_\beta = 0.474 \times 10^{-3}$ cm, $r_\alpha = 1.115 \times 10^{-3}$ cm, and $(c_{Li}{}^{\alpha})_o/(c_{Li}{}^{\alpha})_{sat} = 0.78$. This indicates that the reaction is not limited by diffusion of lithium across the α-Al and that a minimum of approximately 7.8% of the total theoretical capacity could be stored in the α-Al when no β-LiAl remains. Consequently, the available capacity in the negative electrode may be significantly lower than the theoretical estimate, and this could contribute to the apparent limitation observed in this electrode.

Polarization characteristics.—In many applications it is important to know the effect of discharge rate and depth of discharge on the usable capacity of the cell. Figure 12 shows polarization curves that represent a voltage sweep of a cell that has been discharged at a specified constant current density for a given period of time. It should be emphasized that this is not simply a cross-plot of a number of constant current discharges. Before discharge begins, there is a single current-potential curve, but the polarization characteristics will change during the discharge in a manner that depends on the total applied current. In general, polarization is greater at larger depths of discharge and for higher current densities at a given depth of discharge.

An important feature of the curves in Fig. 12 is that they are substantially straight, and there is little error in approximating them by the equation

$$I = Y(U - \Phi_+ + \Phi_-) \qquad [30]$$

where Y is the polarization conductance, given by the reciprocal of the slope of the lines, and U is the apparent open-circuit cell potential, given by the ordinate intercept. In this way, the polarization characteristics of the LiAl/FeS cell can be summarized by the dependence of U and Y on the operating conditions.

Figure 13 shows the dependence of electrochemical resistance on state of charge for several different current densities. Each curve shows that, in an overall sense, the resistance increases as more active material is consumed. However, for $I = 0.1$ A/cm², there is an almost discontinuous reduction in 1/Y at a time that corresponds to the onset of reaction [IIB] (X + 2Li⁺ + 2e⁻ → 2Li₂S + Fe) at the front of the positive electrode. At lower current densities the drop in resistance is neither as marked nor as abrupt, and it occurs later in the discharge (see Table II). At each current density, the resistance rises again as porosity variations in the positive electrode lower the effective electrolyte conductivity. In practice, there is much less distinction between the intermediate reaction steps in the positive electrode. Consequently, it is not expected that the sharp changes in resistance predicted with the model will be observed experimentally. It should also be emphasized that the model does not include the possibility for reaction of additives such as Cu_2S or CoS_2, or for additional intermediates such as J-phase in the conversion of FeS to Li_2S and Fe.

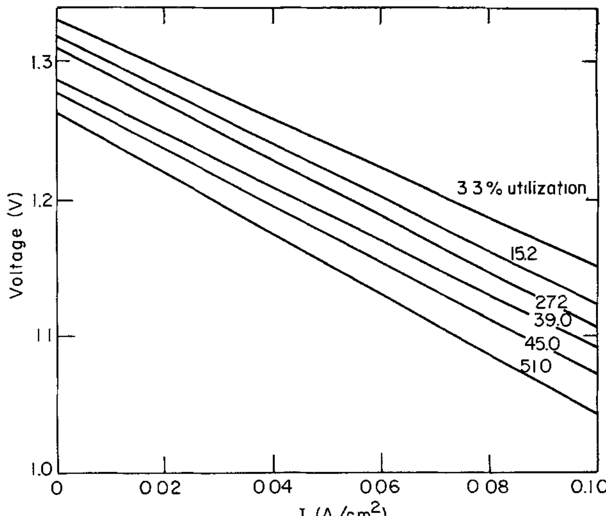

Fig. 12. Effect of state of charge on theoretical cell polarization behavior. Simulation parameters as in Fig. 9, $T_o = 470°C$.

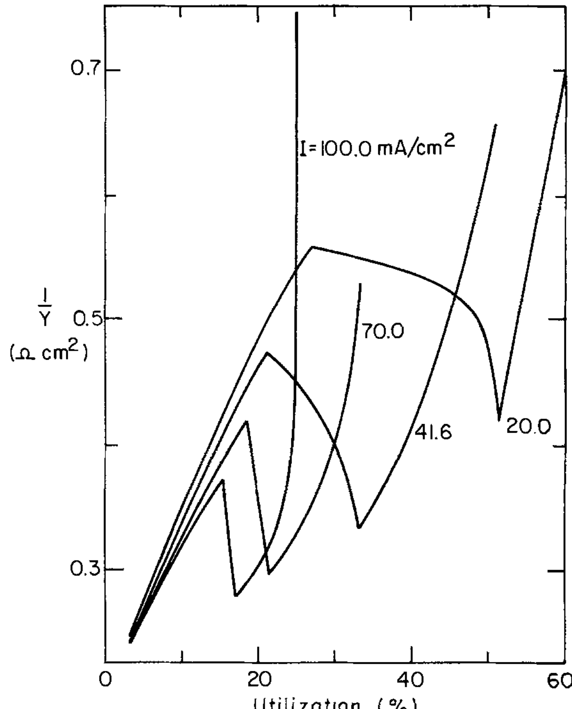

Fig. 13. Predicted dependence of polarization resistance on utilization at different discharge rates. Parameters as in Fig. 9, $T_o = 470°C$.

The dependence of the apparent open-current cell potential on state of charge and discharge current density is presented in Fig. 14 and 15, for theory and experiment, respectively. In both cases, the value of U drops markedly during the discharge. The experimental results lie above the model predictions as a consequence of the presence of additives, such as Cu_2S, which raise the equilibrium open-circuit cell potential. For less than about 30% utilization, the experimental curves show no systematic dependence on current density. At greater depths of discharge, U changes more markedly at higher I, as predicted in Fig. 14.

The reduction in U during the discharge can be associated with concentration polarization caused by nonuniform utilization of active material. In the negative, lithium is preferentially removed from the front of the electrode first, as illustrated in Fig. 4, and a maximum in electrolyte composition can develop part of the way through the electrode. At open circuit, the region with highest electrolyte composition becomes cathodic with respect to the rest of the electrode, and local concentration cells are set up which act in a manner that tends to reduce the composition variations. These variations can be more substantial at higher discharge rates, for a given state of charge, and, consequently, the open-circuit resistance can be higher in the negative electrode, leading to smaller values for U.

In the positive electrode, the situation is complicated by the possibility of simultaneous reactions. Before re-

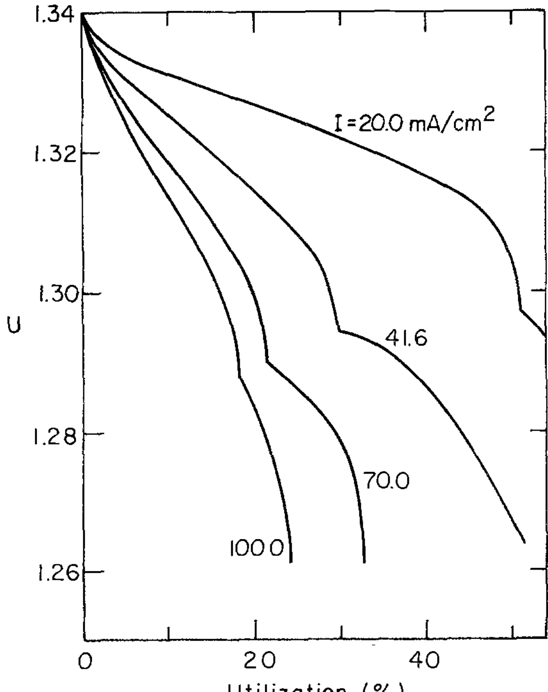

Fig. 14. Effect of discharge rate and state of charge on the theoretical apparent open-circuit cell potential. Parameters as in Fig. 9, $T_0 = 470°C$.

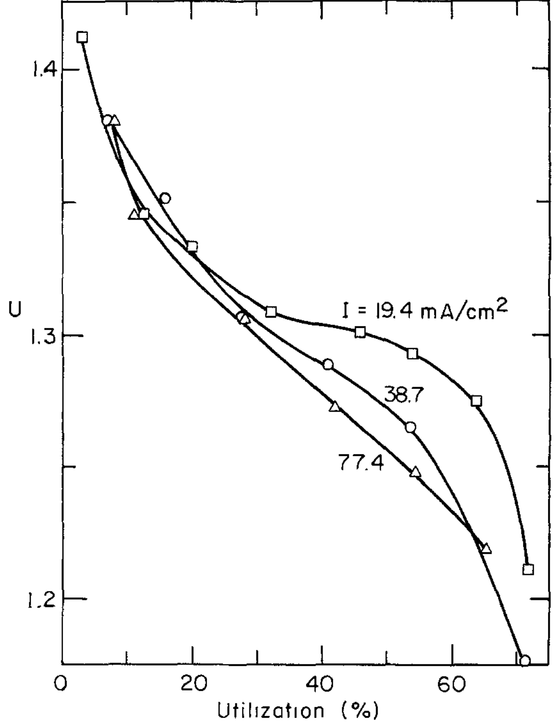

Fig. 15. Variation in experimental apparent open-circuit cell potential with discharge current density and utilization. Measurements taken 15 sec after current investigation (25).

action [IIB] begins, $(\Phi_{+,cc})_{I=0}$ is controlled by local concentration cells that result from electrolyte composition variations, in much the same way as described for the negative electrode. When reactions [IIA] and [IIB] both occur, a corrosion potential can be established on open circuit, which corresponds to cathodic formation of Li_2FeS_2 in the back of the electrode and anodic formation of Li_2FeS_2 toward the front. These reactions would be observed on current interruption, even in the absence of a composition gradient in the electrolyte. As the second reaction, [IIB], progresses, the mixed corrosion potential shifts toward the equilibrium potential $U_{[IIB],o}$.

The positive electrode behavior is the major factor that leads to the predicted reduction in U. At higher current densities, reaction [IIB] begins earlier in the discharge and therefore U declines more rapidly. The less marked dependence of U on current density observed experimentally is further evidence to suggest that there is less distinction between the positive electrode reactions in practice.

Conclusions

A mathematical model has been developed that can describe the time-dependent and position-dependent behavior of a complete LiAl/LiCl,KCl/FeS cell. Composition and reaction distributions can be predicted, as well as variations in volume fractions of individual phases and electric potential within the electrodes. The results of the theoretical analysis show many of the general trends in discharge behavior that are observed experimentally. The model predicts that high internal resistance can develop in the positive electrode as a result of low local porosities which are, in turn, caused by large volume reaction products or precipitated KCl. This implies that, with the electrode capacities currently being considered for electric vehicle applications, swelling may be a prerequisite for successful operation and thermal management of battery modules may also be important. Furthermore, an investigation of the potential distribution across the cell sandwich indicates that, before porosity reductions become critical, variations in total cell voltage are controlled more by changes in apparent open-circuit cell potential than by changes in resistance across the individual electrodes.

Acknowledgment

The authors are extremely grateful to the members of the Chemical Engineering Division at the Argonne National Laboratory for many useful discussions and valuable suggestions. This work was supported by the Division of Solar, Geothermal, Electric and Storage Systems, Office of the Assistant Secretary of Energy Technology, U.S. Department of Energy under Contract No. W-7405-Eng-48.

Manuscript submitted Feb. 22, 1980; revised manuscript received *ca* Aug. 27, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

APPENDIX

Physical Properties of the LiAl/LiCl,KCl/FeS System

Electrolyte conductivity.—The dependence of bulk electrolyte conductivity on composition and temperature is described by

$$\kappa_\infty = (a x_A^2 + b x_A + c) e^{-E/T} \quad \text{[A-1]}$$

where: $a = 18.9803$; $b = -5.0170$; $c = 9.0903$; $E = 1425.76$ K (31, 32). The effective conductivity in the porous medium is estimated from

$$\kappa = \epsilon \kappa_\infty / \zeta^2 \quad \text{[A-2]}$$

where the tortuosity factor ζ is directly related to porosity by

$$\zeta = \epsilon^{(1-q)/2} \quad \text{[A-3]}$$

and the constant q is taken as 1.5.

Transference number.—Measurements of transference numbers in binary nitrate melts show that deviations from the relation $t_i^c = x_i$ are often relatively small (34). Experiments in LiCl-KCl melts (35) also tend to substantiate the use of this assumption which, for the molar average velocity reference frame, gives: $t_1^\star = x_A/2$; $t_2^\star = (1 - x_A)/2$.

Activity coefficient.—If dissociation of electrolyte is disregarded (36), the gradient of chemical potential of LiCl in the LiCl-KCl mixture can be written as

$$\nabla \mu_A = RT \left(1 + \frac{d \ln \gamma_A}{d \ln x_A} \right) \nabla \ln x_A \qquad \text{[A-4]}$$

Information from the LiCl-KCl phase diagram can be used to obtain the composition and temperature dependence of the activity coefficient (37-39). A relationship of the form (40)

$$\ln \gamma_A = \frac{b}{T} \tanh \left(\frac{a(1 - x_A)^n}{b x_A} \right) \qquad \text{[A-5]}$$

with $a = -1023.84$, $b = -1555.11$, and $n = 3$, has been chosen to represent the data.

Molar volume of electrolyte.—The molar volume of electrolyte is defined as $\tilde{V} = \sum_k M_k x_k / \rho$ where the density ρ is given by $\rho = 1.735 - 0.15 x_A$.

Diffusion coefficient.—For the special case where the diffusion coefficients for binary interactions are all equal, it may be shown that

$$D_\infty = \frac{\kappa_\infty RT\tilde{V}}{2\mathbf{F}^2} \left(1 + \frac{d \ln \gamma_A}{d \ln x_A} \right) \qquad \text{[A-6]}$$

On this basis, it is assumed that

$$D_\infty = 2.442 \times 10^{-4}\, e^{-E/T} (x_A + 0.4) \qquad \text{[A-7]}$$

over the composition and temperature range of interest. The molecular diffusion coefficient in the porous media can be characterized by

$$D = D_\infty / \zeta^2 \qquad \text{[A-8]}$$

together with Eq. [A-3].

LiCl-KCl phase diagram.—The equilibrium compositions that characterize the onset of precipitation of LiCl and KCl are approximated by (41)

$$(x_A)_{\text{LiCl,sat}} = 0.34080 - 4.773 \times 10^{-4} T + 1.376 \times 10^{-6} T^2$$

$$(x_A)_{\text{KCl,sat}} = 0.14615 + 1.9117 \times 10^{-3} T - 1.948 \times 10^{-6} T^2 \qquad \text{[A-9]}$$

Matrix conductivity.—In general, the matrix conductivity can be influenced by the volume fraction of the conducting phases, the inherent conductivity of each solid phase, and the manner in which the particles of conducting phases are interconnected. As a first approximation, it has been assumed that parallel conduction pathways exist in the positive electrode so that

$$\sigma = \sum_i \sigma_i \epsilon_i^{q} \qquad \text{[A-10]}$$

and q is taken to be 1.5. In the negative electrode, the conductivities of the active materials and the supporting grid are each very high ($\sigma_{Li} \cong 1.0 \times 10^5\ \Omega^{-1}\ \text{cm}^{-1}$; $\sigma_{Al} \cong 2.2 \times 10^5\ \Omega^{-1}\ \text{cm}^{-1}$; $\sigma_{Fe} \cong 2.34 \times 10^4\ \Omega^{-1}\ \text{cm}^{-1}$, at $T = 450°\text{C}$) and consequently the matrix conductivity is assumed to be infinite.

Current collector resistance.—The combined resistance R_g of the grid and terminal is obtained from a preliminary estimate of the polarization conductance, as defined by Eq. [30]. The resistance R_b of a bicell can be separated into electrochemical and current collector contributions, according to

$$R_b = \frac{1}{2A} \left(\frac{1}{Y} + R_g \right) \qquad \text{[A-11]}$$

In the calculations, it is assumed that $R_b = 4\ \text{m}\Omega$, $Y = 1.013\ \Omega^{-1}\ \text{cm}^{-2}$ (29), and $A = 316\ \text{cm}^2$. This yields $R_g = 1.55\ \Omega\ \text{cm}^2$.

LIST OF SYMBOLS

- a interfacial area per unit electrode volume (cm^{-1})
- a_k relative activity of species k
- A cross-sectional area of electrode (cm^2)

Mathematical Modeling of the Lithium-Aluminum, Iron Sulfide Battery

II. The Influence of Relaxation Time on the Charging Characteristics

Richard Pollard*[,1] **and John Newman***

Materials and Molecular Research Division, Lawrence Berkeley Laboratory and Department of Chemical Engineering, University of California, Berkeley, California 94720

ABSTRACT

A mathematical model of the LiAl/LiCl, KCl/FeS cell has been used to study the behavior of the system during relaxation and charging. The effects of state of charge, cell temperature, and current density are presented, and the influence of a period of relaxation on the subsequent charging operation is investigated. In addition, factors that can have a significant impact on the charging characteristics are identified.

The mathematical model of the LiAl/LiCl, KCl/FeS cell (1) can also be used to investigate the behavior of the system during relaxation and charging. The changes that take place under these conditions could influence the dependence of cell performance on the number of completed cycles.

In the laboratory, current interruption techniques can be used to assess the resistance within the electrodes, separator, and grids. Furthermore, in some experiments, such as post-mortem cell examinations, a period of relaxation may be needed before the temperature is low enough to begin the analyses. Current interruption may also be important in modules for electric vehicle propulsion, where it is anticipated that there will be significant periods when the battery is not in use. Cell behavior on charge can control the overall energy efficiency of the system and may also directly affect the nature of the subsequent cell discharge (2, 3). For these reasons, it is necessary to identify the factors that can limit the system during the relaxation and charging modes of operation.

The governing differential equations presented previously (1) can be used directly in the analysis, and it is only necessary to replace the initial conditions, $x_A = x_A^o$ and $\epsilon = \epsilon^o$, with the appropriate composition and porosity distributions and to modify the model for negative electrode kinetics. At any point in the electrode, it is assumed that an outer layer of β-LiAl forms as soon as charging begins and that the electrochemical reaction is restricted to the solid-electrolyte interface. The analysis of diffusion of lithium through the β-phase and the gradual reduction in thickness of the α-Al region parallels the model for discharge (1, 4), but the limiting transfer current becomes

$$(\nabla \cdot \mathbf{i}_2)_{\text{lim}} = \frac{4\pi NFD_\beta (c_{\text{Li}^\beta})_{\text{sat}}}{(1 - \bar{x}_{\text{Li}^\beta}) \left(\dfrac{1}{r_o} - \dfrac{1}{r_l} \right)} \quad [1]$$

and the reference concentration $(c_{\text{Li}^\alpha})_{\text{sat}}$ should be replaced by $(c_{\text{Li}^\beta})_{\text{sat}}$.

Results and Discussion

Relaxation.—Figure 1 shows composition profiles across the cell sandwich for several times after interruption of the current at the end of a discharge with $I = 41.6$ mA/cm². The concentration variations diminish in both electrodes and, after 2 hr, the electrolyte composition is practically uniform. In the negative, the region with highest x_A, at the back of the electrode, becomes cathodic with respect to the front portions. Local concentration cells, with the reaction

$$\text{LiAl} \rightleftharpoons \text{Li}^+ + \text{Al} + e^- \quad [\text{I}]$$

are established that reduce the initial composition variations. However, there is no driving force for equalization of the local state of charge within the α-Al, β-LiAl alloy, and the reactions that take place to give a uniform electrolyte composition accentuate the nonuniform utilization of reactants. The magnitude of this effect is dependent on the composition profile and the depth of discharge before current interruption.

In the positive electrode, the situation is complicated by the possibility of simultaneous reactions and by precipitation of electrolyte. Initially, the electrolyte concentration is almost uniform across the majority of the electrode due to precipitation of KCl as two spikes adjacent to the reaction fronts and self-discharge reactions in the isolated regions behind the spikes. Adjacent to the current collector, FeS reacts with lithium ions according to

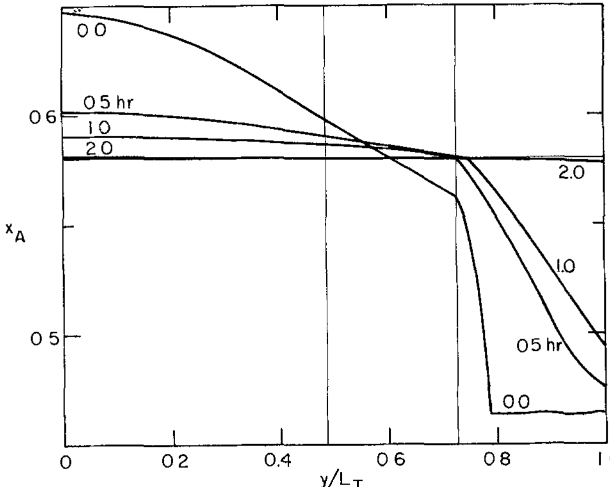

Fig. 1. Position dependence of mole fraction of LiCl at different times after current interruption. Simulation parameters: $Q_- = 2800$ C/cm³, $Q_+ = 4630$ C/cm³, $L_- = 0.32$ cm, $L_s = 0.16$ cm, $L_+ = 0.18$ cm, $N = 5.5 \times 10^7$ cm^{-3}, $h_o = 8.25 \times 10^{-2}$ W/m² · K, $R_g = 1.55$ Ω cm², $h = 0.004$ cm, $w = 0$, $-c_{\text{Li}^\beta}/(c_{\text{Li}^\beta})_{\text{sat}} = 1.0$, $D_\beta = 4 \times 10^{-8}$ cm²/sec. Parameters at start of previous discharge: $\epsilon_-^\circ = 0.39$, $\epsilon_s = 0.75$, $\epsilon_+^\circ = 0.555$, $T_o = 470$°C, $I = 41.6$ mA/cm², $x_A^\circ = 0.58$. Initial stage of charge, $\lambda(t = 0) = 47.9\%$. Additional parameters specified in Tables I and III of Ref. (1).

[1] Present address: Department of Chemical Engineering, University of Houston, Houston, Texas 77004.

Key words: porous electrodes, molten salt electrolyte, cell performance.

$$2FeS + 2Li^+ + 2e^- \rightleftharpoons Li_2FeS_2 + Fe \quad [IIA]$$

whereas, near the front of the electrode, Li_2S reacts anodically with iron, thus

$$2Li_2S + Fe \rightleftharpoons Li_2FeS_2 + 2Li^+ + 2e^- \quad [IIB]$$

The transformation of Li_2S and FeS to the intermediate sulfide reduces the local variations in state of charge although, once all the FeS has been removed, it is not possible for the remainder of the Li_2S to react further. Consequently after approximately 1 hr, there are no more reactions in the positive, and the composition now relaxes under the influence of diffusion alone.

Characteristic times for other relaxation processes can also be identified from the composition profiles. In Fig. 1, the electrolyte concentration changes by less than 1% across the separator after 1.3 hr, whereas the 1% condition is achieved in the negative electrode after only 0.8 hr. This reflects, to some extent, the influence of the electrochemical reaction on the relaxation time (5). However, the 1% criterion is rather arbitrary and, even though the composition is fairly uniform at 0.8 hr, the concentration in the negative still needs to drop by another 2.5%, as diffusion takes place across the separator. In the positive, an additional characteristic time can be distinguished. Self-discharge reactions take place in the region where Li_2FeS_2 is only partially converted to Li_2S. Here, the portion closest to the front of the electrode becomes preferentially cathodic and, after approximately 4 min, a sharp reaction front for the second reaction has been formed.

Heat is not generated in the cell during relaxation, and the temperature falls in accordance with the specified rate of heat transfer to the surroundings. As a result, the saturation concentration for KCl can rise faster than the minimum electrolyte concentration and, under these circumstances, the total volume of precipitate becomes greater than the value at current interruption. However, the reduction in minimum composition soon dominates and, in this example, all the KCl has dissolved after 1500 sec.

Figure 2 shows the variations in total cell voltage that take place after the current is switched off, for simulations A and B described in Fig. 9 of Ref. (1). Curve A is for the example that had a temperature of 450°C at the start of discharge and that achieved 39.2% utilization before the cutoff voltage was reached. The second example had a higher initial temperature (470°C), and a greater utilization was attained before the termination of discharge. In both cases, there is an initial instantaneous rise in cell voltage. The magnitude of this step change can, in principle, be used as a basis for estimation of cell resistance. However, the numerical predictions cannot be used directly because the effects of double layer capacity are not included in the model, and because the final total cell voltage, prior to interruption, can be much lower than expected in practice, due to the acute nature of the predicted failure mechanism. Therefore, separate calculations are necessary to estimate the interrupter resistance.

At the instant of interruption, there is no change in the composition profile. The potential profile retains the same shape within the negative electrode, and the potential difference $\Phi_1 - \Phi_2$ in the positive is constrained to maintain the same value because of the double layer capacity. Consequently, at any point in the system, Ohm's law gives

$$\frac{\mathbf{i}_1}{\sigma} - \frac{\mathbf{i}_2}{\kappa} = -\nabla\eta = \frac{\mathbf{i}_1^o}{\sigma} - \frac{\mathbf{i}_2^o}{\kappa} \quad [2]$$

where the superscript refers to conditions just before interruption. Since $\mathbf{i}_1 + \mathbf{i}_2 = 0$ and $\mathbf{i}_1^o + \mathbf{i}_2^o = I$, one may write

$$\mathbf{i}_1 - \mathbf{i}_1^o = -\frac{I\sigma}{\sigma + \kappa} \quad [3]$$

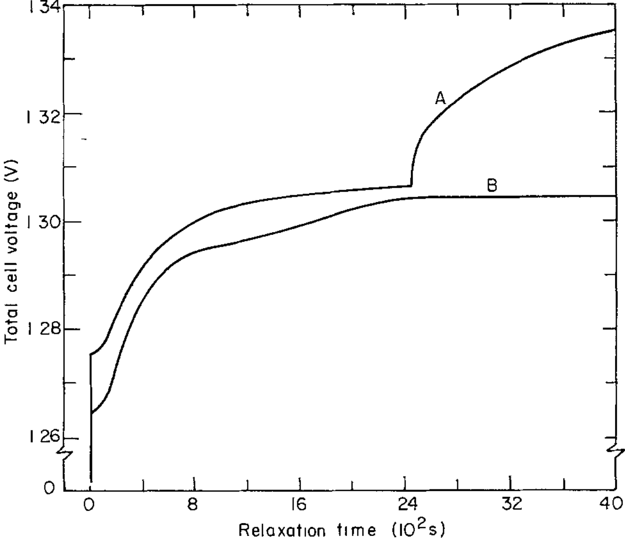

Fig. 2. Dependence of total cell voltage on relaxation time. Simulation parameters as in Fig. 1, except as indicated. Curve A: $\lambda(t = 0) = 60.8\%$, $R_I = 0.15\ \Omega\ cm^2$, $T(t = 0) = 468.2°C$, T_o (at start of previous discharge) $= 450.0°C$. Curve B: $\lambda(t = 0) = 47.9\%$, $R_I = 0.14\ \Omega\ cm^2$, $T(t = 0) = 496.2°C$, T_o (at start of previous discharge) $= 470°C$.

which indicates that the resistance of matrix and solution are effectively in parallel, even though each segment of the electrode is in series. Combination of Eq. [3] and Ohm's law for the matrix phase gives the change in cell voltage, $\Delta(V - V^o)$, as

$$\frac{\Delta(V - V^o)}{I} = \int_0^{L_T} \frac{dy}{\sigma + \kappa} \quad [4]$$

where the left side represents the interrupter resistance, R_I. In the computer calculations, R_I is dominated by the resistance across the separator because the matrix conductivity is assumed to be infinite in the negative and high in the positive electrode. The separator resistance changes only slightly during operation of the cell, in response to variations in electrolyte conductivity.

It should be emphasized that the theoretical models for the LiAl/FeS cell (6) do not include double layer effects since they are not generally regarded as being significant in the normal operation of a cell. Therefore, for the purpose of measuring the cell polarization characteristics, one may prefer the resistance to be measured after charging of the electric double layer has been completed. For this system, the double layer relaxation time, from point to point within an electrode, is estimated as approximately 50 msec (6), whereas relaxation of concentration profiles by diffusion and reaction is on the order of 3000 sec (see above).

After interruption, the voltage gradually approaches the equilibrium open-circuit cell potential. The shape of the curves is determined by the details of the reactions that occur in the individual electrodes. In particular, a corrosion potential is established in the positive by reactions [IIA] and [IIB]. In example A, all the Li_2S has been converted to Li_2FeS_2 after approximately 2450 sec, and the voltage rises sharply to the open-circuit value, $U_o = 1.34V$. Curve B does not show this effect because some Li_2S still remains when reactions [IIA] and [IIB] are completed. In this case, the voltage slowly approaches the open-circuit potential, $U_o - U_{[IIA],o} = 1.3074V$, as the electrolyte composition becomes more uniform. It should also be noted that the small initial rate of rise of cell voltage shown in the examples is atypical, and it results from potential drop across the sharp spike of precipitate that was responsible for the rapid decline in cell volt-

age before current interruption. Both theoretical and experimental results indicate that the initial voltage rise is more rapid when the current is interrupted before the cutoff voltage is reached (7).

Charging.—Figure 3 shows simulated composition profiles at different stages of a constant current charge. A relaxation time of 2 hr was included between the initial discharge and the start of the charging process. The parameter λ represents the overall state of charge; when the cutoff voltage of 1.65V is reached, 89.3% of the total theoretical capacity is available for the next discharge.

In contrast to discharge, lithium ions are now introduced into the electrolyte at the positive electrode and transported across the separator to the negative electrode, where they are incorporated into the LiAl alloy. The composition profiles represent the combined effects of diffusion, migration, and electrochemical reaction. An almost constant composition gradient is established across the separator, but the electrolyte concentration in the reservoir rises significantly during the charge. The model predicts that the electrolyte composition is almost uniform behind each reaction front.

The variations in electrolyte concentration in Fig. 3 can be compared with those in Fig. 4, for the same cell, but without relaxation between discharge and charge. At $\lambda = 77.6$, the profiles are very similar in the two cases, and there is little trace of the composition profile before the charge was started.

The average cell temperature in Fig. 3 falls from 753.5 to 740.0 K during the charge, as a result of reversible heat effects and heat transfer to the surroundings. Consequently, the saturation limit for KCl rises, and precipitation begins at the reaction front in the negative electrode when $\lambda = 85.9$. The temperature of the cell in Fig. 4 also falls, but over the range 769.4 to 751.6 K, and precipitation is delayed until $\lambda = 91.1$. For this reason, 93.7% of the theoretical capacity can be recovered before the resistance across the precipitated region becomes excessive and the cutoff voltage is reached.

The difference in charging behavior caused by the temperature drop during relaxation emphasizes the need for careful thermal management of battery modules. At lower charging current densities the temperature falls even more dramatically, but the maximum and minimum concentrations are smaller at a given state of charge, and precipitation of KCl no longer controls the final value of λ. For the cell characteristics used in the simulations, a current density of -70 mA/cm^2 is needed to keep the average cell temperature reasonably constant.

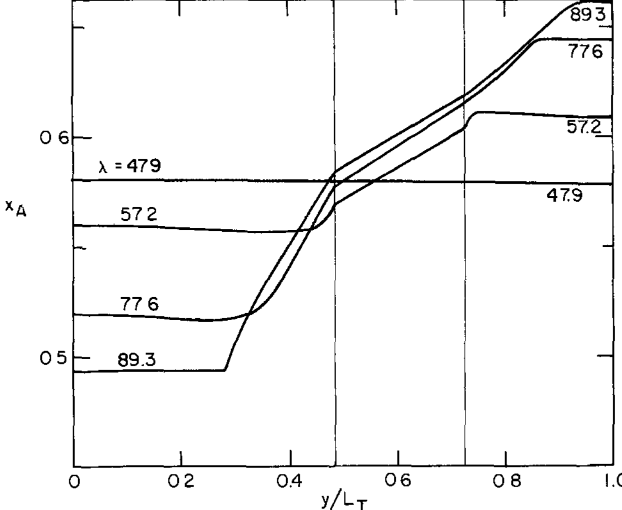

Fig. 3. Position dependence of mole fraction of LiCl at different states of charge for a constant current charge of -41.6 mA/cm^2. A relaxation time of 2 hr is included between the end of the previous discharge and the beginning of the charging process. Simulation parameters: $T(t = 0) = 480.4°C$, see also Fig. 1.

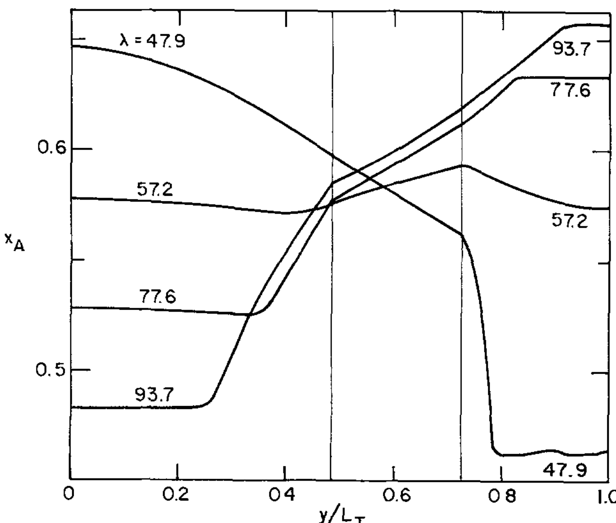

Fig. 4. Position dependence of mole fraction of LiCl at different states of charge for a constant current charge of -41.6 mA/cm^2. No relaxation between the end of the previous discharge and the start of the charging process. Simulation parameters: $T(t = 0) = 496.2°C$, see also Fig. 1.

Figures 5 and 6 show the fraction of active material utilized within the negative electrode, at several overall states of charge, for the examples in Fig. 3 and 4, respectively. A comparison of the curves at $\lambda = 47.9$ ($t = 0$) shows the increase in nonuniform utilization of reactants that results from relaxation of the electrolyte composition. The general charging mechanism is similar in two cases: the region closest to the electrode/separator interface is recharged first, and the reaction front moves back through the electrode as the alloy is completely reconverted to β-LiAl. Further reaction of the β-LiAl is not included in the model because the necessary increase in overpotential of al-

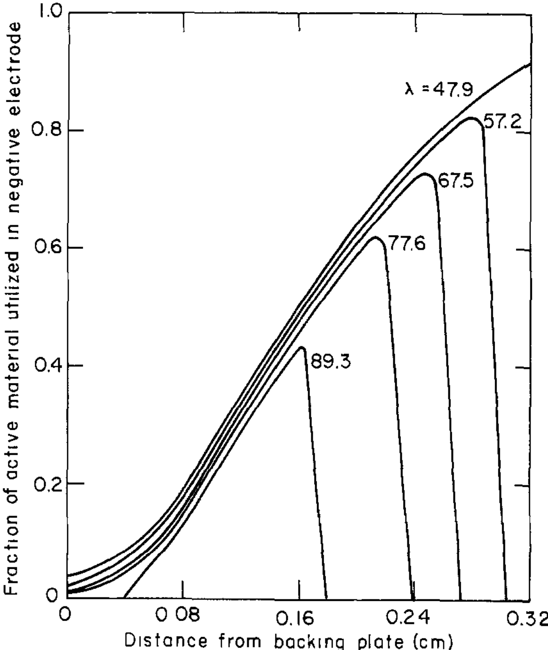

Fig. 5. Fraction of active material utilized in negative electrode at different overall states of charge during a constant current charge of -41.6 mA/cm^2. most 0.3V (8) cannot be obtained with the specified cutoff voltage. However, recent evidence (9) suggests that the change in overpotential when a particle becomes completely converted to β-LiAl may not be as dramatic as reported previously (8). Consequently, reaction may be possible at the surface of particles where no α-Al remains. In general, diffusion of lithium in the β-phase is considerably faster than in α-Al (10), and only very small concentration differences are predicted across the outer β-LiAl layer.

The complementary reaction distributions for the positive electrode are presented in Fig. 7 and 8. The results at $\lambda = 47.9$ show explicitly the equalization in local state of charge that takes place during relaxation. Figure 7 shows that reaction [IIA] occurs preferentially at the front of the electrode, adjacent to the reservoir, and that a sharp reaction front moves through the electrode as Li_2FeS_2 is consumed. This mechanism also predominates in Fig. 8, although the final distribution of unreacted material is shifted from the back of the electrode. Figure 8 also indicates that, early in the charge and at a distance of approximately 0.14 cm, FeS reacts cathodically to form X-phase, in accordance with reaction [IIA]. This self-discharge process corresponds, in part, to the charge equalization predicted during relaxation. The effect is more pronounced at lower current densities.

The variations in total cell voltage for several constant current charges are presented in Fig. 9. In each case, there is a relatively sharp rise in electrode potential when reaction [IIB] is completed in the positive electrode because the corrosion potential can no longer be maintained. Also, precipitation of KCl in the negative electrode is predicted, and the local reduction in electrolyte conductivity that results causes a sharp increase in resistance at the higher current densities. At $I = -20$ mA/cm², charging is completed before precipitation effects dominate. The time for onset of precipitation is sensitive to the cell temperature, and this is largely responsible for the lower final states of charge that are predicted when a period of relaxation is included in the operating cycle.

Experiments on the charging behavior of LiAl/FeS cells (7) show that the positive electrode current col-

trode current collector, and this might be interpreted as a positive electrode limitation on charging. There are several possible reasons for this apparent discrepancy between experiment and theory: (*i*) reduction in positive electrode porosity caused by expansion of the negative, (*ii*) reduction in available electrode capacity and uncertainty in state of charge, and (*iii*) development of high matrix resistance in the positive electrode due to poor electrical connectivity of the phases or large contact resistances.

Additional experiments may be needed to obtain a clearer picture of the factors that limit the charging behavior and to assess the validity of the numerical predictions. The nature of overcharge reactions, and the potentials at which they become thermodynamically feasible, may also need to be investigated.

Conclusions

A mathematical model of the LiAl/FeS cell has been used to investigate the influence of relaxation on the charging characteristics of the system. The analysis indicates that composition variations become less pronounced during relaxation, but the local state of charge within the electrodes can become more nonuniform. The concentration changes induced on charging mask the effects of current interruption, and the effect of relaxation on cell temperature can be more important. The model shows that precipitation of KCl in the negative electrode can cause a rapid rise in applied potential toward the end of charge, but that the effect is not critical at low current densities. The results obtained are sensitive to the details of the heat balance used in the calculation, and this reflects a need for precise thermal management of LiAl/FeS battery modules.

Exothermic Reactions among Components of Lithium-Sulfur Dioxide and Lithium-Thionyl Chloride Cells

S. Dallek,* S. D. James,* and W. P. Kilroy*

Naval Surface Weapons Center, Electrochemistry Branch, White Oak Laboratory, Silver Spring, Maryland 20910

ABSTRACT

Differential scanning calorimetry measurements were made on various components of Li-SO_2 and Li-$SOCl_2$ cells to identify those combinations that react exothermically and might cause batteries to explode. The passivation of Li by SO_2 in acetonitrile (AN) was characterized over a wide range of SO_2 concentration (0.1-14M). In the absence of SO_2, trace additions of water greatly lower the exothermicity of the Li-AN reaction. The Li-$SOCl_2$-$LiAlCl_4$ mixture is inert over a wide range of temperature well above the melting point of Li. However, adding carbon black converts this inert mixture into one which is highly and consistently reactive. The addition of copper powder enhances carbon's catalytic effect on the reactivity of the Li-$SOCl_2$-$LiAlCl_4$ mixture while trace additions of water have the opposite effect.

Batteries based on the Li/SO_2 and Li/$SOCl_2$ electrochemical couples have shown great promise for use in military applications requiring high energy density power sources. However, hazards associated with these batteries may delay their use in future military devices. The incidents involving explosions of these cells under various conditions may be attributable to exothermic chemical reactions among initial cell constituents and/or discharge products.

A thermal analysis study was undertaken to determine the reactivity of various combinations of cell components which could cause thermal runaways resulting in cell explosions. Recent work in this area has been conducted on the Li/SO_2 (1-3) and on the Li/$SOCl_2$ (4, 5) systems. The present work involved the use of hermetically-sealed high pressure sample containers to extend our previous studies (1, 2) of Li/SO_2 cell components to include volatile substances. Another objective was to perform a similar study of the Li/$SOCl_2$ system using the high-pressure sample containers to obviate the problems associated with pressure bursts of sample containers encountered in other Li/$SOCl_2$ DTA studies (4, 5). Finally, the reactivity of the lithium-boron alloy was studied for comparison with that of lithium in combination with Li/SO_2 and Li/$SOCl_2$ cell components. This alloy has shown great promise for use as an anode material in molten salt batteries (6-8).

Experimental

Apparatus.—A du Pont Model 990 differential scanning calorimeter (DSC) was employed to measure the reaction initiation temperatures and the relative reactivity of various combinations of Li/SO_2 and Li/$SOCl_2$ cell constituents. In our DSC curves, since the ordinate corresponds to a rate of heat generation and the abscissa is proportional to time, a measure of the relative reactivity is accomplished by a comparison of peak areas and from the masses of the reactants. We sometimes mention the "temperature excursion" (not illustrated) noted for a particular reaction. This does not refer to a deflection of the DSC curves in the ordinate direction (which measures a rate of heat generation). This term refers to excursions of the actual reaction temperature above the programmed temperature. Most DSC curves were recorded at an ordinate sensitivity of 20 mcal/sec · in. (20×). A sensitivity of 5 mcal/sec · in. (5×) is four times as responsive to enthalpy changes as is a setting of 20×. The sensitivity selection is included in the illustrations to allow comparison of the endothermic (endo) and exothermic (exo) areas. We deliberately used an insensitive recorder setting of 20× since we were mostly interested in comparing relatively vigorous reactions. Thus any reactions that involved relatively small amounts of heat change escaped our attention. The termination temperature on any DSC analysis is referred to in the test as the "cutoff" temperature.

All DSC measurements were made under a flowing atmosphere of dry argon at a programmed heating rate of 10°C/min. The DSC instrument was calibrated with pure metals melting over the temperature range studied (In, 156.6°C; Li, 180.5°C; Sn, 231.9°C; Zn, 419.4°C).

Thermal analysis of solids was performed in crimp-sealed du Pont-type Armco iron crucibles. Armco iron is inert to lithium and offers the advantage of excellent thermal response.

Mixtures containing volatile liquids were studied using high-pressure, corrosion-resistant Ni-Cr alloy (Nimonic) 500 μl crucibles purchased from Mettler Instrument Corporation, Princeton, New Jersey. Hermetic seals, capable of withstanding 100 atm of pressure, were achieved when an open-ended screw cap was tightened onto a gold diaphragm placed between the cap and the crucible. The hermeticity was confirmed by observing no loss of mass on reweighing the sample after the DSC run.

A comparison of the two types of sample cups is illustrated in Fig. 1. There is a large mass difference between the Armco cup (200 mg) and the Nimonic cup (2500 mg). The large size of the Nimonic cups necessitated modification of the DSC analytical procedure. Since the DSC chamber could not accommodate a second Nimonic cup for a reference, a stainless steel rod of similar mass was used as a reference and the instrument was then recalibrated. This disparity of sample cup and reference gives rise to a slightly sloping base line.

Sample preparation.—Lithium-boron alloy, containing 72 weight percent (w/o) lithium, was prepared as previously described (8). All solid mixtures containing either lithium-boron alloy or lithium (99.9% Foote Mineral) were prepared by sandwiching the other solid components into a single piece of the alloy or the lithium. The Li or Li-B fragment was pressed into a thin film and then the other solid powder was

(B) LIQUID SAMPLES, NIMONIC ALLOY (~2.5g)

Fig. 1. DSC sample cups

pressed into this Li surface thus ensuring intimate contact. All samples were weighed, mixed, and sealed in a Dry Room maintained at 0.25% relative humidity. All salts, carbon, etc. were vacuum dried at appropriate temperatures. Lithium hexafluoroarsenate was obtained from U.S. Steel Corporation. The lithium tetrachloroaluminate was Matheson-Coleman-Bell "polaroquality" and was used as received. Lithium thiosulfate (Pfaltz and Bauer) was washed in carbon disulfide then in carbon tetrachloride. With the exception of the lithium bromide (Fisher) and the anhydrous lithium sulfide (Ventron), all the other salts used were anhydrous, Reagent-Grade chemicals. Methyl isocyanate (Aldrich) and thionyl bromide (Alfa) were used as received.

The "active" and "reserve" battery electrolytes (~14M in SO_2) were provided by Honeywell Power Sources Incorporated. The active battery electrolyte was approximately 70, 22, and 8 w/o in SO_2, CH_3CN, and LiBr, respectively. The reserve electrolyte was 72.6, 18.4, and 8.9 w/o in SO_2, CH_3CN, and $LiAsF_6$, respectively. The reserve electrolyte was developed for reserve, Li-SO_2 batteries where exceptional long-term stability of the electrolyte is needed.

Acetonitrile was doubly distilled, first over sodium hydride then over phosphorus pentoxide. Only the middle fractions were collected. Dilute solutions of SO_2 in acetonitrile were prepared by bubbling 99.9% SO_2 into the doubly distilled acetonitrile. The dilute solutions (0.1M) of SO_2 were analyzed by adding a known volume of the solution to an excess of standard iodine in acid buffer. The unreacted iodine was titrated with standard thiosulfate solution. The more concentrated solutions (1.7M) were analyzed by weighing the CH_3CN before and after absorption of the SO_2.

Thionyl chloride was refluxed with lithium for approximately 20 hr under an argon atmosphere followed by distillation under argon. Only the palest portion of the middle fraction was collected for use in the DSC studies. All other liquid chemicals were used as received.

A stock solution of 1.6M $LiAlCl_4$ was prepared in $SOCl_2$. A saturated solution of SO_2 in this electrolyte was prepared by bubbling the SO_2 into the $LiAlCl_4$-$SOCl_2$ solution cooled in powdered Dry Ice. This solution was allowed to equilibrate at room temperature and 1 atm pressure.

Discharge products were obtained by constant current discharge of a pressurized laboratory cell containing 30 ml of Li/SO_2 reserve battery electrolyte. Precaution was taken to insure that the carbon-Teflon current collector was very dry and that only clean-surfaced lithium was used. The cell was assembled under helium and discharged at approximately 2-3 mA/cm^2 current density at ambient temperature. The discharged cell was pumped dry overnight and disassembled in the Dry Room. The products were separated, washed with doubly distilled acetonitrile, and vacuum dried.

Results and Discussion

Sulfur Dioxide System

Table I summarizes the DSC data obtained in this system. The table is arranged in the order of increasing mixture complexity. Mixtures containing the Li-B alloy are segregated at the bottom. Figures 2B and 2C compare the thermal response of the relatively heavy, high-pressure Nimonic sample cups (2.5g) with that of the much lighter Armco iron containers (0.2g). For this purpose we chose the (Li + $Li_2S_2O_3$) reaction which is known to be very exothermic (2). The figure illustrates the generally greater sensitivity of the lighter Armco iron cups. The difference between Fig. 2B and 2C in exotherm initiation temperatures should not be attributed to the mass differences of the sample containers since heterogeneous sample mixtures can often generate irreproducible thermal data. In this connection we note that the curve of Fig. 2B differs slightly from that obtained previously (2). Most of the DSC runs reported herein were performed in duplicate, some in triplicate, to check for reproducibility. Generally, simple mixtures of solid components gave very reproducible results, whereas the initiation temperatures and enthalpic changes of more complicated mixtures, especially those containing liquids, were sometimes less reproducible.

*** Figure in parenthesis represents the increase in the sample temperature above the linearly programmed temperature.
† Active electrolyte: 70, 22, 8% w/w in SO_2, AN, and LiBr (~14M SO_2).
‡ Ingredients within the square brackets are a homogeneous solution.
§ Reserve electrolyte: 72.6, 18.4, 8.9% w/w in SO_2, AN, and $LiAsF_6$ (~14M SO_2).

Lithium thiosulfate and sodium dithionite.—Figure 2A reveals that $Li_2S_2O_3$ begins to decompose endothermically at about 132°C. This indicates that the first exotherms in Fig. 2B and 2C are associated with the reaction of Li with these thiosulfate decomposition products. In agreement with the literature (9, 10), Fig. 3A shows rapid exothermic decomposition at 190°C for a sample of sodium dithionite ($Na_2S_2O_4$) containing 7.5% sodium sulfite and 2.5% sodium thiosulfate as impurities. This is as chemically similar as we could get to the commercially unavailable lithium dithionite which appears to be the primary product in discharged Li/SO_2 cells (18). Figure 3A agrees with previously published data (3). A repeated DSC run on the decomposed salt of Fig. 3A is shown in Fig. 3B. Contrary to a previous report (3) no evidence is seen for sulfur having been formed in Fig. 3A.

Cell discharge products.—Figure 4 shows thermal analysis of mixtures of Li with discharge products taken from an Li-SO_2 cell. This cell contained the "reserve" electrolyte (SO_2-AN-$LiAsF_6$) and was discharged at a constant current density of 2-3 mA · cm^{-2} to a 0.2V cutoff voltage. A grayish-colored spongy product was scraped off the Li anode surface, mixed with Li, and analyzed as in Fig. 4A to a 400°C cutoff. In this range the trace is thermally featureless except for the 180°C endotherm for melting of Li. The discharged cathode was washed with pure acetonitrile to remove SO_2 and salt, dried by evacuation, and then a fragment of it was mixed with Li and thermally analyzed to give Fig. 4B. The sharp exotherm at 251°C appears to be due to the reaction of Li with decomposition products of $Li_2S_2O_4$. DSC curves of discharged cathodes in the absence of Li (not shown) reveal a minor exotherm due to decomposition of $Li_2S_2O_4$ with initiation temperatures from approximately 185° to 230°C. A small exotherm is also visible in Fig. 4B. The exotherm is minor because of the very small

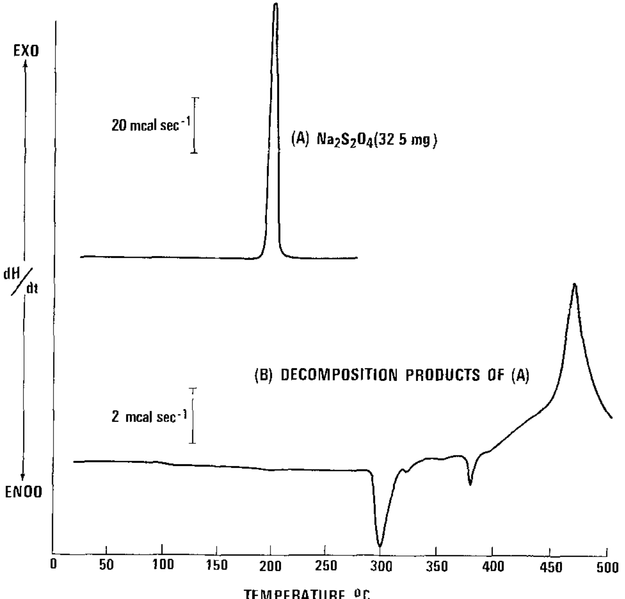

Fig. 3. Thermal decomposition of sodium dithionite

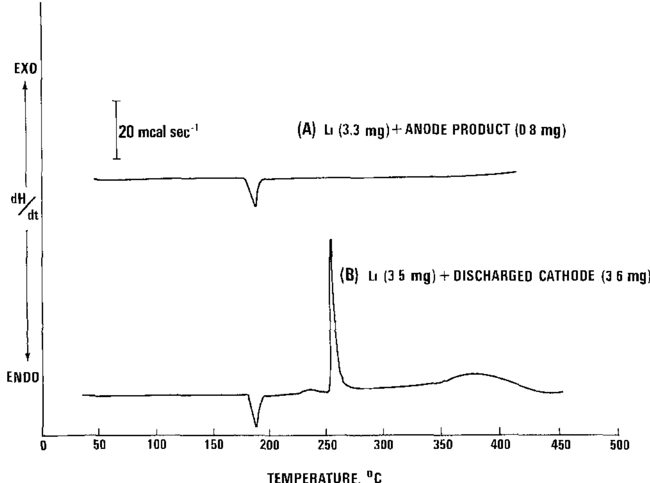

Fig. 4. Lithium reactivity with discharge products of Li-AN-SO_2-$LiAsF_6$ cell.

quantity of $Li_2S_2O_4$ (0.2-0.3 mg) imbedded in the (3.0-4.0 mg) of current collector. The variation in the initiation temperature is a function of the heterogeneous distribution of $Li_2S_2O_4$ in the carbon-Teflon collector. It is reasonable to speculate that under certain abusive conditions of battery discharge, $Li_2S_2O_4$ may undergo decomposition similar to the $Na_2S_2O_4$, thereby generating large temperature increases. The low broad exotherm at about 350°C is associated with the reaction between Li and Teflon binder from the cathode structure. This reaction was characterized thermally both previously (2) and in the present work.

Lithium-acetonitrile reaction.—Lithium and acetonitrile (AN) are unstable at ambient temperatures; a reaction starts slowly then accelerates and generates large amounts of heat. It is generally agreed that the heat and flammable gas generated in this reaction are a possible source of the explosions which have marred the generally good safety record of the Li-SO_2 battery. A typical DSC curve shown in Fig. 5A reveals a characteristic broad exotherm starting at about 40°C. Reaction rate is affected by purity both of Li and AN. Addition of 0.2% w/w of water to the AN greatly suppresses the exothermicity of the reaction (Fig. 5B). A similiar suppression of Li-AN exothermicity is seen when the AN is saturated with LiBr (Fig. 5C). Lithium bromide additions were found to consistently mimic the effect of added water, whether or not excess solid LiBr was present. We presume this is indeed due to the presence of moisture in the very deliquescent LiBr. Even in a 0.2% relative humidity Dry Room, LiBr picks up water quite rapidly. DSC analysis of an (Li + LiBr) mixture gives an exotherm at 140°C despite starting with a vacuum-dried sample and working in a Dry Room (1, 3). This is apparently due to an Li-H_2O reaction. If an easily dried salt like $LiAsF_6$ is substituted for LiBr (Fig. 5D), the low temperature, Li-AN exotherm is again evident. The high temperature exotherm at the melting point of Li appears to involve the $LiAsF_6$, but is also in agreement with the previously recorded DSC curve (1) for Li plus the tetrasolvated salt, $Li(AN)_4AsF_6$ (11).

The effect of SO_2 concentration on the thermal behavior of the Li-AN system was studied in the presence of both the "active" (LiBr) and "reserve" ($LiAsF_6$) salts. Table II makes evident that the initiation temperature of the Li-AN reaction generally rises with increasing SO_2 concentrations. In the absence of SO_2 there is a slow, low temperature reaction as illustrated in Fig. 5A. At a level of 0.1M SO_2 (simulating that present in a discharged, SO_2-depleted Li-SO_2 cell) initiation temperature increases substantially. However, the delayed reaction is both more rapid and more exothermic (Fig. 6A, D, and E). At the 1.7M SO_2 level

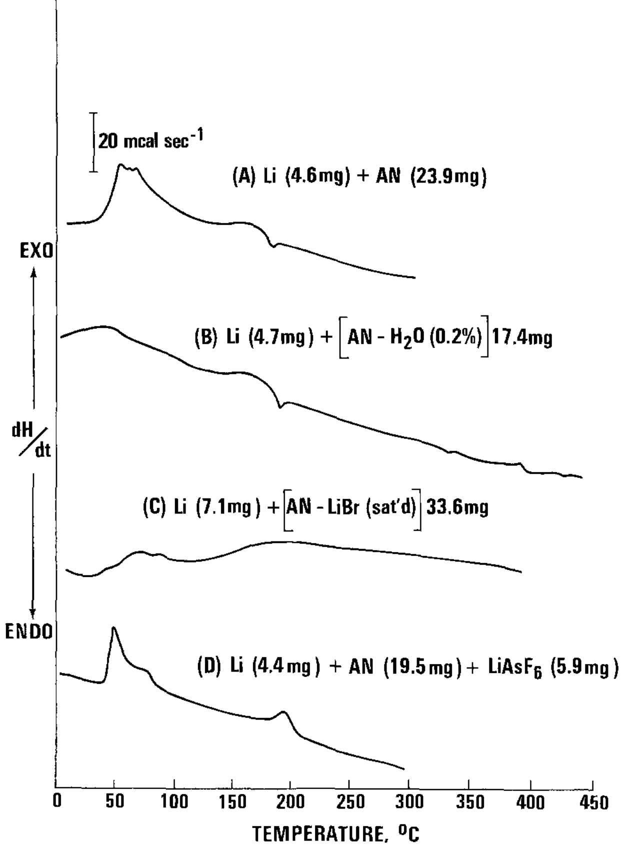

Fig. 5. Li-acetonitrile reactivity in absence of SO_2

(not illustrated) two exotherms were present corresponding to the Li-AN reaction and to one occurring at or near the melting point of Li. Finally, at concentrations of SO_2 found in the actual battery (about 14M), exothermic behavior occurs at higher temperatures (Fig. 6B and C). The heat liberated in the Li-AN reaction is similar to that noted in the absence of SO_2 and the dual peak behavior observed in 1.7M SO_2 is much less evident at these high SO_2 concentrations.

The quenching effect of water evident in Fig. 5 is no longer apparent in Fig. 6 when SO_2 is now present. Figure 6, curves D and E show big, sharp exotherms despite the addition of water. Perhaps the hydrolysis reaction between H_2O and SO_2 removes water from the system rendering it unable to quench the Li-AN reaction. The high temperature exotherm in Fig. 6D appears to result from the Li-$LiAsF_6$ reaction. This exotherm is regularly seen in the presence of $LiAsF_6$, but not in its absence (Fig. 6A).

Addition of propylene carbonate to a mixture of Li with the "active" battery electrolyte [AN-SO_2 (14M), LiBr] revealed that the Li-AN reaction is effectively quenched up to the vicinity of the melting point of Li (Table I, reaction 40).

Methyl isocyanate.—Rapid discharge caused by internal shorting has been reported to lead to the formation of methyl isocyanate (CH_3NCO) in the electrolyte

Table II. Effect of SO_2 concentration on initiation temperature for the Li-acetonitrile exotherm

SO_2 concentration (moles/liter)	Initiation temperature (°C)		
	No salt	LiBr	$LiAsF_6$

of Li-SO_2 cells (12). The DSC curve for the reaction of Li with CH_3NCO is presented in Fig. 7. The reaction is slower than some of the explosive reactions reported here and elsewhere in this system (2). However it begins at 152° (below the melting point of Li) and generates substantial amounts of heat.

Thionyl Chloride System

Table III summarizes the data. The only previous thermal analysis work in this system is that of Dey *et al.* (5). Their work was limited to relatively low temperatures by the use of sealed glass ampuls as sample cups. In Li-containing mixtures, runs were usually terminated at little over 200°C by destructive reaction of molten Li with the glass container. Mixtures containing $SOCl_2$ developed high pressures which burst the cup at temperatures from 76° to 270°C. Cups used in the present work were normally hermetic up to at least 500°C.

Initial components.—Figure 8E shows that the active materials of the Li-$SOCl_2$ battery display no reactivity together up to 335°C cutoff at which the DSC temperature scan was automatically terminated. The chloroluminate by itself melts at about 143°C (Fig. 8A) in agreement with the literature. Mixed with Li in Fig. 8B, the salt rapidly and exothermically reacts near its melting point. Thionyl chloride alone (Fig. 8C) began breaking up (into SO_2 + S_2Cl_2 + Cl_2) at about 212°C, but the thermal effects are small. In Fig. 8D we see essentially the same thing with Li unreactive up to at least 345°C. Finally Fig. 8E brings together conductive salt and both active materials. This combination suppresses both the Li-$LiAlCl_4$ reaction of Fig. 8B and the $SOCl_2$ decomposition evident in Fig. 8C and D. Thus, the initially present components of an undischarged battery seem quite unreactive over a wide temperature range even after the lithium has melted.

Possible discharge products.—Under this heading we include products of the direct electrode reactions and also secondary products resulting from further reaction (*e.g.* direct product S further reacts giving secondary product Li_2S).

Sulfur.—Figure 9 shows DSC curves for combinations containing elemental sulfur. In combination with Li (Fig. 9A) the usual violent reaction at sulfur's melting point was observed. This Li-S reaction is noticeably absent from Fig. 9B where no exotherm appears at all until 400°C. In Fig. 9B's mixture, if all the S dissolved in the electrolyte, its concentration would be about 9M. The solubility of S in the electrolyte rises with temperature and is about 1.5M at 50°C (16). So in this run, above the melting point of S, both molten S and high concentrations of dissolved S should be present. Presumably the $SOCl_2$ protects Li from reacting with both molten and dissolved S by virtue of a passivating film of LiCl as in the battery. The 400°C exotherm may be a belated Li-S reaction occurring 300°C higher than usual. Thus we have confirmed a previous find of the beneficial effect of $SOCl_2$ (5) and extended it to 400°C. Figure 9C shows the in-

* Ingredients within the square brackets are a homogeneous solution.
† Temperature at which the DSC linearly programmed temperature scan was terminated.
‡ Figures in parenthesis are the increase in the sample temperature above the linearly programmed temperature.

ertness of S with the electrolyte. The addition of carbon black to the ingredients of Fig. 9C also gave an inert mixture (reaction 21, Table III). The DSC trace is not illustrated; it was thermally featureless in the range studied (up to 384°C). We have found carbon to catalyze the reaction of $SOCl_2$ with Li (see below) but evidently it has no effect on the (S + $SOCl_2$) reaction. The small endotherms in Fig. 9B and C at about 250°C may be associated with the reaction

$$3S + 2SOCl_2 \rightarrow 2S_2Cl_2 + SO_2 \quad [1]$$

Calculation indicates this to be an endothermic reaction (14). Furthermore we always observed a clear, boiling liquid (presumably SO_2 solution) when cups initially containing (S + $SOCl_2$) were unsealed at room temperature at the end of the run.

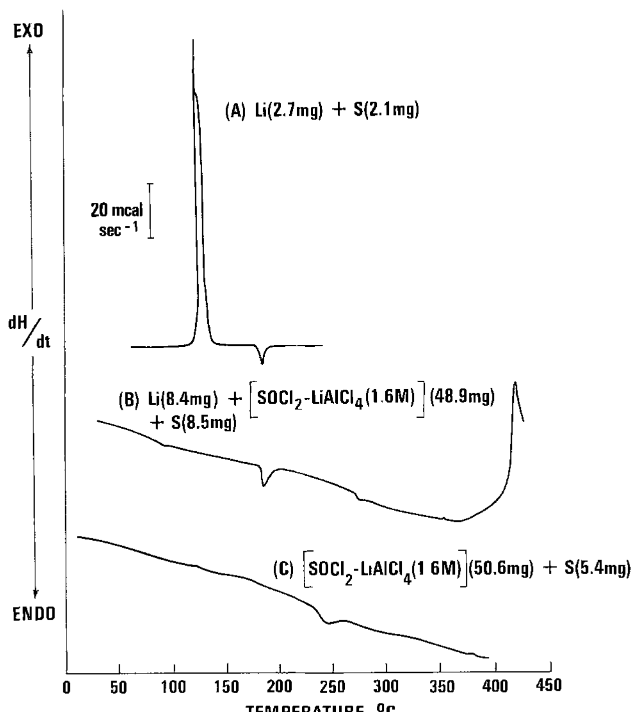

Fig. 9. Reactivity of mixtures containing elemental sulfur

Lithium sulfide.—Some workers have reported (5, 13) that anhydrous Li_2S reacts violently with $SOCl_2$ generating considerable heat and gas while others (14) found this combination to be inert. The present work has shown that Li_2S is essentially unreactive with $SOCl_2$ up to a 276°C cutoff and with $SOCl_2$-1.6M $LiAlCl_4$ up to a 367°C cutoff. The DSC curves were basically featureless and they are not illustrated. (See Table III, reactions 8 and 13.)

Sulfur dioxide.—This is generally accepted as one of the main products of the battery discharge reaction. We showed above that SO_2 retards the Li-AN reaction. We now wished to determine if SO_2 could deactivate the most reactive mixtures in the $SOCl_2$ system. Accordingly, we saturated a portion of the 1.6M $LiAlCl_4$-$SOCl_2$ electrolyte with SO_2 at 1 atm and room temperature. The SO_2 concentration was 3-4M (16). A DSC curve recorded to 414°C for this solution with added Li and S (reaction 26, Table III) showed no significant change in reactivity *vs.* the SO_2-free solution illustrated in Fig. 9B. Furthermore, Fig. 10D shows that the catalytic effect of carbon on the Li-$SOCl_2$-$LiAlCl_4$ mixture (discussed below) proceeded unimpeded, by the presence of SO_2. Thus for these combinations, at least, SO_2 has no passivating effect in the $SOCl_2$ system.

Lithium sulfate, lithium chloride, sulfur monochloride.—Both sulfate and sulfite have been reported as low temperature discharge products of the thionyl chloride battery (14). Lithium sulfite has been previously studied (2, 5) with conflicting results, though the preponderance of evidence favors its nonreactivity. The present work has found lithium sulfate to be quite unreactive to Li up to a 400°C cutoff (reaction 5, Table III). It was also inert in combination with Li, C, and $SOCl_2$-$LiAlCl_4$. Sulfur monochloride, S_2Cl_2, is known to result from the thermal decomposition of $SOCl_2$ especially in the presence of trace catalysts like $FeCl_3$ (14) as described above. Thus we tested its reactivity with Li (reaction 6, Table III). It was quite inert over

the range studied, up to 346°C. Dey (5) had reported a strong exotherm at 302°C for (Li + S + S_2Cl_2). Lithium chloride, one of the main discharge products formed in the cathode appears quite inert (to a 362°C cutoff) in combination with Li, C, and $SOCl_2$ (reaction 23, Table III). If $LiAlCl_4$ is substituted for LiCl, the mixture becomes extremely and consistently reactive; see discussion below of the effect of carbon in catalyzing reactions in this system (Fig. 10).

Catalysis of reactions by carbon black.—We invariably found that whenever an Li/C mixture was contacted with the 1.6M $LiAlCl_4$-$SOCl_2$ electrolyte, a reactive mixture was produced. In these experiments the Shawinigan carbon black was pressed into both sides of a piece of flattened Li and the electrolyte dripped onto this sandwich. The mixture always warmed up the Nimonic cups to about 40°-50°C. Occasionally the reaction was so vigorous that the $SOCl_2$ boiled dry and more was added before the cup was sealed. Accordingly we began precooling cups in Dry Ice (−80°C) before adding electrolyte so as to postpone reaction and record it on the DSC trace. Figure 10 shows four DSC curves of mixtures involving Li-C-$SOCl_2$-$LiAlCl_4$. The addition of carbon black transformed the inert Li-$SOCl_2$-$LiAlCl_4$ mixture into a consistently reactive one. However the data were unpredictable both as to peak height and even peak position. We include Fig. 10C, which actually contained Li-B alloy rather than Li, as the present work has shown the alloy behaves essentially the same as Li. The mixture of Fig. 10D contained S and SO_2 in addition to Li, C, $SOCl_2$, and $LiAlCl_4$. However, we believe that the reactivity of this mixture is due to the presence of carbon rather than to that of S and/or SO_2. This is supported by the fact that the mixture (Li + $SOCl_2$ + $LiAlCl_4$ + S + SO_2) was quite inert up to its 414°C cutoff (reaction 26, Table III). We should point out that the mixture referred to in Fig. 10D contains virtually all of the most reactive ingredients thought to be present in a partly-discharged thionyl chloride battery.

Of the four possible mixtures employing ternary combinations of the ingredients Li, C, $SOCl_2$, and $LiAlCl_4$, none approached the reactivity of the quaternary mixture (Li + $SOCl_2$ + $LiAlCl_4$ was inert, see Fig. 8E; Li + C + $SOCl_2$ was inert to a 343°C cutoff, see reaction 14; Li + C + $LiAlCl_4$ was no more reactive than Li + $LiAlCl_4$, see reaction 15; C + $SOCl_2$ + $LiAlCl_4$ was inert, even with added S to a 384°C cutoff, see reaction 21). Consistent strong reactivity was observed only when all four ingredients were together. This is understandable if we assume that a local cell is formed which activates the Li-$SOCl_2$ reaction. Carbon's function is to provide a catalytically active surface at which $SOCl_2$ can be cathodically reduced at high rates by electrons emanating from anodically dissolving lithium. Essentially we regard each carbon particle stuck in the Li surface as forming a tiny, short-circuited Li-$SOCl_2$ battery.

This is supported by the fact that the corrosion of a variety of metals in the $LiAlCl_4$-$SOCl_2$ electrolyte is greatly accelerated if they are electrically contacted with carbon, probably due to the local cell effect (4). So the only function of $LiAlCl_4$ is to render the $SOCl_2$ highly conductive so as to complete the ionic part of the local cell circuit. Accordingly we tried to replace it with other conductive, nonreactive Li salts. We tried Li_2SO_4 and LiCl separately in mixtures with (Li + C + $SOCl_2$). However DSC curves of these two mixtures showed them to be inert up to their 362°C cutoff (Table III, reactions 23 and 24). Apparently these salts did not impart the necessary ionic conductivity, probably due to a limited solubility in $SOCl_2$.

The local cell idea is of course not new; it is very old and by now obvious to skilled electrochemists. However it is useful to point out the obvious if its important implications for battery safety have been previously overlooked. The above experiments are very suggestive in this connection. Cathode failure in one out of a chain of cells will cause Li to be plated out onto the carbon of the failed cathode. Indeed, complete reversal of cell voltage is not needed. Whenever cathode voltage falls below about 1V *vs.* Li, this potentially dangerous mixture may form by undervoltage deposition of Li into carbon (20). Recent work in our laboratories has shown that the situation may involve more than a simple Li-C mixture. ESCA(XPS) studies indicate that compound formation occurs in intimate mixtures of elemental Li and C.

Effect of copper.—In view of the use of powdered copper metal in the cathodes of some Li-$SOCl_2$ batteries (17) we studied the effect of added Cu on reactivity in this system. Figure 11 shows the effect of adding 99.9% pure Cu powder to the (Li + C + $SOCl_2$-$LiAlCl_4$) mixture. Reactivity seems to be enhanced *vs.* Fig. 10, not so much in terms of a more rapid reaction with high peak temperatures, but rather in terms of a larger total amount of heat liberated. The low temperature exotherm starting at about 80°C is much

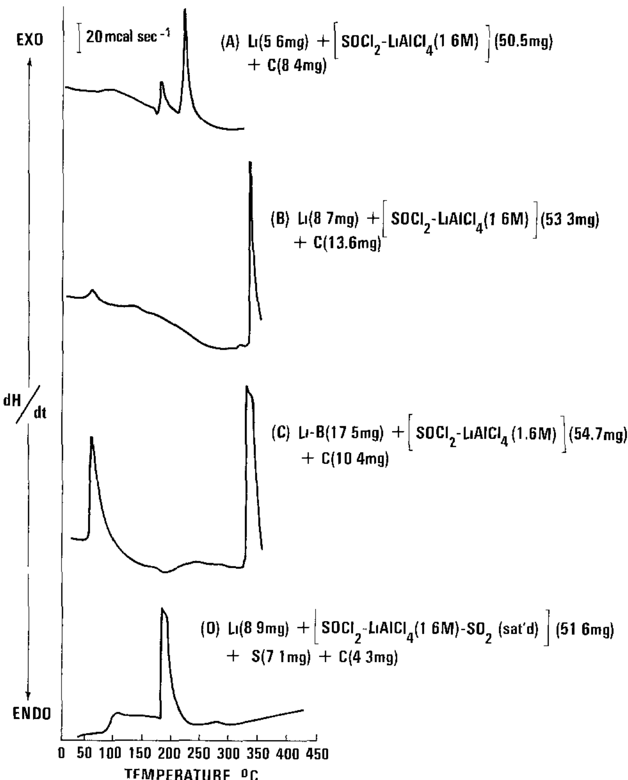

Fig. 10. Catalysis by carbon black of Li-$SOCl_2$-$LiAlCl_4$ reactivity

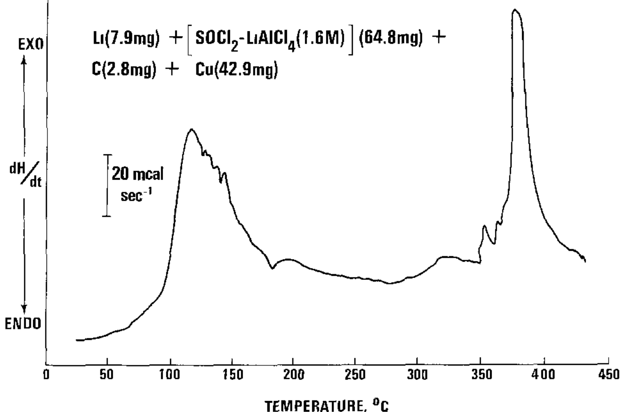

Fig. 11. Enhancement by copper of the carbon-catalysis of Li-$SOCl_2$-$LiAlCl_4$ reactivity.

more pronounced than in the absence of Cu. Reactions 19 and 22 where first C then Li was omitted from the ingredients of Fig. 11 were quite inert up to 410°C. Thus both Li and C are necessary for reactivity. It appears that the basic reactivity of the system is accelerated by the highly conductive Cu.

Carbon catalysis in the SO_2-acetonitrile-electrolyte?—Preliminary work has produced evidence that carbon black is catalytically active also in this electrolyte. In an acetonitrile solution which was saturated with LiBr and 1.7M in SO_2, the Li-AN reaction initiation temperature was 122°C. However in the presence of carbon the reaction began at about 35°C (see reactions 34 and 38, Table I). On the other hand, in a solution that was identical except that it contained no SO_2, added carbon had no clear effect on the reactivity (reactions 24 and 32, Table I). More work is needed to better characterize carbon's effect in the SO_2 battery electrolyte.

Impurities.—Lithium nitride.—Li_3N is a very reactive material. When mixed with water it catches fire and burns violently with great heat. It was recently reported (14) to react violently with $SOCl_2$, but only if it was finely divided and if mixing were done in a normally humid atmosphere. In an argon atmosphere containing 1 ppm water, no reaction occurred. This applied both to the commercially obtained powder and to nodules of reaction product removed from air-reacted Li foil. The reaction with $SOCl_2$ could be hazardous if Li_3N forms on the Li anode during cell assembly or during the disassembly of discharged cells. In the present work no reaction was noted on mixing Li_3N with $SOCl_2$ in our Dry Room at 0.25% R.H. (81 ppm water). Figure 12A shows that Li and Li_3N commercial powder are quite inert together up to the 390°C cutoff, whereas 12B and 12C show that Li_3N undergoes violent exotherms with $SOCl_2$ and with $SOCl_2$-$LiAlCl_4$. At about 130°C, the exotherm shown in Fig. 12C was associated with the biggest temperature excursion (150°C) observed in the present work (see reaction 12, Table III).

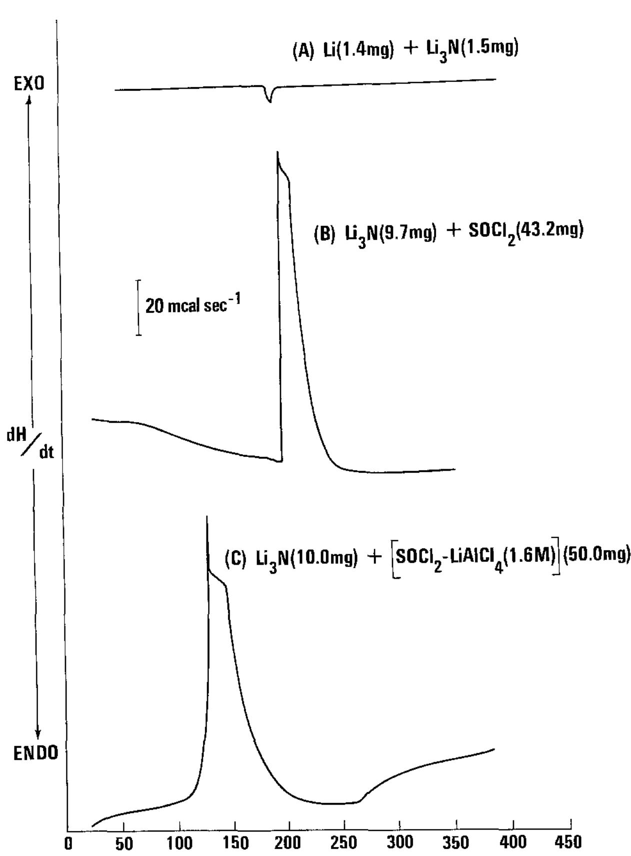

Fig. 12. Reactivity of lithium nitride

Water.—It is of interest to study the effect of added water on reactivities since this material is a ubiquitous contaminant which is very strongly absorbed by most battery active-materials. We added water only to the most consistently reactive combination, namely (Li + C + $SOCl_2$ + $LiAlCl_4$). Water added to the electrolyte to the extent of 1% by weight gave an immediate white precipitate. We homogenized the electrolyte before adding it to the Li/C sandwich so as to include some of this precipitate in the reaction mixture. This work is presently at an early stage, but it appears that this trace amount of water does exert some quenching effect on exothermicity in this system, at least in the lower half of the temperature range of Fig. 10. This contrasts with Dey's finding (5) that moisture enhances the reactivity of $SOCl_2$ with Li_2S, with Li_2O and with LiOH.

Relative Reactivities of Pure Lithium vs. Lithium-Boron Alloy

The Li-B alloy is a refractory Li-B solid compound permeated with fine pores filled with elemental Li. Because of its high temperature rigidity and the presence of the relatively inert boron, the alloy was considered as potentially safer than pure Li as a battery anode. In preparing reaction mixtures for DSC runs we used twice the mass of Li-B *vs.* that of pure Li. Since elemental Li forms 51% w/w of our alloy composition this provides for a just comparison of exothermicity. The results showed with two exceptions, no significant difference in reactivity between the alloy and pure lithium. Reaction initiation temperatures and temperature excursions shown in Tables I and III are quite similar for the two materials.

In only one case was Li-B clearly less reactive than Li. This occurred with $Li_2S_2O_3$, where temperature excursions for the major (~230°C) of the two exotherms were fifteen times greater for pure Li (150° *vs.* 10°, see reactions 13 and 43, Table I). The second difference with pure Li was in the C-$SOCl_2$-$LiAlCl_4$ system. Here the catalytic effect of carbon on this system's reactivity was somewhat greater with the alloy. This is illustrated in Fig. 10C.

Conclusions

1. For Li-SO_2-$LiAsF_6$ cell discharge products, the discharged cathode gave a significant exotherm with Li while films formed on the anode were inert to Li.

2. Trace additions of water greatly lower the exothermicity of the Li-acetonitrile (AN) reaction. Water entering the electrolyte via the extremely hygroscopic LiBr electrolyte-salt had the same effect.

3. The addition of SO_2 delays initiation of the Li-AN reaction to higher temperatures. An SO_2 concentration of 0.1M is sufficient to realize most of the rise in initiation temperature. The delayed, higher temperature reaction occurs more rapidly. The quenching effect of water on Li-AN reaction is no longer observed when SO_2 is present.

4. Addition of propylene carbonate to Li-AN-SO_2-LiBr delays the Li-AN reaction to the vicinity of the melting point of Li.

5. The Li-$SOCl_2$-$LiAlCl_4$ mixture is quite unreactive over a wide range of temperature, well above the melting point of Li.

6. The presence of carbon black converts the inert, Li-$SOCl_2$-$LiAlCl_4$ mixture into one which is highly and consistently reactive. This may affect battery safety because cathode failure in one out of a chain of cells will cause Li to be plated out onto the carbon of the failed cathode. Indeed complete reversal of cell voltage is not needed. Whenever the cathode voltage falls below about one volt *vs.* Li, this potentially dangerous mixture may form by undervoltage deposition of Li into carbon (20).

7. Some evidence was obtained for carbon catalysis also in the Li-SO_2 system.
8. The addition of copper powder enhanced carbon's catalytic effect on the reactivity of Li-$SOCl_2$-$LiAlCl_4$. Trace additions of water, on the other hand, had a counteracting effect on the carbon-catalyzed reactivity.
9. The presence of $SOCl_2$ delays the very exothermic Li-S reaction by at least 300°C.
10. We confirmed the nonreactivity of $SOCl_2$ with Li_2S.
11. Sulfur dioxide seems to have no retarding effect on reactions in the $SOCl_2$ system (in contrast to its suppression of the Li-AN reaction).
12. We confirmed the violent reactivity of Li_3N with $SOCl_2$.
13. We found no significant difference in chemical reactivity between lithium-boron alloy and pure lithium.

Dynamic Microcalorimetry: Thermal Effects of Miniature Alkaline Cells under Load

Frank B. Tudron*

Union Carbide Corporation, Battery Products Division, Parma, Ohio 44130

ABSTRACT

A nonrigorous thermodynamic calculation is performed yielding an expression which relates the rate of heat evolution by a miniature battery under load to the current flowing through the cell. At small values of I, the expression predicts a linear plot of $-dQ/dt$ *vs.* I. To demonstrate this behavior, thermal effects of an Ag_2O-Zn cell are measured under various conditions of constant load. The heat evolution data vary linearly with I over the range 0.300 μA, with a slope of 74.3 mV and an intercept of 2.1 μW. The slope gives a value of -0.175 mV/K for $(\partial E/\partial T)_p$, corresponding to the formation of inactive ZnO as a discharge product at the anode. Additional data obtained for HgO-Zn and MnO_2-Zn cells with alkaline electrolytes are present. The heat release data do not vary linearly with current. Analysis of the discharge mechanism for the HgO system is possible. The discharge mechanism for the HgO cathode can be represented by a simple reduction to elemental mercury with formation of inactive ZnO as the discharge product at the anode.

Recently, the area of battery thermodynamics has shown significant activity (1-4). This activity is in part explained by the commercial availability of very sensitive differential calorimeters designed to accept miniature sized batteries. The utility of these so-called microcalorimeters has been demonstrated in a number of applications. One application is the evaluation of self-discharge processes in small batteries (1, 9). These processes will, of course, determine the shelf-life of the cell and will also be important in determining the cell's operating life. Other processes, however, also contribute to the observed thermal effects. As they may not be related to capacity loss, a straightforward calculation of shelf-life from raw microcalorimeter data is often quite misleading. A second application is in the area of cell discharge mechanisms. Since the thermal effects measured are sensitive to the reaction path, mechanistic information can be obtained by comparing the results of the microcalorimeter experiment

* Electrochemical Society Active Member.
Key words: battery thermodynamics, silver oxide-zinc cells, mercuric oxide-zinc cells.

to predictions based on various models of the cell discharge (3, 4).

The purpose of the paper is twofold. The first goal is the derivation of an equation describing the dependence of the rate of heat release from a battery on the current flowing through the cell. The second goal is to present microcalorimeter data obtained for miniature alkaline cells of the types Ag_2O-Zn, HgO-Zn, and MnO_2-Zn and to analyze these data by means of the equation presented, thereby relating the results to the discharge mechanism.

Theory

The dependence of the rate of heat release in a galvanic cell on current flowing in the cell has been previously derived in a rigorous fashion (5-8). This exercise will be performed here in a totally nonrigorous way merely to establish notation.

The first law of thermodynamics may be written $\Delta U = Q - W$, whereby the increase of the internal energy (ΔU) of the system (battery) is given by the heat flowing into the system less the work done by the system in the surroundings. What is measured by the microcalorimeter is the rate of heat flow out of the system (battery), *i.e.*

$$\frac{d}{dt}(-Q) = \frac{d}{dt}(-\Delta U - W)$$

Now $\Delta U = \Delta H - p\Delta V = \Delta H_f + \Delta H_{nf}$ where $p\Delta V$ term vanishes, the battery being a constant volume, sealed system.[1] Also, $\Delta H_f = \Delta G_f + T\Delta S_f$ and $\Delta H_{nf} = \Sigma_i \Delta H_i n_i$ where the sum is over all non-Faradaic processes. Thus

$$\frac{d}{dt}(-Q) = \frac{d}{dt}[-\Delta G_f - T\Delta S_f - \Sigma_i \Delta H_i \nu_i - I^2Rt]$$

$$= \frac{d}{dt}\left[n\mathbf{F}E_o - Tn\mathbf{F}\left(\frac{\partial E}{\partial T}\right)_p - \Sigma_i \Delta H_i \nu_i - I^2R_Lt\right]$$

where R_L is the load resistance. Faraday's law may be written $It = n\mathbf{F}$. Consequently, for the Faradaic process $dn/dt = I/\mathbf{F}$. For the non-Faradaic processes, $d\nu_i/dt = v_i$ where v_i is the rate of the ith process. The equation can now be written

$$\frac{d}{dt}(-Q) = IE_o - IT\left(\frac{\partial E}{\partial T}\right)_p - \Sigma_i \Delta H_i v_i - I^2R$$

Now IR is the terminal potential and $E_o - IR$ is the polarization, η. Thus

$$\frac{d}{dt}(-Q) = \left[\eta - T\left(\frac{\partial E}{\partial T}\right)_p\right]I - \Sigma_i \Delta H_i v_i \quad [1]$$

which is the desired expression.

The shape of the curve obtained by plotting the calorimeter output *vs.* the current flowing through the battery will be determined by a number of factors. In the region of small polarization (*i.e.*, for small I), the curve will be essentially linear. As the current increases, η becomes larger and a divergence from linearity is observed. This is magnified by the fact that the rates of certain parasitic processes, v_i, are dependent on the concentration of certain species in solution, and a current dependence arises due to the last term in the equation. What we have is a limiting expression: as I approaches zero, linear behavior is observed.

Experimental

The microcalorimeter used in the present study is the Tronac Model 351 RA battery calorimeter. This device has been described extensively in the literature (1). The batteries used in the study are "Eveready" miniature alkaline cells. Pertinent data concerning cell specifications are given in Table I.

[1] The subscript "f" refers to Faradaic process, "nf" refers to non-Faradaic processes.

Table I. Specifications of batteries used in experiments

Cell type	UCC designation	Diameter (in.)	Height (in.)	Rated capacity (mA-hr)	Voltage (V)
Ag_2O-Zn	386	0.455	0.165	120	1.60
HgO-Zn	354	0.455	0.165	150	1.35
MnO_2-Zn	186	0.455	0.165	80	1.60*
HgO-Zn	E41	0.455	0.165	160	1.35

* Sloping discharge. Value reported is open-circuit voltage.

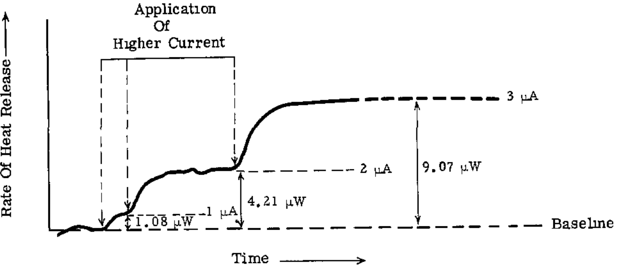
The value of the rate of heat release under open-circuit conditions was measured as follows. These cells were placed in an equilibration chamber immersed in the calorimeter water bath for 8-12 hr. The cells were then introduced into one of the microcalorimeter chambers designated as the sample chamber. The rate of heat release generally increased dramatically, but settled to a steady-state value within about 2 hr. This steady-state value minus the baseline value divided by the number of cells in the chamber is taken as the average rate of heat release.

Attempts to calculate shelf-life of a practical system from open-circuit microcalorimeter data are attended by many difficulties. As has been pointed out previously, many processes not associated with a decrease in capacity give rise to open-circuit heat production. As always, actual experimental determination of capacity following shelf storage is the most reliable indication of capacity maintenance.

To determine the rate of heat release under load, it was necessary to spot weld No. 25 AWG wires to both the cathode can and the anode cup of the cell. After equilibration, the cell was introduced into the sample chamber with the wires leading out to the surroundings. Here voltage measurements were obtained and resistors were attached. The wire was kept in good thermal contact with the aluminum calorimeter block to prevent spurious thermal effects.

To check the effectiveness of this technique, a 1 MΩ precision resistor was connected to two wires just as the cell was. Following equilibration, the resistor was placed in the sample chamber and the wires were connected to a Keithley Model 225 Current source. Figure 1 shows the result of successive applications of 1, 2, and 3 μA currents. The output power recorded agrees with that expected on the basis of heat dissipation due to I^2R loss. The wires exiting the chamber do not constitute a measurable heat leak.

All measurements were made at 25°C.



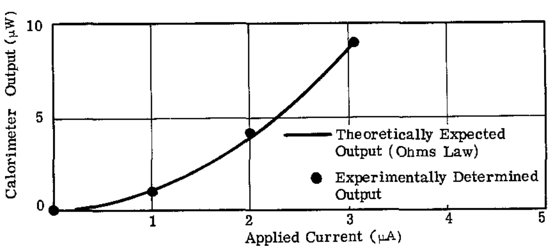


Fig. 1. Calibration of Tronac microcalorimeter by resistive technique.

Results and Discussion

The results of successive application of increasing loads to the cells, specified in Table I, are summarized along with polarization data and calculated values of current in Table II. The systems will be discussed individually.

Ag_2O-Zn.—Table II gives the values of the thermal effect along with the terminal voltage, load, polarization, and calculated current. As can be seen, the thermal output responds as would be expected: a smaller load results in a larger current and consequently, a larger thermal effect. The thermal effect is measured, as always, when the signal attains a steady-state value. Figure 2 is a plot of the rate of heat release (dQ/dt) *vs.* current (I). The discrete points are the experimental data. The data are linear over the region considered with intercept 2.1 μW and slope 74.3 mV. The solid curves are calculated using Eq. [1] with values of $(\partial E/\partial T)_p$ corresponding to formation of the oxidized forms of Zn indicated. The lower curve, that corresponding to the reaction

$$Zn + Ag_2O \rightarrow ZnO + 2Ag^\circ$$

fits the experimental values quite well. As is pointed out by Bode *et al.* (10), the thermal coefficient for the Ag_2O-Zn cell depends on the form in which the oxidized zinc deposits on the anode. Even if the electrolyte solution is not saturated with zincate, a thin film (oxide or hydroxide) is formed on the anode. It is this film that determines the anode thermodynamics, *i.e.*, the zinc electrode is an electrode of the second kind. If the film is inactive ZnO, the temperature coefficient for the cell is -0.177 mV/deg; if it is ϵ-$Zn(OH)_2$, the temperature coefficient is -0.337 mV/deg. Using Eq. [1] and the experimental slope (74.3 mV) yields an experimental value of $(\partial E/\partial T)_p$ of -0.175 mV/K. This analysis of the microcalorimeter data indicates that the discharge product is inactive ZnO.

HgO-Zn.—The No. 354 HgO-Zn cell attains steady-state values of heat release much as does the No. 386 Ag_2O-Zn. Table II summarizes the data. In an attempt to analyze the data using Eq. [1], the plots depicted in Fig. 3 were made. Two cell reactions were considered

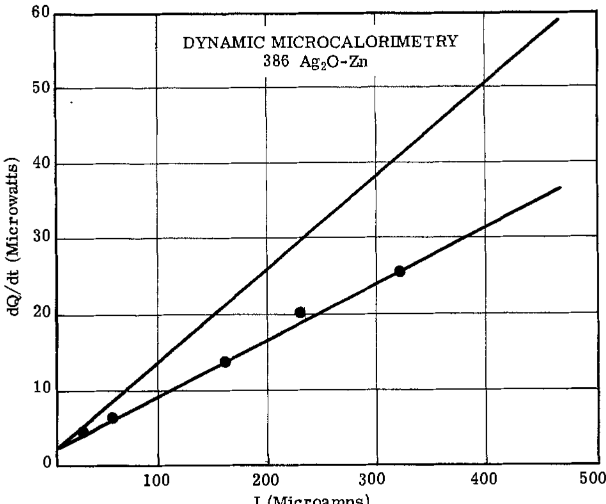

Fig. 2. Current dependence of the thermal effect for a No. 386 Ag_2O-Zn cell. The solid lines are calculated from theory based on $Zn(OH)_2$ (upper curve) and on ZnO (lower curve). The discrete points are experimental data.

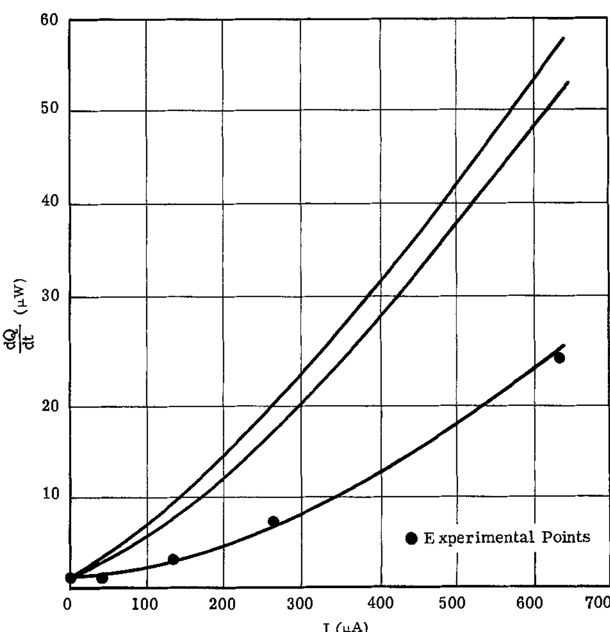

Fig. 3. Current dependence of the thermal effect for a No. 354 HgO-Zn cell. The solid lines are calculated from theory based on a two-electron reduction with $Zn(OH)_2$ formation (top curve), a two-electron reduction with ZnO formation (bottom curve), and a one-electron reduction with ZnO formation (middle curve).

$$Zn + HgO \rightarrow Hg + ZnO$$

$$\left(\frac{\partial E}{\partial T}\right)_p = 0.040 \text{ mV/K}$$

$$Zn + HgO + H_2O \rightarrow Hg + Zn(OH)_2$$

$$\left(\frac{\partial E}{\partial T}\right)_p = -0.128 \text{ mV/K}$$

As shown in the figure, the first reaction represents the experimental data well. Just as in the case of an Ag_2O-Zn cell, the discharge product at the anode is ZnO instead of $Zn(OH)_2$. That this is the case in these systems can be attributed to the small amount of water present in these limited electrolyte cells.

One other possibility which must be considered seriously is an alternate discharge mechanism proposed by Yosizawa *et al.* (11). According to this model, mercuric oxide is reduced to an intermediate product

which then disproportionates to elemental mercury and mercuric oxide

$$HgO + 1/2\,H_2O + e^- = (Hg_2O)_{1/2} + OH^-$$

$$2(Hg_2O)_{1/2} = HgO + Hg$$

Using an estimated value of $S°$ for Hg_2O (12) of 30 eu gives $(\partial E/\partial T)_p = -0.09$ mV/K. The resulting curve is also shown in Fig. 3. Clearly, it does not fit the data. Mercurous species are not part of the mechanism.

The behavior of the No. E41 cell is remarkably different from that of the No. 354 cell (see Fig. 4). The rate of heat release does not come to a steady-state value, but rather increases linearly with time. The difference between this cell and the No. 354 is the presence of MnO_2 in the cathode. The rate at which dQ/dt increases with time is a function of the current flowing through the cell, increasing with increasing current. Figure 4 shows the result of allowing the cell to remain on a 10 kΩ load. Increase of the thermal effect is observed for 17.5 hr. This corresponds to 91% of the MnO_2 contained in the cell, assuming a one-electron reduction. It should be noted that such an effect will not be seen in Ag_2O cells (*e.g.*, No. 386) since the MnO_2 potential is lower than Ag_2O. The first material to discharge in an Ag_2O cell is Ag_2O.

The behavior of the cells is explained by recalling the sigmoid nature of the MnO_2 discharge curve. After a load is applied to the cell, the voltage, and consequently the current, continues to decrease for a rather long time. The basic microcalorimetry equation must be written

$$\frac{dQ}{dt} = \left[\eta(t) - T\left(\frac{\partial E}{\partial T}\right)_p\right] I(t) - \Sigma_{nf}\Delta H_{nf} v_{nf}$$

The variation of the voltage of a No. E41 cell is shown in Fig. 5. If this data is inserted into the above equation, the experimental data (represented by the symbol ⊙) can be fit assuming a value of $(\partial E/\partial T)_p = -49$ μV/K (see Fig. 6).

MnO_2-Zn.—The fact that MnO_2 is responsible for the unique behavior of fresh E41 cells is corroborated by microcalorimetry experiments on the No. 186 MnO_2-Zn cells. Figure 7 shows the data obtained by applying various loads to the cell. The same linear variation of thermal effect with time is observed indicating that MnO_2 is the material responsible for the unique behavior of the E41 cell. Reaction products cannot be determined by this method for systems with cathodes exhibiting such variations of operating potential with time.

Conclusions

It has been shown that microcalorimetry is an effective tool for the generation of mechanistic information for practical battery systems. An expression for the dependence of the rate of heat release on current has been derived. This expression has been used to analyze data obtained for an Ag_2O-Zn and for an HgO-Zn

cell. In both cases it is found that ZnO is formed rather than $Zn(OH)_2$ upon discharge. The effect of time variation of the cell polarization on the thermal effect has been observed in certain cells containing MnO_2. This effect is attributed to the sigmoid nature of the MnO_2

discharge, and thus, ultimately, to the mechanism of MnO_2 reduction.

Acknowledgment

The authors would like to thank S. J. Cieszewski for her able assistance in performing the microcalorimeter experiments and in organizing the data.

Separation Between Deterministic Response and Random Fluctuations by Means of the Cross-Power Spectrum in the Study of Electrochemical Noise

Ugo Bertocci*

National Bureau of Standards, Chemical Stability and Corrosion Division, Washington, D.C. 20234

ABSTRACT

It is shown that by calculating the cross-power spectrum between the input (the electrode potential) and the output (the cell current) of an electrochemical system under potentiostatic conditions, it is possible to identify which part of the cell current is the response to the input voltage and which part is caused by random fluctuations of the parameters characterizing the electrode. The noise introduced by the amplifiers can be measured separately and then subtracted from the signal. As an example, the current noise of an aluminum electrode below and at the pitting potential is examined. Both electrode impedance and spectral power density of the random fluctuations are obtained. It is shown that below the pitting potential random fluctuations are below the minimum detectable value of 10^{-23} A^2/cm^4 Hz.

In the analysis of electrochemical noise, an important problem is that of knowing which part of the output signal is caused by the input (*i.e.*, the deterministic response to the input) and which is caused by random fluctuations of the parameters characterizing the electrochemical system under study. Both parts can give important information, as long as they can be properly identified. The analysis is further complicated by the noise introduced by the amplifiers necessary to detect the generally small signals.

Digital signal processing equipment can be used, with the aid of the Fast Fourier Transform algorithm, to transform the signal received into the frequency domain, which simplifies the task of analyzing and manipulating the results. A two-channel spectrum analyzer can receive a signal which is the difference between reference electrode and working electrode as well as a second signal proportional to the current flowing into a three-electrode, potentiostatted cell, and calculate the cross-power spectrum between the two signals. The purpose of this note is to show that the cross-power spectrum can be employed for separating the various components of the output signal.

* Electrochemical Society Active Member.

Key words: aluminum, cross-power spectrum, electrochemical noise, electrode impedance, pitting.

Statement of the Problem and Mathematical Treatment

In electrochemical studies it is expedient in general to maintain the working electrode at constant potential by means of a potentiostat, and to observe and analyze the current output of the cell. Such a current output can be the deterministic response of the system to the input signal provided by the potentiostat or can be caused by internal fluctuations of the characteristics of the electrode, such as changes in surface area, crystal orientation of the surface, and film coverage, or processes such as passive film breakdown and repair, pitting, or other localized corrosion processes.

The internally generated noise, therefore, can give information relative to the magnitude and relaxation times of the electrode processes (1). It has been used, for instance, for the detection of the onset of pitting (2), to monitor the effect of corrosion inhibitors (3), and to study electrocrystallization (4), and anodic dissolution (5).

The experimental problem consists in detecting the signal, that is, amplifying it to a level sufficient for processing, and distinguishing which part of the signal is deterministic, random, or caused by the instrumentation.

The circuit with its sources of signal can be schematized as shown in Fig. 1. The potentiostat delivers a control voltage, the input to the electrochemical cell, which consists of a constant (d-c) voltage and of broad-band noise caused by the instability of such a d-c level. To this a signal may be added, produced by a signal generator. This additional signal can be a constant amplitude sinusoid, a swept frequency signal ranging between two predetermined frequencies, or white noise. The symbol X represents here the a-c part of the input signal, expressed as a function of frequency, $X = X(\nu)$. Such a signal can be quite small, ranging in amplitude between 10^{-4} and 10^{-8}V. An amplifying stage is therefore necessary for its detection and processing, adding noise with spectrum $N_I(\nu)$ to the signal. The output of the first channel of the spectrum analyzer is therefore $A = X + N_I$.

The input signal generates a current in the cell. H represents the cell transfer function so that the output $Y(\nu)$ in the frequency domain is $Y = HX$. For an electrochemical cell H is the admittance, which is in general complex and frequency dependent. Random fluctuations of the electrode characteristics generate an additional noise current $N(\nu)$. The total current is transformed in an appropriate current-to-voltage converter (schematically indicated in Fig. 1) from which the signal emerges with noise $N_O(\nu)$ added at the output of the amplifying stage. The output of the second channel of the spectrum analyzer is therefore $B = Y + N + N_O$.

The auto- and cross-power spectra are, respectively

$$P_{AA} = (X + N_I)(X + N_I)^* = P_{XX} + P_{II} \quad [1]$$

$$P_{BB} = (HX + N + N_O)(HX + N + N_O)^* = |H|^2 P_{XX} + P_{NN} + P_{OO} \quad [2]$$

$$P_{BA} = (HX + N + N_O)(X + N_I)^* = HP_{XX} \quad [3]$$

The terms marked with an asterisk are the complex conjugates of those without asterisk. In deriving [1], [2], and [3] it is assumed that all noise signals are uncorrelated with the input and with one another, so that the average values of the cross-products are zero

$$XN_I^* = N_IX^* = XN^* = NX^* = XN_O^* = N_OX^* = 0 \quad [4]$$

Fig. 1. Schematic representation of the measurement system with noise sources and spectrum analyzer outputs identified.

It should be remembered also that experimentally the spectrum analyzer averages out a large number of time records of the signals, so that, at least asymptotically, [4] is valid.

Taking [4] into account, Eq. [1], [2], and [3] contain five unknowns. It is therefore necessary to determine experimentally two of the unknowns in an independent way. This can be accomplished in the following manner: when the input of the amplifier of the voltage signal is short-circuited, X is effectively zero and therefore

$$(P_{AA})_{X=0} = P_{II} \quad [5]$$

the auto-power spectrum of the amplifier noise. This spectrum can be measured and stored in an appropriate memory. For the measurement of the current amplifier noise N_O it is sufficient to substitute the electrochemical cell with a resistor. Increasing the value of such a resistor decreases the current signal Y until the output of channel B becomes independent of the value of the resistance. In these conditions

$$(P_{BB})_{Y=0} = P_{OO} \quad [6]$$

Since a resistor has been substituted for the cell, no random fluctuations occur and therefore $N = 0$. The auto-power spectrum P_{OO} is also recorded and stored. Once P_{II} and P_{OO} are subtracted from P_{AA} and P_{BB}, it is easy to solve the system of equations so that H and N can be obtained.

Experimental Procedure

The measurements described here were taken with an experimental setup similar to that reported previously (6), which is a practical implementation of Fig. 1. The potentiostat employed, especially built for its low noise, has been described elsewhere (7). The analyzing instrument was a digital two-channel spectrum analyzer which provided the auto-power spectra of the two channels as well as the coherence function γ^2, which is defined as

$$\gamma^2 \equiv \frac{|P_{BA}|^2}{P_{AA}, P_{BB}} \quad [7]$$

and from which, therefore, the cross-power spectrum can be obtained. As it is well known, the coherence function γ^2 ranges from 1, when the output signal is entirely deterministic, to 0 when there is no casual relationship between P_{AA} and P_{BB}.

The electrochemical system investigated was aluminum in borate buffer (pH = 7.5), to which 0.01 mole/liter of NaCl was added. At potentials more positive than −650 mV *vs.* SCE this electrode undergoes pitting [8], whereupon the noise pattern of the current changes drastically (9). The measurements were carried out at −700 and at −650 mV *vs.* SCE. In some runs white noise of the order of a few $\mu V/\sqrt{Hz}$ were added to the control voltage of the potentiostat. The spectrum analyzer, which has a frequency resolution of 1/256 of the range, was set for a 51.2 Hz range, so that the resolution was 0.2 Hz.

The results reported here were obtained manually; the spectra and the coherence function were recorded on an X-Y recorder and the calculations were done for only a few of the 256 points available. Such an experimental procedure is slow and tedious, but it was used to test the capability of the method. However, the spectrum analyzer can be interfaced to a computer so that acquisition, storage, and subtraction of the instrumental noise spectra P_{II} and P_{OO}, as well as all necessary calculations, can be carried out under software control with minimum time delay.

Experimental Results

The auto-power spectra of the noise N_I ofthe amplifier operating on the input signal (the electrode potential) and that of the noise N_O of the output amplifier operating on the cell current were measured over a

wide frequency range, and are shown in Fig. 2. Since P_{OO}, the power spectrum of the current amplifier, is added to the current signal, it is given in current units, A^2/Hz. These spectra are averages over a number of repeat measurements, ranging from 512 at high frequency to 64 at low frequency, where the total acquisition times are of the order of 1 hr.

Results obtained on the Al electrode below (−700 mV *vs.* SCE) and at the pitting potential (−650 mV) in the absence of an external signal in the control voltage are shown in Fig. 3 and 4. The auto-power spectrum of the voltage is that of channel A and it is given in V^2/Hz. Channel B shows the current power spectrum in A^2/Hz. In order to facilitate comparisons the current spectra are not given in units of current density (P_{OO} is independent of surface area), but they can be easily and quite precisely transformed into A^2/cm^4Hz by dividing by 10, since the electrode surface area in all experiments was 3.17 cm^2. The figures show also the coherence function *vs.* frequency. Figure 5 shows power spectra and coherence function for an electrode at the pitting potential when white noise of 2 $\mu V/\sqrt{Hz}$ was applied as an external signal.

From these data, according to the calculation method described earlier, the auto-power spectrum of the random fluctuations P_{NN} and the absolute value of the electrode impedance $|Z| = 1/|H|$ were obtained. They are shown in Fig. 6 and 7, respectively.

Discussion

The results presented here show a number of interesting features and illustrate the usefulness of quantitative criteria for identifying the sources of noise. For instance, although the voltage spectra in Fig. 3 and 4 are virtually identical, the current spectrum is much larger at −650 mV (Fig. 4), confirming that the noise level increases considerably when pitting begins (9). However, the coherence function in Fig. 3 indicates that a substantial part of the signal in channel B is not

causally related to the input, but such a noise may either be instrumental or may mark the beginning of the breakdown of the protective oxide film. However, when the separation of the noise sources is carried out, it is found that P_{NN} at −700 mV is practically zero over the whole frequency range studied. An upper value can be set for P_{NN} at about $10^{-22}A^2/Hz$ (or $10^{-23}A^2/cm^4Hz$), which is of the order of one-tenth of the instrumental noise as indicated by P_{OO}. The difference between the value of the coherence function in Fig. 3 and unity can be accounted for entirely by the instrumental noise.

The impedance, shown in Fig. 6, corresponds essentially to the behavior of a capacitor of about 1.5 $\mu F/cm^2$. The corrosion resistance cannot be determined with assurance because of the limited frequency range studied, but is larger than 60 $k\Omega \cdot cm^2$. Here the advantage of adding white noise to the input signal is shown by the data in Fig. 5, from which the deterministic response can be recovered in spite of the random fluctuations, while no reliable value of $|Z|$ can be calculated from Fig. 4 below 30 Hz because γ^2 is too close to zero.

In conclusion, with the aid of an instrument capable of processing voltage and current signals simultaneously and of calculating the cross-power spectrum, random noise can be separated from the deterministic response. Sensitivity is also enhanced, and noise about one-tenth of the instrumental noise can still be detected. However, it is evident that the noise level of the amplifier operating on the cell current is the main factor limiting the detectability of the random fluctuations of the electrode characteristics, and that its reduction would improve considerably the performance of the whole system.

As far as the pitting of Al is concerned, these rather limited results give nevertheless some interesting information. First of all, the impedance data of Fig. 6 show that, although pitting causes large current fluctuations, the deterministic behavior below and at the pitting potential is substantially the same. The random noise spectra of Fig. 7 show that reproducibility is only fair, as to be expected since number and size of the pits tend to vary from experiment to experiment. The major point seems to be that the amplitude of the fluctuations decays approximately as the reciprocal of the frequency, like the "flicker" noise observed in electronic devices (10). The decay with frequency also indicates that the capacitance of the electrode undergoes smaller fluctuations than the resistance during the pitting process (9).

Finally, the results have shown that the degree of random fluctuations below the pitting potential is so low that the picture of the protective film on aluminum as being in a state of dynamic equilibrium with continuous breakdown and repair does not seem to be supported by the experimental evidence.

The Dissolution and Passivation of Zinc in Concentrated Aqueous Hydroxide

M. C. H. McKubre* and D. D. Macdonald*,[1]

ABSTRACT

The rotating ring-disk electrode has been applied in this study to the related phenomena of dissolution, current oscillation, and passivation of zinc in concentrated aqueous NaOH. The results of potentiostatic and potentiodynamic experiments are compared with those of previous workers, and a physical model is proposed to describe the anodic behavior of zinc in four successive potential regions: active dissolution, prepassivation, pseudopassivation, and true passivation.

The requirements for high specific energy, high specific power, and low cost make zinc an attractive negative electrode material for aqueous alkaline batteries in electric vehicular applications (1). However, a number of specific limitations await satisfactory resolution. Recent studies have been concerned with the limitations of cycle life associated with dendritic (2-5) and nonadherent (6-9) zinc deposition during charging, and with the problems of electrode shape change with cycling (1, 2, 10). The shelf life and cycle life of zinc battery electrodes is also limited by the corrosion of zinc in concentrated alkali (11-13).

In the present study we focus on the related processes of anodic dissolution and passivation. Rapid discharge of the zinc electrode is associated largely with the high solubility of Zn(II) as a zincate ion (14, 15) in alkaline solutions. At high currents, however, zinc discharge is often inhibited by the formation of a passivating zinc oxide or hydroxide layer by a dissolution-precipitation mechanism (16-28). Before the onset of passivation, the discharge of zinc is generally agreed (21) to proceed via the formation of complex hydroxyl zincate anion. The nature of this anion has been the subject of considerable thermodynamic (14, 29-31) and spectroscopic (15, 32-34) investigation, and is thought to have the form $Zn(OH)_4{}^{2+}$ in strongly alkaline solutions. However, the spectroscopic investigations of Jackovitz and Langer (32) suggest that "only a small fraction, about one-sixth of the anodically dissolved zinc, was converted to $Zn(OH)_4{}^{2-}$"

Experimental Procedure

Experiments were performed using a rotating ring-disk electrode (RRDE). The importance of adequate hydrodynamic control in studies of zinc dissolution and passivation phenomena has been stressed by several authors (20, 26, 35, 36).

The RRDE was constructed using a vitreous carbon[2] ring with a 99.999% purity zinc disk, as shown in Fig. 1. Vitreous carbon constitutes a nearly ideal, nonporous, inert ring material for current collection at large cathodic potentials. The radius ratios r_3/r_2 and r_2/r_1 exceed those tabulated by Albery *et al.* (37) and Pleskov (38), and the electrode collection efficiency was determined experimentally in 0.1M $K_3Fe(CN)_6$ with 1.0M NaOH supporting electrolyte. This calibration procedure has been described previously (39). At 20°C the measured collection efficiency was 70.9 ± 0.2%. Details of the rotating ring-disk electrode construction are shown in Fig. 1.

Experiments were conducted in an all Teflon cell shown in Fig. 2, situated in a water-ethylene glycol bath controlled to within ± 0.1 K. Potentiodynamic control of the disk and *IR* compensation were accomplished using a PAR Model 173 potentiostat and Model 175 potential programmer. The disk current and charge were recorded using a PAR model 179 digital coulometer. Potentiostatic control of the ring electrode was achieved using a purpose-built, high-speed potentiostat electrically isolated from the disk control circuit.

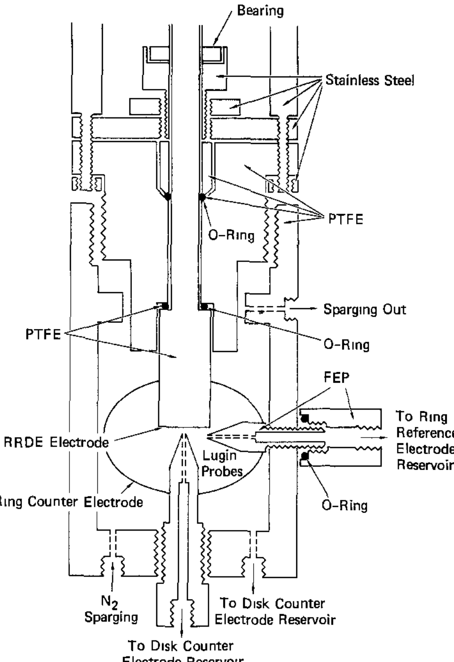

Fig. 2. RRDE cell construction

Details of the ring potentiostat, and six electrode cell geometry have been described previously (39, 40).

RRDE studies were performed in 9.78m [28 weight percent (w/o)] NaOH, prepared using analytical grade NaOH and water doubly distilled from deionized stock. The second distillation was under high purity nitrogen to exclude atmospheric CO_2, and the cell was continuously sparged with N_2 except during periods of measurement.

The RRDE electrode was polished with varying grades of carborundum paper, the final grade having 25 micron particle size. The electrode assembly was degreased with hot ethanol in an ultrasonic bath, then rinsed with distilled water immediately prior to use.

Results

Figure 3 shows schematically the general features observed during a slow anodic potentiodynamic sweep covering the zinc discharge region in initially zincate-free NaOH. The region "b" is characterized by an exponential dependence of the dissolution current on applied potential (31, 36, 41). The current increases in a nearly linear fashion with potential (25, 36) between "b" and "c" reaching a maximum at "d" and attaining a plateau value "e" before passivation. Two peaks in the region "cf" have been observed at very low potential sweep rates (< 1 mV sec^{-1}) by other workers (21, 26, 42). The peaks were interpreted by Powers and Breiter (21) in terms of growth of two surface oxide films. The features shown in Fig. 3 represent the limiting low rate potentiodynamic sweep behavior, and we have observed no evidence for a second peak under controlled hydrodynamic conditions.

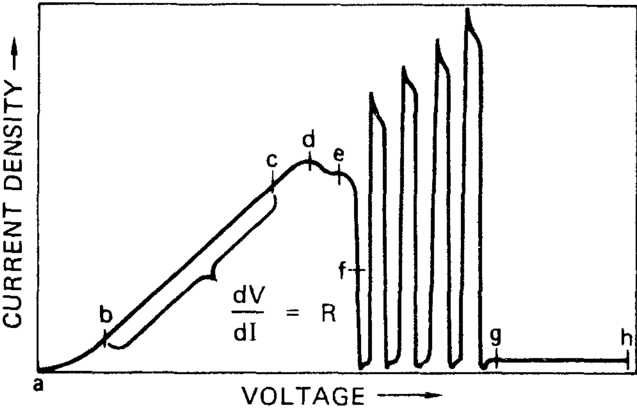

Fig. 3. Anodic potentiodynamic sweep of zinc in aqueous NaOH

Active dissolution.—We observed that the form of the repetitive sweep voltammogram depends critically on both electrode rotation speed and electrolyte temperature. Figure 4 shows the influence of rotation speed and Fig. 5 shows the influence of temperature on the zinc voltammogram. It is immediately apparent from Fig. 4 that the peak and plateau currents, as well as the slope in the linear *I-V* region, are strongly influenced by electrolyte convection at low sweep rates, suggesting that these are controlled not by factors at the zinc/electrolyte interface, but by processes within the diffusion layer.

The data in the region "bc" were analyzed as a function of temperature and rotation speed and the results are presented in Table I. The linearity of this portion of the current voltage curve is reflected in the near-unity values of the regression coefficients shown for an equation of the form

$$V = V_o + IR$$

It is clear from the values in Table I that V_o is effectively independent of ω, while R decreases monotonically with ω and T.

The linear dependence of the dissolution current on applied potential indicates that electrode discharge in

this region is not determined by ionic diffusion of OH^- to, or product from the interface. Sanghi and Fleischmann (42) discounted mass transport limitation by OH^- ions, observing that the maximum dissolution rate is only a fraction of the limiting diffusion current of hydroxyl ions at bulk concentration greater than 0.01M. However, resistive (migration) limitation, which is functionally dependent on the rate of electrolyte convection, suggests that the process that determines the Zn electrode discharge rate occurs either within the diffusion layer or within a surface film, the thickness of which is determined by ablation or dissolution to the bulk electrolyte.

As expected for a process occurring within the diffusion layer, the dissolution resistance values presented in Table I are approximately linear with the inverse square root of electrode rotation speed

$$T = -15°C, \quad R = 12.17 + 60.74\,\omega^{-1/2}, \quad r^2 = 0.992$$

$$T = 0°C, \quad R = 4.74 + 26.38\,\omega^{-1/2}, \quad r^2 = 0.968$$

$$T = 41°C, \quad R = 1.39 + 19.09\,\omega^{-1/2}, \quad r^2 = 0.997$$

$$T = 80°C, \quad R = 0.33 + 20.13\,\omega^{-1/2}, \quad r^2 = 0.992$$

$$T = 106°C, \quad R = 0.48 + 4.08\,\omega^{-1/2}, \quad r^2 = 0.991$$

Powers and Breiter (21) observed for Zn in KOH that, although faceting of the single crystal surfaces occurs in the linear-I-V region, there is no direct evidence of film formation until very near the potential at which the current density is a maximum, *i.e.*, near "d." In a subsequent publication, Breiter (25) suggested that the linear region may result from the initial formation and spreading of a compact film across the surface. This proposal appears to conflict with their previous observation (21), and is clearly inconsistent with the rotation speed dependence of R observed in the present study. Armstrong *et al.* (36, 41) ascribe an observed I^{-1} *vs.* $\omega^{-1/2}$ linearity for the initial dissolution of Zn in NaOH to a $Zn \rightleftarrows Zn(OH)_4^{2-}$ equilibrium process in which current limitation is imposed by the diffusion of zincate to the bulk. This model has been extended (34) to predict an exponential dependence of I_∞, the current extrapolated to the limit of high rotation speed, on the applied overvoltage, $V - V^o$. Figure 6 shows plots of I_∞ and ln I_∞ *vs.* applied potential. Values of I_∞ were calculated by the linear regression of I^{-1} *vs.* $\omega^{-1/2}$ data, extrapolated to $\omega^{-1/2} = 0$, for varying temperatures and voltages in the region "bc," during a slow (5 mV sec^{-1}) anodic potentiodynamic sweep. While the data in Fig. 6(a) may be construed as straight lines in accordance with Armstrong's model (36, 41), a significantly better fit to the data is shown in Fig. 6(b). The vectors shown are regression lines for all data presented in Fig. 6(a).

To elucidate further the mechanisms of Zn dissolution, we determined the fraction of the dissolved zinc species that was reducible at the vitreous carbon ring. Three striking results immediately were apparent from the study.

1. Under all conditions, the fraction of dissolved zinc detected at the ring was less than that predicted by the calibrated collection efficiency.

2. The fraction at the dissolved zinc that was collected was a function at the electrode rotation speed.

3. When corrected for the increasing background current, the percentage of collected material increased with an increasing concentration of dissolved zinc in the bulk electrolyte.

Figure 7 shows the influence of rotation speed on disk and ring currents in initially zincate-free solution. The collection percentages shown at each rotation speed are determined from the current peaks for i_d and i_r, appropriately corrected for background currents, expressed as a percentage of the calibrated collection

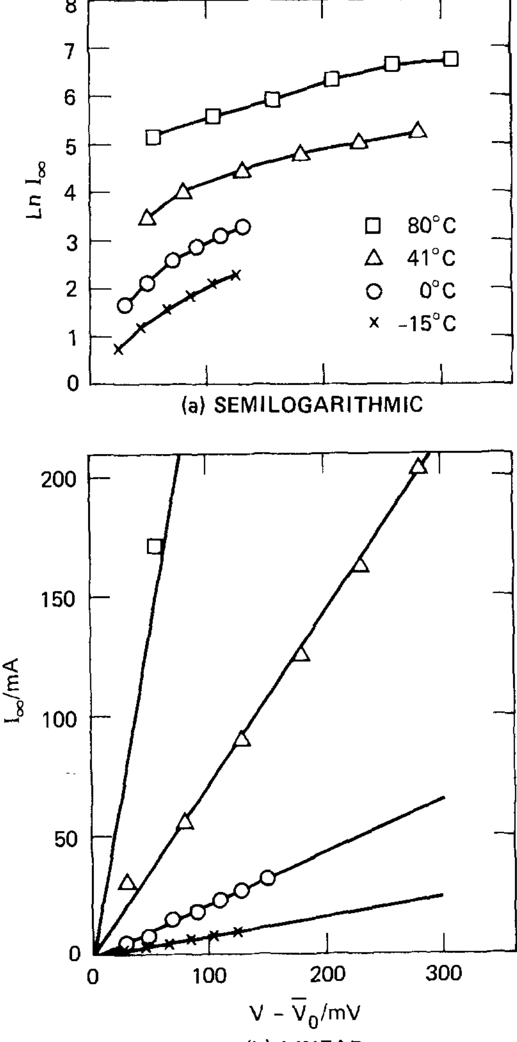

Fig. 6. The current extrapolated to infinite rotation speed *vs.* applied potential: 28 w/o NaOH, sweep rate 5 mV sec^{-1}.

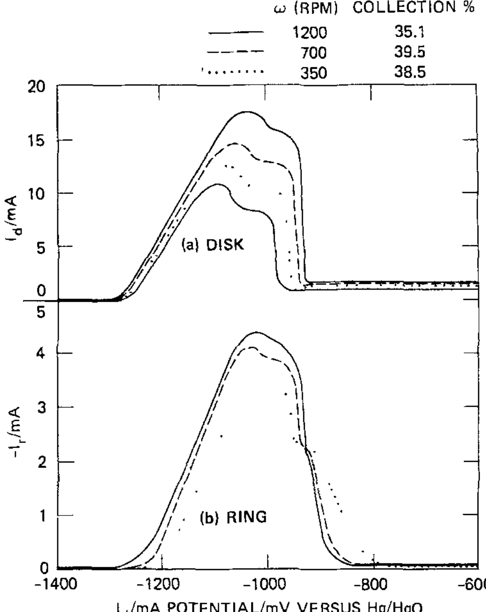

Fig. 7. RRDE study of zinc during anodic potentiodynamic sweep at 5 mV sec^{-1}: 28 w/o NaOH, 15°C.

efficiency. The concentration of dissolved zinc was then increased by controlled coulombic electrochemical dissolution of an auxiliary zinc electrode within the cell. Collection percentages determined at the peak are plotted *vs.* rotation speed in Fig. 8, together with data obtained at a single potential in initially zincate-free NaOH.

It is apparent from Fig. 8 that the percentage of dissolved zinc species that is reducible declines at high rotation speed, but increases with dissolved zinc concentration. The apparent small decreases in collection at very low rotation speeds seems to be an artifact of the ring disk system. A decrease in collection percentage at high rotation speed has been observed previously (17) and may be interpreted as follows. The

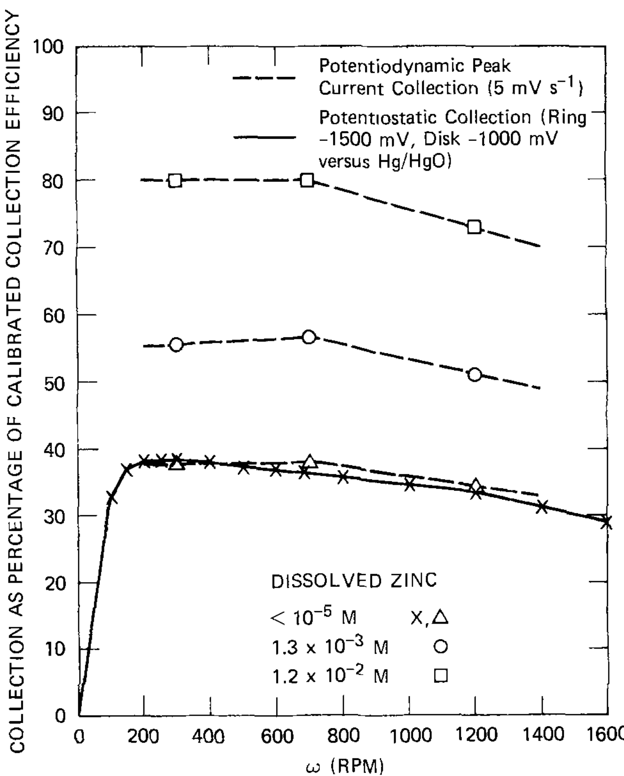

Fig. 8. Collection percentage *vs.* electrode rotation speed as a function of dissolved zinc concentration: 28 w/o NaOH, —15°C.

anodic charge transfer process produces an inactive intermediate, which transforms in time to the electrochemically active products by chemical dissolution. It is this final product that is reducible on the ring. Using laser Raman techniques, Kato and co-workers (17) suggested that this product is $Zn(OH)_4^{2-}$. If we assume that the intermediate is a dissolved Zn(II) species, then the model for dissolution is consistent with that originally proposed by Gerischer (43) and provides a mechanism for subsequent passivation

$$Zn + nOH^- \rightleftarrows Zn(OH)_n^{2-n} + 2e^-$$

$$Zn(OH)_n^{2-n} + (4-n)OH^- \rightarrow Zn(OH)_4^{2-}$$

where

$$0 \leq n \leq 3$$

This second reaction proceeds at a moderate rate. At high rotation speeds the intermediate species has insufficient time to transform to the reducible zincate ion, and the amount of species collected at the ring is less.

Passivation.—It is helpful to divide the passivation of Zn in concentrated aqueous hydroxide into three separate regions of applied potential: prepassive, pseudopassive or unstable, and true passive regions. The potentiokinetic current behavior within these regions is shown schematically in Fig. 3.

Prepassive region.—At potentials more positive than "d," a white flocculent film is observed (21) to be deposited on the electrode. This has been associated (21, 24, 25) with the precipitation of $Zn(OH)_2$ from a near-surface solution supersaturated with $Zn(OH)_4^{2-}$. The dissolution current is reduced by the three-dimensional porous film, possibly as a consequence of the reduced effective surface area. A well-defined current plateau, "e" with current $\alpha\omega^{1/2}$, is seen at low temperatures. It is apparent from the work of Breiter (21, 25) that passivation is not caused by the porous $Zn(OH)_2$ film, but by a thin, compact, adherent film that forms directly on the zinc surface. We will adopt the nomenclature of Powers and Breiter (21), and refer to these films as types I and II, respectively. While the type I film is not passivating, we believe that its existence is required for the formation of a passivating type II film.

Unstable region.—The onset of passivation is rapid but not irreversible. Under potentiostatic or slow potentiodynamic sweep conditions, we have observed zinc electrodes to undergo an oscillatory activation/passivation process within a defined potential region "fg." Current and potential oscillations have been observed previously (44-50) for a variety of systems including Zn in aqueous hydroxide (50, 51). Hampson *et al.* (18) observed that a passivated zinc electrode becomes dispassivated after it is "rested for a few minutes," and that depassivation becomes more rapid as the electrolyte temperature and concentration are increased. Breiter *et al.* ascribed fluctuations (21) and current oscillations (25) under potentiodynamic sweep conditions to buckling and tearing of the compact type II film. A close examination of this phenomenon provides a considerable insight into the mechanisms of passivation.

Figure 9 shows the broad potential region of current instability observable at elevated temperatures under single anodic potentiodynamic sweep conditions. The envelope of current peaks extends the region of current-voltage linearity discussed in the previous section. Thus, the current upon reactivation appears initially to be determined by the same diffusion layer resistance we believe is associated with active zinc dissolution.

Onset potentials for passivation are shown in Fig. 10, superimposed upon the reversible potential profiles calculated (52) for pertinent redox reactions in 9.7m NaOH. Under the conditions of our experiments, passivation occurs well into the potential regions of ZnO

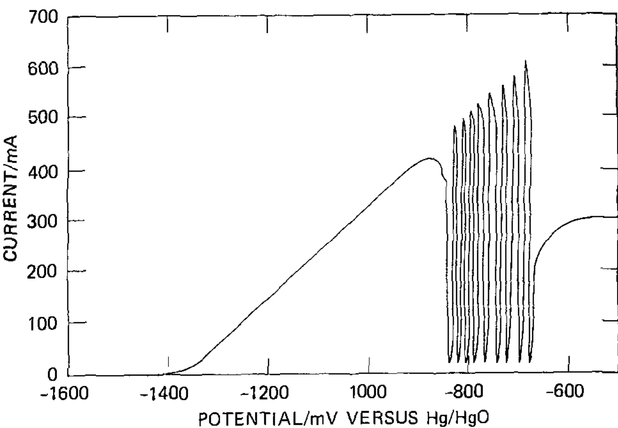

Fig. 9. Current oscillations of zinc during anodic potentiodynamic sweep at 5 mV sec^{-1}: 28 w/o NaOH, 80°C, 600 rpm.

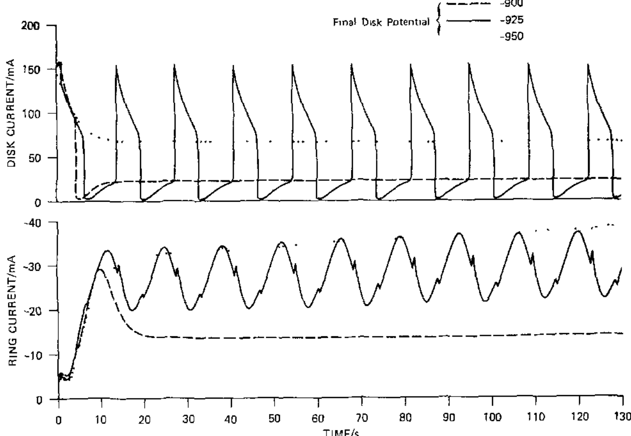

Fig. 11. RRDE potential step experiment for zinc in 28 w/o NaOH at 22.5°C. Ring potential and initial disk potential —1500 mV vs. Hg/HgO.

and $Zn(OH)_2$ stability, and there is little correlation between initial passivation and the reversible potentials calculated for the formation of latently passivating oxide species. Under potentiodynamic conditions the passivation potential increases approximately linearly with temperature, with a slope that increases with increasing rotation speed.

Further information regarding current instability can be obtained by using the vitreous carbon ring to monitor the concentration of reducible Zn species adjacent to the electrode. Figure 11 shows the results of RRDE potentiostatic step experiments at 22.5°C and at 300 rpm. Under these conditions oscillation is confined to a $\pm$ 25 mV region. On the time scale shown, passivation and reactivation occur virtually instantaneously. By using a Biomation Model 805 Wave Form Recorder in the pre-trigger mode, we ascertained that reactivation occurs in tens of milliseconds, and passivation somewhat less quickly. The nearly sinusoidal ring current perturbation reflects the concentration wave of reducible zinc ions that propagates through the electrolyte as a result of intermittent disk dissolution. The glitches appearing on the ring current sinusoid result from coupling of the ring and disk currents (40, 53) and are artifacts of the RRDE system.

Under controlled hydrodynamic conditions, oscillations appear to be sustainable indefinitely. However, both amplitude and period are markedly influenced by step potential, temperature, and rotation speed. Below room temperature, oscillation is observed at $\omega \leq 300$ rpm. At 41°C, oscillation occurs for $\omega \leq 600$ rpm, and above 80°C it may be sustained at all rotation speeds accessible to us (up to 1200 rpm). Figure 12 shows the limits of potential over which oscillation occurs in a quiescent system as a function of temperature.

Discussion

In the preceding sections we described the chronology of Zn anodization under controlled potential conditions, comparing our experimental results with the conclusions of previous authors, as a first step in the development of a self-consistent picture of the passivation of zinc. The sequence of important processes that require explanation may be summarized as follows.

1. Following an initial Tafel region, the zinc dissolution current increases linearly with applied potential, the resistance being proportional to the diffusion layer thickness.

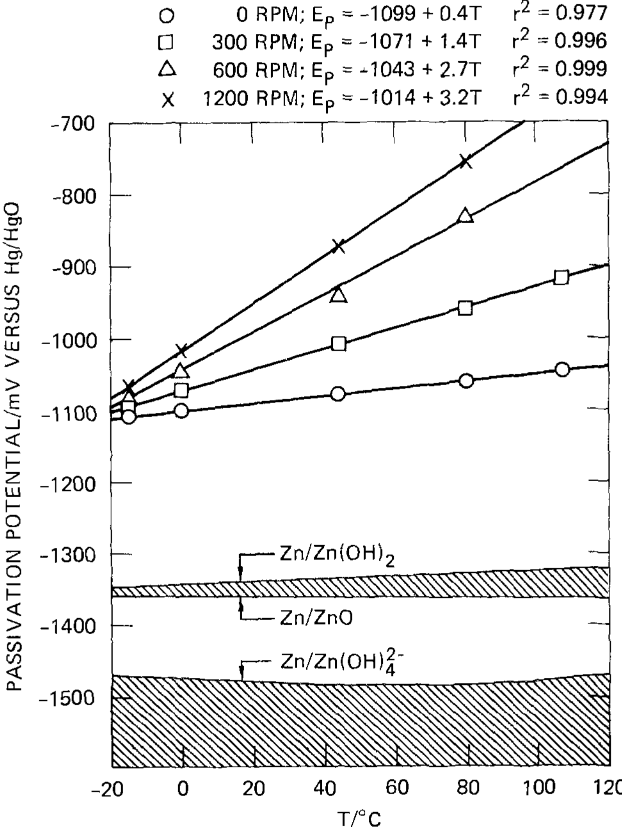

Fig. 10. Measured passivation onset potentials and calculated reversible potentials vs. temperature, for zinc in 28 w/o NaOH.

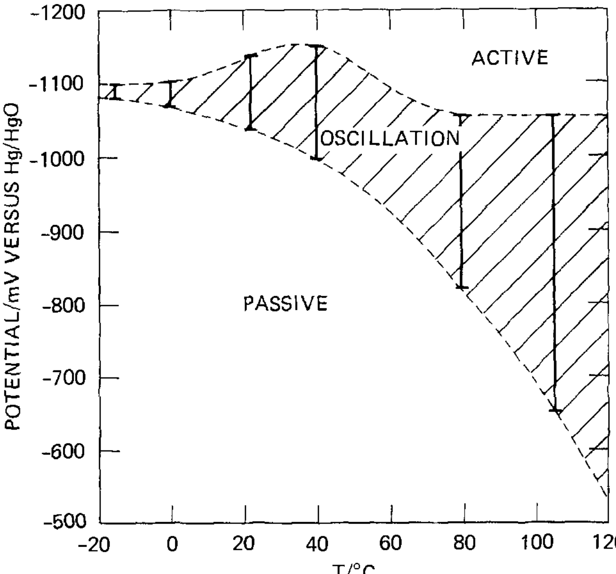

Fig. 12. Region of current instability for zinc in 28 w/o NaOH under quiescent conditions.

2. Zinc dissolves electrochemically via an intermediate species to a final product believed to be $Zn(OH)_4^{2-}$.

3. $Zn(OH)_2$ precipitates on the electrode in a prepassive region, producing a loose flocculent film denoted as type I (21, 25).

4. The temperature and convection dependence of passivation are consistent with a dissolution-precipitation mechanism, but the electrode is passivated by the formation of a compact, adherent (type II) film directly on the Zn electrode surfaces (21, 25).

5. Rapid reactivation may occur within a defined region of potential, the current initially attaining a value equivalent to the extrapolation of the linear *I-V* active dissolution region.

6. Current oscillations may effectively be sustained indefinitely and result in a near sinusoidal reducible Zn concentration wave in the electrolyte. The potential region of instability is strongly influenced by electrolyte temperature and convection, but is not correlated with known thermodynamic processes.

7. At sufficiently large anodic potentials, true passivation occurs, which results in a passive dissolution current independent of potential and time.

These observations are consistent with the following model. Initial dissolution proceeds according to the overall Eq. [1]

$$Zn + 4(OH)^- \rightleftarrows Zn(OH)_4^{2-} + 2e^- \quad [1]$$

At a potential roughly corresponding to the onset of linear current-voltage behavior, the Zn/ZnO reversible potential is exceeded (51, 52) and the predominant electrode reaction becomes

$$Zn + 2\,OH^- \rightleftarrows ZnO + H_2O + 2e^- \quad [2]$$

Because hydroxide ions are the reactant in Eq. [2], there is no supporting electrolyte. Under these conditions an impedance term must be included to account for the migration resistance (54-58). We propose that at moderate current densities the resistance due to the migration of OH^- ions becomes rate limiting.

ZnO forms on the electrode and then dissolves by reaction with further hydroxide to form the zincate ion

$$ZnO + H_2O + 2\,OH^- \rightleftarrows Zn(OH)_4^{2-} \quad [3]$$

When the electrolyte in the immediate vicinity of the electrode becomes supersaturated with zincate, $Zn(OH)_2$ precipitates on the electrode forming a porous (type I) film. Dissolution proceeds according to reaction [3] until the *p*H within the porous film is reduced to the extent that ZnO is insoluble (24). At this stage the electrode passivates due to the surface formation of a thin compact ZnO (type II) layer. With the reduced dissolution current, the zincate concentration declines and the *p*H increases, redissolving the $Zn(OH)_2$ (type I) and ZnO (type II) films. This mechanism is consistent with the observation (59) that Zn can be reactivated in a thin layer cell by the addition of very small amounts of fresh hydroxide. In the absence of the type I film, reactivation results initially in a current limited only by the hydroxide migration resistance. The next cycle is initiated with the precipitation of a new $Zn(OH)_2$ film. The passivation onset potential and the period of oscillation are determined by the difference between the active dissolution current and rate of mass transport (diffusion plus convection) from the electrode surface.

To explain the true passive behavior of the Zn electrode, it is necessary to postulate that the pseudopassivating film undergoes a phase change to form a species that is relatively insoluble at high *p*H.

The model presented above can be used, at least qualitatively, to explain our experimental observations and those of other workers. However, it should not be regarded as definitive and requires substantive verification. A more detailed and quantitative study is currently under way in our laboratory.

ABSTRACT

This paper shows that anodic oxidation of the metals Nb, Ta, and Al through thin solid electrolyte films of calcia stabilized zirconia (CSZ) is possible. The metal oxides grown are stoichiometric and the CSZ behaves like pure anodic oxide, since the electric field in CSZ in the 0.1-10 mA cm^{-2} current density range is comparable with those in anodic oxides. Anodization of Nb|Ta|CSZ or Al|CSZ|Nb|Ta systems shows that only oxygen movements take place in CSZ during oxide growth (*i.e.*, transport number of cations $t^+ = 0$), while both oxygen and cations take part in ionic current in the metal oxides underlying and overlying the CSZ layer (*i.e.*, $t^+ \neq 0$). Thus the transport number of cations can be considered as an intrinsic property of an oxide layer, independent of the nature and of the position of the other layers. Possible microscopic transport mechanisms for oxygen and cations through superimposed oxide films are discussed.

Ionic transport under high electric field through oxide films is generally explained by the thermally activated motion, over discrete energy barriers, of charged point defects (1). It is generally assumed that these defects are injected in the oxide at one of the interfaces (2). For films sufficiently thick ($d > \simeq$ 100Å) the anodization process is believed to be controlled by the migration in the bulk (1). The applied electric field E lowers the energy barrier W, leading to an exponential type relationship between ionic current i and electric field E: $i \simeq A \exp -(W - BE/Kt)$. This expression is obtained with the assumption of a sole migration specie, over a well-defined activation energy barrier. This is generally not the case for the anodization of valve metals, however in a first approach, this convenient theoretical expression has been generally used to describe anodic oxidation of valve metals [for example see Ref. (1-3) and references cited].

A number of works have been devoted to the study of cation or/and anion transport during anodic growth

* Electrochemical Society Active Member.

Key words: solid electrolyte, metals, oxidation, migration, nuclear reactions.

of oxide films. It has been clearly evidenced that the two species, oxygen and metal, may take part in the total ionic current during anodization (4-6), their motion obeying a neighbor-to-neighbor jump process (7, 8). It has been shown that the transport numbers of cations and of oxygen for several oxides (Al_2O_3, Nb_2O_5, and Ta_2O_5) have comparable values (5, 6, 9), although it seems unlikely that cation and oxygen defect species have similar activation energy of motion under a wide range of experimental conditions. Note however that during anodization of Zr only oxygen movements have been observed (10). Following Dignam (2) the microscopic mechanism of ionic movement during anodic oxidation of Ta or Al could be different from that of Zr: network defects (AlO^+ or AlO_2^- for example) in the first case, and oxygen point defects (vacancy or interstitialcy) in the second case.

The study of ionic movements during the anodization of superimposed metallic layers showed that it is possible to anodize a metal M_1 covered with a thin oxide film of a metal M_2 (11) even when their respective transport number for cations (t^+) are different; for example Nb can be anodized through thin Al_2O_3 films (12), or Zr through thin Ta_2O_5 films. In the last case the physical nature of moving defects in ZrO_2 and in Ta_2O_5 can also be different (2). Moreover a strong correlation has been evidenced between oxygen and cation jump probabilities during anodization of superimposed layers (13).

All these results did not allow one to construct an unambiguous model for the microscopic mechanism of ionic movements under high electric field. This is due to the fact that the nature of moving defects which are responsible for ion transport in Al_2O_3, Ta_2O_5 as well as in ZrO_2 is unknown. A possible way to overcome this difficulty is to study ionic movements under high electric field through thin layers of solid electrolyte in which the thermally activated microscopic movements and the nature of moving defects are well known (14). This is the case for calcia stabilized zirconia (CSZ) which is a pure oxygen ion conductor via a vacancy-type mechanism (14). In fact, it has been recently shown (15) that dense and stoichiometric films of CaO doped zirconia of the fluorite-type structure can be obtained by rf sputtering. The conductivity and the activation energy of conduction (Ec) of these films were near to those found for oxygen conduction in bulk material of the same composition, *i.e.*, 3×10^{-7} $(\Omega \cdot cm)^{-1}$ at 300°C and $Ec = 1.2$ eV for $(ZrO_2)_{0.88}(CaO)_{0.12}$. The study of Ni-NiO|CSZ|Pt-O_2 electrochemical cells (16, 17) allowed the authors to conclude that the oxygen transport number in rf sputtered thin CSZ films is near unity (0.99).

The aim of the present work was twofold: to study the ionic movements and the current field relationship in thin CSZ layers under high electric field, and to study cationic movements during anodic oxidation of various metallic substrates covered with superimposed thin CSZ and metallic films, *i.e.*, anodization of metal|CSZ or metal|CSZ|metal systems.

The aim of our study of the current-field relationship in CSZ thin films during the anodization of metal/CSZ systems was to answer the following question: can the convenient theoretical expression

$$i = 2an\nu q \exp - \frac{W - qaE}{KT} \qquad [1]$$

be used to describe the high field ionic transport in CSZ thin films? Let us notice that the CSZ represents the best case to apply this theoretical expression, since in CSZ a sole moving specie (oxygen vacancy) exists, the concentration of which is well known, while in the other classical cases, such as Ta, due to the presence of two migrating species, the theoretical expression has not been proven experimentally. Moreover all terms except the field are known in this expression for $(ZrO_2)_{0.88}(CaO)_{0.12}$ [*i.e.*, $a = 1.27 \times 10^{-8}$ cm, $n = 3.14 \times 10^{21}$ cm^{-3}, $q = 2 \times 1.6 \times 10^{-19}$ C, $\nu = 10^{13}$ s^{-1}, $W = Ec = 1.2$ eV (17)], a theoretical electric field value can be calculated from the relationship [1], for each current density and so can be compared to the value experimentally determined. Thus, in principle, the concept of thermally activated point defects moving under the influence of electric field may be studied in the particular case of the high field ionic conduction in CSZ.

The study of cationic movements during the anodization of metallic substrates covered with thin films of CSZ was carried out in order to check the role played by interfaces in the injection of defects. Moreover in order to establish whether or not cation movements take place in the underlying oxides, anodization of Nb|Ta|CSZ or Nb|Al|CSZ systems were carried out since we have shown (11, 12) that the anodization of Nb|Ta and Nb|Al systems leads to a partial inversion of the order of cations due to cationic movements. In a similar way, we have studied the anodization of Al|CSZ|Nb|Ta systems in order to see if cationic movements exist in the metal oxides superimposed on the CSZ layer. All these experiments may permit us to elucidate the following problem: in the case of various superimposed oxide layers does a sole transport number of metal characteristic of the whole system exist? As the hypothesis of ionic movements in oxide films taking place by injection of point defects at one of the interfaces (metal-oxide or oxide-solution) implies the preservation of the cationic transport number (2), these experiments can give insights on the microscopic transport mechanism of cations.

This work is part of a general program devoted to the study of oxidation mechanisms of duplex layers and to their applications (18), and to thermal, anodic, and plasma treatments of solid surfaces covered with thin films of solid electrolytes acting as selective membranes (19).

Experimental

Sample preparation.—The metallic and CSZ thin films were deposited on silicon or aluminum substrates. The silicon samples were single crystal, [100] oriented with an n-type bulk resistivity of 10^{-2} Ωcm. Prior to deposition they were cleaned by successive dipping in HF, deionized water, and acetone. Niobium and tantalum films were deposited either by electron gun evaporation in high vacuum (less than 10^{-8} Torr during deposition) or by d-c triode sputtering in an argon plasma at a 0.13 Pa pressure. Ta and Nb sputtering targets were supplied by Kawecki Berylco Industries with a 99.98% purity for Ta and 99.9% for Nb. In the same way, Al films were obtained by d-c triode sputtering of an Al cathode in an argon plasma. CSZ films were made by rf sputtering of a sintered CSZ cathode supplied by LCC-France; the technique used is described in detail elsewhere (15).

Anodic oxidations were carried out at constant current density and temperature either in ammonium citrate solutions (0.5 or 2% by weight) or in ammonium borate solutions (0.5% by weight, *p*H kept at 9 by ammonium hydroxide additions). Exactly the same results were obtained whatever the solutions, thus in what follows, the electrolytes used will not be specified. Anodizations were performed using an anode assembly described elsewhere (20), in which a 1 cm² surface is delimited by a pressed Teflon O-ring. In the case of M_1|CSZ and M_1|M_2|CSZ structures, an ohmic contact was made with a conducting Ag paste on the back side of the Al or Si substrate. When metallic layers were deposited on top of CSZ films (Si|M_1|CSZ|M_2 structures), in order to anodize these metallic layers, we established outside the area in contact with the electrolyte an electrical contact (with Ag conducting paste) between the substrate and the metallic layers. Let us notice that it was not possible to anodize the metallic

layers on top of CSZ without the short circuit between these layers and the substrate. Hence we can exclude the presence of defects in CSZ layer which allowed the deposited metal layers to contact the substrate, so the CSZ takes part in the subsequent anodization. Due to possible roughness effects at the CSZ-M_2 interface, we cannot ascertain that all the deposited layer on top of CSZ was anodized without leaving unanodized metal islands. However, the same results were obtained for Si|M_1|CSZ|M_2 as well as for M_1|CSZ|M_2 structures, while the roughness effects must be more important in the last case. Thus we can reasonably assume that unanodized metal islands, if existing, are of very small dimensions (< 5 nm) and do not modify the anodization of the substrate.

Analysis of samples.—Nuclear microanalysis by the direct observation of nuclear reactions and of backscattering particles was used to study the samples before and after anodization. The experiments were carried out using the 2 MeV Van de Graaff accelerator of the Ecole Normale Supérieure.

The ^{16}O content of the films was measured using the $^{16}O(d,p)^{17}O^*$ nuclear reaction as described in detail by Amsel *et al.* (21). Absolute values were obtained by comparison with a reference target known to within ±3% (22).

Rutherford backscattering techniques were used to analyze the depth distribution of cations in the films and in their anodic oxides; lateral homogeneity was assumed for the interpretation of the spectra. The basic concepts and equations pertaining to Rutherford backscattering spectra interpretation can be found in Ref. (23) and will not be presented here; the application to the case of superimposed layers is described in detail in Ref. (11). In all analyses, $^4He^+$ ion beams were used and the backscattered particles were detected at 165° angle by means of a surface barrier detector (21). The energy resolution being about 14 keV. it was possible to evaluate the depth distribution for Nb, Ta, Al, or Zr atoms in the oxide films with a depth resolution of about 20 nm.

Absolute amounts of Nb, Ta, Al, or Zr expressed in atoms/cm² were obtained (assuming the validity of the Rutherford law) by comparison with a Ta film taken as a standard (24). The film thicknesses will be given in nanometers, the equivalence atoms/cm² — nanometer being obtained by assuming, respectively, a density of 4.74 for Nb_2O_5 (25), 8.04 for Ta_2O_5 (25), 3.17 for Al_2O_3 (26), and 5.32 for CSZ [deduced from Ref. (17)].

Results and Interpretation

In order to describe our results on ionic movements under high electric field in terms of microscopic transport mechanisms, we use the concepts of oxygen and cationic transport events [see for details p. 1551, Ref. (11)]. By the term of cationic (or oxygen) transport events, one means the sequence of elementary jumps of one or more cations (or oxygen) which results in a transport of charges from their creation point to that of their recombination.

During the anodization of metals covered with a thin CSZ film some stresses can be developed at the metal oxide-CSZ interface, due to the increase of volume of the underlying metal oxide (Pilling-Bedworth ratio equal to 1.6 or 2.5 for Al or Ta for example). The ductility of anodic oxides is known to be very high (27); this should make easier the displacement of the CSZ layer located on the top of growing metal oxide. But this last phenomenon is not associated with an ionic migration and so will not be taken into consideration in what follows.

Relationships between oxidation potential V and time t: V = f(t).—Figure 1 shows some typical curves obtained by recording oxidation potential as a function of time during the anodization of Ta substrates covered

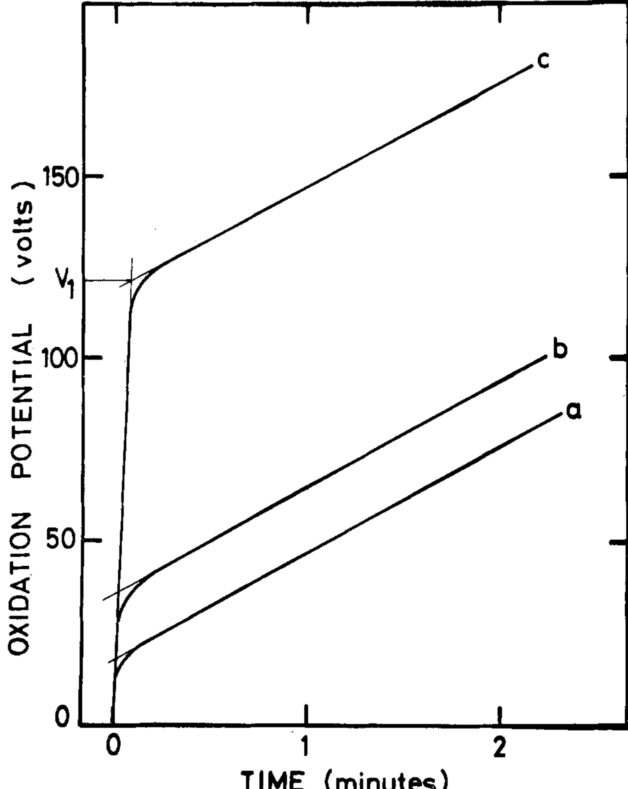

Fig. 1. Oxidation potential *V* as a function of time during anodization at ≃1.3 mA/cm² current density at a 23°C temperature for Ta substrates covered with thin CSZ films of various thicknesses: (a) 40 nm, (b) 80 nm, (c) 270 nm.

with CSZ thin films. The three curves of Fig. 1 were obtained for various thicknesses of the CSZ layer; these experiments were carried out at 23°C temperature with a current density of ~1.3 mA/cm².

Two linear regions can be distinguished on the three curves; the first region corresponds to a rapid potential increase, while the slope observed at high potential is the same as the one measured in the case of pure Ta_2O_5 growth. The nonabrupt transition between these two regions may be due to the roughness of the Ta-CSZ interface. As a slight thermal oxidation of the Ta substrate was observed (17) during CSZ film deposit, we cannot exclude some lateral inhomogeneity of the tantalum oxide thickness which could increase the roughness of the CSZ|Ta interface; let us notice that for Al|CSZ samples this transition region practically disappears.

The intercept of the two straight lines determines an oxidation potential V_1 which was taken as a measure of the potential drop in the CSZ layer. Since the thickness *d* of the CSZ films is determined by backscattering measurements (see experimental), we can evaluate the mean field E_{exp} in the CSZ layer by $E_{exp} = V_1/d$. The linear increase of the potential drop V_1 as a function of the thickness of the CSZ layer excludes any artifacts due to the possible presence of pores in the deposit.

The same values of V_1 were obtained during the anodization of Al or Nb substrates covered with thin CSZ layers of the same thicknesses. This shows that no appreciable influence of the substrate has been evidenced in these experiments.

In Table I, we present the values of the electric field E_{exp} in the CSZ layers at various current densities and for a temperature of 23°C. These values are mean values obtained by more than ten measurements performed either on Ta|CSZ or Al|CSZ systems. The values of the theoretical electric field E_{th} obtained from the expression

Table I. Values of the electric field E_{exp} in CSZ layers and in pure ZrO_2 as a function of current density; E_{th} calculated following Eq. [1]

Current density	$E_{exp} \times 10^6$ V/cm in CSZ	$E_{th} \times 10^6$ V/cm	$E_{exp} \times 10^6$ V/cm in ZrO_2
0.1 mA/cm²	3.5 ± 0.3	19.12	3.6
1 mA/cm²	4.3 ± 0.4	21.39	4
10 mA/cm²	5.5 ± 0.5	23.65	4.3

$$i = 2an\nu q \exp - \frac{W - qaE_{th}}{KT} \quad [1]$$

as described in the introduction are presented in Table I. The values of the electric field during anodization of zirconium, *i.e.*, in pure anodic ZrO_2, for the same experimental conditions, are also given for comparison (28).

Table I shows that E_{exp} in CSZ, which increases when i increases is always much lower than E_{th}. The difference between E_{exp} and E_{th} cannot be explained by our experimental uncertainties on E_{exp} which are of the order of 10%. These uncertainties preclude a precise determination of the $E_{exp} = f(\log i)$ relationship. However, it seems that E_{exp} in CSZ does not increase linearly with $\log i$. Such an effect is also observed in pure anodic ZrO_2 (28) for high current densities. The values of the electric field in CSZ and in ZrO_2 are similar for current densities of 0.1 and 1 mA/cm² and are different for 10 mA/cm². As most of the results presented in this work were obtained at current densities of about 1 mA/cm², in what follows we shall consider CSZ films like zirconia anodic oxides, *i.e.*, with $t^+ \simeq 0$ (10).

Note that this assumption (*i.e.*, CSZ behaves like ZrO_2 anodic oxide) has been checked by experiments on oxygen movement which evidenced a partial inversion of the oxygen atom order in CSZ layers (29) during anodization of underlying metallic layers, like for pure zirconium anodization (28).

Anodization of Metal|CSZ systems.—Figures 2 and 3 represent, respectively, typical backscattering spectra for Ta|CSZ and Al|CSZ samples before and after anodization. In Fig. 2 the Zr spectrum is shaded, and the area of this spectrum does not change after anodization. This means that no dissolution from the CSZ layer occurs. In Fig. 3, the Zr, Hf, and Ca spectra which are clearly separated and isolated from Al background, are exactly the same before and after anodization. Thus it may be concluded that there is no dissolution of any cationic constituents of the CSZ layer.

Two plateaus are observed on the Ta spectrum after anodization (see Fig. 2); plateau 1 corresponds to Ta atoms in the Ta oxide layer while plateau 2 corresponds to unoxidized Ta atoms. As the ratio of plateau heights is the same as the one obtained in the case of pure Ta anodization, it can be assumed that pure Ta_2O_5 is formed during the anodization of Ta|CSZ systems. Similar conclusions for Al are obtained from the analysis of the Al spectrum in Fig. 3. Hence, the anodic oxidation of metal|CSZ systems leads to the formation of stoichiometric metal oxides.

The width of the front edge of the Ta (or Al) spectrum after anodization in Fig. 2 (or 3) is practically the same as the corresponding width before anodization. Note that the arrows in all figures indicate the position of elements on the surface of samples. This result demonstrates that metallic atoms did not enter the CSZ layer during anodization within our experimental resolution (about 20 mn). Let us notice, however, that we do not exclude a slight mixing between the metallic layers and CSZ during the deposit of the latter; the magnitude of such a mixing may be a function of the deposition conditions (17). The interpretation of these results, based on the necessary assumption of current continuity can be sought in the frame of one of the two following assumptions:

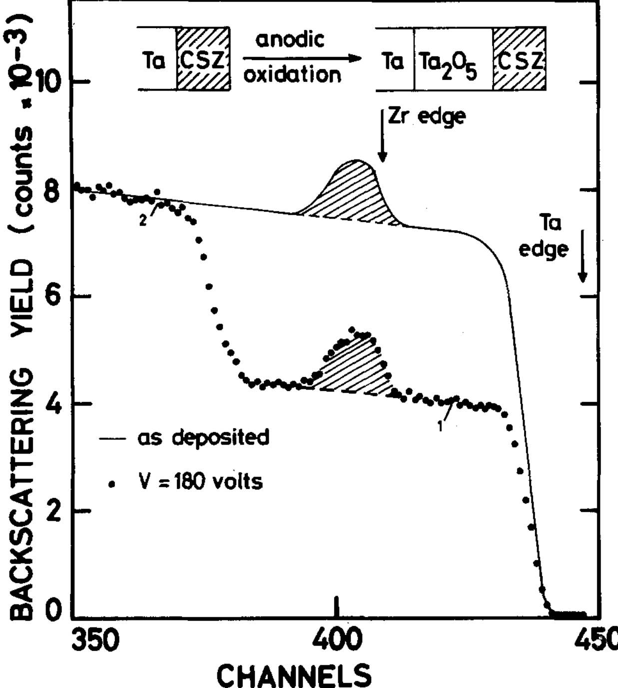

Fig. 2. Rutherford backscattering spectra of 1.6 MeV $^4He^+$ ions (3.2 keV/channel) for a CSZ film (48 nm) deposited on Ta substrate: before anodization (solid line) and after anodization (·) at $V = 180V$ and $i = 1$ mA/cm². The arrows indicate the position of elements at the surface of the sample.

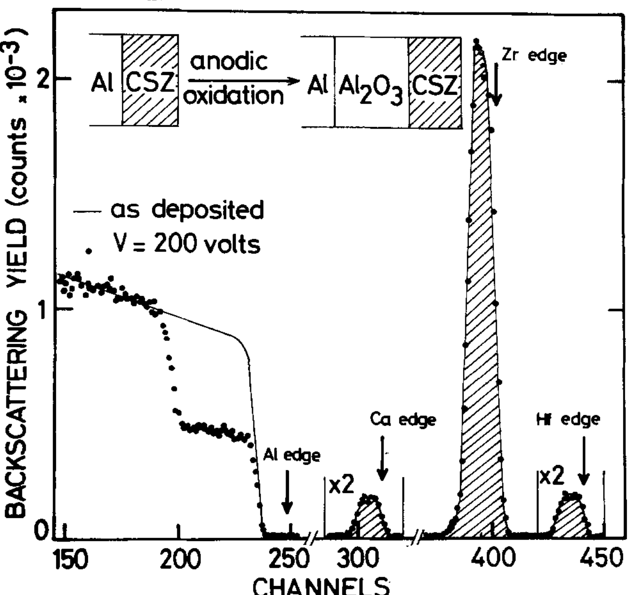

Fig. 3. Rutherford backscattering spectra of 1.8 Mev $^4He^+$ ions (3.3 keV/channel) for a CSZ film (53 nm) deposited on Al substrate: before anodization (solid line) and after anodization (·) at $V = 200V$ and $i = 1$ mA/cm². For arrows see Fig. 2.

(1) The transport number of cations (t^+) is the same in each layer, *i.e.*, in the CSZ layer and in the underlying metal oxide, the value of t^+ being determined by the mechanism of injection of transport events at the interfaces (oxide-solution or metal-oxide interface). This hypothesis means that the fluxes of anionic and cationic transport events are preserved through all the film (*i.e.*, in the CSZ layer and in the metal oxide).

(2) The value of t^+ is different in the CSZ layer and in the underlying metal oxide. This hypothesis means that t^+ may be an intrinsic property of each layer, which does not depend on the other layers nor on the

position of the layer. In this case the t^+ values should be equal to 0.25 and 0.4 in Ta_2O_5 and in Al_2O_3 layers (6, 9), respectively, and to zero in CSZ layer.

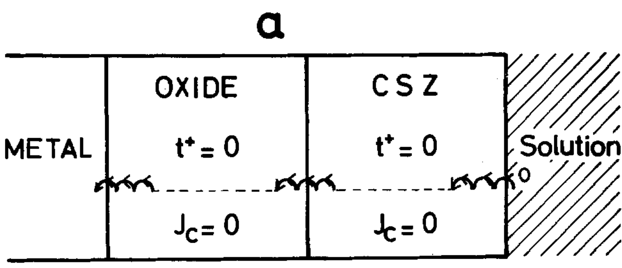
The results presented on Fig. 2 and 3 can be explained by both assumptions. Let us now analyze the mechanisms of ionic movement involved in these two cases.

Two different mechanisms may be considered for the first hypothesis:

(a) The injection of point defects is determined by the nature of the oxide-solution interface. In the case of CSZ-solution interface, due to the properties of CSZ ($t^+ = 0$), it is logical to assume that only oxygen transport events are injected, *i.e.*, the cationic current J_c is thus equal to zero in CSZ and in the underlying metal oxide (Fig. 4a). Following this mechanism (a) the anodization of Ta or Al substrates covered with a thin CSZ layer involves only oxygen movement.

(b) The injection of point defects is determined by the nature of the metal-oxide interface. In the case of $Al|Al_2O_3$ or $Ta|Ta_2O_5$ interfaces, both oxygen and cation transport events are observed ($t^+ \neq 0$) (6, 9) during the anodization of pure metals. According to this fact, in the frame of this mechanism (b) oxygen and cation movements must be preserved through the whole oxide, *i.e.*, in the underlying metal oxide and in the CSZ layer (Fig. 4b). Thus cations move in the metal oxide and in the CSZ layer. As no broadening of the oxide-CSZ interface is observed, this cationic movement, if it takes place, must lead to the conservation of the order of cations. This is possible with some assumptions on the various jump probabilities of cations like those developed for Ta and Nb in a previous paper (11). In fact, to obtain the conservation or the order of cations, we must assume that the jump probability of Ta or Al cations (P_{Ta} or P_{Al}) are lower than that of Zr (P_{Zr}), Ca (P_{Ca}), and Hf (P_{Hf}). Moreover, since no relative movement of Zr, Ca, and Hf occurs (the cation distribution in CSZ film does not change after anodization, see Fig. 3), we must assume that $P_{Zr} = P_{Ca} = P_{Hf}$. Owing to the properties of CSZ previously defined, and to the fact that Zr cations do not seem to take part in the ionic current during Zr anodization (10), this mechanism (b) appears questionable.

The mechanism of ionic movement involved by hypothesis (2) is schematically presented on Fig. 5. In



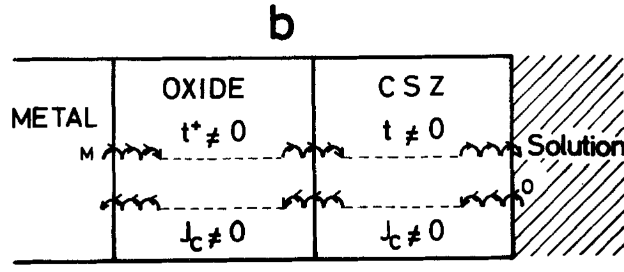


Fig. 4. Schematic representation of ionic movements during the anodization of Metal | CSZ systems with the same value of the transport number of cations t^+ in the whole oxide. (a) $t^+ = 0$, (b) $t^+ \neq 0$.

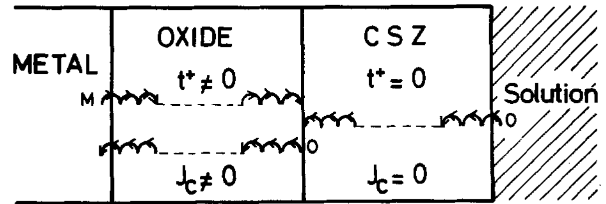

Fig. 5. Schematic representation of ionic movements during the anodization of Metal | CSZ systems with different values of t^+ in each layer.

this case, cationic and anionic movements exist in the underlying metal oxide ($J_C \neq 0$ and $t^+ \neq 0$) while there is only oxygen movement in the CSZ layer ($J_C = 0$ and $t^+ = 0$). With this hypothesis metallic atoms do not enter the CSZ layer and thus this means that metal oxide must be formed partially at the oxide-CSZ interface.

Anodization of $M_1|M_2|CSZ$ systems.—To establish whether cationic movements take place in the underlying metal oxide, anodization of Nb|Ta|CSZ systems was carried out. Figure 6 represents backscattering spectra obtained on such systems before and after anodization. As a result of the preceding experiments, these spectra were analyzed assuming that no dissolution of Zr occurs during oxide growth; therefore the

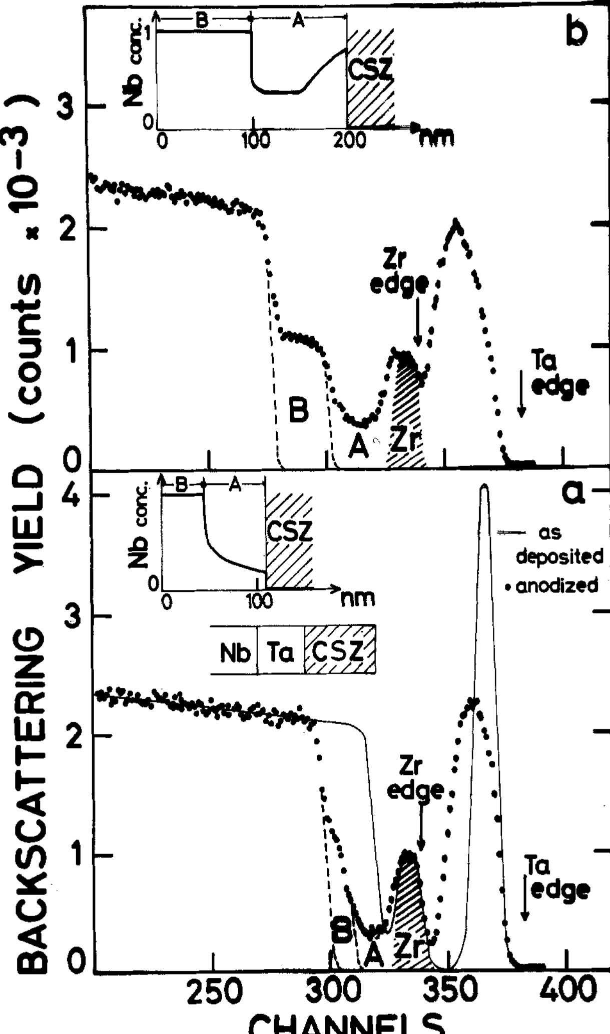

Fig. 6. Rutherford backscattering spectra of 1.8 Mev $^4He^+$ ions (3.2 keV/channel) for a CSZ layer (47 nm) superimposed on a Ta film (21 nm) deposited on Nb substrate before and after anodization at two potentials: (a) $V = 80V$, (b) $V = 120V$, $i = 1$ mA/cm^2. The inserts represent the corresponding schematic Nb depth profiles in the oxide. For arrows, see Fig. 2.

Zr spectrum is shaded with a constant overall area on each figure. The front edge of the Ta peak before and after oxidation on Fig. 6a is located at the same energy, lower than for Ta atoms located at the surface of the sample (shown by the arrow Ta edge). This shift is due to the presence of the CSZ layer and means that Ta atoms did not enter the CSZ layer. On Fig. 6a two regions A and B can be defined in the Nb spectrum after anodization. Region A corresponds to Nb atoms which have entered the Ta oxide and thus have formed a Ta and Nb oxide mixture, while region B corresponds to the remaining oxidized Nb atoms [see Ref. (11) for details]. The corresponding Nb depth distribution in the oxide is schematically presented in the insert of the figure and it shows that Nb atoms have crossed the inner edge of the Ta atom distribution. This fact is evidence for cationic movements in the metal oxide underlying the CSZ layer. The behavior of Nb and Ta cations during oxidation of Nb|Ta|CSZ systems appears qualitatively similar to that observed during Nb|Ta anodization (11).

Figure 6b is obtained at a higher oxidation potential. The area of region A of the Nb spectrum increases when the potential increases. This means that more and more Nb cations penetrate into the Ta oxide layer as anodization is pursued. This is checked by the fact that the front edge of the Ta peak is broadened when the potential increases. It was already observed for Nb|Ta anodization (11). Moreover the Ta peak is not shifted toward high energies, this means that the Ta atoms do not enter the CSZ layer. Hence the broadening of the front edge of the Ta peak (Fig. 6b) is only due to the increase in Nb concentration at the metal oxide-CSZ interface. Penetration of Nb cations into the CSZ layer cannot be detected on the Zr or Nb spectrum, but the analysis of the Ta spectrum (shift of the peak to lower energies and broadening of the front edge) indicates that this Nb penetration, if it occurs, must be so weak that we cannot detect it within our experimental sensitivity. In what follows, we shall thus assume that Nb cations, like Ta or Al cations, do not enter into the CSZ layer during anodization.

The Nb depth distribution in the oxide is schematically represented in the insert on Fig. 6b. The various parts of the oxide film are hence: (*i*) a pure Nb_2O_5 layer at the metal-oxide interface (region B); and (*ii*) a region containing both Nb and Ta cations (region A). In this latter region the Nb concentration is maximum at the oxide-CSZ interface and then drops in the bulk down to a value which remains constant until region B is reached. These results demonstrate that cationic movements exist in the underlying metal oxide, and are consistent with the idea that Nb atoms do not cross the oxide-CSZ interface. Moreover, although no precise measurement of the fraction of the oxidized Nb atoms located in region A [*i.e.*, F_t in Ref. (11)], was carried out, the results obtained on this system are similar to those observed on Nb|Ta samples.

These results allow us to eliminate the first mechanism of hypothesis (1) (only oxygen movement through all the film), since oxygen movement cannot lead to a cation mixing. Let us notice that they can be explained by the second mechanism of hypothesis (1), if we assume that the jump probabilities of Nb and Ta cations (P_{Nb} and P_{Ta}) are lower than that of Zr (P_{Zr}) so that Nb or Ta cations do not significantly penetrate in the CSZ layer. On the other hand the results are in good agreement with hypothesis (2), *i.e.*, the transport number of cations is an intrinsic property of each layer.

Anodization of M|CSZ|M_1|M_2 systems.—In order to establish whether cationic movements take place in metal oxides located above a CSZ layer, *i.e.*, at the oxide-solution interface, and in the underlying CSZ layer, the anodization of Al|CSZ|Nb|Ta systems was studied.

Figure 7 represents backscattering spectra after anodization at various potentials of an Al substrate covered with a CSZ layer (30 nm), itself covered with a 55 nm thick Nb layer on which a Ta film (22 nm) was deposited. On each figure, the Zr spectrum is shaded with a constant overall area. Figure 7a corresponds to an oxidation potential equal to 160V for which the Ta and Nb layers are fully oxidized, the potential drop in CSZ is established and the Al substrate just begins to be anodized. Due to the cationic movements during the anodization of Nb and Ta layers, Nb atoms have crossed the inner edge of the Ta atoms distribution, and thus have formed an Nb and Ta oxide mixture. These Nb atoms correspond to region A of the Nb spectrum, while region B corresponds to the remaining oxidized Nb atoms. The insert in the figure represents schematically the Nb depth profile in the near surface region of the film, as deduced from the spectrum.

On Figure 7b and c, the backscattering spectra correspond to the anodization of the Al substrate at higher

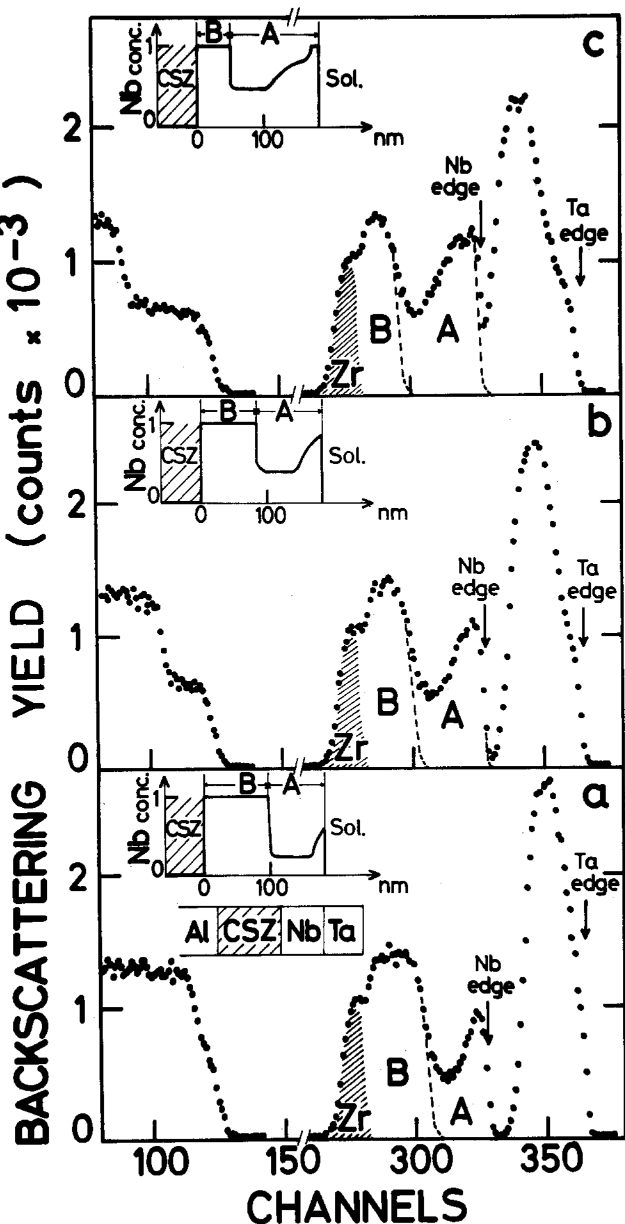

Fig. 7. Rutherford backscattering spectra of 1.8 Mev $^4He^+$ ions (3.5 keV/channel) for multi superimposed layers on Al substrate: Al | CSZ(30 nm) | Nb(55 nm) | Ta(22 nm) anodized at $i = 1$ mA/cm^2 and at various oxidation potentials: (a) $V = 160V$, (b) $V = 210V$, (c) $V = 270V$. The inserts represent the corresponding schematic Nb depth profiles in the oxides. For arrows, see Fig. 2.

potentials. The comparison of these two figures with Fig. 7a shows that the area of region A of the Nb spectrum increases with oxidation potential. This demonstrates that Nb cations go on entering the Ta oxide layer whatever the potential. At the same time, the Al substrate is oxidized and Al_2O_3 is formed as the corresponding plateau can be observed in the Al spectrum. These results evidence cationic movements in the Nb and Ta oxide region, located above the CSZ layer, during the anodization of the Al substrate. It must be emphasized that cationic movements occur while the Nb and Ta oxide mixture is separated from the Al substrate by the CSZ layer.

The analysis of the spectra shown on Fig. 7 is consistent with the idea that Zr atoms (of the CSZ layer) have not entered the Nb oxide layer, and thus inserts in Fig. 7b and c represent schematically the Nb depth profile in the oxide with a sharp boundary at the interface with the CSZ layer.

The assumption of no penetration of Zr cations in the metal oxide was checked by experiments carried on Nb|CSZ|Ta samples. After anodization, the Ta_2O_5 layer at the oxide-solution interface and the Nb_2O_5 layer at the metal-oxide interface were separated by the CSZ layer without penetration of Zr cations into the Ta_2O_5 layer.

Another point to notice about Fig. 7 is that the front edge of the Al spectrum is wider than that observed on Fig. 3; however, as the oxidation potential increases, no further broadening occurs. This probably means that during the deposit of the CSZ layer some mixing with the Al substrate occurred, but during the anodization process no Al atoms entered the CSZ layer. On the three spectra the areas of the Nb and of the Ta components are constant; thus there is no appreciable dissolution of Nb or Ta during anodic oxidation.

These results allow us to eliminate mechanism (b). In fact in the frame of this mechanism, the cation movements evidenced in the Nb and Ta oxide mixture must be preserved in the whole oxide. In order to explain the preservation of the order of cations between the CSZ layer and the Nb and Ta oxide mixture, one must assume that P_{Ta} and P_{Nb} are higher than P_{Zr}. A contradiction appears, since in the frame of mechanism (b) the preceding results (anodization of Nb|Ta|CSZ systems) have been explained assuming P_{Ta} and $P_{Nb} < P_{Zr}$. As the mechanism (a) was eliminated previously, it appears that the hypothesis (1) [assuming the preservation of transport events through the whole oxide] is in contradiction with our experimental results and must be eliminated. It means that the cation constituents of CSZ layer (Zr, Ca, and Hf) do not move during anodization while cationic movements take place in the metal oxide layers located either on the top or under the CSZ layer. These results are in good agreement with hypothesis (2) which assumes that the transport number t^+ is an intrinsic property of each layer.

The results of this last experiment can be compared to those obtained during the anodization of Al|Nb|Ta systems (30) in which during the oxidation of the Al substrate, the Nb and Ta cation distribution, in the oxide mixture, goes on changing as the oxidation potential increases. These results were interpreted (31) assuming that cation transport events, coming from the underlying pure Al_2O_3 layer are preserved in the whole oxide, *i.e.*, move through the mixed Ta and Nb oxide by a neighbor-to-neighbor type propagation process. Since the same results are obtained on Al|CSZ|Nb|Ta systems, we can conclude that the presence of the CSZ layer, in which only oxygen moves, does not eliminate cationic movements by a neighbor-to-neighbor jump in the Ta and Nb oxide mixture at the oxide solution interface.

Very similar results were obtained during the anodization of Al|CSZ|Nb|Al system, *i.e.*, the cation distribution in the oxide in the near surface region of the film undergoes strong changes whereas the Al substrate is oxidized as it is observed for the Al|Nb|Al system (29). In this case also, no penetration of Zr cations in the mixed oxide was evidenced.

Figure 8 represents schematically the main conclusion drawn from these experiments: the transport number of cations t^+ changes from one part of the film to another. t^+ is equal to zero in the CSZ layer, while there is cationic movement ($t^+ \neq 0$) in the metal oxide at the oxide-solution interface. Hence ionic current is transported by cation and oxygen in the outer part of the film while there is only oxygen movement in the CSZ layer.

Anodization of $M_1|M_2|CSZ|M'_1|M'_2$ systems.—All the preceding experimental results are in good agreement with hypothesis (2). In order to further confirm the validity of this hypothesis, we have studied the cation distribution in oxides formed by anodization of Nb|Al|CSZ|Nb|Ta systems. It was expected that cationic movements had to take place in metal oxides above and below the CSZ layer, while in the CSZ layer only oxygen movements have to take place.

Figure 9 represents backscattering spectra from Nb|Al (20 nm)|CSZ (85 nm)|Nb (36 nm)|Ta (14 nm) systems oxidized at two oxidation potentials. On the two figures, the Zr and Ta contributions are shaded while the two Nb parts corresponding to the Nb layer above the CSZ and to the Nb substrate are labelled Nb(1) and Nb(2). Figure 9a corresponds to an oxidation potential equal to 100V, for which the Ta and Nb layers are fully oxidized, part of the potential drop in the CSZ layer is established while the Al layer and the Nb substrate are not oxidized. As a result of cationic movements during the anodization of Ta and Nb layers, Nb atoms have crossed the inner edge of the Ta atom distribution and thus have formed the Ta and Nb oxide mixture at the oxide-solution interface. These Nb atoms correspond to region A of Nb(1), while region B of Nb(1) corresponds to the remaining oxidized Nb atoms. The insert in the figure shows schematically the Nb depth profile in the near surface region of the oxide.

Figure 9b corresponds to a potential equal to 200V for which the Al layer and the Nb substrate underlying the CSZ layer are oxidized. This figure shows that the area of part A of Nb(1) has increased; this indicates that Nb atoms have entered the Ta oxide layer during the anodic oxidation of metallic layers underlying the CSZ film. This result is identical to that obtained in the preceding experiments and can be interpreted by the fact that cationic movements take place in the oxide near the oxide-solution interface whereas the substrate is oxidized. Two regions (A′ and B′) can be distinguished on Nb(2) spectrum. Region B′ represents Nb atoms in a pure Nb_2O_5 layer at the metal-oxide interface, while region A′ corresponds to Nb atoms which have crossed the inner edge of the Al atoms distribution and thus have formed an Nb and Al oxide mixture. This result is similar to that obtained during the anodic oxidation of the Nb|Al system (12). The insert on the figure schematically represents the Nb depth profile in the film. The two Nb distributions (under and above the CSZ layer) are shown with sharp boundaries with the CSZ layer, *i.e.*, assuming, as above, no penetration of Zr cations in the Nb and Ta oxide mixture superimposed on the CSZ layer, and

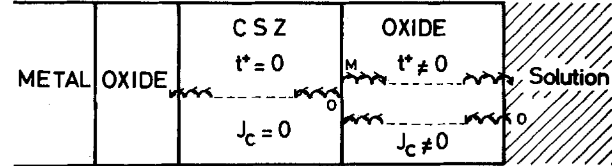

Fig. 8. Schematic representation of ionic movements during the anodization of Metal | CSZ | Metal systems with different values of t^+ in CSZ and in the metal oxide at the oxide solution interface.

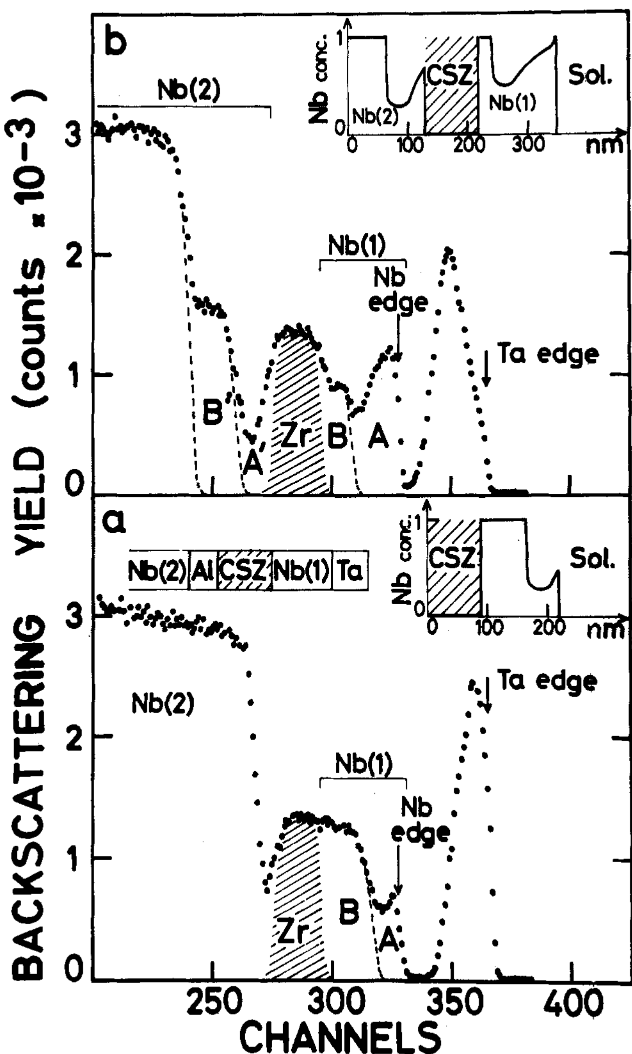

Fig. 9. Rutherford backscattering spectra of 1.8 Mev $^4He^+$ ions (3.5 keV/channel) for multi superimposed layers on Nb substrate: Nb | Al(20 nm) | CSZ(85 nm) | Nb(36 nm) | Ta(14 nm) anodized at i = 1 mA/cm² at different potentials: (a) V = 100V, (b) V = 200V. The inserts represent the corresponding schematic Nb depth profiles in the oxides. For arrows, see Fig. 2.

without penetration of Nb coming from the underlying layer into the CSZ layer.

These results fully confirm the preceding results and are in agreement with hypothesis (2): cationic movements take place both under and above the CSZ layer during the anodization of the substrate. Figure 10 schematically represents this conclusion: the transport number of cations t^+ depends on the nature of each layer while cations move in the metal oxide located above and below the CSZ layer. Note that the confirmation of hypothesis (2) needs the knowledge of the values of t^+ in metal oxides overlying or underlying the CSZ layer. Our experimental conditions do not allow us to measure precise values of F_t, *i.e.*, the transport number of cations in the Nb and Ta oxides located over and under the CSZ layer (11). Thus, at the present time, it is not possible to quantitatively compare these F_t values to that measured during pure Nb|Ta anodization. However, work is in progress to check hypothesis (2), since we have realized a computing calculation of backscattering spectra which allow us to precisely determine the cation distribution in the oxide films. Results of this study will be published in a later paper.

Discussion and Conclusions

In this work we have shown that it is possible to anodize metallic substrates (Nb, Ta, or Al) covered

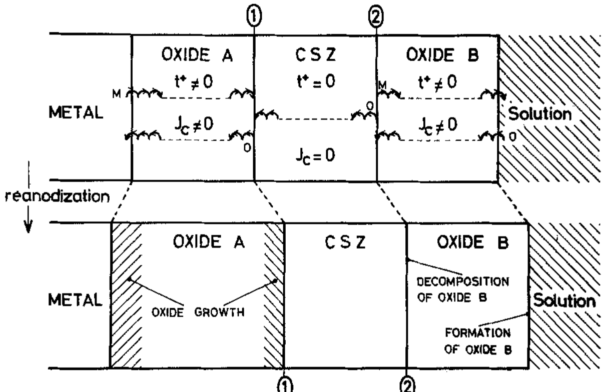

Fig. 10. Schematic representation of ionic movements during the anodization of Metal | CSZ | Metal systems with different values of t^+ in each layer, leading to oxide A growth while thicknesses of the CSZ layer and of oxide B are preserved.

with CSZ thin films. The growth rates of oxide on metallic substrates in metal|CSZ systems are similar to those observed for pure metals, and the current field relationship in CSZ appears similar to the one observed during pure Zr anodization. The anodization of $M_1|M_2|$CSZ or $M_1|M_2|$CSZ$|M'_1|M'_2$ systems gives the experimental proof that cation movements take place in metal oxides located above and below the CSZ layer. Moreover, all these results are consistent with the idea that only oxygen atoms move through CSZ films, *i.e.*, the cationic constituents of CSZ do not take part in ionic current. These results seem to indicate that the mechanism of high field conduction in CSZ film is similar to that of pure anodic ZrO_2 in which the transport number of oxygen is above 0.95 (10). This means that the introduction of 12 atomic percent of Ca to stabilize the fluorite structure of ZrO_2 does not notably affect the high field ionic conduction in zirconia oxide. Two possibilities appear in order to explain this last point: (*i*) anodization of Zr leads to the formation of a highly conducting phase, similar to the one obtained by inclusion of CaO in ZrO_2. In this case, according to the presence in CSZ of a high oxygen vacancy concentration, oxygen ion movement takes place by a vacancy-type mechanism; (*ii*) oxygen ion movement does not take place by vacancy-type mechanism, neither in pure ZrO_2 film nor in CSZ film, in spite of the presence in CSZ of a high oxygen vacancy concentration with a low activation energy of movement (1.2 eV).

In hypothesis (*i*), one must explain the disagreement between E_{th} and E_{exp} (Table I). This disagreement seems to disappear if we use an effective field E_{eff} instead of the one of Maxwell, *i.e.*, the experimental field ($E_{Maxw} = E_{exp}$), in the relationship [1]. In fact in ionic cubic crystals (32) (and the oxygen sublattice is of cubic symmetry), the following relationship is valid

$$E_{eff} \leq E_{Maxw} + \frac{\epsilon - 1}{3} E_{Maxw}$$

where ϵ is the static dielectric constant, *i.e.*, $\epsilon = 25$ for CSZ thin films (17). This means that $E_{eff} \leq 9\ E_{Maxw}$, *i.e.*, $E_{eff} \leq 3.9 \times 10^7$ V/cm for i = 1 mA/cm². A question arises whether E_{eff} or E_{Maxw} (*i.e.*, E_{exp}) must be used in relationship [1]. Dignam has analyzed this question (2) and concludes that the Maxwell field must be used; however this problem has given rise recently to contradictory discussions (33) which indicate that Dignam's approach is not fully accepted.

The second possibility (*ii*) based on the fact that oxygen movement does not take place by a vacancy-type mechanism, implies that one must consider a new mechanism. Some essential features of such mechanism seem to be the following: injection of oxygen

charged species at the oxide-solution interface, which migrate by a neighbor-to-neighbor jump process, the activation energy of movement being lower than 1.2 eV. Works of Dignam (2), Fromhold (34), and Ortega (28) are attempts to provide at least partial informations on these migration mechanisms.

The second purpose of this work was devoted to study the mechanism of ionic movement through various superimposed layers having different values of cationic transport numbers. The essential results of this study are presented in Fig. 10. This figure shows schematically the presence of oxygen and cation transport events in metal oxides below and above the CSZ layer [respectively labelled (A) and (B)], and only of oxygen events in the CSZ film; at steady-state conditions the total ionic current (the electronic current can be neglected) must be preserved through the whole oxide, this means that $J_o(A) + J_c(A) = J_o(CSZ) = J_o(B) + J_c(B)$.

From the macroscopic standpoint, this figure indicates on the one hand the formation of oxide at the metal-oxide(A) and at the oxide(A)-CSZ interfaces, and on the other hand the decomposition of oxide(B) at the CSZ-oxide(B) interface, associated with the formation of the same quantity of oxide(B) at the oxide(B)-solution interface (see Fig. 10). In this way, the overall quantity of oxide(B) is preserved during anodization of the substrate as experimentally observed. It can be noticed that according to the fact that oxide(A) and (B) can have different values of cationic transport number, the quantity of oxide formed and eliminated at the interfaces of the CSZ layer are not necessarily equal. Thus, the role played by these interfaces appears to be very important. However it should be emphasized that the phenomena occurring at these interfaces (injection of charged species and oxide decomposition) are not the rate-determining steps of anodic growth since we have shown that the growth rates of oxide on metallic substrates (Ta or Al for example) covered with CSZ films are similar to those observed for pure metal anodization.

From the microscopic standpoint, the results summarized in Fig. 10 can be discussed by using the concept of oxygen and cationic transport events (see below).

Two extreme assumptions may be made to explain ionic movements in such superimposed layers. First, it could be assumed that oxygen and cation transport events are not distinct. There would be only one transport event implying the simultaneous movement of cations and anions. Thus, at a molecular scale, both cations and oxygen move in a ratio equal to the transport number which is a measure, at the macroscopic scale, of this movement and which appears as an intrinsic property of each oxide. In this frame, the results could be interpreted by assuming that each oxide layer preserves its own transport number. The microscopic jump process which can sustain this proposition could be searched in a similar way as that suggested by Fromhold (34), *i.e.*, some sort of place exchange mechanism.

At the interface between the crystalline CSZ and the amorphous metal oxide, some rearrangement of the structure has to occur. This can be obtained by taking into consideration the property of plasticity (25) of anodic oxides related to their amorphous nature. It is, however, difficult to explain with such a mechanism the absence of noticeable mixing at the two interfaces of CSZ.

The other extreme assumption is that the oxygen and cation transport events are distinct (note that this does not mean that we consider these two charge transport events as independant since we have shown that a strong correlation exists (13) between oxygen and cation jump probability during anodic oxide growth. It appears, in this frame, that the role played by interface 2 is fundamental. In fact, at this CSZ-oxide(B) interface, the following processes must occur: injection of oxygen charged species in the CSZ layer, and simultaneous generation of cationic transport events in the oxide(B). At the interface 1, the total current is due to oxygen injection in a way similar to the one taking place at an oxide-liquid electrolyte interface, CSZ acting thus as a solid electrolyte. Oxygen transport events have to exist in the whole oxide, but the associated charge q^- can be different in the CSZ layer and in metal oxide. For example at interface 2, oxygen transport events may be in the form of interstitialcy O^- in oxide(B) and in the form O^{2-} in CSZ layer. The current continuity, and the continuity of oxygen fluxes imply that a cationic charge M^+ has to be created at this interface. Here enough plasticity of anodic oxides must be assumed to explain the necessary rearrangement of the structure at the interface. In this assumption, the transport number in metal oxide(B) will be determined by the nature of the CSZ-metal oxide(B) interface. In the future work, we will try to answer this question.

Acknowledgments

On the Mechanism of Electrodeposition in the Dimercaptothiadiazole/Copper Pyrophosphate System

Cameron Ogden* and Dennis Tench*

Rockwell International, Electronics Research Center, Thousand Oaks, California 91360

ABSTRACT

Cyclic voltammetric stripping results are presented which show that a dynamic equilibrium exists in the dimercaptothiadiazole (DMTD)/copper pyrophosphate system involving a species which accelerates the copper deposition rate, a decelerating species, Cu^{+2} ions, and other bath constituents. The experimental data are well explained by assuming that the accelerator is the copper-complexed DMTD monomer species, whereas deceleration is produced by the DMTD dimer. A model is presented which explains the additive effects in terms of a critical balance between the nucleation of new growth centers by the accelerating additive species and copper ammine complexes, and the limitations on growth imposed by the decelerating additive species which functions by blocking growth sites. Based on this model, which is supported by a-c impedance data and morphological studies, the important deposit properties can be understood and predicted.

Copper pyrophosphate electroplating baths containing dimercaptothiadiazole leveling additives (1, 2) are widely used in applications for which throwing power, tensile strength, and ductility are important considerations, as in electroforming and the plating of through-hole interconnections in high reliability circuit boards. Our previous work (3) has shown that additives of this class function in a complex way, decelerating the copper deposition rate at higher concentrations while exerting an accelerating effect at lower levels. Such dual decelerating/accelerating behavior results in enhanced leveling power, but also underlies a strong dependence of the deposit uniformity (4) and tensile properties (5) on the additive concentration. Control of this system is rendered more difficult by the slow additive activation required to produce decelerated deposition (3). In the present paper, the additive species present in copper pyrophosphate baths and the mechanisms by which they affect copper deposition are discussed.

Experimental Details

System description.—Unless otherwise noted, all measurements were made in air-saturated copper pyrophosphate baths at 55°C containing 22.5 g/liter Cu^{+2}, 175 g/liter $P_2O_7^{4-}$, 2.25 g/liter NH_3, and up to 50 μmoles/liter of the organic additive 2,5-dimercapto-1,3,4-thiadiazole (Aldrich Chemical Company). This pure compound was used as the additive since it is easier to control and has been shown (3-5) to yield results comparable to those for the proprietary formulation PY61-H (M & T Chemicals, Incorporated). Baths were prepared from concentrates C10XB and C11XB (M & T Chemicals, Incorporated) and were operated at a pH of 8.3.

The cell was Pyrex glass with a Teflon top and had a volume of 150 ml. Temperature was maintained constant within ±1°C by water circulated through a cell jacket from a Haake FT circulator-controller. The Pt-40% Rh counterelectrode and commercial SCE reference were dipped directly in the bath.

Cyclic voltammetric stripping studies.—The cyclic voltammetric stripping (CVS) method (3) was used extensively in these studies to measure changes in the copper electrodeposition rate produced by additive species. In this method, the potential of an inert Pt electrode is cycled in copper pyrophosphate baths at 50 mV/sec between −0.700 and 1.000V *vs.* SCE so that a small amount of copper is alternately deposited on the Pt surface and stripped off by anodic dissolution. The charge required to oxidize the copper deposit is proportional to the average deposition rate for that cycle and is found to be related to the concentration of additive in the bath when adequate solution mass transport is provided. The latter is attained by mounting the Pt electrode in the standard disk configuration (6) and rotating it at 2500 rpm. The rotating Pt disk electrode used for the present studies and its pretreatment are described elsewhere (3).

The effects of other bath species which affect the electrodeposition rate are to some extent cancelled by using the internal standard provided by the static electrode in the same bath. When the electrode rotation is stopped, those additive species which are present in very small concentrations compared to other bath constituents become depleted at the electrode surface as they are destroyed by reduction and inclusion in the

* Electrochemical Society Active Member.

Key words: electroplating, copper pyrophosphate, additive effects, molecular dynamics.

deposit. Thus, the stripping peak area approaches that which would be obtained in the same bath without low-level additive species present. The ratio of the stripping peak area with rotation (A_r) to that for the static electrode in the same solution (A_s) yields a relative rate parameter which reflects only the effect of such additive species on the electrodeposition rate.

Measurements of A_r/A_s were made under complete computer control using a Hewlett-Packard Model 9825 minicomputer in conjunction with a PAR Model 173 Potentiostat/Galvanostat and a PAR Model 179 Digital Coulometer. A Hewlett-Packard Model 6940B Multiprogrammer and a Model 98033A BCD were used as computer interfaces. Steady state for each measurement was assured by establishing a convergence limit of 4% for successive peak integrations.

A-C impedance analysis.—Measurements of the a-c impedance of the electrode during copper electrodeposition at constant potential were made from 0.1 Hz to 10 kHz using a Solartron Model 1174 Frequency Response Analyzer in conjunction with the PAR Models 173 and 179 instruments. Electrodes were rotated at 2500 rpm and comparable steady-state results were obtained with Pt (0.13 cm²) and Cu (0.30 cm²) substrates.

Results and Discussion

Additive activation studies.—A plot of A_r/A_s *vs.* the additive concentration for baths at operating temperature is shown in Fig. 1. Good sensitivity to the additive, which is the basis for use of this method as an analytical technique, is evident. It is also apparent that the additive accelerates the deposition rate at low concentrations ($A_r/A_s > 1$) but exerts a decelerating effect at higher levels ($A_r/A_s < 1$). The dependence of A_r/A_s on concentration is linear in the decelerating region and extrapolates to an A_r/A_s value of unity at zero concentration. This indicates that two additive species are involved, an accelerator and a decelerator, which act independently to affect the deposition rate. The presence of two species is also indicated by the observation that an activation period is required to produce deceleration on addition of the additive to the bath, whereas accelerated deposition is rapidly attained. The data in Fig. 1 were obtained after the baths were allowed to equilibrate for 16 hr at 55°C.

Plots of A_r/A_s as a function of time after addition of the additive to the bath at operating temperature are shown in Fig. 2. It is evident that the accelerating species is formed almost immediately (A_r/A_s rapidly increases to a steady value), whereas the decelerator forms more gradually, at a rate which increases with initial concentration. The minima observed at the higher concentrations are discussed below.

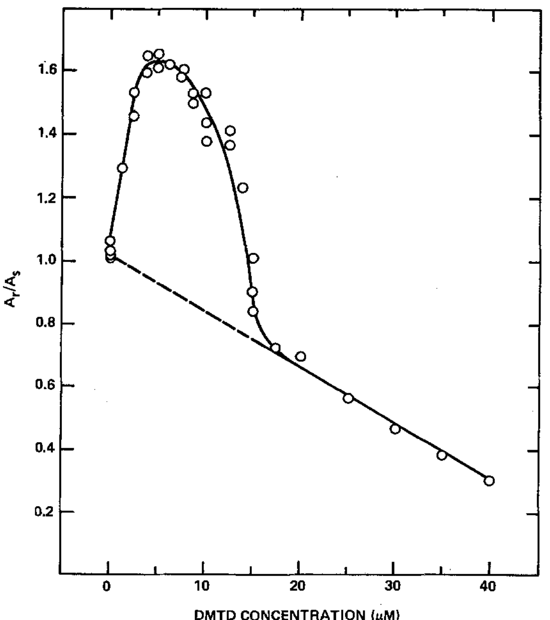

Fig. 1. Relative rate parameter (A_r/A_s) vs. additive concentration for copper pyrophosphate baths at 55°C (after 16 hr).

Analog additive studies.—A_r/A_s ratios were measured at room temperature in baths containing molecular analogs of 2,5-dimercapto-1,3,4-thiadiazole for which amino ($-NH_2$) or methyl ($-CH_3$) groups were substituted for one or both of the mercapto (-SH) groups. To ensure equilibration, baths were heated at 55°C for 16 hr before measurements were made. Data are given in Fig. 3. Both acceleration and deceleration were produced by 2-amino-5-mercapto-1,3,4-thiadiazole, but this analog was less effective than the dimercapto compound. The 2-methyl-5-mercapto-1,3,4-thiadiazole and 2-mercaptothiazoline analogs produced only deceleration, whereas 2,5-dimethyl-1,3,4-thiadiazole had no effect on the deposition rate. These results indicate that acceleration requires two groups which can complex with Cu^{+2} (*i.e.*, -SH or $-NH_2$), whereas one such group can produce deceleration (after activation). It should be noted that other compounds that are not direct analogs of the dimercaptothiadiazoles but contain the —S—C=N— group, like trithiocyanuric acid and sodium thiocyanate, also produce accelerated deposition. All of the accelerating species studied are capable of forming a ligand bridge between two copper ions which permits interaction via a conjugated framework.

Additive equilibria.—The simplest additive equilibrium scheme consistent with the available data is illustrated in Fig. 4. It should be borne in mind that the bath copper ions are highly complexed so that the concentration of free Cu^{+2} is extremely small (6) and may limit the rate of Cu^{+2} reactions. In aqueous solutions, the dimercaptothiadiazole (DMTD) additive (a) is expected (8-10) to exist predominately in the thiol-thione monoanion form (b) which readily complexes with Cu^{+2} ions. Since the analog additive studies showed that two donor groups capable of coordinating Cu^{+2} are required to produce acceleration, the accelerating species is presumably the copper-complexed monomer species (c and d). Since mercaptans also oxidatively dimerize (11), a DMTD dimer species (e) is also expected to form, although more slowly since the additive concentration is small and the oxidation reaction is bimolecular. That the DMTD dimer (e) and its complexed form (f) are the decelerating species is supported by the observation that increasing the Cu^{+2} concentration in the bath suppresses formation of the decelerator, presumably by tying up the DMTD monomer (b) required for dimerization. This is evident from the data in Table I which show that both the final A_r/A_s value and the time required for activation increase approximately linearly with Cu^{+2} concentration. As the additive level is decreased, the effect of increasing Cu^{+2} concentration saturates at progressively lower Cu^{+2} concentrations, as would be expected.

To corroborate the identity of the decelerator, the DMTD dimer (e) was synthesized (by oxidation of the monomer with iodine in acetonitrile/ethanol solution) and was found to be almost immediately active as a decelerator in copper pyrophosphate baths. Although the

dimer produces deceleration even at room temperature, its effectiveness increases with heating at bath operating temperature, which suggests that its copper complexes are more effective decelerators [(f) in Fig. 4 is the expected di-copper species]. Typical activation plots are shown in Fig. 5. At low dimer concentrations, there is a short induction period of several minutes, while low A_r/A_s values are obtained almost immediately at higher concentrations. This also suggests that the dimer must complex with Cu^{+2} in solution before it is active. A_r/A_s increases at longer times for low dimer concentrations (12.5 μmoles in Fig. 5) and accelerating baths are produced when low concentrations of dimer are allowed to equilibrate, indicating that a monomer/dimer equilibrium is established.

Additional strong support for a monomer/dimer equilibrium is found in the experimental verification that the initial monomer concentration must be double that of the dimer to produce approximately the same A_r/A_s value at equilibrium. Thus, a monomer concentration of 25 μmoles results in an A_r/A_s value of about 0.65 (Fig. 2) and the activation curve (Fig. 5) for 12.5 μmoles dimer approaches this value with time. An exact equivalence is difficult to obtain because of the difficulties involved in synthesizing and purifying the dimer and holding the bath composition (particularly the ammonia level) constant for the long times required to reach equilibrium. Also, the dimerization/dissociation is a redox process which must involve other solution redox species (*e.g.*, dissolved oxygen or Cu^+ species) that may be present in small concentrations.

The minimum in A_r/A_s observed early in the activation of higher concentrations of both the dimer and monomer and the peak observed at longer times (Fig. 2 and 5) presumably reflect the presence of appreciable amounts of intermediate species having varied activities. For example, the uncomplexed monomer species [(a) and (b) in Fig. 4] may be decelerating (unlike their Cu^{+2} complexes) so that the presence of significant amounts of these species in the early stages of the monomer and dimer activations could initially suppress A_r/A_s. A_r/A_s would then rise as most of the monomer was complexed with copper to form the accelerating species. The peak would be produced as A_r/A_s again decreased because of formation of di-copper dimer complex [(f) in Fig. 4] which is presumably much more effective as a decelerator than the mono-copper dimer species (not shown in Fig. 4).

It should be mentioned that, although this simple monomer/dimer scheme explains the data well, the situation is probably somewhat more complex. For

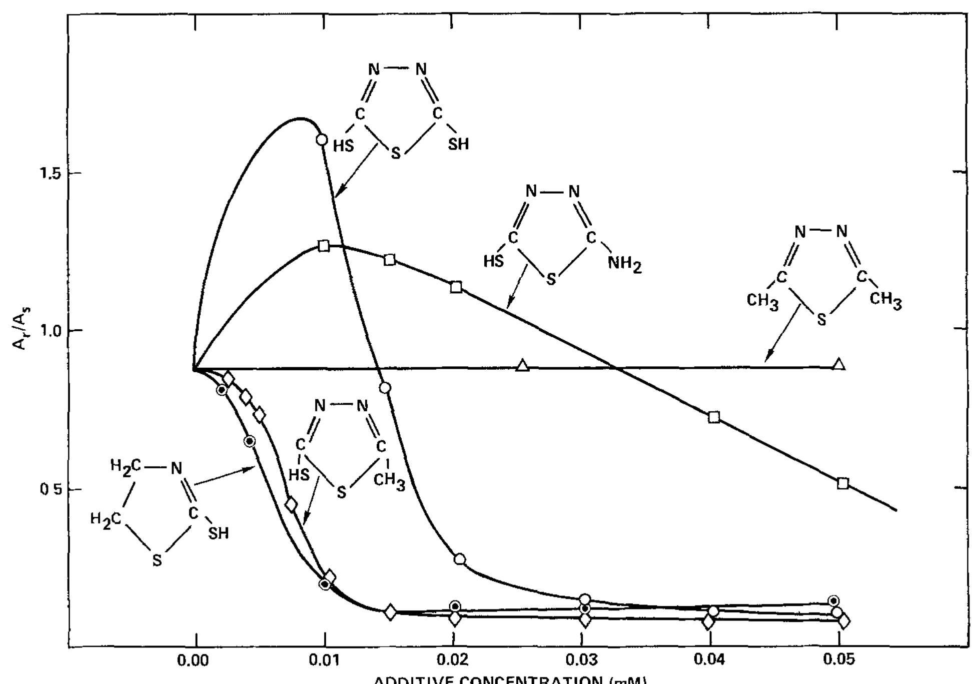

Fig. 3. Relative rate parameter (A_r/A_s) vs. the concentration of various additive analogs. Baths were heated at 55°C for 16 hr, then quenched to room temperature before the measurements.

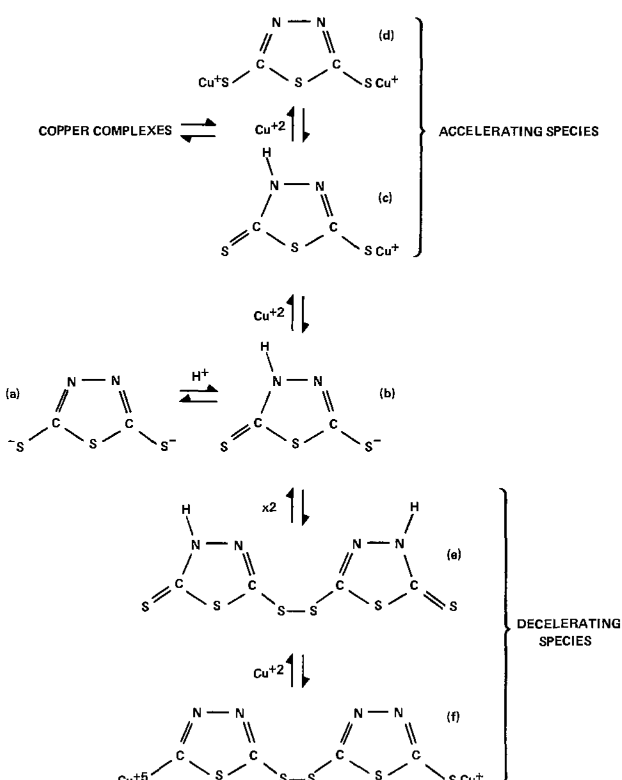

Fig. 4. Proposed equilibria involving the dimercaptothiadiazole additive in copper pyrophosphate baths.

example, in aqueous solutions, DMTD can exist as a monoanion or a dianion, and has several tautomeric forms which can coordinate with Cu^{+2} via mercapto groups, thione groups, an N-S chelate, or the diazo nitrogens of the ring system (9, 10). Large three-dimensional polymeric complexes with DMTD as the sole ligand have also been reported (8).

Considerable insight into the position of the accelerator/decelerator equilibrium and the relative effects of these two types of additive species on the deposition rate can be gained by plotting the A_r and A_s values from Fig. 1 separately *vs.* the overall additive concentration. Such a plot is shown in Fig. 6. These data indicate that the accelerator concentration is higher at equilibrium, but the decelerator produces the larger effect on the deposition rate (per molecule). Thus, A_s increases slowly with additive concentration

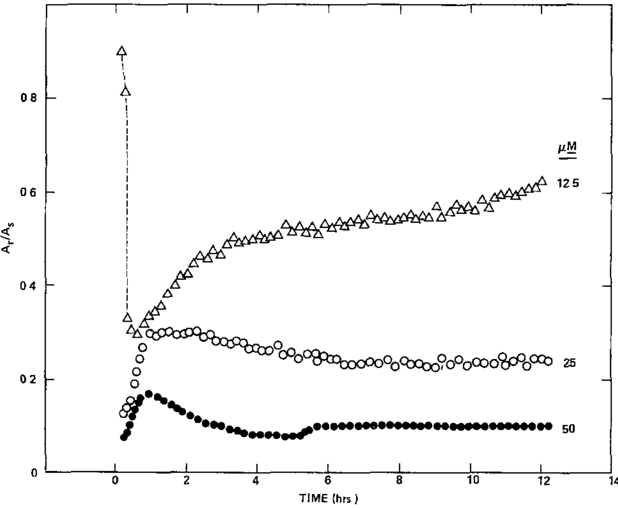

Fig. 5. Relative rate parameter (A_r/A_s) as a function of time after addition of various amounts of DMTD dimer to copper pyrophosphate baths at 55°C.

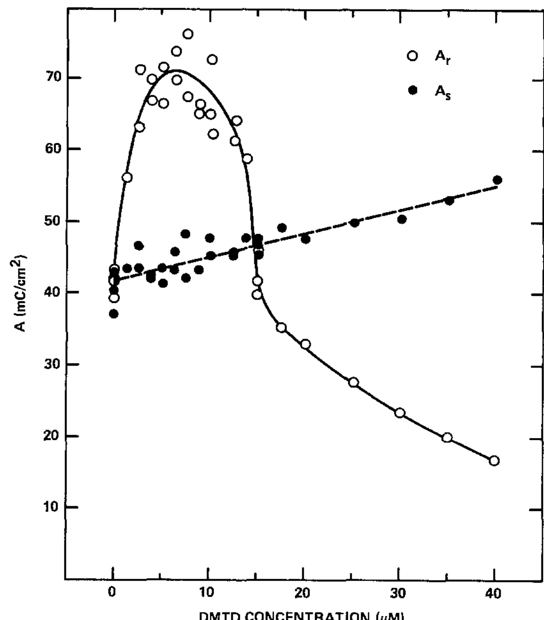

Fig. 6. Rate parameters (A_r and A_s) *vs.* additive concentration for copper pyrophosphate baths at 55°C (after 16 hr).

since in the absence of effective mass transport (electrode rotation), the decelerator concentration is exhaustively depleted at the electrode surface. With electrode rotation, the decelerator effect predominates at the higher concentrations for which sufficient decelerator is formed, so that A_r goes through a maximum then decreases sharply with additive concentration.

The analogous A_s plot is also expected to be linear. Consider the dimerization

$$2M \rightleftharpoons D \quad [1]$$

for which the equilibrium constant is given by

$$K = C_D/C_M^2 \quad [2]$$

where C_D is the dimer concentration and C_M is the monomer concentration. When monomer is added to the bath, the initial concentration (C_o) is always given by

$$C_o = C_M + 2C_D \quad [3]$$

so that

$$C_o = C_M + 2KC_M^2 \quad [4]$$

Thus, if the effect of monomer on the deposition rate is directly proportional to its concentration, which will be shown to be a reasonable assumption, A_s should be linear in C_o at equilibrium unless K is extremely large so that $2KC_M^2$ is not negligible.

It should be mentioned that ammonia in the bath also affects the copper deposition rate. This is not surprising since copper forms a series of ammine complexes, *e.g.*, $[Cu(NH_3)_4]^{+2}$ and $[Cu(NH_3)_2]^+$, which have stability constants comparable to those of the copper pyrophosphate species (7), *i.e.*, in the 10^{12} range. Mixed ammine/pyrophosphate copper complexes would also be expected. Since ammonia is an uncharged ligand, its copper complexes are less negatively charged than the pure pyrophosphate complexes so that copper discharge from the ammine complexes more readily occurs (12) and ammonia would thus be expected to accelerate deposition from copper pyrophosphate baths. As expected, the final A_r/A_s values after activation of copper pyrophosphate baths increase linearly with ammonia concentration. This is illustrated by the data in Table II. The time required for activation of the additive is not significantly affected by the presence of ammonia, indicating that ammonia does not play a major role in the activation process.

Mechanistic/a-c impedance studies.—In order to discuss the mechanism by which the additive species

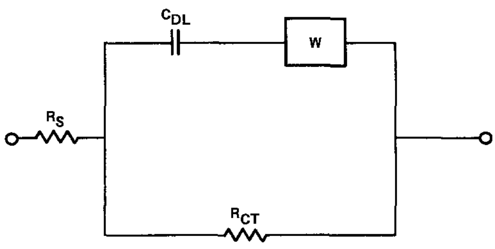
Table II. Effect of NH_3 concentration on the final A_r/A_s value for copper pyrophosphate baths at 55°C

NH_3 concentration (g/liter)	Final A_r/A_s	
	15 μmoles DMTD	30 μmoles DMTD
0	0.52	0.24
1.13	0.77	0.38
2.25	1.0	0.62

affect the copper electrodeposition rate, some additional data must be considered. First of all, we have observed by scanning electron microscopy that copper deposited from pyrophosphate baths in the absence of additives is large grained, whereas deposits from accelerating baths are nodular and those from decelerating baths are fine grained (4). Such dramatic differences in deposit morphology would be expected only if significant changes occurred in the deposition mechanism or rate-determining step. These additive-induced mechanistic changes can be investigated by determination of the charge transfer resistance and double layer capacitance from a-c impedance measurements. The double layer capacitance is particularly important since it reflects the surface concentration of copper adions, which are intermediates in the overall deposition process (13).

The principle of a-c impedance analysis is illustrated in Fig. 7. If we assume that the cathodic half-cell can be represented by the simple electrical network shown at the top of the figure, the electrode impedance can be calculated as a function of frequency (ω) in the complex plane as illustrated at the bottom of the figure (where R_s is the solution resistance, C_{DL} is the double layer capacitance, R_{CT} is the charge transfer resistance, and W is the Warburg impedance). The semicircle obtained is characteristic of a given combination of C_{DL} and R_{CT}, and the linear response at low frequencies is associated with the Warburg (diffusional) impedance.

Impedance diagrams determined during electrodeposition from copper pyrophosphate baths at -0.70 *vs.* SCE are shown in Fig. 8. Behavior is practically ideal for the additive-free and accelerated baths. The diagram for the decelerating bath approximates the ideal



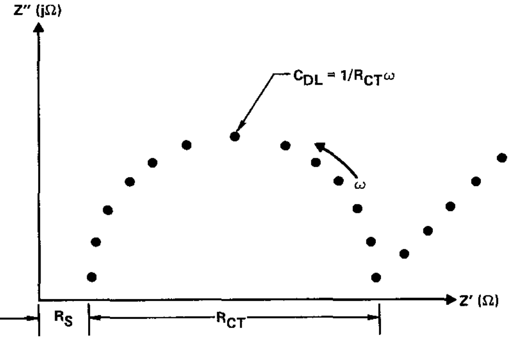


Fig. 7. Simple equivalent circuit for an electrode (top) and the expected a-c response in the complex plane (bottom).

semicircle and should provide semiquantitative information. Data derived from these impedance diagrams are given in Table III. As expected, R_{CT} is slightly smaller for the accelerating bath compared to the additive-free system, and considerably larger for the decelerating bath. The value of 11 $\mu F/cm^2$ for C_{DL} is only slightly smaller in the accelerating system, but is a factor of 24 larger in the decelerating case. This may be interpreted as a significant increase in the copper adion concentration during additive-decelerated deposition since adions reside within the Helmholtz plane and thus reduce the overall extent of charge separation so that C_{DL} increases when the adion concentration increases.

Mechanism of additive effects.—These results provide the basis for understanding the mechanism by which the accelerating and decelerating additive species affect copper electrodeposition. First, consider the overall electrodeposition process in the absence of additives (13) which is illustrated in Fig. 9. Solvated/complexed Cu^{+2} ions in the electrolyte are discharged on surface planes to form partially solvated/complexed Cu^{+1} adions which surface diffuse over lattice planes and along steps to kink sites where they are discharged to Cu^{o} and incorporated into the lattice. It is generally accepted that the rate-determining step at moderate current densities for acid copper sulfate baths is discharge of Cu^{+2} solution species to form adions (13) which has also been shown to apply to pyrophosphate copper deposition in the absence of additives (12). In this case, incorporation of adions into the lattice is fast and the adion surface concentration remains low; growth is orderly and deposits are large grained.

The situation for decelerated deposition is depicted in Fig. 10. In this case, the dimerized additive species adsorbed on the electrode surface interfere with surface diffusion of adions and block lattice growth at kink sites. This necessitates frequent renucleation to sustain a constant deposition rate which is reflected in the increased overvoltage, higher overall charge transfer resistance, and fine-grained deposit morphology. At sufficiently cathodic potentials, lattice incorporation, *i.e.*, growth at kink sites, becomes the rate-determining step and the surface adion concentration increases sharply raising the measured C_{DL}. This change in rate-determining step from adion discharge to lattice incorporation is evident at an overpotential of 250 mV in the C_{DL}-overpotential plot shown in Fig. 11. It should be mentioned that the increased overvoltage may also affect the structure of the double layer electrostatically, especially since pyrophosphate anions are known to desorb at potentials more cathodic than -0.75V *vs.* SCE (14, 15). Such effects were probably minimal in our studies since the electrode potential was always held below this value.

The situation for accelerated deposition is illustrated in Fig. 12. The accelerating additive species apparently lowers the overpotential and overall charge transfer resistance by assisting in the nucleation of new growth centers on surface planes, which ultimately grow to form the almost spherical nodules observed by scanning electron microscopy. As also observed, C_{DL} would be expected to decrease slightly because of the reduction in adion concentration resulting from the shorter average surface diffusional path to the more numerous growth sites.

Table III. Charge transfer resistance (R_{CT}) and double layer capacitance (C_{DL}) during electrodeposition from copper pyrophosphate baths

25 (decelerating)	0.31	57	260

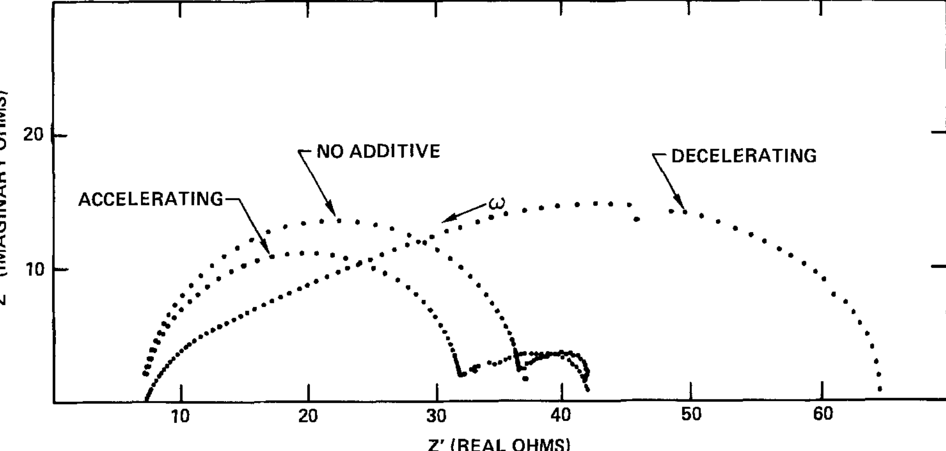

Fig. 8. Complex impedance data obtained during electrodeposition at −0.70V vs. SCE from copper pyrophosphate baths at 55°C.

The way in which the accelerator might assist in nucleation of new growth centers on electrode surface planes can be visualized as follows. For the purposes of discussion, we will assume that the accelerator is the copper-complexed thiol-thione tautomer [(c) in Fig. 4], although the situation for the di-copper monomer species [Fig. 4 (d)] would be equivalent after the initial electron transfer. The accelerating species would be expected to adsorb on the electrode surface with the thiadiazole ring sulfur, which has a lone pair of exo-electrons, serving as the attachment site. As the complexed Cu^{+2} is reduced to Cu^{+}, and ultimately Cu^{o}, to initiate the nucleation process, the charge would be redistributed via the ring structure to form the thiol-thione tautomer which is the mirror image of the original species. The thiol group thus generated would then be available to complex another Cu^{+2} from solution and the reduction process would be repeated. Thus, Cu^{+2} acquisition/Cu^{o} deposition would alternate between the thiol sites which would explain why two Cu^{+2} complexing groups are apparently required for accelerated deposition. If the thiadiazole sulfur-metal interaction is not too strong, the additive could move (via desorption/readsorption) along the surface of the growing nucleus, and the deposition of many Cu atoms could be facilitated before the additive was included in the deposit. The onset of spherical diffusion as the growing nuclei become three-dimensional would also enhance the deposition rate and result in nodular deposits.

Quantitative treatment.—A more quantitative view of the effects of the accelerating species on the electrodeposition rate can be obtained by assuming that the accelerator and decelerator act more or less independently. As mentioned above, this appears to be a good assumption since the plot of the relative rate parameter (A_r/A_s) *vs.* additive concentration in Fig. 1 is linear at higher concentrations and extrapolates to unity for the additive-free system. Thus, we can subtract the decelerating effect of the dimer species according to the linear dashed line in Fig. 1 to obtain the plot shown in Fig. 13 of the accelerator effect on A_r/A_s. Based on the data in Fig. 6, we have assumed that the accelerator concentration is equivalent to the overall additive concentration in this concentration range.

Let us now assume that the monomer acceleration effect can be described in terms of birth and death of nodules so that the relative rate parameter after subtraction of the decelerator effect is given by

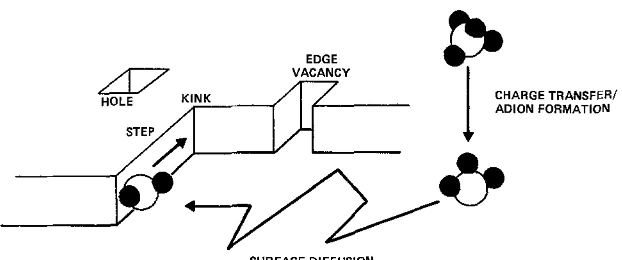

Fig. 9. Representation of copper electrodeposition in the absence of additives at moderate current densities.

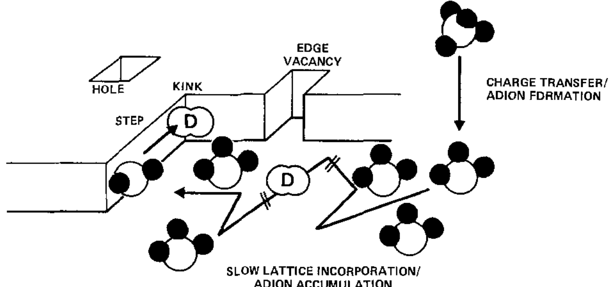

Fig. 10. Representation of additive-decelerated electrodeposition from copper pyrophosphate baths.

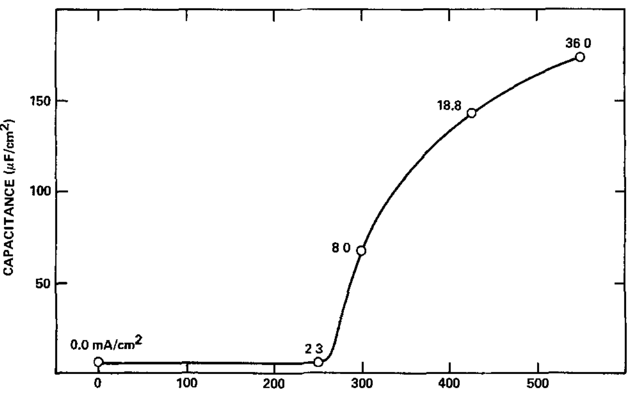

Fig. 11. Double layer capacitance vs. overpotential for additive-decelerated electrodeposition of copper from pyrophosphate baths at 55°C.

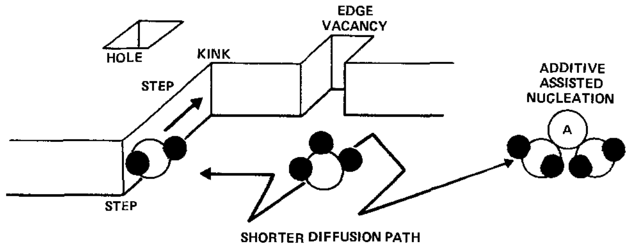

Fig. 12. Representation of additive-accelerated electrodeposition of copper from pyrophosphate baths.

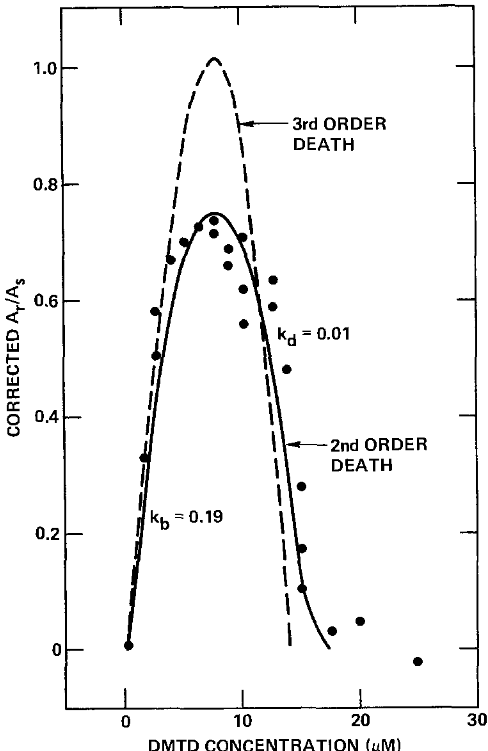

Fig. 13. Plot of A_r/A_s vs. additive concentration after subtraction of the decelerating effect of the dimer species.

$$A_r/A_s = 1 + k_bC_M - k_dC_M^x \quad [5]$$

where $(k_bC_M - k_dC_M^x)$ can only be positive. The assumptions concerning birth are that each nodule exerts an equivalent effect on the deposition rate and that the number of nodules formed is proportional to the monomer concentration. In this case, the accelerating effect on A_r/A_s is given by k_bC_M, where k_b is the proportionality constant. The death process which causes individual nodules to cease growing so that they no longer contribute to accelerated deposition is assumed to be collision with other nodules. Note that collision in this context means that the nodules interact at a small separation distance to stop growth. The collision frequency is assumed to increase with the number of nodules, which is in turn proportional to the monomer concentration so that the net decelerating effect of nodular death is $-k_dC_M^x$, where x is the number of collisions required to produce death and k_d is the death proportionality constant.

In order to test this model, we need to determine k_b and k_d. Assuming that death is unimportant when the density of nodules is low, k_b is obtained from the slope of the corrected A_r/A_s plot (Fig. 13) in the linear region at low additive concentrations. The value of k_d is determined by differentiating Eq. [5] and setting the differential equal to zero at the peak in the corrected A_r/A_s plot. For second-order death, $k_d = k_b/2C_M' = 0.01$, where C_M' is the additive concentration corresponding to the peak in the corrected A_r/A_s plot. The nodule death process seems to be second order as indicated by the excellent fit (solid line in Fig. 13) to the corrected A_r/A_s data. This implies that nodule death involves interruption of growth at specific sites, so that spherical diffusion of copper ions alone would not account for the accelerated deposition and nodular deposits. A plot for third-order death (dashed line) is included for comparison.

A unified model.—The results presented above show that there are two important additive species present in copper pyrophosphate baths. One of these suppresses (decelerates) deposition by blocking growth sites, whereas the other enhances (accelerates) deposition by assisting in the nucleation of new growth centers. Ammonia also enhances deposition, presumably by forming complexes from which copper can be discharged at lower overpotentials to nucleate new growth centers. Nucleation via copper ammine complexes is supported by the observation of nodular deposits at high bath ammonia levels (12).

We propose here that the maintenance of the proper balance between the decelerating and accelerating bath species is critical to the attainment of acceptable pyrophosphate copper deposits. Consider deposition at a high overall additive concentration in the absence of ammonia in the bath. In this case, the limited number of growth sites are quickly blocked by the predominant decelerating dimer species and provisions for generating new sites are inadequate so that appreciable deposition can only occur at high cathodic overvoltages. Under these circumstances, nucleation occurs preferentially at surface microprotrusions where the electric field strength is highest and, once initiated, growth is extremely rapid and disorderly for the short time before it is blocked by adsorption of a new decelerating additive species. The resulting deposits are burnt and powdery with extremely poor crystallinity and mechanical properties.

To obtain acceptable deposits at reasonable current densities, provisions must be made for nucleation of a sufficient number of growth centers at low overvoltages where orderly deposition occurs and deposits are highly crystalline. This can be accomplished by lowering the additive concentration to attain a better balance between the accelerating and decelerating additive species, and by adding ammonia to the bath. On the other hand, sufficient decelerator must always be present to limit the extent to which individual nuclei are permitted to grow. Otherwise, as the nuclei expand in three dimensions, spherical diffusion enhances mass transport and consequently the growth rate, so that growth again becomes disorderly and nodular deposits are obtained. Within this model, it is readily apparent why ammonia is a critical constituent of copper pyrophosphate baths (1) and its concentration must be increased for plating at higher additive levels (16).

Practical implications.—In most applications for which copper pyrophosphate baths are used, the deposit tensile properties are of paramount importance. For example, to avoid cracking problems, plated through-hole deposits in multilayer circuit boards must be highly ductile to relieve stress generated by the excess thermal expansion of the laminant during soldering and must be sufficiently strong to resist fatigue failure upon thermal cycling (17). In addition, deposits must generally be uniform and adherent. Our previous work has shown that both the tensile properties and uniformity of pyrophosphate copper deposits depend strongly on the overall additive concentration and correlate well with cyclic voltammetric stripping data and morphological studies (3-5). Specifically, nodular deposits resulting from additive accelerated deposition were found to have poor tensile properties, and the nonuniform deposition within through-holes known as "foldback" was shown to be a consequence of the dual accelerating/decelerating nature of the additive.

The model presented here, which involves a critical balance between nucleation (initiated by the accelerating additive species and copper ammine complexes) and growth (limited by the decelerating additive species), provides a basis for improving control of copper pyrophosphate plating. First of all, since the three principal species (decelerator, accelerator, and ammonia) which affect the deposition rate (and consequently the deposit properties) vary in activity and concentration, it is clear that the bath additive and ammonia levels must be considered as interdependent variables. Control is therefore rendered considerably less difficult if the additive system is maintained near

equilibrium where the concentrations of additive species are fixed relative to one another. This also ensures that the concentration of monomer which must be balanced by dimer is minimal, so that the total amount of organic material included in the deposit is minimized. An excess of such included material can lead to deposit brittleness. Thus, the additive should be added in such a way as to ensure activation to the dimer form. This implies that, in some cases, making batch additions may be preferable to continuously feeding the additive. Of course, the optimum situation would involve approaching the equilibrium from the other direction by adding dimer directly, if this procedure can be shown to yield deposits with comparable mechanical properties.

Since the three species affecting the deposition rate vary in concentration and relative effectiveness, it might be expected that the effects of changes in bath agitation would be difficult to predict. Fortunately, the decelerator appears to be relatively low in concentration, but highly effective, so that changes in electrolyte mass transport primarily affect the magnitude of the decelerating effect. Thus, if the ammonia concentration is held constant and the additive system is close to equilibrium, variations in agitation can be countered by changes in the overall additive level. Nonetheless, caution should be exercised in making extrapolations for mass transport differences.

It should also be mentioned that the relative rate parameter (A_r/A_s) measured by cyclic voltammetric stripping (3) reflects primarily the concentration of the decelerating additive species in copper pyrophosphate baths. Thus, if the additive system is maintained near equilibrium and the bath ammonia level is held constant, this method provides excellent control of pyrophosphate copper plating.

Summary

The dimercaptothiadiazole/copper pyrophosphate system involves two additive species in dynamic equilibrium. One appears to be the copper complexed DMTD monomeric species which assists nucleation of new growth sites on crystal planes and can lead to nodular deposits. In this case, the electrodeposition rate is accelerated, presumably by some combination of additive-assisted growth randomly over the surface of the nodules, and the onset of spherical diffusion to the new isolated growth sites. The other additive species is apparently the DMTD dimer which decelerates the electrodeposition rate by blocking growth sites. Additive-accelerated deposition can be quantitatively described in terms of birth and death of nodules, where the birth rate is proportional to the accelerator concentration and death results from second-order collision of growing nodules.

Deposition in the dimercaptothiadiazole/copper pyrophosphate system can be understood by assuming that a balance must be maintained between suppression of growth by the decelerating additive species and nucleation of new growth centers via the accelerating additive species and copper ammine complexes. This model could prove to be general for electrodeposition from highly complexed systems.

Energy Dependence of the Quantum Efficiency of CdSe Photoelectrochemical Cells

K. Colbow, D. J. Harrison, and B. L. Funt*

Departments of Physics and Chemisty, Simon Fraser University, Burnaby, Vancouver, B.C., V5A 1S6 Canada

ABSTRACT

Polycrystalline CdSe electroplated on nickel and titanium substrates was used as photoanode in electrochemical cells with S^{2-}/S_n^{2-} as a redox couple. When compared to a single crystal photoanode, the quantum efficiency is found to be larger for photon energies below the bandedge and smaller for those above the bandedge. The single crystal efficiency dependence on photon energy near the bandedge is well described by the Butler equation and dominated by variation of the absorption coefficient and the depletion layer width and less sensitive to the minority carrier diffusion length for the crystal under study. The electroplated samples may be assigned a bandgap of about 1.70 eV compared to 1.72 eV for the single crystal. Information about impurity content may be obtained from the photoresponse for energies below the bandedge.

The aim of this research was to understand the performance of electroplated and single crystal n-type CdSe as solar cells in terms of their fundamental semiconductor parameters, such as absorption coefficient (α), impurity concentration (N_D), depletion layer width (W), flatband potential V_{FB}, energy gap (E_g), hole diffusion length (L_p), and hole diffusion coefficient (D_p). To this end we studied the short-circuit photocurrent efficiency (η) as a function of wavelength in an aqueous electrolyte consisting of 1.0M NaOH, 1.0M Na_2S, and 1.0M S. Photoanodic dissolution does not occur under these conditions (1) and the electrode reactions are the oxidation of S_n^{2-} at the photoanode and the reduction of S_n^{2-} at the platinum dark electrode. We compared the data to the simple Butler equation (2)

$$\eta = \frac{I}{qA\phi_0} = 1 - \frac{e^{-\alpha W}}{1 + \alpha L_p} \qquad [1]$$

where I is the short-circuit current, q the electronic charge, A the cell area, and ϕ the incident light flux. The depletion layer width is given by

$$W = \left\{ \frac{2\epsilon_0\kappa}{qN_D} (V - V_{FB}) \right\}^{1/2} \qquad [2]$$

$\epsilon_0 = 8.85 \times 10^{-12} C^2 n^{-1} m^{-2}$ is the permittivity of free space, $q = 1.60 \times 10^{-19}$C the electron charge, and V the measured or applied potential. The dielectric constant $\kappa = 10$ for CdSe (3).

For the flatband potential of CdSe with an S^{2-}/S_n^{2-} redox couple Gerischer and Gobrecht (4) obtained a value of -1.27V *vs.* NHE (normal hydrogen electrode) from capacitance measurements for CdSe single crystal whose surface had been converted to CdS. This corresponds to -1.51V *vs.* SCE (standard calomel electrode). Ellis *et al.* (1) obtained a flatband potential of -1.45V *vs.* SCE for single crystal CdSe from capacitance or open-circuit voltage at high light intensity and -1.40V from the less accurate onset of photocurrent at high light intensity. Noufi *et al.* (5) obtained -1.34V *vs.* SCE for pressed powder pellets and -1.30V for vacuum-deposited films of CdSe using the onset of photocurrent. We shall choose a value of -1.50V *vs.* SCE. Using a value of -0.72V for platinum in a polysulfide electrolyte *vs.* SCE (6, 7), we obtain $V_{FB} = -0.78$V *vs.* platinum electrode in S^{2-}/S_n^{2-}, which was used in our experiments.

Experimental

Monochromatic excitation was obtained using a 1000W quartz iodine tungsten lamp and a Jarrel-Ash grating monochromator with a 100Å bandpass. Infrared radiation was filtered out by passing the light through 2 in. of water, second-order grating effects were eliminated with a Corning 3.71 filter. The monochromatic beam was expanded by lenses to provide full sample illumination and a reasonably parallel beam.

Polycrystalline samples were prepared by an electrodeposition technique which evolved as an extension of a method reported previously (8, 9). Controlled electrodeposition was performed at -0.72V *vs.* SCE for 15 min on a titanium or nickel substrate, which had been etched, cleaned meticulously, and cathodized for 15 sec in an acidic oxidizing medium. The deposition bath consisted of 1M NH_4Cl, 0.5M $CdSO_4$, and 0.01M SeO_2. Electrodeposition at -0.76V and -0.64V *vs.* SCE was also performed in order to obtain electrodes lacking stoichiometry, being rich in Cd and Se, respectively. The plated photoelectrodes were about 1 μm thick and were subsequently heated under 100 Torr N_2 at 400°C for 15 min. The counterelectrode was platinum.

The single crystal CdSe was obtained from Cleveland Crystal Incorporated, its c-axis was perpendicular to the front surface. Electrical contact at the back side was made with a GaIn eutectic, and a copper wire was attached to this with Ag epoxy. This was then sealed with epoxy and mounted on a Teflon rod. The quartz cell had a flat window, allowing a 2-3 mm optical path length through the electrolyte. The cells were flushed with nitrogen gas prior to and after introduction of the electrolyte and then sealed from the atmosphere.

In order to test the polycrystalline electrodes under equilibrium conditions, the cells were left overnight in the electrolyte, and the open-circuit voltage V_{oc} was monitored to determine if a steady state had been reached. Steady open-circuit voltage always correlated with steady short-circuit current I_{sc} in the dark.

The "short-circuit" current was measured after the cells had equilibrated by determining the voltage drop across a 10Ω resistor in series with the photocell. The voltage in the dark and under illumination was measured and the difference was reported as the photocurrent.

Results and Discussion

Figure 1 shows the experimental points (□) for the quantum efficiency as a function of wavelength of the incident light. The data was obtained for a single crystal under low light intensity and corrected for light absorption by the solution. The curves represent Eq. [1] with the absorption coefficient α as function of wavelength taken from Parsons *et al.* (10) for light polarized perpendicular to the c-axis of the crystal.

Key words: electroplating, photoanode, crystals.

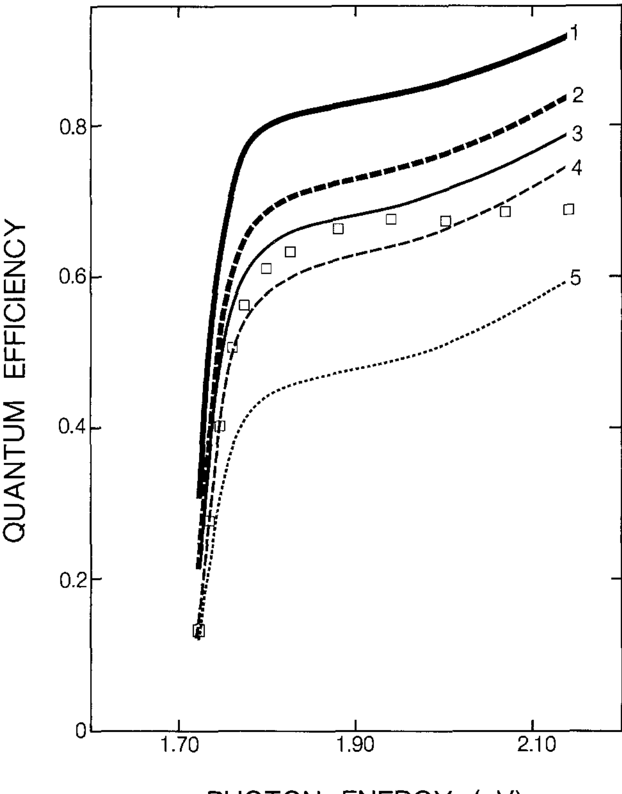

Fig. 1. Quantum efficiency vs. photon energy for a single crystal of CdSe (experiment: □), and theoretical curves for W, L_p values of curve 1, 0.2, 0.1; curve 2, 0.2, 0; curve 3, 0.1, 0.1; curve 4, 0.15, 0, and curve 5, 0.1, 0 μm.

For W and L_p various values were chosen in order to demonstrate the sensitivity of the Butler equation to changes in these parameters. Curve 4 is a least squares fit to the experimental data. Using in Eq. [2] a dielectric constant $\kappa = 10$, and a flatband potential $V_{FB} = -0.78V$, a depletion layer width of $W = 0.15$ μm corresponds to an impurity concentration of $N_D = 4 \times 10^{16}$ cm^{-3}, which appears reasonable. The fact that Eq. [1] provides a reasonable fit to the data with negligible value of L_p merely suggests that $\alpha L_p < 1$ and thus most of the variation of efficiency comes through W.

To obtain a better fit between theory and experiment, one may consider that the most important neglect in the Butler equation is the assumption of no surface recombination. Analogous to Wilson's (11) treatment this may be rectified in the simplest way by multiplying the right-hand side of Eq. [1] by the ratio $S_t/(S_t + S_r)$, where S_t and S_r are the relative probabilities of surface transfer (S_t) and nonproductive surface recombination (S_r) of light-generated charge carriers at the semiconductor-electrolyte interface. This introduces one new parameter, namely the ratio of S_t/S_r. A more detailed theoretical treatment will be presented separately. Reiss' (12) more elaborate theory of photoelectrochemical cells also neglects surface recombination and gives a behavior similar to Butler's equation. A further complication to Eq. [1] arises for samples of thickness comparable to the inverse of the absorption coefficient ($\approx$1 μm). This is a factor for our thin electroplated samples ($\approx$1 μm thickness), but not for the single crystal ($\approx 10^3$ μm thickness) measurements.

Considering absorption coefficients such that $\alpha L_p << 1$ and $\alpha W << 1$, expansion of Eq. [1] yields

$$\eta \approx \alpha(W + L_p) \quad [3]$$

For $L_p \approx W \approx 0.1$ μm this approximation is thus good for $\alpha << 10^5$ cm^{-1}.

The absorption coefficient α has different functional dependencies on photon energy $h\nu$, depending on the nature of the transition (13). For a direct gap material like CdSe near the absorption edge the absorption coefficient is described by

$$\alpha = \frac{A}{h\nu}(h\nu - E_g)^{1/2} \quad [4]$$

Combining Eq. [3] and [4], a plot of $(\eta h\nu)^2$ vs. $h\nu$ should give a straight line with intercept on the x-axis equal to the energy bandgap. This plot is shown in Fig. 2, curve 1, for the single crystal of CdSe.

For comparison we also show plots of $(\eta h\nu)^{1/2}$ vs. $h\nu$ (curve 2) and $(\eta h\nu)^{2/3}$ vs. $h\nu$ (curve 3), whose straight line sections extrapolate to the energy gap in the cases of an indirect semiconductor and a forbidden (phonon assisted) transition in a direct semiconductor, respectively (13). In curve 1 the full line extrapolates to an energy gap for CdSe of $E_g = 1.72$ eV. This compares with a quoted room temperature literature value of 1.74 eV (14-16). Curves 2 and 3, which should not apply, extrapolate to energy gaps of 1.68 and 1.69 eV, respectively. Figure 3 shows an expansion of the efficiency scale for photon energies below the bandedge for the single crystal of CdSe. The data indicates the typical Urbach exponential tail below the bandedge (above 1.60 eV) and what we interpret as impurity absorption below 1.60 eV. The peak at 1.50 eV we believe is due to defect absorption. The peak is 0.240 eV below the bandedge and in analogy to CdS may represent energy absorption by electrons bound to deep acceptors, possibly cadmium vacancies (17).

Figure 4 compares the wavelength dependence of the quantum efficiency for a single crystal of CdSe with electroplated samples of about 1 μm thickness. The latter were plated at -0.72V vs. SCE and subsequently heat-treated for improved response, as described earlier. Titanium substrates gave consistently higher efficiencies than nickel substrates, however, both had

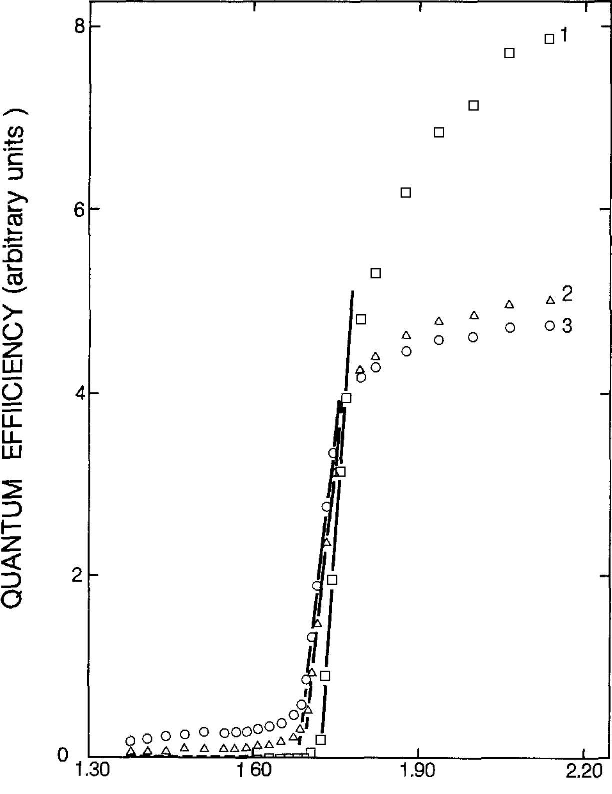

Fig. 2. Bandgap determination. Various fits of the single crystal quantum efficiency data for different functional forms of absorption coefficient vs. photon energy: 1, $(\eta h\nu)^2$, 2, $(\eta h\nu)^{1/2}$, 3, $(\eta h\nu)^{2/3}$.

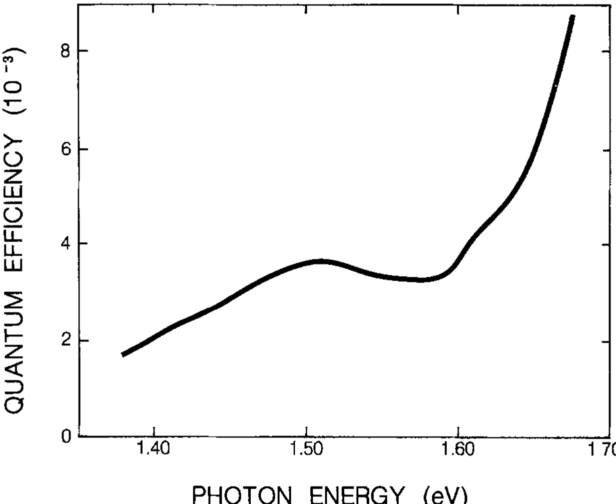

Fig. 3. Expansion of the experimental quantum efficiency (from Fig. 1) below the bandedge for single crystal CdSe.

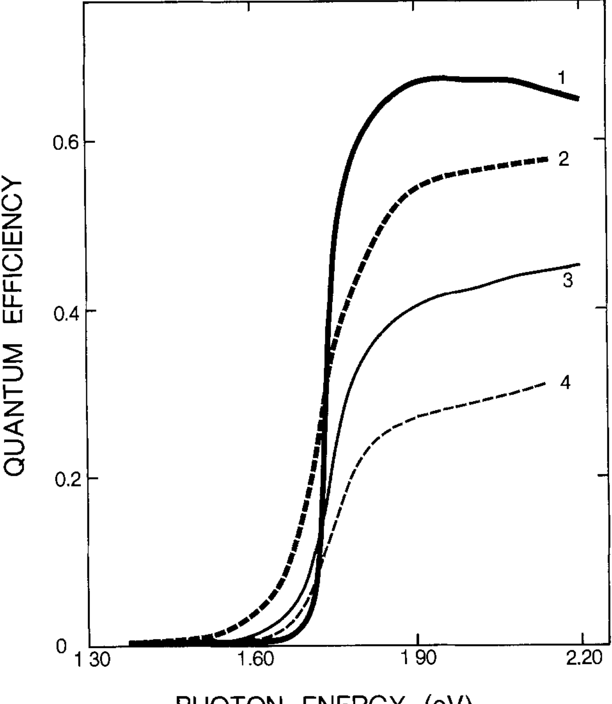

Fig. 4. Experimental quantum efficiency vs. photon energy of curve 1, CdSe single crystals; curve 2, electroplated samples on titanium substrate; curves 3 and 4, on nickel substrate.

a lower efficiency for photon energies above the bandedge and higher efficiencies for lower energy photons. Curves 3 and 4 show measurement on two different samples, which were prepared on different days under supposedly identical conditions to illustrate the reproducibility of sample preparation. Figure 5 shows a plot of $(\eta h\nu)^2$ *vs.* photon energy for two samples each, electroplated on nickel and titanium substrates. The straight line intercepts with the x-axis should give the energy bandgap of the CdSe (13). The samples on titanium substrate (curves 1 and 2) extrapolate to E_g = 1.69 eV and the samples on nickel substrate to 1.71 eV compared to our single crystal value of 1.72 eV.

Figure 6 compares electrodes plated at slightly lower (−0.76V) and higher potential (−0.64V) than the plating potential (−0.72V *vs.* SCE) that produces the most efficient electrodes (curve 1), corresponding to best stoichiometry. Plating at lower or higher potential probably produces electrodes rich in cadmium or selenium, respectively, which show a reduced efficiency

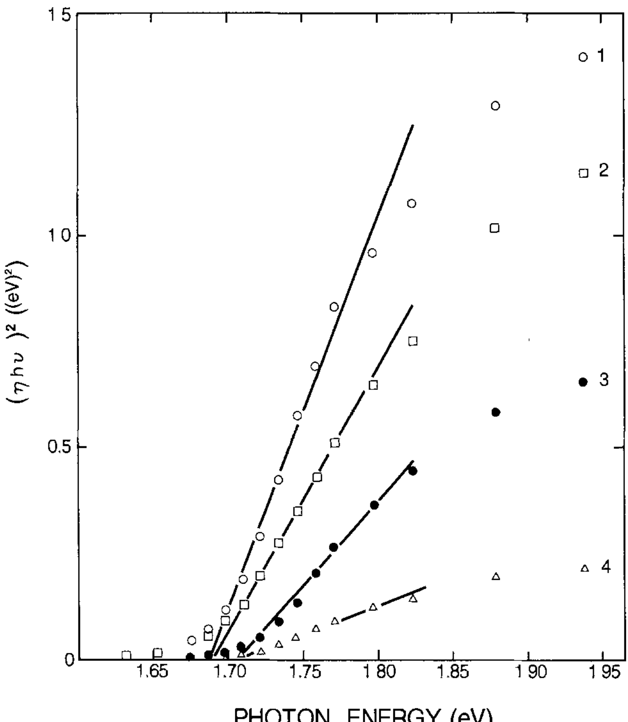

Fig. 5. Bandgap determination. $(\eta h\nu)^2$ vs. photon energy for electroplated CdSe on titanium (○, □) and nickel (●, △) substrates.

at all wavelengths. In contrast to the samples in Fig. 4, those in Fig. 6 did not undergo heat-treatment after plating.

Figure 7 shows on an expanded efficiency scale the photoresponse of electroplated CdSe below the band-

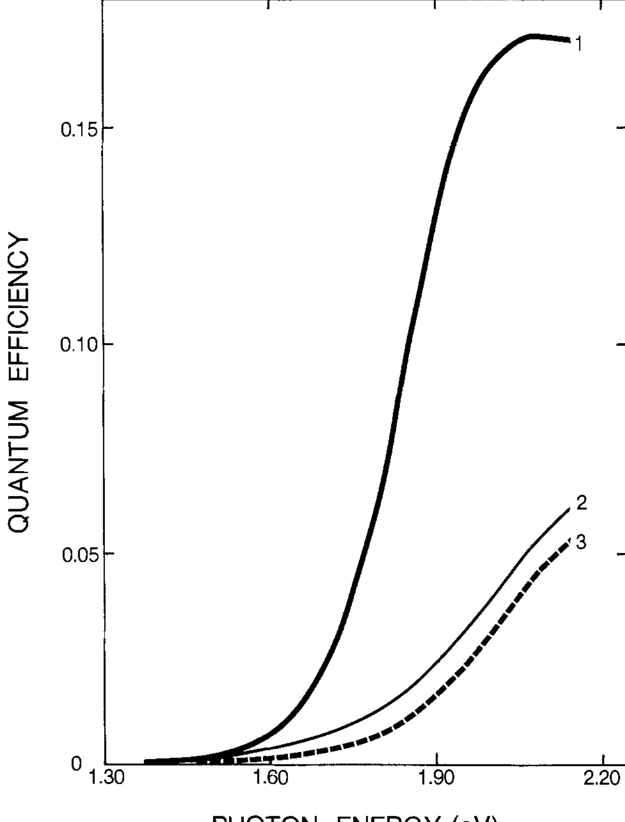

Fig. 6. Quantum efficiency vs. photon energy for CdSe electroplated on nickel substrates at plating potentials vs. SCE of curve 1, −0.72V, curve 2, −0.76V, and curve 3, −0.64V.

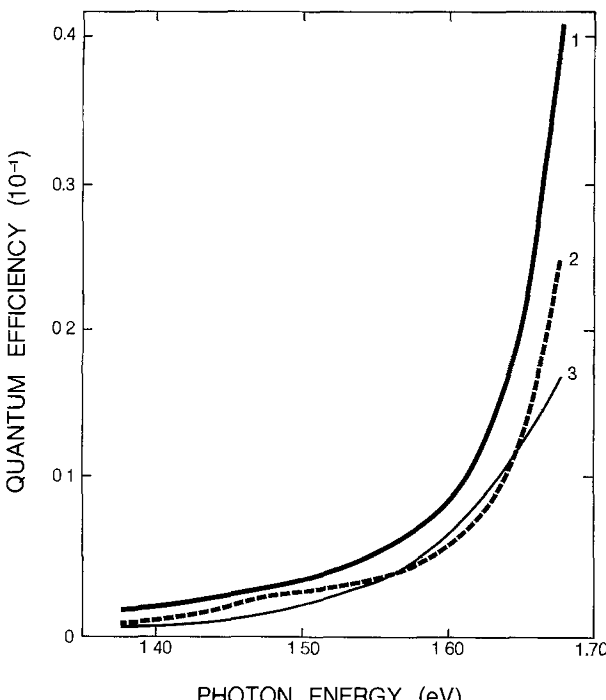

Fig. 7. Quantum efficiency vs. photon energy below the bandedge for CdSe electroplated on nickel substrate at —0.72V vs. SCE. Samples for curves 1 and 2 were heat-treated but that for curve 3 was not heat-treated.

edge. While the response is large when compared to the single crystal data (Fig. 3), a 1.50 eV peak is not always as well defined, and no clear spectral differences due to heat-treatment were observable.

Conclusions

The Butler equation accounts reasonably well for the wavelength dependence of the quantum efficiency in single crystal CdSe for photons near the bandedge. The efficiency is controlled by the absorption coefficient and the depletion layer width, rather than the minority carrier diffusion length.

For photon energies below the bandedge a small photocurrent is observable in single crystal CdSe due to well-defined defect or impurity absorption.

In electroplated polycrystalline CdSe the efficiency above the bandedge is reduced by about a factor of two for 1 μm thick samples on nickel substrate and by half that for samples on titanium substrate, when compared to thick single crystal of CdSe. The efficiency below the bandedge is increased in electroplated samples. The "impurity absorption" is much broader in the electroplated samples.

However, it appears that one still has a well-defined energy gap, which is only 20-30 meV smaller than our single crystal gap.

Preliminary experiments show that the electroplated CdSe efficiency can be enhanced with proper surface treatment.

ABSTRACT

Fast photocurrent transients were recorded in a CdSe/S$^=$, S$^\circ$ cell employing a spark-gap lamp as a source of illumination. From the measured dependence of the decay time on the value of the load resistor it is shown that photocurrent decay is controlled by an R-C time constant which is determined by the properties of the cell. The form of the decay is sensitive to the state of the photoelectrode surface, as shown by the pronounced effect of chemical etching which enhances the amplitude and reduces the decay time of the transients. The damaged surface layer produced by mechanical polishing increases the effective series resistance of the cell and decreases the photocharge obtained (per flash) through the external load.

The importance of kinetic parameters in the determination of the efficiency and stability of semiconductor (SC) photoelectrodes has been stressed by many authors (1). Transient techniques have served as an important tool for the evaluation of kinetic parameters in both electrochemical (2) and solid-state solar cells (3-10). The use of such techniques in photoelectrochemical cells has been introduced very recently (11-18). We present in this contribution results of fast transient measurements in the CdSe/S$^=$, S$^\circ$ photoelectrochemical system, and their analysis in terms of elements of an equivalent circuit.

Experimental

A block diagram of the experimental system for measuring fast transients in photoelectrochemical cells (PEC) is given in Fig. 1. A well-shielded spark-gap lamp served as a white light source, generating pulses of 10 nsec width and 50 Hz repetition rate. The peak power was 10^5W and the spectrum was continuous, peaking around 330 nm. These light pulses were directed at the surface of a single crystal CdSe electrode immersed in a 4.5M NaOH, 0.2M S, 0.2M Na_2S solution.

The hexagonal n-type CdSe single crystals (Cleveland Crystals, Incorporated) were 1-2 mm thick, had a resistivity of 12.2 Ω cm, and a surface perpendicular to the C-axis. The ohmic contact to the crystal was prepared with an In/Ga eutectic, and the crystal was then attached to a copper foil with silver epoxy. The copper foil was coated by a layer of epoxy so that only a single surface of the CdSe crystal was in contact with the electrolyte. The exposed area varied from sample to sample in the range of 0.1-0.2 cm^2. Polishing was performed by 0.3 μm alumina and etching was carried out in 4:1 HCl:HNO_3. The duration of etching was 30 sec, followed by washing in alkaline polysulfide solution and rinsing in distilled water.

The PEC was completed by a load resistor and a reversible brass counterelectrode (19) of large area immersed in the same solution. The brass counterelectrode was wrapped by glass microfiber paper to avoid contamination of the solution by ZnS or CuS particles. The very short wires used to connect the electrodes to the load resistor, as well as the large areas of the CdSe copper foil support and of the brass counterelectrode minimized the inductance of the total circuit. The PEC itself was well shielded electrically.

The high frequency photovoltaic signals were monitored using FET probes, (Type P6045 or plug-in unit 7A11, Tektronix). Photocurrents were measured under conditions close to external short circuit with a current-probe (P6022, Tektronix), and amplified when required by the current-probe amplifier (Type 134, Tektronix). To overcome problems due to lamp jitter and due to the initial delay of the boxcar unit, a compensated delay line was employed. The gate output of the scope (7904, Tektronix) was used to synchronize the scan delay generator (Brookdeal, 425A) while the amplified signal was applied through the delay-line to the linear-gate (Brookdeal, 415). The output signal from the boxcar was displayed on an X-Y recorder.

Results

Figure 2 demonstrates the pronounced effect of surface treatment on the amplitude and the decay time of the measured photocurrent transients: chemical etching of a mechanically polished CdSe electrode resulted in higher photocurrent peaks, in a larger charge per pulse, and in shorter decay times. The pronounced effect of surface treatment on the amplitude and decay time could be reproducibly repeated, while keeping the cell composition and electrode configuration con-

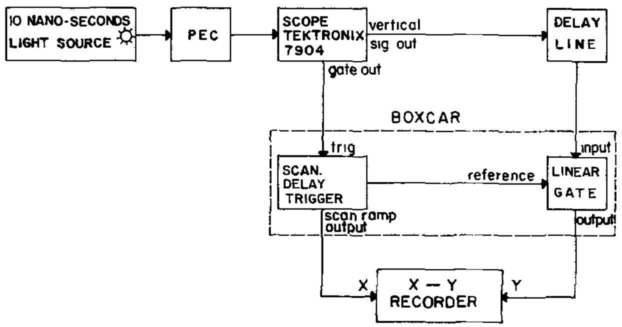

Fig. 1. The instrumental system for fast transient measurements in PEC.

stant. This proved conclusively that interfacial effects were not masked in this mode of measurement by other possible contributions to the time constant of the complete circuit. Figure 3 shows the steady-state photocurrent-voltage curves obtained for the same mechanically polished CdSe electrode prior to and after etching. It is clear that large changes in the steady-state performance of the cell are brought about by the same surface treatment which causes the modification of the transients.

In an attempt to evaluate quantitatively the measured photocurrent decay curves, the dependence of the decay time τ on the value of the load resistor, R_L, was recorded under conditions of small potential perturbations, so as to keep the interfacial parameters practically constant. To ensure such conditions, the light intensity was attenuated by a neutral filter so that the total drop across the load would not exceed 25 mV. The quasipotentiostatic conditions and low intensities employed resulted in simple exponential decay with a single time-constant τ. Figure 4 demonstrates the difference in the shape of decay curves obtained under small and large perturbations. Such differences were pronounced especially for etched electrodes, for which saturation conditions due to bands flattening were reached at full lamp intensity. A τ *vs.* R_L plot recorded at small perturbations is presented in Fig. 5 (the same attenuating filter was employed for all values of R_L). It can be seen that for small values of R_L the curve is linear, but the slope becomes smaller at higher values of R_L. In the same measurement, τ was found to approach an almost constant level for load resistors higher than 5 KΩ. The effect of etching on the τ *vs.* R_L plot is demonstrated in Fig. 6. (Again, small perturbations were employed.) The insert in Fig. 6 is an enlargement of the linear sections (small R_L regions) of the plots obtained before and after etching. These linear sections were evaluated by a linear regression analysis for slope and intercept (correlation function better than 0.99 for both lines). It can be seen that the intercept of the plot has become lower as a result of etching, while the slope has become somewhat smaller.

Discussion

The decay of the photocurrent in solar cells following an illumination pulse may be controlled, in principle, by the following factors (3): (*i*) the diffusion time of minority carriers towards the junction; (*ii*) the transit time through the junction; (*iii*) the Maxwell relaxation time; (*iv*) the lifetime of minority nonequilibrium carriers; and (*v*) a combined cell-circuit *R-C* time constant. Since CdSe is a direct band-gap semiconductor (20), most of the light is absorbed in the space-charge region and factor (*i*) should be insignificant. Strong band bending, imposed by keeping the CdSe electrode close to the potential of the $S^=/S^\circ$ couple, makes factor (*ii*) unimportant. Factor (*iii*) is not expected to play an important role thanks to the low resistivity of both the SC and the electrolyte employed. The most important factors to be considered are thus (*iv*) and (*v*). *In situ* photoluminescence decay-time measurements, conducted for the same photoelectrode by employing a dye laser of 2 nsec

pulse width, revealed that the radiative band-to-band decay is completed in these CdSe samples (under small perturbation conditions) within 20 nsec. It thus seems from the above-mentioned arguments and results that in the time domain investigated ($t > 20$ nsec) photocurrent decay should be controlled by an *R-C* time constant.

The measured time dependence of τ on R_L (Fig. 5 and 6) verifies that τ is indeed controlled in our case by an *R-C* time constant which is determined by properties of the PEC and of the external circuit. The form of the measured variation of τ with R_L at small perturbations can be simulated by a very simple equivalent circuit, in which the semiconductor-electrolyte interfacial region is represented by a photocapacitor, *C*, with a shunt resistor, R_{in}, across it, while the rest of the cell and circuit is represented by a resistor R_{out}. R_{out} is given by

$$R_{out} = R_{series} + R_L$$

where R_{series} is a series combination of ohmic elements due to the PEC. To complete the equivalent circuit the photon flux is represented by a current source, according to the routine adopted in the analysis of solid-state solar cells (20), this leading to the circuit depicted in Fig. 7(a). The measured response of the real system to short light pulses can be simulated by the response of this simple *R-C* network to short current pulses. For a very short current pulse from the source (current delta function) the time variation of the current in the external circuit is calculated for circuit 7(a) [*e.g.*, by Laplace transformation (21)] as

$$i_{out} = \frac{\Delta Q}{R_{out}C} \exp(-t/\tau) \quad [1]$$

where ΔQ is the charge injected by the source into the photocapacitor, and the decay time is given by $\tau = (R_{in}||R_{out})C$. For small values of R_L such that $R_{out} << R_{in}$, the decay time is given by $\tau = R_{out} \cdot C = (R_L + R_{series})C$. Under such conditions a plot of τ *vs.* R_L should be linear, with a slope of *C* and an intercept $R_{series} \cdot C$. On the other hand, at high values of R_L such that $R_{out} >> R_{in}$, the decay time is given by $\tau = R_{in}C$ and is thus expected to be independent of R_L. This is indeed the general form of the experimental τ *vs.* R_L plots depicted in Fig. 5 and 6. It thus seems that for small values of R_L photocarrier decay occurs via the external circuit, while for large values of R_L the decay takes place via an internal leakage route. in the same way as the capacitor in circuit 7(a) discharges primarily via R_{out} or via R_{in} depending on their relative values.

Although the very simple equivalent circuit of Fig. 7(a) seems to explain the general form of the experimental τ *vs.* R_L plots, its validity should be examined considering the complete photoelectrochemical cell it is expected to represent. Thus, when additional elements representing the counterelectrode are added, the more complex circuit of Fig. 7(b) is obtained. Analysis of this circuit shows that the solution for the current in the external cell, following a delta source current perturbation, has the form

$$I_{out} = A_1 \exp(-t/\tau_1) + A_2 \exp(-t/\tau_2) \quad [2]$$

However, when $C_c >> C$, the following relationships apply: $\tau_1 \sim (R_{out}||R_{in})C$, $\tau_2 \sim R_cC_c$ and $A_2 << A_1$. This means that circuit 7(b) will generate transients with, practically, a single decay time: $\tau = (R_{out}||R_{in})C$, provided $C_c >> C$. This condition is fulfilled by the PEC employed, the counter being a metal electrode of large area. Any large capacitor in series with the small photocapacitor is expected, in fact, to act as a short during a fast transient measurement, and the simple circuit 7(a) is, thus, a high frequency form of 7(b) for $C_c >> C$. This was further verified experimentally by replacing the brass counterelectrode by a gold wire, (while employing a 50Ω resistor), resulting in no apparent effect on the measured transients, in accordance with the results reported in Ref. (16). Photocurrent transients with a single decay time may be, thus, expected for this cell when the decay is under pure *R-C* control, provided the potential perturbations are sufficiently small to ensure the constancy of *C* and R_{in}.

From the results of Fig. 6, it is seen that etching lowers the cell resistance, R_{series}, from 12 to 8Ω. Assuming that mechanical polishing produces a damaged surface layer (or a surface film) which can be removed by chemical etching, then such a layer may behave as an additional ohmic element through which photocarriers have to be transported. The effect of such an additional ohmic element on the form of the transient can be examined with the aid of the equivalent circuit in Fig. 7(c), where the damaged layer is represented by the additional resistor R_d. The solution for a delta perturbation in this circuit is

$$I_{out} = \frac{\Delta Q \cdot R_{out}}{(R_d + R_{out})^2 C} \exp(-t/\tau) \quad [3]$$

where $\tau = C\ [R_{in}||(R_d + R_{out})]$. The resistor R_d thus explains the longer decay time and, to some extent, the lower amplitudes obtained in the presence of the surface film. Under short-circuit conditions, the amplitude is calculated to reduce by a factor of 2.5 due to the surface layer when $R_d = 4\Omega$ and $R_{out} = 8\Omega$. However, the description of the damaged layer in terms of the additional resistor, R_d, is not complete. From Fig. 3, it is clearly seen that this layer causes a substantial lowering of the open-circuit potential as well. This is not expected to occur due to the addition of R_d. It seems

that the damaged surface acts also as an active recombination region. If the recombinative process in this layer is very fast, it may not show up as a feature in the decay curve in the time window of our measurement ($t > 20$ nsec).[1] Its only apparent effect in terms of the equivalent circuit considered may be the lowering of the initial ΔQ on the photocapacitor, causing a reduction of the initial photopotential. The total amount of charge passing through the external load was indeed measured by us to increase 2-4 times after etching (Fig. 2). The role of the surface as a region of enhanced recombination has been described before by Nelson *et al.* (23) according to *ex situ* photoluminescence decay measurements. This may be the main kinetic significance of such a damaged layer under open-circuit conditions. However, the additional ohmic effect has to be considered when photocurrents are drawn from the cell.

The value of R_{series} evaluated from the photocurrent decay measurements after etching (8Ω in the case depicted in Fig. 6) is very close to the sum of bulk SC and electrolyte solution ohmic resistances calculated according to the specific resistivities, sizes, and geometries employed. The same value for the cell series was found also from the maximum photocurrent peak obtained for an etched electrode under saturation conditions (high pulse intensity): The maximum measured photocurrent peak was given by

$$(i_p)_{max} = \frac{\Delta\phi_{max}}{R_{series} + R_L}$$

where $\Delta\phi_{max} = 0.7V$ (complete band flattening) and $R_{series} = 8\Omega$. It is thus clear the value of R in the RC time constant found for photocurrent decay in this PEC is determined by the total series resistance of the cell. If R_{series} contains a contribution due to the finite rate of interfacial charge-transfer at the SC-electrolyte interface ("faradaic impedance") this contribution is apparently very small in this case. Further transient measurements with solutions containing less efficient hole acceptors should reveal if the faradaic impedance can be resolved when it is much larger than the ohmic elements due to the bulk SC and electrolyte.

Finally, the value of C evaluated from the τ *vs.* R_L plots is close to that found from a Schottky-Mott plot (80 nF cm^{-2}) for a similar CdSe electrode in an alkaline $S^{=}/S^{\circ}$ solution under the same applied potential (22). This simply means that the photocapacitor is located in the space-charge region of the semiconductor. Etching is expected to increase the value of C if its only effect were surface roughening. The slight lowering of C measured after etching (Fig. 6) probably means that some surface states contributing to the total C measured for a mechanically polished electrode are removed by etching, resulting in a lower capacity in spite of the increased surface area. It should be also noticed that the measured reduction in reflectance due to this mode of etching (24) is calculated to bring about not more than 20% enhancement of the photocurrent, *i.e.*, this cannot be considered a major contribution to the measured effects.

[1] Measurements conducted by us recently, using an Nd-YAG laser, showed that effects of the damaged surface layer on the effective lifetime of the photocarriers could be measured in the time window 10 psec-10 nsec.

Acknowledgment

One of us (S. G.) would like to thank Brookhaven National Laboratory for their assistance in the preparation of this manuscript for publication during his stay there as a Visiting Scientist (Summer 1980).

Manuscript received Aug. 6, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Technical Notes

The Use of Rutherford Backscattering Spectroscopy for Characterization of Surface Films Produced by Aluminum/Water Reactions

General Ionex Corporation, Newburyport, Massachusetts 01950

Surface films formed during the reaction between aluminum metal and aqueous electrolytes at elevated temperatures are of considerable interest in situations where such films may afford some measure of resistance to the onset of pitting attack in the presence of aggressive anions (*e.g.*, Cl^-). The reaction between aluminum or aluminum alloys and aqueous electrolytes may result in a variety of reaction products and surface film morphologies, and is reviewed in detail by Alwitt (1). For the specific case of aluminum alloy radiators in automotive cooling systems, the complexity of the electrolyte is accentuated by a variety of components including an antifreezant, various corrosion inhibitors, buffers, and antifoaming agents. Furthermore, the overall system may contain dissimilar metal components which can ultimately result in plating reactions on freshly exposed aluminum, in the absence of particular inhibitors for these reactions. Characterization of aluminum alloy surfaces used in an active cooling system involves not only an appraisal of aluminum/water reaction products on the surface, but also the degree of inhibitor uptake by the surface, the presence of any dissimilar metals, and the integrity of the surface film as a barrier to pitting attack.

The role of any films formed by surface reaction in the overall process of pitting attack is also of interest. While an initially dense oxide or oxyhydroxide (*e.g.*, pseudoboehmite) film may be advantageous in limiting the rate of aggressive ion ingress, its ultimate role may be deleterious if the film serves to isolate a developing pit from the bulk of the electrolyte (2, 3). In this latter case, the essentially unreactive film allows localized acidity conditions to develop within the pit so that metal dissolution proceeds without benefit of any diluent or buffering effects of the electrolyte external to the pit.

Electron and low energy (*i.e.*, <10 keV) ion beam spectroscopies are often limited in their ability to rapidly assess such features as apparent thickness and overall elemental composition for water-grown films on aluminum. This is due primarily to experimental sampling depths (usually $\sim$100Å or less) which can represent only a limited fraction of the thickest water-grown films [often approaching physical dimensions of $\sim$0.5 μm (1)]. Since elemental depth profiles in these techniques are often achieved by concurrent sputter etching, the results may often require extensive times for data collection, and result in limited depth resolution due to artifacts associated with the sputter process. In this work, the use of Rutherford Backscattering Spectroscopy (RBS) is described with particular application to reactions between a relatively clean aluminum surface and water containing a phosphate-based inhibitor. RBS has the distinct advantages in these applications of permitting the overall film characteristics to be assessed qualitatively, and in a relatively fast, (*ca.* 5 min spectrum acquisition time) though nondestructive manner.

The RBS technique has been employed by a number of investigators for analysis of surface oxides on aluminum and aluminum alloys (4-7). The experimental details are adequately described in the text by Chu, Mayer, and Nicolet (8). In general, a collimated source of monoenergetic high energy ions and associated scatter chamber and detector are used to acquire the energy distribution of ions scattered through a fixed angle from the target surface. For the simplest thin film, the mass of the surface atom is deduced from the kinetic energy of the backscattered ion, through application of simple binary scattering kinematics with the initial ion energy, its mass, and scattering angle as known quantities. Depth information may be obtained when energy losses in the target bulk are considered for the backscattered ions. For the case of $^4He^{2+}$ at primary energies of 2-3 MeV, the accessible depth is sufficient to permit penetration of the surface films, allowing extraction of compositional data for the free surface as well as the metal/oxide interface. Because of the relatively low atomic weights of aluminum and oxygen, the spectral peaks for heavier elements occur where there is minimal background contribution, and with somewhat larger sensitivities due to greater scattering cross sections (8).

In this work, the ion source consisted of a 3.0 MeV Tandetron accelerator manufactured by General Ionex Corporation. A scattering angle of approximately 160° was used, in conjunction with a barrier-type particle detector and counting electronics. The overall experimental resolution was estimated to be 25 keV.

Aluminum coupons of a commercial 1100 type material were prepared by mechanical and electrolytic polishing according to a procedure described elsewhere (9). Surface films were grown at 100°C by immersion of the coupons in either doubly distilled, deionized water or in similar water containing Na_2HPO_4 at 0.05M, which is a known inhibitor of the aluminum/water reaction (10). The surface treatments, as well as several experimental quantities are summarized in Table I.

Key words: backscattering, pseudobeohmite, aluminum, inhibitor.

Table I.

Specimen	Film growth time (min.) Water	Film growth time (min.) 0.05M Na_2HPO_4	ΔE_s Aluminum substrate energy shift (MeV)	O_{FWHM} (MeV)	Approximate film thickness (A)*	Remarks
A	—	—	0.0	—	—	Electropolished surface only
B	15	0	0.079	0.081	1450	No iron peak observed
C	0	15	0.044	0.050	850	Distinct P and Fe
D	15	15	0.117	0.122	2150	Diffuse P and Fe

* Calculated using density of 3.0 g/cm² of AlOOH (boehmite) and tabulations outlined in Ref. (12) and (13).

The RBS spectra for the various surface treatments are shown in Fig. 1. The iron peak observed for the electropolished surface (spectrum A) is believed to be due to residual $FeAl_3$ particulates which remain on the surface following specimen preparation. Iron is the principal impurity in 1100 type alloys, present at levels typically less than 0.5% (wt). The role of the resultant $FeAl_3$ precipitates in corrosion of aluminum has been discussed elsewhere (11). In spectrum A scattering from the essentially clean aluminum substrate shows a spectral edge having the energy of the binary He-Al collision at roughly the half-height of the edge. The effect of growing a pseudoboehmite film in water (spectrum B) is evidenced by two new features of the spectrum: (*i*) the appearance of an oxygen peak due to growth of the oxyhydroxide film, and (*ii*) the displacement of the aluminum substrate scatter edge to a lower energy by the amount ΔE_s due to the associated loss of energy by the helium ions as the layer is traversed during the scatter process. As indicated in Table I, the aluminum substrate scatter edge is displaced by 0.079 MeV from the binary collision energy associated with the relatively clean surface in spectrum A. Because the surface pseudoboehmite film has a lower density of aluminum atoms per cm² than the aluminum metal substrate, the leading aluminum scatter edge occurs at an overall lower signal height. Thus, in principle, the film thickness is reflected in the breadth of the leading surface layer spectral edge (and corresponding ΔE_s for the substrate edge), while the height of this leading edge is a measure of the film density.

In spectrum C, the effect of the inhibitor is immediately apparent in that ΔE_s for the substrate, as well as the oxygen full width at half maximum (O_{FWHM}) are diminished from the values associated with the pure water grown film. The uptake of phosphorus in the surface layer is evidenced by the appearance of a distinct peak having the appropriate binary collision energy for He-P.

In spectrum D, the original 15 min pseudoboehmite film was exposed to an additional 15 min in the phosphate solution. The spectrum indicates continued film growth *i.e.*, increased O_{FWHM} and ΔE_s, but with noticeably less phosphate uptake than that which occurred on the relatively fresh aluminum surface. The passivation of the surface by the original pseudoboehmite film is apparently responsible for retarding the fixation of the aluminophosphate complex as occurred in spectrum C. The original film produced by 15 min water exposure continues to develop with only slight uptake of phosphate.

It can be seen that RBS offers a unique insight into the mechanisms of film formation and growth. The inhibitive effect of phosphate at the fresh metal surface, as reported by Vermilyea and Vedder (10) is clearly observable, as well as the resulting phosphate uptake by the surface. The ability of RBS to observe cumulative elemental compositions in depth, may prove to extend the utility of the technique to a range which is unattainable with many other surface spectroscopies.

Erratum

In the paper "A Thermodynamic Theory of Dissolution Potential and Further Tests of the Theory" by R. P. Rastogi and S. A. Kahn, which appeared in the September 1980 issue of the JOURNAL, Vol. 127, No. 9, the following corrections should be noted: On page 1989, paragraph 3 should precede paragraph 2; on page 1990, in the third paragraph, it should read M = mass of phase; also on p. 1990, the right-hand side of Eq. [8] should read X_2 instead of J_c. On page 1991, the left-hand side of Eq. [34] should read $(\Delta\phi)$ instead of $(\phi\Delta)$; on page 1991, Eq. [44] should read as $\frac{a_2^{(\text{sat'd})}}{a_2^{\beta}}$ instead of $\frac{a_1^{(\text{sat'd})}}{a_2^{\beta}}$. The title of Table II on p. 1993 should be "Dissolution potential of KCl in KCl-HCl aqueous mixtures." Also in Table II, the fourth line in the first column should read 0.025M HCl + 0.075M KCl.

Preparation and Properties of Zinc Oxide Films Grown by the Oxidation of Diethylzinc

James R. Shealy and B. Jayant Baliga*

General Electric Company, Corporate Research and Development Center, Schenectady, New York 12345

ABSTRACT

This paper describes the preparation and properties of zinc oxide films grown by the oxidation of diethylzinc. It is shown that growth above 250°C, with an oxygen to diethylzinc mole ratio in excess of 10, results in stable films of zinc oxide, free from carbon contamination or zinc-ethyl groups. Details are provided of these growth conditions and also of the resulting growth parameters in this paper. The physical properties of films grown by this technique are also described, with particular emphasis on their *IR* absorption characteristics, stoichiometry, refractive index, and crystallographic orientation, as a function of the growth conditions. Films are shown to have an oxygen deficiency which increases with growth temperature, as does their refractive index. Film orientation, along the c-axis, is also found to improve with increasing growth temperatures.

The properties of zinc oxide films have allowed the fabrication of devices such as heterojunction solar cells, surface acoustic wave devices, and optical waveguides. The highly aligned C-axis films which are obtained with the technique to be described display piezoelectric properties (1) and provide a medium for surface acoustic wave propagation (2). The bandgap of zinc oxide (3.3 eV) is sufficiently large to be transparent to most of the solar spectrum, and its conductivity may be controlled over a broad range. These facts together make zinc oxide useful in heterojunction solar cells application. For example, an n-ZnO/p-CdTe heterojunction solar cell has produced solar efficiencies of 4.6% and short-circuit current collection of 19 mA/cm^2 (3). The optical transmission spectrum for the zinc oxide films shows a strong absorption edge at wavelengths around 0.4 μm, with a transparent region in the range of 0.4-2.3 μm. This transparent window makes zinc oxide suitable for optical waveguide fabrication (4). In addition, the authors have used zinc oxide films as a source of zinc for open tube diffusions of zinc in gallium arsenide (5).

This paper describes the growth of zinc oxide utilizing a metal-organic chemical vapor phase deposition (CVD) process. These films are characterized using infrared transmission, resistivity measurements, x-ray diffraction, Auger analysis, and ellipsometry. The conditions for the deposition of stable, C-axis oriented, zinc oxide films grown by the oxidation of diethylzinc have been determined. It appears that zinc oxide films obtained with this process have desirable optical, electrical, and acoustical properties which are potentially suitable for the many applications mentioned above.

* Electrochemical Society Active Member.

Key words: zinc oxide, chemical vapor deposition, organometallic CVD.

Apparatus

The apparatus used for the zinc oxide depositions was a resistance heated, cold wall system which is schematically illustrated in Fig. 1. The substrate heater was approximately 1½ in. in diameter. The reaction chamber geometry was vertical with gas flow normal to the substrate surface. The chamber was maintained at essentially atmospheric pressure with reactants entering at the top and exhausted out of the bottom of the chamber. The chamber was a 12 in. long, 3 in. diam quartz tube. Gases provided to this system were argon[1] and oxygen.[1] The diethylzinc[2] was contained in a stainless steel bubbler maintained at 25°C, and was transported into the reaction chamber by passing argon through the bubbler. An additional argon line was used for dilution purposes. Oxygen was introduced through a separate port at the top of the reaction chamber.

Film Deposition

In this study, the zinc oxide films were deposited by the reaction of diethylzinc with oxygen. Diethylzinc is a pyrophoric liquid which is known to react with air even at room temperature. The deposition of zinc oxide films using diethylzinc vapors was, therefore, studied over a wide range of temperatures ranging from room temperature (25°C) up to 500°C. The oxidation of diethylzinc may be expected to proceed by the following reaction

$$(C_2H_5)_2Zn + 7\ O_2 \rightarrow ZnO + 4CO_2 + 5H_2O \qquad [1]$$

This equation indicates that it is necessary to perform the deposition under a high O_2/DEZ mole ratio to ensure complete oxidation of the diethylzinc.

[1] UHP grade, Union Carbide Corporation.

[2] 5*N* Electronic grade, Ventron Corporation, Danvers, Massachusetts.

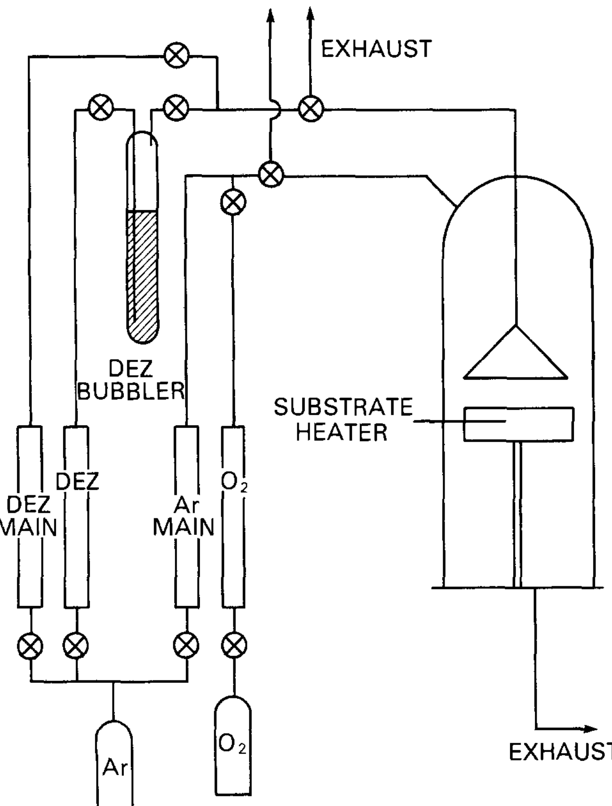

Fig. 1. Schematic diagram of zinc oxide deposition system

The deposition of the zinc oxide films was studied on (111) ± 0.5° oriented, 30 Ω-cm, phosphorus-doped, silicon substrates under the following conditions:

(*i*) For a fixed partial pressure of diethylzinc and a fixed deposition temperature, the effect of the partial pressure of oxygen was observed by changing the oxygen flow.

(*ii*) Keeping the partial pressure of oxygen and the deposition temperature fixed, the effect of the partial pressure of diethylzinc was observed by changing the argon flow through the diethylzinc bubbler. Full saturation conditions were assumed for the argon passing through the bubbler.

(*iii*) Keeping the partial pressures of diethylzinc and oxygen fixed, the effect of the deposition temperature was observed. Prior to film deposition, the substrates were cleaned by degreasing, immersion in Caros solution, and a dip in HF prior to loading into the reactor. After deposition, the film thickness was determined by ellipsometry.

Oxygen flow.—In the absence of oxygen, diethylzinc will decompose at elevated temperatures into zinc-ethyl groups or even into elemental zinc if the temperature is sufficiently high. In this study, it was found that the films deposited with little or no oxygen present showed rapid changes in appearance upon exposure to air after deposition. The effect the introduction of oxygen had upon the growth rate of the films was examined at a deposition temperature of 350°C while maintaining all other gas flows constant. To obtain this data, the argon flow through the diethylzinc bubbler was maintained at 23 cm^3/min and a total argon flow of 6.9 liters/min was used. The growth rate was found to be independent of oxygen flow when the oxygen to diethylzinc mole ratio exceeded 10. Films grown at oxygen to diethylzinc mole ratios of less than 10 showed changes in appearance on exposure to air. This is in accordance with the high ratio of oxygen to diethylzinc indicated by Eq. [1] to ensure complete reaction. Consequently, care was taken in the experiments described below to maintain an oxygen to diethylzinc ratio of greater than 10 to ensure the deposition of stable zinc oxide films.

Diethylzinc flow.—The growth rate of the zinc oxide films could be varied over a broad range by controlling the argon flow through the DEZ bubbler while maintaining all other growth parameters constant. For a deposition temperature of 350°C, an oxygen flow of 12 cm^3/min and a total argon flow of 6.9 liters/min, the growth rate was found to increase linearly with increasing argon flow through the DEZ bubbler as shown in Fig. 2. Similar results were obtained at other deposition temperatures. It should be noted that even at the highest DEZ concentrations used to obtain the growth rate data in Fig. 2, the oxygen to DEZ ratio was maintained at greater than 10 to ensure the formation of zinc oxide films.

Growth temperature.—The growth rate of the zinc oxide films was measured as a function of the deposition temperature over the range from room temperature (25°C) to 500°C, while maintaining all the gas flows constant. The gas flows chosen for these experiments were an argon flow through the DEZ bubbler of 23 cm^3/min, an oxygen flow of 12 cm^3/min, and a total argon flow of 6.9 liters/min. It was found that the films deposited at below 250°C changed their appearance on exposure to air. Consequently, the growth rate of films deposited at 250°-500°C is shown in Fig. 3. It can be seen that the deposition rate decreases when the growth temperature is increased. Reactant depletion at the substrate surface with increasing deposition temperature was found to be responsible for this decrease in the growth rate. This depletion in the reactant concentration at the substrate surface occurs due to a competing gas phase reaction between the diethylzinc and

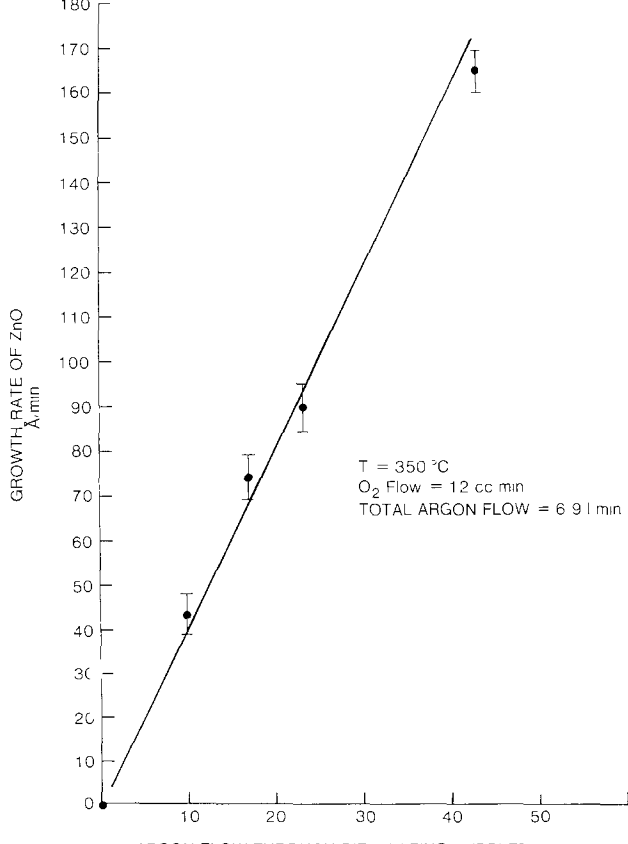

Fig. 2. Increase in the deposition rate of zinc oxide films with increase in argon flow through the diethylzinc bubbler.

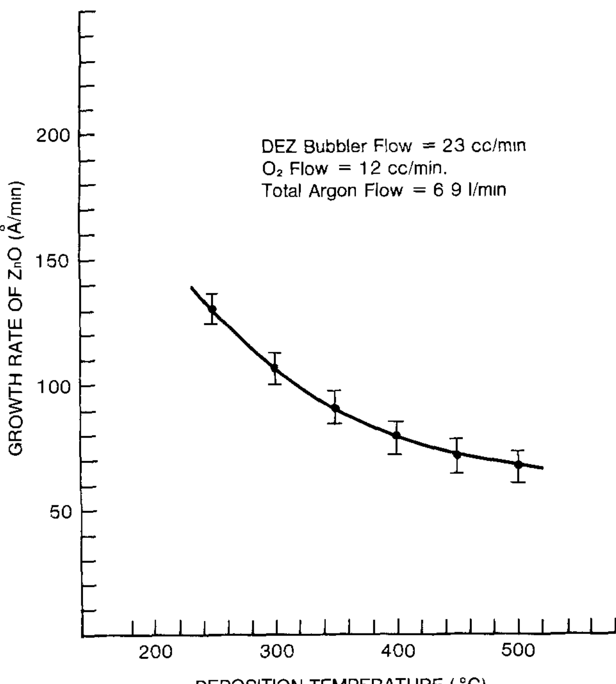

Fig. 3. Dependence of the growth rate of zinc oxide films upon the substrate temperature.

oxygen. Evidence supporting this was obtained by measuring the growth rate, at a fixed deposition temperature, while changing the spacing between the DEZ inlet to the reactor and the substrate surface. For a fixed partial pressure of DEZ in the reaction chamber, the growth rate showed a rapid increase with decreasing spacing between the DEZ inlet and the substrate surface. Although it may be concluded from these results that a small spacing between the DEZ inlet and the substrate surface is desirable for obtaining high growth rates, in practice the DEZ inlet position must be chosen so as to obtain the desired uniformity in the film thickness over the entire substrate area. As an example, for the above growth conditions, a spacing of 3 in. between the DEZ inlet and the substrate surface resulted in a variation in film thickness of less than ±10% over an area of 1.5 in. in diameter.

Film Properties

Chemical, physical, and electrical properties of the zinc oxide films deposited under various growth conditions are described below. This data can be used to evaluate the quality of these films for potential applications.

Infrared absorption.—Infrared absorption measurements over wavelengths ranging from 1 to 40 microns were taken on films deposited at temperatures ranging from room temperature (25°C) to 500°C. Films which were deposited at temperatures above 250°C showed the presence of an absorption band at a wavelength of 23 microns which was not observed in the case of films deposited at below 250°C. Typical absorption spectra for films deposited at 150° and 500°C are shown in Fig. 4 for comparison. Since this absorption band has been observed in bulk zinc oxide and is associated with the zinc-oxygen molecular bond, it can be concluded that zinc oxide films are deposited at substrate temperatures above 250°C, while films deposited below this temperature probably consist of unstable zinc ethyl groups.

Composition.—The stoichiometry of zinc oxide films deposited at temperatures ranging from 250° to 500°C was measured by Auger analysis using a polycrystalline zinc oxide sample as the standard. Films were found to contain an excess of zinc which increased with increasing deposition temperatures as shown in Fig. 5. A similar behavior has been observed in the case of the deposition of tin oxide films by the oxidation of tetramethyltin (6). The presence of excess zinc in the films, as detected by the Auger analysis, is important for understanding the variation in their refractive index and resistivity with growth temperature. It is also worth pointing out that the Auger analysis, taken on these films after ion milling approximately 50Å from the surface, showed that they were free of the carbon contamination that could arise from the use of the organometallic zinc source.

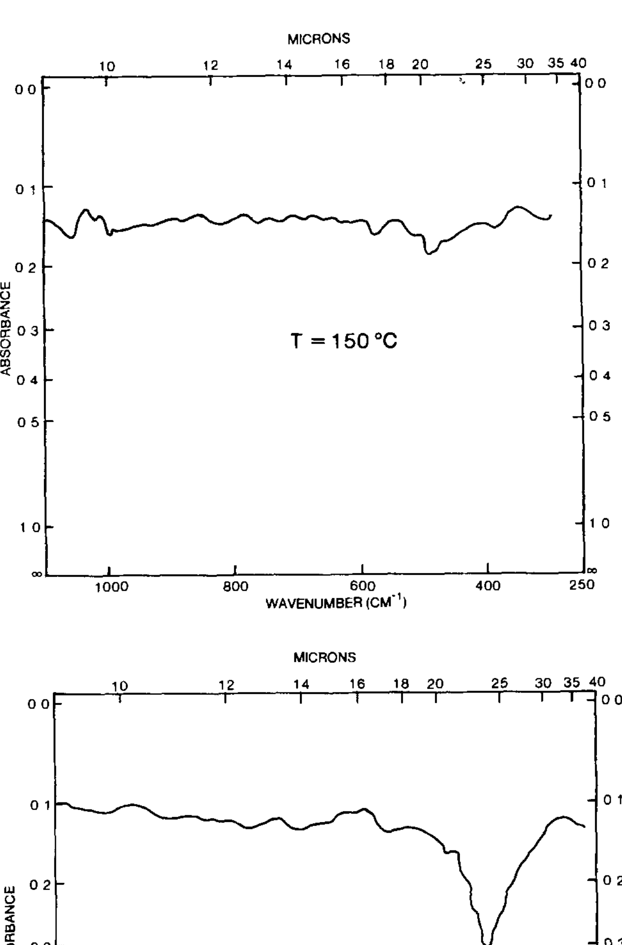

Fig. 4. Infrared absorption spectra of films deposited at substrate temperatures of 150° and 500°C.

Refractive index.—The index of refraction was measured for films at a wavelength of 5461Å by ellipsometry. The conditions used to deposit these films on the silicon substrates were identical to those used to obtain the data shown in Fig. 3. The variation in the refractive index with deposition temperature is shown in Fig. 6. It can be seen that the index of refraction increases when the deposition temperature is increased. This increase in the refractive index with deposition temperature correlates with the observed increase in the excess zinc concentration as was shown in Fig. 5. While a refractive index of 2.03 has been reported for bulk ZnO (8), values similar to those given

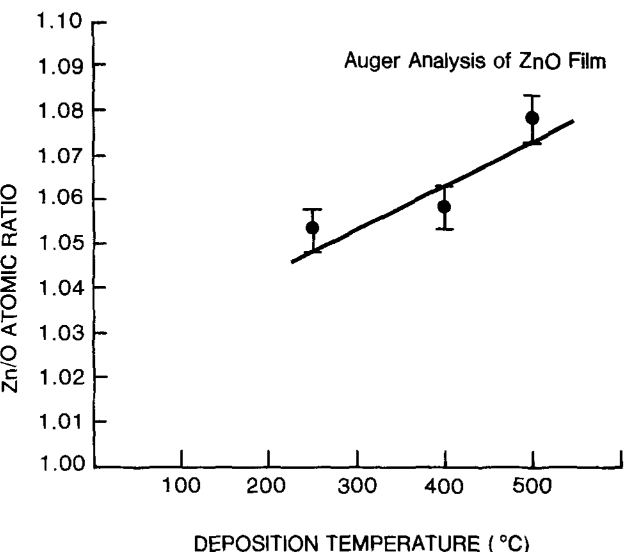

Fig. 5. Auger data of zinc oxide films revealing the increase of excess zinc in the films with increasing deposition temperatures.

in Fig. 3 have been observed for ZnO films deposited by other chemical vapor deposition techniques (9).

Crystal orientation.—X-ray diffraction measurements were made on films deposited on Corning Type 7059 glass at deposition temperatures ranging from 250° to 500°C. No diffraction peaks were observed for films grown at and below 300°C, indicating that these films were amorphous. However, films deposited at above 300°C showed x-ray diffraction peaks as illustrated in Fig. 7 for a film deposited at 400°C. This and other x-ray data taken on these films shows that the films have a high C-axis orientation which improves with increasing deposition temperature. This data as well as the results of deposition on other substrates has been discussed in greater detail elsewhere (7).

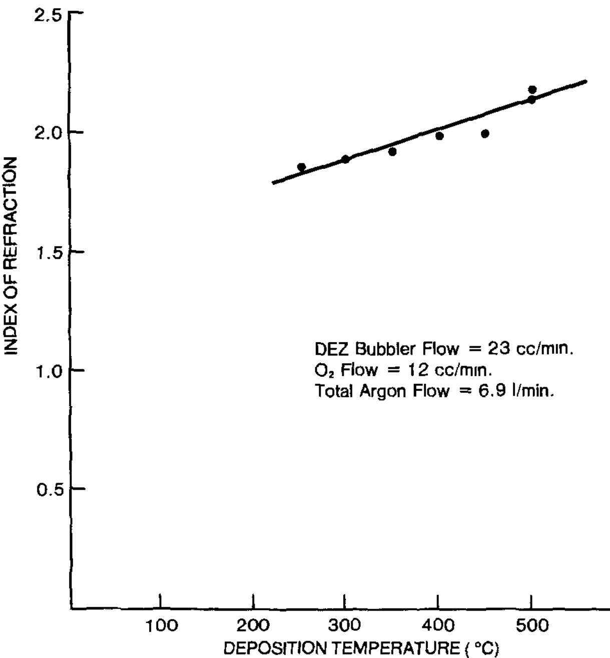

Fig. 6. Refractive index of zinc oxide films grown at deposition temperatures ranging from 250° to 500°C.

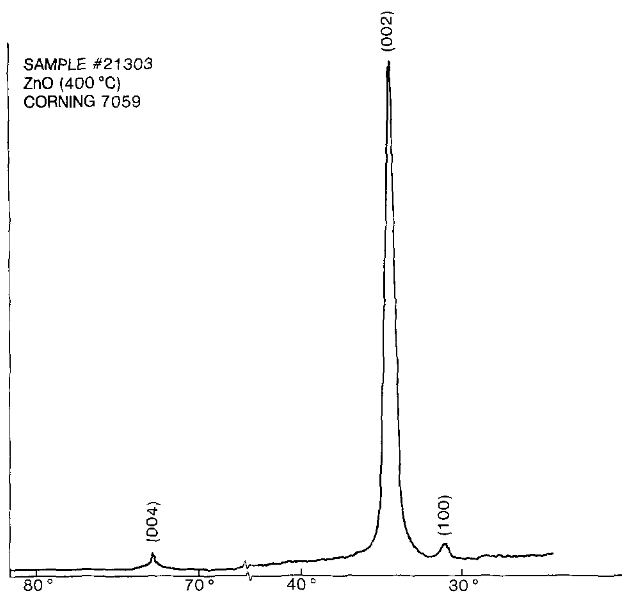

Fig. 7. X-ray diffraction data of a zinc oxide film grown at 400°C on Corning 7059 glass obtained using Copper K_α radiation.

Conclusions

A novel technique for the deposition of zinc oxide films at relatively low temperatures has been outlined. The physical properties of this material, which are of interest for a number of electronic applications, have also been described. It has been shown that films grown in this manner are highly oriented, and should find use in surface acoustic wave application. The use as a zinc source for open tube gallium arsenide diffusion has been outlined in an earlier paper. Further work needs to be done to explore other uses for zinc oxide thin films grown by this CVD technique.

Comparison of the Properties of Molybdenum Silicide Films Deposited by D-C Magnetron and RF Diode Co-Deposition

Ronald S. Nowicki* **and John F. Moulder**

Perkin-Elmer, Physical Electronics Division, Mountain View, California 94043

ABSTRACT

We report a preliminary study in which the physical and electrical properties of d-c magnetron and co-deposited rf diode molybdenum silicide films of varying stoichiometry are compared. It is shown that the d-c magnetron films deposited from a composite target tend to be non-optimal in comparison to the rf diode co-deposited films of the same stoichiometry. Extensive degradation of the d-c magnetron films was frequently observed during heat-treatment at 1000°C in nitrogen or argon ambient. The rf diode films, however, appear to withstand heat-treatment without signs of degradation. There appear to be significant differences in film stress changes during heat-treatment, *i.e.*, the d-c magnetron films exhibit a severe change in stress level resulting in a highly tensile state which causes film cracking and loss of adhesion, whereas the rf diode co-deposited film stress changes to minimal values during heat-treatment. Additional data on crystal morphology, resistivity change during heat-treatment, and general film properties are also discussed.

Refractory metal silicides have been proposed as alternatives to polycrystalline silicon ("polysilicon") for gate electrode or interconnection metallizations in field effect transistor devices of VLSI dimensions (1-4). This trend has evolved as a consequence of the prohibitive values of resistance encountered in conventional polysilicon gate technology as device geometries are reduced.

One significant problem with these newer materials appears to be the relatively high levels of contaminants (*e.g.*, oxides, carbon, and alkalies) presently found in composite, hot-pressed sputtering sources (targets). These contaminants not only can alter device characteristics irreversibly, but also may result in the loss of film integrity during subsequent high temperature (1000°C) device processing steps.

Another potential problem with refractory silicide thin films may be the high levels of intrinsic film stress often found in these films. Additionally, many commercial sputter deposition systems do not provide a means of controlling this film stress through controlled d-c or rf substrate bias (5, 6). Films deposited with high levels of intrinsic stress can also fail in subsequent high temperature processing, where thermal expansion coefficient mismatch between film and substrate is exaggerated.

In this preliminary study, we describe a co-deposition technique in which rf sputtering is done from separate high purity targets of the refractory metal and silicon with and without substrate bias. Additionally, we compare the physical and electrical properties of molybdenum silicide films prepared by this technique with films deposited from a composite target by the d-c magnetron technique.

Experimental

D-C magnetron deposition of molybdenum silicide.—All d-c magnetron depositions were done in a Perkin-Elmer Model 4400 cryo-pumped sputtering system equipped with a hot-pressed source (target) of molybdenum disilicide of 99.9 purity (Metron). The target was solder-bonded to a standard water-cooled copper backing plate and magnet assembly. Depositions were done at *ca.* 7 W/cm^2 (averaged over entire target area of *ca.* 300 cm^2) and 5 mTorr (0.67 Pa) of argon pressure at system base pressure of *ca.* 5×10^{-7} Torr (7×10^{-5} Pa) and 10 rpm substrate table rotation. Deposition rates were typically *ca.* 35 nm/min. Films of *ca.* 250 nm nominal thickness, determined via profilometry of an etched step (HNO_3:HF-200:1), were deposited onto silicon wafers previously coated with *ca.* 100 nm of thermal silicon oxide, 100 nm of rf sputtered silicon nitride, and *ca.* 500 nm of LPCVD-deposited (640°C) polycrystalline silicon (polysilicon). Additional depositions with and without rf substrate bias were done onto 5×25 mm, 63 μm thick sapphire beams for evaluation of film stress and film integrity during subsequent heat-treatment.

Deposition of molybdenum silicide via the rf diode co-deposition technique.—These depositions were done in the same sputter system described above from separate targets of 99.99 purity molybdenum and silicon using the rf power-splitting feature of the system at 10 mTorr (1.33 Pa) argon pressure. For deposition of the silicon-rich ($MoSi_{2.8}$) films, typical target voltages and wattages were: Mo 850V, 300W; Si 2400V, 1500W. Substrate pallet rotation was 10 rpm in all cases. Under these conditions, *ca.* 0.1 nm of molybdenum and *ca.* 0.2 nm of silicon were deposited per one pallet revolution. The resultant deposition rate was *ca.* 2.7 nm/min. Deposition temperature was found to be *ca.* 120°C under these conditions (PTC Model 575 CM surface thermometer).

To study the influence of rf substrate bias on the film properties, additional depositions were done with varying degrees of bias. The effects of this parameter are elaborated upon later in the text (Results section).

Additional rf diode depositions were done from a composite target of 99.9 purity at 10 mTorr argon pressure and 5 W/cm^2 power density. The resultant deposition rate was *ca.* 4.7 nm/min.

Other experimental techniques.—Conventional four-point probe measurements were used for resistivity determinations.

All heat-treatments were carried out with a Lindberg "table top" (Model SB 54542) furnace and quartz diffusion tube using high-purity sources of nitrogen or argon at *ca.* 10 liters/min flow.

CV plotting was done with an MDC controller/plotter and Signatone probe with hot stage.

* Electrochemical Society Active Member.

Key words: films, gates, sputtering, analysis.

Auger and SIMS analyses were done with a Perkin Elmer Model 590 scanning Auger Microprobe.

The elemental sensitivity values reported by Davis *et al.* (7) were used to quantify the Auger electron spectra.

Helium ion backscatter analysis was done with the Cal Tech 3 MeV Van de Graaff accelerator using $4He^+$ ions in the technique reported by Chu *et al.* (8).

Scanning electron microscopy (SEM) was done with a Hitachi S-450-1 system.

Determination of film stress was done on thin sapphire beams using the method reported (9) earlier.

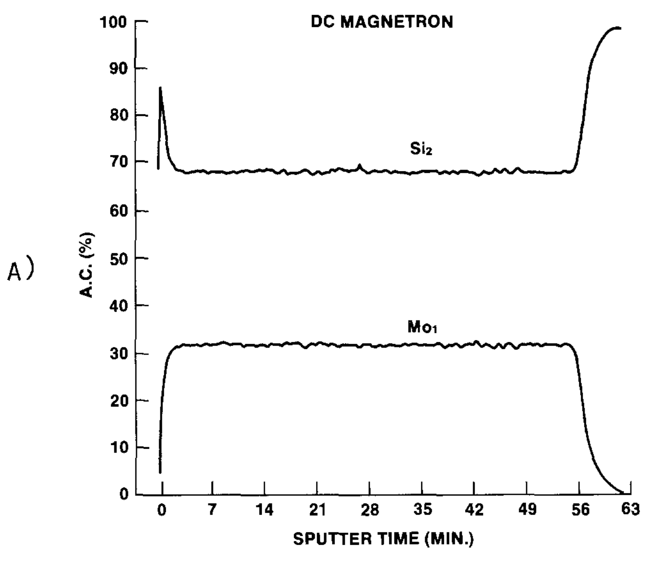
X-ray diffractometry was done with a GE XRD diffractometer using CuKα radiation at 35 kV.

Results

Determination of molybdenum-silicon stoichiometry.—Molybdenum/silicon ratios for both d-c magnetron and co-deposited rf diode films were determined initially in films deposited directly on silicon wafers. This was particularly essential for the co-deposited films, where no prior correlations existed between deposition parameters and stoichiometry. It was hoped that the d-c magnetron and rf diode films deposited from a single composite target of $Mo_{33}Si_{67}$ would serve as "standards" for the stoichiometric determinations. However, it can be seen (Fig. 1) that good stoichiometric correlation between the two deposition methods was not obtained, as shown by the Auger depth profiles of the resultant films. It is apparent that molybdenum/silicon atomic ratio appears to be *ca.* 32:68 for the d-c magnetron films, whereas the ratio appears to be *ca.* 39:61 for the rf diode films.

In an attempt to resolve the question of film stoichiometry and to obtain a "standard" film, a sample of an rf diode co-deposited film having an apparent Mo/Si ratio of 32:68 by Auger analysis was analyzed via helium ion backscattering spectrometry (HIBS). The resultant Mo/Si ratio was found to be 26:74. Since the HIBS analyses are assumed to have an accuracy of approximately ±5%, it is apparent that the Auger results are providing ratios that are Mo rich. It is possible that either differential sputtering effects or matrix effects on the shape of the Auger lines are contributing to this error (10). If the error is assumed to be constant (which may not be the case) a correction factor can be obtained by comparing the Auger and HIBS data. In this case the HIBS Mo/Si ratio was 0.35; the Auger Mo/Si ratio was 0.47. Therefore, a correction factor of 0.74 should be used as an attempt to correct the Auger data.

Figure 2 presents Auger depth profiles which depict the stoichiometry of two rf diode films, co-deposited with differing target voltages on the molybdenum and silicon. From Fig. 2(B), it is apparent that silicon enrichment may be present near the film surface. Appli-



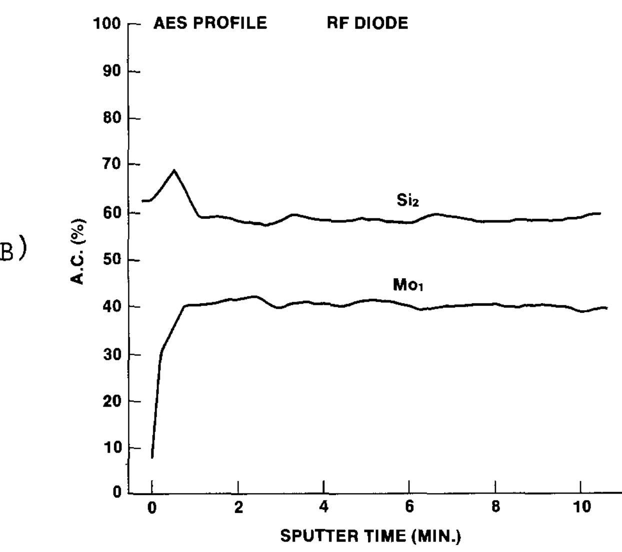


Fig. 1. Auger depth profiles of (A) d-c magnetron and (B) rf diode films sputtered from single composite targets of composition $Mo_{33}Si_{67}$.

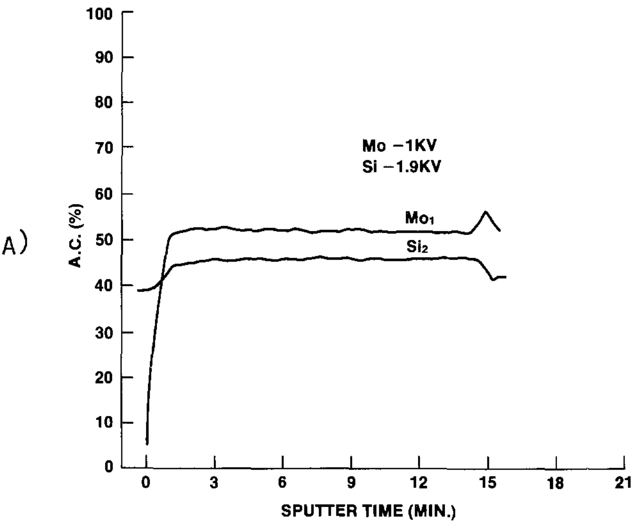

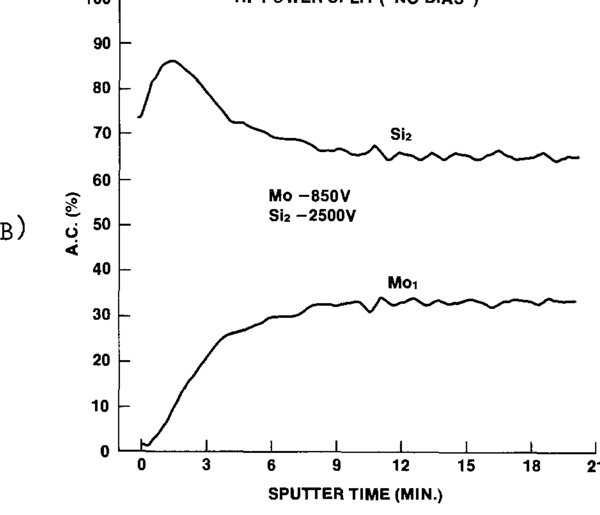

Fig. 2. Auger depth profiles of rf diode co-deposited molybdenum silicide films sputtered at different target voltages.

cation of the above correction factor to these spectra results in stoichiometric ratios of (a) $Mo_{46}Si_{54}$ and (b) $Mo_{26}Si_{74}$. For simplification, these films will be designated (a) "MoSi" and (b) "$MoSi_{2.8}$."

Comparison of morphology and integrity of as-deposited and heat-treated d-c magnetron and rf diode films.—The as-deposited films from all three types of depositions were metallic in appearance and exhibited no visible crystallinity or surface features at magnification up to 30 kX (SEM) on silicon oxide or nitride-coated silicon and sapphire. On polysilicon, all the as-deposited films tended to replicate the crystal morphology of the polysilicon. This observation is evident in Fig. 3(A), which shows the morphology of undoped polysilicon before (insert) and after deposition of the d-c magnetron molybdenum silicide without substrate bias. When this structure was subjected to 1000°C heat-treatment for 30 min in nitrogen or argon, severe cracking was observed in many instances, as shown in Fig. 3(B). Additionally, white fumes, presumably molybdenum oxide, were seen to evolve from the film during heat-treatment. The severity of this degradation precludes further processing. From Fig. 3, one may surmise that these cracks appear to be associated with a grain boundary or film stress phenomenon. The film stress-induced mode of degradation is supported by the observation that the films tended to peel away from the substrate with concavity (Fig. 4A), indicative of tensile stress in the film. (See section on Film stress below for further comment.) This degradation is more severe in films deposited under high values of substrate bias (−120V).

For rf diode co-deposited films having Mo/Si ratios <0.5 on polysilicon, silicon oxide, or nitride, no observable film degradation was observed during and after heat-treatment, as shown by Fig. 4(B) and Fig. 5. From Fig. 4(B), it should be noted that the largest visible crystallites were <100 nm in width. Auger depth profile analysis of the films deposited under rf bias indicated that Mo-Si stoichiometry remained unchanged as a result of the heat-treatment [Fig. 6(A)] when the Mo/Si ratio was <0.5. However, one change which became apparent during heat-treatment was the appearance of a thin (*ca.* 5 nm) layer of silicon nitride on the surface of the silicide film. Figure 6(B) shows the Auger spectrum of the heat-treated film. No molybdenum was detected on the surface. The nitrogen peak, however, is readily apparent in the spectrum. For co-deposited films of molybdenum-rich stoichiometry (Mo/Si>0.5), extensive surface degradation was observed during heat-treatment. It should be noted that no detectable changes in thickness were observed for MoSi or $MoSi_{2.8}$ films on silicon nitride or oxide as a result of heat-treatment.

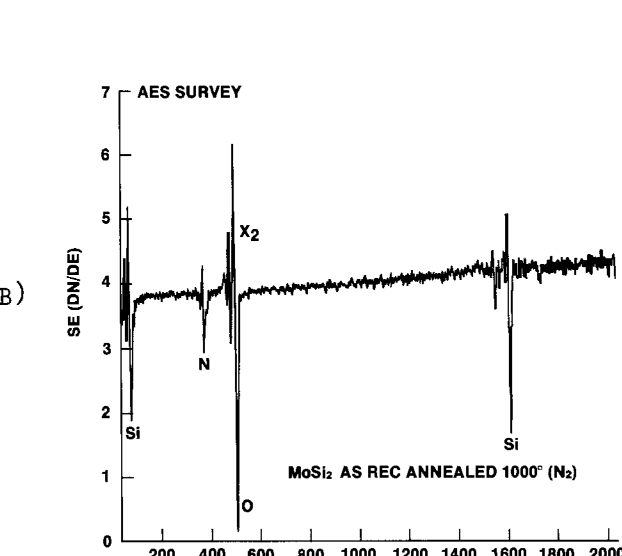

Fig. 6. Auger plots showing (A) depth profile of heat-treated rf diode co-deposited molybdenum silicide having as-deposited composition of $Mo_{32}Si_{68}$ (Auger), and (B) AES survey of film surface.

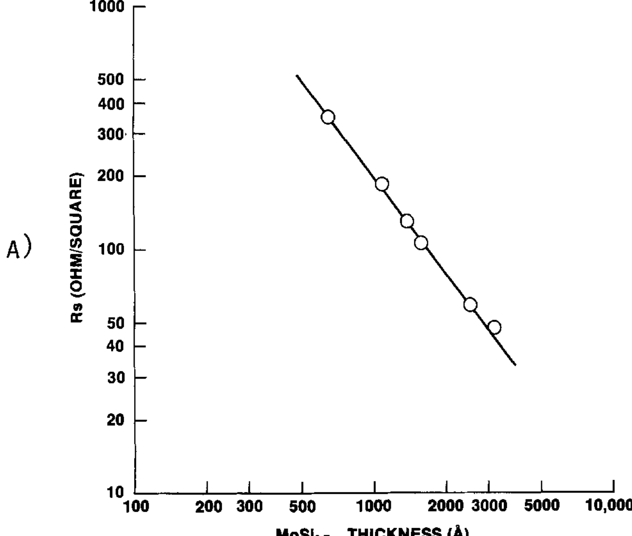
Comparison of the electrical properties of the d-c magnetron and co-deposited rf diode films.—The as-deposited d-c magnetron films had sheet resistance of *ca.* 20 Ω/sq on silicon oxide or nitride. After heat-treatment at 1000°C in nitrogen or argon, the sheet resistance lowered to 4-5 Ω/sq in cases when the film integrity was retained.

For the rf diode co-deposited films, the as-deposited sheet resistance values were dependent on molybdenum-silicon stoichiometry, as expected. Figure 7(A) shows the sheet resistance values plotted as a function of thickness for the composition $MoSi_{2.7}$. Figure 7(B) shows the resistivity plots as a function of Mo:Si ratio for as-deposited and heat-treated molybdenum silicide films of varying composition deposited under "no bias" (floating) conditions. With biased substrate depositions, (−25 to 50V), the heat-treated film resistivity appears to lower *ca.* 50% from the values shown. Thus, resistivity values of *ca.* 8×10^{-5} Ωcm can be obtained.

Capacitance-voltage plots of the d-c magnetron and rf diode co-deposited films were done before and after heat-treatment after using a metal mask to define 750 μm diam electrodes of the silicide on *ca.* 100 nm of thermal oxide on n-type silicon wafers. Figure 8 shows the resultant plots for the as-deposited d-c magnetron film and the rf diode film after heat-treatment. The plot for the as-deposited rf diode film is not shown due to its severe distortion, presumably due to oxide "damage" during deposition. From Fig. 8, it is apparent that alkali and hydrogen-induced flatband shifts (Qm) (11) are excessively high (*ca.* 3×10^{12} charges/cm^2) for the d-c magnetron films, whereas the heat-treated rf diode films have Qm values of *ca.* $8 \times 10^{10}/cm^2$. The high Qm values of the d-c magnetron films were considerably reduced to levels comparable to the rf diode films after heat-treatment at 1000°C in cases where film degradation did not occur. This reduction in Qm with heat-treatment was reported by Learn (12).

X-ray diffractometry.—X-ray diffractometry was done on the as-deposited and heat-treated d-c magnetron and rf diode co-deposited films on silicon nitride coated wafers. The resultant spectra are shown in Fig. 9. Examination of these spectra show that both the as-deposited d-c magnetron and rf diode films [Fig. 9(a), their spectra were superimposable] exhibited minimal crystallinity. The silicon (211) cubic reflection in these spectra may be attributable to unreacted silicon in the as-deposited films; the intensity of this reflection is considerably diminished, or absent, after heat-treatment. Additionally, the heat-treated d-c magnetron film (b) shows strong tetragonal $MoSi_2$ reflections only. The rf diode co-deposited film designated "MoSi" (c) shows tetragonal and hexagonal $MoSi_2$ and cubic Mo_3Si reflections, whereas the film designated "$MoSi_{2.8}$" (d)



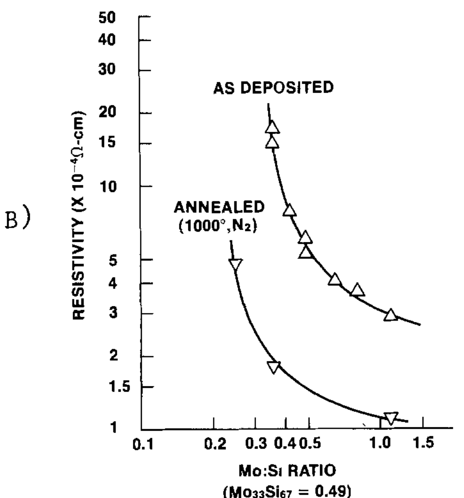


Fig. 7. Plots showing (A) sheet resistance vs. thickness for $MoSi_{2.7}$, and (B) as-deposited and heat-treated film resistivities for molybdenum silicide films of various stoichiometry.

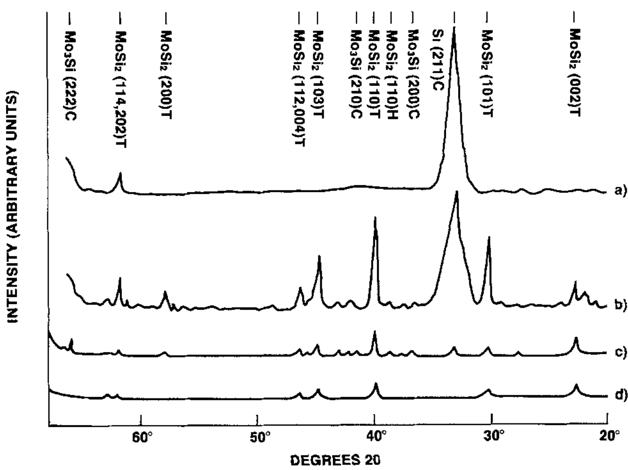

Fig. 9. X-ray spectra showing (a) as-deposited d-c magnetron and rf diode co-deposited $MoSi_{2.8}$ films, (b) d-c magnetron film after heat-treatment, (c) MoSi, and (d) $MoSi_{2.8}$ films after heat-treatment.

shows only weak tetragonal $MoSi_2$ reflections consistent with the SEM micrograph shown earlier (Fig. 4B), indicative of very small crystallite size.

Film stress.—In the as-deposited d-c magnetron films on sapphire, film stress was compressive and was calculated to be *ca.* 1×10^{10} dyne/cm^2. During 1000°C heat-treatment, however, the intrinsic film stress changed to high tensile stress values. This change could actually be observed during heat-up of the film; the substrate could be seen to curl rapidly from a convex to a concave condition, after which the film would tear away from the substrate producing fine particulates. In extreme cases, silicon wafers were seen to fracture during heat-treatment (13), especially when the deposition was done under high (−120V) substrate bias.

No such degrative changes in film stress were observed with the rf diode co-deposited films having Mo/Si ratios between 0.33 and 0.5. As-deposited, the film stress was minimally unmeasurable for films sputtered under "no bias" conditions or at −75V bias. Between −25 and −50V bias, film stress was *ca.* 5×10^{10} dyne/cm^2 (compressive). However, 1000°C heat-treatment of these films yielded a reduction of this stress to unmeasurable values. For films having Mo/Si ratios between 1.0 and 0.5, the film stress appeared to be in varying degrees of tension. Heat-treatment also appeared to reduce this stress to unmeasurable values. This stress behavior during heat-treatment differs from that reported (14) for co-sputtered titanium silicide.

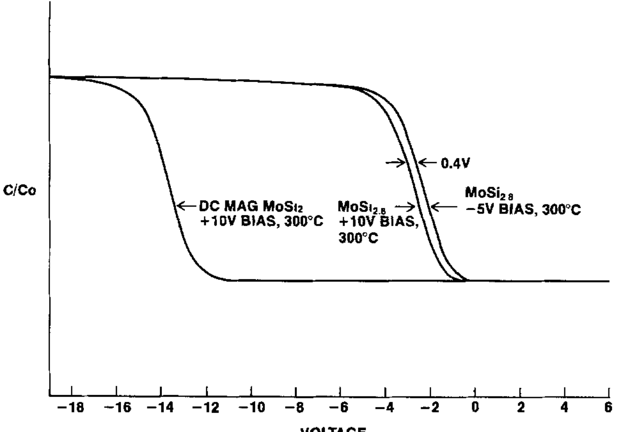

Fig. 8. Capacitance voltage plots of as-deposited d-c magnetron film and heat-treated rf diode co-deposited $MoSi_{2.8}$ film.

Analysis of trace elements.—Analysis for trace elements and hydrogen was done on the as-deposited d-c magnetron and rf diode co-deposited films using the SIMS capability of the Physical Electronics 590 system. Additionally, film samples were also electron beam heated *in situ* and the resultant evolved gases were measured by mass spectrometry. The resultant spectra showed hydrogen and fluorine to be present in all the films. Quantification of the spectra could not be carried out easily using this technique.

Step coverage.—A 250 nm thick co-deposited film of composition $MoSi_{2.8}$ was sputtered onto an oxide-stepped silicon wafer at −50V substrate bias. The film was heat-treated at 1000°C, then photolithographically masked and etched in a parallel plate prototype reactor using Freon-14 as the etch gas. Figure 10 shows the SEM micrograph (in cross section) of the etched film over a one micron oxide step which is slightly "undercut." From Fig. 10, it is apparent that acceptable step coverage was obtained in the as-deposited film.

Oxidation rate.—RF diode co-deposited films of composition $MoSi_{2.8}$ and $MoSi_2$ were oxidized in dry oxygen at *ca.* 6 liters/min flow at 1000°C. The resultant oxidation rate (at *ca.* 50 nm oxide thickness) for the $MoSi_{2.8}$ was only *ca.* 3 Å/min, whereas the rate for the $MoSi_2$ was *ca.* 400 Å/min (resultant oxide thickness *ca.* 300 nm). Additional studies are underway in an attempt to gain more information on the oxidation of these films (15).

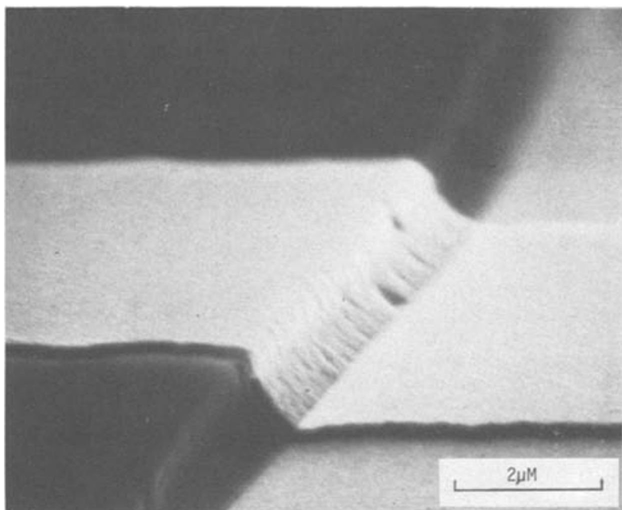

Fig. 10. SEM micrograph showing coverage of rf diode co-deposited film over oxide step.

Summary and Conclusions

This study has shown that molybdenum silicide films deposited by d-c magnetron sputtering from a composite target tend to be non-optimal during subsequent heat-treatment, *i.e.*, film degradation is often encountered for no easily apparent reason. The problem is more acute for films deposited under high values (−120V) of rf substrate bias.

RF diode films co-deposited from separate sources of molybdenum and silicon, however, do not exhibit this degradation when the Mo/Si ratio is $\leqq$ 0.5, providing that the films have not been subjected to acidic cleaning procedures (DI water cleans only are recommended) and annealing ambient is ensured to be inert. The reason for the difference in behavior between the d-c magnetron and rf diode co-deposited films is unclear at the present time. A possible model for the degradation is that trace impurities, *e.g.*, hydrogen, in the d-c magnetron films may result in severe changes in film stress during subsequent heat-treatment. This severe change in film stress level is indeed observed during heat-treatment of the d-c magnetron films and is not observed with the rf diode co-deposited films. However, film analysis by Auger and SIMS shows little differences, if any, in trace element content between the two types of films. Thus, it may be possible that the instrumental sensitivity to trace elements is insufficient to allow for correlations with film properties. However, the Auger analyses done on the rf diode co-deposited films were shown to be essential for the establishment and monitoring of molybdenum-silicon stoichiometry in such a study.

In summary, it appears that the rf diode co-deposition technique is viable for the production of good quality molybdenum silicide films of low resistivity. Fully-operational gate arrays have been fabricated from these films, thus supporting the feasibility of the technique. Further details regarding these devices cannot be provided at this time due to proprietary considerations.

ABSTRACT

High-resolution real-time x-ray topography requires a fluorescent screen with high spatial resolution and good conversion efficiency of x-rays into visible light. We studied the spectral yield and the integral output with respect to screen thickness of common polycrystalline fluorescent materials. Gd_2O_2S:Tb has the best conversion efficiency and shows the highest spatial resolution with a grain size ≤ 1 μm. The optimal screen thickness for our applications was 5 μm. This choice results in a spatial resolution of about 10 μm.

Real-time x-ray topography is a recent tool to study nondestructively the dynamics of defects, like dislocations, and strain fields in crystals under externally applied forces, for example temperature, strain, or magnetic and electric fields. A typical application is reported by Hagen, Miltat, and the present author (1). There are in principle two methods for real-time x-ray topography, the single-stage or direct *vs.* the multiple-stage or indirect method (2). In the single-stage arrangement the x-ray pattern is directly converted into an electronic charge pattern which is read out by an electron beam of a television tube. The resolution of such method is limited to typically 30 μm (3). In the multiple-stage method the x-ray pattern is first converted into an optical picture by a fluorescent screen and then imaged onto the target of a TV camera by a lens system (4). The most important part in this arrangement is the fluorescent screen. It requires a high spatial resolution of a few micrometers and additionally a good conversion efficiency. Many studies have been made about resolution and yield of phosphors (5-12), but no information is available for this special x-ray topography purpose. This paper describes experiments about the spectral yield and the integrated intensity *vs.* screen thickness of various materials. We also investigated the spatial resolution.

Key words: fluorescent screen, real-time x-ray topography, spectral yield, spatial resolution.

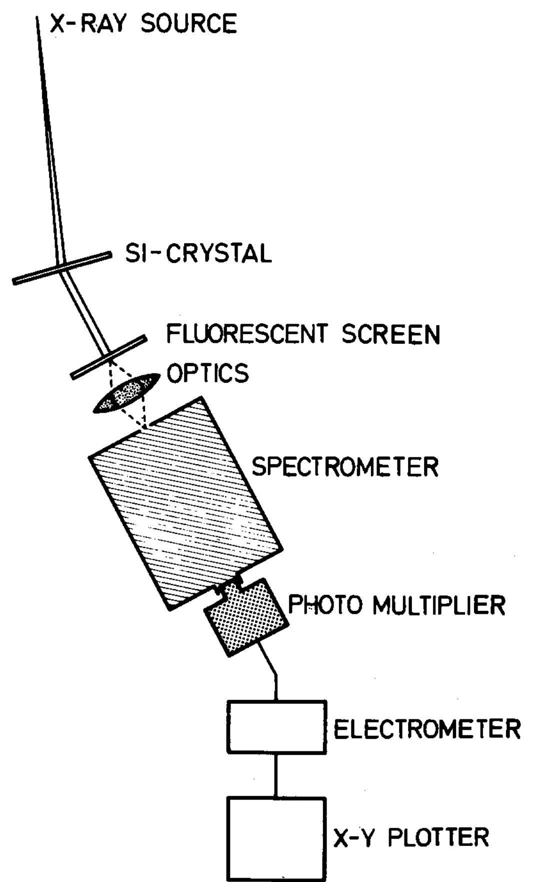

Fig. 1. Experimental setup to study the spectral yield of fluorescent screens for MoK$_\alpha$ radiation.

Experimental

The experimental setup to study the spectral yield is shown in Fig. 1. A collimated x-ray beam enters an Si-crystal which is set in Bragg condition for the {220} reflection of MoK$_\alpha$ radiation. The diffracted beam is converted into an optical picture by a fluorescent screen. The resulting visible light is focused onto the entrance slit of a ¼ m-spectrometer which analyzes the emission spectra. The intensity is measured by a photomultiplier and amplified by an electrometer. The intensity *vs.* wavelength recording is made with an X-Y plotter. The fluorescent screens are prepared in the following way. A defined quantity of the material is weighed on a balance and then mixed with alcohol. The polycrystalline powder is deposited on a glass substrate by a centrifuge. The screen is characterized by density and thickness. The density is investigated

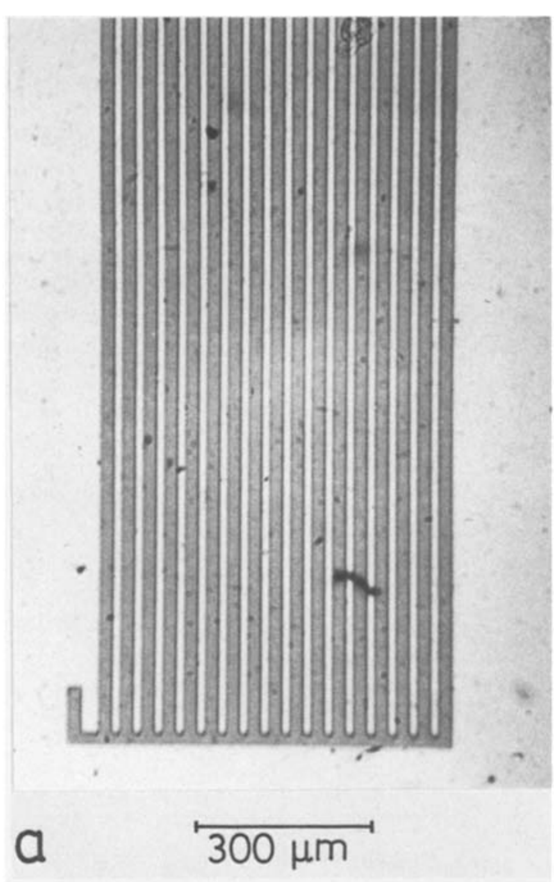
by the weight of the screen minus the weight of the substrate divided by the screen area. The screen thickness is measured by an optical microscope.

Results and Discussion

Figures 2a-c show the spectral efficiency of the studied materials (Zn_2SiO_4:Mn,As; Zn_2SiO_4:Mn; $CaWO_4$; Y_2SiO_5:Ce,Tb; $Y_3Al_5O_{12}$:Ce; CsI:Tl, (Zn,Cd)S:Ag; ZnS:Cu; ZnS:Ag; and Gd_2O_2S:Tb) for one screen thickness.[1] Most of these materials emit light with a spectral intensity distribution over a broad wavelength region. Only Gd_2O_2S:Tb has eight sharp intensity peaks. This localized spectral recombination indicates that the ground and excited states of Tb, which are responsible for the emission spectra, have a small kinetic energy. That means the recombination centers are spatially localized in the material. This fact guarantees that the material is well suited for high spatial resolution.

We have digitized the curves and integrated the area under each curve. Figure 3a shows the integrated intensity *vs.* the screen thickness. Gd_2O_2S:Tb has the best available efficiency. Figure 3b is a blow-up of Fig. 3a which shows more details of intensity differences in the thickness up to about 30 μm. One problem

[1] Some emission spectra differ slightly from the literature. The differences may be caused by contamination either from the producer of the fluorescent material and/or during screen preparation in our laboratory. However, these differences do not affect very much the results.



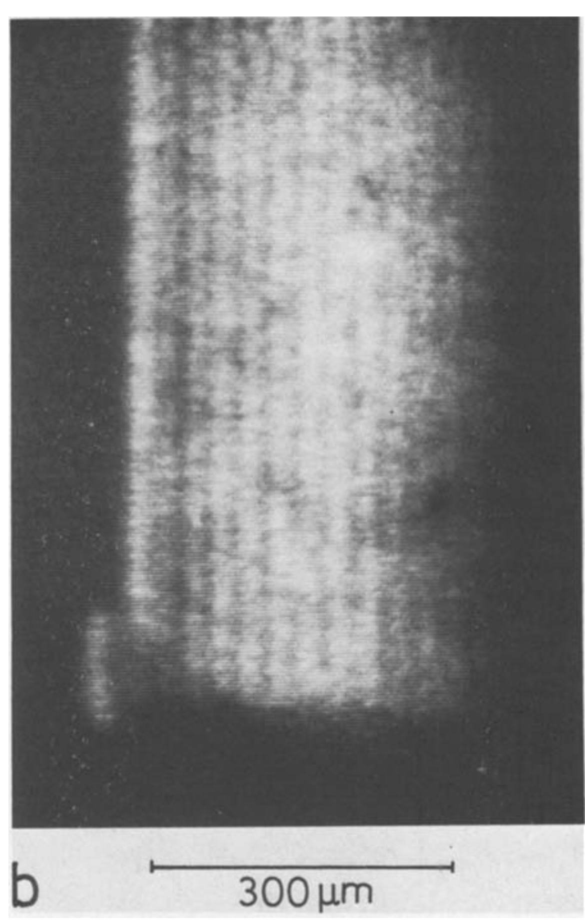


Fig. 4. (a) Optical micrograph of an excise stripe pattern on an Si-substrate with a periodicity of about 15 μm. (b) Corresponding video topograph directly photographed off the TV monitor.

of polycrystalline fluorescent screens still remains The density of Gd_2O_2S:Tb is 7.4 g/cm^3, but the density of a screen with 5 μm thickness is only about 2-3 g/cm^3. Thus, the achieved density is still well below the theoretical density and, therefore, we suffer a loss in the absorption of x-rays and in efficiency.

We need to achieve the highest possible spatial resolution in combination with sufficient yield. That means the grain size of the material used should be $\leq$1 μm, with as little decrease as possible of internal conversion due to such a small grain size. The other parameter which limits the resolution is the screen thickness. The highest possible resolution is roughly twice the screen thickness. We achieved an optimal screen thickness of 5 μm and, therefore, a spatial resolution of $\sim$10 μm. Figure 4a shows an optical micrograph of an oxide stripe pattern on an Si substrate and Fig. 4b is the corresponding video topograph directly photographed off the TV monitor. The contrast of the test pattern has a stripe periodicity of about 15 μm and shows the limitation of our present screens. The most difficult problem in fabricating the screens lies in achieving uniformity in thickness over the entire screen area. The screen preparation is rather difficult to handle. However, because of these difficulties it would be very helpful to have a single crystalline phosphor with a high spatial resolution. A single crystal with special features would combine the high material density and a good thickness uniformity. It would be possible to achieve thinner ($\sim$2-3 μm) screens and, therefore, a better spatial resolution at the same conversion efficiency. Such experiments are currently under progress in our laboratory.

Degradation of Bonding Strength (Al Wire-Au Film) by Kirkendall Voids

Katsuya Okumura

Toshiba Corporation, Toshiba Semiconductor Division, Kawasaki, Japan

ABSTRACT

Degradation in bonding strength of the Al wire-plated Au film system has been studied. When this bonding system is stored at elevated temperatures, the bonding strength degrades following one of the three degradation modes: (*i*) A-mode in which the bonding strength decreases with increasing thermal annealing period until reaching a certain value, (*ii*) B-mode in which the strength starts separating into two values after a certain period of annealing, and (*iii*) C-mode in which the strength rapidly drops down to zero. The physical mechanisms for the three degradation modes have been well explained by Kirkendall void formation at the gold-rich intermetallic phase of the aluminum-gold interface, where the growth rate of the gold-rich intermetallic phase plays a very important role on deciding the degradation modes. When gold film includes a large amount of Pb or Tl, this rate decreases and C-mode or B-mode will take place. Doping of Ag into the gold film sometime results in less degradation in the bonding strength.

The reliability of gold-aluminum bonding strength has a strong influence on the reliability of IC and LSI. Although there have been many reports about bonding of gold wire to evaporated aluminum film on silicon chip, only a few reports about bonding of aluminum wire to gold film have been published (1-4). It has already been discussed that the bonding of aluminum wire to gold film has a higher reliability than of gold wire to aluminum film as long as the ratio of the width of the aluminum wire bonding area to the thickness of the gold film is greater than four (1).

However, the physical mechanism as to why the value four appears to be a threshold value for the degradation in bonding strength has not been made clear.

The purpose of the present study is to obtain a better understanding of the nature of the gold film-aluminum wire metallurgical system and to reveal the degradation mechanism of the bonding strength.

Experimental Results

Sample preparation.—Substrates for bonding were prepared by plating nickel and gold sequentially on rectangular Kovar plates of 50 × 7 × 0.25 mm. Typical layer thickness are 2 μm for nickel and 2-5 μm for gold. The plating solutions for nickel are a Watt bath and for gold a commercial cyanide solution.

Aluminum bonding wire of 2 mil in diameter, ultrasonic bonding grade including 1% silicon, is used, and 300 wires are bonded on each substrate. Here, bonding operations were made on the same ultrasonic wire bonder by the same technician in order to avoid poor reproducibility due to fluctuations coming from a different person and machine. Bonding strength was measured destructively on an automatic vertical pull tester, before and after annealing. Approximately 25 pull testings were carried out under each condition.

Thermal annealing was carried out in an air circulating oven controlled at 200° ± 5°C. After a certain period of annealing, 25 bonded wires were destructively pulled and the break strength was recorded for each test.

Pull strength as a function of annealing time.—The degradation modes of the pull strength at 200°C are phenomenologically classified into three kind of modes, as follows.

A-mode: The pull strength gradually decreases with annealing time and finally reaches a certain time-independent value as shown in Fig. 1. This value remained after 5000 hr at 200°C.

B-mode: The pull strength first decreases, and when annealing time exceeds a certain threshold, the degradation mode is divided distinctly into either A- or C-modes as shown in Fig. 2.

C-mode: The pull strength sharply drops down and becomes zero within a few hours as shown in Fig. 3.

Impurities in the plated gold film.—Impurities in the plated gold film are investigated by using ion mi-

cromass analysis, IMA. The measuring conditions are as follows: Ar ions are used and accelerating voltage is 10 kV. Beam size is 760 μm in diameter, and the maximum measuring mass number is $M/e = 240$. The detected impurities are F, Na, K, Si, Al, Cl, Ca, Mg, Fe, Ni, Co, Ag, Tl, and Pb.

Results and Discussion

Correlations between impurities in Au film, thickness, and bonding strength.—Measured results of impurity concentration in gold, degradation mode, and gold film thickness are listed in Table I. Several characteristic features can be derived from Table I: (*i*) When a sample includes less Pb and Tl, the mode always becomes A-mode. (*ii*) When a sample has a large amount of Pb or Tl, the mode always becomes C-mode. (*iii*) When a sample has a few Ag even though it has a few Pb or Tl, the mode becomes A- or B-mode, but never C-mode. (*iv*) The thicker the gold film is, the more frequently B- and C-modes appear.

The effect of silver.—As pointed out above, even though there was a large amount of Pb or Tl in gold film, the influence of Pb or Tl was canceled by the presence of a small amount of silver. So, the following tests were carried out.

The substrate with a large amount of Tl and few Ag like in the sample No. 8 was prepared by depositing silver in a vacuum of $\sim 10^{-6}$ Torr. After being annealed, Al wire bondings were made on the preceding ultrasonic bonder. When about 400Å of Ag film is deposited, it is difficult to make bonds because of the hardness of the silver-evaporated gold surface. On the other hand, it is easy to make bonds when about 50Å of silver film is deposited and annealing is carried out at 250°C for 30 min. The degradation mode of this sample has completely changed from C-mode to A-mode. In addition to this sample, other samples were also deposited with silver (50Å) by the same procedure. The results of these tests are summarized in Table II.

Mechanism of pull strength degradation.—Let us consider a mechanism that explains what happens when aluminum and gold films are coexisting and are stored at elevated temperatures, and why the pull strength significantly degrades in some cases, but not in other cases.

Many studies, (1, 5-7) have been reported that in the aluminum-gold binary system the growth rate of the gold-rich intermetallic phase is approximately 10 times as large as the growth rate of the aluminum-rich intermetallic phase, and the formation of Kirkendall voids is observed at the interface of the gold-rich intermetallic phase and gold.

At this point, let us set up two working hypotheses as follows: (*i*) The Kirkendall voids formed at the interface have a constant radius, r_0, and the number of voids, n, is directly proportional to the square root of time. (*ii*) The Kirkendall voids are always at the interface. These voids pile up and condense to form an almost continuous line. This has a deleterious effect on the pull strength.

Kidson (8) has shown that if the mechanism of intermetallic phase formation is interdiffusion predominated by volume diffusion, growth rate of the intermetallic layer should follow a parabolic rate law as follows

$$d = k\sqrt{t} \qquad [1]$$

where d is the intermetallic thickness, t is the storage time, and k is the growth rate of the phase.

In fact, the intermetallic phase layer thickness has been observed (3, 7), showing the square root of time dependence even though the storage temperature was as low as 200°C.

As illustrated in Fig. 4, aluminum wire comes in contact with gold film with bonding width W. The length along the gold-rich intermetallic phase-gold interface is given by

$$l = \pi d + W \qquad [2]$$

By substituting Eq. [1] into Eq. [2]

$$l = \pi k\sqrt{t} + W \qquad [3]$$

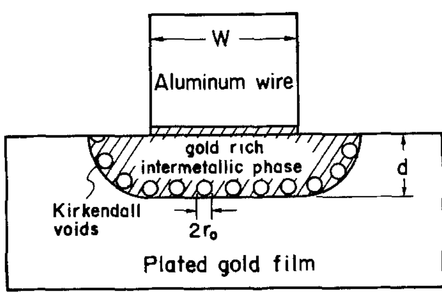

Fig. 4. Schematic representation of the degradation of bonding strength. Kirkendall voids are formed at the intermetallic phase-gold interface.

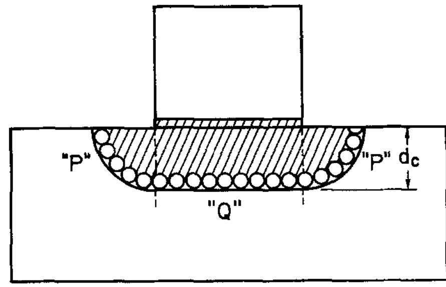

Fig. 6. Schematic representation. When gold film thickness is thicker than the critical depth, d_c, Kirkendall voids will form a continuous line along the intermetallic phase-gold interface.

according to these working hypotheses, when the intermetallic phase grows up to the depth d, the number of Kirkendall voids, n, will be given by

$$n = \alpha\sqrt{t} \quad [4]$$

where α is the rate constant.

Total length of the voids projected to the intermetallic phase-gold interface is given by

$$v = 2r_0 n \quad [5]$$

and thus

$$v = 2r_0\alpha\sqrt{t} \quad [6]$$

where r_0 is the radius of voids.

When Eq. [3] and [6] become equal, the Kirkendall voids form a continuous line and, consequently, the pull strength becomes catastrophically weak.

Equations [1], [3], and [6] are illustrated schematically in Fig. 5. When line 1 intersects line 2 at t_c, the voids form a continuous line at the intermetallic phase-gold interface and the pull strength degrades enormously. The depth of the intermetallic layer at t_c is defined as d_c.

The influence of gold film thickness.—Let us consider the influence of gold film thickness, D, the growth rate, k, and bonding width, W on the formation of Kirkendall voids. As shown in Fig. 6, the intermetallic phase-gold interface is divided into two parts; one is "P," the length of which grows as a function of πd and the other is "Q," the length of which stays constant at W.

When D is thicker than d_c, the voids will form a continuous line at both P and Q in the depth d_c and then the catastrophic weakness occurs, in other words, C-mode will appear.

Now, let us consider what can happen if D is thinner than d_c. When the intermetallic phase grows up and reaches the gold-nickel interface, the total projected length of the voids is represented as follows

$$v_0 = 2r_0\alpha\sqrt{t_0} \quad [7]$$

where t_0 is the time when the intermetallic phase reaches the gold-nickel interface.

After t_0, there can be no increase in voids at Q, namely, the gold-nickel interface, on the other hand, the length of the interface along P, either $\overline{AB} + \overline{A'B'}$ or $\overline{CD} + \overline{C'D'}$ as shown in Fig. 7, is constant at πD but voids at P increase on and on until a continuous line is formed along $\overline{CD} + \overline{C'D'}$.

Let us find out the time t_1, when the continuous line is formed eventually by the voids at the interface along P. To obtain t_1, a graphical solution method is applied as shown in Fig. 8. The time when d grows up to D, namely, d_0, is t_0 and at that time v and l are v_0 and l_0, respectively. t_2 is imaginary time when v shall grow up to l_0, that is, v_2. The point X on $\overline{v_2t_2}$ divides v_2 into W (= $\overline{Xt_2}$) and $\pi k\sqrt{t_0} = \pi D$ (= $\overline{v_2X}$). The point Y is defined as the cross point of $\overline{v_0t_0}$ and $\overline{XO}$.

At time t_0, projected lengths of the voids on $\overline{AB} + \overline{A'B'}$ and $\overline{BB'}$, v_P, and v_Q, are given by dividing $\overline{v_0t_0}$ by the ratio πD:W. On the other hand, the point Y

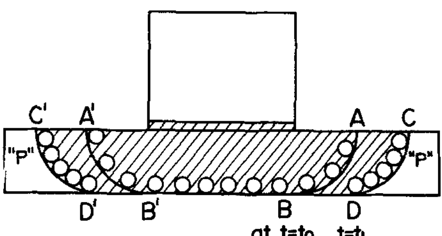

Fig. 7. Schematic representation. When gold film thickness is thinner than d_c, the intermetallic phase grows up and reaches the gold-nickel interface at the time t_0, and then there is still increase in voids at "P" until the voids form continuous line at the time t_1.

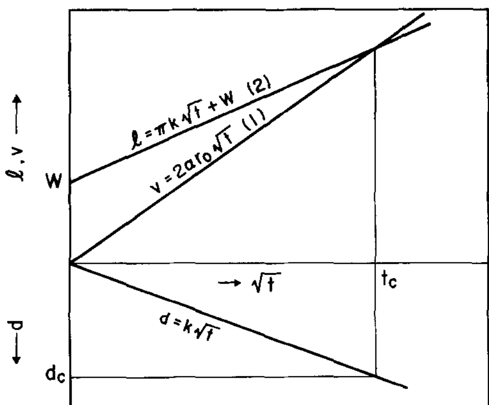

Fig. 5. Schematic representations for d, the intermetallic thickness; l, the length along the intermetallic phase-gold interface; and v, the total length of the voids projected to the interface as a function of t, the storage time.

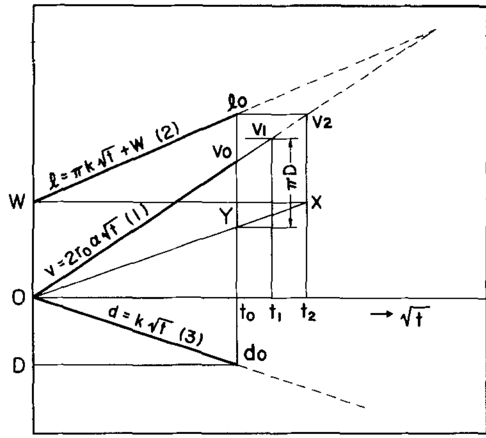

Fig. 8. Schematic representations of l, v, and d as a function of t when gold film thickness is thinner than d_c.

divides $\overline{v_o t_o}$ by the ratio $\pi D:W$, then v_P and v_Q are equal to $\overline{v_o Y}$ and $\overline{Y t_o}$, respectively.

After t_o, the length of the interface along P is constant at πD as shown in Fig. 7, but v_P still grows up from $\overline{v_o Y}$ to πD. t_1 is the time when v_P grows up to πD, that is, the voids along P form eventually a continuous line.

After t_1, both the voids and the gold-rich intermetallic phase stop growing up, because the continuous line of voids shuts off the gold supply to the intermetallic phase and the gold-rich intermetallic phase will change into an aluminum-rich intermetallic phase by being supplied with a sufficient amount of aluminum from the aluminum wire. If the bonding strength at Q is sufficiently strong, the pull strength does not degrade, which results in A-mode.

Whether the gold film is thinner or thicker than d_c, Kirkendall voids ultimately form a continuous line along the interface between the gold and the gold-rich intermetallic phase. This phase will change into an aluminum-rich intermetallic phase after a sufficiently long period of time.

The influence of bonding width.—As shown in Fig. 9, when the bonding width becomes narrower, the critical depth d_c becomes shallower. That means C-mode will appear more easily. When the gold film thickness is slightly thinner than d_c, W plays a dominant role on the degradation, namely, a narrower W will lead to C-mode and a wider W will lead to A-mode.

The influence of the intermetallic phase growth rate.—Figure 9 shows that the critical depth d_c decreases with decreasing k. The influence of k is more prominent than W, because k can affect both Eq. [1] and [2].

The value of k, W, and d_c.—The samples were polished in the cross sections, and then the thickness of the gold-rich intermetallic phase was measured by using an optical microscope and SEM. Figure 10 shows one of the SEM photographs of the A-mode samples. Here, a crack is observed around the periphery of the bond. Figure 11 shows one of the SEM cross-section photographs of the C-mode samples. As noticed, a crack is observed not only in P but also in Q.

Bonding width, W ranges from 26 to 60 μm and its mean value is 40 μm. The thicknesses of the phase of A-mode samples after annealing for 1 hr are in the range of 2.4-3.2 μm and its mean value is 2.8 μm. By this measurement, k for A-mode is found to be 2.8 $\mu m/\sqrt{hr}$.

On the other hand, Kashiwabara and Hattori have reported (1) that $W/d_c \geqq 4$ for the sample which is equivalent to A-mode. These are summarized as follows, $W = 40$ μm, $k = 2.8$ $\mu m/\sqrt{hr}$ and $W/d_c = 4$. Substituting these values into Eq. [1], [3], and [6]

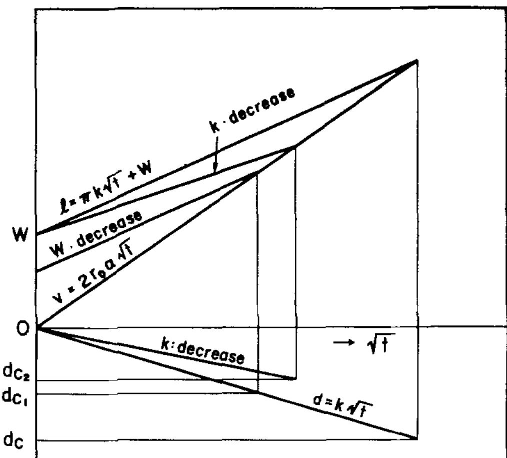

Fig. 9. Schematic representations of l, v, and d as a function of t taking bonding width W and intermetallic phase growth rate k as parameters.

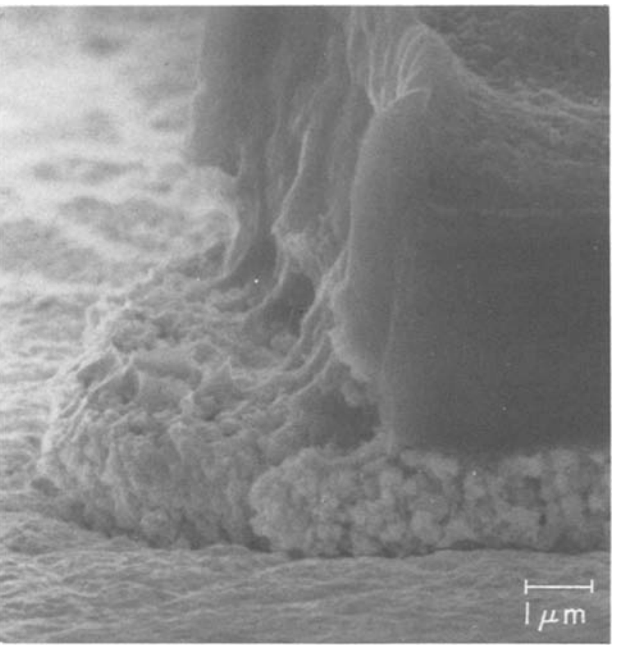

Fig. 10. An SEM photograph of Al-Au intermetallic compound formation (fluffy). A-mode sample stored at 200°C for 10 hr gives rise to the crack which is formed around the periphery of the bond.

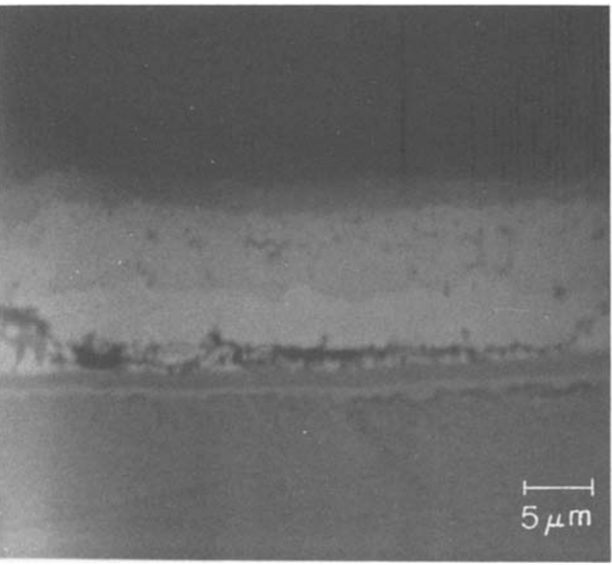

Fig. 11. An SEM cross-section photograph of Al-Au intermetallic phase. C-mode sample stored at 200°C for 10 hr demonstrates the continuous line of Kirkendall voids along the interface of intermetallic phase-gold, in "P" and "Q."

$$10 = 2.8\sqrt{t_c} \quad [8]$$

$$l' = 2.8\pi\sqrt{t_c} + 40 \quad [9]$$

$$l' = 2r_o\alpha\sqrt{t_c} \quad [10]$$

at $t = t_c$, l' is equal to v', then

$$2.8\pi\sqrt{t_c} + 40 = 2r_o\alpha\sqrt{t_c} \quad [11]$$

From Eq. [8], $t_c = 12.7$ hr, then $2r_o\alpha = 20$ $\mu m/\sqrt{hr}$. The critical time t_c is in good agreement with the time when B-mode starts separating into A- and C-modes in Fig. 2.

Table III. Growth rate of the gold-rich intermetallic phase, *k*

Reference	k at 200°C (μm/$\sqrt{\text{hr}}$)	Purity of gold
Onishi (5)	1.1	Gold plate 99.99%
Kashiwabara (1)	2.6	Plated gold film
Philofsky (6)	3.9-4.4	99.999%
Campisano (7)	4.5-5.0	Evaporated gold film
This work	2.8	Plated gold film

Here, we compared the value of k with the previously published values which are summarized in Table III. As shown in Table III, Kashiwabara (1) obtained $k = 2.6$ μm/$\sqrt{\text{hr}}$ for gold-plating film and Onishi (5) found $k = 1.1$ μm/$\sqrt{\text{hr}}$ for gold plate where the purity of gold is 99.9%. Philofsky (6) and Campisano (7) found $k = 4\text{-}5$ μm/$\sqrt{\text{hr}}$ for evaporated gold film, which had a purity of more than 99.99%. These indicate that the lower the purity of gold, the more the value of k decreases.

At $t = t_c$, l is equal to v and $d_c = k\sqrt{t_c}$, then

$$\frac{1}{d_c} = \frac{2r_0\alpha}{W}\left(\frac{1}{k} - \frac{\pi}{2r_0\alpha}\right) \qquad [12]$$

where

$$2r_0\alpha = 20$$

Figure 12 show the relationship between d_c and k for various values of W. When k decreases to be less than 1.4 μm/$\sqrt{\text{hr}}$ and the thickness of the gold film is more than 3.6 μm, C-mode will appear. Moreover, when k decreases to less than 0.8 μm/$\sqrt{\text{hr}}$, even though the thickness of gold film was 1.8 μm, C-mode should take place.

A large amount of Tl or Pb is found in the samples which provide B- or C-mode. Some of the samples have changed from C-mode to A- or B-mode by doping with a small amount of silver. This indicates that Tl or Pb may suppress the value of k drastically, but Ag has an ability to cancel this effect, although the mechanism for this is still uncertain.

Horsting (2) has experimentally shown that the presence of impurities in the gold caused the bondlift type of failure. However, he did not specify the kind of impurities responsible for the failure and the failure mechanism for the bondlift.

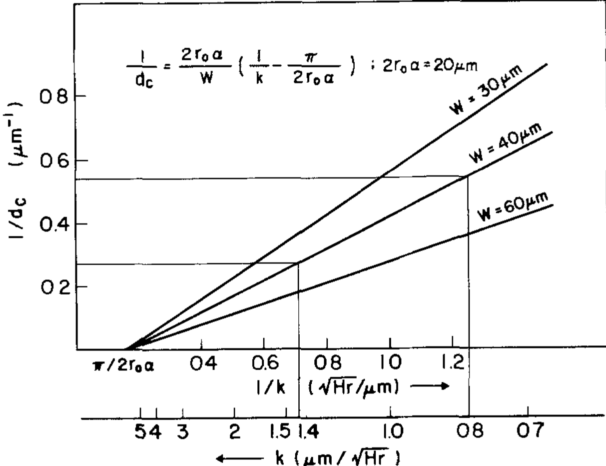

Fig. 12. Relationships between d_c and k for various values of W

On the contrary, in this study we have quantitatively made clear the mechanism of the degradation of bonding strength by introducing parameters such as k, n, W, and D. Our mechanism, described here, can also explain all of the facts which Horsting has found.

Conclusions

Degradation of bonding strength of the aluminum wire-gold film system has been investigated. The phenomena which take place at the aluminum-gold interface have been well explained by the Kirkendall void model.

1. When these bonding systems are heated at elevated temperatures, the degradation modes of the pull strength are classified into three modes: (*i*) A-mode in which the bonding strength decreases with increasing heat-treatment until reaching a certain value, (*ii*) B-mode in which the strength starts separating into two values after a certain period of heat-treatment, and (*iii*) C-mode in which the strength rapidly drops down to zero.
2. A large amount of Pb or Tl is found in the samples whose pull strength degrades rapidly and finally reaches zero.
3. Some of the samples including Pb or Tl are improved in the degradation mode by doping a small amount of silver into the gold film.
4. These phenomena can be well explained by the Kirkendall void model. According to this model, the growth rate of the gold-rich intermetallic phase plays a very important role on deciding the degradation modes. When this rate decreases, the pull strength frequently degrades very significantly.
5. The growth rate of the intermetallic phase, k, for A-mode, is found to be 2.8 μm/$\sqrt{\text{hr}}$ at 200°C.

Densification of SIPOS

H. R. Maxwell, Jr.* and W. R. Knolle*

Bell Laboratories, Reading, Pennsylvania 19604

ABSTRACT

Semi-insulating polycrystalline silicon (SIPOS) can be used as part of a passivation scheme on semiconductor devices. During processing the film experiences temperatures several hundred degrees higher than the SIPOS deposition temperature of 640°C. We have investigated the effect of high temperature anneals on the physical properties of SIPOS films containing 25 atomic percent oxygen. Heat-treatments of 900°C or greater in inert ambients densify the film resulting in a film thickness decrease (densification) on the order of 10% and decrease the etch rate of the film by a factor of 6 in a $6H_2O_2$:1HF:10 NH_4F SIPOS etch solution. Also, the infrared transmission spectrum of the SIPOS film changes as a result of annealing. Similar infrared changes in SiO_2 films have been interpreted to be due to a relaxation of bond strain and a decrease in film porosity. Film stress has also been investigated before and after annealing and was found to change from tensile to compressive. This is consistent with the interpretation of the infrared data.

Semi-insulating polycrystalline silicon (SIPOS) films doped with oxygen (1) can be used as part of a passivation scheme on semiconductor devices. The film is deposited on the wafer by chemical vapor deposition (CVD) at a temperature of ~640°C. Typically, SIPOS is never used as the only passivation layer on a semiconductor device, but rather is followed by SiO_2 and Si_3N_4 layers deposited at 900°C or more. Therefore, it seemed natural to investigate more closely the behavior of SIPOS films after annealing in an inert ambient. In this paper we report the effects of high temperature anneals on the physical properties of SIPOS films containing 25 atomic percent (a/o) oxygen.

Experimental

SIPOS deposition.—An AMT low pressure (LPCVD) system was used to deposit the 25 a/o O SIPOS films by the reactive decomposition of silane (SiH_4) and nitrous oxide (N_2O) in N_2. For this work the deposition temperature was 637°C and the system pressure was 0.16 Torr. The reactant gas flow ratio, N_2O/SiH_4, was 0.22 with an N_2 carrier gas flow of 400 cm^3/min for a deposition rate of 35 Å/min. The SIPOS film thickness was nominally 5000Å.

Two-inch diameter n-type (111) Si wafers were used throughout except for the stress measurements that were made on 3 in. diam n-type (100) Si wafers. Silicon nitride covered Si substrates were used for determination of the oxygen content of the SIPOS films by a gravimetric technique previously reported (2). In order to obtain a representative oxygen content the nitrided and bare Si wafers were alternately placed on a quartz boat with 0.375 in. spacing between them, loaded into the LPCVD furnace, and SIPOS deposited.

Etch rate and film thickness determination.—The SIPOS etch solution consisted of a mixture, by volume, of 6 parts H_2O_2-30%, 1 part HF-48%, and 10 parts of a 40% NH_4F (6:1:10) solution (1). The etch solution was allowed to equilibrate to 30°C for 5 min prior to etching.

The as-deposited etch rate was determined by half-waxing a wafer, cutting it into strips, and etching the strips for various times in the 6:1:10 SIPOS etch. After etching, the wax was removed and the step height measured on a Taylor Hobson Talystep. The effects of annealing in N_2 on etch rate after various times and temperatures were determined in a similar manner.

The thickness change (densification) after annealing was determined by half-waxing the SIPOS deposited Si wafers and etching them in the 6:1:10 solution until bubbling on the wafer surface stopped, indicating that the SIPOS-Si interface was reached (etch rate of Si in 6:1:10 is ~260 Å/min). The height of the step was then measured on the Talystep. These Talystep wafers were then remeasured for the determination of the SIPOS thickness after annealing and were used for the infrared measurements.

Infrared spectra measurements.—The infrared transmission spectrum of the SIPOS sample was taken before and after each anneal or densification process. A clean Si substrate was placed in the reference beam of the Perkin-Elmer Model 621 Grating Infrared Spectrophotometer. The Si in the reference beam nulls out the absorption signal from the Si substrate in the sample beam. The absorbance, A, of an infrared peak was measured by the baseline technique (3) and the area of the absorption was approximated by $A \cdot W$ where W is the full width at half of the maximum absorbance.

Stress measurements.—The stress of the SIPOS film was measured with an optically levered laser technique (4). The difference between the radius of curvature of the Si wafer measured before and after deposition can be related to the stress in the deposited SIPOS film (SIPOS must be etched off the back of the wafer before the measurement is made). The measurements were made on 3 in. diam, 0.020 in. thick (100) Si wafers. The precision of the measurement is about $\pm 1 \times 10^9$ dynes/cm^2.

Results

Etch rate.—The as-deposited SIPOS etch rate in the 6:1:10 SIPOS etch was determined and the data are plotted in Fig. 1 as the amount of SIPOS removed *vs.* etch time. The best fit for the data is shown and results in an average etch rate of ~1200 Å/min for the as-deposited 25 a/o O SIPOS film.

The effects of annealing temperature on etch rate are given in Fig. 2 where the SIPOS film etch rate in the 6:1:10 solution *vs.* annealing temperature is plotted. The anneals were done in N_2 for 1 hr. Initially, the etch rate decreases by a factor of 6 from the as-deposited value and then increases as the annealing temperature continues to increase. This increase in etch rate at the higher temperatures is attributed to the increase in the SiO_2 character of the film which will be discussed later. For reference, the etch rate of 1050°C steam-grown SiO_2 in 6:1:10 solution is shown.

The effect of annealing time on etch rate at the various temperatures is shown in Table I. The anneal

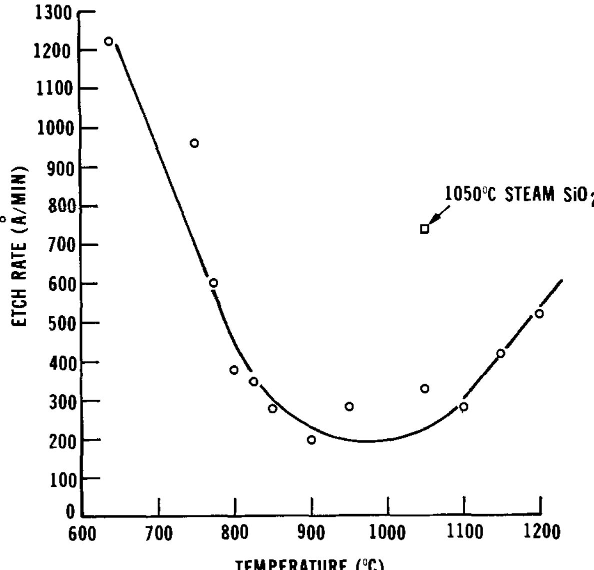

Fig. 2. Etch rate of 25 a/o O SIPOS in 6:1:10 SIPOS etch solution as a function of annealing temperature. Samples were annealed for 1 hr in N_2. The etch rate of a 1050°C steam-grown SiO_2 in 6:1:10 solution is represented by □.

times of 1/2, 1, and 2 hr were used for the three annealing temperatures of 800°, 900°, and 1100°C. The 800° and 900°C temperatures are representative of typical SiO_2 and Si_3N_4 deposition temperatures. As shown, the 800°C anneals are not as effective at lowering the etch rate as the 900° and 1100°C anneals. Also, the etch rate decreases with increasing annealing time for the 800° and 900°C anneals, but does not continue to decrease for the 1100°C anneal. From the change in etch rate it is apparent that the SIPOS films have changed character due to the anneals.

SIPOS densification.—The anneals also cause the films to shrink or densify as shown in Fig. 3 where the change in the SIPOS film thickness (densification) *vs.* time is plotted for a 900°C N_2 anneal. From this

Table I. SIPOS etch rate after annealing in nitrogen. (6:1:10) (Error in etch rate is ~35 Å/min)

tained. The least squares analysis of the Arrhenius-type plot results in an activation energy of 0.32 eV.

Infrared measurements.—Thus far, it has been shown that the SIPOS etch rate decreases from its unannealed value and the film densifies with annealing. It will now be interesting to show how the film physically restructures. To do this, one can examine the infrared spectrum as shown in Fig. 5. This spectrum is for an as-deposited 25 a/o O SIPOS film and shows a strong absorption peak at 1030 cm^{-1} and a weak peak at 865 cm^{-1}. No peak is noted at ~800 cm^{-1} which would be present in the infrared spectrum of SiO_2 (5).

The infrared spectra of SIPOS films after high temperature heat-treatments are shown in Fig. 6. This figure shows the effect of 1/2 hr N_2 anneals at 800°, 900°, and 1100°C on three different wafers. The major 1030 cm^{-1} absorption peak shifts to higher frequency with increasing annealing temperature. The strong absorption occurs at 1045 cm^{-1} for 800°C, 1080 cm^{-1} for 900°C, and 1095 cm^{-1} for the 1100°C anneal. Also the width of the major peak decreases from the initial value of 156 cm^{-1} to 125 cm^{-1} for 800°C, 121 cm^{-1} for 900°C, and 100 cm^{-1} for the 1100°C anneal. Moreover, the maximum absorbance increases in intensity as the temperature increases, yet the area of the strong absorption peak remains approximately the same for all temperatures and is an indication that the oxygen

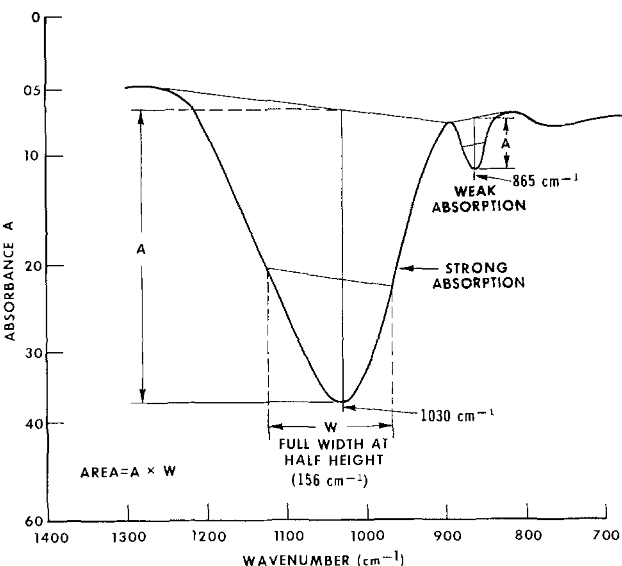

Fig. 5. Analysis of transmission infrared spectrum of 25 a/o O SIPOS film from 700 to 1400 cm^{-1}. The strong infrared absorption occurs at 1030 cm^{-1} while a weak absorption occurs at 865 cm^{-1}. area of the 1030 cm^{-1} absorption is approximated by $A \cdot W$.

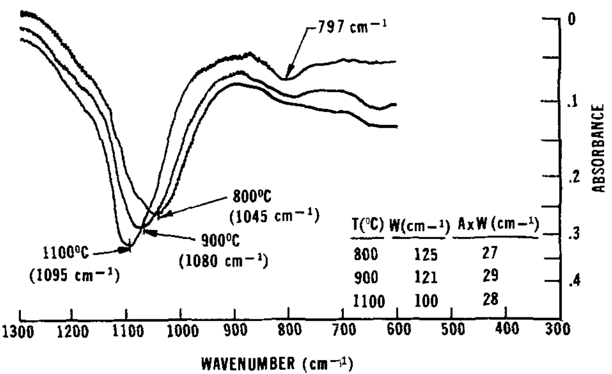

Fig. 6. Infrared spectra of SIPOS films after annealing. Note the shift in the position of the strong absorption to higher frequency with higher annealing temperature. The area of the strong absorption is constant, 28 ± 1 cm^{-1}, indicating no change in the oxygen content of the film.

Table II. SIPOS infrared peak and area ratios (2 hr nitrogen anneal)

Annealing temp (°C)	SiO_2 (797 cm^{-1}) / Si-O (1045-1095 cm^{-1}) Peak ratio	Area ratio
1100	0.071	0.041
900	0.071	0.035
800	0.044	0.019

content is not changing. (This is confirmed by electron microprobe analysis of the same films.) Furthermore, the 865 cm^{-1} peak is eliminated and at 900° and 1100°C a weak peak at 797 cm^{-1} appears. This peak is usually associated with SiO_2 (5).

Obviously the heat-treatments restructure the SIPOS film. A relative measure of this restructuring is given in Table II. The ratio of the intensity of the 797 cm^{-1} peak to the strong absorption peak at 1045-1095 cm^{-1} may be an indication of how much restructuring has been done. In Table II these ratios for peak height and area are given. The 2 hr 900° and 1100°C anneals are roughly comparable and apparently caused more restructuring than the 800°C anneal. The peak ratios indicate less SiO_2 component (797 cm^{-1}) is formed at 800°C as compared to 900° and 1100°C. Likewise, the area ratio would indicate the higher temperature anneals are more effective in forming the 797 cm^{-1} peak.

A measure of the activation energy associated with the restructuring is given in Fig. 7 where the shift of the strong infrared absorption *vs.* the reciprocal of the annealing temperature is plotted. The least squares analysis for this Arrhenius plot results in an activation energy of 0.27 eV.

Additional infrared data resulting in an Arrhenius plot are presented in Fig. 8. The change or narrowing of the full width at half of the maximum absorbance for the strong infrared absorption *vs.* the reciprocal of annealing temperature is plotted and yields an activation energy of 0.27 eV. These activation energies are in reasonable agreement with the activation energy determined for the percent densification, 0.32 eV, (Fig. 4) and are all approximately one-sixth of the energy associated with forming the SIPOS film.[1]

[1] The energy for formation of the SIPOS film was determined from an Arrhenius plot of deposition rate *vs.* reciprocal of deposition temperature (6).

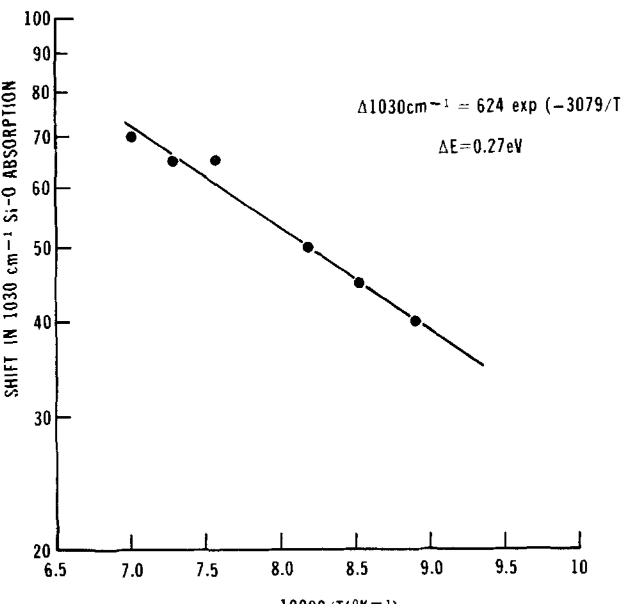

Fig. 7. Shift in the strong infrared absorption vs. reciprocal temperature (K^{-1}). The SIPOS films were annealed for 1 hr in N_2. The least squares analysis yields an activation energy of 0.27 eV.

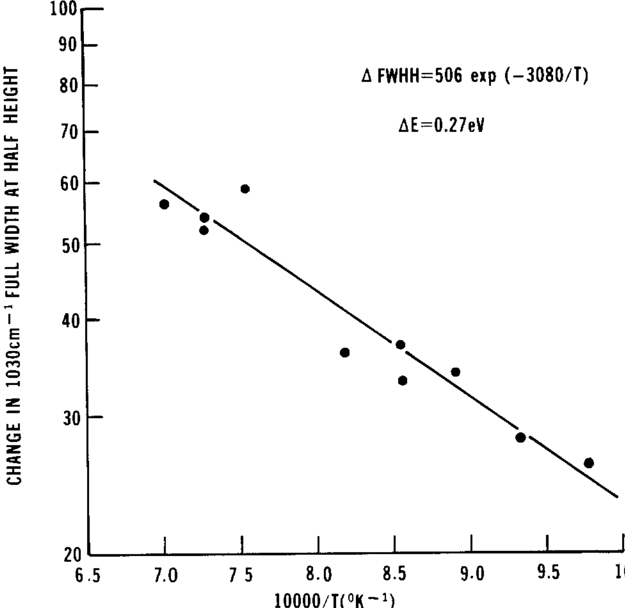

Fig. 8. Change in width of strong infrared absorption vs. reciprocal temperature (K^{-1}). The SIPOS films were annealed for 1 hr in N_2. The least squares analysis yields an activation energy of 0.27 eV.

The results discussed, thus far, are from control wafers that were heat-treated. However, the same effects are observed in device processing during subsequent film depositions such as Si_3N_4 passivation (see Fig. 9). This figure shows the infrared spectra for a SIPOS film before and after Si_3N_4 deposition. The Si_3N_4 was etched off the sample before the infrared spectrum was taken. For this work, the Si_3N_4 was deposited in a LPCVD reactor at a temperature of approximately 892°C by the reaction of SiH_2Cl_2 and NH_3. As shown, the major infrared peak for SIPOS has shifted from 1030 cm^{-1} to 1070 cm^{-1}, the 865 cm^{-1} peak has disappeared, and a new peak at 797 cm^{-1} has appeared. This infrared spectrum is similar to the infrared spectrum of a SIPOS film that has been annealed at 900°C (see Fig. 6).

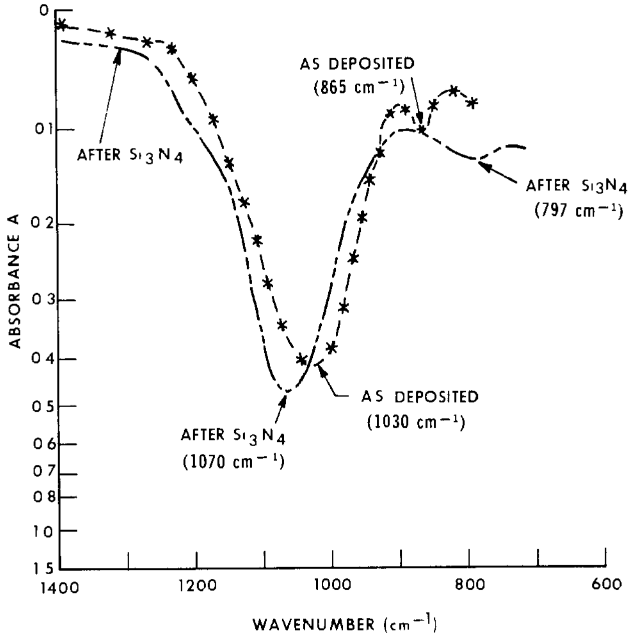

Fig. 9. Infrared spectra of SIPOS before and after deposition of Si_3N_4 at 892°C. –*– as-deposited SIPOS; – – – – after Si_3N_4 deposition. Si_3N_4 was removed before infrared spectrum was recorded.

Stress measurements.—The restructuring caused by the high temperature anneals can be correlated with stress, as shown in Fig. 10, in which the measured stress is plotted for a 5000Å thick unannealed SIPOS film along with data after annealing at 900° and 1100°C for 1 hr in N_2. The stress for the as-deposited film is tensile and is $+1.2 \pm 0.9 \times 10^9$ dynes/cm². After the 1100°C anneal, the stress is compressive and is $-0.8 \pm 1.2 \times 10^9$ dynes/cm².

The total stress (σ_t) of a film is given by

$$\sigma_t = \sigma_{th} + \sigma_i$$

where σ_i is the intrinsic stress and σ_{th} the thermal expansion coefficient mismatch stress. The latter is given by (7)

$$\sigma_{th} = (\alpha_f - \alpha_{Si}) \frac{E_f}{1 - \nu_f} \cdot \Delta T$$

where α_f and α_{Si} are the thermal expansion coefficients of the deposited film and the Si substrate, E_f and ν_f are Young's modulus and Poisson's ratio for the film, and ΔT is the difference in temperature between the film deposition temperature and the temperature at which the stress is measured. For these films, ΔT is about 620°C. For a 25 a/o O SIPOS film α, $E/(1 - \nu)$, and σ_i have been determined (8). These values are $\alpha = 2.18 \times 10^{-6}$/°C, $E/(1 - \nu) = 1.31 \times 10^{12}$ dynes/cm², and $\sigma_i = +1.5 \times 10^9$ dynes/cm². Note that α lies between Si ($\alpha = 2.52 \times 10^{-6}$/°C) and SiO_2 ($\alpha = 0.55 \times 10^{-6}$/°C), as might be expected. Substituting the values for α and $E/(1 - \nu)$ into the expression for σ_{th} yields $\sigma_{th} = -2.8 \times 10^8$ dynes/cm². If the high temperature annealing of SIPOS reduces the intrinsic stress, then SIPOS films should become more compressive according to the expression for σ_t and, in fact, this is what is observed, as shown in Fig. 10.

Discussion

The high temperature anneal of a 25 a/o O SIPOS film causes the film to shrink or densify about 10%. For deposited SiO_2, densification on the order of 3% to 5% has been reported (5) after annealing. The etch rate of the annealed SIPOS in the 6:1:10 SIPOS etch solution has also decreased from the as-deposited value. This observation is consistent with the elimination of voids (reduction of porosity) at anneal temperatures above the deposition temperature. Amorphous thin films commonly have a void network (9). Moreover, the infrared spectrum of the densified SIPOS has changed as well. The strong absorption peak narrows and shifts to higher frequency. Similar

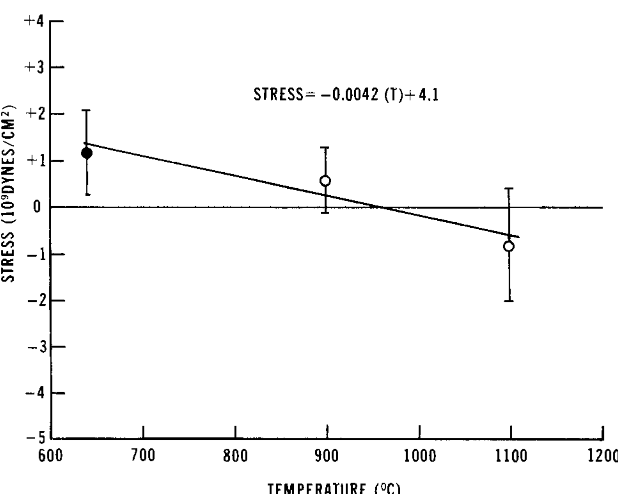

Fig. 10. SIPOS stress vs. annealing temperature. SIPOS was annealed for 1 hr in N_2. The units of stress are 10^9 dynes/cm². Tensile stress is positive and compressive stress is negative. The dark circle is the measured stress of the as-deposited SIPOS.

changes in the infrared spectrum of SiO_2 after annealing have been interpreted to be due to a relaxation of bond strain and a decrease in film porosity (5). In fact, if the temperature of the anneal is high enough, for example after an 1100°C anneal, the infrared spectrum of SIPOS resembles that of SiO_2. Even at 900°C, there is some SiO_2 character as evidenced by the presence of the weak 800 cm^{-1} peak in the infrared spectra.

Other changes occur in the SIPOS film with annealing. For example, from previous work (10), it is known that the as-deposited 25 a/o O SIPOS film is amorphous and that after a 1050°C anneal an average grain size of 40Å is observed. Given the above, it is possible that the formation of polycrystalline Si grains in the SIPOS during the anneal could exclude oxygen from the polycrystalline Si regions (there may still be some oxygen interstitially dispersed). Therefore, more of the remaining Si, not in the polycrystalline region, should be bonded to more than one oxygen atom. Evidence for this is suggested by the infrared spectrum of annealed SIPOS films that show no oxygen is lost during annealing. Thus, it is reasonable that after high temperature annealing the infrared spectrum of a SIPOS film should resemble SiO_2.

The stress measurements of SIPOS before and after an anneal are also consistent with more SiO_2 character of the annealed SIPOS film, in that the SIPOS film stress tends to change from tensile to compressive after annealing (SiO_2 is a film in compression on Si).

We interpret the etch rate data in the 6:1:10 SIPOS etch to indicate that at higher temperatures, more of the SIPOS has been converted to SiO_2 and polycrystalline Si since the etch rate actually starts to increase with the very high temperature anneal.[2] Thus the densification of the SIPOS film after anneal and the change in the infrared spectrum reported here support the models of annealed SIPOS presented by Hamasaki *et al.* (12) and McGinn and Goodman (13).

Conclusions

We conclude that with high temperature annealing the SIPOS films densify. For the 25 a/o O SIPOS films evaluated, this densification is a strong function of temperature. Some time dependence has also been noted for the lower temperature anneals (800°C). The densification is the result of a restructuring of the amorphous as-deposited SIPOS film as evidenced by the change in the infrared spectrum. This same densification takes place during high temperature deposition of Si_3N_4 or SiO_2 which are used as passivation layers on deposited SIPOS.

Evidence of grain growth at temperatures above the deposition temperature have been reported. Such grains exclude oxygen and result in the remaining Si atoms being bound to more than one oxygen atom (formations of SiO_2). The infrared changes and etch rate data are consistent with this interpretation. The change in the SIPOS stress due to the anneal is also consistent with more SiO_2 being formed. Finally, our results lend additional support to the models of annealed SIPOS presented by other workers.

[2] The etch rate variation of SIPOS with anneal temperature may also be interpreted in terms of the stress in the SIPOS films. In Fig. 2 the lowest etch rate is at ~980°C. In Fig. 10, this temperature corresponds to about zero stress in the SIPOS film. At any other temperature the film is stressed and so the etch rate is higher than that at 980°C (11).

ABSTRACT

A discontinuous silicon layer was produced on $(01\bar{1}2)$ oriented sapphire. The early growth of silicon was examined by transmission electron microscopy. During a very short time of deposition, it is shown that islands of {100} orientation had nearly square or rectangular forms. We observed a very rapid decrease of {100} crystallite density together with a nearly constant {110} crystallite density. The lattice of epitaxial Si layers was measured to be distorted in the very early stage of the growth. The interfacial shear strain is calculated. The distortion of the silicon lattice decreases with growing time.

Devices fabricated from heteroepitaxial silicon films on sapphire sometimes presented backchannel leakage currents caused, at least in part, by the presence of defects and impurities in the silicon films. Several authors (1-4) using transmission electron microscopy have shown the presence of stacking faults and microtwins in silicon. Defect density in silicon is very high in the proximity of the sapphire interface, so it is very important to study the structure of the interface and the defects which are present.

In order to investigate the nature of the initially deposited silicon, we have studied, using transmission electron microscopy, the structure and the orientation of silicon islands at early stages of growth.

The presence of residual elastic stresses near the interface, which could affect electrical properties of integrated circuits, is proved by measuring lattice parameters by diffraction microscopy.

Experimental

The silicon was deposited from vapor phase at 980°C on $(01\bar{1}2)$ oriented CZ single crystal sapphire substrates by pyrolysis of diluted silane in H_2. The sapphire substrates were polished wafers from Union Carbide.

Deposition was stopped at various times; with a growth rate of 0.67 $\mu m \cdot mn^{-1}$, we obtained a series of samples with isolated islands of silicon. The samples examined were grown for 0.6, 1.2, 1.8, and 2.4 sec.

The samples were thinned by argon ion bombardment from the sapphire side only. Samples were observed by JEM 100 B electron microscope, operating at 100 keV.

Observations

We first present information contained in the diffraction patterns and electron microscopical images.

Diffraction pattern and electron micrographs.—The selected area diffraction pattern from a sample grown for 1.8 sec is shown in Fig. 1. The indexed pattern is given on the same figure with reference to the interpretation of Abrahams (1). It is seen in Fig. 1 that there are three orientations. The most important orientation of the silicon islands is {100}. For these {100} domains, the plane $(2\bar{1}\bar{1}0)$ is parallel to the (001) plane of the silicon.

There are also two other orientations of silicon islands, that is to say two kinds of {110} oriented domains. These three main orientations are always present with their twin configurations. Each two {110} oriented domains have their twin pairs. They twinned about the <111> axis, which lies parallel to the [011] and $[0\bar{1}1]$ directions of the (100) oriented domains. Only the two twin axes which are parallel to the substrate give well-developed twin crystals. All other spots may be due to multiple diffraction effects.

Bright and dark field electron micrographs of the sample grown for 2 sec are shown in Fig. 2. The micrograph 2a is the bright field image of a sample area. The micrograph 2b is a dark field image with an operative reciprocal lattice vector $\mathbf{g}$ = (004) of the same area. The {100} oriented silicon islands appear light. In the micrograph 2c corresponding to the <111> reflection parallel to the $[0\bar{1}1]$ direction of the {110} domains, the two {110} domains appear light.

It is seen that the silicon films consisted of differently oriented domains smaller than 100 nm in diameter. The crystallites are often composed of one or two {110} domains associated with {100} domains.

We also observed that {110} domains contain a very high density of twins and microtwins. Most of the twins are very thin, one or two atomic layers. The density of twins in {100} domains is much smaller. The results given above concerned developed films before complete coverage. The observations are slightly different at earlier stages under the present growth conditions.

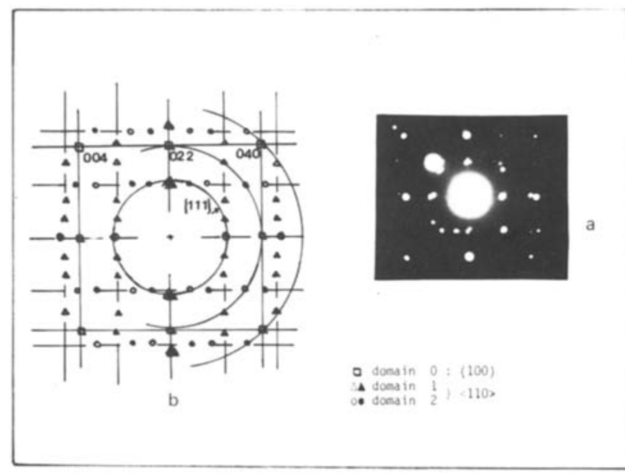

Fig. 1. Diffraction pattern of epitaxial silicon on sapphire. $(100)_{Si}/(01\bar{1}2)Al_{Al_2O_3}$. (a) Diffraction pattern, (b) indexed pattern of {100} and {110} domains.

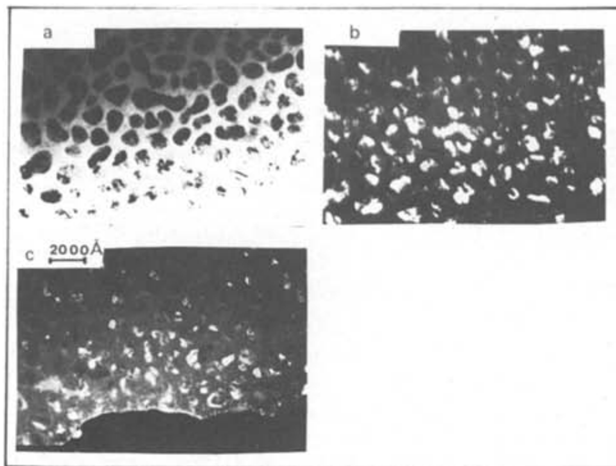

Fig. 2. Bright and dark fields electron micrographs: (a) bright field, (b) dark field {100} domain g = (022), (c) dark field {110} domains g = <111> || |0$\bar{2}$2|.

The size of the {100} domains is always larger than the corresponding {110} domain.

Figure 3 presents for different growing times the silicon islands deposed on sapphire. As seen in Fig. 3, the mean diameter of silicon crystallites increases with growing time, as the density of {100} domains decreases, as a result of island coalescence.

It is very interesting to note that for sample II (t = 1.2 sec, v = 0.67 μmn^{-1}), rectangular or square particles are present. They are much less numerous than the particles of other forms. The sides of the square particles are parallel to the [011] and [0$\bar{1}$1] directions. These particles are always smaller than other particles. The mean diameter seems to be smaller than 200 or 300Å. For longer growth time, the particles develop into larger conglomerates and the geometrical shape disappears.

Fine structure of electron diffraction patterns.—The fine structure in electron diffraction patterns for the sample with the smallest growth time shows: (*i*) elongation of spots (belonging to [100] and [110] domains) and (*ii*) distortion of the silicon lattice. Two distinct types of spot elongations are visible: circular elongation around the origin, and linear streaks. Figure 4 shows the diffraction pattern of [100] zone of {100} domains of silicon (sample II). Extreme variations in contrast made it difficult to obtain print that would

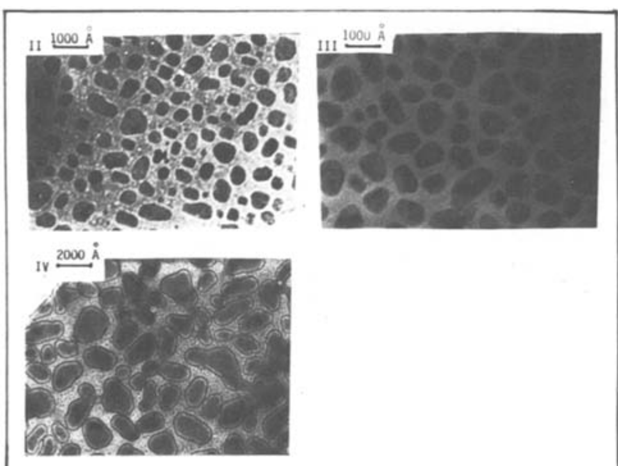

Fig. 3. Electron micrographs for different growing times. II = 1.2 sec; III = 1.8 sec; IV = 2.4 sec.

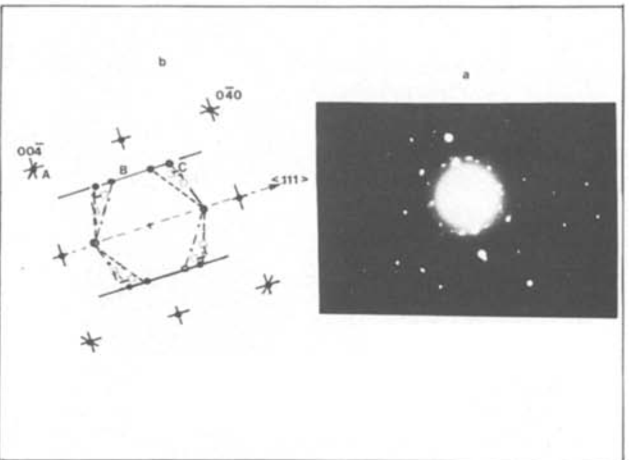

Fig. 4. Fine structure of a diffraction pattern

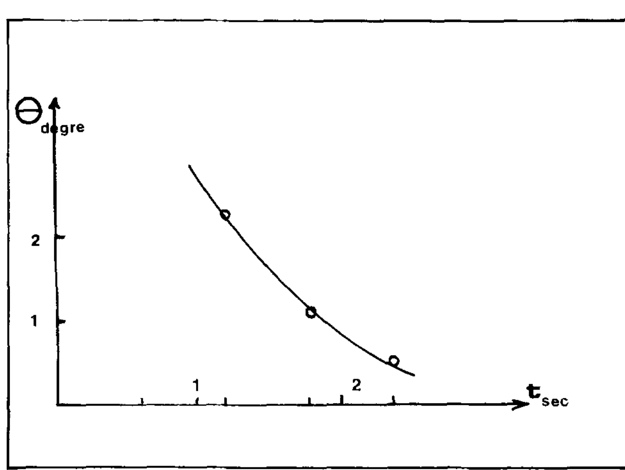
preserve the details of the relrods. These are shown in the accompanying tracing. The most readily identifiable type is circular elongations of the spots, which are due to small misorientations of the {100} or {110} domains.

This elongation is due to small misorientations. The mean angular spread of the spots from the {100} domains is about 3° for the smallest growth time, and decreased to 1° for longer growth time. So experimentally, it is seen that silicon films on sapphire are like a mosaic of silicon islands, which becomes more perfect as the thickness of the films increases. This orientation spread of about 3° was interpreted by Abrahams (4) to nucleation of planes of the {100} silicon islands parallel to sapphire planes; if some of the (0$\bar{2}$2) planes of {100} silicon nucleate parallel to the ($\bar{2}$20$\bar{4}$) planes of sapphire, while some other of the (0$\bar{2}$2) planes nucleate parallel to (20$\bar{2}\bar{4}$) planes of sapphire, the misorientation would be about 4°.

The second type of spot elongations in diffraction patterns appears as linear streaks in both {100} and {110} domains, arising from high density of stacking faults and microtwins (note B and C in Fig. 4). Diffraction patterns of the {110} domains (B) are present at very early stages of growing time; high density of microtwins shows linear streaks in the <111> direction. Only elongations along the <111> twin axis parallel to [011] and [0$\bar{1}$1] directions of {100} domains are well developed, as the twins. We obtain as the diffraction pattern, at very early stages of growth, a network with perpendicular streakings.

The {100} domains are also twinned about the <111> twin axes; at the exact [100] orientation, there are not spots due directly to the twins. But the spots noted C are extra spots due to double diffraction on those twins in {100} crystals. These spots disappear when the growing time increases. Linear streaks are also seen near (004), (022) spots and in the vicinity of the spots C, of the {100} domains. The streaks are parallel to the [010] and [001] directions; they can indicate a high density of stacking faults.

Angular distortion, misfit, and misfit dislocations.—At early stages of growth, before complete coverage, observations of diffraction patterns show that the silicon lattice is distorted. The distortion decreased for increasing growth time deposition. There is an angular distortion, and together a contraction of the reciprocal lattice vector. As the substrate is not cubic, a shear stress exists, which can be established from the nonorthogonality of (0$\bar{4}$0) and (00$\bar{4}$) reciprocal lattice vectors observed on the [100] silicon films patterns.



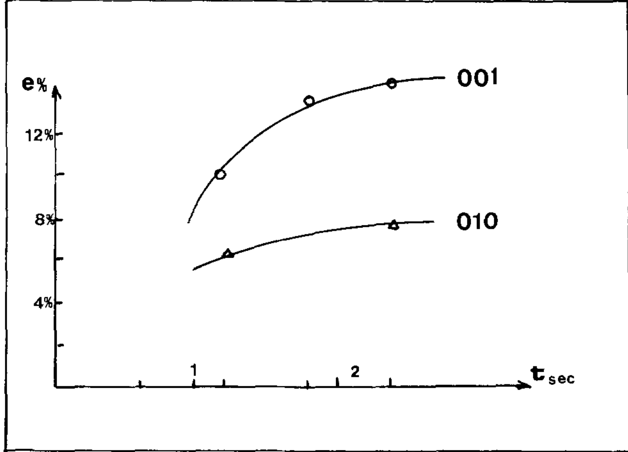


Fig. 5. Distortion of silicon lattice on sapphire at early stage of growth. (a) Deviation θ from theoretical angle between (004) and (040) reflections of epitaxial silicon, (b) misfit between distorted and nondistorted silicon lattice for the (004) and (040) reflection spots.

The angle between the $(0\bar{4}0)$ and $(00\bar{4})$ reciprocal lattice vectors was measured. This angle can be as large as 92°. The theoretical angle for the [100] orientation is 90°. 90° was substracted from the measured angle to give the shift named θ. The variation of θ for different growth time is shown in Fig. 5(a). θ decreases with increasing growth time. The maximum observed value of θ is as large as 2° for 1 sec of growth time. θ reached zero after 3 sec of growth time.

In diffraction patterns, a misfit between the silicon and sapphire lattices can be observed. From the separation of g_{SI} and g_{SA} where g_{SI} and g_{SA} are, respectively, the reflection (004) of the silicon and $(\bar{4}220)$ of the sapphire, we deduce that there is a progressive increase in the misfit between silicon and sapphire lattices with increasing deposit time. If the misfit is defined as

$$e = \frac{a_{SA} - a_{SI}}{a_{SA}}$$

where a_{SA} and a_{SI} are the interatomic spacings in the interfacial plane in sapphire and silicon, then in terms of g_{SI} and g_{SA}

$$e = \frac{|g_{SA}| - |g_{SI}|}{|g_{SA}|}$$

assuming $g_{SA}//g_{SI}$.

Figure 5(b) shows that the misfit e increases from about 8% to 14% compared with a natural misfit e^o of about 14%, for the (004) reciprocal lattice vector of silicon and the $(\bar{4}220)$ of sapphire. The misfits noted e_{004} and e_{040} are related to the (004) and (040) reflections spots for silicon.

The misfit is equal to the natural misfit after 2.4 sec of growth. For this sample, continuous networks of misfit dislocations are also seen in the silicon islands, as seen in Fig. 6. The fringes tend to lie parallel to the [011] and $[01\bar{1}]$ directions. The Burgers vector of the dislocations is consistent with $a/2$ [110] which is the $\vec{b}$ for dislocation in the diamond structure. Their spacing is equal to 38Å, which is in good agreement with the calculated value for pure edge type (37Å).

For this sample (2.4 sec of growing time) the linear density of misfit dislocations is 1/38Å = 2.6×10^6 dislocations·cm^{-1}. For the other samples with shorter growing time, we do not see any misfit dislocations. Misfit dislocations have also been observed by Abrahams (5).

It is very interesting to note the correlation between the lattice deformation of the silicon, which decreases with growing time, and the easy observation of misfit dislocations for longer growing time.

Results

Monoclinic distortion of the epitaxed layers.—If we assume the thickness of the epitaxial layer to be much smaller than the dimensions of the substrate, we may neglect the strains in the substrate. Substrates that were not very thick became curved due to the stresses in the epitaxial layer.

The observations indicate that the silicon lattice at early stages of epitaxy is distorted. From measurements of several d spacings, it is concluded that there are compressional and shear strains in the silicon islands. The simplest distorted lattice is a monoclinic lattice.

Figure 7 gives a schematic drawing of a monoclinic distortion of a silicon layer on sapphire. The lattice

Fig. 6. Misfit dislocations of silicon on sapphire (growth time 2.4 sec).

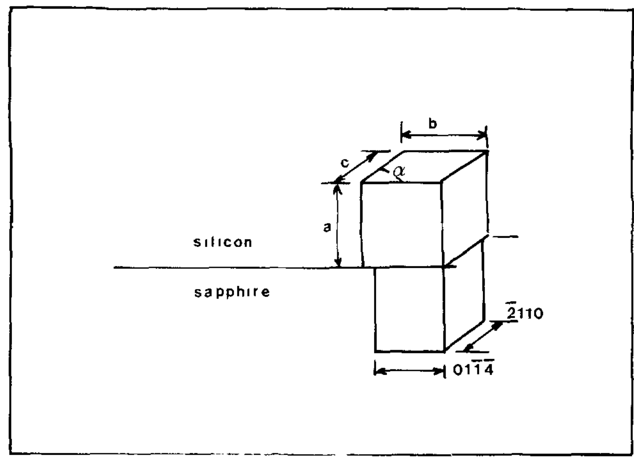

Fig. 7. Schematic representation of a monoclinic distorted silicon lattice on sapphire.

parameter of undistorted silicon is a_0. If ϵ_{100}, ϵ_{010}, ϵ_{001} are the strains along the three axes, the parameters of a distorted lattice become a b c

$$a = a_0(1 + \epsilon_{100})$$

$$b = a_0(1 + \epsilon_{010})$$

$$c = a_0(1 + \epsilon_{001})$$

where α is the monoclinic angle between the [010] and [001] axis, as shown in Fig. 7. α is 90° if the silicon layer is not distorted.

Relations between observable quantities and strain components.—From [100] diffraction pattern, we obtain information about strains in the wafer plane along the [001] and [010] axis, that is to say, c, b, and α. From the angular deviation between (010) and (001) reflections, spots on [100] diffraction pattern, we obtained α, which is related to θ.

Strains ϵ_{001} and ϵ_{010} are approximately related to misfits by

$$\epsilon_{001} = e_{004}{}^{0} - e_{004}$$

$$\epsilon_{010} = e_{040}{}^{0} - e_{040}$$

Strain ϵ_{100} related to the [100] axis perpendicular to the epitaxial plane must be calculated from the [110] pattern of the {100} silicon domains. The parameter a is more difficult to calculate, these parameters can only be obtained from relations between c, b, α, d_{400}, and d_{220}, where d_{400} and d_{220} measured on the {110} diffraction pattern are interplanar spacings of (400) and (220) planes of silicon.

Figure 8 shows variations of lattice parameters ϵ and α of a distorted silicon layer on sapphire with deposition time. As seen in the figure, the lattice parameter normal to the wafer surface increases, while the two lattice parameters parallel to the wafer surface decrease. This result suggests that the first layers of silicon on sapphire are deformed to accommodate the sapphire lattice.

Stresses in epitaxial layer.—The elastic stresses in a cubic crystal are correlated to the strains by a tensor, whose elements are the elastic stiffness coefficients. The elastic stiffness coefficients are given by Hornstra (6). In thin epitaxial layers, forces of the substrate act only in the interface plane, and as the substrate is not cubic, shear strains are present, which are to be added to compressional strains (8).

We calculate stresses along the different axes using the variation of the lattice parameters; the result is for 1.2 sec of growing time (sample II)

$$\sigma_{100} \simeq +1.2 \times 10^{10} \text{ dynes/cm}^2$$

$$\sigma_{010} \simeq +2.9 \times 10^{10} \text{ dynes/cm}^2$$

$$\sigma_{001} \simeq -5.9 \times 10^{10} \text{ dynes/cm}^2$$

The shear stress σ_S is calculated from the angular deviation θ by Abrahams (7)

$$\sigma_S = \text{tg } \theta \simeq 2.7 \times 10^{10} \text{ dynes/cm}^2 \text{ for sample II}$$

The decay of the compressional and shear strains is very quick. For the sample III (t = 1.8 sec) these strains are about a factor of 10 less than the strains of the sample II (t = 1.2 sec). Along the [001] direction, we calculate the values

$$\sigma_{II} = -5.9 \times 10^{10} \text{ dynes/cm}^2$$

$$\sigma_{III} = -0.7 \times 10^{10} \text{ dynes/cm}^2$$

We also observed a very important difference between strains in [001] and [010] directions, which gives rise to a shear strain in the wafer plane.

The precision of our results are best appreciated along the [001] axis, where the compressional strain is the most important. The compressional strain of sample IV (t = 2.4 sec) is impossible to estimate with our method; the precision of the diffraction patterns is too small. In opposition, the shear strain decreases slowly from $3 \cdot 10^{10}$ dynes/cm² for the sample II to 0.6×10^{10} dynes/cm² for sample IV, with increasing growth time.

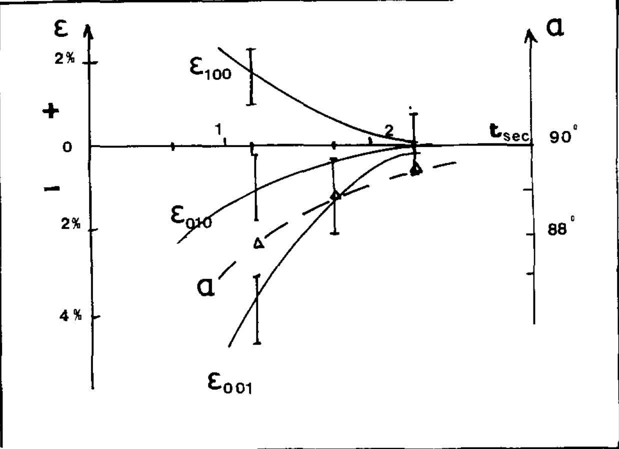

Fig. 8. Variation of lattice parameters of monoclinic silicon with deposit time.

Discussion

Two points are very important in our results, the geometrical form of the silicon islands and the stresses in the wafer plane before complete coverage. We compare first the morphology of the silicon islands with those of Abrahams (1); then some remarks are made concerning the magnitude of the calculated stresses and the asymmetric strains in the plane of the wafer.

The observations of the nucleation of silicon on sapphire are compared with the results of Abrahams. The growing conditions (temperature, growth rate) are approximately the same. They obtained near a rapid initial coverage rate, smooth forms of silicon islands. In opposition our silicon islands present geometric forms and the coverage of the substrate surface *vs.* time is represented by a sigmoid curve. Those islands present a partially coherent growth on the substrate. The morphology of the silicon islands differs only at a very early stage of growth. For longer growth time, our results are similar to those reported by Abrahams.

The important difference in the preparation of the substrate is hydrogen firing used by Abrahams. The surface of sapphire obtained by those authors seem to provide a high density of nucleation of silicon islands. As we do not use hydrogen firing, we obtain a lower density of silicon islands with a lower density of defects. Schmidt and Davey (13) have reported that after hydrogen firing, sapphire surfaces were ordered crystallographically but topologically poor.

Those silicon islands present, on the other hand, important compressional strains. Geometric or thermal considerations could explain the not equal compressional strains in the [001] and [010] directions, greater along the [001] axis. Stresses arise when the layers are cooled to room temperature. They are due to the difference between the thermal expansion coefficients of silicon and sapphire (8). The anisotropy of the thermal expansion coefficient of the sapphire (12) greater along c than perpendicularly gives rise to anisotropy of contraction of sapphire greater along the [010] than the [001] axis.

Crystallographical considerations could also induce stresses in the wafer plane. Nolder (11) compared the relative position of aluminum and oxygen atoms on a $(01\bar{1}2)$ plane in sapphire and the silicon atom on a (100) plane in the cubic lattice of the silicon.

It is seen that the aluminum sites form a face-centered array, which is similar to the arrangement of

silicon atoms in a (100) plane, with the [001] direction of silicon parallel to the [2̄110] direction of the sapphire. The substitution of aluminum by silicon, leads to mismatches along the [001] and [010] directions of about 14 and 8% with reference to the [2̄110] and [01̄14̄] directions of sapphire. The observed strains are of the same order of magnitude and of the same direction as geometric strains.

In general, all the measurements of residual stresses in silicon films on sapphire lead to thermal stresses. Kamins and Meieran (9) calculated stresses of $7 \cdot 10^9$ dynes · cm^2, Dumin (10) found residual stresses to be about $5 \cdot 10^9$ dynes · cm^{-2}. Abrahams (7) gives shear stresses of $1.2 \cdot 10^{10}$ dynes · cm^{-2} near corners of silicon-sapphire interface. The magnitude of the calculated stresses ($5 \cdot 10^{10}$ dynes · cm^{-2} in the [001] direction) at an early stage of growth can exceed the thermal contribution by an order of magnitude. As the film grows, this contribution becomes very small rapidly. We think that there is a superposition of the two sorts of stresses. The crystallographical compressional strain, which is very important at early stage of growth, decreases very quickly with thickness. When the films are thicker, thermal compressional stresses remain the principal stresses.

Experimentally, we observed small islands at the first stage of the deposition of silicon on sapphire, which present the characteristics of partially coherent growth on the substrate surface. That is in opposition with the theory of Van Der Merve (14), which says that a totally coherent growth of a layer film (formed layer by layer) may be expected up until a certain thickness which is related with the misfit of the two lattices. This thickness is for the system Si/Al_2O_3 equal to 1Å, that is to say that the growth of silicon may be totally not coherent. In fact, the growth of islands of silicon instead of layers increases the possibility of coherent growing, by introducing a term of superficial energy of the island.

In conclusion, we observed at a very early stage of growth, a partial coherency of the silicon islands of sapphire. This partially coherent growth appears with compressional strains in wafer plane and at the same time, the coverage of the substrate surface by silicon islands is represented by a sigmoid curve.

Silicon Contamination of InP Synthesized under High Phosphorus Pressure

A. Yamamoto, S. Shinoyama, and C. Uemura

Nippon Telegraph and Telephone Public Corporation, Ibaraki Electrical Communication Laboratory, Tokai, Ibaraki 319-11, Japan

ABSTRACT

An experimental study has been made of processes causing Si contamination of polycrystalline InP synthesized under high phosphorus pressure (~30 atm) via the horizontal Bridgman technique. Silicon content of the grown ingots was determined by measurement of carrier concentrations and by spark source mass spectrometry. The Si content increased by about two orders of magnitude when the maximum temperature in the indium melt was varied from 1050° to 1180°C. The Si content scarcely depended on phosphorus pressure in the range of 5-30 atm. Presence of indium oxides in the indium melt was found to lower the incorporated Si content. As a result of these investigations, high purity InP ($N_d - N_a = 3.2 \times 10^{15}$ cm^{-3}, $\mu_{77K} = 37{,}000$ cm^2/V · sec) was reproducibly obtained by using a quartz boat at a growth rate of 3 mm/hr. The effective distribution coefficient for Si in InP was determined to be 0.53 by the analysis of intentionally Si-doped ingots.

Recent developments of InP-based devices such as InGaAsP-InP lasers or InP FET's require high quality InP crystals as substrates. Single crystals of InP are currently grown by the liquid encapsulated Czochralski (LEC) method. The LEC method uses polycrystalline InP as the starting material. Reduction of residual donor impurities in the starting material is essential

Key words: InP, Si contamination, effective distribution coefficient, synthesis of III-V compounds, horizontal Bridgman technique.

to grow semi-insulating crystals or p-type crystals with low carrier concentrations.

Silicon is known to be a major residual donor impurity in InP and to be introduced from the silica envelope during synthesis or crystal growth (1, 2). Use of pyrolytic boron nitride (PBN) boats in the synthesis of InP is effective in reducing carrier concentrations in the grown ingots (3). Furthermore, the synthesis at lower temperatures (~ 950°C) and under lower phosphorus pressure (~ 2 atm) is successful in obtaining high purity InP with carrier concentrations lower than 10^{15} cm^{-3} (4). Although the reaction of SiO_2 and phosphorus vapor, which provides a source for Si contamination, has been proposed by Bachmann *et al.* (1), details of Si contamination process during synthesis or crystal growth have not been systematically studied.

Segregation behavior of Si in InP, on the other hand, has been unclear since the effective distribution coefficient for Si in InP, k_e(Si), has been scattered in the wide range of 10^{-3} in LEC (5) to 30 in LPE (6). This uncertainty for k_e(Si) is thought to be mainly caused by Si contamination during synthesis or crystal growth (2). Therefore, segregation behavior of Si must be evaluated with intentionally Si-doped materials in which an Si contamination level can be neglected as compared with the Si doping level.

In this work, we studied experimentally the Si contamination process of undoped InP synthesized under high phosphorus pressure via the horizontal Bridgman technique. By carrier concentration measurements and spark source mass spectrographic analyses, we found some factors in the synthesis which governed Si content incorporated into grown ingots. As a result of that, it was proved that bulk polycrystalline InP with carrier concentrations as low as those synthesized using PBN boats could be obtained by using quartz boats. We also obtained a reliable value of k_e(Si) from the analyses of intentionally Si-doped ingots.

Experimental

Not intentionally doped polycrystalline InP was synthesized from the elements via the horizontal Bridgman technique. Approximately 200g of indium (6-9's purity, Mitsubishi Metals or Yamanaka Semiconductors) were charged in a quartz boat. The quartz boat was placed in a quartz ampul (ID: 35 mm, length: 600 mm) together with approximately 100g of red phosphorus (6-9's purity, Mitsubishi Metals) charged in a separate quartz boat. Prior to the sealing of the ampul, the indium was prebaked in vacuum (pressure: 1×10^{-6} Torr) at a temperature in the range of 450°-950°C for 3 hr. After being evacuated and then sealed, the ampul was set in a three-zone horizontal Bridgman furnace. The furnace was in a water-cooled chamber that could be pressurized up to 35 atm with N_2 gas. The furnace was heated to the conditions shown in Fig. 1. The phosphorus pressure in the ampul was controlled by the temperature in the zone A, T_A, and estimated from the pressure-temperature relationship data reported by Bachmann *et al.* (7). T_A was varied from 400° to 600°C, which corresponded to phosphorus pressure from 1.5 to 40 atm, respectively. To prevent breakage of the ampul due to such high phosphorus pressure, the N_2 gas pressure in the chamber was controlled to within ± 5 atm of the phosphorus pressure in the ampul. The indium was heated at the temperature in the zone B, T_B, and then traveled toward the zone A through the highest temperature zone C in which maximum temperature was T_{max}. T_B was fixed at 800°C through all experiments, and T_{max} was varied from 1050° to 1200°C. The ampul was moved at a constant speed of 3 mm/hr when the desired temperature in each zone was reached.

Silicon-doped InP was also synthesized to study the segregation behavior of Si in InP. For Si doping, small pieces (2-5 mg) of an Si wafer (phosphorus-doped,

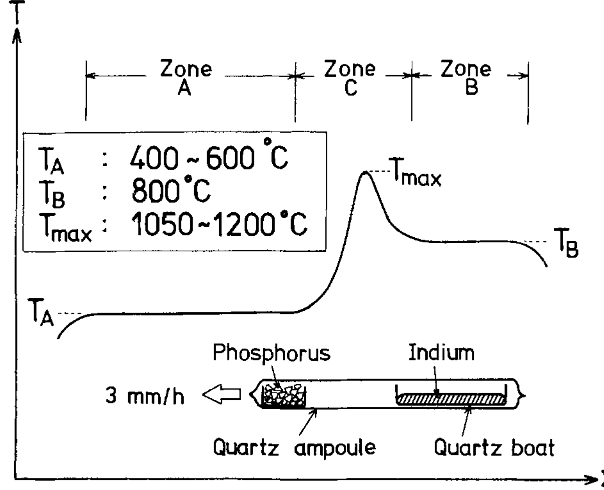

Fig. 1. Schematic of the horizontal Bridgman apparatus used for synthesis of InP.

50 Ω·cm) were added to the indium before the prebaking of the indium.

The electrical properties of InP ingots synthesized were evaluated using Van der Pauw Hall measurements. The residual impurities in the ingots were determined using spark source mass spectrometry.

Results and Discussion

Silicon contamination of nominally undoped ingots.— We studied the dependence of carrier concentration or Si incorporated under various synthesis conditions such as maximum temperature in the zone C, T_{max}, phosphorus pressure in the ampul, P_P, and prebaking temperature of the charged indium, T_{pb}.

First, effects of T_{max} on carrier concentrations and Si contents in grown ingots will be described and discussed. Syntheses were performed under the following conditions: T_{pb} = 500°C, P_P = 7 atm, and T_{max} = 1050°-1180°C. The InP ingots grown under these conditions were fully stoichiometric excepting the last-to-freeze end at which excess indium remained. Figure 2 shows a typical grown ingot weighing 250g. Samples for electrical measurements were sliced perpendicular to the growth direction from each position of the ingots. Figure 3 shows carrier concentration profiles along the growth direction in the ingots grown at different T_{max}. It can be seen that, with increasing T_{max}, the carrier concentration increases drastically and its distribution becomes flat. To confirm that the increase in carrier concentration with increasing T_{max} is due to an increase in Si content in the ingots, spark source mass spectrographic analyses for the ingots were performed. The analytical results for typical two samples as indicated by numbered squares in Fig. 3 are pre-

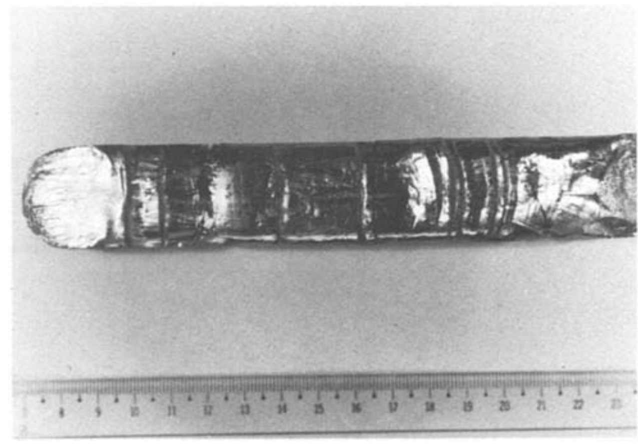

Fig. 2. A typical polycrystalline InP ingot grown, weighing 250g

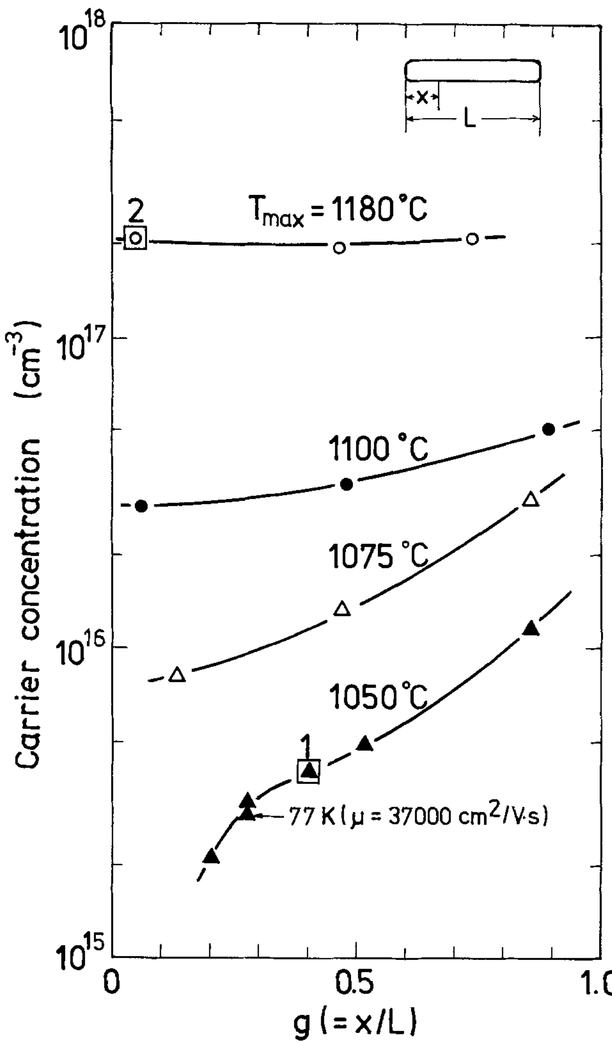

Fig. 3. Carrier concentration profiles along the growth direction for ingots grown at different maximum temperature in the indium melt (T_{max}).

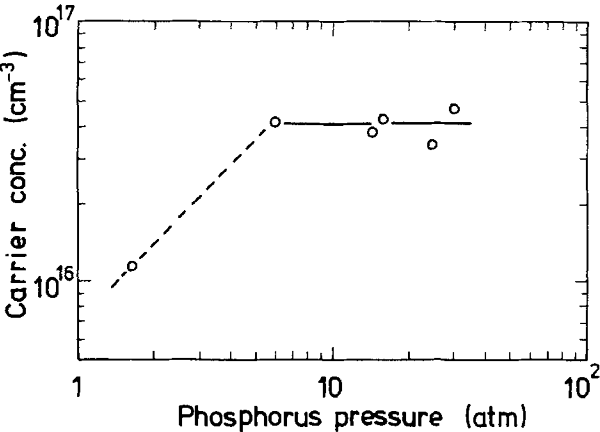

Fig. 4. Carrier concentrations at the first-to-freeze portion of grown ingots as a function of phosphorus pressure (P_P).

sented in Table I. A remarkable difference in Si concentrations between both samples are found, whereas no significant differences in concentrations of other impurities are found. Furthermore, no other donor impurities than Si are detected and the Si concentrations are in good agreement with the carrier concentrations. From these results, it is concluded that Si contents incorporated during synthesis dominate the carrier concentrations in the grown ingots and, also, that the increase in T_{max} drastically enhances the reaction for Si contamination. Although high concentrations of C, N, and O were detected, they are thought to be incorporated during the sample preparation processes for the analysis.

The results shown in Fig. 3 also show that carrier concentrations as low as those in PBN-grown InP (3) can be obtained at a comparable growth rate (3-4 mm/hr) even if quartz boats are used. Hall data for a typical ingot are $N_d - N_a = 3.2 \times 10^{15}$ cm^{-3} and $\mu_{77K} = 37{,}000$ cm^2/V·sec.

It is obvious that curves in Fig. 3 do not represent the segregation behavior of Si because the distribution of Si is governed by the Si contamination process. The increase in "apparent" effective distribution coefficient with increasing Si content incorporated is a phenomenon commonly observed in this study. The segregation behavior will be discussed in the next section.

Next, a phosphorus pressure dependence of the carrier concentration in the grown ingot will be described. The ingots were grown under the following conditions: $T_{pb} = 800°C$, $T_{max} = 1100°C$, and $P_P = 1.5$-30 atm. When the synthesis was carried out using 200g of charged indium, inclusions of excess indium were contained in the ingots grown at P_P lower than about 5 atm. To avoid the In inclusions, it was necessary to reduce either the growth rate or the amount of charged indium. In this experiment, the amount of charged indium was reduced to 20g and, consequently, ingots free from inclusions were obtained at P_P in the range of 1.5-30 atm. Carrier concentrations at the first-to-freeze portions of grown ingots are plotted in Fig. 4 as a function of P_P. The effect of P_P on the carrier concentration is not as large as that of T_{max}. The carrier concentration scarcely depended on P_P in the range of 5-30 atm. At lower P_P than about 5 atm, the carrier concentration seemed to depend on P_P. Similar P_P dependence of carrier concentration was found for InP crystals grown by the synthesis solute-diffusion method ($P_P = 0.6$-1.2 atm) (8). Therefore, it is reasonable to assume that Si contamination level increases with increasing P_P, and becomes saturated at higher P_P ($\gtrsim 5$ atm).

We found that carrier concentrations in grown ingots were different depending on lot or supplier of the charged indium even if T_{max} and P_P were fixed to certain values, as shown in Fig. 5. Differences in the carrier concentration profiles in Fig. 5 were found to be closely related to differences in degree of oxidation of the charged indium. The lowest profile was obtained for the ingot synthesized using the most heavily oxidized indium. The degree of oxidation of the charged

indium was examined by an amount of a scum formed on a molten indium. This fact suggests that oxides of indium included in the charged indium have effects on the Si contamination process. Therefore, we tried to eliminate indium oxides contained in the charged indium, and examined effects of the elimination on the carrier concentration. The elimination was made by prebaking the charged indium in vacuum before synthesis. The prebaking temperature T_{pb} was varied from 450° to 950°C. All charged indium used here were from the same lot. The ingots were grown by using 200g of charged indium under the following conditions; P_P = 8 atm and T_{max} = 1100°C. Figure 6 shows carrier concentration profiles for the ingots grown by using the charged indium baked at different T_{pb}. With increasing T_{pb}, the carrier concentration increases and its distribution becomes flat. Especially, a remarkable difference is observed in carrier concentrations between T_{pb} = 700°C and 800°C. This difference can be explained by the difference in removal rates of indium oxides at both temperatures, because indium oxides such as In_2O_3, In_2O, or InO are sublimated or decomposed in vacuum at temperatures higher than about 800°C. From these results, it can be concluded that indium oxides in the charged indium suppress the reactions causing Si contamination. The effect of indium oxides on the reaction causing Si contamination can be understood qualitatively as follows. According to Bachmann *et al.* (1), an SiO vapor as a source for Si contamination is provided via the reaction

$$10\,SiO_2(s) + P_4(g) \rightleftharpoons 10\,SiO(g) + P_4O_{10}(g) \quad [1]$$

When indium oxides are present in the charged indium, they will be reduced by phosphorus vapor and a P_4O_{10} vapor will be produced prior to the reduction of SiO_2. An increase in P_4O_{10} partial pressure in the ampul by the reduction of the indium oxides can force reaction [1] to proceed to the left-hand side, *i.e.*, suppress the production of SiO vapor.

When the charged indium was prebaked in vacuum, most of the indium oxides were transported to a lower temperature region in the ampul. The presence of indium oxides at a lower temperature region during synthesis had no effect on carrier concentrations in grown ingots. This fact means that the reduction of indium oxides, as well as the reduction of silica, by phosphorus vapor requires a high temperature (~ 1000°C).

Effective distribution coefficient for Si in InP, k_e(Si).—As described in the previous section, distributions of Si concentration in nominally undoped ingots are remarkably different depending on the Si contamination level. Therefore, it is meaningless to evaluate k_e(Si) for those ingots. We prepared Si-doped ingots with carrier concentrations higher than 10^{18} cm^{-3} to examine k_e(Si). The ingots were grown under the following conditions: T_{pb} = 700°C, T_{max} = 1050°C, and P_P = 7 atm. For successful Si doping, it was necessary to dissolve completely the Si pieces into the indium melt before the synthesis. When the Si pieces floated on the surface of the indium melt during the synthesis, they were attacked by phosphorus vapor and transferred to a low temperature region in the ampul and, consequently, Si doping was unsuccessful.

Typical carrier concentration profiles for Si-doped ingots along the growth direction are shown in Fig. 7. Doping efficiencies of Si for these ingots were about 50%. It is reasonable to assume that the profiles represent the segregation behavior of Si because the Si contamination levels in these ingots are estimated, from the growth conditions, to be lower than 2×10^{16} cm^{-3}. The profiles obey the normal freezing relationship and their slopes give k_e(Si) = 0.53. Figure 7 also shows carrier concentration profiles in LEC single crystals grown by using the nominally undoped ingots described in the previous section. We found that the average carrier concentrations in the LEC crystals were in good agreement with those in the starting materials (9). The profiles for the LEC crystals also obey the normal freezing relationship and have a same slope as that for the Si-doped ingots. These facts indicate that the carrier concentrations in the LEC crystals are dominated by Si contents involved in the starting materials.

Summary

We studied experimentally Si contamination of polycrystalline InP ingots synthesized using quartz boats

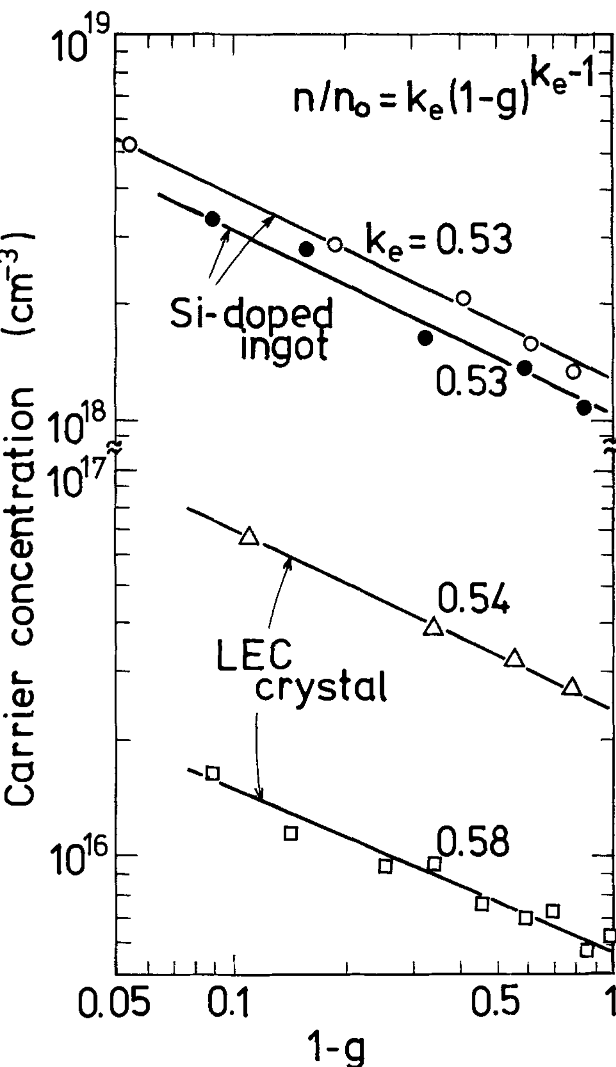

Fig. 7. Carrier concentration profiles for Si-doped ingots and for LEC crystals grown by using nominally undoped ingots. All curves obey the normal freezing relationship.

via the horizontal Bridgman technique. Silicon contamination levels were evaluated by measurements of carrier concentrations and by spark source mass spectrographic analyses. Good agreements between carrier concentrations and Si contents were obtained. Dependences of the Si contamination level on the synthesis conditions such as maximum temperature in the indium melt, phosphorus pressure in the ampul, and prebaking temperature of the charged indium were investigated. Among these conditions, maximum temperature in the indium melt was found to be the most dominant factor. Silicon contamination levels scarcely depended on phosphorus pressure in the range of 5-30 atm, while they decreased at lower phosphorus pressure than about 5 atm with decreasing phosphorus pressure. With increasing prebaking temperature of the charged indium, Si contamination levels were increased. This result is explained by taking into account the fact that indium oxides in the charged indium, which suppress the reaction for Si contamination, are eliminated through the prebaking process.

As a result of the investigations described above, it has been enabled to prepare high purity InP ($N_d - N_a = 3.2 \times 10^{15}$ cm^{-3}, $\mu_{77K} = 37{,}000$ cm^2/V · sec) at a growth rate of 3 mm/hr even if quartz boats are used.

To examine the segregation behavior of Si in InP, we also prepared intentionally Si-doped ingots in which Si contamination levels were neglected as compared with Si doping levels. Carrier concentration profiles for these ingots along the growth direction obeyed the normal freezing relationship and, consequently, gave the effective distribution coefficient for Si in InP, $k_e(\text{Si}) = 0.53$. Carrier concentration profiles for LEC single crystals grown by using nominally undoped ingots contaminated by Si also obeyed the normal freezing relationship and had a same slope as that for the Si-doped ingots. This result indicates that carrier concentrations in the LEC crystals are dominated by Si contents involved in the starting materials.

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Spectroscopic ellipsometry has been used to nondestructively study the optical and interface properties of the GaAs-electrochemically grown anodic oxide system over the energy range 1.5-6.0 eV. Values of the dielectric function of GaAs differ by up to 30% from previously published spectra due to improved sample preparation techniques. Values of the dielectric function of the oxide agree within several percent with previous measurements. Upper limits to the thickness of a layer modeled as amorphous arsenic (a-As) at the GaAs-oxide interface are 3 and 10Å for 60 and 75V oxides grown on <111>B and <100> surfaces, respectively, at 0.1 mA cm^{-2} constant current in a phosphoric acid/glycol based electrolyte. The major discrepancy between measurements and ideal three-phase model calculations arise from the interface region between oxide and ambient. This region shows a total distributed density deficit equivalent to 10Å lost material, probably due to leaching of As_2O_3. A complete description of the optical properties of the oxide requires a small absorptive component in the nominally transparent energy range below 4.5 eV. This absorptive component is equivalent to 0.2% and 0.9% by volume of a-As for the 60 and 75V oxides, respectively. The infrared refractive indexes for the two oxides, calculated from a Sellmeier dispersion relation with the absorptive component removed, are 1.777 and 1.717, respectively.

Intrinsic advantages of GaAs as a material for high-speed electronic devices have stimulated widespread research to develop a passivating oxide by thermal, plasma, and electrochemical anodization techniques. However, the composition, uniformity, and interface properties of native oxides on GaAs all depend rather strongly on the method by which the oxides are prepared. Thermally grown oxides consist almost entirely of Ga_2O_3 owing to the volatility of As and As_2O_3 at typical growth temperatures (1-4). Plasma-grown oxides are primarily mixtures of Ga_2O_3 and As_2O_3, but show accumulations of elemental As in both bulk and interface regions (3, 5-9). Although bulk uniformity and interface widths in electrochemically grown anodic oxides also depend on electrolyte and anodization conditions (10-12), recently reported Raman studies of thermal (13), plasma (14), and electrochemical (14) grown oxide films on GaAs indicate that the elemental arsenic content of the as-grown electrochemically formed oxides can be suppressed for low current density growth. A second feature associated with lowering the current density, and consistent with the Raman scattering results, appears to be a decrease in the width of the oxide-substrate interface region for electrochemically grown anodic oxides (12).

Preliminary reductions of complex reflectance ratio ($\tan\psi$, $\cos\Delta$) spectra that we measured for electrochemically grown anodic oxides supported the above conclusions, and indicated that nonuniformity and interface effects could be as much as an order of magnitude smaller than those observed in our previous work on films produced by rf-plasma (8, 9) and constant-voltage electrochemical (15) anodization methods. This suggested that more accurate values of the intrinsic dielectric response of anodic oxide films could be obtained. These data not only would be of interest in their own right, but also would serve as input data for determining more accurately from their dielectric response the composition, density, interface, and other microstructural parameters of other native oxides grown by different techniques. Moreover, since our previous investigations (15), methods using automatic spectroscopic ellipsometers have been developed (16, 17) for assessing the effectiveness of chemical stripping and cleaning procedures in real time, allowing dielectric function data that are more accurate than previously published spectra (18) to be obtained for the GaAs substrate material. Because these substrate data are used to determine interface and oxide parameters, more accurate analysis is made possible. Finally, we wished to establish new limits to the widths and possible compositions of the interface regions of the electrochemically grown oxides, taking advantage of the sensitivity of spectroscopic ellipsometry to these parameters (7-9, 19).

Since dielectric dispersion data are not available for both Ga_2O_3 and As_2O_3, we found it necessary to generalize the procedure that was previously developed for interface analysis with spectroscopic ellipsometry as it was applied to the thermally grown oxide on Si (20). This was done by using a Sellmeier representation to separate the slowly varying intrinsic dielectric response of the oxide from the more rapidly varying interface-related residual interference oscillations that appear in an approximate three-phase model solution. Thus both oxide and interface parameters could be obtained. This more general approach should also be useful for other oxide systems which can only be obtained in thin film form and for which bulk analytic dispersion expressions have not or cannot be determined.

Experimental

In this work, we analyze in detail two oxide films grown under 0.1 mA cm^{-2} constant current conditions in a phosphoric acid/glycol-based [AGW (21)] electrolyte. The substrates used were n-type GaAs single crystals with carrier concentrations 2×10^{16} cm^{-3} and $\sim 1 \times 10^{18}$ cm^{-3}. The surface orientation of the lightly doped sample was <111>B and that of the heavily doped sample was <100>. Surfaces were prepared by chemomechanical etch-polishing in bromine-methanol solutions. Surface quality was checked by measuring pseudo-(apparent) dielectric function spectra of chemically etched samples prior to anodization. Anodization was performed under white-light illumination to flood the space-charge region with carriers and eliminate any doping dependence of the anodization process. Final oxide thicknesses were $\sim$1200 and

* Electrochemical Society Active Member.

Key words: ellipsometry, dielectrics, interface.

~1500Å corresponding to limiting potentials of 60 and 75V for the lightly and heavily doped samples, respectively.

Optical data were obtained from 1.5 to 6.0 eV with an automatic spectroscopic ellipsometer described in detail elsewhere (22). The angle of incidence was 67.08°. The data were corrected for the optical activity of the quartz Rochon polarizers (23). Anodized samples were rinsed with methanol prior to measurement. Substrate spectra were obtained after chemically stripping the anodic films in a 1:1 mixture of HCl/methanol. This procedure yielded the highest ϵ_2 value [cleanest, least disordered, and/or microscopically smoothest surface (17)] at the 4.75 eV E_2 peak for these substrates. The peak ϵ_2 values after anodizing and stripping were ~0.5 higher than the corresponding values before anodizing, indicating that the anodizing/stripping sequence was improving surface quality (24). To minimize oxidation and contaminant adsorption effects, all chemical processing steps were performed with the samples already aligned in the ellipsometer and enclosed in a dry N_2 atmosphere in a windowless cell. Tanψ, cosΔ, and pseudodielectric function spectra were obtained for the anodized and nominally bare stripped samples, respectively.

Optical Analysis

The basic procedure for determining interface properties from spectroscopic ellipsometric data was developed initially for application to the Si-SiO_2 system and is discussed in detail elsewhere (8, 20, 25). Briefly, in the previous work dielectric function data for crystalline Si, fused quartz, and various possible interface materials were used to calculate in an n-phase laminar model tanψ, cosΔ spectra from 1.5 to 5.8 eV in terms of three frequency-independent free parameters, d_{ox}, f_v, and d_{int}. These free parameters represented the thickness and void fraction (density deficit) of the oxide and the thickness of the interface region, respectively. The calculated spectra were then compared to the measured spectra, with the best-fit values of the free parameters and the residual mean square deviation being determined systematically and objectively by linear regression analysis (LRA) (26). The LRA analysis also provided correlation coefficients and 90% confidence limits to show whether the data were in fact determining the parameters in addition to showing how well the models were fitting the data.

For the Si-SiO_2 system, the method was based on the existence of an accurate analytic Sellmeier expression for the dielectric response of fused quartz (27), which was used with the density deficit parameter f_v to represent the dielectric response of the SiO_2 overlayers. Although Sellmeier expressions have been given for GaAs oxide films (28, 29), the known sensitivity of oxide properties to preparation method suggests that a better approach in the absence of accurate bulk data would be to determine the Sellmeier coefficients themselves in the data reduction process. This is the procedure that we develop here.

Why should a Sellmeier representation by necessary? In principle, the dielectric response of the oxide can be obtained directly by solving the three-phase (substrate, oxide, ambient) laminar model given the tanψ, cosΔ spectra and the dielectric functions of substrate and ambient. For example, the measured tanψ, cosΔ spectra of the 60V AGW oxide on the <111>B GaAs substrate shown in Fig. 1 and the approximate bulk dielectric response of this substrate shown in Fig. 2 can be used in the ideal three-phase model to calculate the approximate dielectric function of the oxide as shown in Fig. 3. Here, the thickness d_{ox} = 1203Å was chosen to make ϵ_2 "zero" in the transparency region below 4.5 eV. These results are calculated without regard to interface effects because the three-phase model supposes mathematically sharp boundaries.

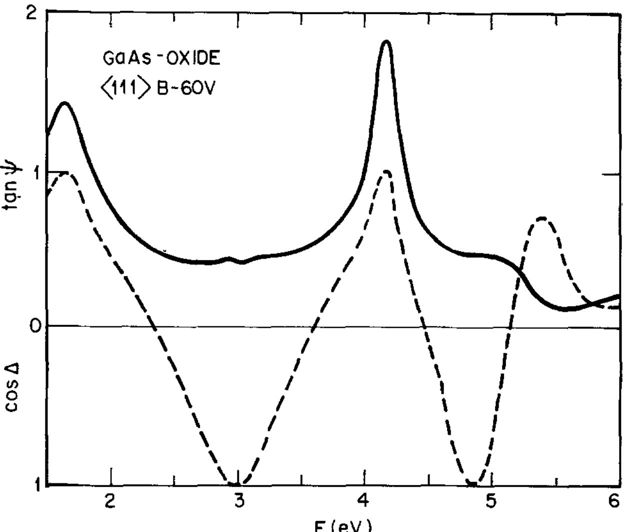

Fig. 1. tanψ, cosΔ spectra for a <111>B GaAs sample electrochemically anodized to 60V.

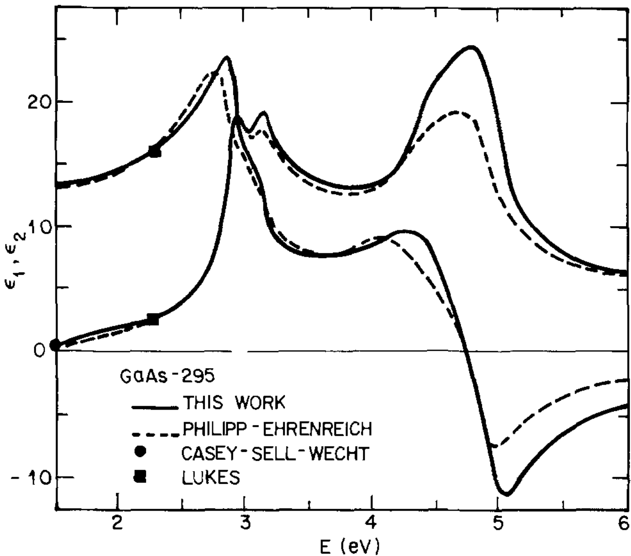

Fig. 2. Ellipsometrically determined dielectric response of the GaAs substrate for the sample of Fig. 1. Also shown for comparison are previous spectra [after Ref. (18)] and single-wavelength results [after Ref. (34) and (35)].

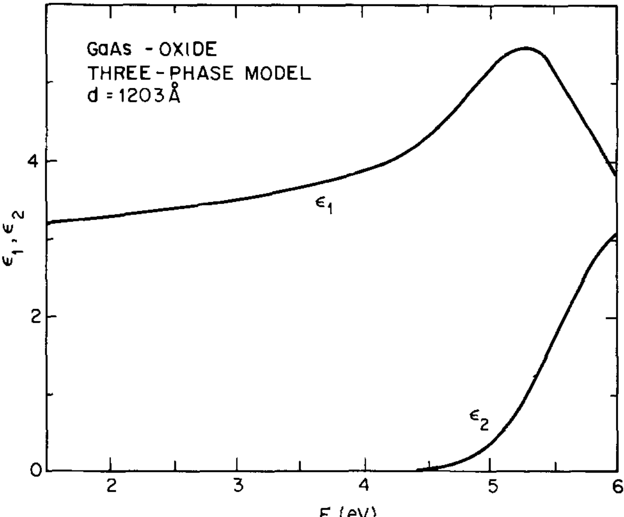

Fig. 3. Approximate dielectric response of a <111>B-60V anodic oxide calculated in the three-phase model from the data of Fig. 1 and 2.

In fact, ϵ_2 is not zero but rather exhibits small oscillations about a slowly varying background. This can be seen clearly in Fig. 4, which shows the ϵ_2 results of Fig. 3 on an expanded scale. The period of the oscillations follows the thickness (compare 60V <111>B and 75V <100> oxide calculations), which shows that they are not part of the intrinsic response of the oxide. Rather, they appear because the three-phase model, with its mathematically sharp boundaries, does not fully describe this system. As previously discussed (8), these oscillations arise from the growth and collapse of s- and p-polarized standing waves within the oxide as the wavelength is scanned. The standing waves modify the field strengths at the film boundaries and consequently the sensitivity to the interface regions. They therefore carry the information desired about the interface regions. Qualitatively, Fig. 4 appears to show that the interface regions of the 60V <111>B AGW oxide are narrower than those of the 75V <100> oxide, but not so narrow as those of the Si-SiO_2 system (20) whose data are also shown for comparison. In fact, we shall show that the major source of the oscillations for the GaAs-oxide system is the oxide-ambient interface region, and that the GaAs-AGW oxide interface region is actually narrower than that between Si and its thermally grown oxide.

To analyze these data for the properties of the interface regions, it is clear that these oscillations must be separated from the slowly varying intrinsic dielectric response of the oxide. Because the oscillations are very small for the 60V oxide, of the order of 1% of $|\epsilon|$, the three-phase-model solution is already a fairly good approximation to the intrinsic response. Accordingly, for simplicity we first use LRA to fit a Sellmeier function to the three-phase solution for ϵ_1 in the region of transparency below 4.5 eV and therefore average out the oscillations that contain the interface information. ϵ_2 in the same region is simply set equal to zero. These analytic expressions are now used as the initial approximation to the oxide response.

A complete description of the oxide film (excluding interface regions) can now be accomplished over the region of transparency with the Sellmeier expression and three frequency-independent free parameters representing, respectively, the oxide thickness, d_{ox}, a volume void fraction or distributed density deficit, f_v, and a volume fraction of optically absorbing material, f_a. The total dielectric response of the oxide film can then be calculated by effective-medium theory (30) using these parameters, the Sellmeier expression for the approximate "intrinsic" response of the oxide, $\epsilon = 1 + i0$ for the voids, and a suitable representation for the dielectric response of the optically absorbing component. Based on available data for this system, we choose the latter to be given by that of amorphous arsenic (a-As) (31), in which case $f_a = f_{a-As}$.

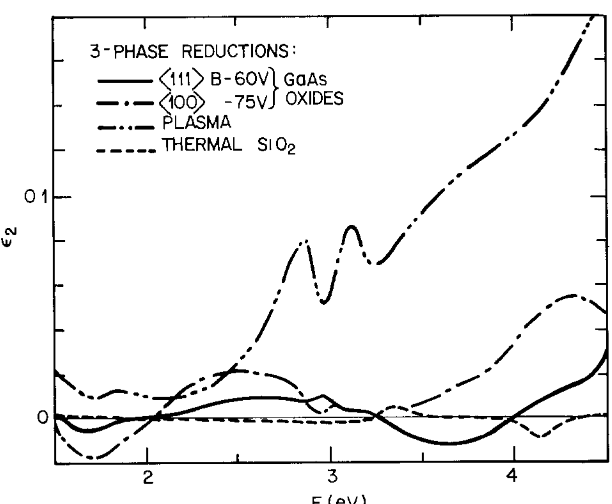

Fig. 4. Energy dependence of ϵ_2 on an expanded scale for selected oxide films in the region of transparency of oxides on GaAs.

The reason for treating an optically absorbing component as an extrinsic feature can be understood by examining the absorptive tails in ϵ_2 in Fig. 4. These differ in all three cases, which shows that optical absorption is clearly not part of the intrinsic response of the oxide. The justification for f_v is less obvious. It concerns the boundary condition that d_{ox} shall be chosen so ϵ_2 is "zero" in the transparency region. This condition obviously cannot be satisfied over the entire transparency range because of the small interface oscillations. Model calculations quickly show that these oscillations may average about zero, or above zero, or below zero depending on interface compositions and widths. The requirement that ϵ_2 oscillate about zero is a fact completely arbitrary, and to make it imposes unintended constraints on the solution.

Now because the optical thickness $n_{ox}d_{ox} = \sqrt{e_{ox}}d_{ox}$ is the fundamental parameter describing interference effects in a thin transparent film, it is clear that changing d_{ox} to properly position ϵ_2 with respect to zero will also affect ϵ_1 since the energy at which interference structures occur is also fixed by the properties of the film. Thus ϵ_1 must be decoupled from d_{ox}. This is the purpose of f_v, which acts essentially as a simple scaling parameter, but one which also describes the amount of polarizable material per unit volume in the film. By incorporating f_v into the model we have generalized the boundary condition to the simple requirement that the interface oscillations shall vanish in the correct laminar model solution for the oxide properties. We re-emphasize that the use of an intermediate Sellmeier representation with corrections as outlined above is legitimate because the GaAs-AGW oxide system is already well approximated by the three-phase model, and that the interface corrections are very small.

Results

Dielectric function of GaAs.—The dielectric function that we consider to be most representative of the bulk dielectric response of the 2×10^{16} cm^{-3}, <111> B-oriented n-type substrate used for the 60V anodization, and therefore that most appropriate for interface analysis, is shown in Fig. 2. This was obtained by *in situ* stripping of the AGW oxide with 1:1 HCl/methanol solution. The peak value observed for ϵ_2 was 23.89 at 4.75 eV. To obtain a better estimate of the intrinsic dielectric response of the substrate in the absence of etching-induced surface disorder, an additional 2Å of a-GaAs (32) was removed mathematically, bringing the ϵ_2 peak to 24.34. A direct experimental proof of the existence of such a disordered layer is not possible, but its presence can be inferred from similar measurements on Ge (33) and because the "bare substrate" dielectric function so obtained gave a somewhat lower residual in the interface analysis.

Whether the dielectric function obtained here accurately represents the intrinsic dielectric response of pure single crystal GaAs is a separate question and one more difficult to assess, but we believe that the ϵ spectra in Fig. 2 do so to within 5%. Bromine-methanol polished and anodized <111>B samples could be stripped with HCl/methanol, HCl/H_2O, or NH_4OH/H_2O solutions and consistently produced peak ϵ_2 values in the 23.0-23.9 range. By the "biggest-is-best" criterion (16, 17) the spectra corresponding to the largest peak value is the best approximation to the true response. Differences may represent surface roughness on a microscopic scale; the highest ϵ_2 values were generally observed by stripping once, with repeated treatments usually resulting in a gradual decline. This history-dependent sample behavior shows that in general the dielectric function spectrum actually used for analysis of very thin interfaces must be that measured on the

stripped sample itself, and not taken from a different sample or from the literature.

Also shown for comparison in Fig. 2 are the previous best spectra for GaAs, obtained from a Kramers-Kronig transform of reflectance data measured over the range 1-27 eV (18). The differences in energy positions of the structures are probably due to the fact that the ellipsometric data were obtained with a 17 meV energy spacing, approximately one-third that of the reflectance data. Consequently, the ellipsometric data were able to follow the intrinsic GaAs structure more faithfully. The substantial discrepancy in absolute values is almost certainly due to the presence of natural oxide or contamination layers on the reflectance samples, which could not be stripped *in situ* as were the ellipsometric samples.

Other single-wavelength values also shown in Fig. 2 are those of Casey *et al.* (34) who found $\alpha = 1.6 \times 10^4$ cm^{-1} at 1.5 eV compared to our value of 1.5×10^4 cm^{-1}, and Lukes (35), who obtained $\epsilon = (16.11 \pm 0.08) + (i2.41 \pm 0.40)$ at 5461Å (2.27 eV), compared to our value $16.13 + i2.80$. The agreement is satisfactory. We add that the ϵ_1 and ϵ_2 spectra obtained here were Kramers-Kronig consistent to better than 0.5%.

Approximate dielectric function of GaAs oxide.—The substrate dielectric function described above was used in the three-phase model to obtain the approximate dielectric response shown in Fig. 3. We now fit a four-term Sellmeier dispersion curve of standard form

$$\epsilon_1(E) = 1 + \sum_{i=1}^{4} \frac{E_{gi}E_{oi}}{E_{gi}^2 - E^2} \quad [1]$$

to these data over the region of transparency. Two of the values E_{gi} are fixed by the known energies of the centroids of the lattice transitions at $E \cong 600\ cm^{-1} = 0.075$ eV (28, 36) and the ultraviolet bonding-antibonding transitions at $E \cong 16$ eV (37).

The value of E_{01} that pertains to lattice absorption follows immediately from E_{g1} and the difference between the infrared dielectric constant [$\epsilon_\infty \sim 3.20$ (28)] and the 1 kHz dielectric constant ($\epsilon_0 \sim 8.2$) (38), that is, $E_{01} \cong 0.35$ eV. This presumes a contribution no greater than a few percent from water contained within the as-grown oxide, as seems reasonable from infrared absorption measurements on similar oxides (28), although the assumption is noncritical because this term has very little effect in the visible-near u.v. spectral range. Because the dispersion representation must describe near-edge absorption, Fig. 3 shows that 5.5 eV is a natural choice for E_{g2}. E_{g3} is essentially arbitrary, but a value of 7.5 eV will adequately describe midrange absorption.

The remaining three parameters are the amplitudes E_{02}, E_{03}, and E_{04}. We determine them by fitting Eq. [1] by LRA to the real part of ϵ_1 in Fig. 3 from 1.5 to 4.8 eV, obtaining 1.62 ± 0.27 eV, 5.5 ± 1.9 eV, and 18.8 ± 3.7 eV, respectively. The large uncertainties in E_{03} and E_{04} do not result from a poor fit, but rather originate because the third and fourth oscillators are highly correlated ($C_{34} = -0.994$). Since these values simply define a starting point for interface analysis, we shall

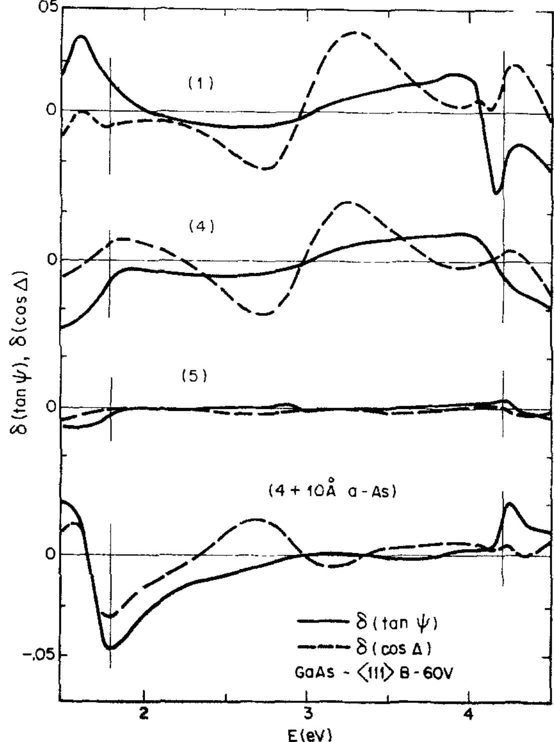

Fig. 5. Spectral dependences of discrepancies between experimental and theoretical spectra for various models for the <111> B-60V AGW oxide on GaAs: (top) 1-parameter model, using the Sellmeier oxide thickness as the single free parameter; (upper middle) 4-parameter model including an a-As interface, voids, and a-As in the oxide; (lower middle) as above, but including a density-deficient outer region; (lower) as above but with 10Å of a-As assumed at the GaAs-oxide interface.

defer a discussion about the fitted values until the section "Intrinsic oxide response."

Interface analysis.—Wavelength-dependent discrepancies between the $\tan\psi$, $\cos\Delta$ data of Fig. 1 and the predictions of selected models are shown for the electrochemically grown 60V anodic oxide in Fig. 5. Model parameters for this oxide are listed in Table I.

The simplest model assumes that the Sellmeier expression derived in the preceding section is directly applicable and that there are no interfaces. Then the only free parameter is the oxide thickness, d_{ox}. This is determined by LRA to be 1197.5 ± 0.5Å with a residual 0.020 as summarized in Table I. The actual fitting was done over the range 1.8-4.2 eV to eliminate the effects of experimental artifacts at the low-intensity long-wavelength limit of the ellipsometer, and to eliminate intrinsic oxide absorption at higher energies which is not included in the Sellmeier model. The range is indicated by the vertical lines in Fig. 5. Neither $\tan\psi$ nor $\cos\Delta$ has its wavelength dependence predicted very accurately, but this is not surprising since interface effects are completely neglected. The result essentially establishes a point of reference from which to judge more elaborate models. It should be noted

Table I. Values of free parameters, 90% confidence limits, and residuals for models of an anodic oxide electrochemically grown to 60V on a <111>B GaAs substrate with $N_0 \sim 2 \times 10^{16}\ cm^{-3}$

that the maximum excursion in $\delta(\tan\psi)$ is only 2% of the peak value in Fig. 1, re-emphasizing our earlier point that the three-phase model is already a very good approximation by the usual standards applied to ellipsometric data.

As the model is made more general by allowing a density change and an absorptive fraction in the oxide, very little improvement occurs as shown in Table I. Virtually no change occurs upon introducing the void fraction f_v, but that is expected because the initial solution from which the Sellmeier coefficients were determined had already set a zero-order density scale. A 25% reduction in the residual occurs when an absorptive component is allowed through a volume void fraction, f_{a-As}, of amorphous arsenic.

We now investigate the effect of interfaces. Since elemental arsenic is known or anticipated to be at the substrate-oxide interface from previous studies, we suppose an interface layer of a-As and determine its thickness by LRA. The results are shown in Table I and at the bottom of Fig. 5. The results show quite definitely that no a-As appears at the interface of this electrochemically grown anodic oxide. In fact, even with three additional free parameters with respect to the original three-phase model we have only succeeded in reducing the residual by 25%, with nearly all of that coming through the assumption of an absorbing fraction in the bulk oxide. Thus the main source of discrepancy between measurement and model must be due to yet another effect.

The small value of interface thickness makes it clear that the calculation has already been optimized with respect to the GaAs-oxide interface, and simply substituting other possible interface materials such as a-GaAs or mixtures of a-As with the oxide will not reduce the discrepancy between theory and experiment. We are thus led to look elsewhere for the cause of the remaining discrepancy.

Noting that radioactive tracer (10), photoemission (39, 40), and ISS (12) studies have all shown As_2O_3 depletion at the oxide-electrolyte interface for anodizations in glycol-based electrolytes, we are led to suppose a density-deficient outer layer at the oxide surface. We therefore generalize the model to include an exterior interface region by allowing an additional density deficit in the outer region of the oxide and using the thickness of this region as a fifth free parameter in an LRA analysis. The results assuming a 15% density-deficient outer layer are shown in Fig. 5 and Table I. The assumption of a density-deficient outer layer results in a sevenfold decrease in the residual and thus accomplishes what the preceding three free parameters could not, *i.e.*, the virtual elimination of discrepancies between the experimental measurement and the $\tan\psi$, $\cos\Delta$ spectra. Furthermore, the discrepancies are essentially eliminated not only over the fitted region but also over the end regions as well. Thus the greatest single source of the discrepancy between the actual GaAs-oxide system and the ideal three-phase model does not occur at the GaAs-oxide interface, but rather at the oxide-ambient interface. The GaAs-oxide interface for electrochemically grown anodic oxides is in fact exceedingly sharp.

To emphasize that the sensitivity to the GaAs-oxide interface region is indeed real, we have calculated the result of minimizing the remaining four parameters in LRA supposing that 10Å of a-As exists at the GaAs-oxide interface. As shown in Fig. 5 and Table I, this artificially imposed condition results in a residual that is larger than that calculated in the initial three-phase model solution, and the good agreement between measured and calculated $\tan\psi$, $\cos\Delta$ spectra is eliminated. We may conclude that 10Å of a-As or its equivalent, as for example an interface 40Å wide consisting of 25 volume percent (v/o) a-As, would be easily detected. Clearly, the statistically negligible thickness of the interface, 0.3 ± 0.3Å, makes meaningless the question of its composition. The point can be emphasized by noting that the residual increases only by 0.00003 if the GaAs-oxide interface region is eliminated from the model entirely.

We have also investigated the effect of changing the void fraction of the outer interface. As can be seen from Table I, the data do not discriminate among density deficits in the 10-25 v/o range. However, all solutions converge on an effective density deficit of 10Å. Our measurements cannot distinguish whether this represents a nonstoichiometry resulting from surface leaching or microscopic roughness. As mentioned above, however, this result is entirely consistent with previous observations of As_2O_3 depletion in the outer film surface of these systems (10, 12, 39, 40). Because the actual depletion depth is sensitive to details of the electrolyte pH, current density, and maximum applied voltage, a further detailed comparison with previous results is not warranted.

The results of a similar analysis for the 75V anodic oxide electrochemically grown on the <100> surface are given in Table II. From Fig. 4, it can be anticipated that a larger absorbing fraction will be necessary to describe this oxide. As expected, the fraction is about four times larger and nearly equivalent to 1 v/o of a-As. The absorbing component of the bulk oxide now represents the single most significant factor in reducing the residual.

Once again, a full five-parameter LRA shows "no" GaAs-oxide interface region to within statistical uncertainty, although the solution is sufficiently indeterminate to allow a few Å to be present. However, the presence of an oxide-ambient interface region very similar to that detected on the 60V oxide is unambiguous. It is interesting to note that the density of the <100>-75V oxide is significantly less than that of the <111>B-60V oxide, indicating that oxide properties may be rather critically dependent on growth and substrate parameters.

Intrinsic oxide response.—The intermediate four-term Sellmeier oscillator representation of the oxides obtained in the three-phase model can now be replaced with expressions representing more accurately the intrinsic dielectric response of these oxides. We retain the characteristic oscillator energies, E_{gi}, and the amplitude, $E_{01} = 0.35$ eV, of the lowest oscillator and determine the remaining three amplitudes by an LRA fit to the dielectric function calculated in the effective-medium approximation from the intermediate representation and the void and a-As fractions calculated in the previous section. Values are given in Table III with and without the a-As contribution, although only

Table II. As Table I, but for an anodic oxide grown to 75V on a <100> GaAs substrate with $N_D \sim 10^{18}$ cm^{-3}

Model	Inner interface		Oxide				Outer interface	Residual
	Composition	d (Å)	$10^3 f_{a-As}$	$10^3 f_v$	d (Å)	Compositional	d (Å)	$10^3 \delta$
(1)	—	—	—	—	1439.6 ± 0.8	—	—	36.8
(2)	—	—	—	−7.4 ± 5.7	1432.6 ± 5.5	—	—	34.5
(3)	—	—	8.2 ± 1.1	91 ± 14	1518.0 ± 12.7	—	—	17.1
(4)	a-As	4.3 ± 3.6	9.1 ± 1.3	91 ± 12	1515.9 ± 11.2	—	—	16.3

(6)	a-As	3.4 ± 3.3	8.8 ± 1.5	87 ± 15	1492 ± 19.5	25% void	26.7 ± 14.1	14.6
(7)	a-As	13.4 fixed	11.0 ± 1.4	82 ± 17	1445.6 ± 38	15% void	65 ± 34	18.2

Table III. Sellmeier oscillator energies for electrochemically grown anodic oxides on GaAs

	E_{gi}	60V with a-As	60V without a-As	75V with a-As	75V without a-As
E_{01}	0.075 eV	0.35 eV	0.35 eV	0.35 eV	0.35 eV
E_{02}	5.5	1.56	1.59	1.28	1.42
E_{03}	7.5	5.48	5.35	5.35	4.75
E_{04}	16.0	18.51	18.46	16.98	16.93
n_∞	—	1.781	1.777	1.734	1.717

the latter have meaning with respect to the intrinsic dielectric response of the oxide. Values of the infrared refractive index calculated from these results are also given.

Not surprisingly, a-As has its greatest effect on the lower-energy oscillators because its oscillator strength is greatest there. The reduction in amplitude of all oscillators, except that of the fixed term, E_{01}, is about 10% indicating a common dispersion characteristic (similar composition) for both, with basically a density difference responsible for the difference in dielectric response.

Discussion

The initial Sellmeier representation, together with the void and effective a-As volume fractions, define the wavelength-dependent dielectric response of these oxides over the region of transparency. The results for the 60 and 75V oxides of Tables I and II are shown in Fig. 6. The real and imaginary parts of the refractive index calculated from these spectra are shown in Fig. 7 along with selected results from the literature (28, 29, 36, 41-45) where with one exception (41) the effects of interfaces were neglected.

Figure 7 shows general agreement among refractive index values for as-grown oxides formed in glycol-based electrolytes. Specifically, our 60 and 75V spectra, those of Palik et. al. (28), and the single-wavelength datum of Umeno (36) are reasonably close. Data from Dinges (41) represent AGW oxides heat-treated in hydrogen for 1 hr at 300°C and have a slightly higher index. Choosing 5461Å = 2.27 eV as a common point, it is clear that the scatter is of the order of ± 0.03 units in n. This scatter may reflect differences in density as modeled here, but it could also represent small differences in the bulk film stoichiometry which arise from selective dissolution of one component in the electrolyte during growth. One should note that this latter feature is both current density and electrolyte

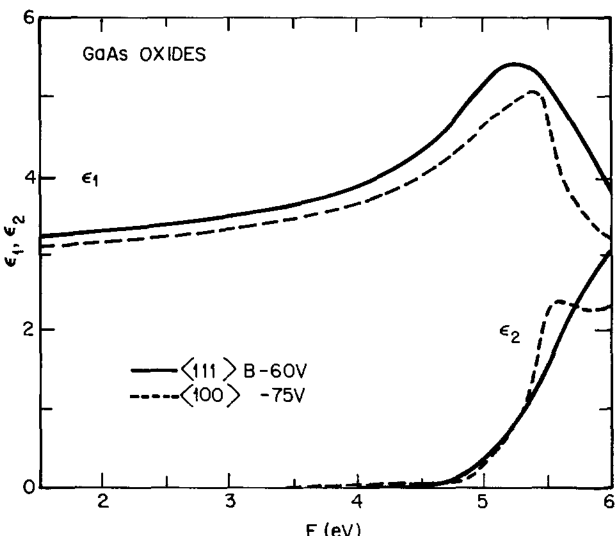

Fig. 6. Intrinsic dielectric functions for <111>B-60V and <100>-75V electrochemically grown anodic oxides deduced from the analysis of the section "Optical Analysis."

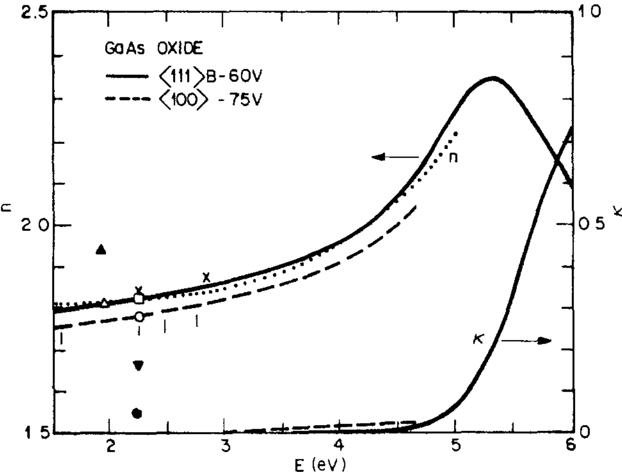

Fig. 7. As Fig. 6, but for refractive indexes. Selected data points and spectra are shown for comparison: AGW, as-grown: (. . . .) Palik *et al.*, Ref. (28); (△) Umeno *et al.* Ref. (36). AGW, heat-treated: (||||) Barnes and Schinke, Ref. (29); (▲) Umeno *et al.*, Ref. (36) (×) Dinges, Ref. (41). Aqueous anodization: (□) Dell'Oca *et al.*, Ref. (42). Oxygen plasma: (○) Weinreich, Ref. (43). Thermal: (▼) Löschke, *et al.*, Ref. (44); (●) Navratil, Ref. (45).

dependent, making it difficult to compare these oxides directly. Oxides produced in nonglycol-based electrolytes show similar scatter; our previous results (15) on samples heat-treated 2 hr at 200°C are essentially identical to our 60V AGW data (and are not shown for that reason), while the Barnes-Schinke data (29) are systematically lower. The single datum of Dell'Oca *et al.* (42) coincides with our 60V AGW result, while the oxygen plasma-grown value of Weinreich (43) coincides with our 75V AGW result.

Similar scatter also appears in the infrared refractive index evaluated from the Sellmeier dispersion expressions. The values of Palik *et al.* (28) and of Barnes and Schinke (29), 1.79 and 1.707, respectively, can be compared with our values including a-As in Table III, which are 1.78 and 1.73 for the <111>B-60V and <100>-75V oxides, respectively.

The measurement presented in Fig. 7 suggests that the index rises slightly by heat-treating in the 200°-300°C range, although it should be noted that Barnes and Schinke (29) reported a reduction in refractive index on five films heat-treated in N_2 at 250°C. We associate the general increase with heat-treating observed in most refractive index data with water removal and a slight densification. Ishii and Jepson (46) have studied the thermally induced desorption of products mass spectrometrically and observe that water is the primary species evolved below 300°C.

Heat-treatments above 300°C subject the film components to a variety of chemical reactions dependent on the nature of the ambient. In an inert atmosphere, the primary reactions involve the direct volatilization of As_2O_3 into the ambient and the reaction of As_2O_3 with the substrate according to the equation

$$As_2O_3 + 2GaAs \rightarrow Ga_2O_3 + 4As \quad [2]$$

The latter reaction has been verified experimentally using Raman scattering (47, 48) and explained thermodynamically based on a determination of the Ga-As-O phase diagram (49). Heat-treatments in reducing atmospheres (principally H_2) will reduce both oxides to their respective elemental forms starting at the oxide-ambient interface at sufficiently high temperatures; the interfacial reaction between As_2O_3 and GaAs will occur simultaneously at the substrate interface. The resulting oxide composition will be difficult to specify and will be dependent on the temperature and length of the heat-treatment. Heating at elevated temperatures in an oxidizing ambient (O_2 or air, typically)

produces similar changes as described for an inert ambient, but in addition the oxide-ambient surface region may contain some fraction of $GaAsO_4$ (50). The diversity of the oxide compositions resulting from the various heating procedures probably accounts for the contradictory nature of reported index of refraction data for films treated above 350°C.

An analysis of the separate Ga_2O_3 and As_2O_3 contents in these films is presently not feasible by spectroscopic ellipsometry due to lack of comprehensive dielectric response data on the structural forms of Ga_2O_3 and As_2O_3 likely to be found in these amorphous films. More definitive information on composition has generally been obtained from photoemission (11, 39, 50), RBS (46), ion-induced x-ray emission (51), ion scattering (12), radioactive tracer (10), and Auger profiling (3) studies. There is some variance in the literature concerning the As_2O_3/Ga_2O_3 ratio of the bulk films, but it should be kept in mind that selective dissolution into the electrolyte during growth coupled with the growth rate (current density) would need to be evaluated for each data set separately before a valid comparison could be made. In addition, ion profiling techniques are subject to selective sputtering during analysis and compensation for ion and electron beam reduction must also be induced. The generally observed trend for AGW oxides grown at current densities of ~1 mA/cm² yields a bulk oxide of ~1:1 ratio between As_2O_3 and Ga_2O_3.

In our opinion, the question of elemental arsenic content in these films is better addressed by the nondestructive optical techniques such as spectroscopic ellipsometry and Raman scattering than by either photoemission or Auger profiling. One does not have to contend with electron and ion beam reduction artifacts of As_2O_3 nor with background interferences close to the substrate which greatly complicate the separation of elemental arsenic and substrate signals. Comparison of our data with profiling data would also require, among other things, careful attention to the question of sample annealing, since it is now known (47-49) that As can be generated at the oxide-substrate interface even if it were not present in as-grown samples. The interface width obtained in spectroscopic ellipsometry is also not subject to sputtering rate, selective sputtering, and ion knock-on effects. The liability of spectroscopic ellipsometry is clearly that it requires either *a priori* knowledge of the disposition of oxide interfaces or considerable physical intuition before a viable model can be constructed.

Our data additionally allow us to draw some inferences about overall film homogeneity. Initial three-phase model analysis of the 60V AGW oxide yielded $|\epsilon_2| < 0.01$ (0.2% in $|\epsilon|$) in the region of film transparency. This represents roughly a factor of 5 improvement over previously analyzed oxides (15) grown in a dilute aqueous solution of orthophosphoric acid at high current densities. Moreover, the AGW oxides showed no ambiguities in the three-phase solutions above the oxide absorption edge. Such ambiguities result from a convergence of substrate and ambient branches of the mathematical solution as absorption in the film gradually closes off optical contact to the substrate. If the film is inhomogeneous so that the three-phase model solutions do not strictly apply, the result is a loss of continuity in the calculated spectra. This effect was observed previously (15) in anodic films and tends to be pronounced in d-c and rf plasma oxidized films [see, *e.g.*, Fig. 5 and 6 in Ref. (8)]. The AGW oxides studied here display comparable bulk uniformity with thermally grown SiO_2 layers on Si. If the refractive indexes for Ga_2O_3 and As_2O_3 are taken to be of order 1.5 and 2.0, respectively, then these anodic films are homogeneous over the bulk (excluding boundary interfaces) to better than 2%.

The inner and outer interfaces deserve some final comment. The density-deficient oxide-air interface has been mentioned previously; it is modeled here as a distributed density deficit equivalent to 10Å of material lost uniformly from a 60Å surface region. Available experimental results (10, 12, 39, 40) strongly suggest that the actual physical situation corresponds to nonuniform As_2O_3 depletion from a comparable region. With respect to the width and elemental arsenic content of the oxide-GaAs interface, our present measurements are at variance with numerous published Auger and photoemission profile studies. Once again we wish to stress the importance of accounting for the current density and any subsequent heat-treating steps before directly comparing data. The present measurements are in fact capable of much higher detection sensitivity than those of Raman scattering (48), another nondestructive analysis technique that failed to observe elemental As in as-grown films. The present results show essentially no (0.3 ± 0.3Å) accumulated arsenic at the oxide-GaAs interface in the 60V oxide, although we feel that due to the possibility of systematic errors an absolute upper limit of 3Å is more reasonable. In addition to this elemental arsenic at the oxide-substrate interface, the bulk oxide would contain ~0.2% or another 2-3Å of absorbing material. The oxide-substrate interface width is essentially nil for AGW oxides produced under optimal (typically $I \leqq 0.1$ mA/cm²) current density conditions. It is somewhat surprising to note that the present measurements indicate that oxide-GaAs interfaces can in fact be obtained with widths comparable to or less than those found in thermally oxidized $Si\text{-}SiO_2$ systems (20). This suggests that the high density of interface states typically observed in oxide-GaAs *C-V* studies may have its origin in parameters unrelated to or at least not dominated by interfacial sharpness.

Manuscript received Aug. 12, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by Bell Laboratories.

The Electromigration Directions of Liquid Au-Ag Alloy Droplets in Single Crystals of Si

T. R. Anthony

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

The electromigration directions and velocities of liquid Au-Ag alloy droplets in single crystals of Si were measured as a function of alloy composition at a temperature at which the electromigration velocities of Ag-Si and Au-Si liquid droplets are equal in magnitude, but opposite in direction. The electromigration null point composition of these ternary alloy droplets occurs at an alloy work function that roughly agrees with an electromigration-null-point work function previously determined with binary alloy droplets in Si.

Liquid metal droplets in a silicon single crystal through which a direct electric current is passing will migrate either towards the anode (+) or the cathode (−) (1-6). The motion of the liquid droplets is caused by a flux of dissolved silicon atoms across the inclusion, induced by the electric current passing through the liquid inclusion. To feed this flux of silicon atoms across the inclusion, silicon atoms dissolve into the inclusion at the forward face, while dissolved silicon atoms deposit on the rear face of the inclusion.

In the redeposited silicon trail left behind the electromigrating inclusion (Fig. 1), trace amounts of the metals comprising the droplet are left behind equal to the solid solubility limit of the metals in crystalline silicon. If one of the metals making up the inclusion is a donor or an acceptor element in silicon, then the redeposited silicon trail will be doped either n-type or p-type, respectively. By electromigration of an acceptor liquid metal droplet through n-type silicon or a donor liquid metal droplet through p-type silicon, p-n junctions can be formed in the silicon crystal. Because the electromigration velocities of liquid metal droplets are orders of magnitude greater than solid-state diffusion coefficients of the same metals, liquid droplet electromigration provides a means of forming p-n junctions all the way through silicon wafers in a manner of minutes instead of days.

Not all liquid metal droplets electromigrate in the same direction in silicon. As shown in Table I, a liquid

Key words: electromigration, alloy, crystals.

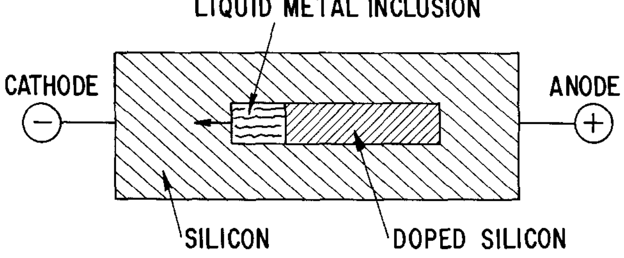

Fig. 1. A metal-rich liquid droplet electromigrating through a silicon single crystal toward the cathode. The redeposited silicon trail behind the electromigrating droplet contains the solid solubility limit in crystalline silicon of the metals comprising the inclusion.

Table I. The electromigration directions of nine liquid metal droplets in silicon and the work functions of these metals. The null-point work function for silicon is 4.55 eV. The work function of silicon is 4.85 eV. The electromigration directions are taken from Ref. (5) and the work functions from Ref. (8)

Element	Electromigration direction	Work function (eV)
Palladium	Anode (+)	5.12
Gold	Anode	5.10
Copper	Anode	4.65
Antimony	No electromigration	4.55
Tin	Cathode (−)	4.42
Aluminum	Cathode	4.28
Silver	Cathode	4.26
Gallium	Cathode	4.20
Indium	Cathode	4.12

droplet of a metal with a work function greater than 4.55 eV electromigrates toward the anode, while a liquid droplet of a metal with a work function less than 4.55 eV electromigrates toward the cathode (5, 6) in silicon.

To manufacture a particular semiconductor device, it may be desirable to have a liquid droplet that electromigrates toward the anode and that dopes the silicon p-type. From Table I, it is seen that all of the acceptor droplets (Al, Ga, and In) electromigrate toward the cathode. Hence, to obtain an inclusion that will both electromigrate toward the anode and dope the silicon p-type, an alloy inclusion must be formed of, say, Al and Pd in the right proportions.

In order to be able to obtain the correct inclusion composition in this and other cases, some information is required on the electromigration directions of inclusions composed of more than one metal. *A priori*, one would expect that the correlation of the work function of the metal comprising the droplet with the electromigration direction of the droplet found for the pure metals might carry over to droplets made up of more than one metal.

To test this hypothesis, the electromigration directions of droplets of Au-Ag alloys of varying compositions were measured. Au and Ag were selected for several reasons. First, both of these noble metals are chemically similar and have almost identical atomic radii. In addition, they form continuous solid and liquid solutions so that extraneous factors such as eutectic points, intermetallics, or liquid immiscibility do not complicate the study. Of particular importance to the investigation is the fact that inclusions of these two noble metals electromigrate in opposite directions: Au-Si droplets move toward the anode, while Ag-Si droplets move toward the cathode (5). Also, a temperature (880°C) can be selected where the absolute magnitudes of the oppositely directed velocities of Au and Ag droplets are equal (5) (Fig. 2). Finally, the work functions of Au-Ag alloys of varying compositions are available in the literature (7) so that a comparison of the electromigration direction of a particular alloy composition with its work function is possible.

Experimental

Sample preparation.—Rectangular samples 4 × 1 × 1 cm were cut from an n-type 10 Ω-cm Si ingot. The long dimension of the rectangular specimen was parallel to the <111> direction. The top and side faces were perpendicular, respectively, to the <1$\bar{1}$0> and the <11$\bar{2}$> directions. On the top (1$\bar{1}$0) face of the sample, thirteen holes were ultrasonically drilled halfway through the crystal (Fig. 3). One hole was 2 mm in diameter and served as the thermocouple cavity, while the other twelve holes were 0.75 mm in diameter and were used to hold Au-Ag alloy droplets of varying composition.

Eleven Au-Ag alloys of various compositions from 0 to 100% Au at 10% composition intervals (*i.e.*, 0%, 10%, 20%, etc.) were cut and weighed from 99.99% Au and Ag wires and melted under vacuum in sealed quartz tubes. During melting the sealed quartz ampuls were mechanically jostled to ensure complete homogeneous mixing of the Au and Ag. Following melting, the alloys were quenched in water. The cast alloys

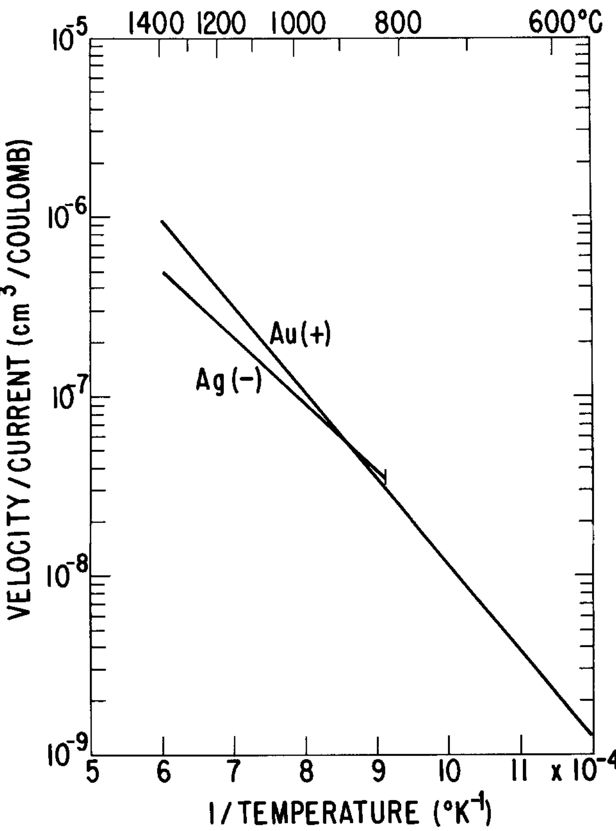

Fig. 2. The electromigration velocities of liquid droplets of Ag and Au in Si. In the temperature range of 880°-900°C, the electromigration velocities of Au and Ag-rich droplets are equal and opposite with Au migrating toward the anode (+) and Ag migrating toward the cathode (—).

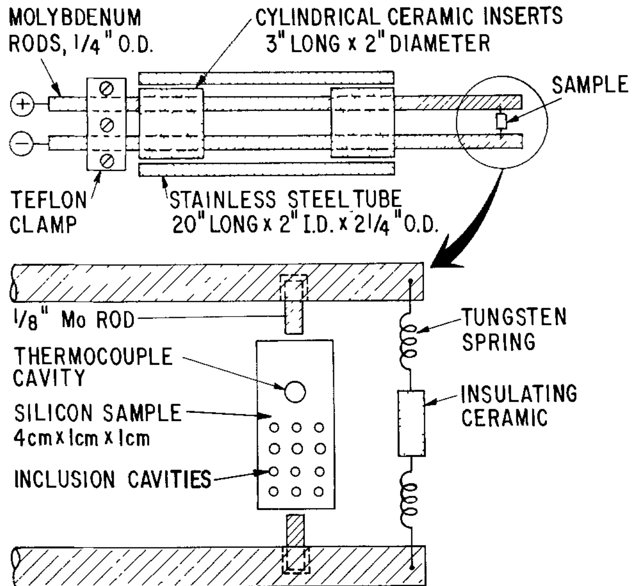

Fig. 3. The electrode jig used to pass current through the Si sample. The stainless steel tube is inserted part way into a diffusion furnace and current is passed through the Si sample in the furnace via the 1/4 in. molybdenum rods that extend outside of the furnace. The replaceable 1/8 in. molybdenom contact electrodes are pressed against the silicon sample throughout the electromigration experiment by the adjacent tungsten springs.

were hammered into thin sheets from which were cut small pieces that were inserted into the sample cavities in the silicon crystal (Fig. 3).

The silicon specimen with the eleven different alloy compositions in eleven separate sample cavities was placed in an annealing furnace with flowing H_2 at 1100°C for 3 hr to form the series of eleven Au-Ag liquid alloy droplets that would later be electromigrated. The silicon specimen was then cooled and removed from the annealing apparatus.

The electromigration apparatus.—The electromigration apparatus consisted of a diffusion furnace to attain the temperature of the electromigration run and an electrode jig, shown in Fig. 3, to apply current to the sample. One-eighth in. replaceable molybdenum electrodes were used as electrode contacts to the silicon sample. A tungsten spring provided contact pressure between the molybdenum electrodes and the Si sample during the high temperature electromigration experiments. A direct current of 15 A/cm² at a temperature of 884°C was used in the electromigration experiments. The temperature was selected so that the liquid inclusions of pure Ag and pure Au would have equal and opposite velocities (5). The current was produced by a Hewlett-Packard 6269B constant direct current power supply. A constant current supply was necessary, because the decrease in the resistivity of silicon with temperature would otherwise lead to an unstable situation. A voltage drop of 4.1V was required by the power supply to drive the 15 A/cm² current in the silicon specimen. Most of this voltage drop occurred at contact points in the circuit rather than in the specimen itself.

Measurement of Au-Ag electromigration directions.—Infrared transmission micrographs were taken of the pre-annealed silicon sample with a Research Devices (Elizabeth, New Jersey) infrared microscope. The silicon sample had been previously polished to a 1 μm finish and fiduciary lines had been scribed on the top surface of the sample with a diamond marker. These fiduciary lines were used as reference points to measure the movement of the alloy liquid droplets through the silicon.

The specimen was then placed in the electrode jig shown in Fig. 3 and inserted in a diffusion furnace. After temperature equilibration at 884°C, a constant direct current of 15 A/cm² was passed through the silicon sample for 24 hr. The temperature of the sample was continuously monitored during the experiment with a Chromel-Alumel thermocouple inserted in the thermocouple cavity (Fig. 3) of the specimen. A flow of a nonexplosive gas mixture of 95% N_2 + 5% H_2 was used to prevent oxidation of the electrode jig.

Following the electromigration anneal, the electrode jig was withdrawn from the furnace tube and allowed to cool. The Si sample was removed from the jig and infrared transmission micrographs were taken again of the Si sample to determine the movement of the eleven liquid Au-Ag alloy droplets through the silicon. Measurements of the inclusion displacements were made on the photomicrographs with respect to the diamond-scribed fiduciary lines on the surface of the sample. Care was taken to center each droplet in the middle of its respective photomicrograph to avoid parallax errors arising from the difference in depths between the droplets in the middle of the sample and the fiduciary lines on the surface of the sample.

Experimental Results

Figure 4 shows the electromigration velocities of eleven Au-Ag alloys *vs.* composition. The velocities are averages of several experiments. Ag-rich alloys electromigrated toward the cathode, while Au-rich alloys electromigrated toward the anode. The null-point crossover composition is approximately 79 atomic percent (a/o) Au-21 a/o Ag. Between 30-60 a/o Ag, the

droplet velocity is independent of composition with experimental error.

Discussion of the Electromigration Direction

In a previous paper, it was found that the electromigration directions of pure metals in silicon (5, 6) and germanium (11) show a strong correlation with the work functions (5) of the pure metals comprising the droplets. Table I shows that droplets of metals with work functions greater and less than 4.55 eV electromigrate, respectively, toward the anode and cathode in a silicon single crystal. In germanium crystals, liquid droplets of metals with work functions greater and less than 5.0 eV (the work function of Ge) electromigrate toward the anode and cathode, respectively, as shown in Table II.

A rationale for the relation between the work function of a metal and its electromigration direction as a liquid droplet in a host semiconductor crystal can be made qualitatively in terms of the electron-atom momentum exchange force that drives electromigration. [Electric field drift and Peltier-induced TGZM contribute less than a few percent of the observed electromigration velocities (2, 5, 6).] The work function of an element is a measure of the attraction between that element and an electron. That is, the larger is the work function, the greater will be the attraction. If two elements are mixed together, one would expect, as a first-order approximation, that some electron transfer would occur from the element with the small work function to the element with the large work function. Because the ion size of an element is a very sensitive function of

Table II. The work functions and electromigration directions of liquid metal droplets in germanium. The work function of germanium is 5.0 eV. The work functions are taken from Ref. (8) and the electromigration directions from Ref. (1)

Element	Electromigration direction	Work function (eV)
Platinum	Anode (+)	5.65
Nickel	Anode	5.15
Palladium	Anode	5.12
Gold	Anode	5.10
Tellurium	Cathode (−)	4.95
Copper	Cathode	4.65
Antimony	Cathode	4.55
Tin	Cathode	4.42
Aluminum	Cathode	4.28

Gallium	Cathode	4.20
Magnesium	Cathode	3.66

its valence state, the electron scattering cross section for an element losing electrons (the low work function element) would be expected to decrease, while the scattering cross section for the element gaining electrons would increase. These respective changes in electron scattering cross sections would be in the direction such that when the liquid alloy is subjected to a direct electric current, the electron wind would tend to preferentially blow the element with the larger work function toward the anode in accord with the experimental observations listed in Tables I and II.

A simple dilute solution theory using the difference in the work function of the metal comprising the droplet and an empirical null-point work function, as the driving force for electromigration, can be formulated as follows.

At the rear interface of the electromigrating droplet, conservation of mass requires that the flux J of silicon atoms impinging on the rear interface equal the velocity V of the inclusion times the difference in silicon concentrations per unit volume between the solid and the liquid

$$J = V(C_s - C_L) \qquad [1]$$

where C_s and C_L are, respectively, the concentrations of silicon per unit volume in crystalline silicon and in the liquid droplet.

The flux J of silicon atoms in the liquid metal is given by

$$J = \text{Force} \times \text{Mobility} \times \text{Solubility} \qquad [2]$$

The force f on the dissolved silicon atoms can be represented by

$$f = \alpha I \Delta W \qquad [3]$$

where I is the electric current density, ΔW is the difference between the work function of the metal comprising the droplet and the empirical null-point work function, and α is an unknown numerical factor. This is a result of an empirical relationship found earlier (5).

The mobility M of dissolved silicon atoms in the inclusion is given by the Einstein Relation

$$M = \frac{D}{RT} \qquad [4]$$

where D is the diffusion coefficient of dissolved silicon atoms in the liquid metal droplet, R is the gas constant, and T is the absolute temperature. The combination of Eq. [1]-[4] gives

$$\frac{V}{I} = \left[\alpha\left(\frac{C_L}{C_s - C_L}\right)\frac{D}{RT}\right]\Delta W \qquad [5]$$

Unfortunately, no data are available for silicon in Au-Ag alloys that would allow one to evaluate the bracketed expression. However, the null-point composition at which the electromigration velocity passes through zero can be predicted by the Au-Ag composition where the work function deviation ΔW of the alloy equals zero.

Figure 5 shows the work function of Au-Ag alloys plotted *vs.* composition. The null-point work function for silicon of 4.55 eV corresponds to a predicted electromigration null-point composition of 60% Au-40% Ag. Since at the temperature of the electromigration experiments, the electromigration velocities of pure Au and pure Ag droplets are equal and opposite, a simple use of the law of mixtures would indicate that the null-point composition would be 50 a/o Au-50 a/o Ag. In the experiments, a shift of the null point to a gold-rich composition is found instead. This shift to a gold-rich composition is predicted by the nonlinear work function of Au-Ag alloys that shows a much steeper change on the gold-rich side of the work-function-composition diagram than on the silver side. Thus, there is qualitative agreement between the experimental null point and the null point predicted by the work functions of the alloys as far as the shift to the gold-rich side of the diagram. However, quantitatively, the predicted null-

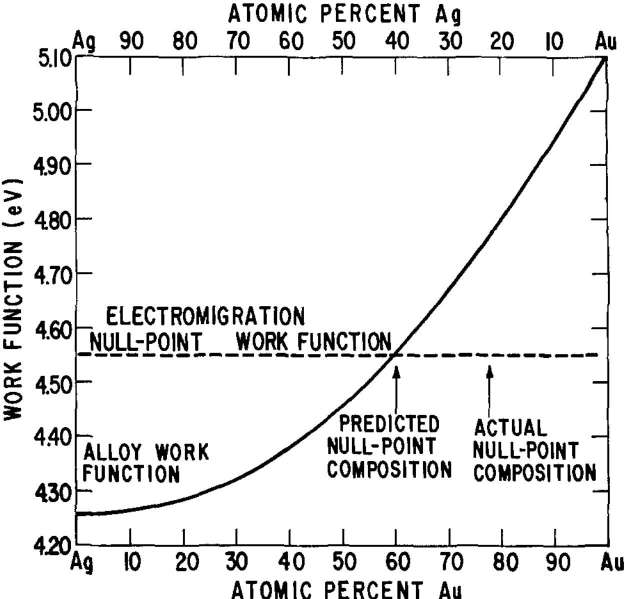

Fig. 5. The work function vs. composition of Au-Ag alloys taken from Ref. (7) and (8). The electromigration null-point work function for various metals is shown along with the predicted and experimental null-point alloy compositions.

point alloy composition of 60% Au-40% Ag does not agree with the experimentally observed null-point composition of 79% Au-21% Ag. This quantitative disagreement is not surprising, since the work function of a pure alloy crystal at room temperature, no doubt, does not equal the work function of the same alloy liquid containing dissolved silicon at 880°C. In view of this quantitative disagreement in the alloy case, the perfect correlation of electromigration directions with work functions found for the pure liquid metal droplets (5) is even more remarkable.

Summary

The electromigration directions of a series of liquid Au-Ag droplets were measured as a function of composition in Si. The electromigration experiments were carried out at a temperature where the electromigration velocities of Au-Si and Ag-Si liquid droplets are equal in magnitude but opposite in direction. Although the law of mixtures would predict an electromigration null-point composition of 50% Au-50% Ag, the actual null-point composition was shifted to a gold-rich composition of 79% Au-21% Ag. This gold-rich shift is predicted qualitatively by a model relating the driving force of electromigration to the deviation of the nonlinear work function of Au-Ag alloys from an electromigration-null-point work function determined previously with simple liquid metal inclusions in Si.

An Improved Model for Analyzing Hole Mobility and Resistivity in p-Type Silicon Doped with Boron, Gallium, and Indium

L. C. Linares[1] and S. S. Li*

Department of Electrical Engineering, University of Florida, Gainesville, Florida 32611

ABSTRACT

Using the relaxation time approximation, and a three-band model (*i.e.*, nonparabolic light-hole band, parabolic heavy-hole, and split-off bands), theoretical calculations of hole mobility and resistivity were carried out for p-type silicon doped with boron, gallium, and indium for dopant densities from 10^{14} to 10^{18} cm^{-3} and temperatures between 100 and 400 K. The theoretical analysis did not consider the effects of compensation, but scattering contributions from acoustical and optical phonons, and ionized and neutral impurities were considered. In addition, interband scattering, the effect of hole-hole scattering, and the nonparabolic nature of the valence bands were also taken into account in the mobility formulations. To verify our theoretical calculations, resistivity measurements were performed on silicon samples (relatively free of compensating inpurities) doped with boron, gallium, and indium with dopant densities ranging from 4.25×10^{15} to 9.05×10^{17} cm^{-3}, for $100 \leq T \leq 400$ K. Agreement between the calculated and measured resistivity values and the published mobilities (4) was within 10% over the range of temperature and dopant density studied.

For purposes of device design it is necessary to know the correct relationship between resistivity and dopant density at different temperatures. Evaluation of the characteristics of semiconductor devices and the study of transport phenomena in semiconductors requires an accurate knowledge of variations in ohmic mobility and carrier density with changes in temperature and dopant density. Because of this, numerous studies of mobility, resistivity, and carrier density in p-type silicon have been carried out (1-15). However, due to the complexity of the valence band of silicon and the various scattering mechanisms involved, these studies, for the most part, have either been conducted in temperature and dopant density ranges designed to explore only a particular type of scattering mechanism, or have not advanced the theory necessary to describe the experimental results. For example, Costato and Reggiani (1) calculated the mobility of holes for pure p-type silicon in which lattice scattering dominates; Braggins (2) considered the nonparabolicity of the valence band and all the relevant scattering mechanisms with the exception of hole-hole (h-h) scattering, but he limited his investigation to dopant densities below 5×10^{16} cm^{-3} and low temperatures; Morin and Maita (3) considered wide ranges of temperature and dopant concentration, but did not provide a theoretical examination of the data. Recently, Li (4) developed a theoretical model capable of describing the mobility and resistivity of p-type silicon over a wide range of temperatures and dopant densities. This improved model was applied to the case of boron-doped silicon with great success (4). The improvement in Li's theoretical treatment of mobility and resistivity consists mainly of the inclusion of h-h scattering effects, and consideration of the nonparabolic nature of the valence band.

With some exceptions (13-15), most of the research in p-type silicon has been conducted with boron as the doping impurity, since boron is the shallowest acceptor in silicon and this material is widely available. A limited amount of data is available on silicon doped with deeper impurities such as gallium and indium. These dopants, especially indium, are of great interest to modern technology because of their application to photo-detector devices. Curves of resistivity and mobility as a function of dopant density (5-7) have been applied to characterizing boron-doped starting material and diffused boron layers in silicon, and have proven to be highly useful. Similar curves developed in this study may be expected to be equally useful for characterizing and integrating infrared detectors based on the deeper levels of indium and gallium with on-chip silicon electronics.

The purpose of this paper is to improve Li's (4) theoretical model by including consideration of interband transitions in the development of scattering relaxation time due to lattice phonons, and to apply this theory to the study of silicon doped with boron, gallium, and indium. The theoretical investigation is carried out over a temperature range from 100 to 400 K and a dopant density range from 10^{14} to 10^{18} cm^{-3}. Because of the complexities brought about by heavy doping effects and uncertainties in accounting for hole density and impurity density at high dopant densities, we have restricted the present analysis to densities below 10^{18} cm^{-3} in which the use of Boltzmann statistics is justified.

In the next section we describe the theoretical approach, presenting the formulation of effective mass in the nonparabolic valence band, and the relaxation time and mobility formulation. Resistivity and carrier density are also analyzed in this section. Next, the theoretical and experimental results are compared. The theory is further verified by comparison with other published data. The section "Summary and Conclusions" summarizes the main conclusions derived from this work.

Theoretical Approach

In this section we present the model used for the valence band of silicon, and the approach used to determine effective masses in the nonparabolic band. The mobility and resistivity in p-type silicon is obtained by considering contributions from lattice, ionized impurity, and neutral impurity scattering. The effects of h-h scattering and valence band nonpara-

Key words: hole mobility, resistivity, dopant.

bolicity are also taken into account in the scattering relaxation time formulation. Interband transitions are considered only for lattice phonon scattering.

Valence band and hole effective masses.—The valence bands of silicon have an extremum at $\bar{k} = 0$ and are degenerate there. The constant energy surfaces for this case are warped spheres. Although warped, the bands are parabolic for small values of $\bar{k}$. However, for larger values of $\bar{k}$, the bands become nonparabolic, and along the <100> and <111> directions the heavy- and light-hole bands are parallel over most of the Brillouin zone. The derivation of an expression for a valence band effective mass which incorporates the nonparabolic nature of the individual bands begins with a simplified model of the warped structure based on the work of Kane (16) and Barber (17). In this model, the heavy-hole band is characterized by holes with an energy independent but direction dependent effective mass, and the light-hole band is characterized by holes with an energy and direction dependent effective mass. The split-off band is separated at $\bar{k} = 0$ by an energy $\Delta = 0.044$ eV (18), and is characterized by an effective mass which is temperature dependent. Thus the heavy-hole band is treated as parabolic for the range of temperature considered in this work, while the light-hole band is parabolic only for very low values of $\bar{k}$. At higher values of $\bar{k}$, the light-hole band has an energy dependent curvature which takes on the same characteristics as the heavy-hole band for energies greater than 0.02 eV.

Using the above band model, expressions were derived for density-of-states and conductivity effective masses, based on the following definitions (19): the density-of-states effective mass, m_D^*, enters in the normalization of the distribution function, and the conductivity effective mass, m_C^*, is the mass of a mobile charge carrier under the influence of an external electric field. Since the crystal structure of silicon has cubic symmetry, ohmic mobility will be isotropic. The warping and nonparabolic character of the bands enters the isotropic mobility via the effective mass formulation. The values of m_C^* and m_D^* calculated in (19) were obtained assuming the Fermi-Dirac distribution function, and unequal relaxation times in the individual bands (20). These values are valid in the temperature range considered in this study, where the warping nature of the heavy-hole band is not strong and this band can be assumed parabolic. The values of m_C^* and m_D^* calculated in Ref. (19) for $100 \leq T \leq 400$ K are listed in Table I.

Mobility and scattering relaxation time formulation.—The calculation of the mobility of holes in the valence band of silicon is accomplished by evaluating the mobility separately in the heavy-hole band, the light-hole band, and the split-off band considering all appropriate scattering mechanisms. The overall mobility is then evaluated as a weighted average of the single-band mobilities over the individual hole densities in each band.

The conductivity mobility in each of the three valence bands is calculated from

Table I. Density-of-states and conductivity effective masses of holes in p-type silicon for $N_A = 10^{14}$cm^{-3} and $100 \leq T \leq 400$ K (19) (masses in units of electron rest mass)

$$\mu_i = \frac{e\langle\tau_i\rangle}{m_{Ci}^*} \quad [1]$$

where

$$\langle\tau_i\rangle = \frac{\int \epsilon^{3/2}\,\tau_i(\partial f_o/\partial\epsilon)\,d\epsilon}{\int \epsilon^{3/2}\,(\partial f_o/\partial\epsilon)\,d\epsilon} \quad [1]$$

for the case of Fermi-Dirac statistics, $\epsilon = E/k_oT$ is the reduced energy, and m_{Ci}^* and τ_i are the conductivity effective mass (19), and the total scattering relaxation time in band i, respectively.

At temperatures above absolute zero, in any semiconductor, the charge carriers may be scattered by a number of different mechanisms. Because each scattering mechanism has its own dependence on scattering energy, a simple closed form expression for total scattering relaxation time as a function of temperature cannot be obtained. The use of numerical techniques is necessary to solve for the relaxation time. In the case of p-type silicon, the peculiarities of a degenerate, warped, and nonparabolic valence band must be taken into account (2). The possibility of interband as well as intraband transitions must also be taken into account in the analysis. With the inclusion of interband scattering as given by Bir *et al.* (21), the total relaxation time in the heavy- (i = 1) and light- (i = 2) hole bands is given by

$$\tau_i = \frac{1}{\delta}\left(1 + \frac{m_{Di}^*}{m_{Dj}^*}\,\frac{\tau_{jj}}{\tau_{ij}}\right)\tau_{ii} \quad i \neq j; \quad i = 1, 2; \quad j = 1, 2 \quad [3]$$

where

$$\delta = 1 - \frac{\tau_{11}\tau_{22}}{\tau_{12}\tau_{21}} \quad [4]$$

and τ_{ii} is obtained by adding reciprocally the contributions from scattering by acoustical phonons, optical phonons, ionized impurities, and neutral impurities with i as the band index. The total relaxation time in the split-off band (i = 3) is obtained in the same manner. Only transitions between the light- and heavy-hole bands are considered; the relaxation time τ_{ji} takes into account a transition from band i to band j.

The procedure for including the nonparabolicity of the band structure into calculations of relaxation time, consists of modifying the relaxation time for a given scattering process by replacing the temperature independent effective mass of the parabolic band by the temperature dependent effective mass of the nonparabolic band. This procedure has been successfully applied to the study of acoustic phonon scattering in nonparabolic bands by Radcliffe (22). Optical phonon and ionized impurity scattering in nonparabolic bands have been considered by Barrie (23) in the same manner. Braggins (2) has used the same method to include nonparabolicity in his study of p-type silicon. In this work, the relaxation times appropriate to degenerate, parabolic valence bands have been used and modified according to the prescription of Radcliffe (22), Barrie (23), and Braggins (2). The anisotropy of the energy spectrum is not considered in this model, because from the transport theory for parabolic bands it is known that this anisotropy has no influence on the temperature dependence of mobility, but only on its absolute value (24). Each of the four scattering mechanisms will now be discussed.

Acoustical phonon scattering.—The relaxation time for scattering by acoustical phonons includes both the possibility of interband as well as intraband scattering. The treatment of the acoustical phonons has been based on the theory of Bir, Normantas, and Pikus (21) where the relaxation times can be expressed in terms of a single constant, τ_o which controls the overall magnitude of the scattering. Both transverse and longitudinal phonons participate in the scattering so that

$$\tau_{ac1}^{-1} = \frac{m_{D1}^{*3/2}}{\tau_o} \left\{ L_{11}^{(2)} + \gamma^3 L_{11}^{(1)} + \frac{C_l^2}{C_t^2} \eta^2 (T_{11}^{(2)} + \gamma^3 T_{11}^{(1)}) \right\} T^{3/2}\epsilon^{1/2} \quad [5]$$

and

$$\tau_{ac2}^{-1} = \frac{m_{D2}^{*3/2}}{\tau_o} \left\{ L_{22}^{(2)} + \gamma^3 L_{22}^{(1)} + \frac{C_l^2}{C_t^2} \eta^2 (T_{22}^{(2)} + \gamma^3 T_{22}^{(1)}) \right\} T^{3/2}\epsilon^{1/2} \quad [6]$$

for intraband scattering, while

$$\tau_{ij}^{-1}\gamma^{-5} = \tau_{ji}^{-1} = \frac{m_{Di}^{*3/2}}{\tau_o} \left\{ L_{ij}^{(2)} + \frac{C_l^2}{C_t^2} \eta^2 (T_{ij}^{(2)}) \right\} T^{3/2}\epsilon^{1/2} \quad [7]$$

for interband scattering. In the split-off band, the scattering relaxation time is given by

$$\tau_{ac3}^{-1} = \frac{m_{D3}^{*3/2}}{\tau_o} (\epsilon - \Delta/k_oT)^{1/2} T^{3/2} \quad [8]$$

In these equations

$$\frac{1}{\tau_o} = \frac{k_o^{3/2}a^2 m_o^{3/2}}{\sqrt{2}\pi\hbar^4 \rho_s C_l^2}, \quad \gamma^2 = \frac{m_{D2}^*}{m_{D1}^*}, \quad n = b/a$$

a and b are valence band acoustic deformation potential constants in the Picus and Bir (25) notation, ρ_s is the density, C_l and C_t are the longitudinal and transverse sound velocities in silicon, and L_{ij} and T_{ij} are the functions of η and γ defined in (21).

Optical phonon scattering.—Optical phonon scattering, while negligible at very low temperatures, cannot be ignored at high temperatures. Ehrenreich and Overhouser (26) have calculated the mobility of holes in silicon and its dependence on temperature. The calculated mobility follows a $T^{-2.3}$ dependence for reasonable choices of the parameters which describe the mixing of optical and acoustical phonon scattering. This agrees with experimental results (3, 7). The relaxation time for scattering by nonpolar optical phonons is given by (27)

$$\tau_{oi}^{-1} = \frac{m_{Di}^{3/2}}{\tau_o} W\theta T^{1/2} \{(n_o + 1)(\epsilon - \theta/T)^{1/2} + n_o(\epsilon + \theta/T)^{1/2}\}, \quad i = 1, 2, 3 \quad [9]$$

where θ is the Debye temperature, $n_o = (\exp(\theta/T) - 1)^{-1}$ is the phonon distribution function, and W is a constant which determines the relative coupling strength of the holes to the optical phonon mode compared to the acoustical phonon mode, $W = D_o^2h^2C_l^2/2k_o^2a^2\theta^2$, where D_o^2 is the optical deformation potential constant. The first term in the brackets of Eq. [9] corresponds to optical phonon emission and is relevant only when this is energetically possible ($\epsilon > \theta/T$). The second term in the brackets corresponds to optical phonon absorption.

Ionized impurity scattering.—The Coulombic interaction between ionized impurities and charge carriers drifting through the crystal under the action of an applied electric field causes scattering of the charge carriers. Scattering by ionized impurities was first considered by Conwell and Weisskopf (28). The basic assumption is that the Coulomb field is cut off at half the distance between charged impurities. This is equivalent to assuming that a charge carrier sees only one charged impurity at a time, the effect of the other charged impurities being sufficiently screened as to be negligible. This approach was improved by Brooks (29) and Herring (30) who associated the cutoff of the Coulomb potential with a screening distance, the free carriers being assumed to provide screening against the charge of the impurities. We have used the Brooks-Herring formula in our calculations.

Neutral impurity scattering.—Scattering by neutral impurities in semiconductors has been considered by Erginsoy (31) as a variation of the problem of the scattering of electrons by neutral hydrogen atoms. The result is a temperature independent relaxation time. Sclar (32, 33) has included the possibility of bound states in the evaluation of electron-hydrogen impurity scattering by using a three-dimensional square well to estimate the influence of a weakly bound state on the scattering. In this case the relaxation time is given by

$$\tau_{Ni}^{-1} = \frac{2^{3/2}\pi\hbar^2 N_N}{(k_oT)^{1/2}m_{Di}^{*3/2}} \left\{ \epsilon^{1/2} + \frac{E_1}{k_oT\epsilon^{1/2}} \right\}, \quad i = 1, 2, 3 \quad [10]$$

where

$$E_1 = 1.136 \times 10^{-19} \left(\frac{m_D^*}{m_o} \right) \left(\frac{\epsilon_o}{\epsilon_s} \right)^2$$

is the binding energy of neutral acceptors.

McGill and Baron (34) report a more accurate calculation of neutral impurity scattering which is not subject to any of the previous approximations to the scattering, and represents an accurate implementation of the neutral-hydrogen approximation. Using this calculation, Baron *et al.* (35) show that neutral impurity scattering is inversely proportional to the ionization energy of the impurity. McGill and Baron's calculations, while predicting significant deviations from the results of Erginsoy and Sclar at low temperatures, agree in general with the predictions of Eq. [10] at higher temperatures ($36 < T < 181$ K for In).

For silicon doped with shallow impurities, neutral impurity scattering is important at low temperatures where neutral impurities may outnumber ionized impurities. The more accurate calculations of McGill and Baron are appropriate in this case, especially for the deeper level impurities. In this study, however, because of the temperature range involved, we felt that Sclar's calculation could accurately represent neutral impurity scattering.

Effect of hole-hole scattering.—The expressions thus far presented for scattering relaxation time neglect the effect of hole-hole (h-h) scattering. Although h-h scattering does not affect the current density directly since it cannot alter the total momentum, it tends to randomize the way in which this total momentum is distributed among holes of different energies. When the scattering mechanism is such as to lead to a nonuniform distribution, h-h scattering gives rise to a net transfer of momentum from holes which dissipate momentum less efficiently to those which dissipate momentum more efficiently, resulting in an overall greater rate of momentum transfer, and lower mobility (36). Thus the size of the effect of h-h scattering on the scattering relaxation time is a function of the energy dependence of the relaxation time. The h-h factor, γ_{hh}, can be derived by means of a classical formulation introduced by Keyes (37). When hole-hole collisions are much more frequent than hole-acceptor collisions, the average relaxation time for a parabolic band in the Keyes (37) approximation approaches the limiting form

$$\langle\tau_{hh}\rangle = \frac{\int \epsilon^{3/2}(\partial f_o/\partial\epsilon)\,d\epsilon}{\int \epsilon^{3/2}\tau^{-1}(\partial f_o/\partial\epsilon)\,d\epsilon} \quad [11]$$

where f_o is the Fermi-Dirac distribution function. On the other hand, if h-h collisions are neglected, the average relaxation time is given by Eq. [2].

Thus the h-h reduction factor (*i.e.*, the ratio of $\langle\tau_{hh}\rangle$ to $\langle\tau\rangle$) can be expressed as

$$\gamma_{hh} = \left\{ \frac{\int \epsilon^{3/2}\tau(\partial f_o/\partial\epsilon)\,d\epsilon \; x \int \epsilon^{3/2}\tau^{-1}(\partial f_o/\partial\epsilon)\,d\epsilon}{[\int \epsilon^{3/2}(\partial f_o/\partial\epsilon)\,d\epsilon]^2} \right\}^{-1} = \frac{1}{<\tau><\tau^{-1}>} \quad [12]$$

For optical phonon scattering, and γ_{hh}^{o}, the h-h reduction factor is evaluated from Eq. [12].

For acoustical phonon scattering it is assumed that γ_{hh}^{a} decreases linearly with increasing dopant density from a value of one to a value of $\gamma_{hh}^{a} = 9\pi/32 \stackrel{\Delta}{=} 0.88$ (4) in a certain range of impurity concentration. The exact relationship ($\gamma_{hh}^{a} = 1.0004 - 4.013378 \times 10^{-19}$ N_A, $10^{15} \leq N_A \leq 3 \times 10^{17}$) is determined empirically with a best fit of the experimental data.

Luong and Shaw (38) using a one-particle-like approximation from the Hartree-Fock theory, have shown that by inclusion of h-h scattering, the Brooks-Herring (29, 30) formula is reduced by a factor which can be expressed in closed form as

$$\gamma_{hh}^{i} = (N_A^-/p')\,[1 - \exp(p'/N_A^-)] \quad [13]$$

where N_A^- is the ionized acceptor density and p' is the screening hole density.

In the case of neutral impurity scattering, h-h scattering has no significance because τ_N is independent of hole energy. Thus the overall scattering relaxation time in each hole band is calculated by adding the contributions from the different scattering mechanisms, each properly corrected for the effects of h-h scattering. The conductivity mobility in each individual band is calculated from Eq. [1] and the combined conductivity mobility in the valence band is then evaluated as a weighted average of the single-band mobilities over the population of holes in each band.

Resistivity and hole density.—The resistivity for p-type silicon is given by

$$\rho = \frac{1}{e\mu_C p} \quad [14]$$

where μ_C is the hole conductivity mobility and p is the hole density

$$p = \frac{4}{\sqrt{\pi}}\left[\frac{2\pi k_o T m_D^*}{h^2}\right]^{3/2} F_{1/2}(\eta) \quad [15]$$

for the general case of Fermi-Dirac statistics. Here, m_D^*, the density-of-states effective mass, contains information pertaining to the nonparabolic nature of the valence band (19). In the limit of low dopant densities, Eq. [15] reduces to $p = N_v \exp(-\eta)$ where $N_v = 2\,(2\pi m_D^* k_o T/h^2)^{3/2}$ is the effective density of valence band states. For the range of temperatures considered in this study, the hole density is determined by assuming that the density of carriers is determined by the impurities present in the silicon sample. The density of ionized acceptor impurities in p-type silicon is computed from the charge neutrality equation, which reduces to $p \simeq N_A^-$ for the case of uncompensated materials.

The density of ionized acceptors is (39)

$$N_A^- = \frac{N_A}{1 + g\exp\left(\frac{E_A - E_F}{k_o T}\right)} \quad [16]$$

where E_A is the acceptor ionization energy, and g is the ground state degeneracy. Excited states have a very minor influence on the carrier concentration due to the large separation between the ground state and the excited states (2, 39). Letting

$$g = 4 + 2\exp(-\Delta/k_o T) \quad [17]$$

enables us to include contributions from the lowest energy state associated with the split-orbit band. Equation [17] assumes that this state is bound to the split-orbit band with the same energy as the ground state is bound to the light- and heavy-hole bands. Calculations of Zwerdling, *et al.* (18) and Baldereschi and Lipari (40) show that this assumption leads to underestimation of the percentage of impurity ionization. On the other hand, tacit acceptance of $g = 6$ (41), overestimates ionization density and introduces a larger error than the assumption of Eq. [17]. The density of ionized acceptors is computed by iterating E_F in Eq. [15] and [16] until $|p - N_A^-| < 0.001$.

Experimental evidence shows that the acceptor ionization energy E_A is not a constant, but decreases with increasing dopant density (9). Penin *et al.* (42) have determined in a study of heavily doped silicon from 4 to 300 K that for shallow impurities such as boron and phosphorus the ionization energy decreases and finally disappears altogether for impurity densities greater than 3×10^{18} cm^{-3}. For impurities with deeper activation energies, it is also expected that at some impurity concentration, the impurity activation energy should become a function of the impurity concentration. However, in this case this should happen at higher impurity concentrations than for the shallower level impurities. This is due to the smaller geometrical dimensions of the wave functions applicable to the deeper levels, so that overlapping effects which promote the reduction in activation energy require higher impurity concentrations (13). For shallow impurities such as boron and phosphorus, empirical expressions (9, 42) relating the dependence of ionization energy to dopant density have been established. In the case of Ga, there are data (14) on activation energy *vs.* concentration, but not enough on which to base an accurate relationship. For this reason the value of $E_A = 0.065$ eV (43, 44) was used. For In, $E_A = 0.156$ eV (45) was used.

Theoretical and Experimental Results

Using the theoretical expressions derived in the previous section and the parameters listed in Table II, we have calculated the hole mobility as a function of hole density at 300 K for boron-doped silicon. The constant, τ_o, was found by fitting the mobility to experimental points in the lattice-scattering-limited range. Our value of τ_o is equivalent to an acoustic deformation potential constant of 8.099 eV. The optical phonon coupling constant, W, was then found by fitting the mobility to the high temperature experimental data. Our value of W is equivalent to an optical deformation potential constant of 6.024×10^8 eV/cm. Curve I in Fig. 1 represents this theoretical calculation, and curve 2 was reproduced from Wagner (7). Our calculated values are within 6% of the values reported by Wagner for $N_A \leq 3 \times 10^{17}$ cm^{-3}. For higher values of hole density our calculated values are substantially higher than those of Wagner. As previously explained by Li (4), this discrepancy is due to Wagner's assumption of complete ionization of boron impurities. This assumption is valid only at low dopant densities or at high temperatures where full ionization

Shown also are the experimental results of this work, Horn (12), and Thurber *et al.* (11). All data points have been corrected for deionization effects.

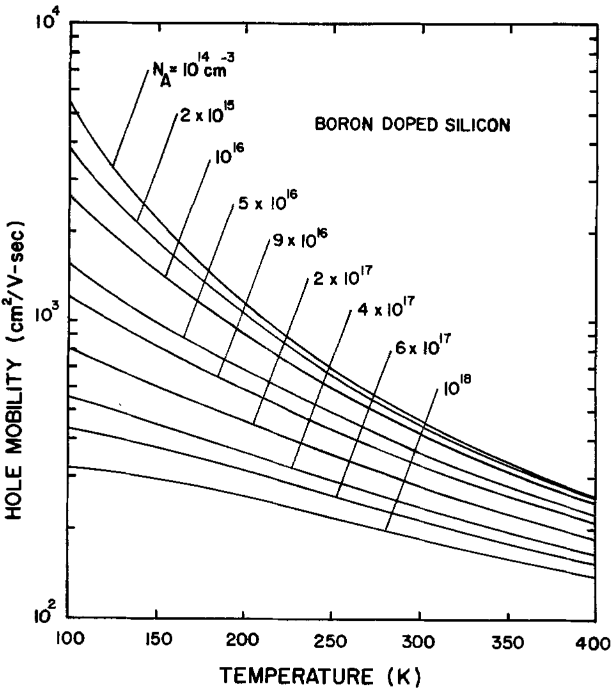

Fig. 2. The calculated hole mobility vs. temperature for boron-doped silicon with dopant density as a parameter.

of boron atoms prevails. The inclusion of interband scattering in the theoretical development results in a minor improvement in the quantitative agreement between theoretical and experimental results for boron-doped silicon. While Li's (4) model predicts a mobility of 475 cm^2/V-sec for low-doped silicon at 300 K, the model presented in this paper predicts a mobility of 465 cm^2/V-sec, and provides better agreement with the data of Thurber *et al.* (11). This value also agrees closely with direct measurements of drift mobility reported by Otaviani *et al.* (46). The theoretical calculation is in excellent agreement (within 3%) with experimental data reported by Thurber *et al.* (11). This gives support to the validity of ionization calculations based on Eq. [15] through [17]. Mobility values reported by Horn (12) are also in reasonable agreement with our theoretical results. The data points shown in Fig. 1 were corrected for deionization effects via Eq. [15] through [17].

The equations derived in the previous section were used to calculate the hole mobility for silicon doped with boron, gallium, and indium as a function of temperature with dopant density as a parameter, for $100 \leq T \leq 400$ K. The results are displayed in Fig. 2 through 4. A major use for Ga- and In-doped silicon is as infrared detectors. In this use it is essential that any residual boron be overcompensated. In the calculations of mobility in silicon doped with gallium and indium, we assumed that very lightly compensated boron impurities were also present. The Ga- and In-doped samples used in this study were specifically prepared with minimum compensation. Values of net background boron density (10^{13} and 5×10^{13} cm^{-3} in the gallium- and indium-doped samples, respectively) were deduced from a best fit of the experimental data. For this reason, especially in the case of indium-doped silicon, the actual role of the impurities at low temperatures and/or low dopant densities is masked by the action of the always present boron impurities. As the dopant density and temperature increase, the assumed background density of boron impurities becomes insignificant compared to the density of ionized dopant atoms, and Fig. 2 through 4 accurately depict the influence of the particular type of impurity on the mobility of holes in p-type silicon. The figures also show that for the case of the shallower ionization energies, mobility depends more strongly on temperature for the lightly doped case where lattice scattering is dominant, and becomes less temperature dependent as the dopant density increases.

In order to verify the adequacy of the theoretical model developed in this work, resistivity measurements were performed on silicon slices doped with boron, gallium, and indium for temperatures between 100 and 400 K. The data were obtained from NBS-4 test patterns fabricated on the silicon slices. Resistivity measurements were made on four-probe square array resistors and collector Hall effect resistors, while the net dopant density in the specimens was determined by the junction C-V method on a gated base-collector diode. These test structures are part of the test pattern NBS-4 (47), and are described in detail elsewhere

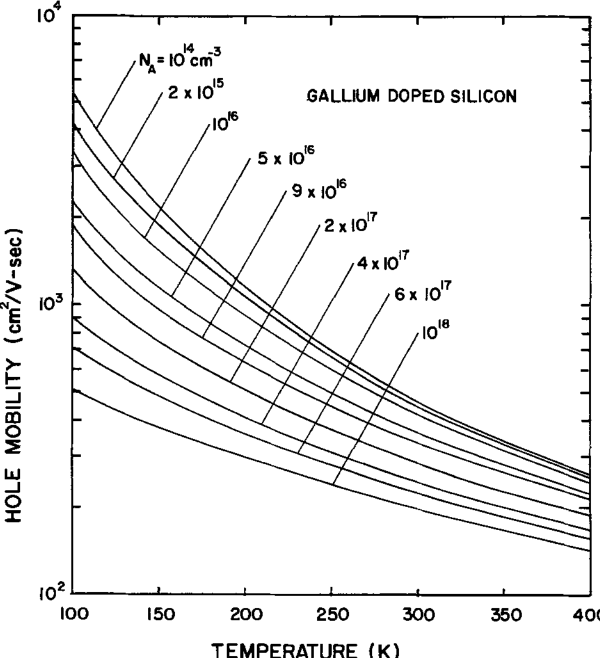

Fig. 3. The calculated hole mobility vs. temperature for gallium-doped silicon with dopant density as a parameter.

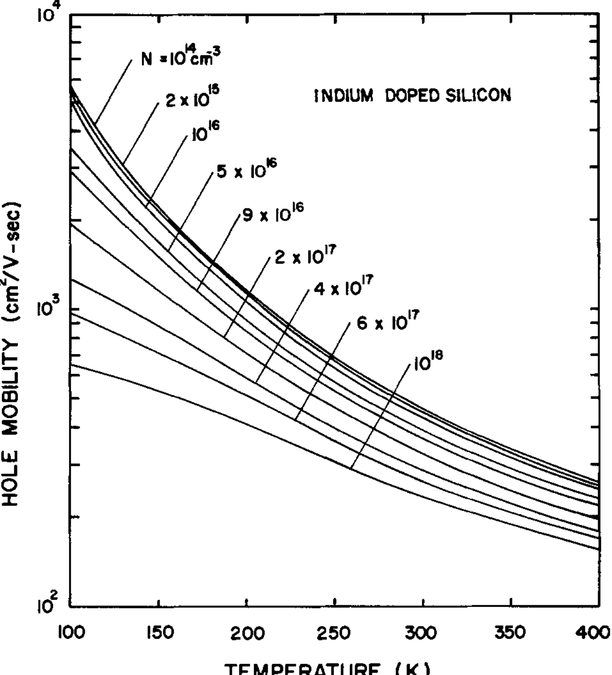

Fig. 4. The calculated hole mobility *vs.* temperature for indium-doped silicon with dopant density as a parameter.

(47, 48). Mean values of resistivity were determined by measuring 5-8 selected test cells with a standard deviation in resistivity values under 5%. Figure 5 shows the resistivity *vs.* dopant density relationship for boron-doped silicon at 300 K. The solid line presents theoretical calculations using Eq. [14], and the solid dots are our experimental data from boron-doped silicon. Resistivity values predicted by this model differ from those calculated by Li (4) by no more than 2% (at 300 K, for $N_A = 10^{14}$ cm^{-3}, our model predicts a resistivity of 134.1 Ω-cm, while Li's model predicts a value of 131.4 Ω-cm). Wagner's (7) resistivity curve and the theoretical line coincide over most of the total boron density range. Our theoretical calculations agree with Wagner's resistivity data within 6% over the entire range of boron densities considered at $T = 300$ K. Excellent agreement exists between our experimental data and the theoretical calculations at $T = 300$ K. Figure 5 also shows excellent agreement between our theoretical calculations and the data of Thurber *et al.* (11). Good agreement was obtained with the data of Thurber and Carpenter where total boron density was obtained by the nuclear track technique (49).

Figure 6 shows the resistivity of gallium- and indium-doped silicon as a function of total dopant density for $T = 300$ K. As expected, because of the deeper ionization energy of indium as compared to gallium, values of resistivity for gallium-doped silicon are lower than values of resistivity for indium-doped silicon at the same total dopant density. Figure 6 does not show this at low dopant densities because of the assumed values of background boron impurity densities. Excellent agreement was obtained between our experimental data and that obtained from Wolfstirn (14) for gallium-doped silicon, and our theoretical calculations at $T = 300$ K. Wolfstirn's data quotes values for activation energy ranging from 0.052 to 0.070 eV as the dopant density changes from 1.62×10^{18} to 1.26×10^{16} cm^{-3}. While Wolfstirn acknowledges that compensation plays a significant role in determining the degree of ionization of excess acceptors, she does not specify the degree of compensation of the samples used. Data obtained from the two indium-doped samples showed good agreement with the theoretical calculations, but the same was not true for the data of Schroder *et al.* (50), and Backenstoss (15). As seen in Fig. 6, for each value of measured resistivity, Schroder *et al.* (50) report two different values of measured indium density. The lower value of indium density was obtained by *C-V* and junction breakdown methods, while the higher value was obtained by Hall measurements and curve fitting. Because of uncertainties in the value of the Hall scattering factor, Schroder

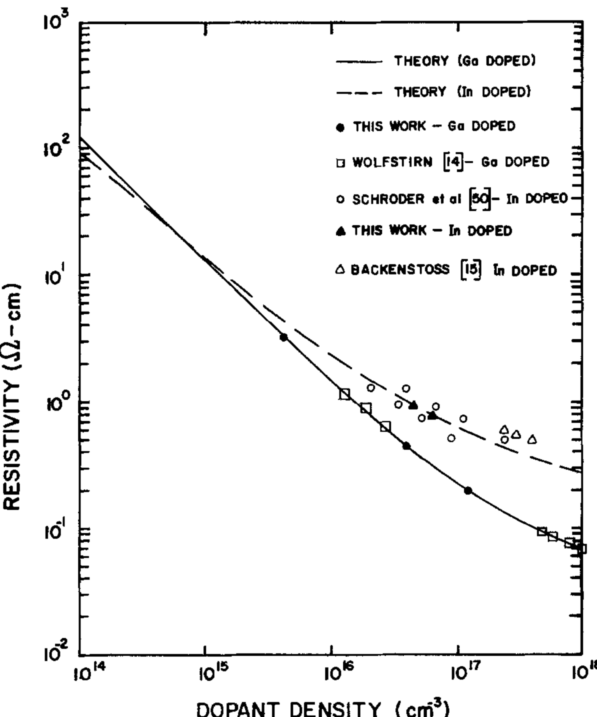

Fig. 6. Resistivity *vs.* dopant density for gallium- and indium-doped silicon at 300 K. Shown are theoretical calculations from Eq. [19] and the experimental results of this work, Wolfstirn (4), Schroder *et al.* (50), and Backenstoss (15).

et al. consider the lower value of density more reliable. Note that our theoretical calculation falls between the two values of dopant density reported by Schroder *et al.* (50). Values of resistivity of indium-doped silicon reported by Backenstoss (15) are about 25% higher than our calculated values. The work of Backenstoss (15), however, was done in the high doping region where dopant densities approach the limit of solid solubility. Backenstoss found that for dopant densities greater than 4×10^{17} cm^{-3} there was a considerable amount of indium precipitation. Thus it is possible that part of the discrepancy between our theoretical calculations and the data of Backenstoss is due to the low solid solubility limit of indium in silicon. Recent theoretical results of Sclar (13) for In-doped silicon also agree very closely with our theoretical calculations at 300 K. Neither Schroder *et al.* (50) nor Backenstoss (15) have indicated the degree of compensation of the samples used in their work.

To find out the adequacy of our theoretical model for temperatures other than 300 K, we compared the calculated and measured values of resistivity for silicon samples doped with boron, gallium, and indium for temperatures ranging from 100 to 400 K. Figure 7 shows the comparison between theoretical and measured resistivities for boron-doped silicon. Except for a couple of data points, agreement between the theoretical and measured values was within 8% over the entire range of temperatures. Figures 8 and 9 show the comparison between theoretical and measured resistivities for gallium- and indium-doped silicon, respectively. Agreement here was not as good as in the boron-doped case, but except for a couple of data points, agreement between theory and experiment was within 10%. For indium-doped samples, the largest discrepancies occurred at low temperatures. This is suggestive of some degree of compensation in the samples. Because the materials used were very carefully prepared to minimize compensation, an experimental estimate of percentage of compensation was not made for any of the silicon samples studied in this work.

Summary and Conclusions

Theoretical expressions have been derived to compute hole mobility and resistivity as functions of dopant density and temperature for silicon doped with boron, gallium, and indium. The valence band of silicon was represented by a three-band model which takes into account the nonparabolic nature of the bands. This attribute of the valence band is included in the

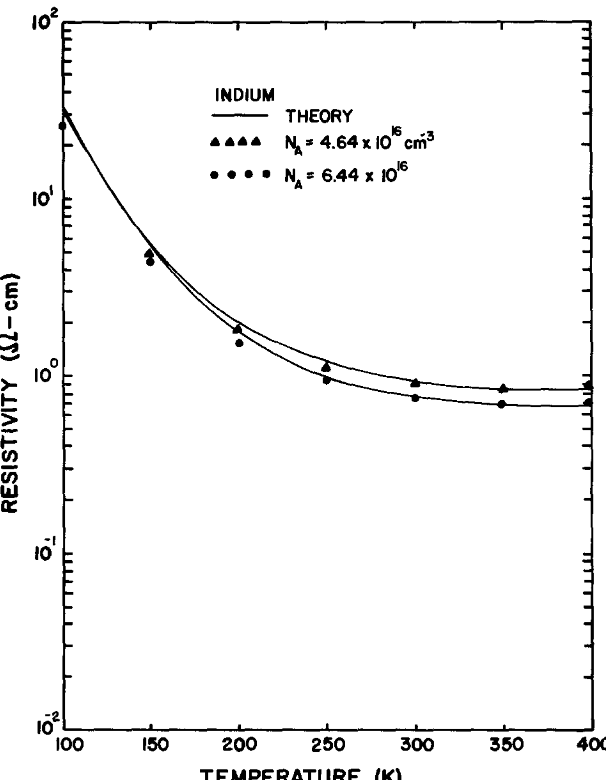

Fig. 9. Resistivity *vs.* temperature for the indium-doped silicon samples. Solid lines are the theoretical calculations.

effective mass calculations. Contributions from scattering by acoustical and optical phonons, ionized impurities, and neutral impurities were considered in the calculation of average relaxation time. In addition, our model also takes into account the effect of (h-h) scattering on both lattice and ionized impurity scattering relaxation times, and the effect of interband transitions on the acoustic phonon scattering relaxation time.

The resistivity analysis for the boron-, gallium-, and indium-doped silicon samples showed agreement between experimental and theoretical results within 10% over the entire range of temperature, $100 \leq T \leq 400$ K. Note that best agreement between theory and experiment was obtained for boron-doped samples, followed by gallium- and indium-doped samples. This may be due to the fact that we neglect the compensation effect and the possible dependence of ionization energy on dopant density in the theoretical calculations for gallium- and indium-doped samples. An experimental estimate of degree of compensation was not made for any of the silicon samples studied here. Data points representing a resistivity-dopant density pair are estimated to have a total error of around 6%.

A comparison between our calculated mobility values with those of Wagner's (7) data on boron-doped silicon at 300 K shows that agreement is within ±6% for $N_A \leq 3 \times 10^{17}$ cm^{-3}. Discrepancies at higher dopant densities can be eliminated if the effect of deionization of boron impurities were included in Wagner's calculations (7). Excellent agreement was found between our theoretical calculations of mobility in boron-doped silicon and the data of Thurber *et al.* (11) at 300 K. We have obtained excellent agreement between theoretical values of resistivity and our experimental data for boron-, gallium-, and indium-doped silicon at 300 K; our theoretical calculations also agreed with the resistivity data by Thurber *et al.* (11) for boron-doped silicon, and Wolfstirn (14) for gallium-doped silicon. From this study, we have found that the theoretical expressions derived in this work are adequate for mobility and resistivity calculations for p-type silicon valid for $10^{14} \leq N_A \leq 10^{18}$ cm^{-3} and $100 \leq T \leq 400$ K. The work presented here may be considered as a further refinement and extension over that published recently by Li (4) for p-type silicon.

Acknowledgment

The financial support received from the National Bureau of Standards and the National Science Foundation is gratefully acknowledged. Thanks are due to Dr. W. M. Bullis and W. R. Thurber of the National Bureau of Standards for their critical review of the manuscript, and their continued interest in this work.

The authors are also indebted to M. R. Riley for preparation and measurement of the boron-doped test structures, and to D. Yuen for resistivity measurements on the gallium- and indium-doped samples. Assistance by H. Mehta in carrying out the numerical computations is also gratefully acknowledged. This research was jointly supported by the National Bureau of Standards Contract 7-35741 and the National Science Foundation Grant ENG 76-81828.

Manuscript submitted July 30, 1979; revised manuscript received Sept. 15, 1980. This was Paper 551 presented at the Los Angeles, California, Meeting of the Society, Oct. 14-19, 1979.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by the University of Florida.

Measurement and Identification of Distortion, Alignment, and Mask Errors in IC Processing

K. H. Nicholas,* I. J. Stemp, and H. E. Brockman

Philips Research Laboratories, Redhill, Surrey, England

ABSTRACT

Measurement and identification of misregistration between patterns in integrated circuits is becoming increasingly important as finer geometry processes are being developed for VLSI. Various forms of the Stickman resistor pattern are described. These enable measurement of the alignment errors, mask errors, and distortions that occur when using any alignment apparatus. The properties of the different forms of Stickman resistors are compared and examples of applications to studying mask making errors, slice/mask distortions, projection distortions, and process induced slice distortions are described. It is shown that misregistrations of 0.1 micron or even less can be measured and identified. Direct measurements on simple apparatus are shown to be reproducible to ±0.003 micron and accuracy is estimated at 5% of the misregistration with simple apparatus and 2% for a one micron misregistration if on chip measurement of sheet resistance is made.

Automatic measurement of the misregistration between patterns in integrated circuits and identification of the causes are necessary to the development of high packing density circuits. A resistor pattern for measuring misregistrations automatically has been described (1) that is more accurate and sensitive than other methods (2-5). In this paper three forms of the pattern (1), called the Stickman pattern from its shape, are described. They enable measurement of mask errors, alignment, and distortion in any alignment apparatus.

The basic pattern is first outlined and then the standard, small displacement, and protected edge forms are described and compared. Examples of measurements of mask faults and slice and image distortions are given to illustrate the flexibility and accuracy of the methods.

Throughout the paper misalignment is used to describe errors in aligning the new pattern with the slice as a whole and generally has only one value per slice. There can be several values with steppers. Misregistrations refer to errors at each measurement site including misalignment. Residual misregistrations are the values when apparent alignment errors have been removed. Distortions are the misregistrations when alignment and mask errors have been eliminated.

Stickman Types

Basic pattern.—The basic Stickman resistor pattern is shown in Fig. 1. It can be formed by a conducting layer on a mask or slice substrate or by doping in a silicon slice. The two resistors connected at one end are formed by two definition stages. One defines the outside edges shown with a solid line while the inside edges, shown by a dotted line, are defined at the other stage. Misregistration leads to differences in widths and hence to differences in resistances. It can be shown (1) that the misregistration, Δx, is given by

$$\Delta x = \tfrac{1}{2} \rho L (R_1^{-1} - R_2^{-1})$$

where ρ is the sheet resistance, L is the resistor length, and R_1 and R_2 are the resistances. The length of the resistor and sheet resistance are scaling factors. The sheet resistance can be measured on van de Pauw patterns adjacent to the Stickman patterns and the length is made large. The value for Δx is independent of resistor width and so is independent of systematic lithographic variations. Accuracy is better than 2% (0.02 micron for 1 micron misregistration) with typical measuring apparatus and linewidths.

* Electrochemical Society Active Member.

Key words: integrated circuits, resistivity, semiconductor.

Devices to measure misregistrations in X and Y directions are generally formed at each site. A pattern of resistors to do this is shown in Fig. 2. A constant current is passed from I to 0 and voltages across the resistors (1-2, 2-3, etc.) measured to evaluate their resistances.

The values can be analyzed in a computer to produce misregistrations and these are further analyzed in the computer in terms of position on the slices.

Standard.—The two patterns used to define resistors in the standard method are on two separate masks if conventional lithography is used. The patterns are indicated by different cross hatching in Fig. 3. Such patterns can be included on appropriate mask levels in production integrated circuit processes. The standard form is therefore ideal for monitoring total misregis-

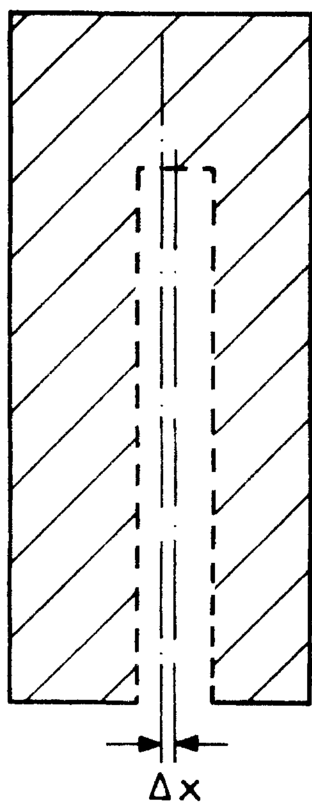

Fig. 1. Basic resistor pattern

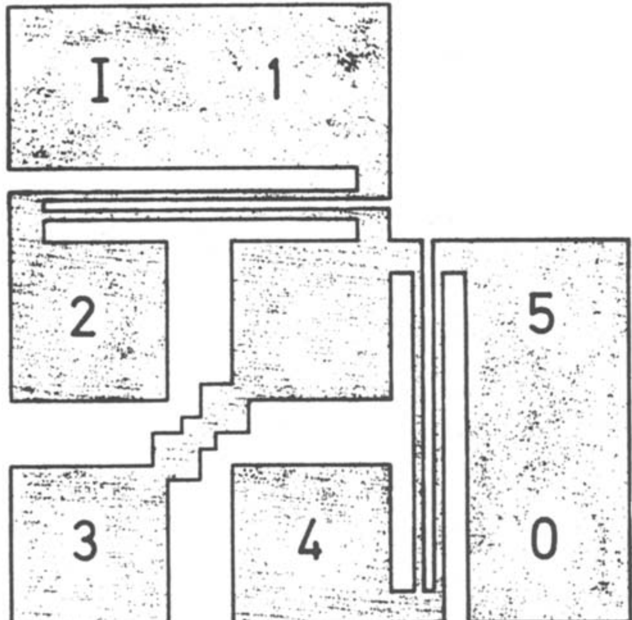

Fig. 2. Pattern with probe pads for misregistrations in both directions.

trations in integrated circuit process lines and can be used on any aligner.

Errors in alignment can generally be separated from other effects in the computer analysis program (6) but mask effects and distortions cannot necessarily be separated. In principle mask errors can be checked by using a "low distortion" process and finding errors that are reproduced on several slices. Some errors can be observed by this method or by studying the pattern of misregistrations but it is only generally possible if the errors are of the order of 0.1 μm or greater and a genuine "low distortion" process can be achieved. Subtracting the values of mask errors so obtained can allow distortion values to be derived but again the accuracy is limited.

The standard form can be used to assess mask makers directly. The two patterns are exposed successively on a bright chrome mask and the chrome layer defined. The thin film chrome resistors and the sheet resistance of the chrome can then be measured to give values for the misregistrations produced in the mask maker. This method can be extremely sensitive and accurate as will be shown in the Results section.

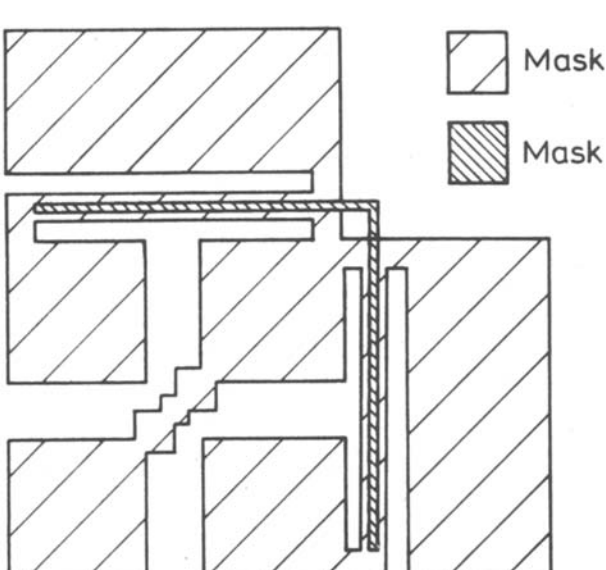

Fig. 3. Standard two mask level form

The mask stepping error can be greatly reduced by including both patterns on the same mask and displacing the second mask to superimpose it. Step and repeat errors of translation are virtually eliminated but any slight rotation of the chip leads to errors because the displacement has to be hundreds of microns to clear the pad areas. Also, it is not possible to misalign by hundreds of microns accurately in some aligners. The standard pattern is therefore unsuitable for accurate measurement of distortion.

Small displacement.—The small displacement pattern (7) was designed to eliminate mask stepping and some mask lithographic errors by using a single mask and reducing the displacement at the second alignment to a few microns. A single pattern has only to be misaligned by about ten microns. Chip rotation effects are negligible and the displacement only has to be accurate to about 2.5 μm. The pattern is shown in Fig. 4. If, for example a conducting layer is being etched, the layer is first defined to leave the shaded area. At the second definition stage the mask is misaligned by a small amount so that the small square at the top right falls in the larger one and the layer is redefined. The resulting pattern is shown in Fig. 4b, with the resistors indicated by heavy shading.

Distortion values are the misregistrations with the misalignment values removed by the computer (6) as mask errors are virtually eliminated. The misalignment values are not generally meaningful because of the special alignment situation associated with the displacement. The small displacement pattern cannot be used with most automatic aligners because of the need for a larger displacement to accommodate the larger auto-align mask.

Protected edge.—A new form for measuring distortion on an automatic aligner and for measuring alignment accurately has been developed. It is called the protected edge form because there are two edge protection masks as well as one critical mask. The critical mask is shown in Fig. 5a. It is designed to be like a perfectly aligned final pattern.

If a conducting layer is defined with negative resist the procedure is most straightforward because the layer has to remain where either the critical mask or

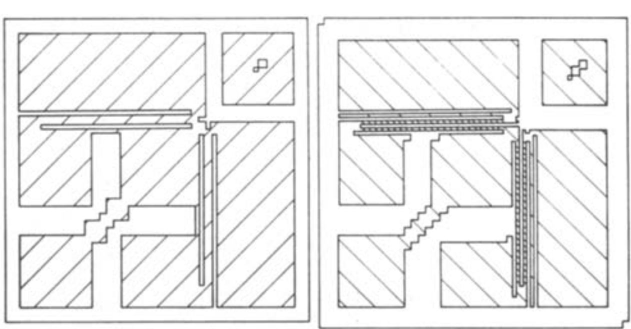

Fig. 4. Small displacement form

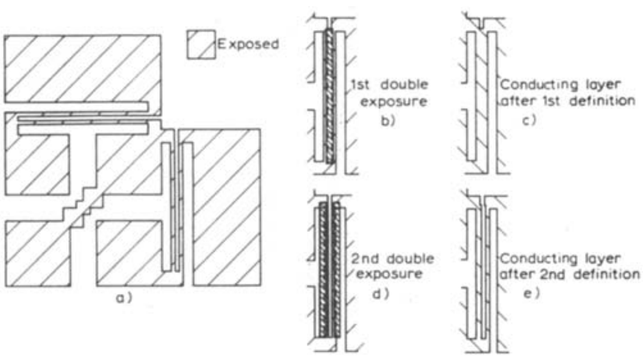

Fig. 5. Protected edge form

the edge protection mask is clear. The critical mask and the inner edge protection mask (dotted) are both exposed as shown for the X-direction in Fig. 5b. The layer is then etched leaving the layer shown in Fig. 5c with outside edges defined by the critical mask. At the second definition step the critical mask is again exposed but an outer edge protection mask is used for the second exposure as shown in Fig. 5d. This time the inside edges are defined by the critical mask and so after etching the final pattern shown in Fig. 5e is obtained.

The misregistration so measured is independent of step and repeat mask errors because resistor edges are defined by the same critical mask. The accuracy with which the resistors are matched on the critical mask will affect these results but this can be measured by a separate test in which only the critical mask is exposed and a measurement made. These measurements can then be removed from other results to give the true misregistration values. The matching on masks is often good enough to make the correction unnecessary.

The independence from step and repeat errors and smallness of other mask errors makes the protected edge form suitable for accurate measurement of distortion. It is ideal for measuring alignment as the same critical mask is used twice so that errors between alignment marks and patterns do not affect the results. The only disadvantages are the more complex processing and somewhat lower sensitivity. The lower sensitivity follows from the need for the protected edge masks to protect one edge of the resistors but not the other. This requires the resistors to be wider.

Comparison between different forms.—In this section the different forms of Stickman pattern are compared. The comparison is summarized in Table I. All forms can be used with any integrated circuit process though some modifications may be necessary.

Alignment apparatus can be assessed on both the standard and protected edge forms, but in the case of the standard form mask errors may be included particularly if alignment markers and measurement patterns are separately exposed. The small displacement pattern has special alignment requirements and so it is not generally suitable.

The standard form is ideal for overall misregistration measurements, particularly on work slices in production, and alignment errors can be separated even with the few process control sites normally present on such slices. The standard form is also the one to use for mask error studies. This can be done using a "low distortion" process, such as double exposure of a single resist layer to define resistors, and looking for common pattern of errors on different slices. The accuracy is then limited by residual distortions including temperature effects. The assessment of mask makers is best done using bright chrome mask layers to form thin film resistors after double exposure.

Distortions can be measured accurately by the small displacement and protected edge forms. The former cannot be used with most automatic aligners but has the advantage of simpler processing and higher accuracy.

Typical device length is 200 microns and an average resistor width of three microns is used to measure errors up to two microns. The minimum lithographic dimension on the mask is six microns as the resistor edges are defined in separate exposures. The only case of a complete resistor appearing on a mask is in the protected edge critical mask when the width is greater anyway. The greater width reduces sensitivity from 6.7% resistor difference per 0.1 μm to 3.3% difference in resistance per 0.1 μm. As misregistrations are decreased finer geometries can be used and sensitivity is further increased. The only limitation is that the resistivity is linear with width and so in general widths should be much greater than conductive layer thicknesses. It is generally possible to measure resistor values to better than 1% on a normal automatic probe and measurement apparatus if four terminal measurements are used. The accuracy is therefore better than 0.01 μm for a 1 μm misregistration. In the Results section it is shown that small misregistrations can be measured with a reproducibility of an order of magnitude smaller than this.

The different forms are suitable for different applications but at least one is suitable for any particular measurement.

Table I. Main properties of different Stickman forms

Device pattern	Standard (STD)	Small displacement (SD)	Protected edge (PE)
Measured directly			
Alignment	yes		yes
Overall misregistration	yes		
Mask errors	yes		
Distortions		yes	yes

Automatic stepper	yes		yes
Electron image proj.	yes	yes	yes
Direct slice writing	yes		
X-ray	yes		yes

Results

Applications are described that illustrate the usefulness of the technique in measuring and identifying causes of misregistration. The different forms can be used to study misalignments, mask errors, and distortions. The measurement of misalignment is straightforward, as described earlier, and the applications outlined here are to the measurement of mask errors and distortions.

Mask errors.—Mask errors have been identified by repetition of errors on different slices (6) and by the pattern of errors (1) using the standard form. Distortion variations were minimized but they do limit the accuracy.

A better method for studying errors on mask machines is to double define bright chrome layers in the mask making machine, again using the standard patterns, and measuring the thin film chrome resistors so formed. The technique has been applied to optical and electron beam mask makers.

Rotational misalignment has little meaning on mask makers or on direct slice writers working from marker arrays. It is useful in these cases to dispense with computer processing of data and have direct read-out of misregistrations. A circuit for direct reading onto a chart recorder is shown in Fig. 6. The resistors r_1 and r_2 are chosen to have the same value but much lower than the Stickman resistors R_L and R_R. By applying the same circuit and voltage V to X and Y direction devices and the outputs to an X-Y recorder, misregistration vectors can be drawn. The technique is also applicable on slices to Y-misregistrations in columns and X-misregistrations in rows where displacements due to rotation are virtually constant. The technique is not applicable if sheet resistance of the conducting layer is variable or if contact resistance is large and variable.

The two standard patterns had to be exposed consecutively on a widely used commercial mask maker as there was no facility for aligning reticles accurately with masks. Even so some misregistrations were ob-

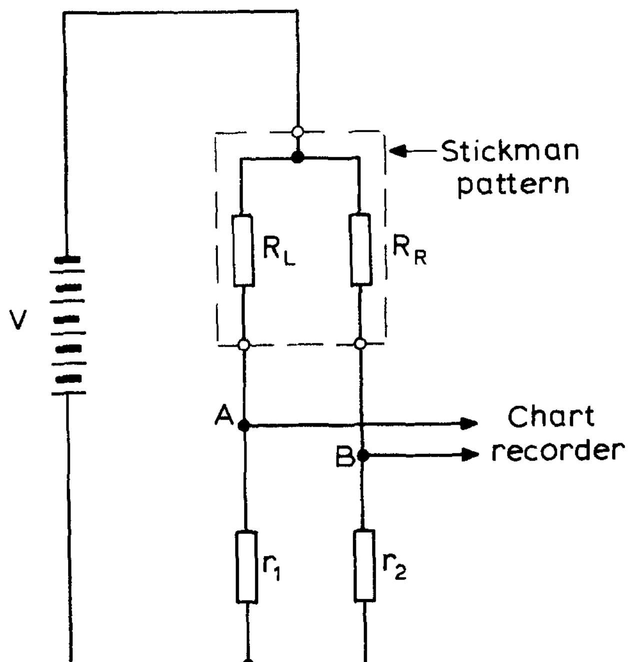

Fig. 6. Circuit for direct recording of misregistrations

served. The reticle contains an 8 × 8 array of devices. Misregistrations in the X-direction for two rows of devices (extending in the X-direction) are shown in Fig. 7(a) and (b). There is a repetitive pattern every 3.8 mm equal to the step and repeat distance. Errors within the pattern (up to 0.06 μm) are due to errors or distortion in the reticle or rotational errors in its placement. It was made on widely used commercial equipment. Misregistration values for each position in a chip are compared to the equivalent position in the first chip to evaluate step and repeat errors. The average values and standard deviations for the 16 positions are plotted against chip number in Fig. 8. Reproducibility over the chip is generally about ±0.003 μm (a few atomic layers) showing how sensitive the technique is. The absolute accuracy is limited by sheet resistance variations and accuracy of the voltage measuring apparatus to about 5% of the misregistration. Step and repeat errors are less than 0.04 μm except for the relatively large change by about 0.15 μm around chip 7. This represents two λ/8 counts on the laser interferometer (λ = 633 nm). The reason for the counting error is being investigated.

It is possible to position patterns on masks with some more advanced mask makers enabling patterns to be written at well-separated times. This gives a more realistic measurement of alignment between different masks or different layers in direct slice writing. Results on an experimental electron beam pattern generator, with a six weeks gap between exposures and

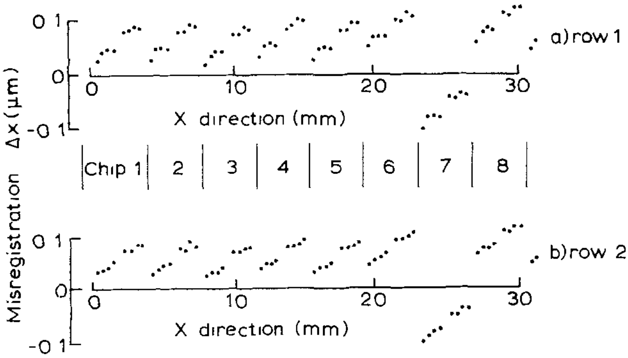

Fig. 7. Misregistrations in double written mask from optical mask maker.

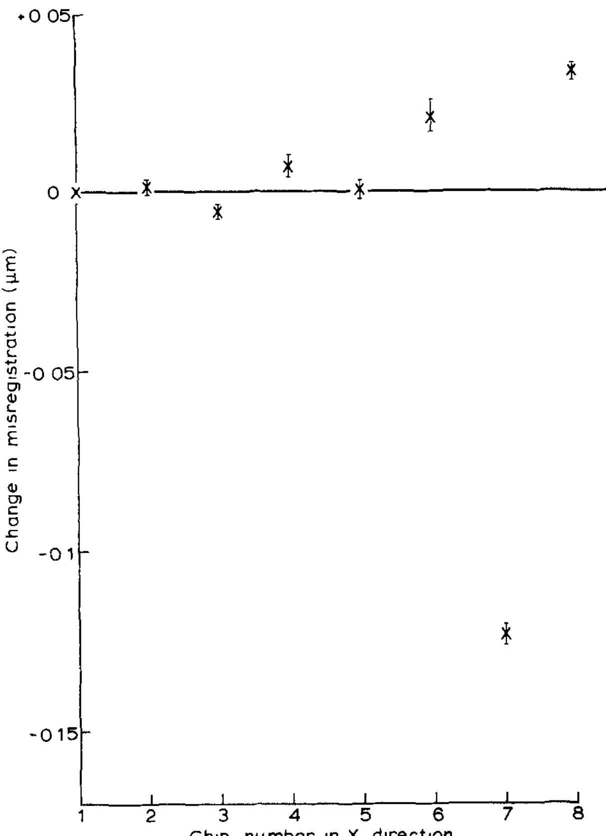

Fig. 8. Step and repeat errors in optical mask makers

incorrect adjustment the second time, are shown in Fig. 9. The outside rectangle represents the edge of the chip and the vectors give errors at 16 places in the chip. The scale for the vectors is given at the top. The sets of three vectors represent three different chips. There can be seen to be a general magnification error common to all chips which is due to a setting up error, but closer inspection shows an additional error in the X-direction. The corners of each chip are defined by markers. The markers in chip 3 (crosses) were read correctly but it appears that the bottom left-hand marker in chip 1 (diamonds) which determines the origin in the X-direction was differently read on the two occasions by about 0.08 μm. This led to differences in the X-direction from chip 3 on the left-hand side of the chip but improving agreement on moving to the right. The same marker was misread in chip 2 (plus signs) but this time it was the right-hand marker and so there is a magnification error causing increasing errors to the right of the chip. This illustrates how the causes even

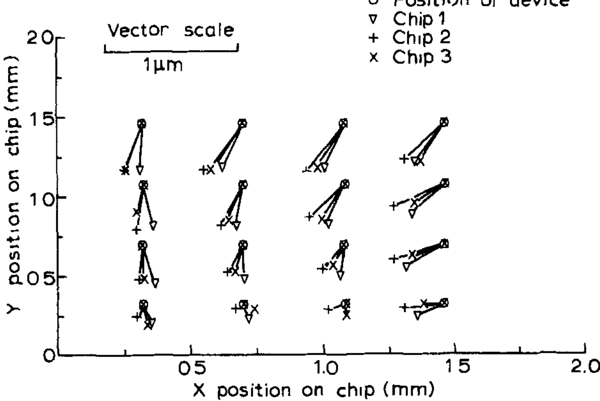

Fig. 9. Repetitive errors in different chips due to electron beam machine adjustment errors.

of small errors can be identified so that steps can be taken to reduce them. Errors were generally less than 0.1 μm when the machine was correctly adjusted (1).

Matching of pairs of resistor patterns is required for the critical mask in the protected edge form. If the critical mask alone is used to define resistors the matching can be investigated. Even with a mask made on an experimental pattern generator errors were only +0.007 μm and correction for such errors is normally unnecessary.

Distortions.—Misregistrations caused by lateral distortions can be measured with the small displacement or protected edge forms. The three common causes are (*i*) mask/slice distortion in the alignment equipment, (*ii*) pattern distortion on projection, and (*iii*) process-induced slice distortion. Distortions only contribute to misregistrations if they change between the two alignment stages.

An example of mask/slice distortion difference is shown in Fig. 10. Vectors representing misregistrations with alignment effects removed are shown in their position on the slice. The misregistrations are due to thermal expansion as the temperature (6) at the two alignment stages differed and the mask had a much higher temperature coefficient of expansion than the silicon slice. The effect can be reduced in some advanced alignment apparatus but such expansion is still important.

One way of compensating for the effect in some aligners is by intentional pattern distortion (8). Such distortion is shown in Fig. 11 where a contraction has been produced intentionally on an electron image projector. Analysis shows the contraction to be linear. On this machine any expansion can be compensated for automatically using signals from markers on the slice.

Distortion of slices by processing have also been observed. Most distortions are roughly linear but if stresses are very large nonlinear effects can occur. An example is shown in Fig. 12 where large stress was intentionally produced by a 0.14 micron thick layer of silicon nitride with a very thin oxide layer below. Such nonlinear distortions have only been found in the presence of a large density of defects.

Conclusions

Three forms of the Stickman resistor pattern (*i*) the standard (*ii*) the small displacement, and (*iii*) the protected edge forms have been described and compared.

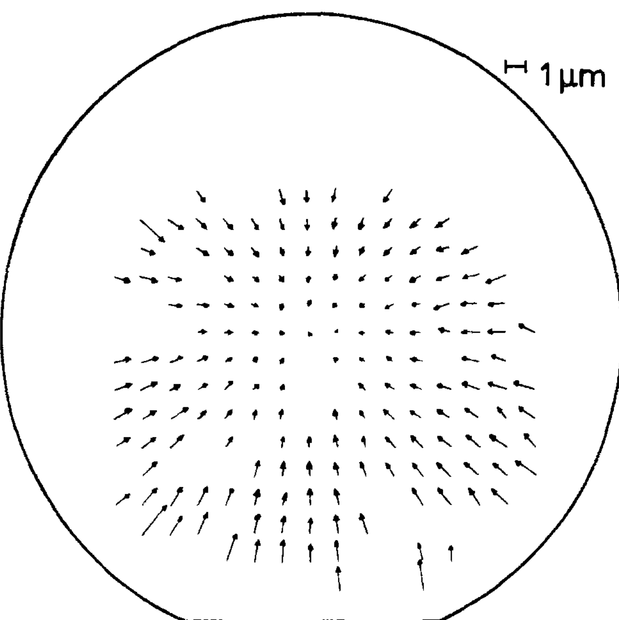

Fig. 11. Contraction of patterns in an electron image projector

It has been shown that alignment, mask errors, and distortions can be measured on any aligner using the appropriate form.

Identifications of errors in optical and electron beam mask makers have been described and observations of slice/mask distortion, projection distortion, and slice distortion outlined.

It has been shown that sensitivity and reproducibility are such that misregistration effects much less than 0.1 μm can be identified and measured to reproducibility of ±0.003 μm using simple apparatus. Accuracy of measurement is limited to about 5% of the total misregistration if the simple apparatus is used but improved to 2% for 1 micron misregistration if sheet resistance is measured on each chip.

ABSTRACT

Surface charges in a zinc-borosilicate glass/silicon system were studied by measuring capacitance-voltage curves of metal-glass-silicon capacitors at various temperatures. The capacitance-voltage curves change remarkably with measurement frequency and temperature. The density of positive fixed charge decreases significantly with increasing glass firing temperature and also when nitrogen gas is added to the oxygen firing atmosphere. On the other hand, the density of the surface state is about (2-6) $\times$ 10^{12} cm^{-2} $\cdot$ eV^{-1} and insensitive to glass firing conditions. The surface charge is positive for n-type silicon and negative for p-type silicon when the Fermi level is near the intrinsic energy level. The surface charges are reversed, however, when the Fermi level is near the bandedge.

Surface passivation using glass powder is effective for achieving good reliability in high voltage silicon power devices since glass is electrically stable, easy to coat as a thick film, resistant to humidity, and has a low ion mobility. Therefore, many glass passivated silicon devices, such as thyristors, transistors, and diodes, have recently been developed.

Glasses as passivants for silicon devices are classified roughly into zinc-based glass and lead-based glass. Zinc-based glass is very stable at high temperature and high electric fields (1, 2), and therefore, is more suitable for achieving high reliability.

It is necessary to know better the surface charge configuration in a glass/silicon system in order to design glass passivated silicon devices accurately. However, not many investigations on this topic have been reported before. It is known that surface charge density changes with glass firing conditions, such as firing temperature and the content of the ambient (3). Many surface states exist at the glass/silicon interface (1, 2) and the flatband voltage is positive for n-type silicon and negative for p-type silicon (2).

However, the changes of surface charge configuration in a glass/silicon system with glass firing conditions have not been studied.

Key words: charge, films, glass.

In this paper, the variations of fixed charge density and surface state density with glass firing conditions and the conductivity-type of silicon substrates are discussed by measuring capacitance-voltage (C-V) curves at various temperatures.

Experimental

In this work, surface charge in a glass/silicon system was measured by metal-glass-silicon (MGS) capacitors at various temperatures. This method, as proposed by Gray and Brown (4), can separate the effects of the fixed charge in glass and surface states at glass/silicon interface, on the surface potential. Table I shows the properties of silicon substrates. The composition of the glass used is: ZnO, 65 weight percent (w/o); B_2O_3, 21 w/o; SiO_2, 8.5 w/o; PbO, 4 w/o; SnO, 1 w/o; and Sb_2O_3, 0.5 w/o. This glass has a

Table I. Properties of silicon substrates

softening point of 645°C, crystallization point of 719°C, and thermal expansion coefficient of 4.0 10^{-6}/°C. MGS capacitors were prepared by following procedure. The glass powder was deposited on the silicon substrate by the electrophoretical method. The colloidal suspension used consisted of isopropyl alcohol as a suspension medium with a small amount of additive electrolyte and glass powder whose size was controlled by decantation. The glass film thickness was controlled to about 10 μm. The deposited glass powder was fired in an oxygen or a nitrogen-oxygen (4:1) mixture at various temperatures. The metal electrodes were formed on the glass film by evaporating aluminum. Capacitance of the MGS was measured in the evacuated chamber at various temperatures by a capacitance bridge. The measurement frequency was 1 MHz unless otherwise noted.

Results and Discussion

Effects of measurement frequency and temperature on the C-V curves.—Figure 1 shows the effect of measurement frequency on the C-V curves for samples made with the glass fired on n-type silicon at 710°C in a nitrogen-oxygen mixed atmosphere. The C-V curve shifts to the positive voltage direction with increasing frequency. It can be seen from this that many surface states with various time constants exist. Figure 2 illustrates the effect of measurement temperature on the C-V curves for the same sample. Here the C-V curve shifts significantly to the negative voltage direction with increasing measurement temperature.

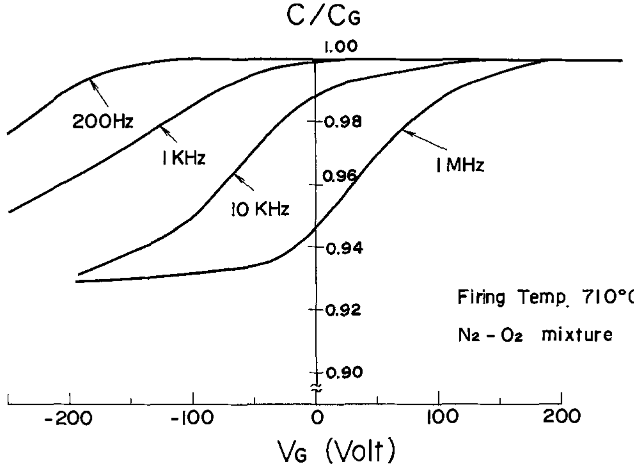

Fig. 1. The effect of measuring frequency on the capacitance-voltage curves of the sample made with the glass fired on n-type silicon at 710°C in a nitrogen-oxygen mixture.

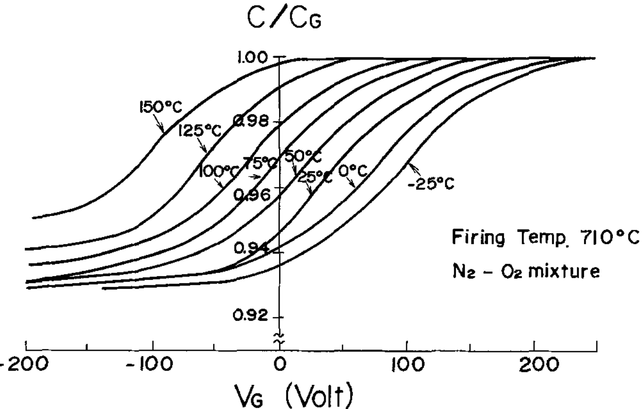

Fig. 2. The effect of measuring temperature on the capitance-voltage curves of the sample made with the glass fired on n-type silicon at 710°C in a nitrogen-oxygen mixture.

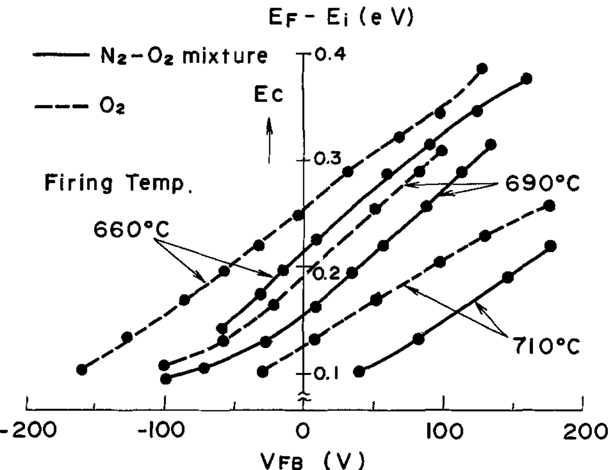

Fig. 3. Flatband voltage of the samples made with the glass fired on n-type silicon at various conditions vs. energy level.

This shows that the surface states are distributed over a wide range of energy levels.

Effect of glass firing condition on surface charge configuration.—Figure 3 shows flatband voltage (V_{FB}) of the samples made with the glass fired on n-type silicon at various temperatures in an oxygen or a nitrogen-oxygen mixed atmosphere *vs.* energy level $E_F - E_i$, where E_F is the Fermi level and E_i is the intrinsic level. The energy level decreases with increasing measurement temperature. The flatband voltage increases with increasing energy level and the curves shift in the positive voltage direction as the glass firing temperature increases. That is, the net surface charge density is more negative as the glass firing temperature increases. These curves are nearly linear and their slopes, nearly equal. That is, the surface state density is nearly equal over a wide range of energy levels. The surface state density for glass firing temperature of 660°C is shown in Fig. 4, as calculated

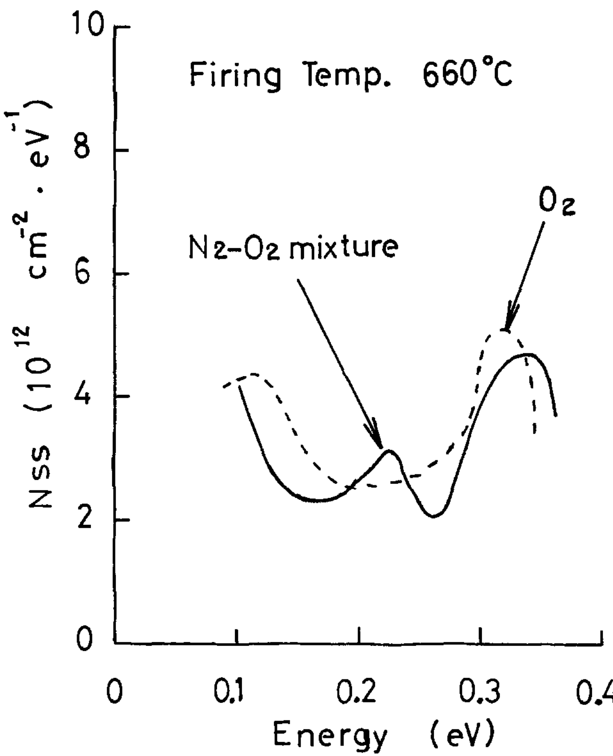

Fig. 4. Surface states density of the samples made with the glass fired on n-type silicon at 660°C in an oxygen or nitrogen-oxygen mixture vs. energy level.

from the experimental results given in Fig. 3. The surface state density is (2-6) $\times 10^{12}$ $cm^{-2} \cdot eV^{-1}$. Therefore, it is felt that the variation of the flatband voltage with the glass firing temperature is due to the fixed charge rather than surface states. So, the positive fixed charges decreases as the glass firing temperature increases. The flatband voltage for the firing atmosphere of a nitrogen-oxygen mixture is larger than that for an oxygen alone. The positive fixed charge decreases when nitrogen is added to the oxygen firing atmosphere.

Effect of the conductivity type of silicon substrate on surface charge configuration.—Figure 5 shows the flatband voltage of the samples made with the glass fired on n-type and p-type silicon *vs.* energy level. The flatband voltage of the glass fired on p-type silicon decreases as the Fermi level moves closer to the valence band. On the other hand, the flatband voltage of the glass fired on n-type silicon shifts to the positive voltage direction, as the energy level moves closer to the conduction band. That is, the flatband voltage of the glass fired on p-type silicon varies differently with measurement temperature as compared to that of the glass fired on n-type silicon. However, the change of flatband voltage with energy level for n-type and p-type silicon are qualitatively the same. The slopes of curve for n-type silicon is nearly equal to that for p-type silicon. Saying it differently, the surface states are distributed similarly in the energy level of the conduction band side and the valence band side as in Fig. 6 calculating from Fig. 5. Only the displacement of the curve along the flatband axis is different. Flatband voltage for p-type silicon at room temperature is negative and that for n-type silicon is positive. These results agree with the results of Goodwin (2). This difference is considered as the difference of the sign of fixed charge. That is, the fixed charge for n-type silicon is positive, that for p-type silicon is negative.

Conclusions

Surface charges in a zinc-borosilicate glass/silicon system were studied by measuring capacitance-voltage curves of metal-glass-silicon capacitors at various temperatures. Capacitance-voltage curves changed remarkably with measuring frequency and temperature due to the existence of many surface states. Net surface charge density varies with glass firing conditions as follows. The positive fixed charge density decreased remarkably with increasing glass firing temperature and also when nitrogen gas was added to the oxygen firing atmosphere. On the other hand, surface state density was about (2-6) $\times 10^{12}$ $cm^{2} \cdot eV^{-1}$ and hardly changed with glass firing conditions. Moreover, the surface charge was positive for n-type silicon and negative for p-type when the Fermi level is near the intrinsic energy level. On the other hand, the surface charge was reversed when the Fermi level is near the bandedge.

Tapered Windows in SiO_2, Si_3N_4, and Polysilicon Layers by Ion Implantation

J. Götzlich and H. Ryssel

Fraunhofer-Institut für Festkörpertechnologie, 8000 München 60, Germany

ABSTRACT

In integrated circuit production, tapered windows are important for good step coverage of subsequent deposited layers. We show that by implantation of Ar and As ions into SiO_2, Si_3N_4, and polysilicon layers the slope angle of window walls can be reduced. The slope angle is determined by the ratio of the etch rates of the undamaged region to the damaged top region of the layer. Depending on ion species, ion dose, ion energy, and etching conditions we could achieve minimum angles of about 10° in these layers.

In semiconductor technology, the definition of structures in layers of SiO_2, Si_3N_4, or polycrystalline silicon is usually made by photolithography, which is followed by chemical or plasma etching of the film. If the etched structure is coated by another film, the step coverage of this second film at the windows is determined by the wall contour of the window. The step coverage is especially important with metal layers, since at a steep edge the metal is thinner and can cause severe problems with reliability (1). Many investigations have been performed to optimize step coverage by a proper design of the evaporation equipment. New evaporation techniques using magnetron sputtering have brought a significant improvement. The most reliable method is, however, the tapering of the slope of window walls.

Since all layers to be tapered are amorphous or polycrystalline, they are etched isotropically using wet chemical etches or standard plasma etching. If the adherence of the etching mask is good, the slope of the window wall will reach asymptotically 90° in case of overetching (2). Shallow slopes in homogeneous films can be produced by lifting-off the photoresist during the etching process. The slope angle is then determined by the ratio of lateral lift-off rate to the etching rate of the film. However, this technique is hard to control and therefore the results are not well reproducible.

A more reliable and very often used method is the reflow of phosphorus-silicon-glass (PSG). PSG is deposited at low temperatures from silane, oxygen, and phosphine in a nitrogen atmosphere and reflowed at about 900°C, resulting in very smooth window edges (9). Another reliable method for tapering windows is the application of a two-level structure, in which the top part of the layer etches faster than the lower part. The sine of the slope angle of the lower part of the layer is given by the ratio of the etching rates of the two components of the film. Even if the layer is overetched, this angle will have a constant value (3). This sandwich structure can be achieved in two different ways: First, by changing the chemical compounds during the deposition of the layer (*e.g.,* CVD layers) (4), and second, by bombardment of the layer with energetic ions which damage the surface and thus enhance the etching rate.

Moline *et al.* (5) reported on the tapering of SiO_2 using Ar ions. North *et al.* (3) also used Ar ions to taper PSG glass and Bell and Hoepfner (6) used Ar ions from an ion-etching machine for tapering SiO_2 layers.

In this paper we report on the tapering of window walls in SiO_2^-, $Si_3N_4^-$, and polysilicon layers by ion implantation using argon, arsenic, and boron ions with subsequent chemical or plasma etching.

Key words: ion implantation, tapered windows, damage enhanced etching.

Experimental Techniques

For all experiments, phosphorus-doped <111>-oriented silicon with a resistivity of 1-10 Ωcm was used. For the experiments with SiO_2, the silicon wafers were oxidized at 1000°C for 1 hr in a wet oxygen atmosphere, forming an SiO_2 layer of about 0.4 μm. The silicon nitride layers were deposited in an SiH_4-NH_3-N_2 atmosphere at 800°C. The film thickness was 0.4 μm. The deposition of the polysilicon layers was done in an SiH_4-N_2 atmosphere at 700°C. The 0.9 μm thick polysilicon was deposited on a thin SiO_2 layer, which acted as an etch stop.

The wafers were then implanted with Ar-, As-, and B-ions at energies between 50 and 200 keV and doses of 10^{12}-10^{16} cm^{-2}. To obtain the different implantation doses, a variable beam stopper was used, which made it possible to implant up to six various doses on one wafer. Thus, all samples to be compared were processed in the same way during the photolithographic and etch processes.

Before applying the photoresist to define the etch windows in SiO_2 and polysilicon, the wafers were baked in a nitrogen atmosphere at 300°C for 30 min. Nevertheless, it was necessary to apply an adhesion promoter solution to obtain reliable results. The nitride layers were CVD coated with a 200 nm thick oxide layer in an SiH_4-O_2-N_2 atmosphere at 450°C. The SiO_2 was etched in buffered hydrofluoric acid. The Si_3N_4 was etched at 160°C in conc H_3PO_4, using the SiO_2 layer as a mask. The etching solution for the polysilicon consisted of 100 HNO_3:3HF:4H_2O. Besides these procedures, polysilicon layers were etched in a CF_4 plasma in order to compare plasma etching with wet chemical etching.

The etching times were 2-4 min for the SiO_2, 60-80 min for the Si_3N_4, and 0.5-1 min for the polysilicon layers. The relative amount of overetching after etching through the layer was about 10%. After etching, the samples were cleaned using organic solvents and then cleaved. The cross section of the window wall was determined using a scanning electron microscope (SEM). The uncertainty in the determination of the slope angle of the window walls was ± 2°. The reproducibility was also ± 2°.

Results and Discussion

In Fig. 1, SEM photographs are shown for typical etched structures in Si_3N_4 layers implanted with argon ions. For all doses shown, a reduction in the slope angle can be seen. The top layer of 1000Å shows a steeper slope. This can be attributed to the thickness of the damaged layer, which shows a nearly constant enhanced etching rate. Using lower implantation energies, this effect can be reduced.

The implantation of Si_3N_4 layers with As ions (80 keV) reduced the taper angle to 11° for a dose of

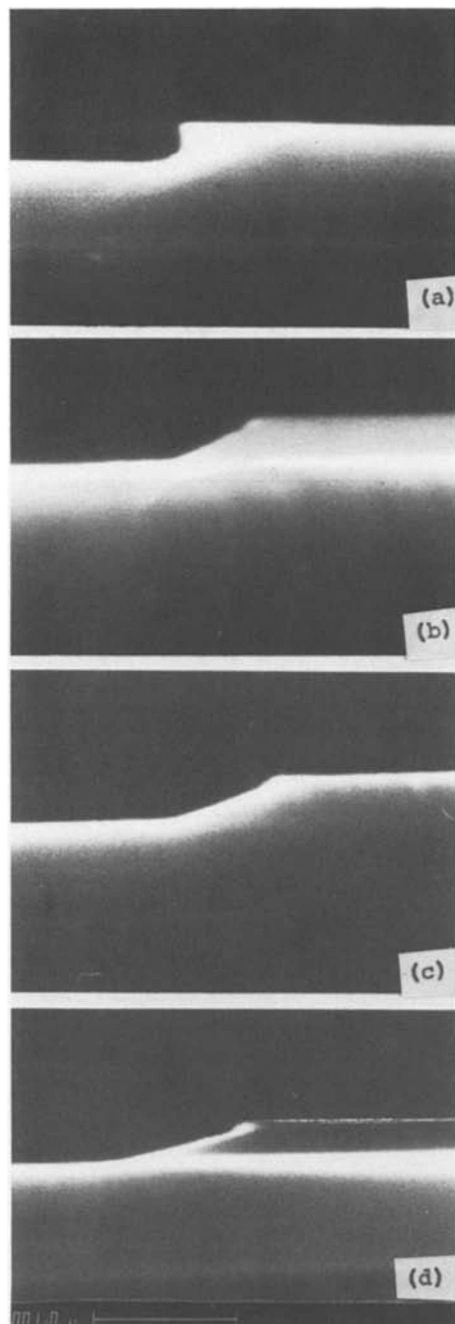

Fig. 1. Scanning electron micrographs of wall profiles in Si_3N_4 layers after Ar implantation with 50 keV and various doses: (a) no implantation; (b) $1 \cdot 10^{15}$ cm^{-2}; (c) $5 \cdot 10^{15}$ cm^{-2}; (d) $1 \cdot 10^{16}$ cm^{-2}.

10^{16} cm^{-2} (Fig. 2). There seems to be a saturation effect for the higher ion doses. This saturation does not occur until doses greater than 10^{15} cm^{-2}. The same dependence is observed for the implantation of 50 keV Ar ions; the slope angle decreases continuously to 14° for the 10^{16} cm^{-2} dose. In both cases (Ar and As ions), there was a step in the profile for doses greater than 5×10^{14} cm^{-2} (see Fig. 1). This step was not taken into consideration for the results in Fig. 2. The height of this step (about 0.1 μm) should indicate the depth to which the enhanced etching occurs.

In Fig. 3, the slope angles of window walls in SiO_2 after implantation with Ar and As ions, respectively, with different ion doses are shown. Implanting Ar ions with 50 keV or As ions with 80 keV, the slope angle can be reduced to 11° or 12°, whereas by implantation of Ar ions with 200 keV the minimum angle is about 24°. In all cases there is a saturation effect which depends on ion dose, species, and energy. This saturation

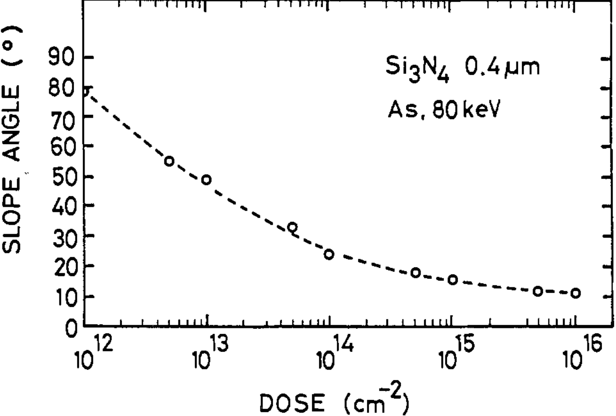

Fig. 2. Slope angles of window walls in Si_3N_4 vs. ion dose after implantation with 80 keV As.

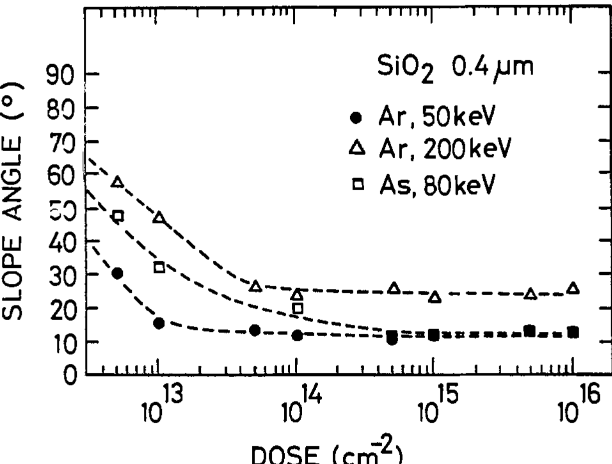

Fig. 3. Slope angles of window walls in SiO_2 vs. ion dose after implantation with 50 keV and 200 keV Ar and 80 keV As.

effect should be correlated with the saturation of defects produced by ion implantation. The As-implanted samples showed a step in the window profile for doses greater than 5×10^{13} cm^{-2}. The height was the same as for the Si_3N_4 layers (see above). In the case of Ar implantation, no step could be observed.

The results of the experiments with polysilicon layers are shown in Fig. 4 and 5. These measurements showed no effect of the ion implantation on the etching rate for doses up to 10^{13} cm^{-2}, *e.g.*, a steep slope of 80°-90° was observed. For ion doses greater than

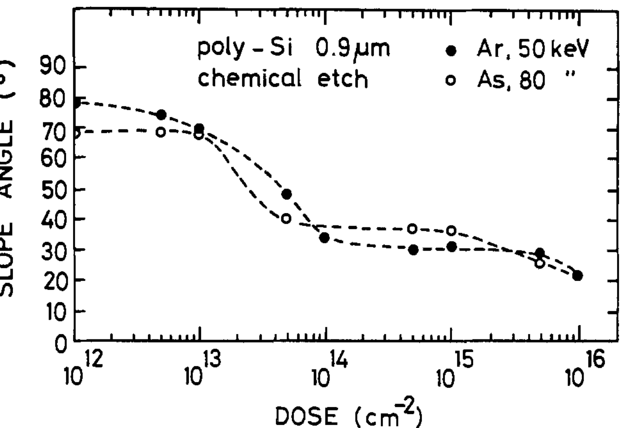

Fig. 4. Slope angles of window walls in polysilicon vs. ion dose after implantation with 50 keV Ar and 80 keV As and chemical etching.

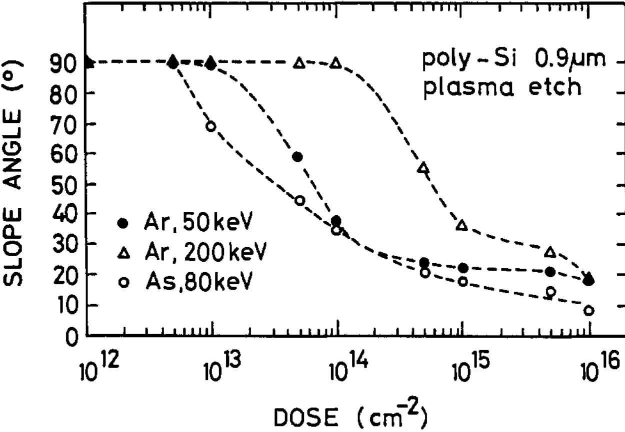

Fig. 5. Slope angles of window walls in polysilicon *vs.* ion dose after implantation with 50 keV and 200 keV Ar, 80 keV As and plasma etching.

10^{13} cm^{-2} there was a reduction of the slope angle in the case of the 50 keV Ar and the 80 keV As implantation for the chemically etched samples as well as for the plasma-etched layers. The minimum slope angle achieved with plasma-etched samples was 9° (1×10^{16} As/cm^2, 80 keV), whereas with the chemically etched samples the angle could only be decreased to 23° (1×10^{16} cm^{-2}, 80 keV As and 50 keV Ar). There is also a different behavior in respect to the formation of a step in the wall profile between the two sets of samples. The chemically etched samples showed no step, whereas for the plasma-etched samples, there was a step with a height of 0.1 µm (Ar, 50 keV) or 0.2 µm (As, 80 keV) for doses greater than 5×10^{14} cm^{-2}. The implantation of Ar with 200 keV in polysilicon layers only had an influence on the slope angle for ion doses greater than 1×10^{14} cm^{-2}. The slope angle of these 200 keV samples could only be measured in the case of plasma etching because of the steep overhanging step in the case of chemical etching. The height of this step was about 0.25 µm. This step can be explained by a lower etch rate at the surface, since the damage is produced predominantly in a deeper region. The plasma-etched samples showed only a step for the 10^{16} cm^{-2} implantation; the height was as above.

The implantation of B ions with 60 keV in SiO_2 and polysilicon layers gave no reliable results. At the higher ion doses (10^{15}-10^{16} cm^{-2}) a taper angle of about 40° could be observed but the reproducibility was only ± 10°. Most of the samples also showed a high step of about 0.3 µm in the wall profile, due to the large range of the ions.

All layers (SiO_2, Si_3N_4, poly-Si) showed the formation of a step profile for some implantation conditions such as high ion energy or high ion doses. The height of this steeper step on top of the layers was generally greater than the range of the implanted ions, and especially greater than the range of the damage created during the ion bombardment. Usually, the height of this step is about 0.05 to 0.1 µm more than the projected range of the ions. A possible explanation is that there exists a transition region with the above thickness, in which the steep slope at the surface is passed into the reduced slope (which is determined by the ratio of the etching rates of the damaged to the undamaged region). This observation should be taken into account if one adjusts the ion energy for tapering window walls. Moreover, one should take into consideration that any annealing of the implantation damage could change the slope angle of the wall profile. Such an annealing can occur not only during technological processes at low temperatures, but also already during the implantation process due to substrate heating (7, 8).

Conclusion

We have shown that in SiO_2, Si_3N_4, and polysilicon layers, the slope angle of window walls can be tapered by ion implantation. The slope angle depends on ion species, ion dose, and ion energy. The minimum angles achieved here were about 10°, *e.g.*, the etch rate of the damaged surface region showed a maximum enhancement of about 6 by ion implantation. The observed step in the profile can be reduced by reducing the ion energy. The reduction of the energy at lower ion doses gives the same slope angle as with the higher energy.

Neutron Activation Study of a Gettering Treatment for Czochralski Silicon Substrates

ABSTRACT

A pre-process gettering treatment is described for Czochralski silicon substrates which removes essentially any transition group metal contaminants present in the wafer and continues to getter contaminants during subsequent device processing. Laser induced damage (LID) on the back surface of the wafer, a modified high temperature HCl treatment, and formation of oxygen precipitates in the bulk of the wafer only, are used as a three-step gettering process. Neutron activation analysis (NAA) was used to monitor the gettering behavior of each individual contaminant species and shows that the combined treatment is indeed nearly 100% effective in removing impurities, both from starting substrates and from processed wafers. Removal of impurities from the starting substrates is important in order to prevent the formation of oxidation induced stacking faults (OSF), which are nucleated by impurities and then become decorated with impurities making them much harder to getter (1). Holdtime performance of 4K and 16K dynamic RAM's fabricated on substrates treated in this manner served to evaluate the effectiveness of the treatment. Significant improvement can be achieved for bulk substrates. However, the performance of epitaxial silicon on low resistivity substrates cannot be matched since the low resistivity substrate in the EPI case additionally suppresses the minority carrier diffusion current from the bulk of the wafer. The individual steps of the treatment are: (*i*) produce laser induced damage on the back surface of the wafers by means of powerful, partially overlapping laser pulses; (*ii*) ramp from 950° to 1250°C in 0.5% O_2, 0.5% HCl, balance argon; (*iii*) oxidize at 1250°C for 8 hr in dry O_2 + 0.5% HCl, then ramp down to 950°C. Keeping the oxygen concentration to 0.5% during step (*ii*) is important to prevent formation of a thick oxide film during this step. The long oxidation at 1250°C both depletes interstitial oxygen at the Si surface, thus preventing formation of OSF, and causes formation of oxygen precipitates in the bulk if the initial O_i concentration is high enough. Oxygen precipitates in the bulk are a valuable means of gettering.

The detrimental effect of transition group metal impurities on device performance is well documented, both through the formation of microdefects in the silicon lattice during high temperature treatments and through their action as regeneration-recombination centers. The microdefects are in fact decorated by impurity precipitates. Impurities located at the surface are implicated in the formation of oxidation-induced stacking faults. Careful cleaning, prior to oxidation is a necessary but often insufficient condition for avoiding the OSF. The device sensitivity to transition group metal contamination depends on the required performance of the device and on the process technology used.

Metal impurities can be "gettered" from the bulk of the silicon by a variety of means, such as volatilization as chlorides during heat-treatment in Cl-containing ambients, diffusion into regions of enhanced metal solubility (N+ or P+ regions), or precipitation at deliberately introduced crystal defects. A number of techniques have been used for the controlled introduction of such crystal defects, such as ion implantation damage, stress-inducing surface films, surface abrasion, and oxygen precipitates, to which now is being added lattice damage from laser pulses of sufficient power to cause local melting of the silicon. The wavelength employed determines the distance over which the energy is absorbed by the silicon, and hence the depth of damage introduced. All of the lattice-damage-type gettering procedures require that the damaged region be located remote from the device areas; usually the back side of the wafer is used for this purpose (except in certain ion implantation applications) (2). The metal impurities are then made to diffuse into the deliberately damaged regions during a high temperature treatment, where they are held quite tenaciously and are not then involved in space charge leakage currents, provided the lattice damage survives the subsequent heat-treatments.

Gettering by oxygen precipitates poses certain problems of its own. Oxygen is a regular unintentional dopant in Czochralski grown silicon, though the level of oxygen concentration depends on several factors, such as rotational speed during crystal growth (3), ingot diameter, distance from the seed end, etc. If the oxygen concentration is high enough for precipitation of oxygen to occur during heat-treatments, then precipitates can form in the device areas, giving rise to microdefects and deterioration of device performance. On the other hand, oxygen precipitates are a valuable means of gettering. Their presence is thus desirable, but only in the bulk of the silicon, not in the device areas near the front surface of the wafer. The means of achieving this oxygen distribution was previously (4) described; it requires a prolonged heat-treatment in oxygen at 1250°C.

Gettering treatments are usually applied fairly well into the processing sequence, often as one of the last high temperature treatments. At this stage, however, the original crystal perfection of the surface-near layers of the wafer may already have been degraded, and impurities are precipitated at lattice defects where they are difficult to getter. In a way, the gettering treatment is being applied too late. Table I shows how

* Electrochemical Society Active Member.
Key words: gettering, HCl, laser damage, silicon defects.

inefficient N+ diffusion gettering from the back surface can sometimes be at this stage. In this example, a 4K dynamic RAM wafer pulled from the processing sequence, the gold contamination was reduced significantly, but the copper contamination remained high; the inverse occurs just as frequently, sometimes even both Au and Cu remain high.

Gettering studies in the past have mostly utilized device performance after the gettering step as the main diagnostic criterion. However, no detailed information about the concentrations of the different contaminant species present in the device regions of silicon wafers before and after the gettering step can be obtained in this way. In view of the exceedingly small amounts of contaminants already sufficient to degrade device performance, only neutron activation analysis has the necessary sensitivity to produce such information. NAA has therefore been applied throughout this study and has given firm quantitative results. Device performance after gettering confirmed the predictions based on NAA and expected from general principles. Systematic NAA is also a valuable and versatile method of process control.

Table II illustrates the correlation between level of contamination and generation lifetime or device holdtime. Concentrations of more than a few times 10^{12} atoms of Cu or Au per 3 in. silicon wafers are definitely to be avoided. While Cu and Au are among the most deleterious contaminants, other transition group metals also give rise to deep lying recombination-generation levels in silicon and can be equally detrimental. The concentration at which a given impurity species begins to cause trouble is a complex function of its capture cross sections for electrons and holes, its solubility and diffusivity, etc. However, one may expect that these concentrations will be higher than for Cu or Au.

The ideal gettering treatment for transition group metals in silicon should accomplish the following objectives:

1. It should remove detrimental impurities from the surface-near layers of the silicon wafer prior to the first high temperature oxidation step while maintaining the perfection of the silicon lattice near the surface where devices will be located.

2. It should continue to exert a gettering action throughout the device fabrication process, *i.e.*, the gettering mechanism must be able to survive prolonged high temperature treatments.

3. In particular, it must prevent impurities introduced into the silicon during later steps of device fabrication from becoming lodged at crystal defects near the sensitive front surface, in other words, it must prevent formation of oxidation-induced stacking faults throughout the device fabrication process.

These objectives can be achieved by a 3-step gettering process which consists of the following steps:

1. Applying laser induced damage (LID) to the back surface of the silicon wafers. The resulting damage is so severe that it survives essentially any annealing steps without losing its gettering ability, as demonstrated in separate experiments (5).

2. A high temperature HCl treatment in the presence of only a trace of oxygen. Some oxygen is necessary to prevent attack on the silicon, but higher concentrations of oxygen would cause growth of a thick (≧1000Å) oxide film; this impedes the outdiffusion of many transition group elements which therefore cannot react with and be transported away by the chlorine. Gold and the platinum group metals cannot be gettered by the HCl treatment because of the thermodynamic instability of their chlorides at high temperatures. For the gettering of these elements, a solid-state sink (LID layer, oxygen precipitates, or N+ diffused layers) is thus indispensable.

3. Depletion of interstitial oxygen (O_i) in the surface-near layers of the silicon wafers to a depth of about 120 microns by means of a high temperature anneal in oxygen (4). Formation of a thick oxide film eventually starves the Si/SiO_2 interface of oxygen from the gas phase (parabolic rate law), so that apparently the interstitial oxygen near the silicon/SiO_2 interface is consumed by this reaction. This depletion of oxygen in the surface-near layers has been proved both by charged particle activation analysis ($^{16}O(^{3}He, xp)F^{18}$; work performed for Bell Labs at the Texas A&M University, Center for Trace Characterization), and by microscopic examination in conjunction with cleavage and Secco-etch studies.

We have chosen 450 min at 1250°C in dry O_2 + 0.5% HCl for this step. In silicon wafers with an initial (O_i) content of more than about 30 ppm,[1] this treatment also results in the simultaneous precipitation of oxygen-silicon complexes in the bulk, but not in the surface-near layers of the wafers. These precipitates then become sinks for impurities introduced via the front surface during device processing. On silicon wafers with less than about 30 ppm (O_i) such precipitates cannot form and here the LID layer on the back surface continues to exert its gettering action. This is an important point because the interstitial oxygen concentration on some ingots can be less than 30 ppm and can also be nonuniform, so that even an average oxygen content above 30 ppm does not really guarantee formation of oxygen precipitates forming a continuous sheet in the bulk of any given wafer. This is particularly true of the butt end of an ingot. The thick oxide film grown during the 1250°C anneal can also be used as the initial oxide for device fabrication.

Experimental

Materials preparation.—All of the silicon wafers were cut from Czochralski boron-doped (100) oriented ingots of 3 in. diam and a fairly high oxygen content (~35 ppm). The resistivity ranged from 5.5-9.3 Ω-cm, and nominal thickness of the finished substrates was 20 mils. They were chem-etched on both sides and polished on one. Their back surfaces were subjected to laser damage as detailed in Table III. Prior to use they were again cleaned in hot ammonium hydroxide-hydrogen peroxide solution.

In many experiments previously oxidized and then neutron activated wafers were used for investigation of the three separate gettering mechanisms (HCl, LID, layer, oxygen precipitates). The activity of these samples had decayed to essentially zero over periods of

[1] The infrared oxygen concentration determination is based on ASTM F-121-79 "Interstitial atomic oxygen content of silicon by infrared absorption."

Spot overlap	30%

many months of storage, but their impurity contents were accurately known from the previous NAA results. These wafers, of course, contain initially very severe lattice damage from the previous neutron activation step. Some but not all of this damage can be annealed out. [During our neutron irradiation, fast neutrons with energies above 1 MeV were present as well, at a concentration of about 10% of the thermal neutrons. While fast neutrons do not contribute to the activity of isotopes formed by (n,gamma) reactions, they cause most of the lattice damage; this severe damage, in conjunction with appreciable contamination, makes complete annealing of lattice defects very difficult.] These wafers are therefore especially difficult to getter, and results obtained on them represent "worst possible cases."

High temperature treatments.—Table IV summarizes the separate steps of the cleaning-gettering-oxidizing treatment. Step 2 details the HCl cleaning and gettering during ramp-up from 950° to 1250°C, step 3 the 1250°C anneal in dry O_2 + 0.5% HCl. Neither the oxygen nor the HCl concentration is very critical; in fact, it is quite difficult to maintain a flow rate of exactly 0.5%. However, the oxygen concentration, on the one hand, should be kept to the level necessary to prevent pitting of the silicon surface, but, on the other, should be low enough that not more thon 100-200Å of oxide will grow during step 2. The HCl concentration, on the one hand, should be kept high enough to remove contaminants from the silicon as chlorides and to prevent indiffusion of additional impurities during the 8 hr 1250°C anneal in dry O_2, but, on the other hand, must be low enough to avoid any trouble due to phase segregation at the Si/SiO_2 interface (6). Throughout this work we have not observed troubles neither due to phase segregation, nor due to penetration of dislocations from the LID layer to the front surface, however, these are potential difficulties one has to watch for.

Neutron activation and analysis.—Many of the transition group metals, especially those of the stainless steel family, produce only very long-lived radioisotopes under neutron bombardment. In order to have sufficient sensitivity for these elements at the concentration levels at which they can be detrimental in silicon, long irradiation and long spectrum acquisition times are required (the saturation factor of the activity reached during neutron irradiation is given by $S = 1 - e^{-\ln 2 \cdot T_{irr}/T_{1/2}}$, where T_{irr} is the time in the reactor, and $T_{1/2}$ the half-life of any given isotope, both measured in the same time units. It is obvious that S will remain very small if $T_{irr}/T_{1/2}$ is a small quantity). Samples were therefore routinely irradiated for 120 hr at core face of the Union Carbide Research Reactor at Tuxedo, New York 10987; the flux at this position is approximately 7E12 thermal neutrons cm^{-2} sec^{-1} (averaged over the diameter of a 3 in. wafer), with an epithermal component of about 3%. Further details are given in the preceding paper by Schmidt and Pearce. (7).

Table IV. Details of gettering procedure

1. Subject back surface to laser-induced damage (LID).
2. Ramp up from 950° to 1250°C over a period of about 20 min in a mixture of 0.5-1% O_2, 0.5-1% HCl, balance argon.
3. At 1250°C, substitute dry O_2 for the argon, but keep HCl flowing; keep at 1250°C for about 8 hr. Ramp down to 950°C in the same ambient.

After cleaning, wafers were measured for 18 hr in close proximity to the end cap of a 46 cm^3, closed-one-end coaxial lithium-drifted detector, connected via a spectroscopy amplifier and ADC to a computerized 4096 channel analyzer. The measuring system and the concentration evaluation have been described in Ref. (8). It should perhaps be pointed out that the volume of data generated by this study as well as by continual production control was so large that it could not have been handled readily by conventional neutron activation analysis in which a standard for each element to be determined is co-irradiated with the unknown samples. The Absolute Counting method of analysis does not require such standards and is consequently much faster. It is also described in Ref. (8).

Distribution of impurities between the silicon wafer and the LID layer were determined by measuring the same wafer before and after etch-off of the LID layer in 5 parts nitric, 3 parts hydrofluoric, 3 parts acetic acid mixture. The acid etch was always followed by a double clean in hot $HCl-H_2O_2$ solution to remove chemisorbed impurities from the silicon surface; without this precaution, especially gold determination can give completely misleading results.

Device fabrication.—4K and 16K dynamic memory devices were fabricated on substrates of the description given under "Materials preparation." Half of the wafers received the laser treatment only, the other half received LID plus the "full treatment"[2] (see Table IV) prior to being fed into the normal device fabrication process. Split lots of the normal production served as controls. In the case of 4K dynamic RAM's, comparison was made between the performance of devices on untreated bulk substrates and on bulk substrates having undergone the procedures of Table IV described before. In the case of 16K dynamic RAM's, a comparison was also made between the performance of devices on gettered bulk substrates and on epitaxial silicon on highly doped but nongettered substrates.

Results

Table V shows impurity concentrations on two starting substrates of good crystal quality before and after removal by etching of the LID layer. Only a few impurities show up, and their concentration, with the exception of gold, is very low. This is a consequence either of the purity of the starting material or of the gettering by the HCl treatment. Removal of the LID layer then eliminates the remaining impurities.[3]

The situation changes drastically if previously oxidized and then neutron activated substrates are used for the experiment as shown in Table VI. As shown in a companion paper (7), oxidation in steam or in dry oxygen without HCl leads to a strong contamination of the silicon. These impurities are tightly held at crystal defects produced by the oxidation and by the neutron irradiation and mostly refuse to be gettered into the LID layer. Note, in particular, the very high

[2] By "full treatment" we mean LID + 0.5% HCl-0.5% O_2 ramp-up in argon + 8 hr heat-treatment at 1250°C in dry oxygen.

[3] The high temperature treatments were performed in a furnace located in a laboratory otherwise engaged in gold metallurgy on silicon. As a consequence, contamination with small amounts of gold was very difficult to avoid.

remaining copper concentration, a consequence of the omission of the HCl gettering step in this experiment.

Table VII shows that the combination of gettering by HCl and LID layer is capable of extracting the impurities even from a severely damaged silicon lattice. Only the gold concentration remained unchanged. As pointed out in footnote 3, we cannot be sure in the case of gold that we are not looking at an accidental recontamination after the high temperature treatment. Combining the information of Table VI and VII leads to an interesting conclusion. If depleting impurities at the silicon/ambient interface were the only function of the HCl at high temperature, *i.e.*, providing a concentration gradient, then one would expect that the concentration gradient provided by the LID layer should also suffice to attract impurities into the LID layer (case of Table V); this, however, essentially does not happen in the absence of HCl.

In the presence of HCl, however, impurities do diffuse into the LID layer and remain there, at least in part, in spite of the presence of the HCl. It appears that the impurities in the silicon are mobilized in the presence of HCl in a high temperature ambient.

It is generally considered that chlorine (the active species resulting from the interaction of HCl with oxygen) does not penetrate into the silicon. Neutron activation studies on silicon wafers oxidized in dry oxygen + 1% HCl at 1150°C have indeed shown that essentially all of the chlorine present on the sample is contained in the oxide film near the SiO_2/Si interface, and disappears from the sample upon etching in HF.[4] This result, however, was obtained on wafers cooled down to room temperature after the oxidation in dry O_2 + 1% HCl and does not give information about the presence of chlorine in the silicon at the high temperature.

[4] P. F. Schmidt, unpublished work.

* Iron completely removed, concentration of other impurities decreased by the ramp-up 950°-1250°C in 0.5% HCl-0.5% O_2.

All observed facts would find a logical explanation if chlorine is indeed to some extent soluble in silicon at high temperature, but is expelled from the crystal during cool-down due to a strong retrograde solubility as a function of temperature.

The effect of oxide films on suppressing the outdiffusion of certain impurities during the 950°-1250°C ramp-up in 0.5% HCl (no LID gettering) is shown in Table VIII. Only copper is always gettered under these circumstances. The getterability of Fe and of Cr depends on their location: if contained in the oxide film itself (probably even in the outer layers of the oxide film) they are quantitatively removed. But if contained in the silicon substrate, they are not. This effect is discussed in a companion paper (7). Co and Ni are very difficult to getter from a damaged Si lattice in the presence of an oxide film. Data on gold have been omitted in this table since gold cannot be gettered by high temperature HCl treatment due to the thermodynamic instability of its chloride. The conventional "dry oxygen + 1% HCl" treatment at 1000°-1100°C is thus not really a gettering treatment. It keeps additional impurities from getting into the silicon, but the concentration of impurities already in the silicon, with the exception only of copper, will not be strongly decreased by this treatment.

Oxygen precipitates forming in the bulk of the silicon wafer will eventually compete with the LID layer for the available impurities. Thus removing a LID layer from the wafer which has seen the 1250°C anneal in oxygen +0.5% HCl will result in a wafer which appears to be slightly more contaminated than a wafer which was merely subjected to the ramp-up-and-down in 0.5% each of O_2 and HCl, balance argon, with the LID layer in place. However, the impurities remaining on the wafer are tied down in oxygen precipitates and are not located near the surface of the wafer.

A comparison between device performance on gettered *vs.* nongettered bulk substrates, and also between gettered bulk substrates *vs.* epi on low resistivity p-type substrates, is given in Table IX in terms of the ratio of the percentage of devices failing the 4.4 msec Holdtime test. The gettered bulk substrates outperform the nongettered bulk substrates significantly, but the devices made on epitaxial silicon also outperform the devices on gettered bulk substrates by a similar margin.

Table IX. Improvement of hold time by pre-gettering of substrates

Dynamic RAM's on bulk Czochralksi silicon

Ratio % of device failing 4.4 millisecond test (at 90°C)

4K Dynamic RAM, lot 819	Non-gettered / Gettered = 3.28
4K Dynamic RAM, lot 7228	Non-gettered / Gettered = 1.91
16K Dynamic RAM, lot 1044	Non-gettered / Gettered = 1.57
16K Dynamic RAM's, lot 1044 and devices made on epi on low resistivity substrates	Gettered bulk substrates / Epi on low resistivity p-type = 2.52

This is a consequence of the suppression of the minority carrier diffusion current from the bulk of the wafer by the low resistivity epi substrates. This component of the leakage current is especially significant at elevated temperatures (9). Suppression of the diffusion component of the leakage current on bulk silicon can also be achieved by buried isolation diffusions.

Conclusions

The treatment described removes essentially any transition group metals from the front surface-near layers of the silicon, thus preventing formation of OSF, and resulting in improved holdtime performance of devices prepared on bulk Czochralski substrates gettered in this manner. However, the performance of devices fabricated on epitaxial silicon on low resistivity substrates cannot be matched since the low resistivity substrates suppress the minority carrier diffusion current from the bulk of the wafer.

To our knowledge this is the first deliberate gettering approach in which the gettering action continues throughout the device fabrication process and is not eliminated by high temperature treatments.

High temperature HCl gettering in the presence of only a very thin oxide film has been shown to be a much more effective means of removing transition group metals than is the conventional "dry oxygen + 1% HCl" treatment.

AES Investigation of the Chemical Structure of Plasma-Deposited Silicon Nitride

H. H. Madden

Sandia Laboratories, Albuquerque, New Mexico 87185

ABSTRACT

Auger electron spectroscopy (AES) measurements have been made on a 500Å thick, plasma-deposited silicon nitride film. The refractive index of the film was 2.06, and it was deposited at 300°C. The silicon-$L_{2,3}VV$ uncorrected derivative signal had a sharp, high energy feature whose energy location and shape were suggestive of those from elemental silicon. Based on the supposition that the Si-$L_{2,3}VV$ signal from the plasma nitride is a superposition of signals, the background-corrected, loss-deconvoluted integral signal could be resolved into three signals: one which represented elementally bound silicon (and which was modeled by the signal from the silicon substrate); a second which was representative of silicon-hydrogen bonding; and a third which was found to have the shape of a signal from pyrolytically deposited silicon nitride. Because hydrogen is not directly detectable by AES measurement, and its effects on the shape of the Si-$L_{2,3}VV$ signal are small and more subtle than those of either oxygen or nitrogen, the effects of hydrogen on the Si-$L_{2,3}VV$ signal decomposition could only be assessed by making use of auxiliary data from a separate study of the silicon-hydrogen system. The uncorrected peak-to-peak, first derivative signals from oxygen and silicon in the plasma nitride indicated an oxygen content of less than 0.5 atomic percent (a/o). This was consistent with the lack of any indication of oxygen influence on the shape of the plasma-nitride Si-$L_{2,3}VV$ signal. These results for plasma-nitride are compared with the results of a similar study of silicon-oxynitride samples.

Silicon nitride is a dielectric material that has been found useful for a number of applications in the semiconductor-device industry. It is mostly used in the form of amorphous films, and although a number of other film growth techniques have been studied, chemical vapor deposition (CVD) and reactive plasma deposition are the most common thin film fabrication processes used. Films deposited by these methods may have electrical and structural properties which are strongly influenced by the presence of excess silicon or of contaminants in the films. The most important contaminants are thought to be oxygen, which results for oxidants present during the deposition reactions, and hydrogen derived from the hydrogen-bearing gases, silane and ammonia, used in both the CVD and plasma processes. The effects of nonstoichiometry and of oxygen and hydrogen impurities in silicon-nitride films are subjects of continuing interest. The persisting uncertainties in these subjects are consistent with the complex nature of silicon-nitrogen chemistry (1).

Of the many physical properties used in defining the characteristics of silicon nitride films, the index of refraction is the most widely used in practice. It has been found that excess silicon in a film causes an increase in the refractive index above the value of ~2 which is thought to be indicative of stoichiometric Si_3N_4. An oxygen contamination causes a decrease in the refractive index toward a value of 1.44 characteristic of SiO_2. The effect of hydrogen on the refractive index has not been clearly delineated.

Direct Si, N, and O signals appear in the AES spectrum and they have been employed for compositional analysis (2). There have been some disagreements in the interpretations of the lineshape of the silicon signals, however. Some authors (3, 4) have described the shape of the uncorrected derivative silicon $L_{2,3}VV$-AES signal from stoichiometric Si_3N_4 as being composed of a strong negative peak on its high energy side, with a broader shoulder at its low energy end. The energy location of the high energy peak is close to that of the corresponding signal from elemental silicon. This has led other workers (2, 5) to interpret this peak as being due to elemental or "free" silicon and thus the shape of the Si-$L_{2,3}VV$ signal as being due to the superposition of a low energy signal from silicon in silicon nitride and a high energy signal due to free silicon.

In contrast to these interpretations, recent results from our laboratories (6) have indicated that the $L_{2,3}VV$ lineshapes from oxygen-contaminated CVD silicon-nitride films may also have the high energy peak/low energy shoulder structure but that the high energy peak is due to the presence of oxygen in the films. These results are in agreement with the AES and x-ray photoelectron spectroscopy (XPS) results of Wittberg, Hoenigman, Moddeman, Cothern, and Gulett (7), also on oxygen-contaminated CVD nitride films, which showed that the "free" silicon in such CVD films was less than 3 a/o. In our study the CVD nitride film with the least oxygen contamination exhibited only a single peak in the location (~84 eV) of the shoulder of the two-feature signals. This single peak line was judged to be the "true" AES lineshape for silicon bonded to nitrogen.

The apparent contradiction in interpretation of the high energy peak in the more complex AES lineshape, together with an expectation that the signal from a silicon-rich nitride film should be the simple superposition of a nitride-related signal and a signal from "free" silicon, prompted the measurements reported below. The plasma-nitride films used in this new investigation had an Si/N ratio closer to 1.05 than to the stoichiometric value of 0.75; and although oxygen was detectable, its level was very low. After corrections for instrumental and electron-energy-loss distortions, the integral $[N(E)]$ silicon-$L_{2,3}VV$ signal from our plasma-nitride samples could indeed be resolved into a "free"-silicon signal suprimposed on a silicon-nitride-like (6) signal, but with a third component representing silicon-hydrogen bonding in the film.

Other measurements (8) on nitride films deposited under nearly identical conditions to those in this AES

Key words: silicon nitride. hydrogen, chemical bonding.

study indicate that the films contain some 20-25 a/o hydrogen. A large portion of this hydrogen is bonded to the excess silicon and the question naturally arises as to the role that hydrogen plays in determining the shape of the $L_{2,3}VV$ silicon line. Although direct AES signals from hydrogen do not exist, the effects of hydrogen could be reflected in silicon lineshape changes. This possibility has been ignored in the interpretations cited above (2-6). While separate studies (9) on the chemisorption of hydrogen onto a clean silicon surface have shown that the changes in the silicon AES lineshape due to hydrogen-silicon bonding are less dramatic than the changes that accompany nitrogen- or oxygen-bonding to a silicon surface, the changes are discernable and the results of our plasma-nitride silicon lineshape decomposition are consistent with the idea that the high energy component is due to some hydrogen-bonded silicon and not solely to excess "free" silicon.

Experimental

The plasma-nitride films were deposited to a thickness of ~500Å in an AMT Plasma I reactor. This is a production scale system incorporating a rotating horizontal platen, capacitive-coupling to drive the glow discharge in a radially flowing gas mixture, and a stationary resistance-heater block positioned below the rotating platen to control its temperature. The temperature of the 3 Ω-cm, n-type (111) Si wafers onto which the films were deposited was 300°C; and the gas-discharge mixture consisted of an N_2 carrier gas fed at a rate of 670 std cm³/min with ammonia and silane fed at a flow ratio of 2.67:1 (NH_3-360 cm³/min; SiH_4-135 cm³/min). The refractive index of our film was 2.06. Other predeposition processing and deposition conditions were identical to those described in the report by Stein, Wells, and Hampy (8), where the results of a series of optical, structural, and electrical measurements made on these films are discussed. The major difference between the films used for our AES investigations and those studied by Stein *et al.* was the thickness. Their films were some 8-10 times thicker. Anderson (10) has discussed the effects on radiation hardness in the use of these plasma-nitride films for passivation of CMOS integrated circuits.

The AES data are taken with a single-pass cylindrical-mirror analyzer (CMA) using a 5 keV, 5 μA primary electron beam from an electron gun coaxial with the CMA. The modulation voltage was 2V p-p and the data was recorded using signal-averaging techniques in the first-derivative mode. Before processing to arrive at a loss-corrected integral $[N(E)]$ signal the data were first corrected for the linear dependence of the CMA response on energy. The "true" Auger signal must be extracted from the raw data by corrections for electron-energy-loss features. These include simple subtraction of a secondary-electron-background function (11) and a subsequent iterative deconvolution procedure (12) to remove a low energy tail from the background-corrected $N(E)$ signal. This tail results from Auger electrons which have suffered energy losses before leaving the solid. The deconvolution technique makes use of a near-elastic spectrum of backscattered electrons as an approximation to the total system (spectrometer resolution and Auger-electron loss features) response function. It was the loss-corrected $N(E)$ signal that was analyzed in terms of a superposition of signals from silicon atoms in different chemical environments.

During the transfer of the samples from the deposition system to the AES unit, the nitride films developed an oxide layer (13). This layer was removed by sputtering with 1 keV argon ions prior to analysis. A representative sputter profile recorded during our investigations of oxynitride films (6) is shown in Fig. 1 with the $L_{2,3}VV$-silicon AES signals taken at various sputter depths given in the insert to this figure. The silicon lineshape taken before sputtering, A, is "SiO_2-like," but without the electron-beam-reduction peak (6, 14) at ~ 90 eV. Signals B and C are typical of a superposition of an SiO_2 and an oxynitride line. Only when a "plateau" was reached, *e.g.*, curves D-F in Fig. 1, did the silicon lineshape become "nitride-like." Similar changes in the Si-$L_{2,3}VV$ lineshape with sputter depth were observed for the plasma-nitride film. All of the AES data presented below were taken in the sputter-plateau region, *i.e.*, after the surface oxide layer had been removed.

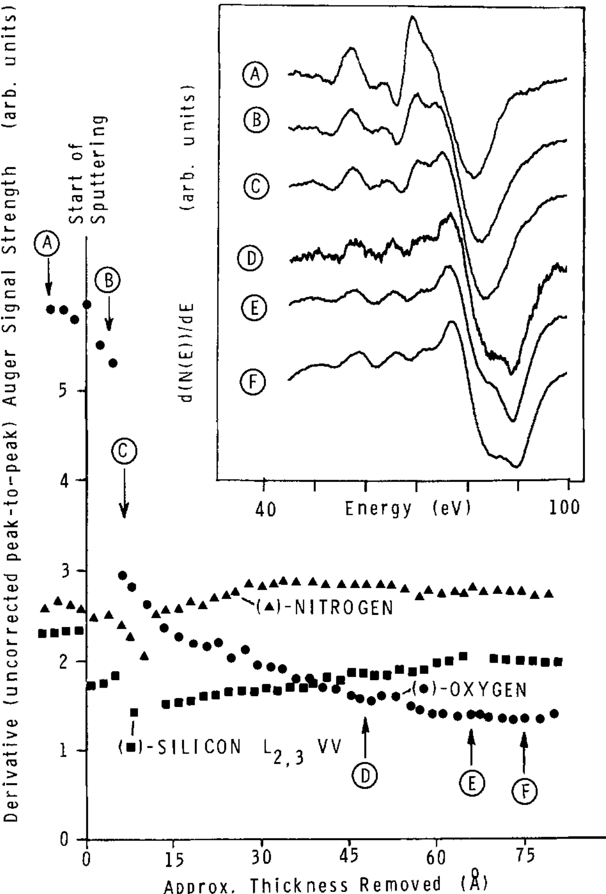

Fig. 1. AES sputter profile for a silicon-oxynitride film with ~10 a/o bulk oxygen [this film denoted as "74 ppm" in Ref. (6)]. Insert gives silicon-$L_{2,3}VV$ spectra taken at various points indicated on the sputter profile. The differences in signal-to-noise for curves D through F in the insert are the result of differing numbers of scans used in data averaging. For general survey work one set of scans (*e.g.*, curve D) was taken while, for data that were to be used in deconvolution (curve E or F) a larger number of scans was taken so that the buildup of noise expected in the deconvolution process [Ref. (12)] could be mitigated.

The AES data were taken with the ion-bombardment beam off and only after the argon pressure in the experimental chamber had fallen below 7×10^{-7} Pa (the base pressure was ~ 3×10^{-8} Pa). In earlier work (14) it was found that AES data taken during ion bombardment were subtly distorted. These distortions were found to be related to the presence of argon gas at ion-bombardment pressures (~ 5×10^{-3} Pa) in the experimental system during AES measurements. The samples in the present work were not annealed and hence contained embedded argon. Studies (15) of argon-ion bombarded, single crystal silicon samples, however, indicated that the presence of embedded argon and the associated damage does not have a very significant effect on the silicon AES lineshape. Carbon was a persistent contamination but for the data discussed below the carbon level was always low enough that it did not have an effect on the silicon lineshape (15).

Results and Discussion

Si-N, Si-Si, and Si-H contributions to the Auger lineshape.—Figure 2 shows both the uncorrected derivative $L_{2,3}VV$ signal (left-hand column) and the corresponding, loss-corrected $N(E)$ signal (right-hand column) from a plasma-nitride sample. For comparison, signals from elemental silicon, from our lowest-oxygen-content CVD nitride sample (6), our 74 ppm CVD oxynitride sample (6), and from an SiO_2 sample (16) are also plotted in this figure. The elemental silicon signals were obtained from the silicon substrate after sputtering through the plasma-nitride film. The energy location and shape of the high energy feature in the derivative spectra from our plasma-nitride and oxynitride samples are indeed suggestive of elemental Si. The SiO_2 data shown in Fig. 2 were recorded (16) in the presence of an oxygen atmosphere in order to minimize the electron beam reduction effects which give rise to a sharp peak commonly seen in the derivative spectrum from silicon dioxide at ~ 90 eV, which is also interpreted as due to elemental Si. Of the other $N(E)$ signals of Fig. 2 (right-hand column) the plasma-nitride signal most closely resembles the CVD nitride and oxynitride signals on their low energy sides in shape and energy location.

In order to test the supposition that the high energy feature in the uncorrected, derivative spectrum from the plasma nitride is due to elemental or "free" silicon, an elemental-silicon signal in the loss-corrected $N(E)$ form (Fig. 2) was subtracted from the $N(E)$ plasma-nitride signal (Fig. 2) to get a difference signal whose shape could be checked against the CVD-nitride signal (Fig. 2). The elemental-silicon signal was scaled in the resolution such that it had the maximum amplitude without resulting in a difference signal exhibiting negative $N(E)$ portions. This is a condition that one would expect for a simple superposition of signals. For the results presented here the curves involved in the resolution were not shifted in energy relative to one another. Allowing relative energy shifts would have introduced an additional (undesirable) adjustable parameter into the curve resolution. Some shifts might indeed be appropriate due to core-level shifts or to differences in work functions for the surfaces involved. Such differences, although not measured, were assumed to be negligible however, and the only adjustable parameter in the curve resolution was the scaling factor, as was also true for the our oxynitride studies published earlier (6).

The difference signal from our plasma-nitride curve resolution, using the elemental silicon signal as one of only two components, is shown as the solid curve in Fig. 3a. It is seen to closely resemble (6, 14) a signal from an oxynitride sample with appreciable oxygen content. This might be interpreted to suggest that there is a third, oxygen-related component in the difference signal for plasma nitride, but the low oxygen concentration in the film determined by AES peak-height analysis runs counter to this suggestion. What was needed to obtain a more nitride-like difference curve was a different component signal which was more-or-less elemental-Si-like in shape but which occurred ~ 1 eV lower in energy than the elemental-Si signal used in Fig. 3a. Such a signal was found (9) in the $L_{2,3}VV$ signal from a hydrogen-covered silicon surface. A component curve that reflects Si-H bonding might indeed have been expected because infrared measurements indicated appreciable Si-H bonding in these plasma-nitride films (8).

Although a direct AES signal from hydrogen does not exist, hydrogen may be detected indirectly by its effects on an AES line of its host material. Such an effect of hydrogen on the Si-$L_{2,3}VV$ line is shown in Fig. 4, the results of a study of the chemisorption of hydrogen onto a clean (100) silicon surface (9). The amount of hydrogen on the hydrogen-covered surface for the signal shown in Fig. 4 was enough to have two

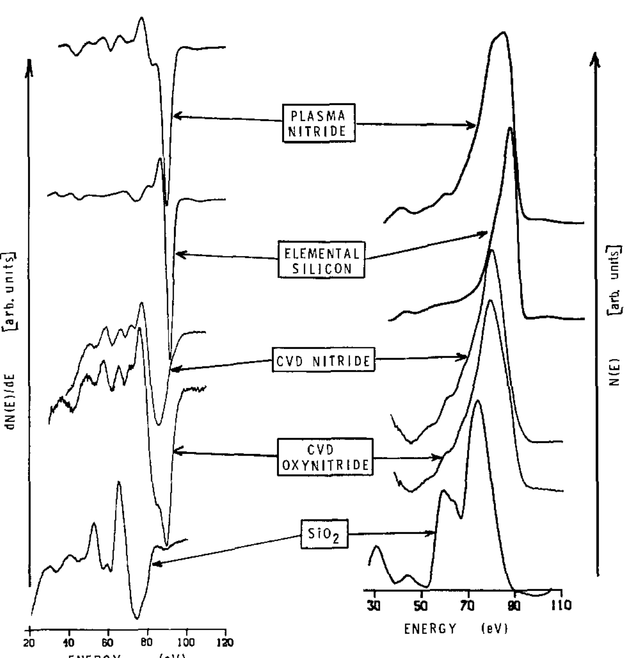

Fig. 2. Silicon-$L_{2,3}VV$ signals from plasma-nitride; elemental-silicon; CVD-nitride [Ref. (6)]; CVD-oxynitride [74 ppm, Ref. (6)]; and SiO_2 [Ref. (16)] samples. The left-hand side of this figure gives uncorrected, first-derivative signals while corresponding background-corrected, loss-deconvoluted integral signals are shown as the right-hand side. Zero levels for the integral signals are given by the right-hand side of each *N(E)* curve.

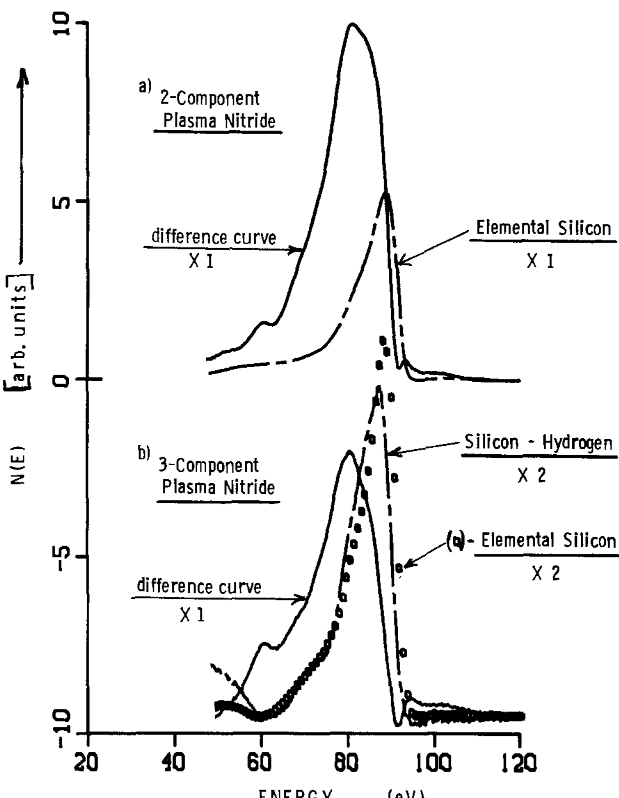

Fig. 3. $L_{2,3}VV$-silicon component signals for a plasma-nitride sample. a) 2-component decomposition using only an elemental-Si signal as the high energy component; b) 3-component decomposition using both the elemental-Si and the Si-H signals from Fig. 4 as the high energy components. The solid curves are the difference curves in both cases.

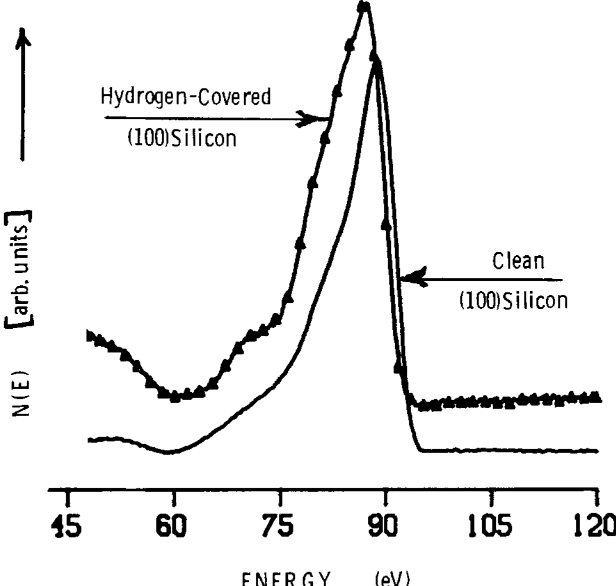

Fig. 4. Loss-corrected $N(E)$, $L_{2,3}VV$ signals from a clean, and a hydrogen-covered (100) silicon surface. Zero levels for the signals are given by the right-hand side of each curve. Triangles mark the curve for the hydrogen-covered surface.

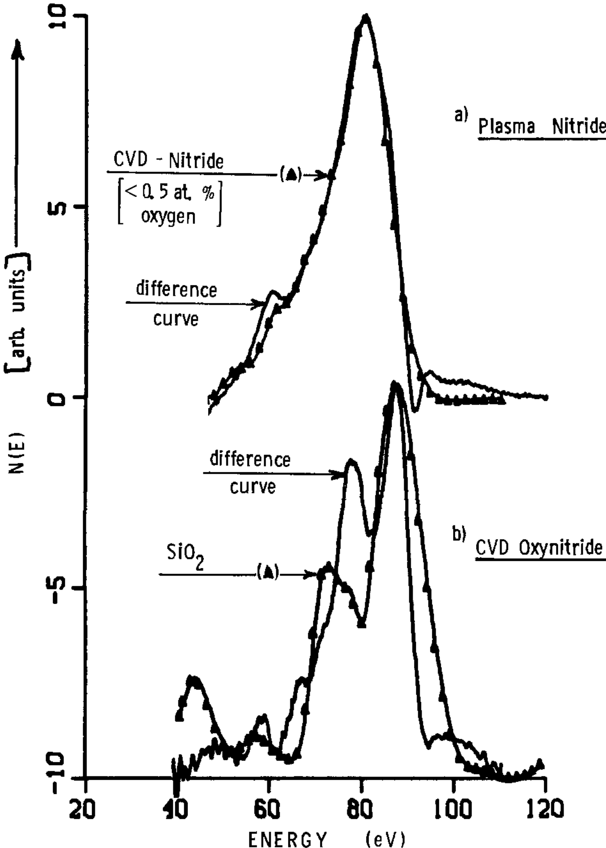

Fig. 5. Comparisons of a) curve-resolved difference curve from 3-component plasma-nitride decomposition results of Fig. 3b with our CVD-nitride signal [Ref. (6) and Fig. 2] and b) curve-resolved difference curve from our CVD-oxynitride results [Fig. 2 of Ref. (6)] with an SiO_2 signal [Ref. (16)]. The SiO_2 signal has been shifted higher in energy by 13 eV, but the CVD-nitride signal is in its original energy location. Both the CVD-nitride and SiO_2 signals are marked with triangles.

hydrogen atoms bonded to each surface silicon atom (17). Thus each surface silicon atom is bonded to two hydrogen atoms and to two substrate silicon atoms. The hydrogen chemisorption caused the reconstructed (2×1) surface characteristic of the clean (100) surface to form a (1×1) structure characteristic of the dihydride layer on this substrate (17). The $L_{2,3}VV$ signal from the hydrogen-covered surface (Fig. 4) is a superposition of a hydrogen-influenced signal from the surface region and an elemental-Si signal from the substrate. This signal by itself was thus thought to be a better approximation to the high energy component curve in the plasma-nitride-film case than is the elemental-Si signal.

Subtracting this hydrogen-covered-surface signal from the plasma-nitride signal did produce a difference curve that was a better fit to the CVD nitride signal in the region near the peak but the lower part of the high-energy side of the difference curve was still too broad. The best-shaped difference curve was obtained by using both the hydrogen-covered-surface signal and the elemental-Si signal from Fig. 4. This difference curve is shown as the solid curve in Fig. 3b and once again in Fig. 5a. For comparison the CVD-nitride signal is also plotted in Fig. 5a. The good agreement in shape between these two curves indicates that the $L_{2,3}VV$ signal from our plasma-nitride sample can indeed be regarded as the superposition of three components: the silicon-nitride signal, the elemental-Si signal, and a signal due to Si-H bonding in the film.

Comparison of spectra from plasma-nitride and CVD-oxynitride.—These results for the plasma-nitride film are in sharp contrast to our earlier results (6) for CVD-oxynitride films. There the uncorrected derivative Si-$L_{2,3}VV$ signal also had a high energy feature that had earlier been interpreted as being due to free silicon but which our curve-resolution results found to be more indicative of silicon-oxygen bonding than to free silicon. The difference curve for the CVD oxynitride had a double-peak structure that resembled the SiO_2 signal more closely than it did the elemental-Si signal. Despite the similarities in shape of the oxynitride-difference and SiO_2 curves, there are significant differences that should be discussed. The prominent peak of the difference signal occurs some 13 eV higher than the corresponding peak in the SiO_2 signal. The peak separation in the difference signal is also somewhat less than in the SiO_2 curve. This is seen in Fig. 5b where the SiO_2 curve has been shifted up in energy so that the prominent peaks of the two curves are aligned.

The differences in shape between the two curves in Fig. 5b suggest that the difference curve is not simply an SiO_2-like curve shifted up in energy relatable, perhaps, to formation of a suboxide in the films. The prominent peak of the SiO_2 curve occurs fairly close to ($\sim$ 3 eV below) the secondary peak of the difference curve. Thus the high energy peak of the difference curve could alternatively be interpreted as a spectrum feature peculiar to the incorporation of oxygen in the amorphous silicon nitride matrix. It should be remembered that AES is a local probe of a material's electronic configuration. The prominent peak in the oxynitride difference curve could signal a local configurational change in the nitride. If the oxygen enters the nitride substitutionally, as suggested in our earlier report (6), the divalent oxygen will leave one unsaturated bond which could lead to so-called dangling-bond states at the local sites of the replaced trivalent nitrogen.

Alternatively, the incorporation of oxygen into the nitride could be accompanied by a local restructuring of the nitride matrix and the formation of new and different Si-Si and Si-H bonds. Such local "disordering of the nitride skeleton by oxygen" has already been suggested by the results (18) of a study of short-range order in silicon-oxynitride films using the method of radial distribution functions determined from electron diffraction measurements. AES is a probe of the local electronic structure of a material and should hence be sensitive to such local disorder. In any case the AES

data indicate that, below an oxygen level of ~ 50 a/o, the incorporation of oxygen into the nitride does not lead to a simple mixture of SiO_2 and silicon nitride but to a more unique substance. On the other hand, the fact that signals indicating Si-Si and Si-H bonding can be reasonably shown to be components of the Si-$L_{2,3}$VV lineshape for plasma nitride suggests that excess silicon and silicon bonded to hydrogen may exist as independent entities in a two (or three) phase amorphous mixture with silicon nitride in plasma-nitride films.

Comments and Conclusions

The high energy peak in the uncorrected, derivative Si-$L_{2,3}$VV signal from a plasma-nitride film is due to Si-Si bonds in the film. In our sample this peak is also identifiable with some Si-H bonding. The overall $L_{2,3}$VV lineshape for our plasma-nitride sample is thus consistent with the presence of excess silicon, of silicon bonded to hydrogen, and of silicon bonded to nitrogen in the film. The AES signal decomposition indicates that the Si-Si and Si-H bonding in the plasma nitride can be detected as separate signals from the Si-N signal. This suggests that plasma-nitride films prepared with excess silicon may be simple mixtures of silicon (with incorporated hydrogen) and silicon nitride.

These decomposition results are in contrast to our earlier results (6) for CVD silicon-oxynitride films where the Si-$L_{2,3}$VV signal, which in its uncorrected derivative form also has a high energy peak that has been interpreted as being due to free silicon, was found to be composed only of a component indicating silicon-nitrogen bonding and a second component indicating silicon-oxygen bonding. No clear-cut elemental (or "free") silicon component was found. This contrast indicates that the assignment of compositional information based primarily on the energy locations of AES lines in uncorrected, derivative spectra can be misleading and that more careful attention should be given to the shape of the AES lines in interpreting AES results.

The analysis of our $N(E)$ data might perhaps be considered speculative. It is based on the supposition that the background-corrected, loss-deconvoluted AES signal is a simple superposition of component signals. This is certainly not unreasonable; and the decomposition (or curve-resolving) that was done was performed with the restriction that no adjustments of relative energy positions of the as-measured component signals was allowable. This meant that whereas the high energy portion of the plasma-nitride signal could actually have been modeled by two elemental-Si signals shifted relative to one another, the physical and chemical significance of such a pair of elemental-Si signals must be considered unclear, at the least. The Si-H signal used in the curve-resolving presented above, while not differing greatly in shape from the elemental-Si signal, does give the energy shift needed with a chemically identifiable reason for the shift. In this regard, it should be noted that the 13-eV shift made to the SiO_2 signal in Fig. 5b was not involved in the curve-resolving procedure (6), but was made merely to make the shape comparison with the silicon-oxynitride difference curve easier.

These results illustrate the utility of AES as a probe of the chemical, as opposed to merely elemental, composition of solid surfaces. Energy (chemical) shifts of Auger lines can be larger than corresponding shifts of XPS lines; and, with care, these shifts can provide useful information about the chemistry of materials. Auger lineshape changes have been shown to aid in such interpretations.

Acknowledgments

The preparation of the plasma nitride films by J. J. Clement and the assistance of W. O. Wallace in making the Auger measurements are gratefully acknowledged. Very useful information concerning other measurements on these films was supplied by H. J. Stein prior to publication. This work was supported by the U.S. Department of Energy under Contract DE-AC04-76-DP00789.

Manuscript submitted Jan. 24, 1980; revised manuscript received Aug. 6, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by Sandia Laboratories.

A Neutron Activation Analysis Study of the Sources of Transition Group Metal Contamination in the Silicon Device Manufacturing Process

P. F. Schmidt*

and C. W. Pearce*

Western Electric Company, Allentown, Pennsylvania 18103

ABSTRACT

A survey is given of the sources, species, and quantities of transition group metals residing on starting silicon substrates and introduced during the device manufacturing process. The survey begins with the polysilicon feed for silicon ingot fabrication and extends through all customary device fabrication steps, such as wafering, polishing, oxidations, epitaxy, ion implantation, etc. High temperature furnace operations in the absence of HCl, such as steam oxidations, are presently the major source of contamination if all other steps of the fabrication process are under full control. However, contaminated polishing slurries, contaminated handling tools or carriers, impure SiC boats or susceptors, or choice of unsuitable materials for beam catcher plates, etc. in ion implantation, can also lead to trouble. Several options are available to avoid the contamination introduced during high temperature treatments, and these are reviewed.

Minority carrier lifetime is an important parameter in silicon (integrated) device technology. However, the amounts of contaminants which suffice to degrade lifetime are so small that they cannot be detected and quantified by conventional chemical analysis. Only neutron activation analysis (NAA) has this capability among techniques applicable to measuring the total impurity concentration.[1] A systematic application of NAA to the silicon device manufacturing process does not seem to have been carried out before.

We report here on NAA starting with the polysilicon used for crystal growth and extending through the fabrication process. Some of the results are what one would expect to find, others came as surprises.

Some Background Information

Gamma-ray spectrometry of reactor neutron activated samples has a very high sensitivity for most elements of the periodic system beyond neon. Notable exceptions are the light elements B, P, and S, and the heavy elements Tl, Pb, and Bi, which do not become gamma-ray emitters but only beta emitters.[2] Since the electrons emitted in beta decay have a continuous spectrum, beta spectroscopy is not an attractive tool to identify individual elements among a multitude of beta emitters. However, determination of the half-life and maximum beta energy can sometimes be used to measure some beta emitters, especially phosphorus. We shall limit ourselves here to gamma-ray emitters.

Among the gamma-ray emitters, there exist also a few elements (V, Al, Cl, and F being the most important) whose half-lives are so short that their determination must be carried out immediately after end of reactor irradiation, and these elements are therefore not seen at all if analysis is carried out a day or so after end of irradiation. Manganese, too, has a relatively short half-life (2.58 hr) and will be detectable a day after end of irradiation only if the total number of manganese atoms in the sample approaches about 1E15.

Si-31, the only radioisotope formed during reactor irradiation of silicon, has a short half-life of 2.62 hr. This fact is of great help in the instrumental analysis of silicon samples: about 27 hr after even a long irradiation, the emission intensity from the silicon matrix has decayed to the extent that the samples can be analyzed nondestructively, without any need for chemical separations. The high purity of semiconductor silicon also guarantees that there are no self-shielding effects for any of the impurities contained in the silicon, and the thermal cross sections and infinite dilution resonance integrals given in the literature for the various isotopes can be used without correction factors for concentration determinations. This fact makes absolute counting of silicon samples especially attractive. In this method, one does not need standards for each element to be determined, one must merely measure accurately the thermal and epithermal flux in the reactor at the time and location of irradiation. A method of measuring the thermal and epithermal flux in a very convenient manner has been described before (1). Since silicon is a light element, there is also very little self-absorption of the emitted gamma rays, and again one does not have to worry about correction factors when applying instrumental analysis.

Two of the common dopants in silicon, boron, and phosphorus do not become gamma-ray emitters after irradiation. Phosphorus, however, becomes a 14-day half-life emitter of high energy betas, which in turn give rise to copious generation of Bremsstrahlung x-rays, raising instrumental deadtime and background at lower energies to unacceptable levels. Thus highly phosphorus-doped silicon samples are not very suitable for nondestructive analysis. Boron, on the other hand, is an ideal dopant for NAA purposes. The fission reaction of B-10 with thermal neutrons, resulting in the emission of Li-7 or of alpha particles, generates no radioactivity, and the beta activity resulting from the B-11 (n,gamma) B-12 reaction has a half-life of much

[1] Ion microprobes have similar sensitivities as NAA in terms of total number of atoms needed for detection, but in the microprobe case these atoms are confined to the very small volume being sputtered, *i.e.*, representing relatively high concentrations. NAA is a global technique, does not give information about impurity distributions in very small volumes, and is most useful for determination of impurities present in extreme dilution, The two techniques are thus complementary.

[2] Except boron.

less than 1 sec. Thus boron-doped silicon is ideally suited for investigating at which process steps contaminants are being introduced. Most of the work described in this paper was performed with 3" ϕ boron-doped Czochralski silicon.

There are certain practical constraints on the maximum or minimum number of samples one usually activates together during a reactor irradiation. Since the irradiations are fairly expensive, one clearly wants to co-irradiate as many samples as possible. On the other hand, one should be able to measure all samples before the short-lived species on the last samples to be measured have decayed to too low levels of activity. One thus needs a high throughput capability of the measuring equipment and computer evaluation of the gamma-ray spectra becomes a practical necessity.

There are many computer programs described in the literature which take spectrum evaluation to the point where identification of the isotopes present as well as determination of the intensities of the various photopeaks has been accomplished. Converting these intensities to concentrations, however, is usually done by comparison to the intensities of standards for each element co-irradiated with the unknown samples. A hybrid technique in which standards for each element are irradiated in a very well-known flux, and comparison to the spectra obtained in another reactor or a different flux is made possible through the co-irradiation of so-called comparators, has also been described (2). These techniques, however, involve a considerable amount of computation and [in the hybrid technique (2)] some degree of control over the irradiation facility.

The method of absolute counting (1), by contrast, requires the co-irradiation of only two flux monitors and the use of a minicomputer and is applicable to irradiations in any reactor. It is therefore much faster and only slightly less accurate than the relative method. Altogether, in survey work of this type precision is more important than accuracy, and the precision of absolute counting is excellent. The large volume of data generated in this study could not readily have been handled by a relative method.

Experimental

Whenever feasible, boron-doped silicon wafers were used, mostly in the resistivity range 4-9 Ω-cm, and of (100) or (111) orientations. Samples were cleaned in hot H_2O_2-NH_4OH and H_2O_2-HCl solutions prior to insertion into the process steps to be tested, prior to measurement after neutron irradiation, and, of course, also prior to neutron irradiation if the purpose of the test was to determine the impurities worked into the silicon surface rather than deposited on the surface (slicing, lapping, and polishing of wafers).

Samples were irradiated for 120 hr with rotation at core face of the Union Carbide reactor[3] at Tuxedo, New York, and were measured nondestructively the next day. All samples were measured first for 2000 sec only for determination of short-lived species and were then measured again for 18.2 hr for determination of the long-lived species. Coarse profiling of impurity distributions was done by removal of oxide films in HF followed by cleaning in HCl-H_2O_2, by etching in 5:3:3 nitric:hydrofluoric:acetic acid mix (sometimes with one surface masked against attack) followed by cleaning in H_2O_2-HCl, and also by removing the peripheral portions of the wafer by scribing and breaking in order to learn about the lateral distribution of the impurities. Autoradiography served the same purpose on wafers with only one predominant emitter.[4]

[3] Typical flux of 1.5×10^{13} thermal neutrons cm^{-2} sec^{-1}, with 3-5% epithermal neutron.

[4] One should bear in mind that the sensitivity of the photographic plate is much higher for betas than for gammas and that presence of pure beta emitters could completely falsify an autoradiograph. Presence or absence of beta emitters can usually be inferred from the low energy x-ray background (below 100 keV) generated by a given sample.

Both the measuring equipment and the method of absolute counting used, as well as the method of flux determination by means of Fe-Ru flux monitors, has been discussed before (1).

In irradiating high purity materials it is necessary to use high purity materials as irradiation containers. Impurities contained in the irradiation container can be transferred and implanted into the unknown sample by knock-on events of fast neutrons and cannot always be removed by nondestructive cleaning. One also needs a container material which does not become very radioactive even after long irradiations, so that samples can be handled readily after irradiation, and the containers reused after some cool-down periods to let induced activities decay. These considerations limit the practical choice of irradiation containers to silicon, quartz, graphite, or vanadium, all of the highest purity. The half-lives of V-51 and of Si-31 are 3.76 min and 2.62 hr, respectively, thus containers made from quartz, silicon, or vanadium can be handled after conveniently short waiting periods. On the other hand, the neutron capture cross section of C-13 is so low (0.9 millibarns, at an abundance of 1.11%) and the half-life of C-14 so long (5730 years) that the activity generated in the matrix is very low even after long irradiations[5] and in any case stems only from a very low energy beta emitter. We have chosen 7 nines pure graphite for irradiation containers, both because of its ready availability and its ease of machinability.

While the graphite matrix is extremely pure, surfaces of graphite workpieces can be significantly contaminated from contact with metal or carbide tools during fabrication. We have especially noted significant molybdenum contamination on some batches. Fortunately, these surface contaminants can be removed by the manufacturer by means of a high temperature cleaning treatment at little extra cost. Their elimination is necessary because of the knock-on and implant events during irradiation already mentioned. Especially molybdenum seems to diffuse quite deeply into silicon during reactor irradiation. Contamination of graphite containers inevitably will also occur from contact with the (contaminated) silicon wafers placed into the containers. It is, however, possible to repurify the graphite (at a somewhat lower temperature than the original heat-treatment) after the activities of these surface contaminants have decayed. Long-lived impurities located deeper in the graphite will have little tendency to be released since they were not removed by the original heat-treatment at the higher temperature.

Our graphite containers consisted of 1.5 in. high cylindrical boxes with screw-on lids, and 1 mm thick graphite spacers to be inserted between the 10 silicon wafers (full load) for avoidance of cross contamination between wafers.

Results

Starting materials and fabrication of starting substrates.—Crystal growth.—The polysilicon used for crystal growth is extremely pure, with only weak traces of impurities detectable.[6] The crystals grown from this polysilicon also proved to be exceedingly pure, with only traces of Cr, Co, Ta, W, Sb, and Na being present. The polysilicon residue in the quartz crucible, however, turned out to be severely contaminated as shown in Table I. The residue constitutes

[5] The activity generated as a function of irradiation time is given by the saturation factor $S = 1 - \lambda/t_{irr}$, with $\lambda = \ln 2/T_{1/2}$; $T_{1/2}$ is the half-life of the radioactive species formed.

[6] By weak traces we mean photopeaks which are still clearly discernible as to their position in energy, but too weak for meaningful quantitative evaluation because of the statistical uncertainty involved. Detection limits for the more important transition group metals, using our detectors, irradiation, and counting conditions, as stated above, and decay times of about 2 weeks, would be approximately (for 3" ϕ silicon wafers): Fe, 1E14 atoms; Ni, 5E13; Zr, 7E13; Cr, 1.5E12; Mo, 1E11; Co, 5E10; Au, 1E9. Detection limits depend, of course, on the background, *i.e.* are higher in the presence of longer lived species having photopeaks at higher energies.

about 10% of the original charge, its level of contamination subsequent to crystal growth thus cannot be due simply to the reduced volume. Since the hot silicon melt dissolves a substantial amount of the crucible during a run, it was initially thought that impurities in the crucible were responsible for the buildup of contamination in the melt, and the quartz from several suppliers was analyzed (see Table II). While the amount of impurities in the quartz is not negligible, it is not sufficient to explain the massive contamination of the melt; the contamination had to originate somewhere else in the crystal grower. Next we suspected the quality of the graphite susceptor, but it, too, proved to be quite clean (Table III). However, when the upper edge of the susceptor was examined, it was found to be severely contaminated with molybdenum and with the various components of stainless steel (Table IV). The source of contamination turned out to be seed shafts made from molybdenum or stainless steel and attached to the graphite chuck carrying the silicon seed crystal. These were positioned close enough to the hot portions of the crystal grower to reach obviously excessive temperatures. Since not only the silicon melt became contaminated, but the edge of the surrounding graphite susceptor as well, a major portion of the contamination must have occurred through the vapor phase.

The high purity of the silicon crystals pulled from the contaminated melt is thus due to the large segregation coefficient for transition group metals. A rough calculation based on the observed concentrations of the various impurities in the crucible residue showed that the impurity traces in the silicon ingot just correspond to the segregation factors. Since the quality of the ingot material is adequate, the observed contamination of the melt is not serious as long as the polycrystalline residue in the crucible is indeed discarded and is not added to further silicon charge. Somewhat surprising is the purity of the silicon ingot in spite of its contact with the vapors of the contaminants.

Slicing, mechanical and chemical lapping, and polishing.—Slicing and mechanical lapping are very dirty operations, carried out on industrial equipment not designed for maintaining cleanliness. Wafers at this stage are therefore badly contaminated with a variety of impurities, not always removable by simple cleaning. The level and species introduced during slicing and mechanical lapping depend on the kind of slicing saw, the lapping compound, and the composition and corrosion resistance of other metal parts involved in the process. Fortunately, almost all of this contamination is again removed in the chem-etching step, thus there is little purpose in listing specific contaminants observed in the slicing or mechanical lapping process. Some comments, however, are in order concerning the edge beveling and the chem-etching steps.

Until recently, edge beveling wheels had their diamonds embedded in a solder consisting of a mixture of Cu, Ni, Mn, and Sn. This type of wheel deposited large amounts of impurities at the wafer periphery, which, strangely enough, could not be efficiently removed by chem-etching, even when the duration of the chem-etching step was extended by a factor of 4. The only reasonable explanation for this kind of behavior appears to be the assumption that the high density of vacancies generated at the silicon surface during beveling, in conjunction with local high tempera-

tures, caused impurity diffusion into the silicon and that these impurities retreated before the advancing solution/silicon interface during chem-etching in the manner described by Wagner for copper in aluminum during electrolytic polishing (3).

More recently, beveling wheels have become available in which the diamonds are embedded in nickel only, with an increased ratio of diamonds/nickel binder. These wheels seem to deposit next to no contamination, not even nickel, at least when new.

In view of the heavy contamination of sliced or mechanically lapped wafers with transition group metals, it is necessary to change the etching solution frequently enough to prevent impurity buildup in the solution. Otherwise the electrochemical potential of the impurities can rise to the point where the solution ceases to be an effective cleaning agent. This phenomenon is quite analogous to the deposition of heavy metals on silicon from contaminated nitric acid-hydrofluoric acid solutions reported by Politycki and Rädlein (4).

Polishing slurries usually appear to be clean enough not to deposit large amounts of impurities on the polished silicon surfaces (Table V), but again it is necessary to limit the length of time the same solution may be reused by recycling. Table VI shows the disastrous results of using a polishing slurry for too long.[7]

The analysis of an alumina-based lapping compound is given in Table VII. These are only examples and may not be typical of other lapping compounds or slurries. An interesting aspect of contamination during polishing is the difference in susceptibility to contamination of differently doped and differently oriented silicon surfaces. (100) and (111) oriented silicon wafers, boron (p-type) and phosphorus (n-type) doped in the 10^{14} cm^{-3} range, were polished using an alkaline, SiO_2-based slurry deliberately contaminated with very dilute copper sulfate. The (100) oriented surface of the p-type wafers became plated with a continuous copper film, the (111) oriented large surface of the n-type wafers remained visually free of any copper, but showed some copper deposition on the edge; the amount of copper on the other two combinations, (111) oriented p-type and (100) oriented n-type silicon, was intermediate. This behavior is in accord with the known electrochemical behavior of silicon crystals, but should be kept in mind: (100)-oriented p-type silicon is most prone to contamination during polishing.

Device fabrication.—Wafer handling.—Prior to entering the device fabrication process, polished substrates are cleaned in different ways, all of which seem to do an adequate job of removing impurities adhering to the surfaces. The wafers are then subjected to a variety of processing steps, which require handling of the wafers for inspection, insertion in furnaces, application of photoresist, etc. Until fairly recently, metal tweezers were in widespread use for this purpose. Table VIII shows that this is not the best way of handling wafers, especially bare silicon wafers which are hard enough to abrade the tweezer material; an oxidized wafer is much "softer" in this respect. More recently, plastic tweezers have been substituted, and the "roll-over" technique from one (plastic) container

[7] Impurities on silicon wafers are usually concentrated in surface near layers, but their exact distribution is not known. We prefer to give impurities detected on silicon wafers in terms of atoms/wafer. Conversion of atoms/wafer to ppm requires knowledge of the wafer thickness at a given diameter. A 20 mil thick, 3 in. diam silicon wafer contains about 1.15E23 atoms silicon, and weighs about 5.39g.

to another has eliminated much of the handling of individual wafers, resulting in a considerable reduction in the degree of contamination with stainless steel components. There persist two rather insidious modes of contamination: use of the same containers or of the same tweezers for handling metallized and virgin wafers. Containers or tools used for handling metallized wafers should not be used at earlier fabrication steps.

Once oxidized, the silicon surface becomes much less vulnerable to contact contamination, including contact with liquids. Etching with HF, however, generates a highly active silicon surface on which noble metals, if present, will readily plate out by contact potential. If a contamination problem seems to exist on the line, an HF etching step exposing bare Si should always be followed by a cleaning in hot H_2O_2-HCl, which both cleans and oxidizes the silicon surface.

Deposition of epitaxial silicon.—In the MOS technology epitaxial silicon is usually deposited on low resistivity substrates, which has a high solubility for transition group metals. This is a fortunate feature in that the substrate effectively blocks the transfer of impurities, emanating from impure graphite or SiC susceptors, into the epitaxial layer by solid-state diffusion. Because of the lower metal solubilities at lower temperatures, there is, of course, a practical limit to the degree of blockage even a low resistivity substrate can exert (5), and cleanliness of the susceptors, especially absence of particulate impurities, is still very important. Diffusion of impurities from the susceptors through the vapor phase into the growing epitaxial layer is essentially prevented by the presence of chlorine or chlorine-containing species during the epitaxial deposition process. In addition, the low oxygen content and the purity of the higher resistivity epitaxial silicon offers few sites for precipitation of contaminants.

The effect of particulate (*i.e.*, highly concentrated) contamination in the susceptor was demonstrated by Pearce and McMahon (6). Dragging a stainless steel tweezer over the surface of an SiC susceptor resulted in the appearance of the same pattern in the epitaxial layer of a wafer placed over the contaminated area for epitaxy. The pattern in the epilayer consisted of stacking faults and saucer pits (after Secco etching). Contamination of graphite susceptors with nickel and copper-containing particulate matter was revealed also by laser-induced emission spectroscopy (7) and by autoradiography of wafers neutron-activated after epitaxial deposition: the radioactive spots were confined to the back surface of the wafer. These particulate sources of contamination probably stem from the machining process and could perhaps be removed by the manufacturer by a cleaning treatment subsequent to the shaping operation.

Oxidation.—High temperature oxidations, in the absence of HCl, especially steam oxidations for production of the "initial oxide" are probably the process step normally introducing the largest quantities of detrimental impurities. Yet this need not be so.

Table IX shows the typical contamination resulting from a high temperature steam oxidation as well as from an oxidation in dry oxygen (no HCl) at about the same temperature and for the same length of time. There is not much difference between the level of contamination, thus it is not necessary to speculate on transportation of volatile impurity species by the steam: the impurities must be diffusing out of the quartz tube. Table X gives the analysis of a piece of an unused quartz tube. While the level of contamination is not insignificant, it is obvious that the total amount of impurities present could not possibly act as the reservoir for the observed contamination of the silicon wafers over an extended period of time. In steady state, impurities must be diffusing from the outside through the walls of the quartz tube.

Quartz tubes are conventionally operated inside mullite or SiC liners; both of these materials are, however, very impure and can serve as a virtually inexhaustible reservoir of impurities. Table XI gives impurity concentrations in mullite and in SiC from furnace liners.

Diffusion of transition group metals through quartz furnace tubes possesses an extremely steep temperature dependence. In one set of experiments the existing temperature gradient in a furnace was utilized, with silicon wafers positioned at locations of accurately measured temperatures. The concentrations of Fe, Co, Ni, and Cr were all found to increase by a factor of 200 over a temperature range of only 30°C (1140°-1170°C), whereas copper and tantalum increased only by a factor of 3. The ambient, dry oxygen or steam, did not appear to be a factor. We believe, however, that these results do not reflect a true activation energy for diffusion, but rather a different degree of devitrification of the quartz tube kept at the different temperatures for a long period of time, and thus providing more or

easier diffusion paths. Fe, Co, Ni, and Cr thus appear to diffuse preferentially along (incipient) grain boundaries, the lower "activation energy" of copper may be indicative of a bulk diffusion process.

Table XII shows impurity concentrations on silicon wafers oxidized at the same temperature, but for different periods of time in steam. It can be seen that there exists probably a sublinear time dependence. Combining these two results suggests that from the contamination point of view it would be advantageous to carry out steam oxidations at the lowest feasible temperature.

Table XIII gives the impurities on a wafer oxidized in dry oxygen + 1% HCl at 1000°C for 1 hr. The presence of the HCl prevents contamination of the silicon; unfortunately, no such protection occurs during steam oxidation in HCl, not to mention the exceedingly corrosive nature of the steam-HCl mixture.

A particularly insidious, but easily avoidable, source of contamination during high temperature furnace treatments are impure SiC boats or paddles (or impure graphite coated with a thin layer of SiC). Table XIV shows the enormous contamination that can result from the use of such boats. This particular oxidation was carried out in dry O_2 + 1% HCl, otherwise the contamination would have been even worse. Autoradiography also showed that the contamination was heaviest where the wafer had been in contact with the boat. Contamination can also result from the use of impure diffusion sources. Table XV shows the impurity content of a BN diffusion disk. This BN disk, as well as others, were found to be very nonuniform, and segments from one and the same disk gave strongly different results. The isotopes Cu and Mn could not be determined on this sample, the 511 keV peak of the positron annihilation radiation due to Cu-64 being interfered by pair-production from other high energy gamma emitters, and the Mn-56 emission having decayed due to the short half-life of Mn-56 (2.58 hr). From the absence of the weak 1345.6 keV gamma line of Cu-64 it can be inferred that the Cu concentration must have been less than about 10^{14} atoms cm^{-3}.

By analyzing the impurities not in the BN disk but on silicon wafers diffused from BN disks it has been shown that Cu and Mn are in fact impurities transferred from the BN disks to the silicon during diffusion treatment. Which impurities are significantly volatile will depend on the activity coefficient of the impurity in the BN matrix, a topic on which essentially nothing is known. In calculating the impurity concentrations in boron or BN from the gamma-ray spectra of neutron-activated samples one must take into consideration the reduction in thermal neutron flux inside the sample, due to the extremely large cross section of B-10 for thermal neutrons (8).

Ways to avoid contamination during steam oxidation.—1. A guaranteed way to eliminate contamination would be the use of a double-walled quartz tube with an HCl-containing gas being passed between the inner and outer walls of the tubes (and discharged into a separate outlet from the steam). This would increase the outer diameter of the tube, but would eliminate the need for a furnace liner.

2. High purity alumina liners are available, an analysis of this material is shown in Table XVI. The high purity alumina is orders of magnitude cleaner than the customary mullite liners (and therefore also more expensive). There should be very little transition group metal diffusion into quartz tubes heated inside high purity alumina liners, as long as the alumina liner does not become saturated with impurities diffusing from the heating elements of the furnace, etc. We do not have at this time experimental data to clarify this question.

3. Another attractive approach is the use of low temperature-high pressure steam oxidation. Table XVII shows results obtained on wafers oxidized in a system built at Bell Labs, Allentown (9). In this particular system the steam comes in direct contact with a highly corrosion resistant cobalt alloy, a condition avoided in commercially available systems. The contamination with cobalt, nevertheless, is moderate. The wafers after oxidation are rather clean, except for an unaccounted for contamination with some copper. Es-

sentially all contamination should be avoidable, at 750°Cl, in a system which prevents the steam from coming in contact with any metal parts.

Ion implantation.—Our experiments were carried out on two different types of implanters. One is a high voltage, low current commercial machine in which only one wafer at a time is being implanted. The other is a low voltage, high current machine designed and built internally. In this latter machine up to 30 wafers may be implanted simultaneously, a large target holder moving in front of the stationary beam. The commercial high voltage-low current machine has excellent focusing and mass resolution, and no contamination with transition group metals attributable to the implantation step was detectable. In the low voltage, high current machine, on the other hand, the ion beam is permitted to strike the walls of the waveguide, the beam stop, and the beam catcher plate. Impurities can and are being sputtered off these metal parts, and attention must therefore be paid to the material from which they are made. Table XVIII shows an example of the contamination resulting from the use of a stainless steel beam catcher plate. The contamination was not confined to the back surface of the wafer, about 1/3 was found on the front surface. Impurities from the material of the hot cathodes were also shown to find their way to the silicon wafers, but this does not appear to constitute a major problem.

Plasma etchers.—Plasma etching is beginning to replace wet chemical etching steps due to the better resolution and avoidance of undercutting. The plasma, however, constitutes a very effective means of redistributing impurities deposited outside the target area in previous runs. Thus, for instance, plasma etchers which have been used to pattern gold metallurgy should not be used for other work without very thorough cleaning if the sample to be etched will undergo still some high temperature treatments after the plasma etch. Exposed copper parts also have been shown to be a source of contamination, as is the copper contained in aluminum-copper alloys used as the base plate in some etchers; in the latter case, however, the aluminum plate becomes oxide covered if the working gas in the etcher contains oxygen, and the contamination decreases with time.

Packaging.—At this stage, wafers are no longer exposed to high temperatures, thus contaminants other than those that give rise to electrolytic conduction, such as NaCl, are no longer of importance. A special case, however, is the packaging of static memories in alumina ceramics. Information in static memories is not periodically refreshed, but must be maintained indefinitely. Alumina ceramics, however, often contain small amounts of uranium and thorium and other members of the uranium decay chain, all of them alpha emitters. Due to the large energy of alpha particles, and the very small charge stored on an individual capacitor in such memory arrays, direct hits by alpha particles can result in loss of information. This fact requires that static memories be shielded against direct alpha hits, a relatively easy task in view of the very short range of alpha particles in matter. Most of the alpha emission, incidentally, does not stem from the very long-lived U-238, but from shorter lived members of the decay chain. However, the (n,gamma) reaction on U-238 is the most convenient method for determining the uranium content, and hence establishing the presence or absence of the problem (Table XIX).

Summary

A survey has been given of the sources of contamination in silicon device processing. The polysilicon used for growing ingots is very pure, but very strong contamination of the silicon melt can occur from the exposure of metal parts (Inconel and/or molybdenum in our case) in the crystal growers to high temperatures. Transfer of the contamination appears to occur preponderantly through the vapor phase. The large segregation coefficients of the transition group metals protect the silicon ingot against significant contamination provided the polysilicon residue in the crucible is not recycled.

Lapping and polishing can be sources of very undesirable contamination of the starting substrate surface if the lapping and polishing compounds are dirty to start with or are being reused for too long. Edge beveling wheels of a new design were found to introduce very little if any contamination as compared to older types of wheels. High temperature oxidations in the absence of HCl were shown to be preponderant sources of contamination. The impurity diffusion through the walls of the quartz tubes and into the silicon approximately follows an exponential behavior with temperature. Presence of HCl suppresses this contamination. Possible alternatives for preventing contamination during high temperature furnace treatments are described. The special role of HCl (or other chlorine-containing compounds) in removing contaminants as chlorides during high temperature gettering is examined in a companion paper.

Metal Silicon Reactions Induced by CW Scanned Laser and Electron Beams

T. Shibata,[1] T. W. Sigmon,* J. L. Regolini,[2] and J. F. Gibbons*

Stanford Electronics Laboratories, Stanford, California 94305

ABSTRACT

Scanned CW-laser and electron beams have been utilized to react thin metal films of Pd, Pt, Mo, W, and Nb deposited by electron beam evaporation onto single crystal silicon substrates to form silicides. Formation of large area uniform layers of Pd_2Si or PdSi is controlled by selection of the power level of the scanning laser or electron beam. Single phase $MoSi_2$, WSi_2, and $NbSi_2$ are also found after CW-beam reaction. For the Pt/Si system mixed phase silicides are found after CW-laser reaction with a superconducting ($T_c \cong 4$ K) metastable compound, Pt_2Si_3, observed as the dominant phase. In contrast, single-phase PtSi is found after electron-beam reaction. Comparison is also made with electron beam evaporated films and argon sputter-deposited films.

The reaction of thin metal films with both single and polycrystalline silicon to form silicide compounds is an area which has received wide attention in the past few years. Future integrated circuit technology will require increased device packing density along with decreased dimensions resulting in a need for low resistance interconnects. Desirable properties of these interconnects will include high temperature process compatability and controlled metal-silicon-interface reactions for both Schottky and ohmic contact reliability (1-3). The bulk of the research to date has been carried out in thermal equilibrium furnace reactions and an excellent review is given in Ref. (4). There both the film deposition and furnace annealing processes are discussed in detail along with useful measurement techniques for determining reacted film composition and quality.

Certain limitations have been found in the furnace thermal equilibrium processing, however. As a result of these limitations, within the last year, the use of energetic beams to react metal silicon films has been investigated by a number of research groups. Both laser (5-7) and electron beam (8) reaction and ion beam mixing (9) have been used in this work. Each of these techniques has led to several unique results, differing in many cases from that found for standard furnace processing.

The main features offered by the laser or electron beam processing of these films include shorter reaction times, localized heat-treatment, and rapid heating and cooling rates. Similar to the case of energetic beam annealing of semiconductors, a natural division of the physical mechanisms and results can be made for pulsed *vs.* scanned CW energetic beam-induced reactions. In this paper we will discuss results we have obtained using scanned CW-laser and electron beams to react various metal/silicon systems. In contrast to the results found for the pulsed case, uniform, essentially single-phase silicide films are obtained with the scanned CW beams. However, under certain conditions, metastable mixed-phase systems are also obtained. Both MeV Rutherford backscattering and glancing angle x-ray diffraction analysis have been utilized for characterizing the structure of the layers. Four-probe resistivity measurements have been utilized to obtain bulk resistivity using the film thickness data obtained from the backscattering.

Experimental

In Table I we list the various metal/silicon systems reacted in this work. Also listed are the pertinent properties characterizing each system, such as thickness and whether or not a silicon overcoating is used. All metal films were deposited by electron beam evaporation onto p-type <100> silicon substrates in a high vacuum oil-free system, unless otherwise noted. Thin amorphous silicon layers were deposited on the metal layers to be reacted by the laser to provide an antireflection coating for the metal surface. Without the silicon overcoating, a high laser power is required to compensate for the power reflected from the metal surface. However, the smaller reflectance of the silicide compound results in an increased power absorption in the film during the reaction, leading to difficulty of control of the reaction. This problem can be avoided by the use of this thin silicon overcoating. Naturally, since the reflectance does not change for the electron beam this overcoating layer is not required for the scanned electron beam experiments.

The laser used in this work was a CW argon laser operating in the multiline mode. The laser output was focused by a 135 mm lens onto the sample and scanned by the apparatus described in Ref. (10). Typical pa-

rameters used in these experiments were, approximately 50 μm spot size and 12 cm/sec beam scan speed. The substrate was held at fixed temperatures during the laser irradiation. The substrate temperatures used for the various reactions are listed in Table II. Electron beam irradiation was performed in a Hamilton Standard electron beam welder, Model EBW7.5 at a working vacuum of 10^{-4} Torr. The samples were mounted on a copper heat sink with Dow Corning 340 heat sink compound and maintained near room temperature during the reaction. Typical electron beam parameters used for the reactions were, substrate temperature approximately 50°C, electron beam energy 31 keV, current 0.1-0.3 mA, beam spot size (as measured by the reacted path) approximately 100 μm, scan rate of 13 cm/sec, and a step size of less than 100 μm. All reacted layers were studied by MeV ^{4}He ion backscattering, glancing angle x-ray diffraction analysis in a Read camera, Nomarsky optical microscopy, and four-probe resistivity measurements.

Results and Discussion

Pd/Si.—In Fig. 1 we show an optical micrograph of a sample consisting of Si (200Å)/Pd (1300Å)/Si <100> laser beam scanned as a function of laser power levels. It can be seen from Fig. 1 that the reaction of the Pd/Si is initiated at about 4W of laser power. The laser-induced reaction is easily detected by the unaided eye through a surface color change. For this particular sample the reaction began at a power level of 4W where the surface color changed from blue (unreacted film) to yellow (reacted film, low power phase). This low power phase was found to be stable to a threshold power of about 7.0W, above which a different high power phase appears in the center of the beam scan line. At this power level, the surface color changes to a gray color characteristic of the high power phase. In order to obtain uniformly annealed areas, overlapped scans were performed in such a way that each adjacent scan line overlapped by at least 40%.

For the remainder of this paper we will normalize the output power level of the laser (P) to the power at which the surface of a virgin silicon wafer just begins to melt (P_o). This normalized power ($p \equiv P/P_o$) is experimentally reproduceable, thereby minimizing the dependence on the laser system and/or other conditions. For our experimental configuration, typical values of P_o are 9.0 and 5.0W for 50° and 350°C substrate temperatures, respectively. This normalized laser power is also related to the important parameter of the CW-beam process, *i.e.*, the ratio of beam power to the spot radius (P/w). This relation is given by P/w (W/μm) = 0.337p or 0.191p for T_{sub} = 50° or 350°C, respectively, using the formulation of Ref. (11). Here the beam radius, w, is defined by the $1/e$ point of the beam intensity assuming a Gaussian distribution. Since

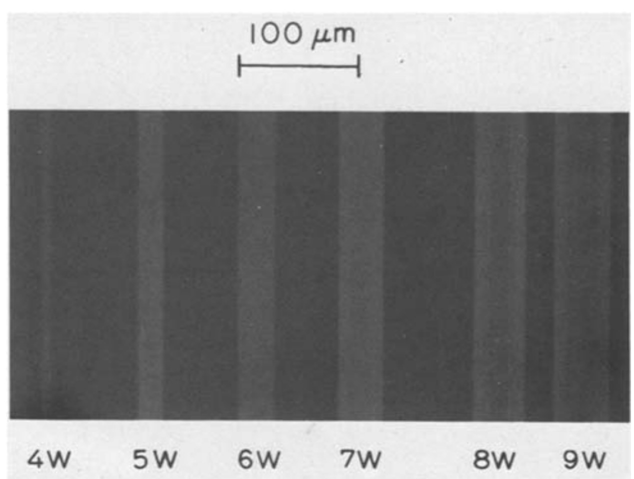

Fig. 1. Optical micrograph of a sample consisting of Si (200Å)/Pd (1300Å)/Si <100> after single laser scans at various laser power levels. The low power phase is formed between 4 and 7W and the high power phase at and above 8W.

the actual power absorbed by the sample is reduced by the reflection, the essential power parameter is $(1 - R)\ P/w$, where R denotes the reflectance of the sample. This parameter is listed in Table II and has been calculated by using experimentally determined values for R. Since reflectance is not important for the electron beam experiments the actual P/w values are listed in Table II. For the electron beam data the beam diameter used was determined by measuring the width of the reacted material for a single scan. This technique gives a slightly different value for w as compared to the laser case, where w is determined from the melting power (P_o).

Backscattering spectra for the Pd/Si samples which were laser annealed at p = 0.71 (low power phase) or p = 1.1 (high power phase) are shown in Fig. 2(a). The spectrum for the unreacted sample is shown by the solid line. Since this is a sample prepared for laser annealing, the peak in the solid line near 1.2 MeV on the energy scale is the signal from the 200Å of silicon antireflection overcoating previously discussed. The peak at higher energy is the signal from the Pd, and the step in the backscattered yield at about 1.1 MeV represents the signal from the underlying silicon substrate. It is clearly seen in Fig. 2(a) that the entire metal layer has been reacted with the substrate and surface silicon after laser irradiation. From the areas underlying the backscattering spectra for the different atomic species, one can determine the average composition of the reacted materials. This was determined to be Pd_2Si for the low power phase and PdSi for the

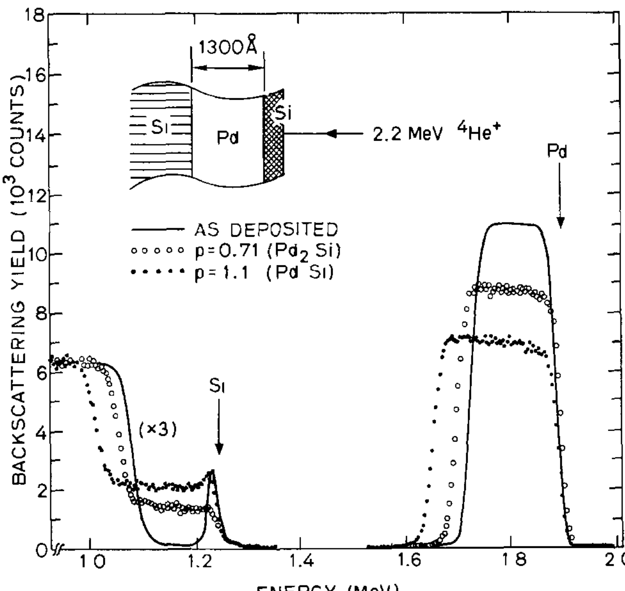

Fig. 2. (a). Backscattering spectra for Si/Pd/Si laser annealed samples for various normalized laser power levels. The solid line (——) represents data taken on unreacted samples, the circles (○ ○ ○) on samples reacted at low powers, and the closed circles (● ● ●) samples reacted at high power levels.

high power phase. It should be noted that the spectrum of the high power phase (PdSi) did not change significantly with laser powers ranging from $p = 0.9$ to 1.4. This result is quite different from those obtained using a pulsed laser beam, where the average composition of the silicide layers are observed to change continuously with increasing laser power (5, 12). In Fig. 2(b) we show the x-ray diffraction pattern obtained from the sample reacted at high power ($p = 1.1$) using a Read x-ray camera. The lines from the PdSi phase are indicated by the solid circles and the most intense lines from the Pd_2Si phase by the open circles. It can be seen from this diffraction pattern that the compound is essentially single-phase PdSi containing a trace amount of Pd_2Si, thereby verifying the backscattering results. Similar results were obtained for the sample reacted at low power where the compound was found to be mainly Pd_2Si, with a trace amount of PdSi observed. Identical results were also found for the electron beam reacted Pd/Si samples. These results are also in contrast with those obtained using a pulsed laser beam, where the reacted layer was found to consist of PdSi, Pd_2Si, Pd_4Si, Pd_5Si, and Si precipitations (12, 13).

It should be noted that the formation of uniform PdSi layers is difficult by conventional furnace techniques unless ion beam mixing (14) is used, usually leading to a PdSi island microstructure containing Si between or inside the islands (15). In Table II various properties of the PdSi and Pd_2Si films formed by both the laser and electron beams are presented.

The surface morphology of the Pd_2Si layers can be best described as a rather patchy surface appearance similar to that obtained in the furnace reacted case (15). The effective temperature calculated for the laser-scanning conditions used to form the Pd_2Si is about 778°C for $p = 0.71$, with an effective annealing time of $T_{eff} = 12.1$ msec. This results in a calculated Pd_2Si thickness of about 1530Å assuming that the furnace annealing data (16) holds for the laser process. [The formulas in Ref. (11) have been used for the calculation.] These calculations are in good agreement with the experimentally observed result (1930Å) determined by backscattering (Table I). These results indicate that the formation of Pd_2Si by the CW laser occurs by a process quite similar to that of the furnace reaction. Using recently obtained furnace annealing data for the activation energy of the Pd_2Si formation (17), we have concluded that the formation of this phase proceeds via a solid-state interdiffusion mechanism (18).

The PdSi films exhibit a laminar-like surface morphology indicative of a spontaneous nucleation process. A Nomarsky interference micrograph of the surface is shown in Fig. 3. Although the mechanism responsible for the PdSi formation is not completely understood, we have evidence indicating that a nucleation-induced process is responsible (7).

Pt/Si.—Scanned laser reaction of the Si (200Å)/Pt (1000Å)/Si <100> samples resulted in surface color changes similar to those found for the Pd/Si samples. The reaction was found to begin at $p = 0.5$ with the transition from a low power to a high power phase occurring at a value $p = 0.74$. The backscattering and x-ray diffraction results were found to be quite different from those obtained for the Pd/Si films. In Fig. 4(a) we show backscattering data for the laser-reacted Pt/Si films, and in Fig. 5 similar data is shown for the electron-beam reacted layers.

The average composition calculated from the backscattering spectrum in Fig. 4 for the low power laser-reacted sample is close to Pt_2Si; however, it was found from x-ray analysis that the layer consisted mainly of Pt_3Si and PtSi with trace amounts of $Pt_{12}Si_5$ and Pt_2Si.

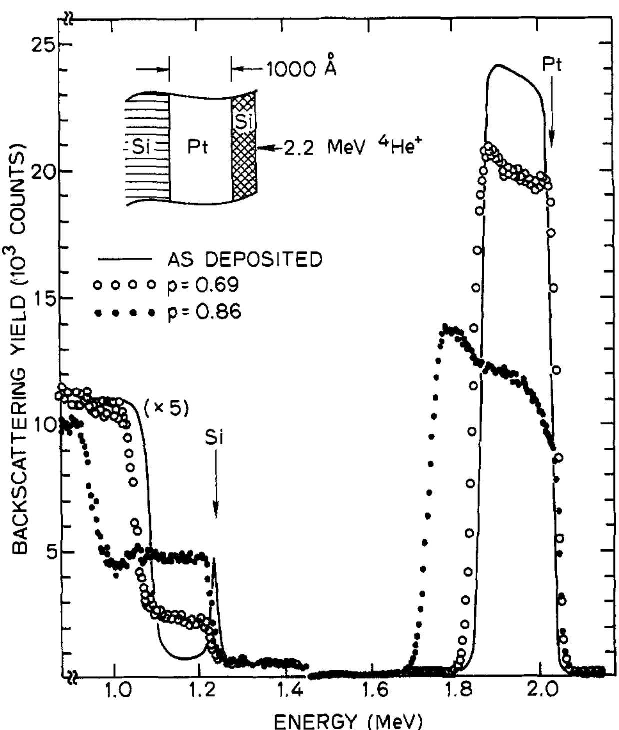

Fig. 4. (a) Backscattering spectra for as-deposited (——) Si/Pt/Si structures and laser annealed [(○○○) p = 0.69 and (●●●) p = 0.89] Si/Pt/Si structures.

The average composition determined from Fig. 4 for the high power phase was approximately $PtSi_2$. This compound does not exist in the equilibrium phase diagram (19). The x-ray diffraction pattern obtained from the high power phase ($PtSi_2$) is shown in Fig. 4(b). The intense lines appearing in this diffraction pattern cannot be fit by any equilibrium Pt/Si compounds. However, they are found to fit very well the diffraction pattern of metastable Pt_2Si_3 (20). Small amounts of Pt_2Si_3 were also found in the samples reacted at low power. To further verify the existence of this phase for these samples we performed superconductivity measurements. The observed transition temperature (T_c) was found to be approximately 4 K corresponding well to that observed in Ref. (20).

In Fig. 5 backscattering data obtained for the Pt/Si films reacted by scanned electron beams are shown. Using the near-surface approximation for the energy loss and cross section, this data indicates the entire film has been reacted to form PtSi. That this is a uniform reaction is indicated by the uniformity of the platinum and silicon signals corresponding to the PtSi layer. This is in contrast to that observed in Fig. 4(a), for the Pt/Si layers reacted by the laser. Glancing angle x-ray diffraction analysis of the electron-beam reacted layers confirm the results of the backscattering that we do indeed have single-phase PtSi. Further parameters measured for these films are listed in Table II.

The observed difference between the laser and electron beam ability to form PtSi can be caused by two phenomena. The basic physical differences between the laser and electron beam experiments are sample structure and beam energy deposition profile. Although we cannot rule out the possibility of interfacial effects (such as bond breaking) created by penetration of the electron beam into the Pt/Si interface, we speculate

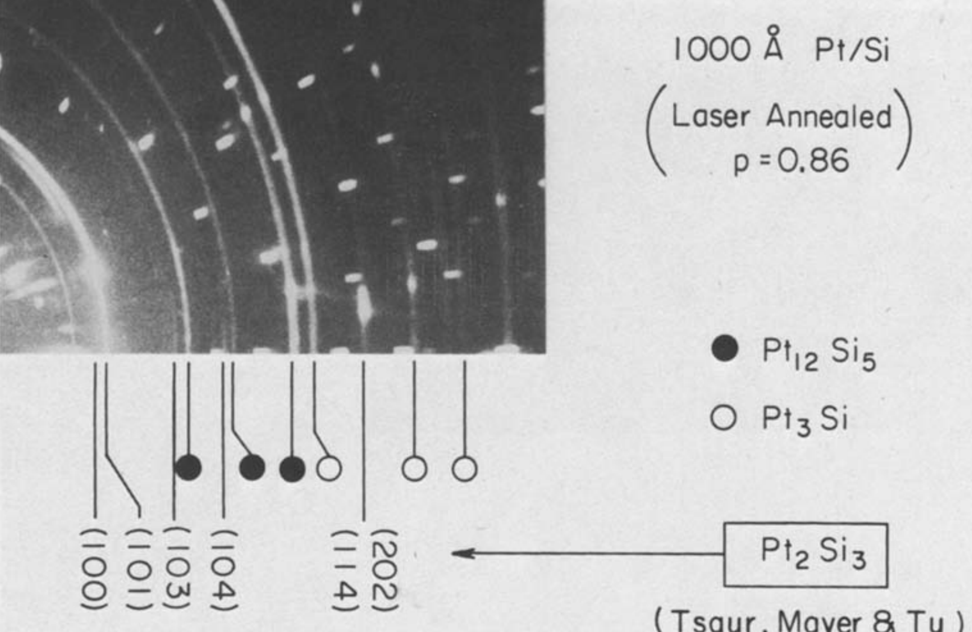

Fig. 4. (b) Glancing angle x-ray diffraction pattern for the Pt/Si structure laser annealed at p = 0.86 as shown in Fig. 4(a). Formation of superconducting Pt_2Si_3 phase is evident.

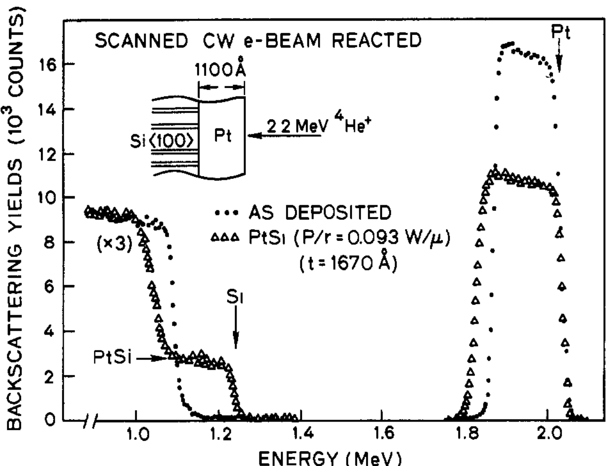

Fig. 5. Backscattering spectrum shown for Pt/Si film reacted by a scanning electron beam. The closed circles (● ● ●) represent the spectrum from the as-deposited film while the triangles (△△△) are for the e-beam reacted.

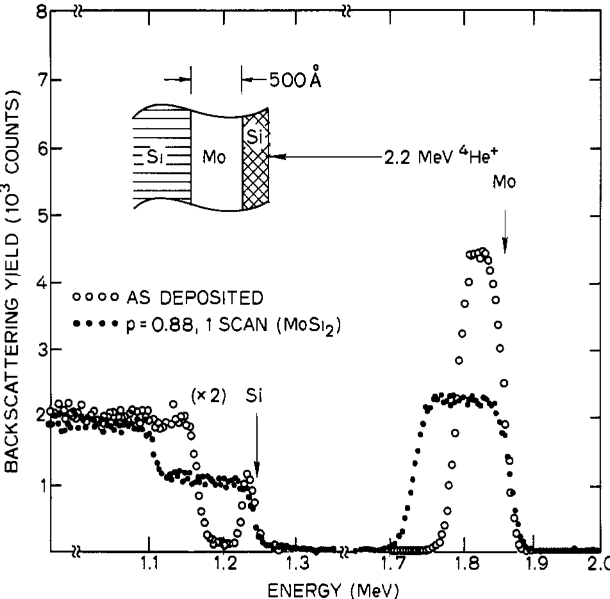

Fig. 6. (a) Backscattering spectra for Si (200Å)/Mo (530Å)/Si <100> structures before (○ ○ ○) and after (● ● ●) laser reaction. A layer of $MoSi_2$ of about 1450Å thickness was obtained after 1 laser scan at $p = 0.88$.

that the observed difference is due to the presence of the thin overcoating of silicon on the laser-reacted samples.

Refractory metals (Mo, W, Nb)/silicon.—We have successfully used the scanned CW laser and/or electron beam to react thin films of Mo, W, and Nb with Si. For films to be reacted by the laser a thin overcoating of silicon was again used to control reflectivity. In Fig. 6(a) we show backscattering spectra for both before and after CW laser irradiation of Si(200Å)/Mo (530Å)/Si <100> samples. It can be seen from this data that the deposited film of Mo was completely reacted with the Si after laser irradiation at a normalized power of $p = 0.88$. The average composition of resulting layer can be calculated from the spectrum and was found to be $MoSi_2$. The x-ray diffraction pattern, shown in Fig. 6(b), also verifies that the reacted layer is single-phase $MoSi_2$ free from unreacted Mo or Si precipitates.

For both the W/Si and Nb/Si samples multiple laser scans were required to fully react the metal with the underlying silicon. For example, for the Si (200Å)/W (440Å/Si <100> and Si (200Å)/Nb (1100Å)/Si <100>, laser irradiation at a normalized power of $p = 0.85$ and 0.90, respectively, resulted in only a limited amount of reaction observed at the interface between the metal and silicon. The results of backscattering analysis for both the W/Si and Nb/Si samples are shown in Fig. 7(a) and 8, respectively. In Fig. 7(a) it can be seen that the 440Å tungsten layer was completely reacted forming a WSi_2 layer of about 1200Å in thickness. It should also be noted that ten passes with the laser were required to complete this reaction. The backscattering data show that the film is quite uniform with a well-defined interface at the silicide/silicon crystal interface. In Fig. 7(b) the x-ray diffraction pattern obtained for this sample is shown. The maor lines of WSi_2 are seen without presence of W and/or Si precipitate lines.

In Fig. 8 the backscattering spectra for the Nb/Si samples are shown. Here we see the advancement of the interface between the silicon and niobium occurring for constant laser power as a function of the number of laser scans. It can be seen that the thickness of the silicide film ($NbSi_2$) increases with the number of scans. The average composition of this reacted layer is found to be $NbSi_2$, determined from the backscattering spectra and verified by x-ray diffraction analysis. Using the near-surface S factor, $[S_o]_{Nb}^{NbSi_2} = 83.7$ eV/Å, the film thickness *vs.* the number of scans are plotted in Fig. 9. One can clearly see that a parabolic growth behavior exists for the $NbSi_2$ film since the number of scans is proportional to an effective annealing time. This result is in agreement with the general behavior of the refractory metals which form disilicides

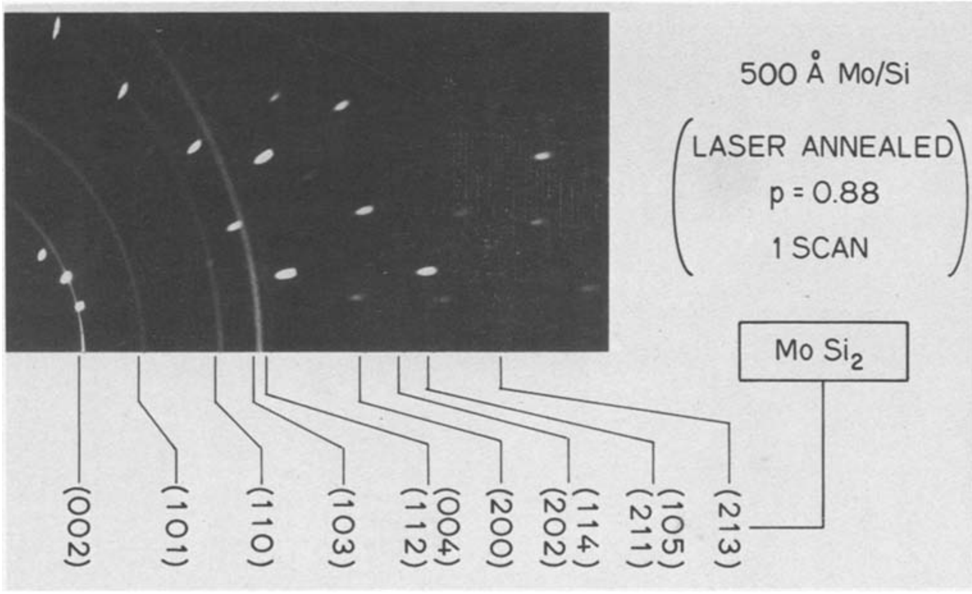

Fig. 6. (b) X-ray diffraction pattern obtained from the Mo/Si sample laser annealed at $p = 0.88$.

by furnace annealing (4). The facts suggest that the laser-induced reaction for $NbSi_2$ formation occurs essentially by a solid-phase diffusion mechanism.

In Fig. 10 we show backscattering data taken on unreacted Nb/Si and e-beam reacted $NbSi_2$ for two different values of P/w (0.155, 0.173 W/μ). The growth front of the $NbSi_2$ layer into the Nb/Si couple can be seen directly from this data. Verification of the $NbSi_2$ phase has been done again using x-ray diffraction. The calculated thicknesses of the two layers are 780 and 1200Å for the 0.155 and 0.173 W/μ power levels, respectively.

Sputtered films (Pd, W)/Si.—The thin film samples used in the experiments discussed so far were all prepared by e-beam evaporation of the metal and silicon layers in an oil-free free vacuum system. Similar experiments have been performed on samples prepared by argon sputtering of the layers. However, significant differences have been found in the resulting reacted films from those prepared by evaporation.

The Si(200Å)/Pd (1000Å)/Si <100> samples prepared by argon sputtering were laser irradiated at power levels of p = 0.5-1.4. For the lower power

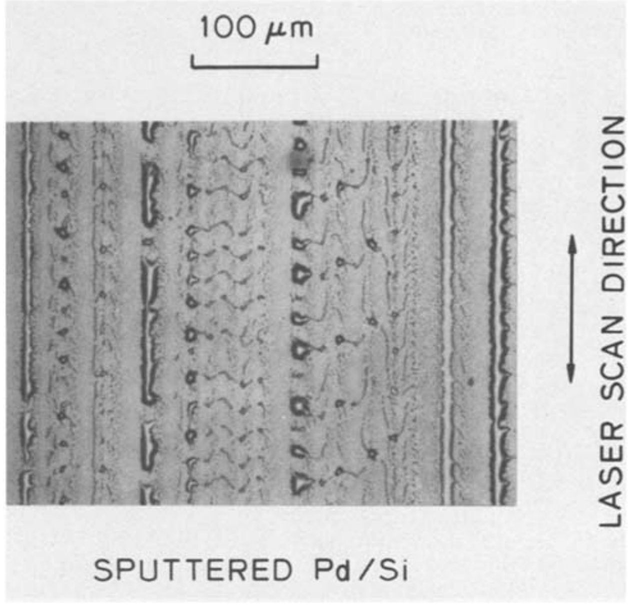

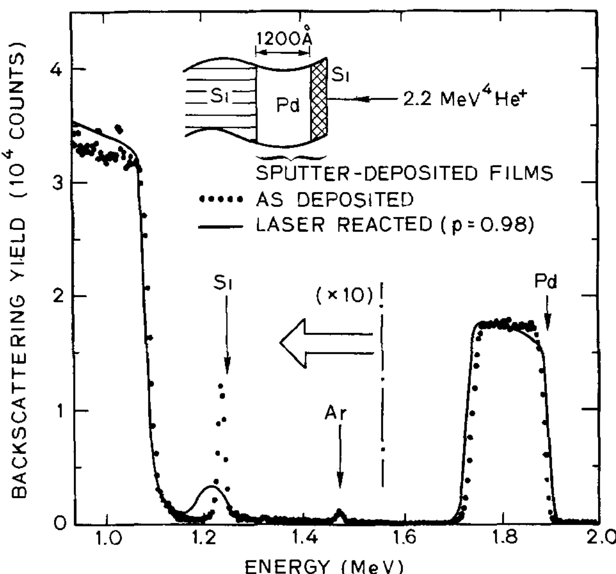

Fig. 11. (a) Optical micrograph of a sputtered Si/Pd/Si sample laser irradiated at a power level of $p = 1.2$. (b) Backscattering spectra of as-deposited (● ● ●) and laser reacted (——) Si/Pd/Si sputter deposited films. A small peak corresponding to Ar in the surface Si layer is seen.

levels (0.5-1.0), the surface color changes observed optically were similar to those observed for the e-beam evaporated films, *i.e.*, the surface color changed from blue (unreacted film) to yellow (low power reaction). However, at the higher power levels ($p \gtrsim 1.0$), a damaged surface was observed optically in contrast to the high power phase appearing for the e-beam, evaporated samples.

In Fig. 11(a) we show an optical micrograph of a sputtered Pd/Si sample laser irradiated at a power level of $p = 1.2$. A severely damaged surface can be seen to result. This micrograph should be compared to that shown in Fig. 3 for the e-beam evaporated Pd/Si sample laser irradiated under similar conditions. The backscattering spectrum of a sputtered sample which was laser irradiated at a power of $p = 0.98$, slightly below the power causing surface damage, is shown by the solid line in Fig. 11(b). The spectrum for an unreacted sample is also shown by the solid circles in this figure for comparison. Only a limited amount of reaction is observed from this data at the Pd/Si interfaces (to be compared with Fig. 1). Also a small peak can be seen at an energy of 1.48 MeV in the spectrum of the as-deposited sample, corresponding to argon in the near-surface region. Although it is not observed in the backscattering spectrum, considerable amounts of Ar can exist in the Pd films. The argon atoms and/or other possible impurities (such as carbon, oxygen, etc.) can be incorporated during the sputtering process. These impurities can have a crucial effect on the silicide-forming reactions (21). Similar results were obtained for the W/Si samples prepared by argon sputtering.

Conclusions

Silicide-forming reactions induced by scanned CW laser and electron beams have been described. The characteristic features of the scanned CW-beam process found differentiating it from those using pulsed beam systems are: scanned CW beams can be used to form large area, uniform, essentially single-phase silicides; different phases within a particular system (such as Pd_2Si or PdSi) can be formed by adjusting the beam power level; and the reactions proceed basically by a solid-phase mechanism.

We have also succeeded in forming both the PdSi silicide and metastable Pt_2Si_3 silicide phases. These phases are difficult or impossible to form by conventional furnace annealing techniques. Both laser and electron beams have exhibited similar reaction effects for most of the metal/Si systems examined here, an exception occurring for the Pt/Si system. We speculate that the effects from the thin overcoating of silicon on the laser-reacted samples could be responsible for this difference. At this writing further experiments are underway to verify this hypothesis. Finally, it is pointed out that for the case of sputter-deposited metal films impurities incorporated into the films during sputter deposition have a deleterious effect on silicide formation.

Acknowledgments

We would like to thank Dr. S. S. Lau, Cal Tech for providing the e-beam evaporations and D. Keith, CMR Stanford for providing the sputter-deposited films. We also would like to acknowledge Dr. R. Reynolds for continued encouragement and support of this work through DARPA contracts MDA903-78-C-0290 and MDA903-78-C-0128 and one of us (T. Shibata) would like to acknowledge partial support of Toshiba Corporation during the course of this work.

Evaluation of Dislocation Generation at Si_3N_4 Film Edges on Silicon Substrates by Selective Oxidation

Y. Tamaki, S. Isomae, S. Mizuo, and H. Higuchi*

Hitachi Limited, Central Research Laboratory, Kokubunji, Tokyo 185, Japan

ABSTRACT

The density of dislocations generated at Si_3N_4 film edges on silicon substrate by selective oxidation is measured and the relation between the selective oxidation conditions and dislocation generation at the film edges is investigated. Dislocations are observed using Secco etching. The results show that the density of dislocations does not continuously increase with oxidation temperature, but decreases markedly at temperatures above 1000°C. A further experiment with recessed oxide. structure reveals that the generation of dislocations depends strongly on the cross-sectional structure of the sample These results are interpreted in terms of viscous flow of SiO_2 film. Another experiment suggests that high pressure oxidation is not effective for suppressing dislocation generation, although it is useful for reducing oxidation time. Finally, collector-emitter shorts of transistors in bipolar integrated circuits are examined quantitatively using a simple statistical method in relation to the dislocations generated at Si_3N_4 film edges.

In silicon device technology, chemical vapor deposited (CVD) Si_3N_4 films on silicon substrates have been widely used as selective oxidation masks or passivating films. These Si_3N_4 films on silicon substrates have a large intrinsic stress of about 10^9 N/m^2 that often leads to the generation of dislocations in silicon substrates during thermal treatment (1-3). Since these dislocations are detrimental to the characteristics of transistors, insertion of SiO_2 film between Si_3N_4 film and silicon substrate has been used in order to avoid generation of dislocations. However, in selective oxidation the SiO_2 film causes the formation of a long bird's beak at the perimeter of the silicon islands (4, 5). This bird's beak constitutes an insuperable barrier to reducing the dimensions of oxide-isolated devices. Therefore, selective oxidation conditions that can prevent the generation of dislocations on silicon substrate without inserting an SiO_2 film have been sought. Although several papers dealing with the generation of dislocations in selective oxidation have been reported (5-8), no reports which quantitatively examine the oxidation condition have been published.

In this paper, first the relation between the heat-treatment conditions (Si_3N_4 film thickness, temperature, time, atmosphere, etc.) and dislocation generation at the film edges is described quantitatively using the dislocation density per unit length of Si_3N_4 film edge. From this experiment the difference in the temperature dependence of dislocation generation between N_2 annealing and selective oxidation becomes clear. Then the cause of this phenomenon is discussed, taking the behavior of SiO_2 films grown during oxidation into account. The effects of Si etching and high pressure oxidation on dislocation generation are also examined. The influence of sample structure on dislocation gen-

* Electrochemical Society Active Member.

Key words: defect density, mechanical property, viscosity of SiO_2, bipolar transistor.

eration and the suitability of high pressure oxidation are also discussed. Next, in order to examine the effect of dislocations on collector-emitter shorts of transistors, defect density obtained from transistor yield was compared to the dislocation density after selective oxidation.

Experimental Procedures

Sample preparation.—The samples were (001) oriented p-type, 0.2-0.3 Ω-cm, dislocation-free, 350 μm thick Czochralski-grown silicon wafers with 10 × 10 μm square masks consisting of only an Si_3N_4 film. The Si_3N_4 film was deposited by reacting SiH_4 and NH_3 in N_2 at 950°C. The deposition rate was 25 nm/min and the NH_3/SiH_4 flow rate ratio was 150. The films were 100-200 nm thick. The pattern of the film was formed by conventional H_3PO_4 etching technique using phosphorus-doped SiO_2 film as a mask.

The force acting on the Si_3N_4 film edge is proportional to the film thickness, with a constant of proportionality of about 9.2×10^{-1} N/m per nanometer of film thickness (9). For some samples the exposed silicon substrate was anisotropically etched 0.9 μm using KOH solution containing isopropyl alcohol in order to make a recessed oxide structure.

Thermal treatment and oxidation.—In order to investigate dislocation generation at the film edges, the samples were divided into three groups. The samples in the first group were annealed at 950°-1150°C for 2 hr in N_2 atmosphere. The samples in the second group were oxidized at 900°-1150°C for 2 or 16 hr in wet O_2 atmosphere. Some of the samples were silicon-etched before oxidation for comparison. The samples in the third group were silicon-etched and oxidized to grow 1.8 μm thick SiO_2 at 900°-1125°C in wet O_2 under atmospheric pressure (1 atm) or high pressure (7 atm) to form recessed oxide structures. The conditions for the third sample group correspond to those for isolation oxidation of bipolar integrated circuits. Cross sections of the samples were observed by scanning electron microscope (SEM) to evaluate the bird's beak and bird's head.

Dislocation observation.—In order to detect dislocations generated at the film edges, surface films were removed from the samples using diluted hydrofluoric acid after heat-treatment. Photographs of dislocations revealed by Secco etching (10) are shown in Fig. 1. In this figure, dislocation pits appear near the film edges. Since the force acting on the Si_3N_4 film edge is very large, it is expected that the density of dislocations depends on the perimeter length of the film edges. If the occurrence of dislocations can be represented by a Poisson distribution, the yield of patterns (the probability that a pattern has no dislocations) is given by

$$Y = e^{-\lambda l}$$

where λ is the dislocation density per unit length of the film edge and l is the perimeter length of the pattern. Consequently the dislocation density can be obtained by measuring the yield of 10 × 10 μm square patterns.

Transistor fabrication.—In order to apply the above results to the fabrication of integrated circuits and investigate the relations between dislocations generated by selective oxidation and collector-emitter shorts of bipolar transistors, npn array-transistors were fabricated by a conventional planar process. A 150 nm thick Si_3N_4 film was deposited directly on the silicon substrate and selective oxidation was performed at 1100°C in wet O_2 under high pressure (7 atm) to reduce oxidation time. The time required to grow 1.8 μm thick SiO_2 film was only 50 min. The base and emitter were formed by boron ion-implantation and arsenic diffusion in an ampul tube, respectively.

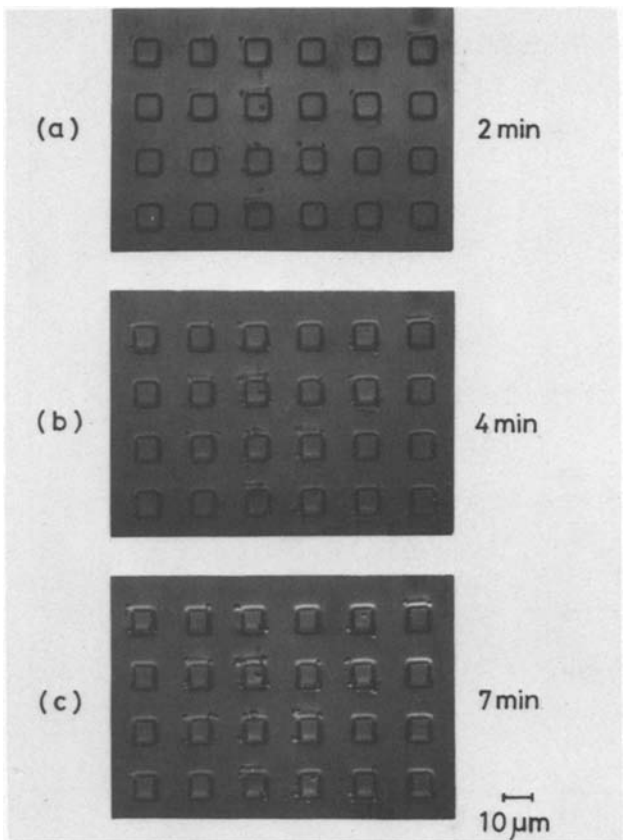

Fig. 1. Photographs of dislocation pits revealed by Secco etching for various etching time. Dislocation pits become more clear as the etching time increases. The square patterns were the regions covered by 150 nm thick Si_3N_4 film during oxidation.

Results and Discussion

Dislocation generation in N_2 annealing.—The samples in the first group were annealed for 2 hr in N_2 at 950°-1150°C. Dislocation densities of these samples are shown in Fig. 2, where "x," "Δ," and "o" represent the results for 200, 150, and 100 nm thick Si_3N_4 films, respectively. It is easily seen that the dislocation density increases with annealing temperature. This is because the critical stress for dislocation generation in Si becomes smaller as temperature increases. Since the force acting on the Si_3N_4 film edges is proportional to the film thickness, dislocation density increases with Si_3N_4 film thickness. Figure 3 shows the annealing time dependence of the dislocation densities at 1000°C. This figure indicates that the dislocation density becomes larger with annealing time.

From these results it is clear that the dislocation generation depends on the force acting on the Si_3N_4 film edges, annealing temperature, and annealing time. The data of a creep experiment (11) indicate that the time required to generate dislocations becomes shorter with increasing temperature.

Dislocation generation in oxidation.—The samples in the second group were oxidized for 2 or 16 hr in wet O_2 at 900°-1150°C. Dislocation densities of the samples oxidized for 2 and 16 hr are shown in Fig. 4 and 5, respectively. A distinguishing feature of both figures is that the dislocation density decreases with increasing temperature above 1000°C. It should be noted that the present results are entirely different from the results obtained in N_2, which are shown in Fig. 2. This suggests that SiO_2 film grown during oxidation plays an important role in dislocation generation.

Two factors that reduce the stress effect during oxidation are considered. One is reduction in Si_3N_4 film thickness. During oxidation the surface of Si_3N_4 film is gradually converted to SiO_2 film (12). The reduc-

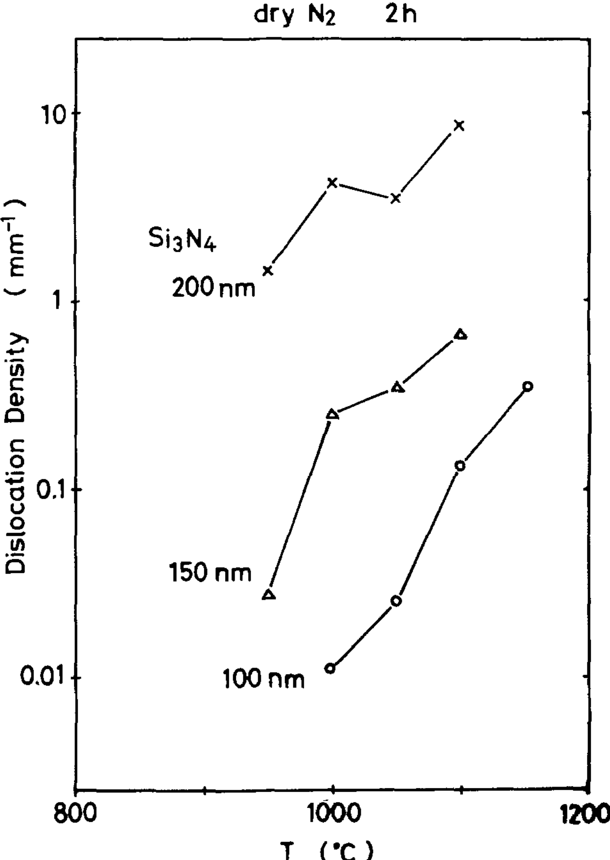

Fig. 2. Temperature dependence of dislocation densities of the samples annealed for 2 hr in N_2. The marks "×", "△", and "○" show that the thickness of Si_3N_4 films were 200, 150, and 100 nm, respectively.

tion in Si_3N_4 film thickness by oxidation are shown in Table I. The other is relaxation due to the viscous flow of SiO_2 film grown under the Si_3N_4 film edges. The dislocation density of the sample with 150 nm Si_3N_4 film oxidized in wet O_2 at 1100°C is smaller than that of the sample with 100 nm Si_3N_4 film annealed in N_2 at

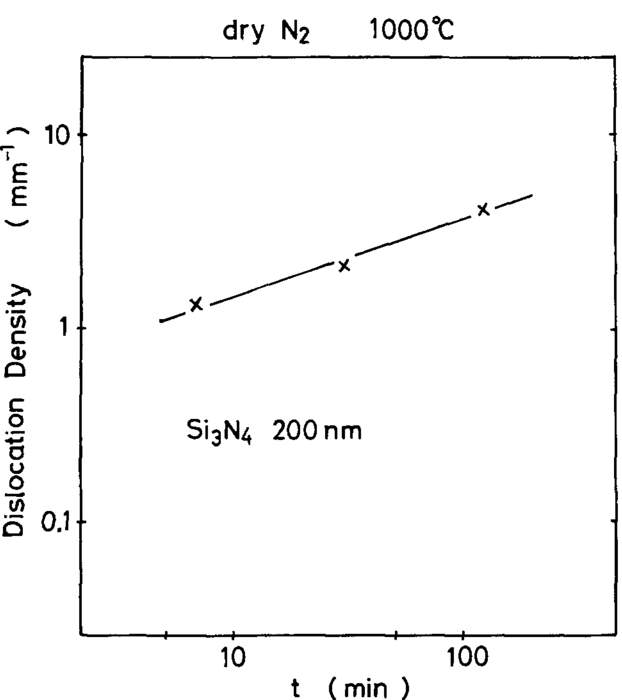

Fig. 3. Annealing time dependence of dislocation densities at 1000°C.

1100°C, as seen from Fig. 2 and 4. This suggests that the effect of the latter factor is much larger than that of the former. It is known that the viscosity of SiO_2 decreases rapidly with increasing temperature and that viscous flow of SiO_2 occurs at temperatures around 950°C (13-15). Consequently, it is expected that the dislocation density tends to decrease with temperature, as shown in Fig. 5. Since relaxation of the stress

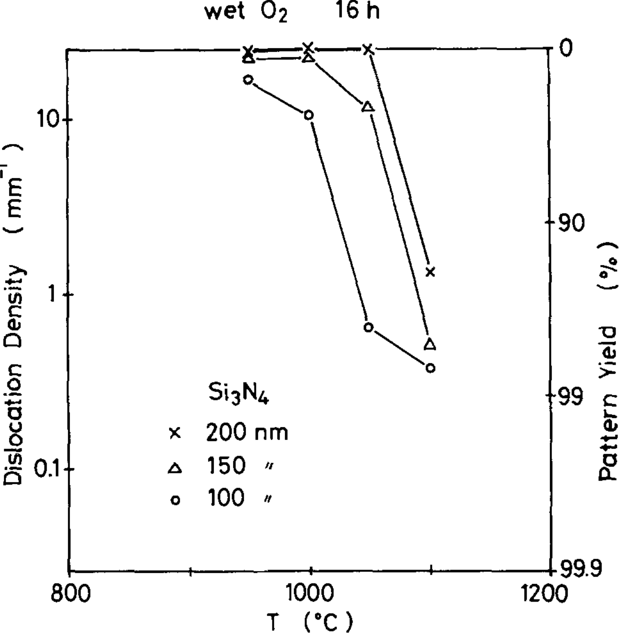

Fig. 5. Temperature dependence of dislocation densities of the samples oxidized for 16 hr in wet O_2.

Table I. Reduction in Si_3N_4 film thickness by oxidation (in wet O_2 at 1 atm)

		Oxidation time	
		2 hr	16 hr
Oxidation Temperature	1000°C	6 nm	30 nm
	1100°C	22 nm	98 nm

is caused by the SiO_2 film grown under the Si_3N_4 film, the degree of the relaxation depends on the stress fields in the silicon substrate under the Si_3N_4 film edges and the extent of lateral oxidation (in this case this is nearly half of the SiO_2 film thickness). Therefore, when the SiO_2 film is thin, relaxation will not occur. Although the stress fields near the film edges are different from the theory of elasticity (9, 16), the extent of lateral oxidation that the generation of dislocations can be suppressed is estimated to be 0.4-0.5 μm from the thickness of the SiO_2 film (0.8 μm) grown at 1050°C in wet O_2 for 2 hr. Because the temperature that the dislocation density in Fig. 4 becomes smaller than that in Fig. 2 is about 1050°C. As the results of oxidation for 2 hr at temperatures under 950°C are similar to those of N_2 annealing, stress relaxation due to oxide does not occur in these conditions. Thicknesses of SiO_2 films were about 0.4 μm at 950°C and 0.3 μm at 900°C. For these reasons, the maximum of dislocation density is found at about 1000°C in Fig. 4 (solid line).

In order to examine the effect of Si etching on dislocation generation, Si substrate is etched and oxidized for 2 hr. As the stress due to the expansion of SiO_2 grown by oxidation concentrates, the effect of viscous flow of SiO_2 film becomes dominant. Therefore, the dislocation densities of these samples are large at temperatures below 1000°C and decrease rapidly with temperature at temperatures above 1000°C, as shown in Fig. 4 (dashed line).

From these results it is concluded that the dislocation generation at Si_3N_4 film edges by selective oxidation depends on the strength of Si crystal, the thickness of Si_3N_4 film, the viscosity of SiO_2, and the topological structure of the Si substrate. Although the latter two factors are not so important in N_2 annealing, they play an important role in selective oxidation.

Dislocation generation in recessed oxide structure.— The samples in the third group were silicon-etched and oxidized to grow 1.8 μm thick SiO_2 at 900°-1125°C in wet O_2 under atmospheric pressure or high pressure. This coplanar structure is used for high speed bipolar integrated circuits. As the oxidation time is inversely proportional to the pressure, high pressure oxidation is useful to reduce the oxidation time drastically (17). Dislocation densities and oxidation times of the samples with this structure are shown in Fig. 6 and Table II, respectively. It is seen that the dislocation density decreases rapidly with temperature. The results are ascribed to the effect of viscous flow of SiO_2 film. The effect may be understood by observing the cross section of the sample. Photographs of the samples observed by SEM are shown in Fig. 7. The shape of SiO_2 film grown by selective oxidation changes with oxidation temperature. Inspecting the shape near the edge of SiO_2, Si is lifted up and a number of etch patterns

produced by large strain in Si are seen at temperatures of 1000° and 1050°C. The amounts of the lift-up were 0.15, 0.09, and 0 μm at 1000°, 1050°, and 1100°C, respectively. The higher the oxidation temperature is, the smaller the deformation of Si becomes. The lift-up and etch patterns correspond to the generation of dislocations in Si substrate. This temperature dependence of dislocation generation coincides with that in Fig. 6. Since the viscosity of SiO_2 becomes very small at 1100°C, the stress produced by the growth of SiO_2 is almost relaxed by the viscous flow of SiO_2. The stress acting on Si substrate is reduced to a great extent, and thus dislocation generation is prevented. Although the generation of dislocations can be suppressed by oxidizing at 1100°C, the bird's beak lengthens to about 0.3 μm. The bird's beak is defined as the distance between the Si_3N_4 mask edge and the top of the beak. From Fig. 7 the beaks were 0.60, 0.61, and 0.92 μm at 1000°, 1050°, and 1100°C, respectively. It is expected that the bird's beak reduces the stress acting on the silicon substrate. In order to evaluate the increment in bird's beak, the oxidation mechanism of Si, and the mechanical strength of Si, SiO_2 and Si_3N_4 at high temperatures must be considered. Further investigation will be necessary.

Next, the effect of pressure during oxidation is discussed. It is seen that the dislocation density at 7 atm is larger than that at 1 atm. As the growth rate of SiO_2 is proportional to the oxidation pressure, the time required to grow SiO_2 of a given thickness becomes shorter with increasing pressure. If the generation of dislocations depended only on oxidation time, the dislocation density at 7 atm might be smaller than that at 1 atm. Therefore it is concluded that the generation of dislocations depends not only on oxidation time but on oxidation rate. This behavior is considered to be related to the relaxation time τ of viscous flow of SiO_2 Here, τ is defined by $\tau = \eta/E$, where η and E are, respectively, the viscosity and the shear modulus of the

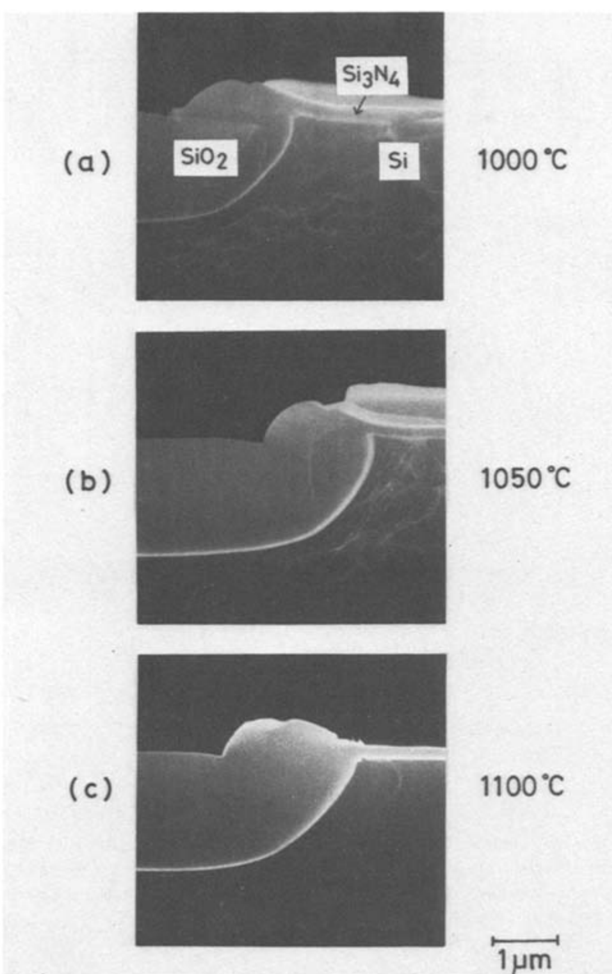

Fig. 7. Cross sections of recessed oxide structure for various oxidation temperatures. The samples were lightly etched by HF-HNO_3 before SEM observation.

SiO_2 film. Using the values of η and E for vitreous silica (18, 19), τ is estimated to be around 1 min at 1100°C. This is different from EerNisse's estimated time, which is only a few seconds (14). Although it is not certain which time is correct, it is clear that the effect of viscosity appears at the beginning of the oxidation. As the initial oxidation rate is very large, the effect is reduced in high pressure oxidation.

Transistor characteristics.—It is known that process-induced dislocations cause collector-emitter shorts of bipolar transistors (20). However, the relation between the collector-emitter shorts and the dislocation density after selective oxidation has seldom been investigated. In this study, in order to treat the shorts quantitatively, collector-emitter breakdown voltages (BV_{CEO}) of fabricated transistors were measured and the transistors with $BV_{CEO} > 5V$ at $I_{CE} = 10$ μA were defined as good. If the occurrence of defects can be represented by a Poisson distribution, the yield of good transistors is given by (21)

$$Y = e^{-(\lambda_A A + \lambda_L L)}$$

where λ_A is the defect density per unit emitter area, λ_L is the defect density per unit length of the emitter perimeter, and A and L are the emitter area and perimeter length per transistor, respectively. From the yield of transistors with emitter size of 3×5 μm² and 70×110 μm², $\lambda_A = 0.24$ mm^{-2} and $\lambda_L = 0.048$ mm^{-1} were obtained. Comparison of λ_L with λ at 1100°C in Fig. 6 shows that they are in good agreement. Since the size of the emitter is about 1/3 that of the pattern with selective oxidation, it is expected that about 1/3 of the transistors with dislocations generated by selective oxidation fail by collector-emitter shorts. In order to examine the close relation between the dislocations and the collector-emitter shorts, further investigation of multiplication and movement of dislocations are needed.

Conclusions

From the results obtained in this study, several conclusions can be made.

1. The density of dislocations generated at Si_3N_4 film edges by selective oxidation decreases with increasing oxidation temperature. This phenomenon is explained by the effect of the viscous flow of SiO_2 film.
2. When Si is etched and oxidized to form a recessed oxide structure, the effect of the viscosity of SiO_2, *i.e.*, oxidation temperature dependence of dislocation generation, becomes significant. This effect is confirmed by observation of cross sections of samples. Furthermore, the Si substrate is deformed by selective oxidation with Si_3N_4 mask at temperatures below 1050°C.
3. The dislocation generation at Si_3N_4 film edges by selective oxidation depends on Si_3N_4 film thickness, oxidation temperature, oxidation time, and oxidation rate.
4. The dislocations generated by selective oxidation cause collector-emitter shorts of bipolar transistors. The probability of the occurrence of collector-emitter shorts caused by dislocations depends on the heat-treatment conditions and the pattern geometry. This is considered to be related to the multiplication and movement of dislocations.

Interdiffusion of Titanium and Gold: A Comparison of Thin Films Deposited in Technical Vacuum and Ultrahigh Vacuum

G. W. B. Ashwell and R. Heckingbottom

British Telecom Research Laboratories, Martlesham Heath, Ipswich IP5 7RE, England

ABSTRACT

Thin films of 0.5 μm Ti and 0.5 μm Au have been deposited on Si and SiO_2 substrates in technical vacuum (HV, $\leq 10^{-6}$ Torr) and ultrahigh vacuum (UHV, 10^{-9} Torr). After deposition and subsequent annealing in N_2 containing $\leq 1\%$ O_2 at 300°-350°C, the films were analyzed, principally using Auger sputter ion profiling, but also using electrical resistivity, x-ray, Rutherford backscattering, and SEM/microprobe measurements. While the UHV films were clean to the techniques used, several percent of C and O were present in the HV deposited Ti films. On SiO_2 substrates the reaction proceeded via formation of Au_4Ti and oxidation of Ti to TiO_2 as it came in contact with the air interface. The rate of alloy formation was almost an order of magnitude faster in the UHV deposited films and the oxidation rate was also enhanced. The importance of these usually unmonitored impurities in determining the reactivity of films deposited in technical vacuum is stressed.

Gold is widely accepted as the preferred metallic conductor for interconnection patterns on semiconductors, particularly where high current densities are encountered. Its advantages include high electrical conductivity, corrosion resistance, and full compatibility with gold wire thermocompression bonding. Its two main drawbacks, poor metallurgical bonding to the semiconductor and catastrophic reduction of carrier lifetime in the semiconductor, can both be solved by the use of an intermediate layer of titanium between the gold and the semiconductor. While more complex three-layer metallizations incorporating a third layer of Pd or Pt to reduce the Au-Ti interaction are widely used, extremely reliable transistors can be fabricated using Au-Ti metallization only (1).

The interaction of Au-Ti thin film couples under thermal stressing and varying humidity has been studied previously (2-4), reflecting its importance both individually and as part of the three-layer metallization schemes. All these studies used films prepared in technical vacuum comparable with that used in device fabrication. As part of a wider program aimed at optimization of the Ti-Au system we have also studied films prepared in ultrahigh vacuum. This paper describes the significant differences between films formed in the two different ways. Resistivity/anneal time plots have been used to identify distinct stages in the interaction and compositional analysis, principally by Auger electron spectroscopy with sputter ion profiling, was carried out at these points. The importance of low levels of impurities such as oxygen and carbon in determining the stability of the layers used in device fabrication is clearly illustrated.

Experimental

Sample preparation.—The main series of Au-Ti layers were deposited on a thermally grown SiO_2 layer (3500Å thick) on Si(111) slices to allow simple resistivity determinations. Other series of Au-Ti layers, deposited directly on Si(111) substrates, were also subjected to compositional analysis to check for any effects due to the introduction of the SiO_2 layer. A standard deposition sequence involved (*i*) deposition of 0.5 μm Ti with a substrate temperature of 75°C, (*ii*) increase of the substrate temperature to 250°C followed by deposition of a further 250Å of Ti, and (*iii*) deposition of 0.5 μm Au with the substrate at 250°C. Matched deposition sequences were carried out in technical vacuum (HV) and in ultrahigh vacuum (UHV). In both cases beam pressures were $\simeq 5 \cdot 10^{-6}$ Torr with background pressures of $\simeq 10^{-6}$ and $\simeq 10^{-9}$ Torr, respectively. There was a detectable drop in the former background pressure during Ti evaporations. Additional samples with only 0.1 μm Au layers were prepared for Rutherford backscattering analysis (RBS).

Key words: reaction rate, impurities, Auger profiling.

Analysis techniques.—Auger analysis was performed with a conventional CMA analyzer at 3 keV primary beam energy. The sputter ion profiling used argon ions at 500 eV from a broad focused gun. RBS spectra were generated using 1.5 MeV He^+ ions and were provided by Dr. P. L. F. Hemment of the University of Surrey, England. A separate examination for nitrogen was carried out using x-ray photoelectron spectroscopy (XPS) because of a partial overlap between N and Ti peaks in the Auger spectrum. The XPS analysis was provided by Dr. R. M. Waghorne at Fulmer Research Institute, England. The x-ray data was produced using a cylindrical texture camera (5). In this technique the sample is rotated normal to its surface which is at a glancing angle to the incident x-ray beam. The resulting pattern of arcs of diffracted x-ray reveals the extent of any orienation effects in the thin surface layers in addition to the lattice spacings. Scanning electron microscopy (SEM) with energy dispersive microprobe facilities was also used to check for any spatial heterogeneity in the samples.

Results

Electrical resistivity.—Standard 0.5 μm Ti-0.5 μm Au layers on SiO_2 were annealed in N_2 containing $\leq 1\%$ O_2 for varying times at 350°C The changes in sheet resistance with anneal time are shown in Fig. 1 for layers formed in HV and UHV systems. Several distinct stages in the plots are present for both samples, with the time taken to reach a given stage being almost an order of magnitude shorter for the UHV plot. The actual values of resistance at each stage are also significantly lower for the UHV samples for reasons considered in the discussion. These differences show through in Fig. 1, even though R_T/R_O is plotted, as R_O values were similar in the two cases: 3-4 10^{-6} Ω cm for HV films and 3.5-4.0 10^{-6} Ω cm for UHV films, cf. 2.06-2.44 10^{-6} Ω cm for bulk Au. For convenience in the following descriptions we may distinguish the following regions in the plots. First a slow initial in-

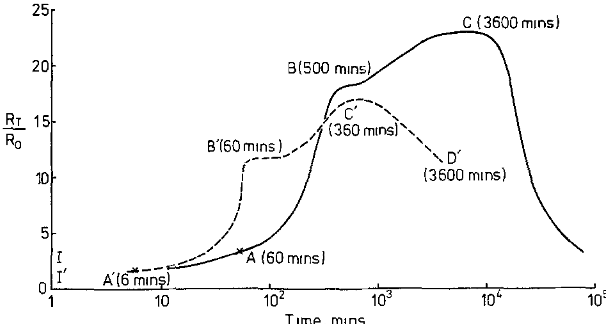

Fig. 1. Resistivity vs. anneal time plots for Au-Ti films deposited on SiO_2 in technical vacuum — and ultrahigh vacuum - - -, and annealed in air at 350°C. Points A, A′ etc. are described in the text.

crease with time (stage A), second a rapid climb to a plateau (stage B), third a further steady climb to a peak (stage C), and finally a fall off (stage D). The UHV plot stages will be further distinguished by a prime *e.g.*, A′.

Auger sputter ion profiles.—Auger profiles were recorded at each of the key stages identified in the resistivity plots. First, however, the as-deposited films were examined. In Fig. 2a a standard film on SiO_2, deposited in technical vacuum is shown. Several important features are immediately apparent. The gold film is clean by Auger criteria, with a small amount of carbon contamination on the surface. The titanium film, on the other hand, has up to ≃10% of oxygen and carbon impurity, levels which increase as the deposition continues, *i.e.*, they are quite different from an initial surface contamination broadened by the sputtering process. In contrast, the SiO_2 surface was free from carbon contamination. By comparison, both the metal films deposited in UHV (Fig. 2b) were free from impurities. In both cases there was a detectable amount of apparent interdiffusion at the Au/Ti interface with a significant Au tail extending into the Ti. In neither case had the Ti penetrated to the Au surface.

The initial stage of interaction on annealing is shown in Fig. 3. The profile was taken after annealing a UHV deposited film for 6 min (stage A′). The major change is that Ti has penetrated to the Au surface and has accumulated with oxygen. Though there has been measurable broadening of the Au/Ti interface, the Ti level within the gold film has remained undetectable. An example of slightly increased reaction (still in stage A) is shown in Fig. 4. In the HV deposited film annealed for 60 min, some Ti is detectable throughout the Au film, but there is a marked concentration gradient approximately half-way through the Au film. An increased amount of Ti and O have accumulated on the Au surface.

Stage B is illustrated in Fig. 5 where the profile was obtained from a sample deposited in technical vacuum and annealed for 500 min. The new feature is the alloying of all the Au layer. The titanium oxide buildup on the surface has increased toward 2000Å and the Au tail has extended to the SiO_2 substrate. Traces of Fe and Ni are detectable on the outer surface in this sample. Oxygen is present throughout the film with Ti. All the same major features were present at stage B′ for the UHV deposited sample (not shown). As this stage was

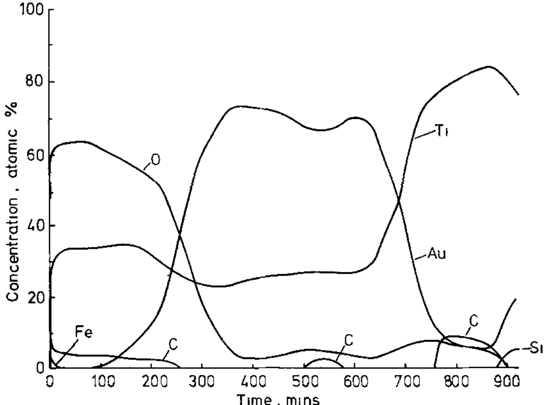

Fig. 5. Composition/depth profile of an Au-Ti film deposited in HV on an SiO_2 substrate and annealed for 500 min at 350°C.

reached after only a 60 min anneal the oxide buildup on the surface amounted to only a few hundred angstroms. A more substantial level of Fe impurity persisted throughout the film in this sample.

The final distinctive stage in the reaction is shown in Fig. 6. This profile corresponds to stage C′ on a UHV deposited sample annealed for 360 min. Here the key feature is that the oxidation of the Ti is so extensive that all elemental Ti has reacted either with O or Au. As in the earlier samples, several percent of C are present in the oxide film. Again Fe persists as an impurity throughout the films on this sample. A comparison of the fourth stage, D′, with C′ shown in Fig. 6 revealed no major differences. There was, however, a measurable enhancement of the Au level *vs.* Ti both near the peak of the Au signal and at the interface with the SiO_2. Stage C was only reached after annealing for 4000 min and, although the outlines of the profiles were similar to those shown in Fig. 6, there had clearly been much more intermixing in C between the Au/Ti alloy and the titanium oxide layers.

The similar series of samples prepared on Si substrates proved unsuitable for Auger profiling after annealing at 350°C. Although after a 6 min anneal of the UHV deposited sample the reaction had started in a similar manner to that shown in Fig. 3 a separate heterogeneous interaction (described later) rapidly began to dominate.

Further series of samples with 0.1 μm Au on 0.5 μm Ti on both Si and SiO_2 substrates were prepared and annealed at 300°C. These samples were more suitable for RBS analysis. Anneal times of 960 and 1380 min were used and no differences due to the two kinds of substrates were observed in the Auger profiles under these conditions. Both anneal periods were sufficient for the whole of these thinner layers of Au to have reacted with the Ti. The longer anneal periods differed only in that a thicker layer of titanium oxide formed above the Au/Ti layer. The extent of oxidation was also greater on the UHV prepared samples. That is a thicker oxide layer had formed after 960 min on the UHV sample than had formed after 1380 min on an HV sample. On the other hand, the surface oxygen did not penetrate beyond the Au/Ti layer in the UHV deposited sample, whereas in the HV deposited sample oxygen from the surface merged with that already in the Ti as shown in Fig. 5.

X-ray, RBS, XPS, and SEM/electron microprobe.— The x-ray diffraction data were dominated by the contributions from the layers containing gold. In addition to Au itself, the only phase detected was Au_4Ti, as identified in earlier work (3). This phase was present in all the films where Auger indicated significant interaction between Au and Ti. Both identifiable layers showed marked texturing.

As can be seen from Fig. 7 the RBS analysis supported the overall results from Auger and x-ray measurements. The slight interdiffusion during deposition was confirmed, particularly by the high energy edge of the Ti signal. Following the anneal, the appearance of Ti on the surface and throughout the gold layer is clearly evident. It is also clear, however, (particularly from the rounding of the gold peak in the annealed sample spectrum) that there is some continuous variation of composition with depth. The composition of the Au/Ti is not quite as straightforward as might be inferred from the x-ray data. While the identification of the main phase as Au_4Ti is supported, the Au/Ti ratio corresponding to the Au peak in the annealed sample RBS spectrum is $\simeq$4.7.

No nitrogen could be detected in the films, using XPS combined with argon ion sputtering.

SEM/electron microprobe analysis on the majority of the samples confirmed that the layers remained intact, so that the averaging implict in the broad area technique described above retained validity. Two conditions occurred where this situation broke down, however. First, after very long anneal times at 350°C for layers on SiO_2 substrates (stage C) where the Auger profiles for different elements showed much overlapping, this was shown to be due to a physical mixing of different matrices. SEM/microprobe analysis following a light etch in 40% HF solution showed that the Au_4Ti remaining had been honeycombed with titanium oxide.

A second, more serious exception, invalidated the profiling approach for layers on Si substrates annealed at 350°C. After about 10 min anneal a reaction involving film break-up began to spread from local

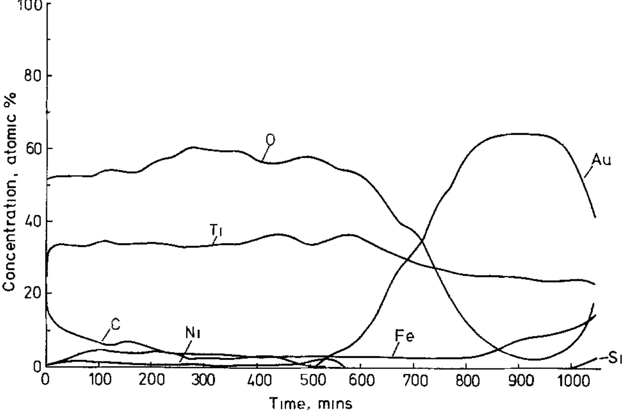

Fig. 6. Composition/depth profile of an Au-Ti film deposited in UHV on an SiO_2 substrate and anneealed for 360 min at 350°C.

areas often at the sample edge. By 30 min the reaction had occurred over the entire surface. High magnification pictures of the reaction at different stages are shown in Fig. 8. The Ti_5Si_3 crystallites were identified by electron microprobe analysis and x-ray diffraction following removal of the surrounding Au in I_2 solution. This etching also revealed that the formation of pinholes in the Ti film preceded the crystallite formation (Fig. 8c). Subsequent removal of the crystallites in 40% HF solution revealed small amounts of Au between them and the Si substrate, which had been protected from the earlier iodine etch.

Discussion

The detailed Auger profiles in Fig. 2-6 allow considerable progress to be made in understanding the basic resistivity data of Fig. 1 and the underlying interaction between Au and Ti. The basic difference between the HV and UHV deposited layers is the significant concentration of C and O in the Ti layers of the former. These impurities are the most likely cause of the slower interdiffusion rates (by almost an order of magnitude) in the HV samples. The higher resistivity at stage B compared with B′ is also likely to be dominated by these impurities, though in the comparison of C with C′ the honeycombing of the intermetallic layer by oxide will also be important. It should be stressed that these contaminant levels are to be expected for all evaporations of active metals in vacuum systems with background pressures of $\simeq 10^{-6}$ Torr. Most films studied previously (2-4) and in general use will be of the contaminated kind. The "pumping" of the background gases during the evaporation is exactly the same phenomenon that makes titanium sublimation pumps an effective aid to obtaining UHV. As a first approximation the contaminant content will reflect the ratio of the bombardment rate of the background gas molecules on the sample ($\simeq 10^{15}$ cm^{-2} sec^{-1} at 10^{-6} Torr) and the evaporant flux (which may be calculated from the amount of film deposited in a given time).

The main interaction sequence appears to be similar in the UHV and HV deposited films. It simply occurs faster in the former. Thus from Fig. 3 it seems most likely that the Ti has reached the surface by grain boundary diffusion through the gold. This mechanism is thus identified as the fastest process, as first recognized by Tisone and Drobek (2). However, as pointed out by Hall and Morabito (6) in their studies of the Au/Pd system, diffusion within the grains is also required to explain any substantial compositional change in the Au layer. Simple application of the formula $x = (Dt)^{1/2}$ to the position of the diffusion front in Fig. 4 allows an estimate of this bulk diffusion constant D. Taking x as 3000Å for $t = 3600$ sec gives $D \simeq 2.5$ 10^{-13} cm^2 sec^{-1}. As noted previously for Pd-Au (6), values of this kind are five or six orders of magnitude higher than would be expected by extrapolation of data obtained for bulk diffusion couples at higher temperatures (2). In general this result would be expected in samples cooled from high temperatures; at some point the activation energy obtained in high temperature measurements (which includes both formation and mobility of defects) would cease to apply and a lower value (which represents only the mobility term) would replace it. What is interesting is that it seems to be the norm that films formed directly at lower temperatures also have extremely high values of defects in them. Any growth methods that reduced these nonequilibrium concentrations of defects could lead to much improved metallization systems.

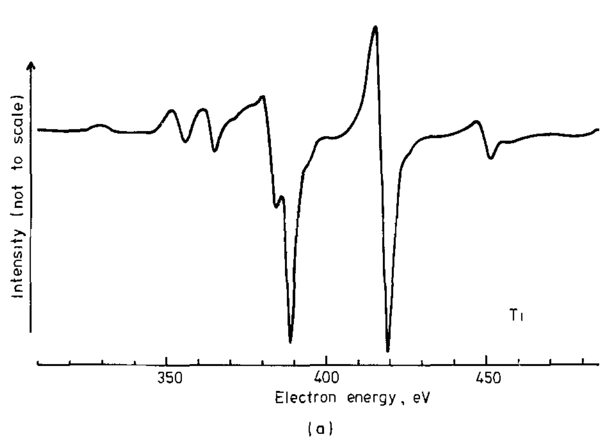
Figure 4 also shows that these enhanced diffusion rates within the grains are becoming comparable to the grain boundary diffusion rate. Thus the original Ti/Au interface is a more effective source of Ti than the grain boundaries, at least when the latter are also acting as a source for the oxidation. Otherwise one would not see a concentration gradient in Ti but a steady rise with time of a flat Ti level through the Au layer as discussed by Poate *et al.* (3) in their analysis of RBS profiles of the Pd-Au system.

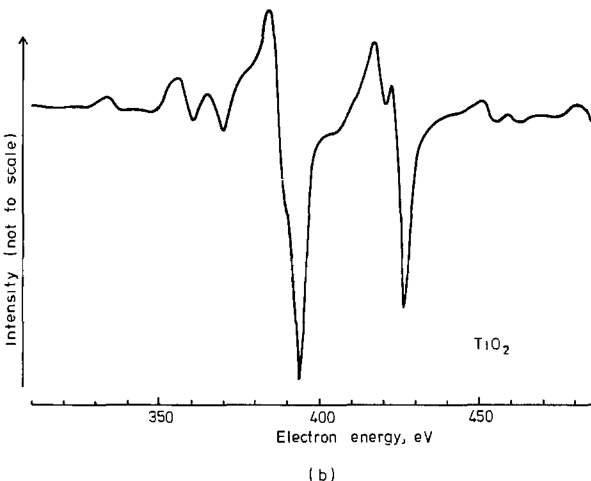
Although the experiments were primarily designed to study the intermetallic layers, it is also possible to learn something from them about the accompanying oxidation of titanium which reaches the surface. First, it is clear that the UHV deposited layers also oxidized much faster than the HV deposited layers. Thus in Fig. 6 there is approximately three times as much oxide as

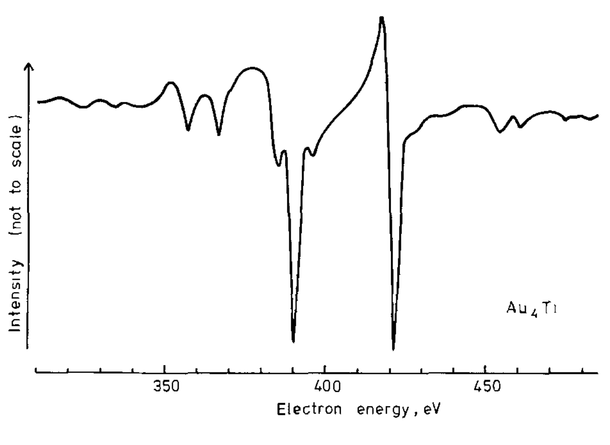
in Fig. 5 even though the anneal time in the former is shorter. A similar conclusion is provided by the data from the 300°C anneals. Second, all the oxidation rates are much greater than expected from extrapolation of literature values obtained at high temperatures. Close comparison is difficult because of the variety of rate laws reported for low temperature oxidation of titanium (7). However, the size of the effect can be gauged from the following estimate. At 600°C a parabolic oxidation law is followed (8) with kp = 0.16 exp $(-45{,}000/RT)$ g^2 cm^{-4} sec^{-1}. Extrapolation to 350°C gives $kp \simeq 2.8\ 10^{-17}$ g^2 cm^{-4} sec^{-1}, whereas from Fig. 5 with 3000Å of oxide formed in $3 \cdot 10^4$ sec $kp = 5.3\ 10^{-13}$ g^2 cm^{-4} sec^{-1} which is some four orders of magnitude higher. Even without assuming the parabolic rate law at 350°C there is the simple comparison that a slightly thicker oxide layer has grown at 350°C than in the earlier experiments with titanium (8) at 600°C. More recent work on titanium (9, 10) also shows no evidence of the faster oxidation rates reported here. However Poate *et al.* (3) did find a comparable amount of oxidation, suggesting that the faster rate is characteristic of the gold-rich Au/Ti alloys. In both these studies of the Au/Ti alloys the presence of excess nitrogen in the gas phase had no detectable effect.

The above discussion of diffusion has not depended on accurate quantitative elemental concentrations from the Auger profiles. However, it is clear from Fig. 2-6 that the Auger data is providing a good quantitative guide at many points. The values shown were obtained using Chang's basic formula (11) together with our own elemental and compound standards. The thicker layers of oxide are very close to TiO_2. The apparent excess of Ti is due to the presence of TiC also, as it is clear from the shape of the C_{272} peak that the carbon is present as carbide not in a graphitic form. In the Au/Ti alloy, on the other hand, the composition indicated by the Auger profile is too rich in Ti; in Fig. 5 the Au/Ti ratio is only $\simeq 2.7$ not 4. Errors in alloy composition are to be expected when elemental standards are used (12). For instance the Ti signal in the alloy should be enhanced due to the greater backscattering coefficient from the Au in the alloy. Also, as reported earlier for Ti and TiO samples (13), the Ti Auger spectrum undergoes strong changes in the relative intensities of the two peaks at 387 and 418 eV with matrix. Although this makes detailed quantitative work difficult it can be turned to advantage and used as a guide to the chemical state of the titanium. In Fig. 9 this region of the Ti spectrum is illustrated for the four distinct matrices occurring in the present work. The Ti_5Si_3 spectrum was recorded after an iodine etch removal of the Au, similar to that described in the SEM results section, but on a completely reacted sample. These peak intensity differences may often be amplified for ease of detection during profiling by choice of appropriate modulation voltage (14).

Following the chemical analysis, the main features of the resistivity plots shown in Fig. 1 can be interpreted as follows. The initial slow rise in resistivity is due to "removal" of free Au by alloying with Ti, as the Au layer is expected to carry $\simeq 95\%$ of the current initially (15). By stage B no free Au remains and







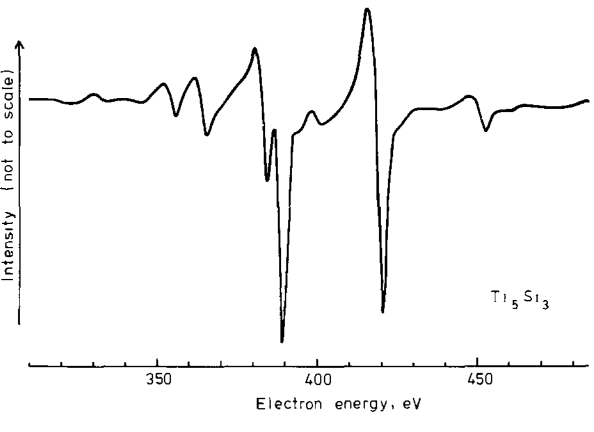


Fig. 9. Auger spectra from titanium in the 350-450 eV energy range taken with an energy resolution of 0.6% and showing the effect of different chemical matrices on the relative peak intensities: (a) metallic Ti, (b) TiO_2, (c) Au_4Ti, and (d) Ti_5Si_3.

the current is carried by both Au_4Ti and Ti layers. At stage C all the Ti has been oxidized and only the Au_4Ti layer remains conducting. A comparison between stages C and B suggests the conductivity of the Au_4Ti is comparable with that of Ti, perhaps $\simeq$30% higher. Finally, as oxidation proceeds further, some free Au is regenerated and the resistance falls again quite markedly.

Sylwestrowicz *et al.* (4) have rightly stressed that some of the mechanisms of interaction studied at high temperature may not be relevant to metallizations used on devices operated nearer room temperature. On SiO_2 substrates we have three mechanisms at least, grain boundary diffusion, bulk diffusion of Ti-Au, and oxidation of Ti, all influencing the reaction. In principle these reactions could all show quite different dependences on temperature. In practice, however, they are all likely to be quite similar. The temperature dependence of the defect mobility term in the bulk diffusion coefficient has been found to be 0.80-0.85 eV for several metals in Au (16, 17). Similarly the equivalent defect mobility term in TiO_2 has been estimated at $\simeq$ 1.0 eV (7). There appears to be no direct measurement of the activation energy for grain boundary diffusion of Ti in Au but an estimate of 0.87-0.9 eV has been calculated for Pd in Au (3, 6) and initial penetration of Ti through Au occurs at similar temperatures to Pd in Au (3). Thus in the system studied here the high temperature results reported should provide a worthwhile guide to the expected behavior of metallizations used in long-lived devices.

The results from high temperature anneals (350°C) of Au-Ti on Si substrates clearly illustrate Sylwestrowicz's point, and it is likely that they were quite unrepresentative of room temperature behavior. The detailed mechanism is not established, but it appears that a Ti-Au-Si eutectic which is molten at 350°C must form. Starting at discrete flaws in the film, the reaction then spreads rapidly. A similar phenomenon was reported by Sinha in the $Si/SiO_2/W/Au$ system (18). Both the appearance of the reaction zone in Fig. 8b and the complete envelopment of the Ti_5Si_3 crystallites in the Au matrix strongly support the idea of melting during reaction. Figure 8c suggests that the spread of the molten zone, like many other reactions, proceeds first at grain boundaries. Independent of the precise details of the reaction mechanism, it is evident that the reaction product Ti_5Si_3 is more stable than the possible Au-containing alloys, a point that it might be possible to exploit in future metallization schemes.

Conclusions

Auger sputter ion profiling has shown that deposition of Ti films in technical vacuum results in the incorporation of C and O impurities at the 1-10% level. Comparison with films deposited in UHV, and so free from the above impurities, shows that the C and O play a crucial role in determining the interdiffusion rates and hence effective lifetimes of Ti-Au thin film couples. The results suggest that monitoring and control (even controlled introduction) of such impurities, normally ignored in device production, might lead to significant improvements in current metallization schemes.

Liquid Phase Epitaxial Growth of $(Hg_{1-x}Cd_x)Te$ from Tellurium-Rich Solutions Using a Closed Tube Tipping Technique

J. A. Mroczkowski* and H. R. Vydyanath*

Honeywell Electro-Optics Center, Lexington, Massachusetts 02173

ABSTRACT

The liquidus temperatures for $(Hg_{1-x}Cd_x)_{1-y}Te_y$ have been determined for $x = 0.067$, $x = 0.10$, and $0.7 \leq y < 1.0$ compositions by differential thermal analyses. $(Hg_{1-x}Cd_x)Te$ films with compositions of $x = 0.35$, 0.31, and 0.24 have been grown by liquid phase epitaxy on CdTe (111)A oriented substrates. The Cd segregation coefficient has been determined to be $k = 3.5 \pm 0.1$. Films grown at around 550°C from 3 mm thick melts at slow cooling rates showed thicknesses close to those expected for equilibrium growth. The residual impurity in the LPE films was usually n-type and was less than 10^{15} cm^{-3} in the better films. Photovoltaic diodes fabricated in the films have shown performance comparable to those fabricated in bulk grown crystals.

The II-VI compounds of CdTe and HgTe form a continuous series of solid solutions with cubic zincblende structure. $(Hg_{1-x}Cd_x)Te$ consists of a mixture of the wide gap semiconductor CdTe ($E_g = 1.6$ eV) with the semimetallic compound HgTe which can be considered as a semiconductor having a negative energy gap. The gap in the alloys varies nearly linearly with x between the two end-point values. Alloys of $Hg_{1-x}Cd_xTe$ with x-values in the range 0.2-0.4 corresponding to bandgap energies in the range 0.1-0.5 eV are of particular interest for the detection of infrared radiation in the 2-20 micron range.

Initial LPE $(Hg_{1-x}Cd_x)Te$ film growth was pursued from pseudobinary melts due to the absence of phase diagram information in the Hg-rich and Te-rich corners. Since the pseudobinary film growth involved temperatures around 700°C and Hg pressures on the order of 10 atm a closed tube tipping technique was adopted. The work reported here concerns the subsequent determination of liquidus temperatures and LPE $(Hg_{1-x}Cd_x)Te$ film growth development from Te-rich solutions.

LPE $(Hg_{1-x}Cd_x)Te$ film growth from Te-rich solutions has only recently been reported in "open" systems (1-3), but no liquidus data covering a range of x, y values has been documented. Our initial use of a closed tube system for film growth at temperatures around 550°C, where the Hg pressure is about 1/3 atm, has permitted the study of film growth under near equilibrium conditions without concern over melt composition changes from Hg loss due to evaporation.

With phase diagram information limited to binary and pseudobinary compositions initial work was concentrated on determining the liquidus temperatures for Te-rich $(Hg_{1-x}Cd_x)_{1-y}Te_y$ solutions suitable for $x = 0.20$ to $x = 0.40$ film growth. Subsequently, stoichiometric $(Hg_{1-x}Cd_x)Te$ films were grown from slightly undersaturated 3 mm thick LPE melts. Measured film thicknesses and composition gradings obtained from slow growth conditions were then compared with calculated values based on measured liquidus temperatures and the Cd segregation coefficient.

Liquidus Temperatures

Thermal analyses were conducted by the slow cooling of homogenized $(Hg_{1-x}Cd_x)_{1-y}Te_y$ liquid samples. Charges with weights close to 15g were placed in 12 mm ID, 1 mm thick wall quartz ampuls with a thin 2 cm re-entrant thermocouple well. The free space inside the ampuls was about 5 cm^3. The change in composition due to evaporation was calculated to result in an error in the liquidus temperature interpolation of much less than 1°C. A similar ampul containing silicon was used as a reference. After sealing, the ampuls were placed very close together in two symmetrical cavities drilled in a nickel cylinder fitted with a nickel lid. A Chromel-Alumel thermocouple was inserted in each ampul, and the two were connected for simultaneous recording of the sample temperature and the temperature difference between the sample and reference as a function of time. To obtain high sensitivity sample and differential temperature readings, the sample signal was largely balanced out with a potentiometer, and the differential signal was amplified ten times. The two signals were then fed into an XYY' recorder.

Temperature data for each composition were taken after at least 6 hr of solution homogenization at temperatures at least 15°C above the anticipated liquidus temperatures. Cooling rates were typically 2°C/min, an order of magnitude larger than used in the subsequent LPE film growths. Supercooling was observed in all the thermal analysis runs, and from later liquidus temperature interpolations supercooling at the cooling rates used was found to range mostly between 5° and 15°C.

The actual liquidus temperatures were estimated by extrapolation from a plot of the degree of supercooling *vs.* temperature at which supercooling stopped. The amplitude of the differential temperature overshoot was used as a measure of the degree of supercooling.

Heating runs for the eutectic temperatures gave a range of values lying between 410° and 420°C. Since the eutectic compositions cannot be specifically defined under nonequilibrium cooling conditions the eutectic temperatures are not displayed.

The thermal analysis data taken for $x = 0.067$ and $x = 0.10$ compositions together with $x = 0$ data for Hg,Te[4] are summarized in Table I and displayed in Fig. 1. The data for the liquidus slopes at varying compositions x, y defined as $m_x = \partial T/\partial x)_y$ °C/mole and $m_y = \partial T/\partial y)_x$ °C/mole were obtained from the best slope fitting of the data shown in Fig. 1.

LPE Film Growth Procedures and Results

LPE film growth using the tipping technique was accomplished in a POCO DFP 3-2 grade graphite boat shown in Fig. 2. The outer radius of the base of the graphite boat was designed to fit the inside radius of an evacuated sealed quartz ampul. The component

preparation and the film growth processes are described in the following.

The LPE melt was usually obtained from a section of a rapidly quenched $(Hg_{1-x}Cd_x)_{1-y}Te_y$ ingot. Six nines purity quadruply zone refined Cominco Cd and Te were used for the compounding. *In situ* preparation of the melt from HgTe, CdTe, and Te in the graphite boat just before growth was also used. In both of the preparation methods the elements were homogenized in closed ampuls in the LPE tipping furnace used in a rocking mode. In the case of the *in situ* preparation method, the rocking angles were chosen such as to prevent the melt contacting the CdTe substrates before the actual growth process was initiated.

The dimensions of the CdTe substrates used were typically 10 × 37 mm; the substrates, purchased from II-VI Incorporated, were also prepared from 6 nines pure Cd and Te obtained from Cominco. Almost all the substrates used were (111)A oriented. The initial polishing of the substrates to mirror flatness involved a method using diamond milling with a single diamond edge along a select direction (5). Subsequent surface preparation involved light chemical-mechanical and chemical etching in a bromine methanol solution with the final chemical etch being performed immediately before the loading of the growth ampul.

To ensure a minimum of process contamination, the $(Hg_{1-x}Cd_x)_{1-y}Te_y$ compounding and the pre-LPE growth component assembly procedures were all performed in a VAC argon glove box which included a Mettler Electronic balance. Quartz ampuls used for compounding or film growth were baked out at 800°C under ion pump vacuum. LPE graphite boats were rf baked before each film growth run for 3 hr at 1600°C under a diffusion pump vacuum of 2×10^{-7} mm pressure. Component transfer between the glove box and vacuum stations either under vacuum or with the glove box atmosphere was performed with the use of closed bellows valves which isolated the inside of the ampuls from the ambient.

For each LPE film growth run, 10 ± ½g of $(Hg_{1-x}Cd_x)_{1-y}Te_y$ were used. The CdTe substrate and $(Hg_{1-x}Cd_x)_{1-y}Te_y$ were placed at opposite ends of the graphite boat. To prevent substrate to graphite sticking a 0.010 in. thick sapphire plate was placed in between.

After loading the graphite boat and components into a quartz ampul and subsequent evacuation and sealing, the quartz ampul with the contents was placed in the growth furnace near the center of a 12 in. sodium heat pipe. The steady-state temperature profile was ± ¼°C over the 6 in. length of the ampul. The thermal history of each growth run was recorded using the analog output of an Omega 2176A thermometer with simultaneous digital display reading to 0.2°C. The temperature and the times involved in a typical growth run are shown in Fig. 3. The recording thermocouple was checked against the melting point of Te; the melting point of Te was recorded at 452.6°C.

In most growth runs slight undersaturation was used. The CdTe substrate was then allowed to equilibrate with the solution at constant temperature for about 15 min before a slow linear cool was initiated for typically a 5°-7°C temperature drop. Figure 4 illustrates the small changes in liquidus composition after the 15 min equilibration time, and at the end of near equilibrium film growth. At the end of the cooling cycle, the solution was decanted off the film and the ampul was removed from the furnace.

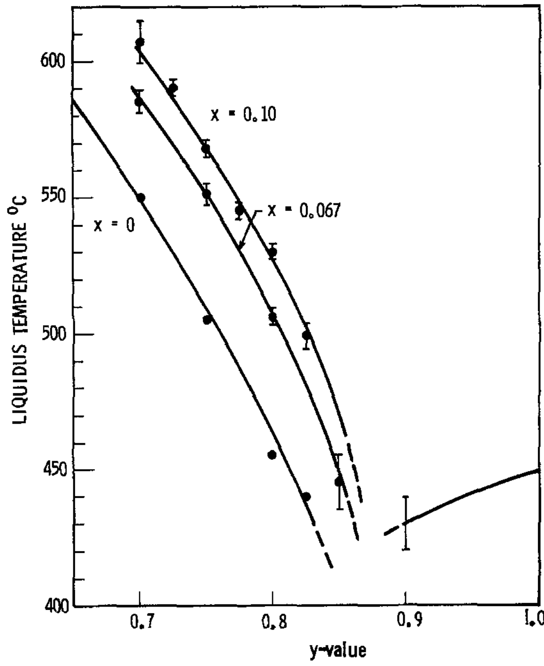

Fig. 1. Liquidus temperature data on $x = 0.067$ and $x = 0.10$ $(Hg_{1-x}Cd_x)_{1-y}Te_y$ solutions. $x = 0$ data is from Ref. (4).

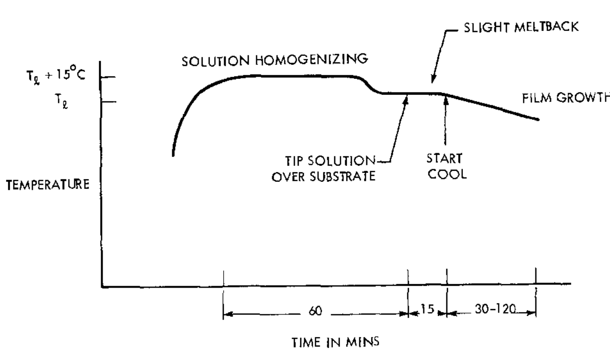

Fig. 3. Typical thermal history of an LPE film growth run; the liquidus temperature is denoted by T_l.

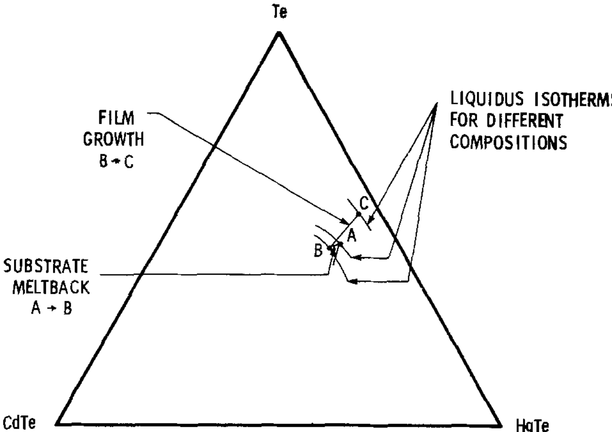

Fig. 4. Schematic of changes in the LPE solution composition (A→B→C) following the growth conditions shown in Fig. 3.

Some problems that develop in the LPE film surface morphology during growth can be traced to local changes in the melt depletion region composition. Several triggering situations are possible, including initial surface uneveness and/or substrate contamination affecting the initial nucleation and melt trace impurities. Any of these situations can result in an increasingly irregular interface, as melt diffusion in the affected areas takes on a nonuniform three-dimensional aspect. Depressed growth areas can then become increasingly covered by slightly lower liquidus temperature compositions resulting in further slow down of the growth rate in those areas and the problem can escalate, particularly under severely diffusion-limited growth conditions. Since, in the initial portion of this work, fast film growth rates appeared to be detrimental to film surface morphology, most of the film growth concentrated on slow growth rates controlled by slow cooling rates.

Film thickness *vs.* temperature drop data for films grown from solution compositions initially compounded as $(Hg_{0.90}Cd_{0.10})_{0.225}Te_{0.775}$ and $(Hg_{0.933}Cd_{0.067})_{0.25}Te_{0.75}$ are shown in Fig. 5. All of the solutions used for growing these films were undersaturated by 0 to 3°C at the time of the initial contact with the substrate. Under these conditions, after 15 min of equilibration, the new very slightly different solution compositions were considered to be very close to their liquidus temperatures.

The film thickness measurements were made optically from cleaved $(1\bar{1}0)$ planes perpendicular to the (111)A film surface. The film thickness was readily identified from a distinctly different visible reflectivity of $(Hg_{1-x}Cd_x)Te$ compared to that of the CdTe substrate. The film growth thickness was taken as the total thickness less 4 microns of interdiffusion into the substrate side of the interface.

Measured film growth thicknesses *vs.* temperature drop data given in Fig. 5 show that for cooling rates on the order of 0.05°C/min the film thicknesses were close to those expected for equilibrium film growth from 3 mm thick solutions.

X-ray microprobe analyses were performed across $(1\bar{1}0)$ cleaved surfaces of the films perpendicular to the (111)A surface. HgTe and CdTe were used as standards and the composition of films was determined using a KEVEX Magic 5 program with a ZAF correction. Composition profiles shown in Fig. 6 were made on lightly etched film surfaces and also on as-grown surfaces.

The microprobe measurements on the as-grown films and films which were lightly etched indicated that the Cd concentration increases near the as-grown surface. Evidence of an increase in the Cd concentration near the film surface was also provided by visible color differences of the film surfaces before and after etching which were the same as those seen in cleaved film sections between the CdTe substrate and the $(Hg_{1-x}Cd_x)Te$ film. Auger and ellipsometer analyses on the as-grown and etched surface areas confirmed that the composition increased by abut $\Delta x = 0.5$ within about a tenth of a micron of the surface.

The increase in surface x-value occurs after the LPE solution is decanted off, and the closed ampul cools to ambient temperatures in about 5 min. The probable explanation for this is that during cooldown the ratios of the activities of Hg and Cd over the melt and film change in a manner that favor the formation of a CdTe-rich surface layer on the film.

Infrared transmission scans were used to determine the composition of films with x-values around $x = 0.35$. For a linearly graded film composition the fraction of energy transmitted relative to the peak transmission can be expressed as (6)

$$I_{tr} = I_{pk} \exp - (2K/3\beta m)(E - E_s)^{3/2} \quad [1]$$

where E_s denotes the surface bandgap energy, E the

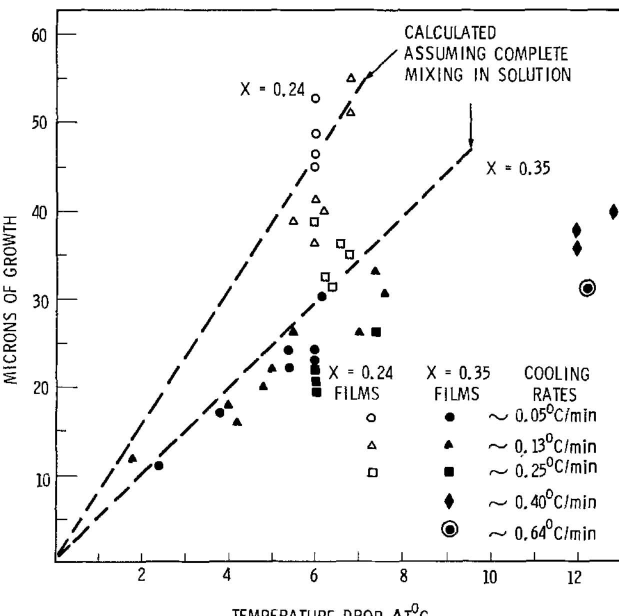

Fig. 5. Film growth thicknesses *vs.* temperature drop for $(Hg_{0.90}Cd_{0.10})_{0.225}Te_{0.775}$ and $(Hg_{0.933}Cd_{0.067})_{0.25}Te_{0.75}$ solutions.

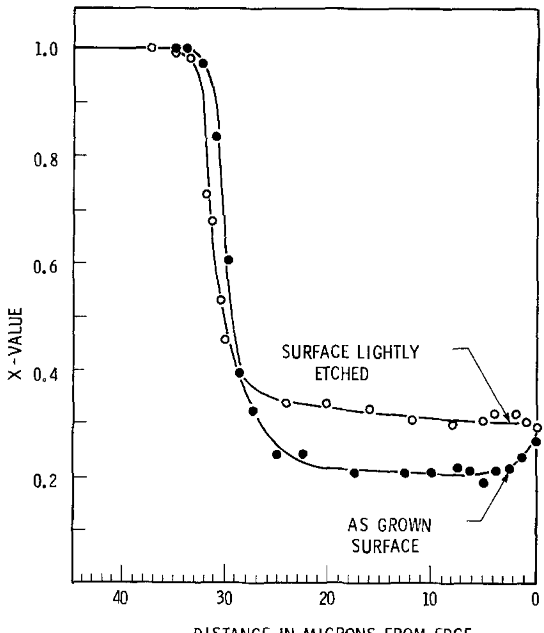

Fig. 6. X-ray microprobe data on films grown from $(Hg_{0.90}Cd_{0.10})_{0.225}Te_{0.775}$ and $(Hg_{0.933}Cd_{0.067})_{0.25}Te_{0.75}$ solutions.

photon energy satisfies $E_s + \beta md \geqq E \geqq E_s$, m is the composition grading/unit distance, β is the incremental change in energy gap/Cd mole, d is the depth from the film surface in which absorption can take place, and the parameter K is related to the bandgap energy E_g through the standard expression $\alpha = K(E - E_g)^{1/2}$ where α is the absorption coefficient at the photon energy E. Transmission curve fitting to Eq. [1] and the use of calibrated data for the absorption coefficient at $\alpha(E) = 500$ cm^{-1} *vs.* x-value (7) enabled an accurate assessment of the film surface composition to be made.

Films grown from $(Hg_{0.90}Cd_{0.10})_{0.225}Te_{0.775}$ solutions around 550°C with thicknesses around 25 microns beyond the interdiffused region showed surface x-values close to $x = 0.345$. Films which were grown from $(Hg_{0.91}Cd_{0.09})_{0.232}Te_{0.768}$ solutions at the same temperatures showed surface compositions of around $x = 0.31$ close to those expected for a 10% reduction in solution x-value. A few films which were grown from $(Hg_{0.90}Cd_{0.10})_{0.175}Te_{0.825}$ solutions at around 500°C indicated essentially no discernible change in the segregation coefficient with increase in y-value.

The segregation coefficient of Cd, k, obtained from the more extensively investigated $x = 0.10$ and $x = 0.09$ LPE solutions at growth temperatures around 550°C was taken to be $k = 3.5 \pm 0.1$. The more accurate composition determinations of films grown from $x = 0.067$ solutions at around 550°C were made using infrared spectral response measurements at 77 K; the composition of these films was $x = 0.235$, which agreed with the value kx expected from the definition of k.

Most of the film growths were carried out on (111)A CdTe substrate surfaces rather than on the (111)B and (100) surfaces. Evaluation of over 100 films grown from Te-rich solutions has shown that the best films were grown using only about 1°C of undersaturation resulting in a slight meltback of the substrate surface which could not be detected in optical examination of the film cross sections.

For 3°C of undersaturation, substrate meltback was uneven and film morphologies were very uneven, particularly when relatively fast cooling rates were used. In addition, the LPE solution was trapped in the more heavily depressed film regions after the melt decanting operation. When growth conditions used solutions estimated to be supersaturated by 2°C the quality of the film surface was generally poorer and homogeneously precipitated $(Hg_{1-x}Cd_x)Te$ crystals deposited on the film surface. It appeared that without some undersaturation, initial nucleation on the substrate may have been inhibited by traces of oxides on the substrate in the closed tube growth. The cross section of a typical LPE film is shown in Fig. 7.

A feature observed to some degree on most film surfaces was the presence of isolated, very flat plateau areas surrounded by depressed areas as seen in the micrograph of Fig. 8. The completely flat areas were exact (111)A planes with dimensions up to 1 mm across. The changes in film thickness between these areas were fairly gradual and generally within 3 microns for film thicknesses typically averaging 30 microns. However, in a few cases, thicknesses varied by more than a factor of two over distances on the order of 1 mm. These features appeared most prominently in films grown at slow cooling rates, when initial undersaturation was relatively high and when (111)A substrates oriented to within 5 min were used. Figure 8 shows the plateau areas adjacent to the more depressed areas. These morphological features are believed to be caused by convection currents in the melt since the lower, more depleted melt regions are less dense. Estimates of the solution stability using a Reynolds number criterion such as reported by Crossley and Small (8) support the possibility of solution convection during LPE film growth from Te-rich solutions, particularly when slow cooling rates are used.

Electrical characteristics.—Electrical characterization of the LPE films was used to determine the residual impurity concentration, the carrier mobilities, and the carrier concentrations. Since the CdTe substrates used for the growth of the LPE films were almost insulating it was assumed that the LPE films were electrically isolated from the CdTe substrates and therefore the electrical measurements were made on the films without etching away the substrate. Hall effect and resistivity measurements were made using the Van der Pauw method (9).

The residual impurity as measured from the Hall effect measurement at 77 K (subsequent to an Hg-rich anneal at a temperature of 250°C or less) was usually of the donor type (possibly indium) and varied between 3×10^{14} to 1×10^{15} cm^{-3} in the better films.

The electron mobility at 77 K in the better films exceeded 10^5 cm/V sec for $x = 0.2$ and 2×10^4 cm/V sec for $x = 0.3$ compositions. These values compare well with those reported for the bulk grown crystals (10) and, hence, indicate the crystallinity of the films to be sound.

Diode characteristics.—Some n$^+$-p diodes were fabricated in the LPE films. Figure 9 shows the characteristics of these diodes at 130 K in terms of R_oA (product of the zero bias resistance and p-n junction area) *vs.* the material cutoff wavelength $\lambda_{1/2}$. Data for some of the better diodes fabricated in bulk grown material are included in Fig. 9 for comparison purposes. Details of

the LPE diode characteristics will be presented elsewhere.

Discussion

Calculations of the film thicknesses and composition gradings due to Cd and Hg depletion in the solution, based on equilibrium growth conditions, have been made. These calculations provided an additional method for estimating solution liquidus temperatures based on the depth of meltback from excessively undersaturated solutions. Solution undersaturation was then optimized to provide the best film surface morphology.

A slight change in the LPE solution composition occurs during the heat up of the growth system and subsequent homogenization of the solution. This composition change is due to the interaction of the CdTe substrate with the vapor species in the growth ampul before the melt contacts the substrate. In order to assess the extent of this interaction, a CdTe substrate that was exposed only to the vapor interaction was microprobed as shown in Fig. 10. If one assumes that all the Cd loss from the CdTe substrate in exchange for Hg is uniformly dissolved in the $(Hg_{1-x}Cd_x)_{1-y}Te_y$ solution, the increase in x-value of the solution can be estimated to be about $\Delta x = 0.003$ resulting in an increase of the liquidus temperature of 2°C. These changes were expected to be reproducible in film growth runs using comparable homogenization times and temperatures.

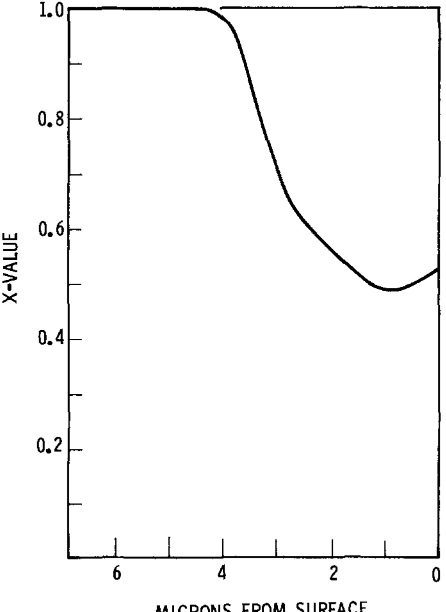

Fig. 10. X-ray microprobe analysis of a CdTe substrate exposed to the vapor (Hg, Cd, and Te_2 species) of a $(Hg_{1-x}Cd_x)_{1-y}Te_y$ growth solution during heat up and homogenization of an LPE growth run.

Consider N mole fractions of $(Hg_{1-x}Cd_x)_{1-y}Te_y$ very slowly precipitating ΔN moles of stoichiometric solid $(Hg_{1-kx}Cd_{kx})_{0.5}Te_{0.5}$ following a temperature drop ΔT°C below the liquidus temperature. Cd precipitation satisfies the follwing equation

$$\Delta[Nx(1-y)] = \Delta Nx(1-y) + \Delta xN(1-y) - Nx\Delta y = 0.5kx\Delta N \quad [2]$$

Similarly, Te precipitation gives

$$\Delta[Ny] = N\Delta y + y\Delta N = 0.5\Delta N \quad [3]$$

An additional constraint on the final solution composition is given by

$$\Delta T = \left.\frac{\partial T}{\partial x}\right)_y \Delta x + \left.\frac{\partial T}{\partial y}\right)_x \Delta y \quad [4]$$

where $\partial T/\partial x)y = m_x$ and $\partial T/\partial y)x = m_y$ are the liquidus slopes for $(Hg_{1-x}Cd_x)_{1-y}Te_y$. From Eq. [2] to [4]

$$\Delta x = \left[\frac{x(k-1)}{m_x x(k-1) - m_y(2y-1)(1-y)}\right]\Delta T \quad [5]$$

$$\Delta y = \left[\frac{-(2y-1)(1-y)}{m_x x(k-1) - m_y(2y-1)(1-y)}\right]\Delta T \quad [6]$$

$$\frac{\Delta N}{N} = 2\left[\frac{(1-y)}{m_x x(k-1) - m_y(2y-1)(1-y)}\right]\Delta T \quad [7]$$

The change in the Cd concentration C in the solution for a given change in x and y is given by

$$\Delta C = (1-y)\Delta x - x\Delta y$$

Using Eq. [5] and [6], the liquidus slope for equilibrium growth defined in terms of the Cd concentration is given by

$$m = \frac{\partial T}{\partial C} = \frac{m_x x(k-1) - m_y(2y-1)(1-y)}{(1-y)(k+2y-2)x} \quad [8]$$

For film thickness determination the densities of the LPE melt and precipitated solid $(Hg_{1-x}Cd_x)Te$ are taken as $\rho_m(x,y)$ and $\rho_f(kx,0.5)$, respectively. The LPE film thickness l_f for equilibrium growth can then be obtained with the use of Eq. [7] and [8], while noting that the ΔN for the film is opposite in sign to that for the solution. Denoting the molecular weights of the film and melt by M_f and M_m we obtain

$$l_f = -\frac{\rho_m(x,y)M_f}{\rho_f(kx,0.5)M_m}\left[\frac{2l_m\Delta T}{mx(k+2y-2)}\right]$$

Estimates of $\rho_m(x,y)$ were obtained from the sum of the proportionately weighted stoichiometric solid and pure Te densities $\rho(x,0.5)$ and ρ_{Te}, respectively, *i.e.*

$$\rho_m(x,y) = 2(1-y)\rho(x,0.5) + (2y-1)\rho_{Te}$$

The density of solid $(Hg_{1-x}Cd_x)Te$ at room temperature (11) was taken as

$$\rho(x,0.5) = 2.226(3.628 - x)$$

and the density of pure Te at 550°C (12) was taken as 5.75 g/cm^3.

Table II lists some of the growth parameters used to obtain films with compositions of $x = 0.35$ and $x = 0.24$, and also the calculated equilibrium values of film growth thickness/°C of temperature drop and the composition grading/micron of growth from 3 mm thick solutions.

Under equilibrium growth conditions the change in the solution x-value due to the depletion of Cd and Hg

Table II. Summary of film growth parameters and calculated substrate meltback depths and film composition changes due to initial solution undersaturation, and film thickness and composition gradings in subsequent film growth

		Film compositions	
		$Hg_{0.65}Cd_{0.35}Te$	$Hg_{0.765}Cd_{0.235}Te$
Parameters			
Melt thickness	l_m mm	3	3
Melt composition	$(Hg_{1-x}Cd_x)_{1-y}Te_y$	$(Hg_{0.90}Cd_{0.10})_{0.225}Te_{0.775}$	$(Hg_{0.933}Cd_{0.067})_{0.25}Te_{0.75}$
Liquidus slopes	m_x °C/mole	630	600
	m_y °C/mole	−862	−770
	m °C/Cd mole	3850	3915
Densities: melt	$\rho_m(x, y)$ g/cm³	6.7	6.8
film	$\rho_f(kx, 0.5)$ g/cm³	7.3	7.5
Segregation coefficient	k (Cd ratio)	3.5	3.5
Film growth			
Thickness	l_f microns/°C	4.9	7.35
Film grading	$\frac{d(kx)}{dl_f}$ Cd moles/micron	−0.0007	−0.0004
Meltback $Hg_{0.5}Cd_{0.5}Te$ surface			
Effective segregation coefficient	k' Cd ratio	5.0	7.46
Liquidus slope	m' °C/mole	3504	3053
Film x-value increase	$k\Delta x$ Cd moles/°C	0.0039	0.0043
Meltback depth	l_d microns/°C	−3.6	−4.0
Meltback CdTe surface			
Effective segregation coefficient	k' Cd ratio	10.0	14.9
Liquidus slope	m' °C/mole	3135	2716
Film x-value increase	$k\Delta x$ Cd mole/°C	0.0047	0.0050
Meltback depth	l_d microns/°C	−1.9	−2.2

during growth results in proportional changes in the precipitated solid composition x-values. From Eq. [5] and [8], $\Delta x/x$ in solution can be expressed as

$$\frac{\Delta x}{x} = \frac{(k-1)\Delta T}{(k+2y-2)(1-y)mx}$$

The change in the x-value of the film is then

$$k\Delta x = \frac{k(k-1)\Delta T}{(k+2y-2)(1-y)m} \qquad [9]$$

Using Eq. [9], the change in x-value as a function of film thickness can be obtained

$$\frac{d(kx)}{dl_f} = -\frac{\rho_f(kx,0.5)M_m}{\rho_m(x,y)M_f}\left[\frac{(k-1)kx}{2(1-y)l_m}\right] \qquad [10]$$

To estimate substrate meltback depths and the increase in the film composition profile resulting from a Cd and Hg increase in the solution the same formalism as used for growth can be used for meltback, provided that k and m are appropriately redefined by their effective values in meltback, that is k' and m'. On the basis of the microprobe data shown in Fig. 10 two values of k' have been considered for the meltback process. First, for the case of light meltback of no more than about 2 microns of the substrate surface with x-value around $x = 0.5$, k' was taken as $0.5/x$ where x is the solution x-value. Second, for the case of significant meltback involving essentially pure CdTe k' was taken as $1/x$. The increase in the whole film x-value profile for $\Delta T'$°C of undersaturation could then be obtained from

$$k\left[\frac{(k'-1)\Delta T'}{(k'+2y-2)(1-y)m'}\right] \qquad [11]$$

With most undersaturated solution contact temperatures controlled to within ±½°C of each other the measured film x-value variations between films of comparable thickness, grown from the same solution compositions, were observed to be within $\Delta x = \pm 0.002$. These results are consistent with the composition variations expected on the basis of Eq. [11] and listed in Table II.

Average meltback depths l_d into $Hg_{0.5}Cd_{0.5}Te$ and separately into CdTe substrate surface compositions were determined from

$$l_d = -\frac{\rho_m(x,y)M_s}{\rho_s(k'x,0.5)M_m}\left[\frac{2l_m\Delta T'}{m'x(k'+2y-2)}\right]$$

where M_s and ρ_s denote the molecular weight and density of the surface with composition $k'x$. The calculated values of l_d in Table II show that the meltback depth per °C of undersaturation is significantly less on CdTe than on $Hg_{0.5}Cd_{0.5}Te$. In films grown from supersaturated solutions the Cd/Hg interdiffusion depth on the CdTe substrate was typically 4 microns. Based on this information, the meltback depth data in Table II and observation on over a hundred films showing that excessive undersaturation led to uneven meltback reaching into the CdTe, we have associated an undersaturation of about 2°C as the temperature at which meltback could just be seen. Using meltback observations as a reference point for estimating solution undersaturation, it was estimated that the optimum degree of solution undersaturation for the best film morphology appeared to be about 1 ± ½°C.

Two liquidus temperatures estimated from thermal analyses and meltback considerations are given in Table III. The liquidus temperature data obtained from thermal analysis appear to be about 3°C higher than those interpreted from LPE film growth. This temperature difference is believed to be largely due to the interaction between the substrate and solution via the vapor phase before solution tipping over the substrate. Allowing also for the solution depletion during growth, the Cd segregation coefficient for solutions with $y \geq 0.75$ and low x-values is estimated to be $k = 3.5 \pm 0.1$.

Summary

Thermal analyses have been made of Te-rich $(Hg_{1-x}Cd_x)_{1-y}Te_y$ solutions with compositions suitable for growing $(Hg_{1-x}Cd_x)Te$ films with compositions

Table III. Liquidus temperatures obtained by DTA and from LPE films

Solution composition		Film surface kx	Liquidus temperatures determined from	
x	y		DTA	LPE
0.10	0.775	0.35	545 ± 3°C	549 ± 1°C
0.067	0.75	0.24	551 ± 4°C	554 ± 1°C

$x = 0.2$-0.4. The liquidus temperatures obtained in this way are consistent with estimates inferred from substrate meltback prior to the film growth process.

LPE $(Hg_{1-x}Cd_x)Te$ films grown at slow cooling rates under almost nondiffusion limited conditions showed thicknesses and composition gradings close to those calculated for equilibrium growth. In the absence of Hg loss in the closed system used, an accurate assessment of the Cd segregation coefficient was possible for low x-value $(Hg_{1-x}Cd_x)_{1-y}Te_y$ solutions with $y \geqq 0.75$; the value obtained was $k = 3.5 \pm 0.1$.

Using slight undersaturation, smooth films up to 40 microns thick were grown. Electrical characterization of the LPE films showed electron mobility and residual impurity concentration characteristics comparable to bulk grown material. In addition, the performance of photodiodes made in the LPE films was similar to those made in the bulk grown material.

ABSTRACT

Homojunction, graded bandgap GaAlAs:Si LED's have been demonstrated to be highly reliable. During accelerated aging (30 mA forward bias, 250°C), these LED's generally degrade slowly without the formation of dark lines or dark spots. It has recently been found, however, that some LED's show a rapid reduction of light output even when aged without current bias at 200°C. <110> oriented dark lines appeared in the electroluminescence image of heavily degraded devices. To determine the source of the DLD's, the material quality of degraded LED's and unaged LED's from the same wafer was assessed using etch pitting and transmission cathodoluminescence. Examination of the devices revealed the presence of small pyramids, composed mainly of silicon, on the p-surface of some of the LED's; no unusual features were found on the remaining LED's. A dislocation network surrounding each pyramid was found to be initially present. Due to bonding and thermal stresses applied to the pyramids, these networks enlarged with aging along the {111} planes and appeared as <110> DLD's in the electroluminescence image upon reaching the p-n junction. In degraded LED's from pyramid-free regions of the wafer with pyramids, <110> DLD's initiate at dicing damage and regions of the p-surface subject to high bonding stress, *i.e.* edges and corners. The growth of these DLD's is identical to those initiating at pyramids. A similar study of LED's from a wafer that is totally free of pyramids shows that DLD's are not formed in devices that degrade slowly.

Graded-bandgap, homojunction GaAlAs:Si LED's are presently used as high efficiency light sources for opto-isolators (1, 2). Bias tests of these devices, accelerated by applying a thermal stress, demonstrated high reliability; with 30 mA forward current bias, a mean-time-to-failure (MTTF) of $\sim 10^5$ hr at 250°C (1) and $\sim 10^8$ hr at 25°C (3) was determined. The electroluminescence of degraded diodes appears to differ from unaged devices only in relative brightness. Both degraded and undegraded LED's exhibit uniform light emission; no dark lines or spots are observed. Recently, however, aging studies (4) have shown that some LED's degrade rapidly when aged at 200°C even without current bias; degradation to 10% of initial efficiency occurred within 400 hr. Examination of the

electroluminescence image of many of the most heavily degraded devices showed the presence of <110> oriented dark line defects (DLD's). The drop in LED efficiency is thus attributed to nonradiative recombination at the DLD's. Since dark line formation has not been previously observed in graded bandgap GaAlAs: Si LED's, this paper reports on their origin and growth behavior.

Formation of dark spots and dark lines oriented in the <100> and <110> directions is a degradation mode for LED's fabricated from many semiconductors, *e.g.*, GaP (5), GaAs/GaAlAs (6-13), and GaAsP (14, 15). <110> DLD's grow by glide motion of dislocations on the {111} slip planes (6, 7, 9, 10) whereas the growth of <100> DLD's is consistent with climb of dislocations (11-13). Studies have shown that formation of <100> DLD's require minority carrier injection whereas <110> DLD formation can be induced with either minority carrier injection or stress (7). Since the GaAlAs:Si LED's under discussion developed <110> DLD's without current bias, a source of stress was searched for.

Studies of stress-induced DLD's in GaAs/GaAlAs double heterostructure crystals provide a useful background for the present study. These studies showed that a threshold stress is required to form <110> DLD's (6, 7, 9, 10). This threshold level decreases for increasing minority carrier injection (6, 7, 10). For no injection, the threshold stress is $\sim 8 \times 10^9$ dynes/cm^2 (7). This value rapidly decreases to $\sim 2 \times 10^9$ dynes/cm^2 under the low excitation level of 3 W/cm^2 from a 6471Å Kr-ion laser beam, equivalent to a current density of $J \sim 1$ A/cm^2 (7). A lower stress level of $\sim 6 \times 10^8$ dynes/cm^2 is found for $J = 58$ A/cm^2 (10). These stress values are comparable with values from typical sources of stress. Stresses from dielectric coatings can be as high as 10^{10} dynes/cm^2 (15), stresses due to dicing damage are 2-7 $\times$ 10^7 dynes/cm^2 (14), and the thermal stress on a mounted LED, assuming a 100°C temperature difference between header and LED, can be $\sim 10^9$ dynes/cm^2 (8).

In a reliability study by King (4), LED's from the same wafer as those that showed poor reliability were examined visually. Pyramidal protrusions of various sizes were found on the p-surface of some of the LED's (4). These pyramids occasionally occur in this device material and their exact cause is presently under investigation. LED's from the same wafer were separated into groups with and without pyramids. Bonded LED's with pyramids were found to degrade at a faster rate than those without pyramids, but both groups degraded faster than previous devices (1, 3, 4). A mean-time-to-failure (MTTF) of $\sim 10^5$ hr (250°C, 30 mA forward current) has been found for the latter whereas the LED's with pyramids show a MTTF of $\sim 4 \times 10^2$ hr even under reduced stress conditions (200°C, 0 mA forward current). Dark regions and lines in the electroluminescence image were observed only in the devices degraded to less than $\sim$10% of their initial efficiency.

In the present study, the material quality of unaged and aged devices from a wafer exhibiting pyramids on the p-surface was determined by KOH etch pitting (17) and transmission cathodoluminescence (TCL) (18). A dislocation network was found to surround each pyramid initially. During aging, <110> DLD's develop from these networks. In the pyramid-free LED's, <110> DLD's initiate at processing damage and at high stress points (*e.g.*, edges and corners) on the p-surface. To determine whether bonding stress or internal stress is responsible for the growth of the DLD's, a defect study was made of similar unbonded LED's aged at 200°C without current bias. Finally, a high dislocation density ($\sim 10^5$ cm^{-2}) and stacking faults were found in the degraded devices. This result suggests that the susceptibility of the pyramid-free LED's to stress-induced DLD's may be simply due to a high dislocation density or to the presence of stacking faults. Low and high defect density GaAlAs:Si LED's fabricated from a wafer without pyramids on the p-surface were then tested. High reliability was found for the LED's irrespective of the defect density. The degradation of these LED's did not involve the formation of DLD's. These experiments and results are summarized in Table I. The remainder of this paper comprise the details of this study.

Experimental

Device characteristics.—The GaAlAs:Si LED's were grown by a single-step liquid phase epitaxy (LPE) technique as described by Dawson (1). A schematic of the LED structure is presented in Fig. 1. An epitaxial layer of $\sim$200 μm thickness is grown on a <100> oriented GaAs substrate. The aluminum content of this

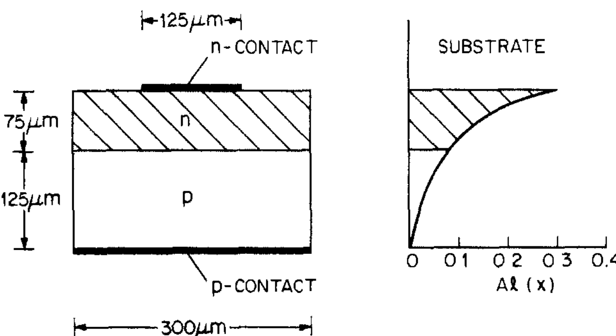

Fig. 1. Schematic of GaAlAs:Si LED

layer varies from an initial value of $x \sim 0.30$ to a final value of $x \sim 0.0$. The p-n junction is formed by Si amphoteric doping; the aluminum concentration is $x \sim 0.08$ at this junction which is located ~75 μm from the substrate-epilayer interface. After epi-growth, the GaAs substrate is chemically removed from the LPE layer, contacts are evaporated, and the wafer is diced into 300 × 300 μm square diodes. The p-surface receives a full surface metallization of 1% BeAu alloy whereas the n-contact consists of a 125 μm diam dot of SnAu. To minimize dicing damage, the saw cuts are aligned along the <100> directions (45° from the <110> cleavage directions) and then etched to remove the sawing damage. The etch consists of 30% H_2O_2 whose *p*H is adjusted to 8.4 by the addition of NH_4OH (1). The devices are bonded with epoxy with the p-surface toward the header so that the higher aluminum content, *i.e.*, higher bandgap, n-layer forms a window for the light emitted at the p-n junction. The typical operating condition is 10 mA forward current, corresponding to a current density of $J \sim 10$ A/cm^2.

Material evaluation technique.—As noted above the material quality of degraded and undegraded devices was assessed using KOH etch pitting (17) and transmission cathodoluminescence (TCL) (18). Dislocations appear as dark spots in the TCL image due to nonradiative recombination. An exact one-to-one correspondence between dislocation pits produced by the KOH etch and dark spots in TCL images of the {100} surface of GaAlAs:Si has been previously established (18). For most of the study the TCL technique was used since etch pitting of small devices is difficult.

Both etching and TCL require removal of the LED from the header used for aging and testing. Other techniques for detecting material defects, *e.g.*, cathodoluminescence (CL) and electron beam induced current (EBIC), that do not require demounting of the LED, were tried unsuccessfully. Although mechanical damage appears as a dark region in TCL, CL, and EBIC images, grown-in dislocations and DLD's are apparent only in the TCL images (19, 20).

For TCL measurements, the devices were carefully demounted from the TO-18 headers by softening the bonding epoxy with heat ($T \sim 300$°C) applied to the header. The residual epoxy was removed using an oxygen plasma. The contact metallization was chemically stripped with a solution of 450g KI, 150g I_2, and 400 ml H_2O. Since the contact is alloyed into the semiconductor and since the metallization etch mildly attacks GaAlAs, the etched surfaces are rougher than the as-grown surface. This surface is, however, sufficient for TCL imaging.

Material quality and degradation.—Figure 2 shows an electroluminescence image of a typical, rapidly degraded LED. The dark circle in the center is the n-contact. Several <110> oriented DLD's are observed. These dark lines are located at the p-n junction where the light is emitted. To determine the source of the DLD's, the degraded LED's were first visually inspected on the headers using the SEM and Nomarski interference microscopy. Some damage was found, but it was not considered unusual or excessive. After demounting the LED's, small pyramids of various sizes were found on the p-surface of some of the LED's. Figure 3a is a secondary electron (SE) image of an unaged LED with several pyramids. X-ray microanalysis on an SEM showed that these pyramids are composed mainly of silicon (21).

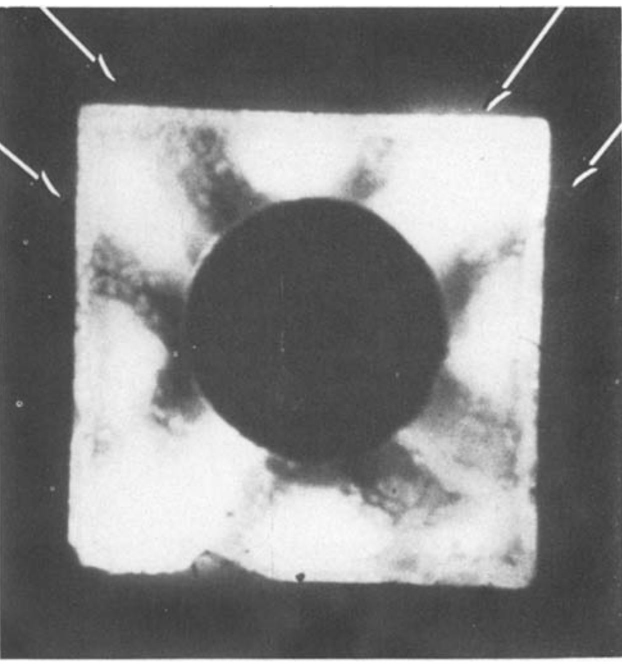

Fig. 2. Electroluminescence image of the n-surface of a degraded LED. The black dot in the center is the n-contact. The arrows indicate the <110> DLD's.

Figure 3b is the TCL image of the region shown in Fig. 3a. The pyramids appear dark due to the low luminescence efficiency of these regions. In addition to dark regions, dark lines extending from the pyramids along the <110> directions are observed. These dark regions and lines are part of a dislocation network and have no corresponding features in the SE image of Fig. 3a. These dislocation networks are probably a result of lattice mismatch between the GaAlAs epilayer and the Si pyramid. Using the KOH defect etchant (17), these dislocation networks are also revealed. The surface of a wafer, examined with Nomarski interference microscopy before and after etching, is shown in Fig. 4a and 4b. A comparison of the two figures shows that the pyramids have been etched away by the KOH. The dislocation network surrounding the pyramids appears as a rectangular region containing a high density of etch pits. The <110> dark lines appear as a series of pits after KOH etching.

Figures 5a and 5b are, respectively, the SE and TCL images of the p-surface of typical degraded, bonded LED's. Although Fig. 3 and 5 correspond to two different LED's, comparison of these figures shows clearly that with aging the dislocation networks originating at the pyramids enlarge along the <110> directions and form <110> DLD's. A similar study of unbonded LED's was performed to determine whether bonding stress or internal strain was responsible for the growth of the DLD's. The TCL images of the aged, unbonded LED's were similar to Fig. 3b. No noticeable growth of the dislocation networks was found. It is thus concluded that bonding stresses applied to the pyramids is one source of DLD's. These stresses include those that result from the differences in the thermal expansion coefficient of the LED, header, and bonding material.

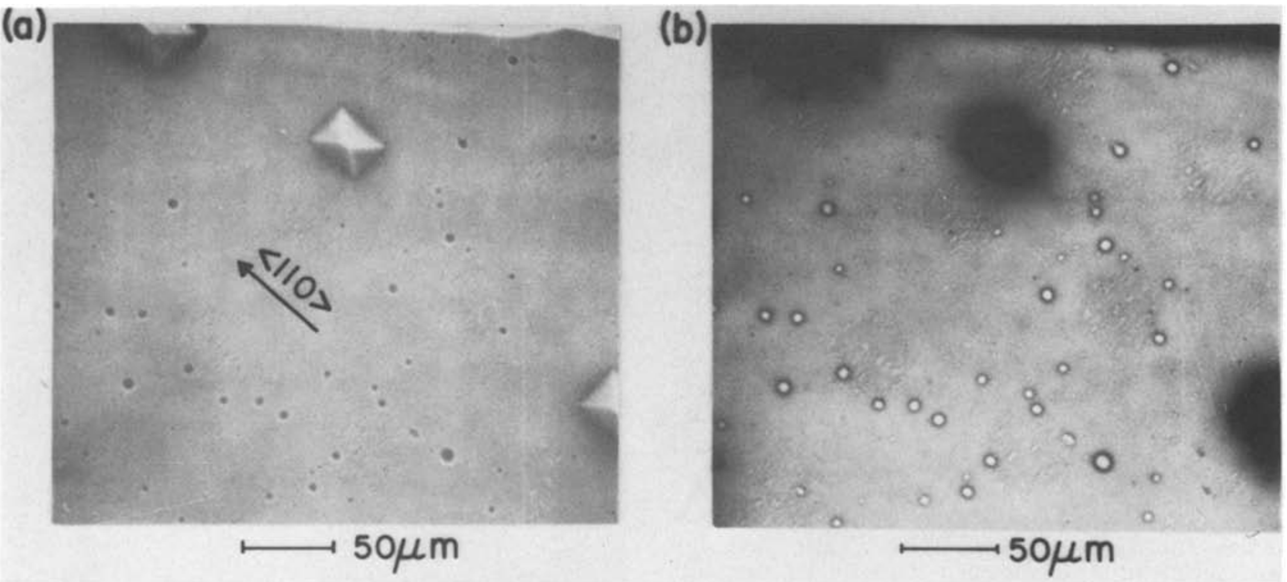

Fig. 3. a. Secondary electron image of the p-surface of an unaged LED with pyramids. The sides of the pyramids are parallel to the <110> directions. b. TCL image of the region in Fig. 3a. The dark area surrounding each pyramid is a dislocation network. The short dark lines are dislocations extending along the <110> directions.

Bonded devices without pyramids selected from the same wafer as the LED's in Fig. 3 and 5 were also found to degrade although at a slower rate (4). After 10^3 hr at 200°C without current bias, the efficiency is generally reduced to $\lesssim$ 0.1 of its initial efficiency. As in diodes with pyramids, <110> DLD's were observed in the electroluminescence image only after the efficiency had fallen below $\lesssim$ 0.1 of its initial efficiency.

TCL examination shows <110> DLD's initiating at dicing damage and high stress points, *e.g.*, edges and corners, on the p-surface. Typical DLD's are shown in Fig. 6. Dicing damage is visible in the SE image of Fig. 6a; DLD's extending from the dicing damage are visible in the TCL image of Fig. 6b. These DLD's are found in the TCL image of all aged LED's examined, even those that do not show DLD's in the electroluminescence image. Although similar damage was found

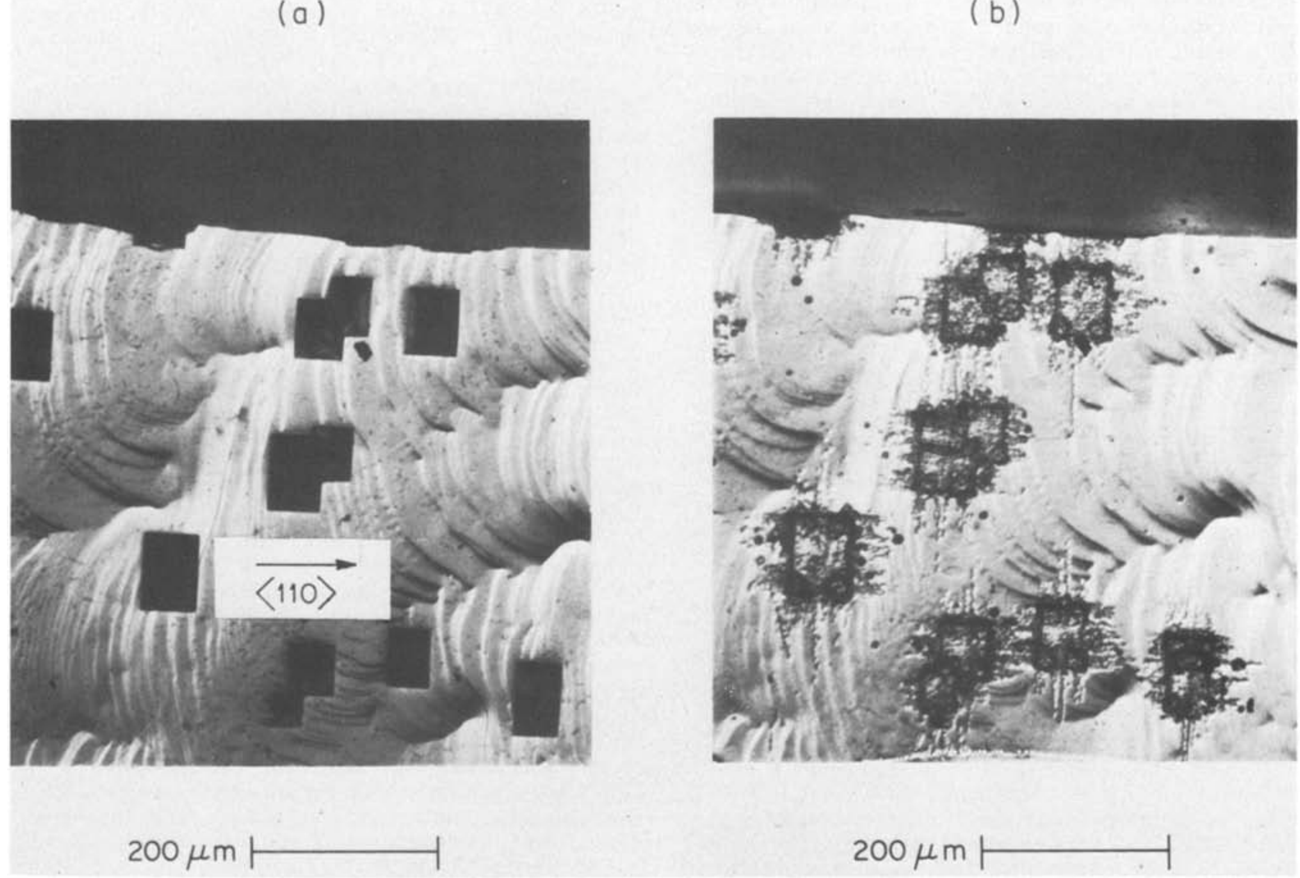

Fig. 4. a. Region of p-surface containing pyramids. b. Region of p-surface after etching in KOH. The pyramids have been removed by the etch and a high density of etch pits is observed beneath the pyramid (rectangular regions of pits). Linear arrays of pits extend along the <110> directions.

in unaged devices, only dark regions and not dark lines were associated with them. It will be shown below that the susceptibility to DLD formation is peculiar to the device wafers with silicon pyramids.

DLD growth behavior.—The study in the above section concentrated on the p-surface due to the presence of pyramids there. To determine whether the DLD's originate only on the p-surface, the top n-surface and (100) sides of the LED's need to be examined. In unaged devices, the usual dislocations, stacking faults, and processing damage were found on these surfaces. In degraded devices, TCL images of the n-surface were similar to those of unaged LED's, but <110> DLD's were found on the sides. By examining the sides of partially and highly degraded LED's, the DLD's were found to initiate at the p-surface and propagate

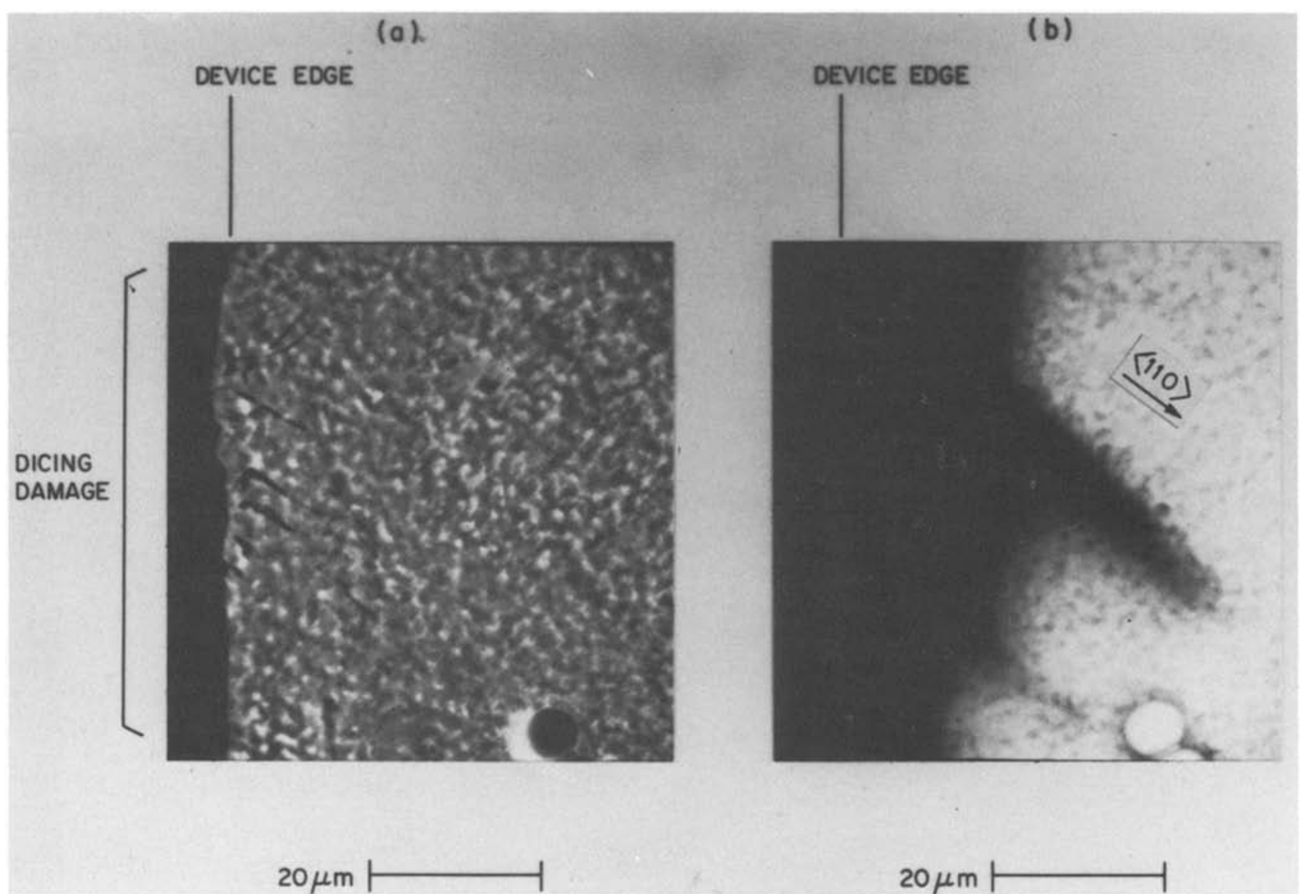

Fig. 6. a. SE image of the p-surface of an LED showing dicing damage along an edge. b. TCL image of the region in Fig. 6a. <110> DLD's initiate at the damage.

toward the p-n junction; the DLD's did not extend beyond the p-n junction into the n-region even in the most heavily degraded LED's ($\eta/\eta_0 < 0.01$).

SE and TCL images of the (100) side of a partially degraded LED are shown in Fig. 7. The SE image shows that the etch used to remove dicing damage removes more of the n-layer. The p-n junction appears as a dark line in the TCL image since the built-in electric field separates the electron-hole pairs generated by the electron beam and prevents recombination (22). The n-layer is brighter than the p-layer due to higher intrinsic luminescence efficiency rather than a result of degradation. DLD's were not observed in the electroluminescence image although the luminescence efficiency was 0.62 of its initial efficiency. However, DLD's were found by TCL imaging of the p-surface and the sides. The DLD's initiate at dicing damage on the p-surface and extend up the side as shown in Fig. 7b. The DLD's intersect the {100} p-surface at an angle of 45°, suggesting that the DLD's lie on the {111} slip planes.

Figures 8a and 8b are the SE and the TCL image of the {100} sides of heavily degraded LED. After aging, this {100} side was ground with 3 μm alumina grit and etched in Br/methanol to observe the p-n junction clearly. The efficiency was $\lesssim 0.01$ of the initial value; DLD's were observed in the electroluminescence image. As shown in Fig. 8b, the DLD's propagate up to the p-n junction, but do not penetrate into the n-layer. Similar examination of LED's with various degrees of degradation shows that the DLD's always initiate at the p-surface and propagate toward the p-n junction.

The DLD's stop their growth upon reaching the p-n junction probably due to lower stress in the n-layer. Since the etch used to remove the saw damage removes more of the n-layer than the p-layer, the n-layer may have a lower surface damage induced stress. A high internal electric field at the p-n junction is unlikely to hinder the propagation of the DLD's. Similar stress-induced <110> DLD's in GaAs/GaAlAs wafers have been shown to propagate through the p-n junction (23). Further study, *e.g.*, an examination of degraded LED's using transmission electron microscopy or a reliability study of LED's that have been etched more uniformly, is required to determine the exact cause of this effect. Such studies are beyond the scope of this work.

Degradation of high and low defect density LED's.—During evaluation of device wafers with pyramids, a high dislocation density (up to $\sim 10^5$ cm^{-2}, ~100 dislocations/LED) and stacking faults were found. Additionally, the dislocation networks beneath the pyramids were resolved as individual dislocations or parts of dislocation loops even after 50-100 μm of material have been chemically etched from the p-layer. The susceptibility of the pyramid-free LED's to DLD formation was thus possibly a result of a high defect density. To investigate the influence of such defects, a separate set of LED's from a wafer completely free of

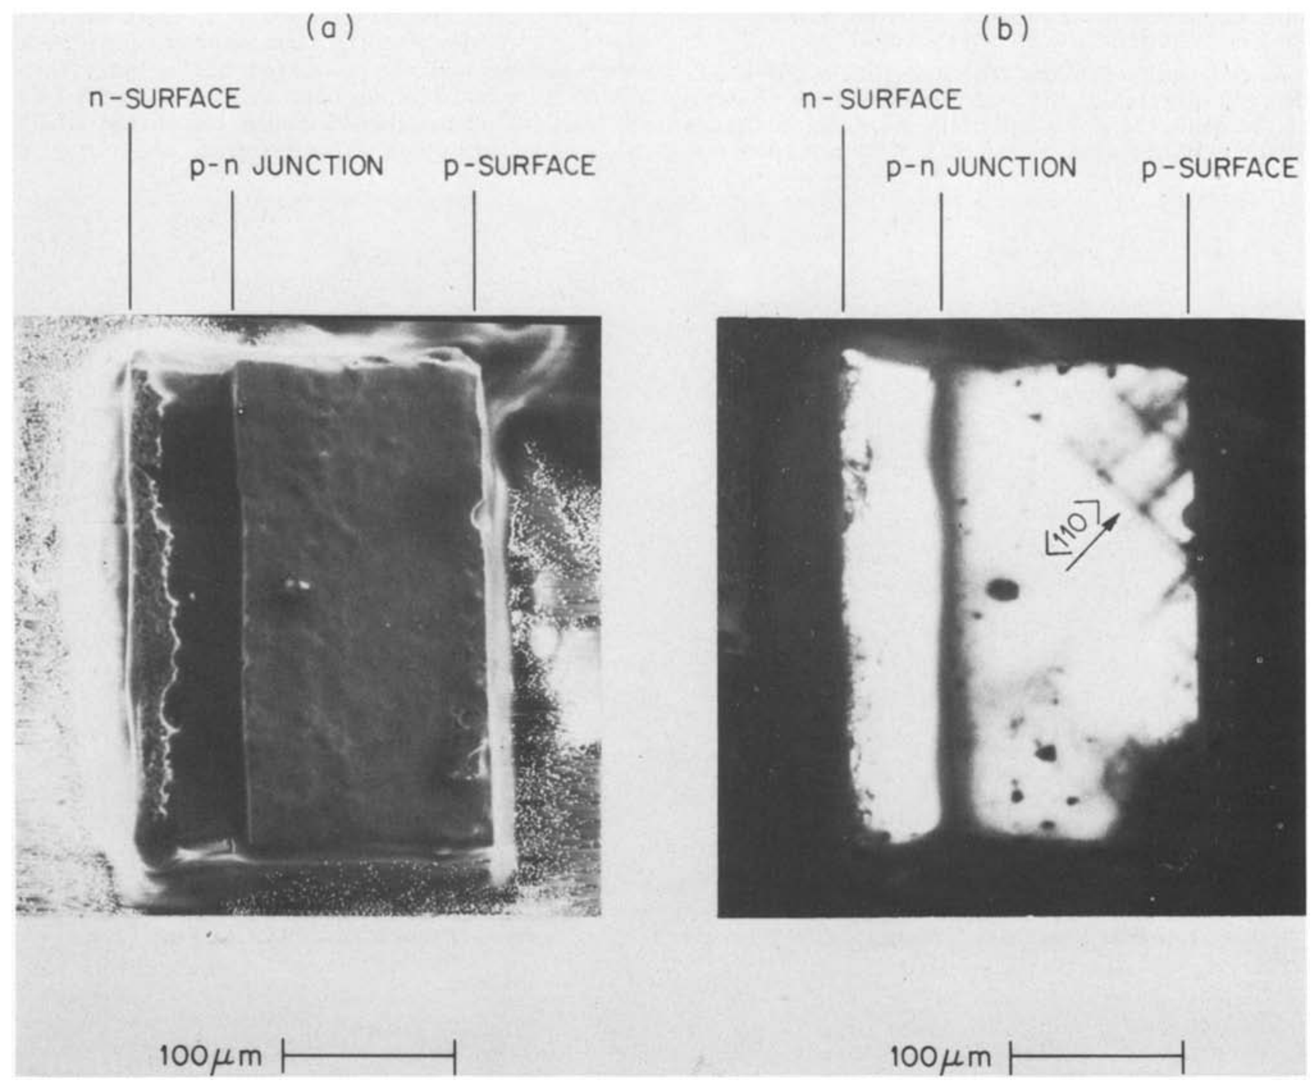

Fig. 7. a. SE image of {100} side of a partially degraded ($\eta/\eta_0 = 0.62$) LED. b. TCL image of the region in Fig. 7a. <110> DLD's initiate at the p-surface and propagate along the (111) planes toward the p-n junction.

Fig. 8. a. SE image of the {100} side of a heavily degraded (η/η_o = 0.01) LED. The surface has been ground and etched. b. TCL image of the region in Fig. 8a. <110> DLD's initiate at the p-surface, propagate along the {111} planes toward the p-n junction, and terminate at the p-n junction.

pyramids was separated into a group containing a high defect density (stacking faults and 20-40 dislocations/LED) and a group containing a low defect density (5-15 dislocations/LED). The two groups were then tested in the usual fashion (250°C, 30 mA forward bias).

The defect density of each diode was determined in the following manner. The surface of the device wafer was Br/methanol polished to provide a smooth surface; ~25 μm of material was removed. Saw cuts, 25 μm deep, were made into the wafer to define the locations of the LED's. The p-surface of each LED was imaged using TCL to determine the defect content. After processing, the wafer was diced along the original saw marks. The LED's were demounted from the cutting block and individually etched to preserve their identity.

The results of the reliability study on these LED's are plotted in Fig. 9. The average efficiency of each group is plotted *vs.* the square root of time in hours; each group contains 10 LED's. Essentially, the results show that the defect density of the devices from a wafer free of pyramids has little or no effect on the reliability. From the data in Fig. 9, an MTTF of $\gtrsim 10^5$ hr at 250°C with 30 mA forward current is estimated for both high and low defect density LED's. These values of MTTF are similar to those found by Dawson (1). No catastrophic degradation was observed in any of the devices, and no DLD's were observed in the electroluminescence image after the ~4000 hr of operation.

Ten of the LED's were demounted and examined using TCL. In general, some additional dark spots developed during aging, but short ($\lesssim$ 25 μm), dark lines were found only in one of the devices. These dark lines were present at the edge of the LED on the p-surface as shown in Fig. 10. Figures 10a and 10b are the SE and TCL images, respectively. Two <110> DLD's and

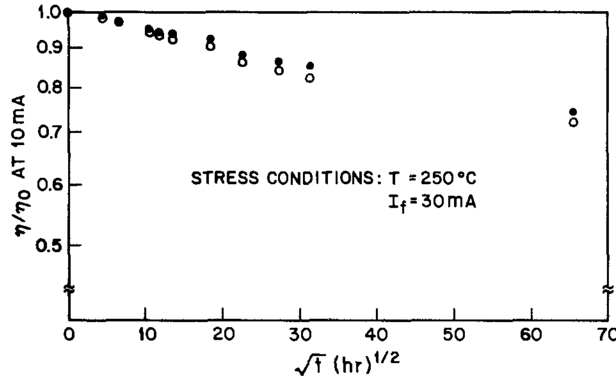

Fig. 9. Normalized efficiency *vs.* $\sqrt{t}$ for two sets of LED's. LED's in set 1 (dots) contain stacking faults and 20-40 dislocations. LED's in set 2 (open circles) contain 5-15 dislocations.

one <100> DLD are observed in Fig. 10b. The presence of this <100> DLD is unusual and suggests that these DLD's are not stress induced (11-13).

Summary and Conclusions

The present results show that GaAlAs:Si LED's fabricated from wafers with Si pyramids on the p-surface are prone to stress-induced <110> DLD formation. The origin of the silicon pyramids is not presently known and requires further study. Two sources of DLD's were found. First, a dislocation network was shown to initially surround the pyramids. These networks with the addition of bonding and thermal stresses extended on {111} planes toward the p-n junction. When they reached the p-n junction they were observed in the electroluminescence image. No DLD's were found in the n-layer. The etch used to remove dicing damage removes more of the n-layer and thus reduces the associated stress.

An internal stress of 2-7 $\times$ 10^7 dynes/cm^2 due to dicing damage was found by Hirahara *et al.* (16) in GaP LED's; this stress was sufficient to enhance the degradation rate of such devices. A similar stress is probably present in the GaAlAs:Si LED's. At room temperature, it is known that a threshold stress level of 8 $\times$ 10^9 dynes/cm^2 produces <110> DLD's in GaAlAs/GaAs double heterostructure crystals (7). This threshold level is probably greatly reduced for the GaAlAs:Si LED's at 200°C and the presence or absence of internal stress may cause the total strain to either exceed or be below the threshold required for stress-induced DLD's. Additionally, DLD's on devices selected from pyramid-free regions of the wafer with pyramids were found to initiate at mechanical damage or high stress points of the p-surface. The DLD growth proceeded as in devices with pyramids, but at a slower rate. Since LED's from pyramid-free wafers do not degrade by DLD formation, the presence of pyramids indicates a material problem. A high density of precipitates, unresolved either by KOH etching or TCL, may be present in wafers with pyramids.

The susceptibility of the LED's from wafers with pyramids to stress-induced DLD's was shown not to be a result of a high dislocation density or the presence of stacking faults. The tests used to determine the influence of such defects showed that the reliability of normal GaAlAs:Si LED's seems to be relatively independent of the diode defect density. Examination of normal LED's operated at 250°C, and 30 mA forward bias for 4000 hr shows that the degradation mechanism is not DLD formation.

Acknowledgments

We wish to thank H. Temkin for aging the LED's and for helpful discussions, E. Lassiter for mounting and demounting the LED's, D. D. Roccasecca for some device processing, K. B. Bauer for electroluminescence imaging, S. Jabbar for supplying some of the LED's, and O. G. Lorimor and R. H. Saul for helpful discussions.

The Properties of Iron in Silicon

K. Graff and H. Pieper

AEG-Telefunken, Serienprodukte AG, Semiconductor Division, D-7100 Heilbronn, West Germany

ABSTRACT

The properties of iron in n-type and p-type silicon were studied by means of DLTS, carrier lifetime measurements, and infrared absorption spectroscopy. Only one donor level was observed, situated at $E_v + 0.43$ eV and correlated to iron on an interstitial site. In p-Si:B iron-boron pairs were formed at room temperature. Their activation energy was determined to be $E_v + 0.10$ eV. The reaction proceeded in two phases. In the second phase a thermal equilibrium between iron and iron-boron pairs was found which could be shifted by annealing and illuminating the specimen, respectively. In aluminum-doped silicon crystals two levels were observed after iron diffusion correlated to iron-aluminum pairs. Their activation energies were determined to be E_v $+0.21$ and 0.13 eV. It is assumed that iron-boron pairs form also two levels, a donor and an acceptor. The acceptor must be situated in the upper half of the silicon bandgap. Reaction mechanisms are discussed.

Iron is one of the main heavy metal impurities in silicon devices. Because of its considerable high solubility and fast diffusion at high temperature iron is easily introduced into silicon crystals during heat-treatments. Hence it has been detected even after presumably clean annealing and quenching processes (1-3).

First investigations on the behavior of iron in silicon were carried out in the fifties and early sixties applying radiotracer techniques, resistivity measurements, and ESR spectroscopy (4-7). The fundamental knowledge about the properties of iron in silicon are based on these results: after quenching iron-doped specimens from high temperature iron forms a deep donor level at $E_v + 0.4$ eV which is paramagnetic in neutral state and detectable by ESR as iron on an interstitial site. This interstitial iron reacts with shallow acceptors such as B, Al, Ga, and In even at room temperature forming pairs which are oriented in <111>-direction with the exception of FeIn showing <100>-symmetry. These pairs dissociate during annealing at moderate temperatures and finally iron precipitates at somewhat higher temperature (100°-200°C).

Recently an increasing number of papers concerning the properties of iron in silicon was published showing a growing interest in this subject. This may be due to further increasing requirements to device performance accompanied by the development of improved measurement techniques including Deep-Level-Tansient-Spectroscopy (DLTS) (8), Mössbauer-spectroscopy, and neutron activation analysis of higher sensitivity (9). On the other hand, investigations on thermally induced donors resulted in a correlation of these defects to electrically active iron impurities (2, 10-12). Most of the publications show, however, a wide spread in results as shown in Fig. 1. Various experimentally determined activation energies of iron in silicon are scaled in the bandgap of silicon (2, 5, 7, 11, 13-23). The histogram deduced from these values at the right side of the figure shows a peak at $E_v + 0.42$ eV and a second broader one at $E_c - 0.60$ eV. The spread of values can be caused by (*i*) additional undesired impurities introduced especially during extended treatments of the specimens at high temperatures, (*ii*) iron reactions with dopant atoms or other impurities, and (*iii*) precision of differing method for the determination of the activation energy (resistivity, photoconductivity, Hall-measurements, and DLTS).

In order to avoid systematic errors, more sophisticated experiments were carried out in the present study, regarding specifications of the silicon crystals and utmost cleanliness of specimen preparation and heat-treatment. The undesired introduction of additional impurities was checked and the concentrations

Key words: iron-boron pairs, iron-aluminum pairs, room temperature impurity reactions, haze.

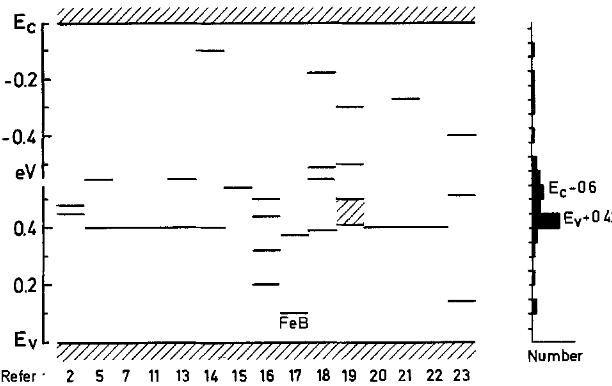

Fig. 1. Activation energies of iron in silicon as published in the literature and histogram deduced from these results.

of defect levels were monitored. The reaction mechanism of iron in p-type silicon was studied by observing variations of the levels as a function of time elapsed after quenching the specimen. This paper shall contribute to clarify the properties of iron in silicon taking into account results obtained by the following measurement techniques: four-point probe, DLTS, carrier lifetime measurements, infrared absorption, and Sirtl-etch technique.

Experimental Procedure

Specimen preparation.—Iron doping experiments were performed on p-type and n-type silicon wafers with resistivities in the range 1-100 Ωcm. The crystals were grown dislocation-free by Czochralski and floating-zone techniques, respectively. Most of the crystals were free of swirl-defects.

Iron contamination was performed either by evaporation of iron onto the polished clean surface of the wafer or by scraping with a piece of iron wire on the rougher back side. Before scraping the iron wire was etched. This procedure, so far, seems to be the cleanest method to obtain intentional impurity contamination.

Diffusion of iron was carried out in an oven with silica tube and specimen holder. The silicon wafer was mounted on top of two oxidized silicon specimens preventing a direct contact of the wafer to the silica substrate holder. The atmosphere in the furnace tube consisted of oxygen or nitrogen. Some diffusions were performed in argon and hydrogen, respectively. High cooling rates were achieved by quenching the specimen in Diffilen, ethylene glycol, or liquid nitrogen. In order to achieve low cooling rates the power of the furnace was switched off.

After diffusion 50-100 μm were removed from both surfaces by etching the specimen in a mixture of nitric acid, hydrofluoric acid, and acetic acid. For applying DLTS, Schottky contacts 1 mm in diameter were evaporated using Pd for n-type and Ti or Mg for p-type silicon. Silicon specimens $2.5 \times 5 \times 25$ mm^3 in size were used for the determination of the carrier lifetime. Ohmic contacts were prepared onto the two small opposite sites of these specimens by rubbing gallium onto the silicon surfaces.

Measurement techniques.—Several measurement techniques were applied in order to gain more information about the properties of iron in silicon. Usual Sirtl-etch technique revealed the distribution of iron after diffusing wafers containing iron scratches on the surface. Four-point probe measurements exhibited the degree of free-carrier compensation after diffusion of iron in p-type silicon. Measurements of the recombination lifetime of minority carriers were carried out by applying an improved photoconductive decay (PCD) technique as reported previously (24).

The reactions of iron with shallow acceptors boron and aluminum were studied by means of infrared absorption spectroscopy which enabled us to determine the concentration of boron and aluminum at low measurement temperatures. For this purpose a Perkin-Elmer 621 double-beam grating infrared spectrometer was used. Specimens 2×2 cm^2 in size were cut from the wafers and cooled to about 25 K with the aid of a CTI Cryogenics refrigerator, which was mounted in the measurement beam. The boron concentration [B] was calculated from the absorption coefficient α of the main absorption band at 320 cm^{-1} applying the following calibration factor (25)

$$[B] = 3.5 \times 10^{13}\, \alpha \text{ cm}^{-3}$$

No absolute values were determined for the concentration of aluminum.

For deep-level analysis the improved double-correlation equipment (DDLTS) of Lefèvre and Schulz (26) was applied. Spectra were recorded during the cooling cycle of the refrigerator mentioned above. The specimen temperature was determined by means of a calibrated silicon diode. The Schottky diodes were usually supplied with a reverse bias of 5V. The first pulse of 5V resulted in a final reverse bias of zero volts. The second pulse was adjusted to 1V. Pulse durations of 70 μsec were used. An emission time of 1.42 msec was achieved by adjusting the correlator-windows at 1 and 2 msec, respectively. Most of the spectra were recorded between 310 and 50 K.

In order to determine the activation energy of an unknown defect level the temporal signal decay was studied for several fixed temperatures in the region of maximum DDLTS-signal. The decay curves were stored in 100 storage channels of a Waveform Eductor and the corresponding lifetime was determined with the aid of a digital voltmeter and a calculator. The activation energy finally resulted from the best fit of an Arrhenius plot.

Experimental Results

Intentionally iron-doped silicon.—Intentionally iron-doped n- and p-type silicon specimens exhibited no deep-level impurities in DLTS if slow cooling rates were applied after iron diffusion. Quenching n-type silicon specimens after iron diffusion resulted in two levels of minor concentrations in the upper half of the bandgap which, however, were not correlated to iron. They appear after any etching procedure showing a steeply decreasing concentration towards the bulk of the wafer.

Quenching p-type silicon specimens after diffusion of iron resulted in one strongly marked deep-level impurity with an activation energy of $E_v + 0.43$ eV. This level was also observed in n-type silicon when light pulses were applied for discharging the defects. The same level was found in iron-doped p-type silicon specimens which were slowly cooled from 900°C for the first time, shortly annealed at 900°C for a second time, and finally quenched to room temperature. The concentration of this level depended on the diffusion temperature applied and to a minor extent on the atmosphere during annealing. A reducing atmosphere yielded somewhat higher final impurity content in the silicon crystal than an inert gas atmosphere or oxygen. The impurity concentration as a function of annealing temperature was found to be in good agreement with the solubility of interstitial iron as published by Weber and Riotte (ESR results) (1). After iron diffusion in p-type silicon the resistivity of the specimens increased more or less depending on its initial value and the respective iron concentration. At the same time the minority carrier lifetime was considerably reduced.

Room temperature reactions in boron-doped silicon.—In iron-doped p-type silicon crystals containing higher boron concentrations a second shallower impurity level was observed. Its activation energy was

determined to be $E_v + 0.10$ eV. This level was also obtained in high resistivity crystals after a certain period of time elapsed after quenching the specimen. The appearance of this shallower level was accompanied by the disappearance of the deeper level, the sum of both concentrations remaining constant. The time required for this transmutation of impurity levels was found to depend on the initial boron concentration of the starting material, being short for high concentrations and longer for low boron content. After an appropriate time the deep level disappeared completely in all specimens studied so far. Investigations were performed, however, in specimens where the boron concentration always exceeded the iron content in order to enable quantitative measurements by means of DLTS.

During this level transmutation no changes were observed neither in resistivity nor in carrier lifetime, both of which were compatible with the respective change in impurity concentration. Soon after quenching the iron-doped specimens the concentration of the boron acceptor was strongly reduced, as determined by means of infrared absorption spectroscopy. A further storage of this specimen at room temperature for several days resulted only in an additional minor reduction in boron concentration although the level transmutation in similar material took place within this period of time.

Reaction in aluminum-doped silicon.—Experiments performed on a p-type silicon crystal doped with boron and aluminum resulted in the formation of two further levels after a certain period of time elapsed after quenching the iron-doped specimen. The activation energies of these levels were determined to be $E_v + 0.13$ and $E_v + 0.21$ eV, respectively. Besides the disappearance of the boron acceptor, infrared absorption spectra showed a considerable reduction in the absorption bands correlated to the aluminum acceptor. These results are shown in Fig. 2. The concentration of the aluminum acceptor still decreased with the storage time of the specimen at room temperature. The two additional DLTS signals $E_v + 0.13$ and $E_v + 0.21$ eV correlated to aluminum increased in the same way with the elapsed time as the boron-correlated signal ($E_v + 0.10$ eV), whereas the deep level ($E_v + 0.43$ eV) decreased simultaneously as shown in Fig. 3.

Reactions during illumination of boron-doped silicon.—When the level transmutation in boron-doped p-type silicon was terminated, resulting in only one impurity level at $E_v + 0.10$ eV, the reaction could be

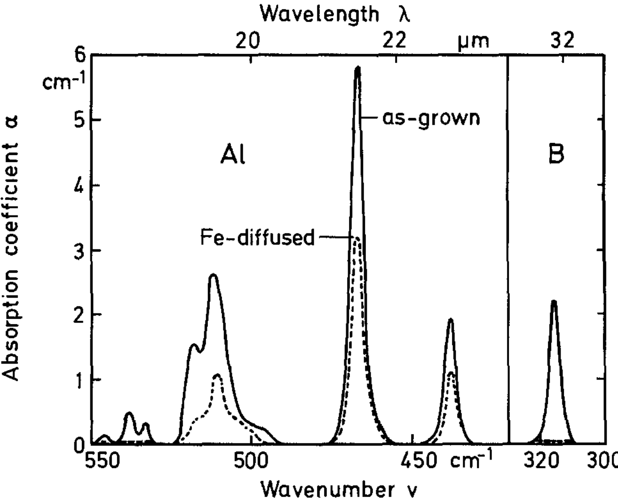

Fig. 2. Reduction of aluminum and boron infrared absorption bands due to complexing with iron observed at 25 K in a p-type silicon wafer doped with boron and aluminum before (solid curve) and after (dashed curve) iron diffusion.

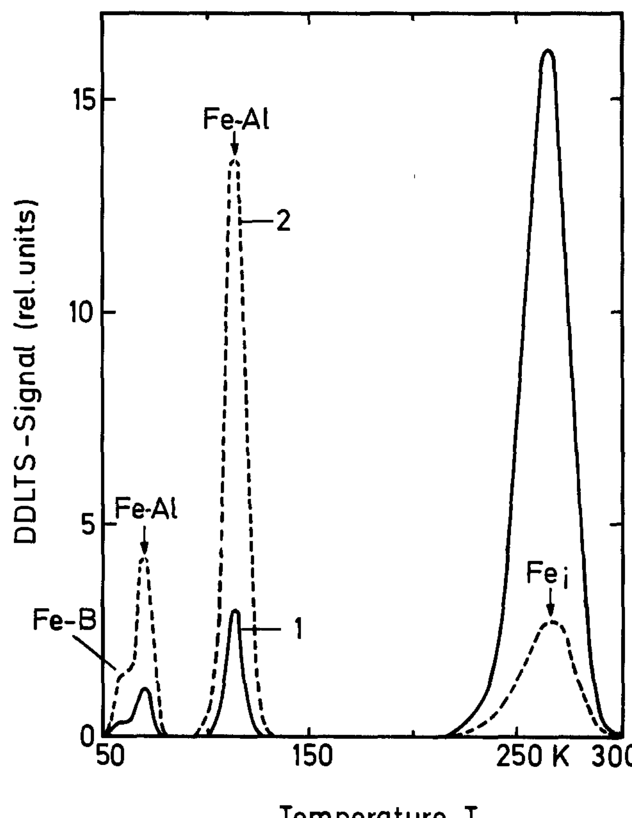

Fig. 3. Deep-level spectra after iron diffusion in a p-type silicon crystal doped with boron and aluminum at two different elapsed times (1: solid curve = initial, 2: dashed curve = final) after quenching of the specimen.

reversed in a rather short time by illuminating the specimen with intense white light. This was carried out by focusing the light of a 50W halogen lamp on the surface of the silicon specimen. The illuminated area amounted to about 0.5 cm in diameter. During illumination the specimen was kept at room temperature by mounting it on a heat sink which was cooled by the aid of compressed air. After illuminating the specimen for 1 hr Schottky contacts were evaporated again and deep levels were monitored. As in the initial state soon after quenching the specimen the impurity was concentrated in the 0.43 eV level. This is shown in Fig. 4. Similar results were obtained repeatedly in crystals of various specifications. Infrared absorption spectra showed an increase in boron concentration with the duration of the illumination. For the application of infrared absorption the illuminated area was considerably extended and the intensity of the light correspondingly reduced. After illumination was terminated the level transmutation from the deeper to the shallower one preceeded as observed soon after quenching the specimen.

Annealing properties of boron-doped silicon.—During transmutation of the 0.43 eV level into the 0.10 eV level a storage of the iron-doped specimen at elevated temperature (100°C) was obviously of no influence. This is shown in Fig. 5 phase 1, where the ratio of the concentration of 0.10 eV level to the total concentration is plotted as function of storage time at 100°C. When, however, the transmutation was terminated (after about 10 days room temperature storage, phase 2) the ratio of the concentration of the shallow level to the total iron content proved to be dependent on the temperature resulting in a thermal equilibrium. This is shown in Fig. 5 and 6 as function of annealing duration at 100° and 130°C and temperature, respectively. At higher temperatures this equilibrium shifted to increasing deep level and vanishing shallow level.

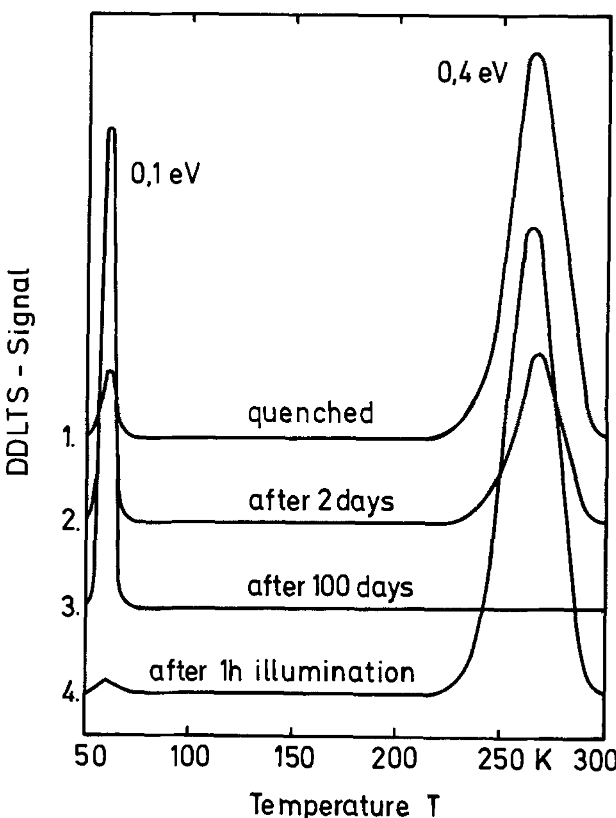

Fig. 4. Deep-level spectra after iron diffusion in boron-doped p-type silicon at three different elapsed times after quenching of the specimen and finally after illumination of the specimen.

Beyond about 150°C the total concentration of both levels decreased after extended annealing durations. This latter reaction was accelerated at higher temperatures. At the same time the boron (and aluminum) acceptor increased finally up to the initial value of the starting material as deduced from infrared absorption spectra and shown in Fig. 7. Simultaneously the resistivity of the specimen was restored. The electrical activity of the iron impurity could not be restored before a second treatment at high temperatures and quenching was performed.

Diffusion properties of iron.—Even during quenching iron-doped silicon wafers from high temperatures iron tends to diffuse to the surfaces of the specimen. This resulted in lower iron contents for shallow penetration depths. In order to obtain bulk values the surfaces were removed after heat-treatment. Moderately fast cooling rates after iron diffusion (within 5 min from 1050°C to room temperature) already resulted in the formation of precipitates which were detected by x-ray topography. Whereas the Lang-topography exhibited the area of distorted silicon lattice the section topography showed an accumulation of precipitates within the middle of the wafer. Towards both surfaces the density of precipitates was strongly reduced. The distribution of iron after diffusion was also detected by usual Sirtl-etching of the wafer showing an accumulation of shallow etch pits in the same area as marked by the Lang-topography. The distribution of these etch pits is frequently called "haze." One example is shown in Fig. 8. The symbol "Fe" was scratched on the back side of a Czochralski-grown p-type silicon wafer with the aid of a piece of iron wire. The wafer was then annealed at 1150°C for 10 min, moderately cooled to room temperature within 5 min, and treated by Sirtl-etch. For taking the photograph the wafer was illuminated by means of a spot light. Whereas the Sirtl-etch technique works for Czochralski-grown and floating-zone silicon, x-ray topography resolved precipitates and strain only in the case of Czochralski-grown silicon. This is probably caused by the larger size of precipitates in pulled crystals due to initially formed oxygen agglomerates.

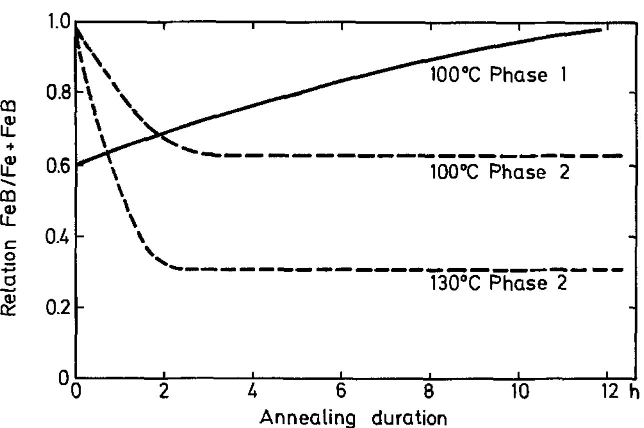

Fig. 5. Ratio of the concentration of the 0.10 eV level and the total iron content as function of storage time at elevated temperatures (100° and 130°C). Phase 1 (solid curve): soon after quenching the specimen, phase 2 (dashed curve): after completing complex formation about 10 days later.

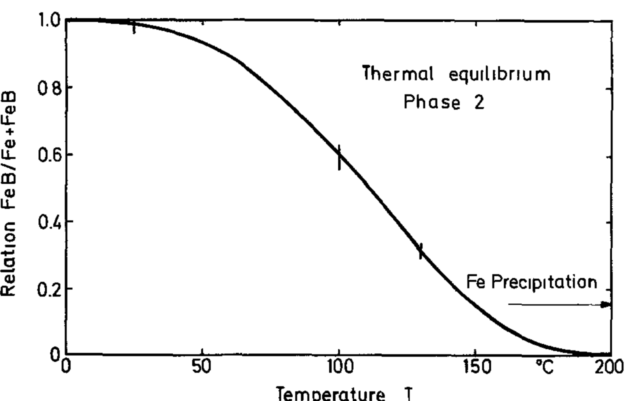

Fig. 6. Ratio of the concentration of the 0.10 eV level and the total iron content as function of storage temperature in phase 2.

Iron content in as-grown silicon crystals.—After having investigated intentionally iron-doped silicon crystals the undesired iron content of some commercially available crystals of various specifications was determined. Measurements were carried out in as-received state and after a short heat-treatment at 1000°C and quenching. Utmost clean conditions were observed for handling and heat-treating the specimens. The iron content of as-received silicon crystals

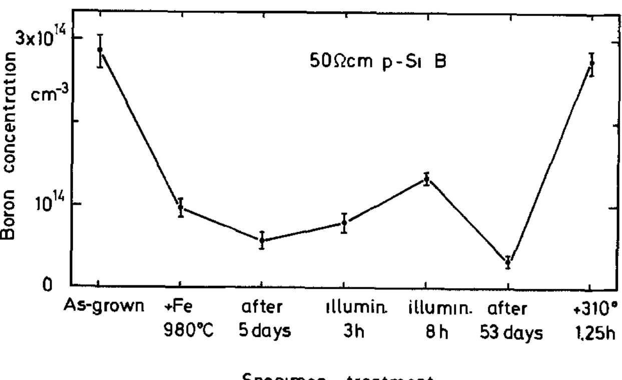

Fig. 7. Boron concentration calculated from infrared absorption of a boron-doped p-type silicon wafer before and after iron diffusion, illumination, and annealing of the specimen.

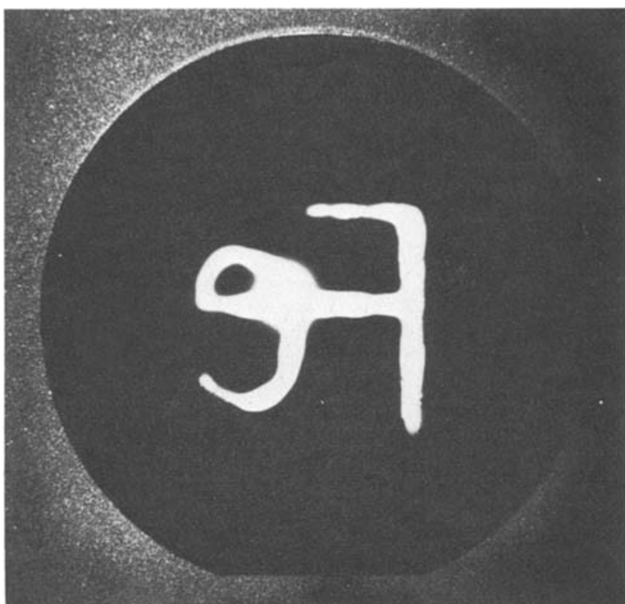

Fig. 8. Czochralski-grown silicon wafer with "Fe" scratched on the back side with the aid of a piece of iron wire, annealed at 1150°C for 10 min and treated in Sirtl-etch.

investigated so far did not exceed the detection limit (about 10^{-4} of the carrier concentration). After quenching these specimens, rather low iron concentrations were observed not exceeding 5×10^{11} cm^{-3} in floating-zone and 5×10^{12} cm^{-3} in Czochralski-grown crystals. These results are in contrast to previous publications (1, 12).

Discussion

From the experimental results the following properties of iron in silicon were deduced: only one impurity level is formed by electrically active iron in n- and p-type silicon situated at $E_v + 0.43 \pm 0.04$ eV. This level is obviously correlated to iron on an interstitial site as detectable by means of ESR spectroscopy. This level has the properties of a donor. The best fit to our experimental results for the solubility of iron in silicon as function of the temperature [Fe] is represented by the Arrhenius equation published by Weber and Riotte (1)

$$[\mathrm{Fe}] = 5 \times 10^{22} \exp (7.3 - 2.87\ \mathrm{eV}/kT)\ \mathrm{cm}^{-3}$$

Because of the high diffusion coefficient of iron in silicon even at rather low temperatures, iron tends to precipitate during a cooling cycle if the specimen is not quenched rapidly. The precipitates can be dissolved once more by a second heat-treatment of the specimen up to a concentration corresponding to the respective solubility.

So far no infrared absorption bands correlated to iron in silicon were observed. As a deep level impurity iron reduced the carrier lifetime in n- and p-type silicon. The capture cross section for holes in n-type silicon $\sigma_p{}^\circ = 3 \times 10^{-16}$ cm^2 (27) seemed to be in reasonable agreement with most of our experimental lifetime results. The electron capture cross section in p-type silicon $\sigma_n{}^+ = 15 \times 10^{-16}$ cm^2 (27), however, is still doubtful, since the iron donor is not stable in p-type silicon but reacts with all common shallow acceptors even at room temperature.

The iron-boron pairs formed in p-type silicon after quenching the specimen were detected by means of DLTS and a level at $E_v + 0.10$ eV was found. This value is identical with recent results of Feichtinger (17). So far no infrared absorption bands could be correlated to this complex. If the boron concentration exceeded the iron content in the crystal all interstitial iron reacted with boron in an appropriate time which depended on the boron concentration. In the first stage after quenching the specimen this reaction took place quantitatively, independent of the storage temperature within the range 20°-150°C. In a second phase, after termination of the level transmutation, a thermal equilibrium between interstitial iron and iron-boron pairs was observed, following the mechanism

$$\mathrm{FeB} \rightleftharpoons \mathrm{Fe_i}^+ + \mathrm{B_s}^- \quad \text{(phase 2)}$$

This equilibrium could be shifted to the right side by increasing the temperature and by illuminating the specimen, respectively. At higher temperatures exceeding about 150°C most of the complexes were dissociated. Since the thermal mobility of iron is rather high, the iron then precipitated irreversibly after an appropriate time.

In order to explain the reaction mechanism in phase 1 two facts were illuminating: the thermal equilibrium was not observed soon after quenching the specimen and at the same time the concentration of the boron acceptor was strongly reduced although almost no pairs were detected. To explain these observations it was assumed, that the boron acceptor reacted with an intrinsic defect during quenching the specimen. Then the following reaction may take place

$$\mathrm{Fe_i} + \mathrm{B_sI} \rightarrow \mathrm{FeB} + \mathrm{I} \quad \text{(phase 1)}$$

I symbolizes an intrinsic defect being a vacancy or self-interstitial, which is formed at high temperatures in the silicon lattice and which is highly mobile even at room temperature. In the present case a self-interstitial seems more likely to react in the same way as iron on an interstitial site. After the formation of the iron-boron pairs the isolated intrinsic defect can react with a second boron atom or finally diffuse to the surface of the specimen. This reaction proceeds only in one direction because one participant disappears. When all the intrinsic defects have disappeared then the phase 2 reaction takes place.

During the reaction of iron with boron no strongly marked change in carrier lifetime was observed as would be expected during the change of a deep-level impurity into a shallow one. This could be explained by assuming the existence of a second level for the pair which must be situated in the upper half of the silicon bandgap and which must be a deep level. Usually a level in the upper half of the bandgap cannot be observed by DLTS in p-type material by applying Schottky contacts. On the other hand the iron-boron pair is not formed in n-type silicon, so the second level of this pair is not detectable by this method. In some specimens which were highly compensated because of high iron concentrations, however, an additional level was observed after the formation of the complexes was completed. The activation energy of this level was determined to $E_v + 0.6$ eV, so it must be situated in the upper half of the bandgap. This result agrees well with the value $E_c - 0.55$ eV published repeatedly in the literature as an additional impurity level of iron in silicon (Fig. 1). Furthermore in aluminum-doped silicon two levels were detected which were correlated to iron-aluminum pairs.

If an ionic binding in the iron-boron pairs predominates, the charge carriers may be bound to one atom. Only the following three charge states are possible: $(\mathrm{Fe}^\circ\mathrm{B}^-)$, $(\mathrm{Fe}^+\mathrm{B}^-)$, and $(\mathrm{Fe}^+\mathrm{B}^\circ)$. $(\mathrm{Fe}^\circ\mathrm{B}^\circ)$ is not existent, since Fe° and B° are always situated on opposite sites of any Fermi level as shown in Fig. 9. The sum of the charge states of iron and boron determines the charge of the complex. From the figure it is deduced that the $E_v + 0.10$ eV level then forms a donor (change from positive to neutral charge) whereas the $E_c - 0.55$ eV level forms an acceptor (change from neutral to negative charge). This assumption would explain all experimental findings and can be extended in the same way to explain the two levels of the iron-

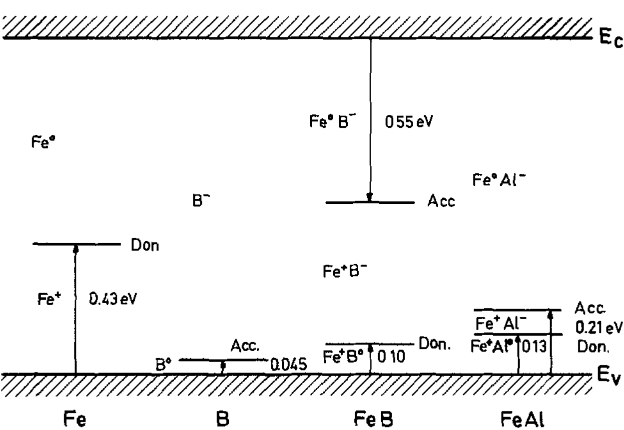

Fig. 9. Activation energies of iron, boron, iron-boron, and iron-aluminum pairs in silicon.

aluminum pairs. In this pair the ionic character of the binding may be reduced so the two levels approach one another. The formation and detection of the iron-boron acceptor level and its correlation to the iron-boron pair should be proved, however, by another measurement technique.

Conclusion

The knowledge of the impurity level of iron in silicon and those of the most frequent iron-acceptor pairs is quite useful for the examination of the impurity content in silicon crystals especially after technological processes for device production. Usually iron is precipitated at least partly. Therefore a certain preparation technique is needed to transform it into a detectable electrically active impurity. The experimental finding, that iron-boron pairs dissociate during illumination of the specimen facilitates the detection of the total iron content of a specimen. The iron analysis is then limited to usual measurement temperatures (270 K). The DLTS-signal of the FeB, however, is not observed at temperatures exceeding 60 K applying an emission time constant of 1.42 msec.

The present investigations were limited to impurity reactions of iron with boron, aluminum, and phosphorus. In order to complete the knowledge about possible reaction mechanisms further impurities should be added intentionally and the resulting deep-level spectra studied.

Effects of Multiple Slice Epitaxy and Front End Processing on Generation Threshold Current in Bubble Memory Devices

R. L. Guldi, R. E. Fontana, Jr., and D. C. Bullock

Texas Instruments, Incorporated, Dallas, Texas 75265

ABSTRACT

The factors affecting generate threshold current, Ig, (the minimum current required to reliably nucleate a bubble under a hairpin generator) are reviewed. Ig data are presented for bubble memory devices fabricated using YSL-CaGe garnet (1) epitaxial films with nominal bubble sizes of 5.3 and 3.8 microns. Where multiple slice epitaxy employing large vertical stacks (up to 16 singly spaced slices/stack) is used, it is found that Ig measured on an aluminum generator without overlying Permalloy elements or passivation is shown to depend on position in the epitaxy stack, decreasing by as much as 4 mA (1%) per slice position with increasing depth of slices in the melt. In contrast, slices ion milled to remove a 0.4 micron thick surface layer show no dependence of Ig on stack position. Removal of the surface layer has the additional effect of significantly decreasing the variation of Ig across a slice by up to 67%. These observations are interpreted in terms of the existence of a low anisotropy surface layer approximately 0.2-0.5 microns thick grown as slices are slowly withdrawn from the epi melt without rotation. The properties of this layer are discussed. In particular, the layer is shown to have a lower anisotropy than the bulk film, and it is estimated that the growth rate appropriate to the surface layer is approximately 20% of the value for normal film growth (0.4-1.0 microns/min). Finally the dependence of Ig on subsequent front end processing is presented, and it is shown that the Ig value measured on an aluminum generator without overlying oxide and Permalloy is reduced by approximately 30% after subsequent oxide and Permalloy processing steps.

Generate threshold current (Ig), or the minimum current required to reliably nucleate a bubble under a hairpin generator, is a parameter that must be understood and controlled in order to produce reliable, interchangeable, and easily used bubble memory devices. Some of the factors contributing to Ig variations in devices have been discussed previously by Wolfe and Johnson (2) who have related Ig variation to stress effects in the epitaxial garnet layer due to the silicon oxide and the aluminum metallization and to changes in the stress because of the presence of the overlying layers, and through annealing effects arising during oxide and Permalloy deposition.

This paper describes another major source of Ig variation that can be found in slices grown using multiple slice epitaxy employing large vertical stacks of slices, namely a contribution from an anomalous surface layer on the top of the epitaxial garnet film.

Experimental

Figure 1 shows an artist's concept of the particular type of multiple slice holder used in this study. This holder has capacity for 16 singly spaced, 2 in. diam slices. The circular ring that ties the legs of the holder together for extra strength in the center of the holder separates the top eight slices from the bottom eight and increases the distance between the eighth and ninth slices in the stack, producing an effect on the stack dependence of Ig that will be discussed later.

The generator geometry for this investigation is shown in Fig. 2. The generator element is a conventional hairpin generator, made of evaporated aluminum containing approximately 2 weight percent (w/o) copper, separated from the epitaxial film by a plasma-deposited silicon oxide layer, and patterned by ion milling at an angle of 45 degrees. Silicon oxide and aluminum thicknesses are 4000 and 5000Å, respectively, for five micron bubble circuits and 4000 and 4000Å for three micron bubble circuits. The dimensions given in Fig. 2 apply to a three micron bubble circuit which is a scaled-down version of a five micron circuit as far as considerations dealing with the generator are concerned. All data reported were taken on neon-implanted slices (2.5 E14 at 100 keV for 5 micron films and 2.0 E14 at 100 keV for 3 micron films).

Generate threshold data as reported in this paper are taken on the structure shown in Fig. 2 without overlying oxide and Permalloy layers in order to avoid effects due to stress or problems with the alignment of aluminum and Permalloy elements. Ig measurements are made by contacting the generator lead structure with fine-tipped probes, pulsing the generator with a 500 nsec current pulse with a rep rate of 500 Hz to minimize heating, and increasing the pulse amplitude until the first bubble is observed optically. It is estimated that the Ig values obtained are reproducible

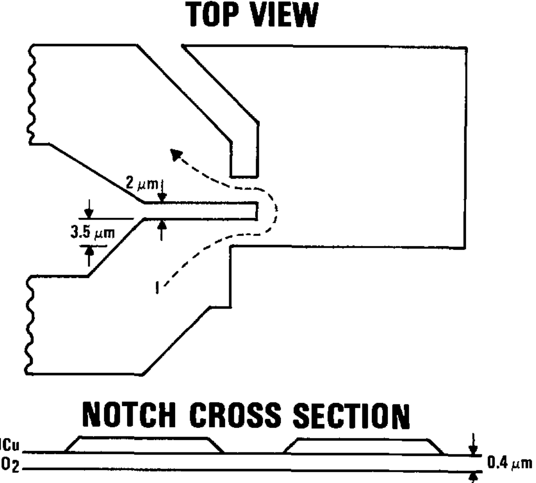

Fig. 2. Generator design for 3 micron bubble circuits

to about ±5 mA. All data presented were taken at room temperature. For consistency the threshold is measured with the bias field 10 Oe below free bubble collapse. It will be noticed that the Ig values discussed throughout the paper are approximately 30% higher than those found in actual packaged devices. This discrepancy arises because Ig decreases with annealing during the high temperature processing used in depositing subsequent oxide and Permalloy layers, as will be described later.

Results

The dependence of Ig on position in the epitaxy holder for a typical epitaxial run is shown in Fig. 3 for three micron bubble films. The X-axis is drawn using a linear distance scale as measured from the top slice holder ring, with numbers labeling the position of each slice in the stack, starting with the No. 1 slice at the top of the stack. The larger than average separation between the eighth and ninth slices results from the presence of the middle support ring on the slice holder (see Fig. 1). The top eight slices in the stack show practically no dependence of Ig upon stack position, but slices in the lower eight positions show a decrease in Ig with stack position of up to 7 mA/slice position.

This type of dependence of Ig on stack position is typical of both 5 and 3 micron bubble films. Run-to-run variations in the degree of stack dependence in the range of approximately 2-7 mA/stack position exist and these are correlated with a variation in epitaxial film anisotropy throughout the stack which is associated with small vertical temperature gradients in the epi-melt. Runs for which the measured film anisotropy is higher for slices from the top of the stack than for slices from the bottom show an increased Ig stack variation compared to runs for which the measured film anisotropy gradient is reversed, but in all cases Ig decreases with increasing stack position. Another common trend is for the Ig value for slices in position 1 and 9 to be slightly less than the average for adjacent slices in the stack, and it is interesting that these films are grown with the device side faced down whereas all other films are grown with the device side faced up. However, the universal trend is that slices from the bottom of the stack exhibit reduced Ig. It should be noted that there is a minimal dependence of Ig on spacer oxide thickness, aluminum thickness, and generator linewidth provided these parameters are controlled within ± 5%.

As an explanation for the dependence of Ig upon stack position, it was proposed that a low anisotropy surface layer grown on the epitaxial film during withdrawal from the melt is responsible for controlling Ig. In order to investigate this hypothesis, 5 micron films from alternating stack positions were ion-milled to remove a 5000Å thick surface layer before ion implanting and beginning generator processing. The results of this experiment are shown in Fig. 4. The unmilled slices exhibit a strong dependence of Ig on stack position, but the milled slices do not. Hence the existence of a surface epi layer which controls Ig was verified.

To investigate this effect further, four slices, one each from positions 2, 6, 10, and 16 of a sixteen slice 5 micron bubble stack, were quartered and each quarter was ion-milled to remove either 0, 2000, 4000, or 6000Å of material before generator processing (see Fig. 5), and generators were fabricated on these quartered slices. The measured Ig values were independent of milled thickness for slices 2 and 6, which are from the top of the stack, but increased dramatically with increasing thickness milled for slice 16, which was grown at the bottom of the stack.

Slices No. 10 and 11 were processed as whole slices. Slice No. 10, which was not milled, showed an Ig value approximately 20 mA less than the slice grown in the adjacent stack position No. 11, which had 6000Å of material removed by milling before generator processing.

Again the quarters of all four slices which received no milling show the same type of dependence of Ig on stack position presented in Fig. 3 and 4, while practically no stack dependence is found on the quarters of the slices which had a sufficiently large thickness removed, namely 6000Å. Hence, one could estimate the maximum thickness of the surface layer for the 16th slice in the stack as approximately 6000Å.

In a related experiment, the variation of Ig over a single slice was investigated. Figure 6 shows the distribution of Ig measured for slices number 2 and num-

Alternating slices were either unmilled or ion milled to remove a 5000Å layer before generator fabrication. Distributions are shown for measurements after AlCu patterning without overlying oxide and Permalloy elements and for measurements after NiFe patterning.

ber 15 in a sixteen slice stack of three micron bubble films. A tighter distribution of Ig about the mean value is found for the slice from the top of the stack ($\sigma = 3.8$ mA for slice No. 2 *vs.* $\sigma = 6.7$ mA for slice No. 15). Consistent with previous data, slice No. 15 also shows a lower value of Ig.

The Ig distribution for all chip positions in all 16 slices from the same three micron epitaxial run was also investigated. Alternating slices were either unmilled or milled to remove a 5000Å layer before generator fabrication. The Ig distributions measured after aluminum patterning and also after Permalloy patterning are shown in Fig. 7. For this lot after aluminum patterning, a fairly narrow distribution was observed for milled slices, while a broader distribution was observed for unmilled slices. After the NiFe was patterned, both distributions broadened somewhat with the unmilled distribution still broader than the milled. In this example, the Ig broadening arising from epi-related effects is approximately 3 times more significant than broadening related to aluminum or Permalloy processing.

In order to confirm the existence of a surface layer of composition different from the bulk, SIMS or ion probe profiles of composition *vs.* depth were obtained for epitaxial films. Figure 8 shows one such profile for a three micron bubble film. For simplicity the Y, Ca, and Fe profiles which were relatively constant are not shown. Similar results have been obtained for both three and five micron films. In general there exists on all films a surface region with a composition significantly different from the bulk of the film, although the exact nature of the profiles in the surface region varies considerably from epi run to epi run. For the slice at the bottom of the stack, the thickness of the surface region is approximately 5000Å. Usually the surface region is lower in components that contribute to anisotropy such as samarium and lutetium, or it is lower in germanium content than the bulk, a condition that would tend to increase $4\pi M_s$ and decrease anisotropy.

The existence of an anomalous surface layer on epitaxial films is consistent with the basic understanding of the epitaxial growth process. During the growth of the primary film, extensive melt mixing occurs because of the stirring action of the rotating slices. Indeed mixing is required in order to maintain the proper concentrations of the various components sufficiently near the surface of the growing film to incorporate the correct amount of each component into the film as required to achieve desired film properties (3-5). It has also been shown that the rotation conditions used during immersion of slices into an epi melt can significantly affect film coercivity and lattice parameter because of compositional variations near the film-substrate interface (6). After primary film growth terminates, the stack of slices is slowly withdrawn from

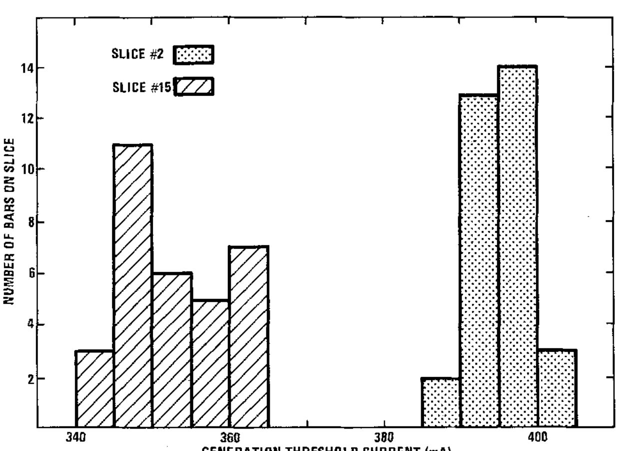

Fig. 6. Distribution Ig for slices No. 2 and 15 in a 16 slice stack of 3 micron films.

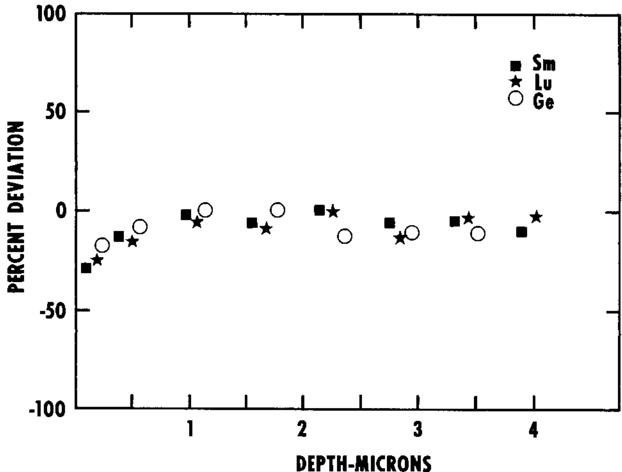

Fig. 8. Composition profiles of garnet wafer determined by ion probe (SIMS). The Y, Ca, and Fe contents were relatively constant.

the melt without rotation in order to minimize the occurrence of flux droplets which cause defects on the slice. The lack of rotation during withdrawal from the melt significantly reduces melt mixing so that growth then occurs under drastically different conditions such as with a reduced growth rate, a wider diffusion boundary at the film-melt interface, and changed values of the segregation coefficients of the constituents. Reduced surface anisotropy at reduced growth rate is consistent with reduced segregation coefficients of high anisotropy components such as samarium and lutetium and with a reduced effective segregation coefficient for germanium, all of which have segregation coefficients less than unity. The reduced samarium and lutetium concentrations directly decrease the anisotropy of the surface layer, while the reduced incorporation of germanium leads to a tendency toward higher $4\pi M_s$ and lower l, conditions which are also associated with reduced anisotropy.

One can estimate the reduction in growth rate that occurs during withdrawal of slices from an epitaxial melt without rotation in the following manner. The milling experiments suggest that the surface layer thickness, t, for a bottom slice in a 16 slice stack is approximately 0.5 microns. For the withdrawal rate of slices from the melt used in this work, 7.5 cm/min, and for conditions in which the bottom slice is grown at a depth of 18 cm below the melt surface, the withdrawal time, T, for the bottom slice is calculated to be 2.4 min. The average growth rate, R' appropriate for growth of the surface layer is then calculated as t/T or 0.21 microns/min. Since R, the growth rate which applies during the growth of the primary portion of the epitaxial film while slice rotation and melt mixing are present, is of the order of 1 micron/min, one can calculate a value for the growth rate reduction factor during withdrawal as $R'/R = 0.21$. Hence during withdrawal, the growth rate drops to approximately 1/5 its normal value.

In order to relate measurements of Ig on aluminum generators without overlying Permalloy elements to measurements on finished devices, we have measured Ig after specific stages of front end processing. Figure 9 shows the reduction that occurred in the average Ig for a slice as it progressed through normal processing and was measured after plasma resist stripping at 75°C, plasma oxide deposition at 350°C, NiFe sputtering at 375°C followed by ion milling and plasma resist stripping. All temperatures cited are nominal. When Ig was measured on slices after generator patterning and then remeasured after annealing the slices through the NiFe time-temperature schedule, a 14% decrease in Ig was found, compared with a 30% decrease when oxide and NiFe layers were actually deposited and patterned. These results are similar to data presented by Wolfe and Johnson (2) who attributed the Ig reduction to a localized decrease in film anisotropy caused by stresses from overlying oxide and metallization layers and to annealing effects which modify the stresses of the conductor metallization on the garnet film.

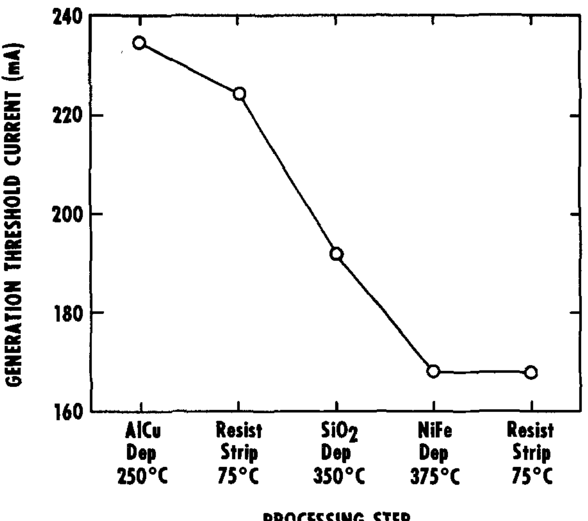

Fig. 9. Generation threshold current after various front end processing steps.

Conclusions

An anomalous surface layer with composition and anisotropy different from the bulk exists on slices grown in large vertical stacks in LPE melts and withdrawn slowly from the melt. Although the composition and anisotropy of this layer depend upon melt temperature and on melt temperature gradient, the primary dependence of surface layer thickness is on stack position, with a maximum surface layer thickness approximately 0.5 micron being found for a slice in the lowest position of a sixteen slice stack. For the withdrawal speeds used, the growth rate during withdrawal from the melt (without mixing) is estimated as 0.2 micron/min for melts in which the nominal film growth rate is 1.0 micron/min.

The variation in generation threshold current due to the anomalous surface layer presents a problem that may become increasingly more severe as film thickness is reduced to produce smaller bubble films required for advanced devices. Although Ig is the only device parameter presently identified as being sensitive to the presence of the surface layer, it is reasonable to expect other device parameters to be influenced by this layer. The control of Ig and other such parameters may involve techniques to reduce the surface layer thickness such as increasing the withdrawal rate or reducing stack height, or it may involve techniques to remove the layer such as milling or etching. Alternatively, new device designs which are less sensitive to epi surface film layers would be attractive.

Chemical Reaction of Sulfur Dioxide at High Humidity and Temperature: Implications for Accelerated Testing

Daniel L. Flamm, D. D. Bacon, E. Kinsbron, and Alan T. English

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

The interaction of SO_2 with humid air was studied in a Teflon chamber (SEAT facility) as a function of flow rate (50-180 std. liters/min), humidity (7-87%), temperature (23°-85°C), and SO_2 concentration (2-9 ppm). Both SO_2 and the reaction products were monitored using wet chemical and pulsed fluorescence techniques. Sulfur dioxide is oxidized to SO_3/H_2SO_4 in dark reactions at elevated temperature and humidity. The experimental data were represented by the rate equation

$$\frac{dp_{SO_2}}{dt} = -k(T)p_{SO_2}p_w$$

where p_{SO_2} is the partial pressure of SO_2 in the chamber, p_w the partial pressure of water vapor, and $k(T)$ the rate constant. The reaction has a low activation energy ($\lesssim$ 5 kcal/mole) and appears to occur in the gas phase rather than on the chamber walls. The significance of secondary corrosive products in the design and use of accelerated tests is covered in detail. When field failure of a device occurs via the attack of SO_2 and water vapor alone, the quantity of product acid in accelerated test chambers should be carefully limited. It is shown how this requirement can be quantitatively specified in the form of an operating diagram derived from the rate expression. Other simulation regimes and the significance of catalytic oxidation processes are also discussed.

Introduction

Accelerated test environments.—Assurance of long-term reliability is an important consideration for most mechanical and electronic equipment in the telecommunications industry. The development of a sound basis for prediction and specification of reliability is thus a vital research and engineering objective. Typically, components are expected to function continuously and without interruption for a number of years. To provide timely information, reliability tests must be short; therefore, they must somehow be "accelerated" with respect to normal conditions of use in order to produce failures within a reasonable period of time.

Usually, elevated temperature and/or high humidity have been used to realize this acceleration: tests at 85°C and 85% relative humidity (RH) have been extensively employed for Bell System studies. Accelerated reliability tests have been used to make qualitative comparisons which are useful for device selection or for identification of the predominant modes of failure (1, 3b, 4). In a few cases there has been a post hoc attempt to determine scaling factors which relate failure times under field conditions to those observed in the laboratory test (2). More often, the extrapolation from laboratory to use conditions is based on some assumptions concerning the mechanism of failure and the dependence of the kinetics of that process on accelerated test parameters.

The concern with chemical pollutants in our environment has extended to reliability studies (3). A number of workers (3b, 4, 6) have introduced various pollutants into the test environment in an attempt to mimic the effects of atmospheric contaminants on chemical or "corrosion" sensitive failure. A crucial problem in this work is the unavailability of scientific or empirical guidelines which can be used to specify a suitable polluted atmosphere for use in accelerated tests, or a method to calculate or even to estimate the resulting acceleration factors.

Key words: atmosphere, oxidation, kinetics, corrosion.

Recently, Schwartz and Bacon (5) proposed theoretical guidelines for "Simulated Environment Accelerated Tests" (SEAT). It was assumed that the effect of atmospheric contaminants on failure could be attributed to the solution of these compounds in a thin adsorbed layer of water and by the sequential reaction of dissolved species with devices. With the exception of those involving NO and NO_2, the rate of chemical degradation processes leading to failure were assumed to be of the form

$$r_p = A_p \prod_i C_{is}^{n_i} C_{H_2O,s} e^{-\Delta E/kT} \quad [1]$$

where A_p is a numerical coefficient, $C_{H_2O,s}$ is the surface concentration of adsorbed water, C_{is} are the average concentrations of contaminants on the surface, n_i is the reaction order (exponent) of the ith component, ΔE is the activation energy, and kT, the Boltzmann constant and temperature. It was further assumed that the surface concentrations, C_{is}, could be obtained by Henry's law equilibria and that $C_{H_2O,s}$ would be nearly a function of relative humidity alone. In general it was presumed that the various atmospheric contaminants underwent no synergistic reactions (outside of the failure interaction, Eq. [1]) as long as the temperature in the accelerated environment was restricted to 85°C.[1]

According to the procedure stipulated by Schwartz and Bacon, accelerated failure would be accomplished by a manipulation of the variables in the rate expression, Eq. [1]. In particular, it was proposed that the rate could be increased by an increase in temperature, thereby relating failure rate in the field to failure rate under accelerated conditions by an Arrhenius law

$$\frac{r_p^{accel}}{r_p^{field}} = e^{\frac{-\Delta E}{k}\left(\frac{1}{T_{accel}} - \frac{1}{T_{field}}\right)} \quad [2]$$

where ΔE is the activation energy for the failure re-

[1] Several exceptions to this scheme were explicitly given.

action. Relative humidity (RH) was to be held constant—it was argued that the surface concentration of water, $C_{H_2O,s}$, would be nearly unchanged under these conditions. Finally, the concentration of each species in aqueous solution was to be maintained near the upper end of the range of values encountered in field use (3a). It was stated that this would occur if the gas phase partial pressure of each component was adjusted at each temperature in proportion to the corresponding value of its Henry's law constant in a pure solution

$$\frac{p_i^{accel}}{p_i^{field}} = \frac{H(T_{accel})}{H(T_{field})} \quad [3]$$

There was no experimental confirmation of these propositions.

Schwartz and Bacon (5) constructed a heated Teflon chamber (SEAT facility) in order to apply these principles to actual failure tests in the presence of SO_2, NO_2, and ozone. In initial experiments, employing humid air and SO_2 analysis of the chamber ambient was attempted using a pulsed fluorescence analyzer to monitor the concentration of SO_2; there was an apparent discrepancy between the quantity of SO_2 entering the chamber and that detected in the humid air emerging downstream. This effect was again confirmed in subsequent reliability studies involving the electroplated leads of light emitting diodes (LED's) (6). Furthermore, when SO_2, NO_2, and O_3 were introduced in various combinations, there was a large interaction between contaminants as the loss of each was dependent on the concentrations of the other components.

These results are highly significant since other workers have carried out accelerated tests under the assumption that gases introduced into a test chamber maintain their chemical integrity (7). Kemmerer and Hartwig (7a), for example, assumed that 0.5 ppm SO_2 introduced into a stream of air at 85°C and 80% RH provides an atmosphere containing 0.5 ppm SO_2 for the exposure of metallizations in a test chamber; however the SEAT studies (5, 6) demonstrate that large SO_2 losses occur and, as will be shown, SO_3 and sulfuric acid are the main corrosive agents under those test conditions.

Restrictions on the simple model.—Clearly there are a number of additional assumptions implicit in the simple model, Eq. [1]. As noted by the authors (5), it is assumed that the relative humidity is a proper scaling factor. Consecutive chemical processes of all kinds are neglected. For instance, if pollutant A forms a product B and B is the corrosive agent, then the corrosion process

$$A \rightarrow B \quad [4a]$$

$$B + (\text{Device}) \rightarrow C \quad [4b]$$

cannot, in general, be characterized by a single reaction and activation energy. Thus the attack of metallizations by sulfuric acid, alluded to above, falls outside of the scope of this model. Of course far more complex multiple reaction schemes are conceivable and the actual failure process (as opposed to precursor formation, as illustrated above) may involve several consecutive reactions and even alternate pathways.

The elementary model also neglects mass transfer limitations. A pollutant must be transferred to the interface solution and, ultimately, to the liquid-device interface. In addition, the actual corrosive agent may be formed through intermediate reactions at the gas-liquid or solid-liquid phase boundaries. A simple universal rate of the form given in Eq. [1] can only apply when consumption or transport of reactant in one of these processes is always slow (and therefore dominant) compared with the others. If these requirements are not met, then the rate law and detailed chemistry of failure will be a function of the specific concentrations, temperature, humidity, and gas flow parameters in the test.

Previous studies of SO_2 oxidation.—The oxidation of SO_2 in the atmosphere is an important process in the chemical evolution of air pollutants and as such has received a great deal of attention (8). While there seems to be many parallels with the present study, including synergistic effects on the reaction from NO_2 and water vapor (9), the atmospheric process is photochemical and therefore differs fundamentally from the dark reaction occurring in the present study. In the polluted atmosphere, hydroxyl radicals are formed from photochemical reactions involving other species (*e.g.*, NO, hydrocarbons) and the oxidation process can be quite complex (10). In the laboratory, the formation of SO_3 and subsequent nucleation of sulfate has been studied through photochemical oxidation involving excited states of SO_2 and the ground state of oxygen. In any case the homogeneous photo-oxidation of SO_2 in the atmosphere is very slow ($\sim$ 2%/hr in sunlight at solar zenith) (11). In the presence of water, laboratory photolysis rates (12) are greatly increased (about 200 times), presumably due in part to hydration of SO_2 molecules which promotes H_2SO_4 formation. Negligible oxidation occurs at ambient temperature in the absence of irradiation (12).

The homogeneous dark oxidation of SO_2 has, by comparison, been little studied. Tokunaga *et al.* (13) found that in dry mixtures of SO_2 and high purity synthetic air, no oxidation could be observed, even at 100°C and after irradiation by 10 Mrad of 1-2 MeV electrons. In the presence of water, irradiation produces substantial oxidation. However these workers did not report the rate, if any, of oxidation of the wet mixtures without irradiation. Urone *et al.* (14) found no homogeneous reaction in an SO_2/air mixture ($\sim$ 10-20 ppm) at 25°C and 50% RH. Evidently there are no other published data for the homogeneous oxidation of SO_2 in air at elevated temperature.

A number of workers have investigated the oxidation of SO_2 by molecular oxygen in aqueous solution (15). At 25°C, the oxidation proceeds via the mechanism[2] (15a)

$$SO_{2(g)} \rightleftarrows SO_{2(aqueous)} \quad [5a]$$

$$H_2O \rightleftarrows H^+ + OH^- \quad [5b]$$

$$SO_{2(aqueous)} + H_2O \rightleftarrows HSO_3^- + H^+ \quad [5c]$$

$$SO_{2(aqueous)} + OH^- \rightleftarrows HSO_3^- \quad [5d]$$

$$HSO_3^= \rightleftarrows SO_3^- + H^+ \quad [5e]$$

$$SO_3^= + \tfrac{1}{2} O_2 \rightarrow SO_4^= \quad [5f]$$

where the oxidation of $SO_3^=$ to $SO_4^=$ occurs by a first-order reaction as indicated and no oxidation of HSO_3^- occurs directly. To a good approximation, the rate of oxidation is given by (15a)

$$\frac{d[SO_4^=]}{dt} = 1.58 \times 10^{11} [H]^{-2.16} p_{SO_2} \frac{\text{moles } SO_4^=}{\text{liter-s-atm.}} \quad [6]$$

where p_{SO_2} is the partial pressure of SO_2 in equilibrium with water; the overall reaction appears to be rate controlled by the oxidation of sulfite (Eq. [5f]), even in a static chamber, and the rate was verified for pH between 2 and 6 and temperatures of 3° and 25°C. The reaction rate was zero order with respect to O_2 over a wide range of concentrations.

Finally, it is well known that certain metal oxides catalyze the air oxidation of SO_2 to SO_3 (14) and a number of transition metal ions catalyze the oxidation of sulfite to sulfate in solution (17). The action of some catalysts is clearly very temperature sensitive since, for instance, vanadium and chromium oxides produce very slow oxidation at room temperature (14, 18), whereas vanadium pentoxide is a catalyst for sulfuric acid

[2] It should be noted that some workers studying the oxidation of other sulfur species in aqueous solution were apparently unaware of this previous work and utilized erroneous assumptions for the oxidation of sulfite (16).

production at ~400°C (18). Metallic catalysts also can enhance the photochemical oxidation of SO_2 (14).

In this connection it should also be noted that higher alcohols and phenols inhibit the aqueous oxidation of sulfite (18, 19). The wet chemical analysis, described below, utilized isopropanol as an inhibitor in order to separately collect sulfate.

Scope of the investigation.—SO_2 is one of the most pervasive pollutants and it is known to accelerate failure and corrosion in a variety of situations. Compared to the complex chemistry which occurs in many gas mixtures, or even with other elementary pollutants such as NO_2, SO_2 represents a simple contaminant system. Nevertheless, as mentioned above, several investigators have been unable to obtain a mass balance on humid, SO_2-contaminated air streams entering an empty Teflon chamber; one objective of the present study was to characterize any chemical processes which occur and could account for the loss of SO_2. A second objective was to identify those conditions for which the loss of SO_2 and the formation of secondary corrosive agents would be negligible—only under these circumstances would there be some hope of establishing an analytical relationship between SO_2-induced failure processes in the field and those observed in an accelerated laboratory test environment.

Low concentrations (1-5 ppm) of SO_2 were added to the humid air and the effluent composition was measured as a function of temperature (23°-85°C), humidity (7-87% RH), and flow rate (50-185 std. liters per minute [slpm]) in an empty Teflon (SEAT) chamber. Wet chemical and instrumental analyses were in good agreement and revealed that substantial amounts of SO_2 in the feed gas were converted to SO_3 and sulfuric acid. The kinetics of this reaction were determined and it was found that the loss of SO_2 in an accelerated environment can be minimized by the judicious selection of residence time, temperature, and humidity.

Apparatus and Technique

SEAT flow system.—The SEAT test facility, which has been described previously (5), was modified and used to conduct the present investigation. Its construction and current mode of operation will be discussed briefly.

A schematic of the entire apparatus is shown in Fig. 1. Dry nitrogen and oxygen were metered in a 1:4 ratio through a Tylan mass flowmeter gas blending unit. This stream passed through a packed column containing activated charcoal and molecular sieves to insure the absence of reactive trace impurities. This "synthetic air" then flowed over a humidification tray in the oven that housed the Teflon SEAT chamber and into a mixing plenum leading to the chamber proper (Fig. 2). A precalibrated SO_2 mixture (5% SO_2 in N_2) was metered through a separate mass flowmeter and injected into the mixing plenum (Fig. 2) of the 16 × 17 × 15 in. chamber.

The chamber temperature was measured using a sheathed thermocouple inserted via the exhaust port, and humidity was measured with a Humitemp Model PCRC-55HPT humidity/temperature sensor, a wet/dry bulb system built into the oven, and water collected by condensation of the chamber effluent (water collection

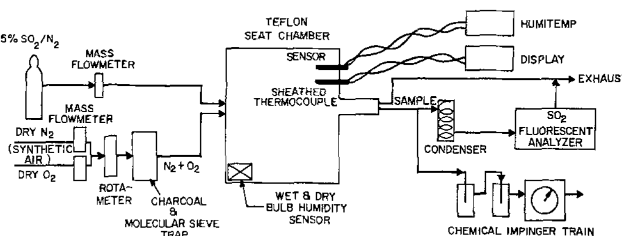

Fig. 1. Schematic of apparatus

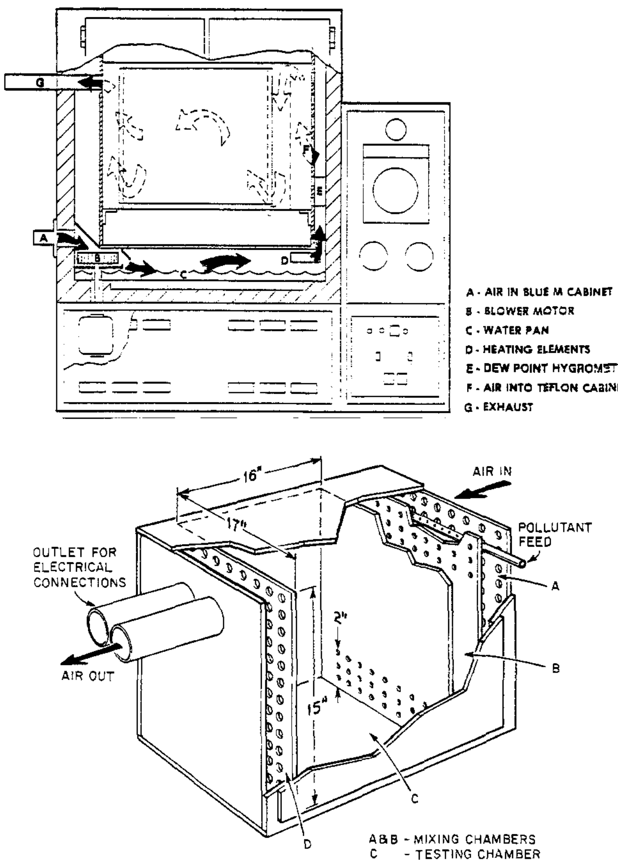

Fig. 2. SEAT Chamber. (a, top) humidity oven and airflow, (b, bottom) chamber detail.

occurred as part of the chemical analysis—see below). SO_2 concentrations in the effluent were determined by pulsed fluorescence while an independent chemical technique was used to analyze SO_2 and the combined quantity of SO_3 and H_2SO_4.

The SO_2 flowmeter was periodically calibrated against a Brooks mercury-sealed piston displacement calibrator and the N_2 and O_2 flow rates were calibrated against a wet test meter. The wick of the wet/dry bulb sensor deteriorated with use and this measurement was not consistently made through all the experiments. In order to insure against chemical degradation of the Humitemp sensor, the remote element was regularly replaced with a new, calibrated unit. The precision of water collection was best at high temperatures and moderate to high humidity; under favorable conditions the humidity determined in this way was in good agreement with the humitemp measurements (±3°C dewpoint).

Sampling and analyses.—SO_2 concentrations reported in previous investigations with the SEAT facility (5, 6a) were determined using the sampling system in Fig. 1 and a Thermoelectron Model 43 pulsed Fluorescence SO_2 Analyzer. While this method of analysis was continued throughout the present investigation, *a priori* its accuracy was uncertain due to possible losses in the sampling process and the failure of previous investigators to obtain an SO_2 mass balance (5, 6a). However, parallel wet chemical determinations made during the present study were in good agreement with the analyzer and thus verified its accuracy (Fig. 3).

The fluorescent analyzer is essentially a transfer standard and must be carefully calibrated to make absolute measurements. Periodically, the analyzer was zeroed and spanned against a dry, standard 1 ppm (nominal) SO_2/N_2 mixture and a dynamic SO_2 permeation tube system. Independently, the 5% SO_2/N_2 supply tank was standardized using the wet chemical procedure (see below) and diluted with "synthetic air" to

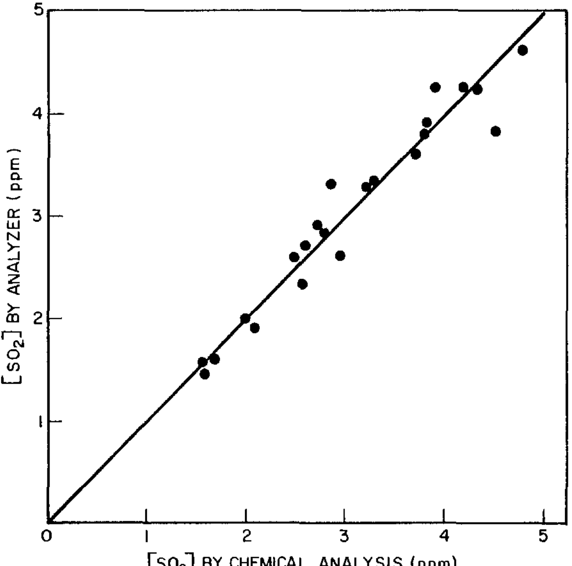

Fig. 3. SO_2 analyzed chemically vs. SO_2 measured by pulsed fluorescence (46°-85°C, 7-90% RH).

verify the analyzer calibration. These procedures were also used to standardize new tanks of SO_2/N_2 mixture.

The atmosphere emerging from the Teflon SEAT chamber is generally hot and humid. Since the analyzer will not function under such conditions, a glass water-cooled condenser was used to cool and dehumidify the gas (Fig. 1). Evidently, negligible SO_2 is absorbed during this process because (*i*) the condensate is acidic due to dissolved sulfuric acid and SO_2 is relatively insoluble in neutral and acid solution and (*ii*) the contact time is short.

A possible cause for the earlier mass balance discrepancies was the oxidation of SO_2 in the chamber. In order to quantify the significance of this process and to account for all products in the effluent, we added a wet chemical sampling train (Fig. 4) and titrimetrically analyzed SO_2 and its oxidation products. The method used was a modification of the hydrogen peroxide "stack sampling" technique (20, 17, 19b). Approximately 100 liters of the chamber effluent was sampled at 0.25-0.5 liter/min into two Smith-Greenberg impingers (Fig. 4). A small auxiliary vacuum pump was used to draw the sample and total gas volume was measured with an in-line wet test meter. Typical collection times were ~2-4 hr. Both impingers were immersed in an ice bath to condense water vapor and the short sample line sloped downward in order to drain any condensate into the first impinger.

Impinger 1 was charged with 150 ml of a fresh solution containing 80% isopropanol in distilled water. The

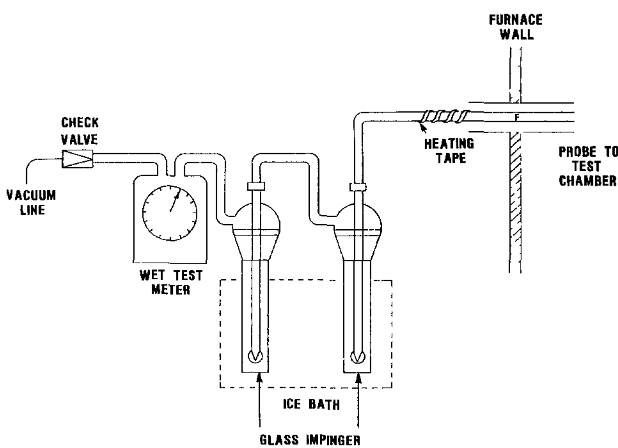

Fig. 4. Impinger train for sample collection

second impinger contained 150 ml of 3% hydrogen peroxide solution. SO_3, H_2SO_4 aerosol, and water vapor in the sampled stream are collected in the first impinger, while SO_2 is captured in impinger 2. After the sample has been collected, dry air is passed through the train for several minutes to sweep any traces of SO_2 in the first impinger out and into the second impinger. SO_2 is relatively insoluble in the aqueous, acidic isopropanol solution in impinger 1 and the isopropanol inhibits the slow oxidation of SO_2 to sulfate in solution (17, 19). The hydrogen peroxide in impinger 2, on the other hand, rapidly absorbs SO_2 and oxidizes it to sulfate (17). The quantity of water vapor collected in impinger 1 was measured by the volume or weight change and provided an independent measure of relative humidity. Negligible water accumulated in impinger 2 under these conditions.

The efficacy of this collection process was verified in several distinct ways. Blank runs using SO_2 alone confirmed that negligible SO_2 was collected in the first impinger. A third impinger with peroxide absorbent was temporarily inserted into the train after impinger 2; this also failed to collect SO_2 and thus proved that impinger 2 had a high absorption efficiency. The combination of SO_2 and SO_3/H_2SO_4 determined by this analysis consistently agreed with the total quantity of SO_2 fed to the chamber. Finally, as already mentioned, these SO_2 analyses were in good agreement with pulsed fluorescence.

The absorbent solutions were analyzed as follows. 80 ml of isopropanol was added to 20 ml aliquots of the impinger samples. These were then titrated with 0.005m $BaClO_4$ using 6 drops of 0.013% methylene blue solution and 6 drops of 0.2% thorin as an indicator (17). At the endpoint of the reaction

$$Ba^{++} + SO_4^{=} \rightarrow BaSO_4\downarrow \quad [7]$$

the greenish color changes to pink.

Results and Discussion

Reaction and rate.—The chemical analysis revealed that SO_2 is converted to SO_3 and H_2SO_4 in the SEAT chamber. Under steady-state operation, the total sulfur determined by chemical analysis of the product gas was ordinarily within 5% of that based on the feed gas flow rates and there was no accumulation of water or acid in the chamber; therefore any H_2SO_4 so formed must emerge as an aerosol or fine mist. Reaction data for 100 slpm air feed rate and various temperatures are shown in Fig. 5. At high temperature and humidity more than 70% of the SO_2 was converted to products. No significant reaction was observed at 23°C. Experiments performed at constant temperature, humidity, and air flow rate, but with varying concentrations of SO_2 in the feed (2-9 ppm), revealed that the extent of reaction is independent of SO_2 concentration. Thus at least in this 0-10 ppm SO_2 range, the curves in Fig. 5 apply for any concentration of pure SO_2 introduced into the SEAT chamber.

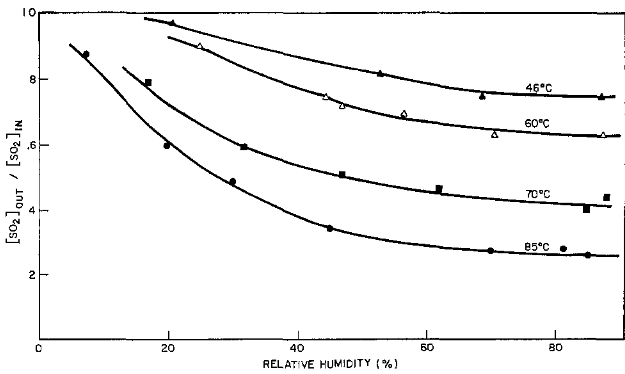

Fig. 5. Unreacted fraction of SO_2 vs. relative humidity at 100 slpm and various temperatures. SO_2 concentrations were 5-7 ppm.

If the kinetics of this reaction process were of the form given by Eq. [1], where relative humidity determines $C_{H_2O,surf}$, then the logarithm of SO_2 conversion plotted against RH would be a straight line at each temperature; however the data do not support this hypothesis. In fact the data are consistent with the first-order rate equation

$$\frac{dp_{SO_2}}{dt} = -k(T)p_{SO_2}p_w \quad [8]$$

This may be seen as follows. Equation [8] is integrated to give

$$\ln \frac{p_{SO_2,out}}{p_{SO_2,in}} = -k(T)p_w\tau \quad [9]$$

where τ is the mean residence time. If the chamber gas is well mixed

$$\tau = \tau_0 \equiv V/F \quad [10]$$

where V is the volume of the chamber, approximately 66.86 liters, and F is the total combined volumetric flow rate of air and water vapor entering the chamber (the volume of SO_2 is neglected). On the other hand, even if mixing were incomplete, τ and τ_0 would only differ by a constant factor as long as the degree of mixing were insensitive to changes in the flow rate. Equation [9] may then be rewritten in the form

$$\log_{10} \frac{p_{SO_2,out}}{p_{SO_2,in}} = -k'(T)p_w\tau_0 \quad [11]$$

where

$$k'(T) = k(T)\frac{\tau}{\tau_0}\log_{10} e \quad [12]$$

If the data obey this relation, a plot of log ($p_{SO_2,out}/p_{SO_2,in}$) against p_w will form a distinct straight line at each temperature. Figures 6 and 7 show the experimental data plotted in this fashion. If the 85°, 50 slpm data (upper line) in Fig. 7 are temporarily disregarded, it may be concluded that the results are indeed in satisfactory agreement with Eq. [11].

As noted, the 85°C, 50 slpm data form a distinct group. While superficially, this appears to be contrary to Eq. [11], it is possible to rationalize these data within the above framework. Feed gas entering the bottom of the chamber wall (Fig. 2) creates a complex flow pattern due to entrainment of the surrounding fluid, the effect of nearby surfaces, and, possibly, flow separation. Temperature gradients may also influence the flow. Since the Peclet number (based on the lengths subtended by the feed jet array) is large (~350) and the Reynolds number is moderate ($N_{Re} \approx 500$), the mixing within the chamber is primarily brought about by flow circulation rather than diffusion or turbulence. By analogy to other hydrodynamic phenomena, it is reasonable to assume that this circulation pattern will exhibit drastic changes at particular values of the Reynolds number. Thus without direct experimental evidence, it might be assumed that there is less circulation at the lowest flow (50 slpm, 85°C); this will lower τ. A decrease in τ results in a smaller $k'(T)$, (Eq. [12]) which is in accordance with the data.

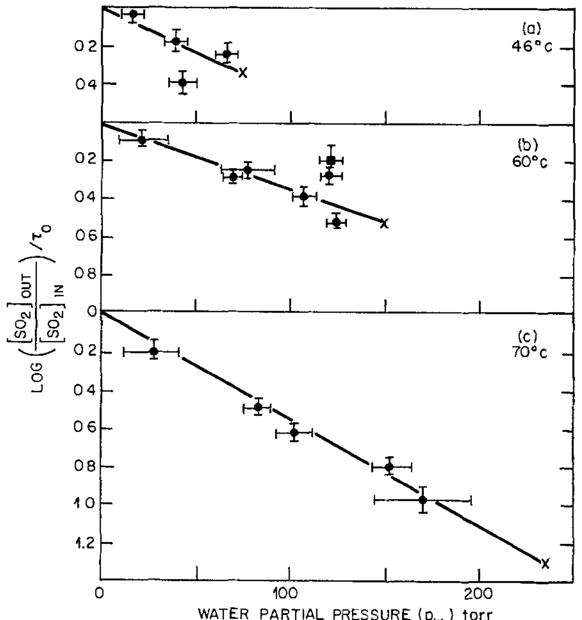

Fig. 6. $-\log \frac{[SO_2]_{out}}{[SO_2]_{in}} / \tau_0$ vs. p_w at (a) 46°C, (b) 60°C, and (c) 70°C. The dry air flow rate was 100 slpm except (■) 50 slpm. Inlet SO_2 concentrations ranged from 5 to 13 ppm. The lines terminate at saturation (100% RH denoted by x's).

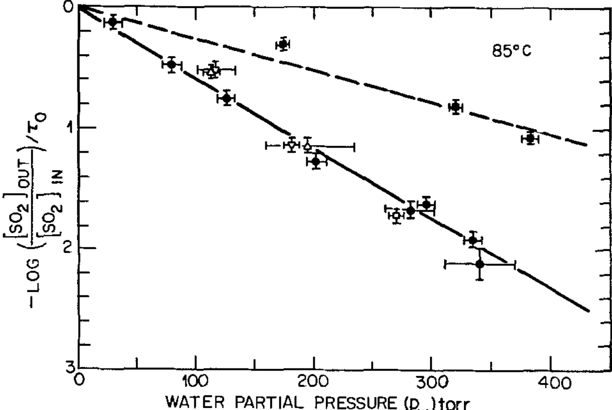

Fig. 7. $-\log \frac{[SO_2]_{out}}{[SO_2]_{in}} / \tau_0$ vs. p_w at 85°C. (■) 50 slpm, (●) 100 slpm, (▽) 120 slpm, (□) 150 slpm, (△) 180 slpm dry air flow rates. SO_2 concentrations ranged from 5 to 11 ppm. The lines terminate at 100% RH [p_w· (85°C) = 433.6 Torr].

The available precision and range of the present data foreclose the possibility of detecting a similar mixing effect at the lower temperatures (60° and 46°C). At low p_w and temperature, little SO_2 reacted and the variability in conversion was comparable to its magnitude. A large p_w cannot be used under these conditions since p_w is limited by the vapor pressure at saturation and this decreases rapidly with temperature (Fig. 6 and 7).

The slopes of the (high flow) 85°C and 60°C lines (Fig. 7 and 8) correspond to rate constants [$k'(T)$] of 0.0058 and 0.0035 $Torr^{-1}$ min^{-1}, respectively. The derived activation energy is ~5 ± 2 kcal/mole, but this is a very crude estimate because of the scatter and the possibility that part of it can be attributed to systematic changes in τ/τ_0.

Mechanism of reaction.—There is insufficient information to infer detailed mechanisms for the oxidation of SO_2 in the SEAT chamber. However, some rather general observations suggest that the reaction does not take place on the chamber walls. A combination of homogeneous reaction, and reaction at the surface of sulfuric acid aerosol nuclei is consistent with recent photochemical oxidation studies and the present data.

Since water vapor is required for the reaction to proceed at a measurable rate, the direct oxidation of SO_2 to SO_3 on the Teflon walls may be excluded. Furthermore, in the presence of water, sulfuric acid should be the principal oxidation product. Sulfuric acid has a negligible vapor pressure and thus any acid produced on wall sites would accumulate in the chamber and absorb additional water vapor from the humid

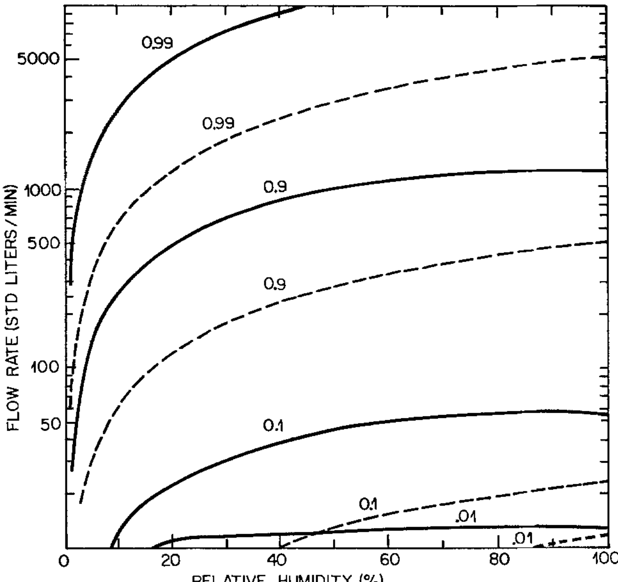

Fig. 8. Theoretical air flow/relative humidity operating curves for a constant fraction of unreacted SO_2 in the SEAT chamber (based on Eq. [13]). Fraction noted on curves. Solid lines (——) at 85°C; dashed lines (- - - -) at 60°C.

gas. Since (*i*) liquid did not normally accumlate in the chamber and (*ii*) essentially all sulfur was accounted for in the emerging product gas, this type of process can be excluded.

It has been proposed (21) that SO_2 may cluster with water molecules in the gas phase at high humidity. Such hydration would facilitate its oxidation and nucleation to form an H_2SO_4 aerosol. The surface of aerosol droplets could, in turn, provide sites for subsequent heterogeneous oxidation within the gas phase. Substantial homogeneous reaction within the liquid phase of aerosol droplets is unlikely, since the total volume of liquid would be small and the rate of this oxidation process (Eq. [5]-[6]) is retarded by low pH.

Significances of reliability tests.—These experiments show that secondary products can be highly significant in contaminative humid atmospheres at elevated temperature. Since the temperature, humidity, residence time, and flow profile will greatly influence the chemical environment, the chamber composition should be monitored and these variables manipulated to attain the desired test composition.

Ideally, a test should not be sensitive to small fluctuations in the operating parameters. Thus the temperature, flow rate, and humidity should be chosen so that only a small extent of reaction is possible or, alternatively, so that gaseous reactions proceed to near-completion. These requirements may be expressed as a series of "operating curves" as shown in Fig. 8. In Fig. 8, SEAT isothermal $[SO_2]_{out}/[SO_2]_{in}$ isopleths are shown on the RH-air flow plane. The curves are computed from Eq. [11] using $k'(T)$ values determined from Fig. 6 and 7 (see above). Thus more than 90% of SO_2 in the inlet gas will be unreacted for values of flow and RH which lie above and to the left of the $[SO_2]_{out}/[SO_2]_{in} = 0.9$ isopleths. Likewise, for example, the extent of reaction will be more than 90% for flow and RH values which lie below and to the right of the $[SO_2]_{out}/[SO_2]_{in} = 0.1$ isopleths. In fact, the curves in Fig. 8 may overstate conversion somewhat since they do not include possible effects of flow rate on τ (see Reaction and Rate, above).

Another consideration is the relation of chamber data to field conditions. If field failure of a device occurs via the attack of SO_2 and water vapor alone, exposure to SO_3 and H_2SO_4 may lead to unrepresentative failure modes. In this case the test should be conducted in the low conversion regime of Fig. 8. In other instances, field failure may be induced by sulfuric acid from the dark or photo-oxidation of SO_2 on oxide or metallic surfaces. In that event, a test environment containing SO_2 and its oxidation products may be quite appropriate.

This point has been overlooked in previous studies. Feinstein and Sbar (7b), for example, report that both nickel sulfite and nickel sulfate were formed on the metallizations in their accelerated tests using 0.5 ppm SO_2 at 85°C and 85% RH. While those workers and others (7) attribute the sulfate corrosion to SO_2 attack, this premise should be carefully scrutinized in light of the present findings.

Even when SO_3 and H_2SO_4 are normal ingredients in SO_2 induced field failure processes, more sophisticated analyses will be required to carry out scalable accelerated tests. Consider a case in which SO_2 is catalytically oxidized on the surface of a component under test. The product acid may be responsible for failure in both field and accelerated test environments; however surface reactions will be rate limiting in the field, whereas the supply of SO_3/H_2SO_4 in a chamber can be governed by volume production.

Conclusions

Sulfur dioxide is oxidized during accelerated life test at elevated temperature and humidity. The products are sulfuric acid, and possibly, SO_3. The reaction is first order in SO_2 and water concentrations and appears to occur in the gas phase, either homogeneously or on aerosol nuclei, rather than on the walls of a Teflon test chamber. A rate equation has been formulated to represent the experimental data, but at present its numerical values should only be applied to the SEAT test facility.

In order to conduct meaningful tests which mimic the effects of atmospheric contaminants, it is necessary to consider the oxidation and interaction of pollutants since secondary corrosive agents are formed under accelerated conditions. The acceleration guidelines proposed by Schwartz and Bacon (5) require stringent assumptions which do not appear to be met in practice.

The formation of product acid from SO_2 can be controlled by a judicious selection of operating parameters. The manifolds of constant product formation are two dimensional; it is therefore possible to select various combinations of temperature and humidity which accelerate failure, and simultaneously to control product formation by adjusting the gas flow rate.

Manuscript received July 21, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Preparation of Tin Oxide Films from Ultrafine Particles

Hisahito Ogawa, Atsushi Abe, Masahiro Nishikawa, and Shigeru Hayakawa

Matsushita Electric Industrial Company, Limited, 1006 Kadoma, Osaka, 571 Japan

ABSTRACT

A highly reproducible procedure for preparing films from ultrafine particles of metal oxides has been developed. The ultrafine particles of several tens of angstroms in size are grown by the evaporation of the metal in low oxgen gas pressure, and subsequently, the film is constructed from the ultrafine particles aligned in a specific direction on the substrate. The particles' size and film structure were studied under various deposition conditions, *i.e.*, oxygen gas pressure, rf activation power, evaporation temperature, and others. The ultrafine particle films prepared with this procedure may serve as a highly sensitive gas sensor.

Increasing attention is being paid to studies on tin oxide materials, especially on the method of preparation of sintered materials and thin films of tin dioxide and evaluation of their electrical properties for gas sensors. It is important to pay special attention to the surface quality of the tin oxide materials, because the change in conductance of gas sensors takes place at the boundary between the gaseous and solid states.

The specific surface area of crystals, *i.e.*, the surface area of the crystals per unit weight (cm^2/g), increases as the particle size decreases. Hence, if one studies the physical properties associated with the crystal surface, such as gas adsorption and light dispersion, the properties are strongly dependent on the particle size (1-3), and may be enhanced with ultrafine particles. In order to supply samples for studying the physical properties of ultrafine particles, we have studied the preparation of ultrafine particles in the size range of several tens of angstroms and films of these particles deposited on a glass substrate.

The preparation methods for fine particles which are usually considered are the following: (*i*) mechanically grinding large particles to a smaller desired size, and (*ii*) nucleation and growth of particles by chemical reaction of the constituent elements under controlled conditions. The latter method, combined with a gas-evaporation technique, which can easily produce low surface distortion, high purity, and small size particles, is preferable to the grinding one. Many studies on the growth and morphology of metallic particles (4-8) have been carried out by the gas-evaporation technique. A few reports have been made on metal oxides (9, 10). None of these studies, however, supplies enough information on the formation of films made with ultrafine particles of metal oxides which is the subject of this report.

We found a new procedure for growing the appropriate ultrafine particles of certain metal oxides in oxygen atmosphere, and subsequently, a method for producing films consisting of the ultrafine particles aligned in a specific direction on the substrate. The details of the preparation and the optimized conditions will be described below.

Deposition of Metal Oxides

The vacuum deposition chamber used in this study is illustrated in Fig. 1. The specific features arranged in the chamber were (*a*) a quartz cylinder guiding the ultrafine particles from an evaporator boat to a substrate, and (*b*) an rf coil electrode consisting of several turns of stainless steel tubing. The rf coil was operated with a 13.56 MHz oscillator through a matching box.

Key words: ultrafine particle films, tin oxide, gas-evaporation technique, oxygen gas plasma, gas sensor.

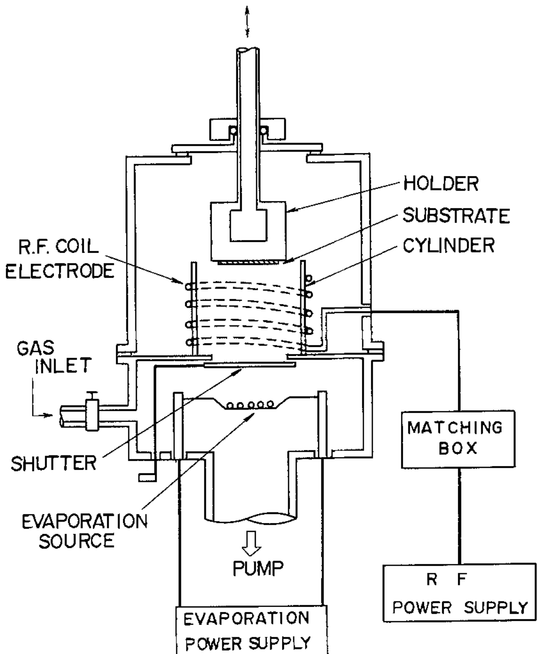

Fig. 1. The apparatus arrangement in this experiment

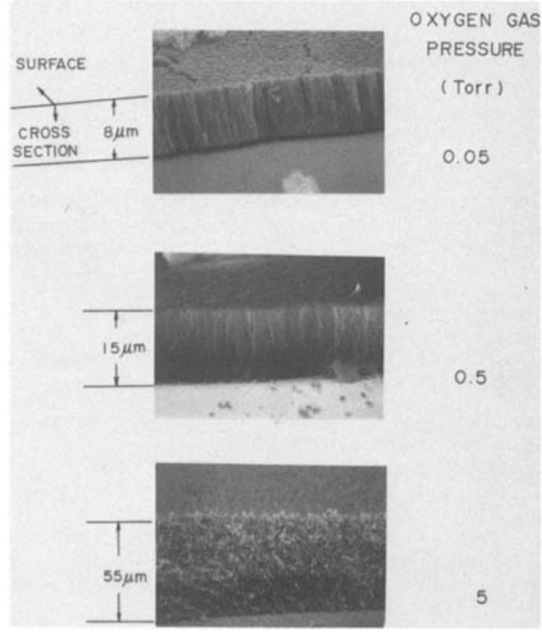

Fig. 2. Scanning electron micrographs showing the stucture of tin oxide ultrafine particle films deposited at three different oxygen gas pressures.

The glow discharge of the oxygen in the vacuum chamber was produced in the region adjacent the rf coil by applying the high oscillating field between the coil and chamber.

The samples were prepared using the following procedures. A glass substrate was supported by a sample holder. A high purity metal (greater than 99.99%) such as Sn, Mn, Zn, or Cu was placed in the evaporator boat. The chamber was pumped down to approximately 2×10^{-6} Torr and then oxygen gas was introduced into the chamber. A glow discharge in the oxygen gas (white color) was produced by applying the rf power. Then power was supplied to the boat to evaporate the metal. The growth of the ultrafine metal oxide particles in the glow discharge of oxygen gas was easily detected with the observation of the discharge color turning to purple (in the case of tin oxide) from white.

When the boat temperature was stabilized, a shutter was opened to deposit the ultrafine metal oxide particles on the substrate. The deposition was continued for several minutes, depending on the desired thickness of the final ultrafine particle film.

The metal oxides deposited on the substrate were significantly dependent, both physically and chemically, upon the oxygen gas pressure in the vacuum chamber. Most of our studies were with Sn as the metallic reactant and are thus the principal subject of this report. Evaporation of Sn metal yields a film consisting of a mixture of SnO_2 and SnO for oxygen gas pressures between 0.1 and 10 Torr. It can be seen that no peaks from tin metal ultrafine particles exist in the x-ray diffraction spectrum, indicating extensive chemical reaction between evaporating tin atoms and oxygen molecules in the chamber. The percentage (Γ) of SnO_2 content in the final products was estimated from the ratio of the intensities of the given x-ray diffraction lines of SnO_2 (at $2\theta = 26.6°$) and SnO (at $2\theta = 29.9°$), with the aid of a calibration curve made from a physical mixture of SnO_2 and SnO powders. As described later, the value of Γ was a sensitive function of the oxygen gas pressure, evaporation temperature, and activation power in the plasma.

The appearance of the metal oxide ultrafine particle films deposited on the substrate is also affected by the oxygen gas pressure. Figure 2 shows photomicrographs, taken by a scanning electron microscope, of tin oxide ultrafine particle films deposited at oxygen gas pressures of 0.05, 0.5, and 5.0 Torr, respectively. It may be seen that the structure and thickness of the ultrafine particle films are markedly dependent upon the oxygen gas pressure and vary from oriented columnar to spongy structures. When the oxygen gas pressure is less than 0.05 Torr, the ultrafine particle film has a smooth, flat surface with an inferior columnar structure perpendicular to the surface of the substrate. For oxygen gas pressures greater than 0.2 Torr, derangement occurs in the columnar structure and the thickness of the ultrafine particle film is increased. The growth of the ultrafine particle film is accelerated with the oxygen gas pressure at 5 Torr, resulting in a spongy appearing film with a rough surface.

Determination of Particle Size

An ultrafine particle film, even a single column in the film, consists of an agglomeration of many ultrafine particles, of the order of tens of angstroms in size. The particle sizes and crystallization of the ultrafine particles were determined first from observation with an electron microscope.

Figure 3 shows an electron micrograph and an electron diffraction pattern of ultrafine tin oxide particles.

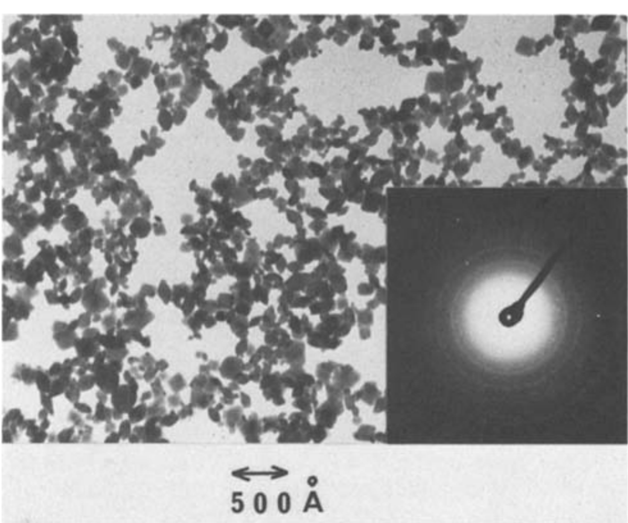

Fig. 3. Transmission electron micrograph and electron diffraction pattern of ultrafine tin oxide particles.

One may see the spotty diffraction rings, indicating that the ultrafine particles are crystallized well. This is consistent with the observation of flat crystal faces in the micrograph. Microcrystallites consisting of octahedra and truncated octahedra are clearly evident (9). The distribution of sizes of the ultrafine particles is log-normal. The sizes of 185 particles on the micrograph were measured by a ruler, and the result is shown in Fig. 4 in a size distribution histogram. The calculated curve of the log-normal distribution is also shown with a solid line. The median particle size (4) D is calculated from the data to be 152Å.

The determination of particle size distribution by the electron microscope may be accurate and precise, but is very tedious. It is found that the mean particle size D of the ultrafine particles can also be estimated from the broadening of the lines in the x-ray diffraction spectrum, by applying Hall's equation (11)

$$\frac{\beta \cos\theta}{\lambda} = \frac{1}{D} + 2\epsilon \frac{\sin\theta}{\lambda} \qquad [1]$$

where λ is the wavelength of x-ray used (in this case, $\lambda = 1.5404$Å), β is the width of the line at the half-maximum intensity, and ϵ is the degree of crystal distortion. The estimated values of D and ϵ (for the same sample observed in the electron microscope) were $D =$ 160Å and $\epsilon = 3 \times 10^{-3}$, respectively. This means particle size D is in good agreement with the value of the median particle size D measured using the electron microscope. Thus, we can determine the size of the ultrafine particles by means of the x-ray diffraction lines, instead of the tedious method by the electron microscope. We used the x-ray diffraction method for further size measurements of ultrafine particles in deposited films.

Particle Size Dependence on the Oxygen Gas Pressure

Figure 5 shows the curves of the D values for ultrafine tin oxide particles determined from the x-ray diffraction spectrum as a function of oxygen gas pressure under the evaporation conditions of the evaporation temperature $T = 1100$°C, the rf power $RF = 0$ watt (*i.e.*, no plasma), and the distance between the evaporation source and substrate $L = 7$ cm. Similar results were also obtained with different T and L. The results shown in Fig. 5 indicate that the growth

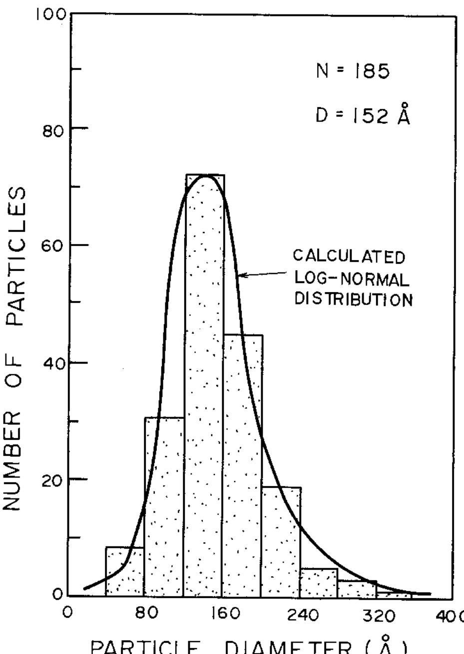

Fig. 4. A histogram of the particle size of tin oxide (shaded). The solid curve represents a log-normal distribution calculated for $\bar{x} = 152$, $\bar{\sigma} = 1.4$.

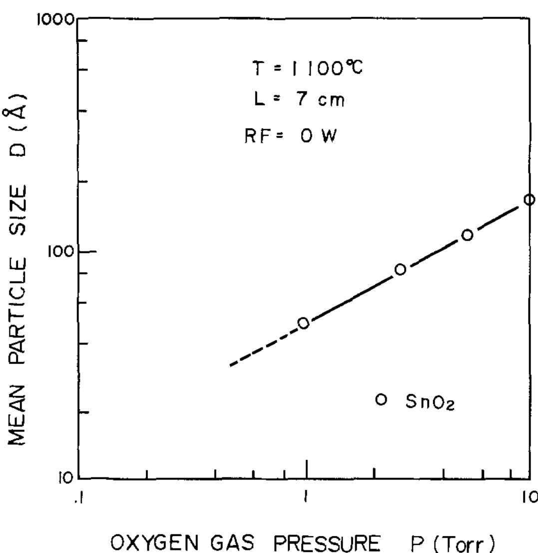

Fig. 5. The mean particle size D of SnO_2 particles as a function of oxygen gas pressure.

rate dependence of ultrafine particle films of SnO_2 on oxygen gas pressure (P) can be expressed by

$$D = kP^{1/2} \qquad [2]$$

where k is a constant determined by T and L.

The growth mechanism of ultrafine metal oxide particles on the substrate is not yet well understood, even though a mutual collision-coalescence of particles and a complicated chemical reaction of the oxidation between metal atoms and oxygen molecules have obviously occurred during the deposition. Therefore, we cannot propose a model to explain the sublinear dependence of the particle size on the oxygen gas pressure.

Evaporation Conditions for Tin Oxide Films

As already mentioned, the composition of the film of the ultrafine tin oxide particles (*i.e.*, SnO_2 and SnO), as revealed by the x-ray diffraction analysis, is markedly dependent on the evaporation conditions. Figure 6 shows the values of D and Γ as a function of the distance L between the evaporation source and substrate, for two evaporation temperatures of 1100° and 1350°C. For evaporation temperatures below 1100°C, the values of D and Γ are essentially independent of both T and L, ($D_{SnO_2} = 40$Å and $\Gamma = 16\%$). For $T >$ 1100°C, the values of D and Γ are increased with increasing T and L, showing an increase in the content of large SnO_2 particles in the film with T and L. The measured temperature of the oxygen atmosphere for different values of L are also plotted in Fig. 6. These temperature profiles show that in the case of $T =$ 1350°C, the oxygen gas at $L < 7$ cm is heated enough for the conversion of SnO to SnO_2 (the conversion easily occurs above 170°C, as described later). Thus, the increase in the values of both D and Γ is caused by the reaction in the oxygen gas. If SnO $\rightarrow$ SnO_2 is the sequence of the reaction of the evaporating metal particles with the active oxygen gas, this reaction would be favored by the particles travelling longer distances, *i.e.*, large D and Γ would result for large L. The heated oxygen gas may be active at the evaporation temperature of 1350°C. When an rf field is applied, the oxygen plasma gas should be very active for oxidation even at a lower temperature. This has been examined for $T = 1100$°C.

The rf power (RF) was varied from 0 to 500W. Figure 7 shows the dependence of D and Γ on the rf power. The mean particle size D_{SnO_2} of SnO_2 particles in the film increased from 40 to 52Å as the rf power was increased to 150W, and the percentage of SnO_2 progressively increased from 16 to 66%. The values of

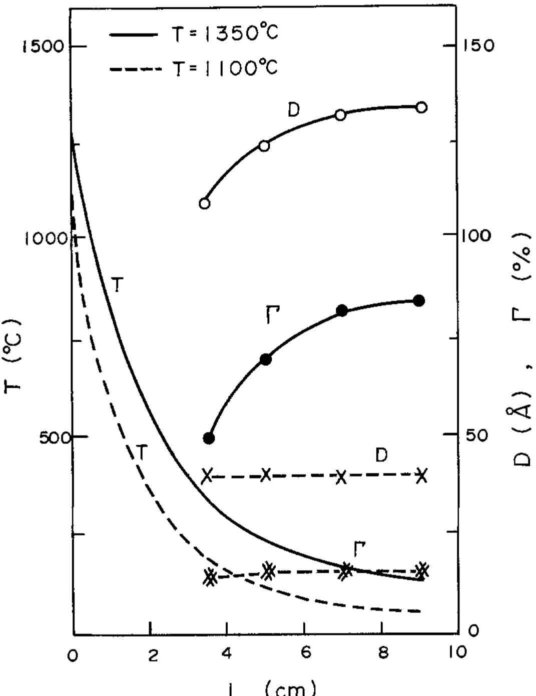

Fig. 6. The mean particle size D of tin oxide particles and the percentage Γ of SnO_2 content in films as a function of the distance L between the substrate and source. The tin oxide particles were prepared at temperatures $T = 1350°C$ and 1100°C.

D and Γ increased linearly with rf power up to 100W and, for rf power greater than 150W, the values of D and Γ were almost constant ($D \sim 50Å$ and $\Gamma \sim 70\%$). The temperature of the oxygen gas slightly increased during the operation of the rf discharge, less than 150°C even with an rf power of 500W, therefore, the growth of SnO_2 ultrafine particles could not be attributed solely to the temperature rise of the oxygen gas. Thus, the oxidation of SnO ultrafine particle is promoted in the active oxygen gas plasma even though the oxidation is not completed; the value of Γ is saturated at 67%. To obtain a pure SnO_2 film with $D = 52Å$, another treatment was necessary.

In order to understand the conversion of SnO to SnO_2, we have studied the thermogravimetry (TG) and differential temperature analysis (DTA) of the film in air. Two samples prepared under the following conditions were tested.

Sample No. 1 $P = 1$ Torr, $T = 1100°C$, $RF = 150W$, $\Gamma = 66\%$

Sample No. 2 $P = 1$ Torr, $T = 1100°C$, $RF = 0W$, $\Gamma = 16\%$

Figure 8 shows the TG and DTA curves obtained with the temperature rising at a rate 10°C/min. The results show the complete oxidation of SnO to SnO_2 at 300°C. This is confirmed by the x-ray diffraction analysis. The SnO is stable below 150°C. As the temperature is raised, the DTA curve shows an exothermic band, between 170° and 300°C with the peak at 220°C, showing that the oxidation of SnO to SnO_2 occurs in this temperature region. The TG curve shows an increase in weight, in the same temperature range, also indicating the oxidation of SnO to SnO_2. On the basis of these observations, we could say that the conversion of SnO to SnO_2 by means of the heat-treatment is dependent on the initial value of Γ. To confirm the oxidation of SnO to SnO_2, the ultrafine particle films prepared were annealed at various temperatures up to 250°C. Each sample was held for 30 min in air at the given temperature. The results obtained are shown in Fig. 9.

For the ultrafine particle film prepared under no plasma ($RF = 0W$) (Sample No. 2), the values of D and Γ increased progressively with annealing temperature, to a maximum of $D = 70Å$ and $\Gamma = 84\%$ which did not fit our requirements. Because, in detecting combustible gases, the tin oxide film comprising 100% SnO_2 ultrafine particles (*i.e.*, $\Gamma = 100\%$) has high sensitivity as compared with the film comprising mixed SnO-SnO_2 ultrafine particles. It is also found that there is an optimum particle size for the gas sensing film.

On the other hand, the samples deposited under $RF = 150W$ (Sample No. 1) convert completely to pure SnO_2 with only a small increase in size (from 52 to 56Å at 250°C). Observation of the annealed ultrafine particle film with the scanning electron microscope re-

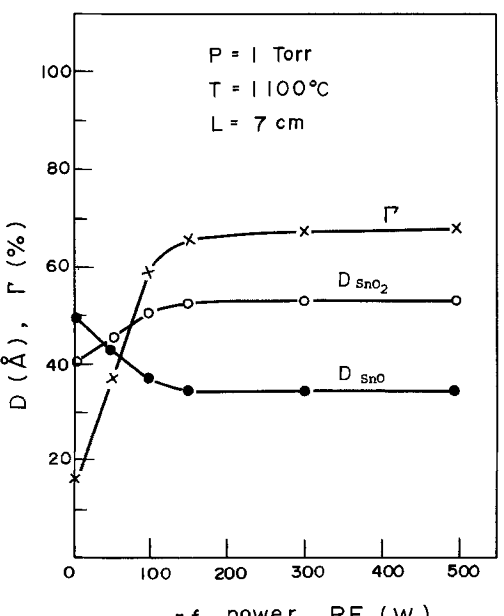

Fig. 7. The mean particle sizes D_{SnO_2} and D_{SnO} and the percentage Γ of SnO_2 content in films as a function of rf power (RF).

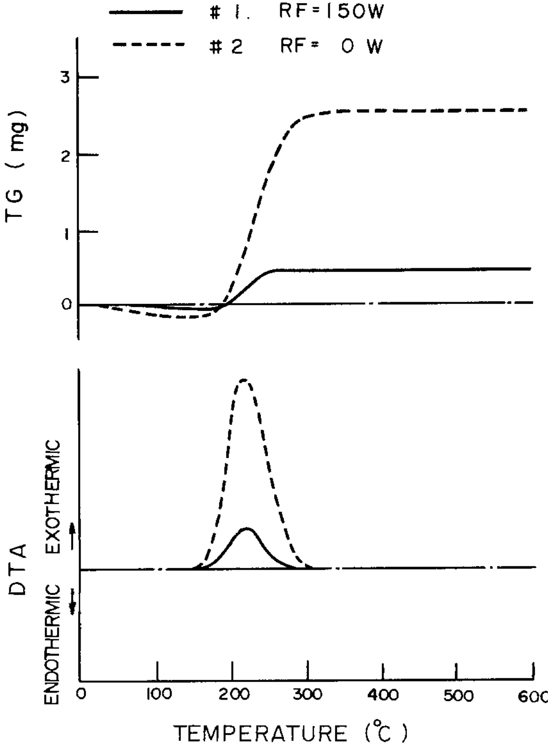

Fig. 8. Thermogravimetry and differential temperature analysis curves of tin oxide particles prepared with two different rf powers, $RF = 150W$ and 0 W.

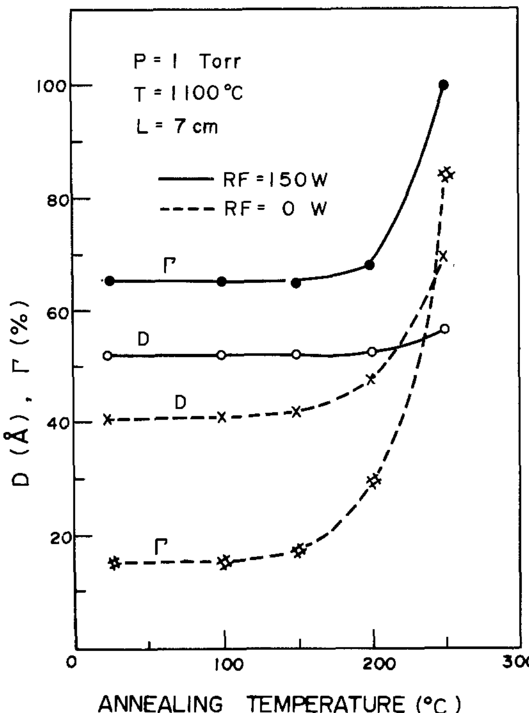

Fig. 9. The mean particle size *D* of SnO_2 particles and the percentage Γ of SnO_2 content in films of Fig. 7 as a function of annealing temperature.

vealed the columnar structure. Thus, the film structure is not altered by the annealing. Because the *D*-values of SnO_2 and SnO ultrafine particles grown at 1100°C in $RF = 150W$ are less sensitive to deposition conditions, good reproducibility was obtained for the film.

Summary and Conclusions

We have developed a procedure for preparing a columnar structure film of SnO_2. A film comprising 100% SnO_2 particles about 50Å in size was realized with a high reproducibility by the following procedure. An initial deposit of mixed SnO-SnO_2 ultrafine particles was prepared in an oxygen gas plasma with an rf power input of 150W, subsequent heating of this deposit at 250°C in air for 30 min fully converted the film to SnO_2 without significant particle growth. This film may serve as a highly sensitive gas sensor.

On the Kinetics of the Thermal Oxidation of Silicon

III. Coupling with Other Key Phenomena

William A. Tiller

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

A new model of transformation is proposed which leads to a much reduced excess free energy storage. Silicon is transformed to α-cristobalite plus interstitial Si ions. Subsequent oxidation of these interstitials produces rapid distortion of the lattice and speedy transformation of the structure to vitreous silica. The model allows a satisfactory qualitative explanation of both the orientation and temperature dependence of oxidation-enhanced diffusion (OED), oxidation-induced stacking faults (OISF), interface states (N_{it}), fixed oxide charge (Q_f), oxidation velocity (V), oxide density interface stoichiometry (SiO_x), and silicon interstitial partition coefficient (k_I).

In Part I (1) of this series a general overview was given of the partitioning of the total driving force for the oxidation process into the key parallel subprocesses. Attention was focused on the free volume supply condition needed to sustain such a transformation and on the specific mechanism available for free volume generation. In Part II (2), the transport subprocess was predicted to be electric field and orientation dependent and to involve charged as well as neutral species. The excess free energy subprocess due to the

Key words: semiconductor processing, thermodynamics, point defects, silicon dioxide, interstitials.

large molecular volume difference between Si and SiO_2 was shown to dominate the Si/SiO_2 oxidation and to lead to a possible interface structure wherein a cross-grid of extra half-planes terminated at the Si side of the Si/SiO_2 interface. Propagation of the interface to the Si phase required continuous removal of these extra atoms via one of several mechanisms.

Associated with the oxidation process in Si, there are a number of other phenomena that beckon for understanding. There is the oxidation-enhanced diffusion (OED) phenomenon (3-6), the oxidation-induced stacking fault (OISF) formation phenomenon (5, 7), plus the interface charge (N_{it}) and fixed oxide charge (Q_f) phenomena which all need to be understood in relationship to the oxidation process. One would also wish to understand their orientation and temperature dependences.

The primary purpose of this paper is to present a new way of looking at the oxidation process that allows one to qualitatively explain all of the foregoing phenomena with their associated orientation and temperature dependences as well as the orientation and temperature dependence of the oxidation velocity, V, the interface oxide density, and the interface stoichiometry SiO_x. Some quantitative assessment of these phenomena is given as well.

Analysis

Structural model of phase change.—Let us first consider what crystalline phase of SiO_2 would be the best match to continuously transform Si in the <100> direction. We shall assume that the system selects that phase which lowers the excess free energy contribution, ΔG_E (1, 2), the most, and then we shall look at the consequences of this choice and this approach.

The SiO_2 molecular volume increases from β-quartz (38.8Å^3) to α-cristobalite (43.6Å^3), β-cristobalite (45.3Å^3), and then to tridymite (52.0Å^3) compared to the atomic volume of Si (20.0Å^3) and vitreous silica (44.5Å^3). Transformation of the Si phase to these SiO_2 phases requires massive reconstruction except for the cristobalites and the vitreous phase. Direct intrusion of O atoms between each Si-Si bond in the Si lattice creates the β-cristobalite lattice under a compressive strain of 31%. Similar direct formation of vitreous SiO_2 from the Si lattice results in an amorphous film under a 30% compressive strain. However, the direct formation of α-cristobalite seems to offer a potentially much lower value of ΔG_E.

Consider the (100) face of the Si unit cell and the (100) face of the tetragonal α-cristobalite unit cell whose projections are shown in Fig. 1. In the Si unit cell we have 8 atoms. By completely removing the 4-Si atoms at the ¼ and ¾ positions and slightly displacing the other 4-Si atoms followed by oxidation of these 4 remaining Si atoms, we obtain the α-cristobalite unit cell. This produces a biaxial tension in the film parallel to the interface of $\sim$ 9% and no strain in the perpendicular direction because the unit cell can expand freely in this direction. This would yield a strain energy < 9% of that generated by forming the β-cristobalite directly. However, we still have the 4 removed Si atoms per unit cell to place back into the system in interstitial positions and this will move the system toward compressive strain and will increase the excess free energy. Placing these interstitials into the Si and the SiO_2 at the interface will stretch the respective unit cells to varying degrees depending on the degree of partitioning of these 4 extra Si atoms between the two phases. Thus, if the majority of these extra Si atoms enter the SiO_2, we can expect relaxation to occur at the interface such that some extra half-planes on the Si side will terminate at the interface (see Fig. 2). The number of these planes per unit area of interface will depend on the partitioning ratio of the Si interstitials between the two phases. Since the dangling bonds at the interface ends of these half-planes constitute interface electronic states, this is probably the source of N_{it} (8). We thus see that the magnitude of N_{it} depends critically on the interstitial partitioning ratio at the interface. In addition, we note in Fig. 1 that, at 45° to the α-cristobalite unit cell, the structure is pseudo diamond-cubic with a lattice spacing slightly smaller than that of β-cristobalite. Thus, the proposed transformation leads to a relatively well-matched diamond-cubic phase that is then stressed in compression by the interstitials placed therein. This leads to an increased density of the interfacial silicate and to an interface silicate stoichiometry of SiO_x where $x \approx 1$. If the β-cristobalite phase or the vitreous phase had formed directly from the Si, it would not have been possible to obtain this interface stoichiometry or excess interfacial density.

The key point of this concept is that the SiO_2 forms a suitable structure with extra atoms being placed in interstitial positions rather than forms a structure without interstitials. We shall see later that the former choice is the energetically favorable one. The second point concerning this concept relates to the actual structure that the interface SiO_2 takes. There is only a slight preference for α-cristobalite over β-cristobalite since both produce extra half-planes of Si at the interface that must end up in interstitial positions. There is less reason to choose vitreous SiO_2 because this requires some additional disordering mechanism and there is no rationale for choosing which Si atoms are destined to become interstitial species. We shall see later that a mechanism exists for the rapid transition of the crystalline SiO_2 phase to the vitreous SiO_2 phase within a few molecular distances of the interface. The crystalline SiO_2 phase thus exists only as a buffer layer between the Si and the vitreous SiO_2, but it plays a crucial role in the overall transformation process.

Point defect thermodynamics.—Neglecting any electric field or strain field effects, Appendix A gives the

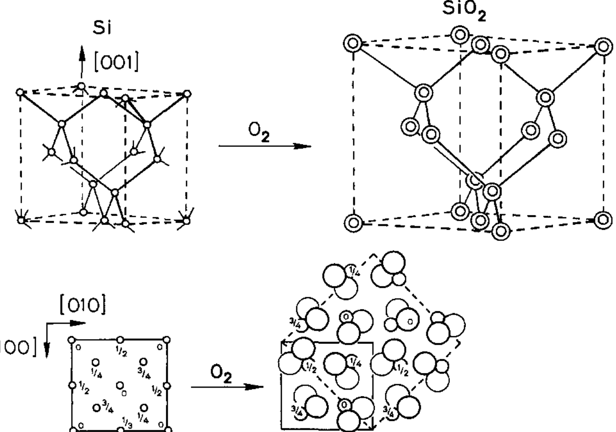

Fig. 1. Projection of the Si and the α-cristobalite unit cells onto their (100) planes. The dashed square represents the pseudo-diamond cubic unit cell of α-cristobalite.

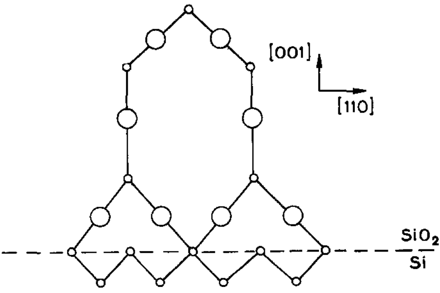

Fig. 2. Projection of Si/SiO_2 interface cross section illustrating the extra half-planes of Si that terminate at the interface with α-cristobalite.

chemical potential of defect species i, i = vacancy (V) or interstitial (I), in each phase j = Si or SiO_2 to be (9)

$$\mu_{ij} = kT \ln \left[\frac{n_{ij}(n_{sij} - n_{ij}^*)}{n_{ij}^*(n_{sij} - n_{ij})} \right] \quad \begin{matrix} i = V, I \\ j = Si, SiO_2 \end{matrix} \qquad [1]$$

Here, n_i is the average number of i-defects per unit cell, n_{si} is the number of possible i-defect sites per unit cell, and n_i^* is the average equilibrium number of i-defects given by

$$\frac{n_i^*}{n_{si} - n_i^*} = e^{\Delta S_i^V/k} e^{-\Delta H_i/kT} \qquad [2]$$

where ΔS_i^V is the vibrational entropy contribution and ΔH_i is the enthalpy of formation of the i-defect. In general, we expect $n_i^* << n_s$ for each phase. For Si, $n_{sV} = 8$, $n_{sI} = 5$ (10), $\Delta H_V = 2.4$ eV while $\Delta H_I \sim 8$ eV (11). For α-cristobalite, $n_{sV} = 4$ for Si, O, or SiO_2 vacancies, while $n_{sI} \sim 15$ (one I-defect adjacent to each O site in a ring), and no information is available on the ΔH values; however, it is well known that many different kinds of interstitial ions enter the interstitial spaces in natural β-cristobalite so it is expected that ΔH_I will be small for this defect in SiO_2 (10). Certainly, it is expected that $\Delta H_I^{SiO_2} << \Delta H_I^{Si}$ (11, 12). For the vacancy species as well as the interstitial species in SiO_2, one must consider Si, O, O_2, SiO, SiO_2, SiO_3, SiO_4, and $(O\text{-}Si\text{-}O)_n$ chains as candidates. For each of these defect species, the free energy change for the phase, ΔG_{ij}, has the form given by Fig. 3 where the minimum gives the location of the equilibrium i-defect content, $n_i^*(\mu_i^* = O)$. For our interest here, we will generally be interested in i-defect contents far removed from n_i^* where ΔG_{ij} is no longer negative, but may have a large positive value.

Since so little is known about point defects in SiO_2, let us consider the consequences of adding large numbers of I-defects to the Si phase. Since the I-defects are so much more energetic than the V-defects, the free energy of the system will be lowered by recombination events between I- and V-defects. If there were no vacancy sources in the system, the V-concentration would be greatly reduced until its chemical potential, μ_V, had been sufficiently reduced that

$$\frac{\partial G}{\partial n_I} + \frac{\partial G}{\partial n_V} = 0 \qquad [3a]$$

or

$$\frac{n_V n_I}{n_V^* n_I^*} \left[\frac{(n_s - n_I^*)}{(n_s - n_I)} \right] \approx 1 \qquad [3b]$$

Thus, since μ_I will be large and positive, μ_V will be large and negative. At this point, the recombination

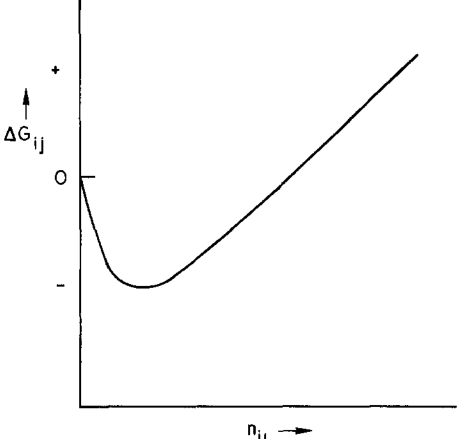

Fig. 3. Excess free energy of formation, ΔG_{ij}, of i-type defects in phase j as a function of number of defects per unit cell, n_{ij}.

process no longer lowers the free energy of the system and it will stop. This leaves us with $n_I >> n_I^*$ and $n_V << n_V^*$. In general, we can expect two or three types of vacancy sources in the system. The first is the small voids in the Si created by vacancy supersaturation due to initial cooling of the crystal from the melting temperature. This should give a total potential vacancy supply of $\sim 10^{15}/cm^3$ (*i.e.*, all those formed at the melting point). The second is dislocation lines which can climb in a direction so as to generate vacancies (total potential supply $< 10^{14}/cm^3$, *i.e.*, $\sim 10^3$ lines/$cm^3 \times \sim 4 \times 10^7$ sites/line $\times \lesssim 2500$ climb steps/site). The third is the Si/SiO_2 interface where vacancies in the SiO_2 lattice may transfer to the Si phase. Depending on the kinetics of supply of vacancies from these sources, the vacancy concentration of bulk Si may or may not be reduced to levels such that Eq. [3] is satisfied.

The probability of interstitial annihilation, P_A, is given by the product of P_{VN} = probability that a vacancy is in a neighboring site and P_J = probability of a net jump into the vacant site. Thus, since there are 6 possible lattice sites in the ring surrounding each interstitial site, we have

$$P_A = 6X_V \frac{\nu}{6} e^{-Q_A^*/kT}(1 - e^{-(\mu_I - \mu_V)/kT}) = P_A' n_V \qquad [4]$$

where X_V is the fraction of vacancies, $P_A' = P_A/8$, ν is the vibrational frequency, and Q_A^* is the activation barrier between the ring center and a lattice site on the ring. The differential equation governing the interstitial content is

$$D_I \nabla^2 n_I - P_A' n_V n_I = \frac{\partial n_I}{\partial t} \qquad [5]$$

While that governing the vacancy content is

$$D_V \nabla^2 n_V - P_A' n_I n_V + \dot{Q}_V^S = \frac{\partial n_V}{\partial t} \qquad [6a]$$

where $\dot{Q}_V^S$ is the volume source supply rate per unit cell of Si. The strength of this vacancy source is given by (13)

$$\dot{Q}_V^S = \frac{A_V^S}{\Omega^{2/3}} \frac{\nu}{6} e^{-Q_S^*/kT} [f_V^S - X_V e^{(\mu_V - \delta E)/kT}] \qquad [6b]$$

where Ω is the atomic volume of Si, A_V^S is the active area of the vacancy source, f_V^S is the fraction of surface sites from which a vacancy can be introduced into the Si with activation energy Q_S^*, and δE is the energy change of the source due to the loss of one vacancy, *i.e.*

$$\delta E = \left(\frac{dE_V^S}{dr} \right) \Delta r = \frac{2\Omega\gamma}{r} \qquad [6c]$$

for a spherical source of radius r and surface energy γ. In Eq. [6b], μ_V is negative.

Interstitial partition coefficient.—The equilibrium partition coefficient, k_I^*, between the concentration of interstitial species in SiO_2 at the interface to the concentration in Si at the interface will be determined by the quality of the electrochemical potential, η_I, of this defect species, Si_I, in each phase at the interface

$$\eta_I^{Si} = \eta_I^{SiO_2} \quad \text{at Si/SiO}_2 \qquad [7]$$

Neglecting any electric field or strain field effects, Eq. [1] is inserted in Eq. [7] with $\eta_I = \mu_I$. It should be noted in Eq. [1] that the value of n_{Ij}^* is dependent on the actual conditions applying at the interface; *i.e.*, on thermal expansion stresses, disregistry stresses due to interfacial orientation constraints when one alters the Si orientation, and on the presence of electric or macroscopic stress fields. Thus, in general, $\eta_I \neq \mu_I$. These refinements will be considered as second-order effects for this paper; however, it should be recognized that

there will undoubtedly be some circumstances when they may become first-order effects.

We are actually interested in the nonequilibrium partition coefficient, k_I, for the I-defect at the interface. The initial I-defects can be thought of as being created in the α-cristobalite lattice by the breaking of Si-Si bonds (thermally activated process) so that the corner Si atoms are free to become SiO_2 while the 4 inner Si atoms become I-defects. The entrance of the I-defects into the Si side of the interface then involves an activation step because the enthalpy of formation of the I-defect in Si is expected to be much higher than in SiO_2 (11, 12). This is conceptually illustrated in Fig. 4. Actually, instead of the two-step process proposed above, the process of I-defect partitioning is a single-step process which is outlined mathematically in Appendix B. However, because the two-step process is more tractable mathematically at this stage in our understanding, we shall utilize it.

For the two-step process, a chemical potential difference, $\Delta\mu_I(V, \theta)$, develops between the I-defects on the SiO_2 side of the interface compared to the I-defects on the Si side of the interface in order to supply I-defects to the Si at a rate determined by the oxidation rate, V. This can be thought of in analogy with water trickling through a leaky dam; the higher the water level, the greater the leak rate. As indicated in Appendix B, this leak rate is expected to be a function of orientation, θ, because the activation barrier existing right at the interface in Fig. 4 is expected to be a function of orientation. It is also expected to be a function of interface velocity, V, since the flux, J_{I1}, of I-defects into the Si depends on V. Using classical reaction rate theory for the two-step process (see Appendix B), we expect to find

$$J_{I1} \approx A e^{-Q(\theta)/kT} e^{+\Delta\mu/kT} \quad [8a]$$

where A is a constant with a slight orientation dependence for a given number of I-defects in the SiO_2 and

$$Q(\theta) = \Delta H_I^{Si} + Q^*(\theta) - \Delta H_I^{SiO_2} \quad [8b]$$

(see Fig. 4). Thus, instead of Eq. [7], for the zero interface field case we must use

$$\Delta\mu(V, \theta) + \mu_I^{Si} = \mu_I^{SiO_2} \quad [9]$$

to determine the nonequilibrium interface partition coefficient, $k_I(V, \theta)$.

Utilizing Eq. [9], [7], and [1], k_I is given by

$$k_I(V, \theta) = \frac{n_{I2}(O)}{n_{I1}(O)} = \frac{\beta}{\left[1 + \frac{n_{I1}(O)}{n_{s2}}\left(\beta - \frac{n_{s2}}{n_{s1}}\right)\right]} \quad [10a]$$

where the subscripts 1 ≡ Si and 2 ≡ SiO_2 and where

$$\beta = \left[\frac{1 - n_{I1}^*/n_{s1}}{1 - n_{I2}^*/n_{s2}}\right] \frac{n_{I2}^*}{n_{I1}^*} \exp\left[\Delta\mu(V,\theta)/kT\right] \quad [10b]$$

In our case, $n_{I1}^*/n_{s1} << 1$ and probably $n_{I2}^*/n_{s2} << 1$ as well so that the first term on the right of Eq. [10b] is ~1. From Eq. [8a], we also note that $\beta \propto J_{I1}$. Although we do not have any information on $\Delta\mu(V,\theta)$ or on n_{I2}^*/n_{I1}^*, we can evaluate k_I in terms of β. In Fig. 5, plots of k_I and $n_{I2}(O)$ are given as a function of $n_{I1}(O)/n_{s2}$ for a range of β-values. We note that k_I decreases from its saturation value of $\sim\beta$ at very small values of $n_{I1}(O)$ to an inverse dependence on $n_{I1}(O)$ at large values of $n_{I1}(O)$. We note from the previous discussion that $n_{I2}(O) = k_I n_{I1}(O)$ increases toward its ultimate value of 4 per unit cell of Si transformed as $n_{I1}(O)$ increases and at a rate less than linear.

If we make the approximation that $n_{I2}(O) \approx 4$ in the derivation leading to Eq. [10a], then we are led to the result that

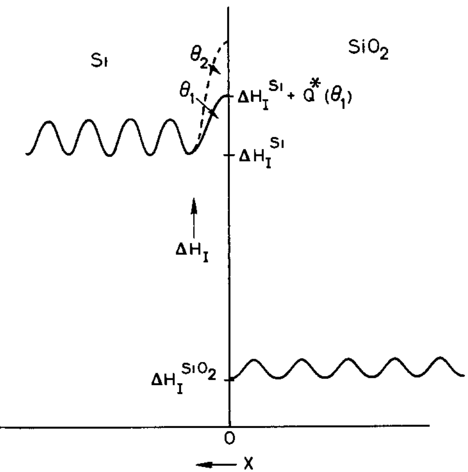

Fig. 4. Schematic illustration of the enthalpy of formation, ΔH_I, for I-defects as a function of distance from the interface. Also included is the interface barrier for two different Si wafer orientations θ_1 and θ_2.

$$k_I \approx \beta\left(1 - \frac{4}{n_{s2}}\right) + \frac{4}{n_{s1}} \quad [11]$$

since $k_I \approx 4/n_{I1}(O)$. Thus, in this limit, from Eq. [8a] and [10a], we see that $k_I \propto J_{I1}$. For this same approximation, we shall find the excess free energy stored in I-defects, ΔG_E, to be given by (see Appendix A)

$$\Delta G_E = mkT\left\{4 \ln\left[\frac{4(n_{s2} - n_{I2}^*)}{n_{s2} n_{I2}^*}\right] + (n_{s2} - 4)\ln\left(\frac{n_{s2} - 4}{n_{s2}}\right)\right\} \quad [12a]$$

$$\approx mkT\{4 \ln(4/n_{I2}^*) + 11 \ln(11/15)\} \quad [12b]$$

assuming that $n_{s2} = 15$ for α-cristobalite. For $n_{I2}^* = 10^{-2}$ and 10^{-4}, this amounts to values of $\Delta G_E \approx 6.5$ and 12.4 kcal/mole, respectively, at ~1100°C. Thus by the type of structural transition involving interstitials proposed here rather than a direct transition with no interstitials, the value of ΔG_E is reduced from ~150 kcal/mole to ~20 kcal/mole for this step in the process.

Interstitial conservation condition.—There are 4 Si atoms per unit cell of Si transformed that become

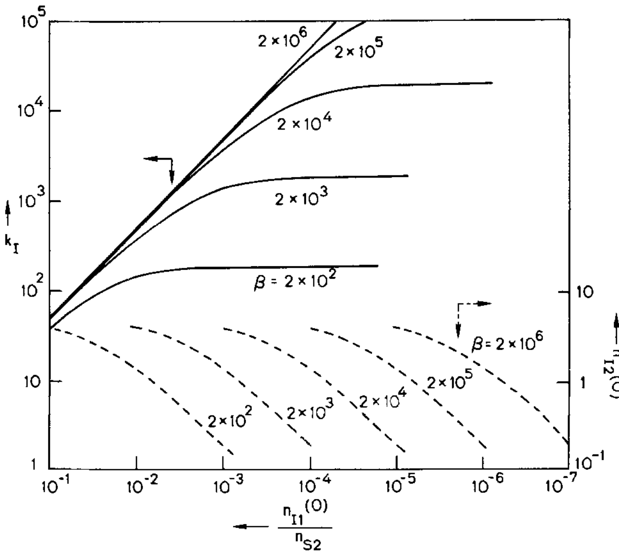

Fig. 5. Plot of k_I and $n_{I2}(O) = k_I n_{I1}(O)$ as a function of $n_{I1}(O)/n_{s2}$ for several values of the parameter β.

I-species. Thus, the interface conservation condition is given, on an Si unit cell basis, as

$$\frac{4V}{\lambda_o^3} = J_{I1} - J_{I2} \quad [13a]$$

where λ_o is the unit cell size of the Si. Neglecting any interface field effects, this becomes

$$\frac{4V}{\lambda_o^3} = -\frac{D_{I1}\nabla n_{I1}}{\lambda_o^3} - \frac{Vn_{I1}}{\lambda_o^3} + \frac{D_{I2}\nabla n_{I2}}{\lambda_o^3} + \frac{Vn_{I2}}{\lambda_o^3} \quad [13b]$$

Here, D_{Ij} is the interstitial diffusion coefficient in the j-phase. From Eq. [13b]

$$[4 - (k_I - 1)n_{I1}(O)]V \approx \frac{D_{I1}[n_{I1}(O) - n_{I1}(x_1^*)]}{x_1^*} + \frac{D_{I2}[n_{I2}(O) - n_{I2}(x_2^*)]}{x_2^*} \quad [13c]$$

where x_j^* is the characteristic diffusion length in the j-phase. In Eq. [13b]and [13c], drift of the interstitial species in either an electric or a stress field at the interface has been neglected. In phase 2, subsequent oxidation of the I-defects tends to fill the interstitial spaces with SiO complexes. This increases the formation energy and decreases the diffusion coefficient of the I-defect with increasing distance from the interface. Thus, an interface field effect must really be introduced to model J_{I2}. Diffusion in this phase extends only a short distance ($x_2^* \sim$ 15Å-25Å) before it is almost completely stopped and D_{I2} has dropped to very small values. This leakage into the region $|x| > |x_2^*|$ is the limiting value of $J_{I2} - (Vn_{I2}/\lambda_o^3)$. The value of $x_1^* \approx \sqrt{\pi D_{I1} t}$ should be used for semi-infinite Si and $x_1^* \approx l$ for an Si slab of thickness $2l$ at times $t \gtrsim l^2/\pi D_{I1}$.

From the earlier discussion, it is clear that $n_{I1}(O)$ and k_I are functions of time, especially since J_{I1} and V are functions of time in the oxidation process. In the limit where almost all of the I-defects remain in the SiO_2, $k_I \propto J_{I1}$ from Eq. [11] and $n_{I1}(O) = b/J_{I1}$ where b is an orientation-dependent constant. With this approximation, the flow of interstitials into the Si can be uncoupled from the flow into the SiO_2 and we can treat each phase in turn. For the SiO_2 phase, we choose $J_{I1} << -J_{I2}$ in Eq. [13a] and let $n_{I2}(O) \approx 4$. For the Si phase, we choose $n_{I2}(O) \approx 4$ and let k_I have the value given by Eq. [11]. Following this procedure, we can consider time-dependent events in each phase.

Consequences for the Si-phase.—The I-defects partitioned into the Si slab of thickness $2l$ will diffuse into the bulk Si and some will recombine with vacancies to deplete the population. At short times, Eq. [5] will govern the diffusion of the I-defects subject to the conditions (*i*) $n_I = 0$ at $t = 0$ for all x, (*ii*) $\partial n_I/\partial x = 0$ at $x = 0$ for all t, and (*iii*) $J = J_{I1}$ from Eq. [8a] at $x = \pm l$ for all t. Initially, let us assume that $P_A' = 0$ (no interstitial sinks) and look for a solution in the time domain $t \lesssim 10^3$ sec. In this time domain, diffusion in a slab $l \sim 10^{-1}$ cm with $D_I \sim 10^{-5}$ cm^2/sec is almost complete. If we assume that diffusion is complete, then we have the average slab I-defect concentration, $\bar{n}_{I1}$

$$\bar{n}_{I1} \approx n_{I1}(O) = \frac{1}{l}\int_0^t J_{I1}dt' \quad [14]$$

which leads to

$$\frac{dn_{I1}(O)}{dt} = \frac{J_{I1}}{l} \quad [15]$$

Combining Eq. [1] and [9] with [8a], we find that

$$J_{I1} = Ae^{-Q(\theta)/kT}\left[\frac{(n_{I2}/n_{I1})(n_{s2}/n_{s1})n_{s1}}{(n_{I2}^*/n_{I1}^*)(n_{s2} - n_{I2})}\right] \quad [16a]$$

which yields

$$n_{I1}(O) \approx \frac{4}{J_{I1}} Ae^{-Q(\theta)/kT}\left[\frac{n_{s2}(n_{I1}^*/n_{I2}^*)}{(n_{s2} - 4)}\right] \quad [16b]$$

Inserting Eq. [16a] into Eq. [15] leads to

$$n_{I1}^2(O) \approx \frac{8Ae^{-Q(\theta)/kT}}{l}\left[\frac{n_{s2}(n_{I1}^*/n_{I2}^*)}{(n_{s2} - 4)}\right] t \quad [17]$$

Thus, in the time domain $t \gtrsim t_o \sim 0$, $n_{I1}(O)$ increases as $t^{1/2}$ provided we neglect recombination events with vacancies or other sinks. Incorporating the effects of such events will decrease the time exponent in this relationship.

To incorporate the effect of vacancy recombination events, let us assume that $P_A'n_V$ in Eq. [5] is independent of x and is a slowly varying function of t. Then, following Carslaw and Jaeger (14), we find our new I-defect content in the Si, $n_{I1}^\dagger$, to be given by

$$n_{I1}^\dagger = n_{I1}e^{-P_A'n_V(t-t_o)} + P_A'n_V\int^{t-t_o} n_{I1}(t')e^{-P_A'n_Vt'}dt' \quad [18]$$

where $n_{I1}(t)$ is given from Eq. [17].

Because n_V has been so strongly decreased in the Si close to the oxidizing interface, vacancies flow in from the bulk Si to reduce n_V close to the interface. This diffusion of V-defects along substitutional sites produces a type of "vacancy wind" which moves substitutional solutes deeper into the Si. The movement of I-defects deeper into the Si also produces an "interstitial wind" of strength proportional to J_{I1}. The analogue for this wind effect comes from electromigration experiments where the momentum exchange between electrodes and lattice ions often causes movement in the opposite direction from that expected based on ionic charge. In terms of the thermodynamics of multicomponent systems, the flux, J_a, of species a is given in terms of the mobilities, M_{ia}, and the electrochemical potential gradients, $\nabla\eta_i$, of the various species i by (15)

$$\bar{J}_a = -\sum_{i=1}^{n} M_{ia}\nabla\eta_i \quad [19]$$

Thus, depending on the sign of M_{ia} and the $\nabla\eta_i$ ($i \neq a$), the diffusion of a may be greatly enhanced. Here, for $i = I$, $\nabla\eta_I \propto J_{I1}$. This enhanced drift of the substitutional species has been labeled oxidation enhanced diffusion (OED). We see that it arises from the interstitial flux generated at the Si/SiO_2 interface as a natural consequence of the oxidation model described here.

From Eq. [18] we expect $n_{I1}^\dagger$ to build up in the Si slab in a manner proportional to t^p where $p < 1/2$. At some time, t_1, the supersaturation of I-defects will be sufficient that stacking faults will nucleate and begin to grow and Eq. [5] must then be replaced by

$$D_I\nabla^2 n_I - P_A'n_Vn_I - \dot{Q}_{SF} = \frac{\partial n_I}{\partial t} \quad [20a]$$

where

$$\dot{Q}_{SF} = \frac{2\pi bN_{SF}}{\Omega_I}\bar{r}\frac{d\bar{r}}{dt} \quad [20b]$$

with N_{SF} and $\bar{r}$ as the number and average radius, respectively, of the stacking faults as a functions of time, b is the thickness of the fault, and Ω_I is the atomic volume of the condensed I-defect in Si. This interstitial sink should deplete the supply in the bulk Si. However, it is noted that significantly changing N_{SF} has a negligible effect on $d\bar{r}/dt$ (16), which suggests that the interface source strength is so strong, I-defect diffusion in Si is so fast, and the barrier to attachment at the stacking fault edge so large that $n_{I1}(O)$ remains relatively unaltered by the increased sink strength. Eventually, of course, the total line length of stacking fault increases to the point that the drain of interstitials

exceeds the supply and $d\bar{r}/dt$ must shrink to zero. The retrograde portion of the stacking fault growth curve can then come about either by continued vacancy supply from bulk sources plus from the Si/SiO_2 interface or by a change in diffusive flux of I-defects into the bulk SiO_2 from the interface so that N_{I2} decreases. If the latter occurs, N_{I1} begins to decrease and I-defects begin to flow from the Si to the SiO_2 so that the stacking faults then become the I-defect sources.

Consequences to the SiO_2.—Let us now look in the opposite direction, *i.e.*, to the interstitials flowing into the SiO_2. It is most probable that these will be partially charged, but they will not be nearly as mobile as those in the Si. In fact, they may be fairly immobile because of the incoming oxygen species. These interstitials, almost 4 per unit cell, will swell the unit cell in the direction lateral to the interface making the interface SiO_x more dense than the bulk SiO_2 (17, 18). As oxygen diffuses through the SiO_2 and reaches the interface region, it will oxidize these interstitial Si ions partially blocking the outward diffusion paths of other Si ions. This immobilized group reacts further to form O-Si-O polymer chains. These chains may be thought to interconnect the interstitial spaces in the diamond cubic structure until flow produces enough volume that the more stable SiO_4 tetrahedra may form. It is well known that SiO_4 tetrahedra link together by sharing two of the four corners to form a continuous chain of composition $(SiO_3)_n$ (12) constituting the pyroxene group of chain silicates. In the amphibole group, the SiO_4 tetrahedra are linked to form chains having double the pyroxene chain width and having a composition $(Si_4O_{11})_n$. The mica group of silicates form sheet structures with hexagonal nets which lead to a composition of Si_4O_{10} (12).

Several features are important to note about the proposed interstitial chains. First, they may be considered to have a range of enthalpies of formation and some particular distribution of chain lengths will minimize the free energy of SiO_2 (short chain lengths probably). Second, the strain energy will increase with the degree of advancement of the oxidation process and very quickly exceed a few kcal/mole so that the α-cristobalite lattice will quickly distort to the vitreous-type structure. Third, the incompletely oxidized Si (chain ends) are expected to contain unsatisfied bonds which will be positively charged. Since the positive ions occupy less space, the reduced strain energy favors the ionization. This is proposed as the origin of Q_f. Fourth, since these chains place the unit cell under swelling stresses, there will be a slow yielding of the SiO_x as free volume flows into the interface region from the bulk SiO_2 via viscoelastic processes (19). As the system yields, complete oxidation of these interstitial I-defects become possible and they may make the transition to stable SiO_4 tetrahedra which completely transforms the SiO_x to vitreous SiO_2. Thus, an interface layer of enhanced density and thickness, ΔZ, exists wherein the stoichiometry is of the form SiO_x with $1 \lesssim x < 2$. This layer becomes a steady-state condition moving with the interface wherein new bare Si or SiO interstitials enter at one side and completely oxidized interstitial chains or interstitial tetrahedra exit at the other side. The point here is not to make a case for chains *vs.* partial tetrahedra, but to allow both possibilities at this qualitative stage. Important thermodynamic calculations need to be made concerning these various interstitial defect species and such subsequent calculations will allow discrimination between these two possibilities. A residual interstitial density, such as to produce a swelling stress equal to the SiO_2 flow stress at the oxidation temperature, is predicted in accordance with the findings of Taft (20). For high pressure oxidation, this residual density effect will be higher because of the decreased SiO_2 viscosity at the higher pressure.

An important point to be underlined here is that the oxidation of Si occurs via two streams. In the first stream, 4 Si atoms per unit cell of Si oxidize directly to SiO_2 and form the lattice of α-cristobalite. In the second stream, almost 4 I-defects per unit cell of transformed Si oxidize in steps as SiO_x with an increased activation energy and decreased free energy release being associated with oxidation as x increases from 1 to 2. The larger x is for this stream, the slower the oxidation process because of the associated strain energy. From qualitative theoretical reasoning, one expects x to increase from ~ 1 to ~ 2 in about 4 unit cell distances. This internal swelling and flow process cannot help but produce a highly densified and integral oxide.

Temperature dependence.—As the temperature is increased, the yield stress of the α-cristobalite is reduced and the system flows more easily. Thus, the stored strain energy due to the I-defects in SiO_2 will be reduced, which will reduce $\Delta\mu$ for the same value of N_{I2}. This will cause a decrease in $J_{I1}(O)$ and an increased fraction of the I-defects are partitioned to the SiO_2. Since there are fewer I-defects flowing into the Si as T increases, the driving force for both the OED and the OISF phenomena must decrease beyond a certain temperature as T increases. From the work of Eernisse (19), we see that the critical temperature range for strong changes in the vitreous SiO_2 flow properties is $\sim 950°$-$1000°C$. Thus, changes in OED and OISF should begin to be seen at $T \gtrsim 1000°C$.

With respect to expected Q_f and n_{it} changes with T, since $J_{I1}(O)$ decreases and k_I increases as T increases, one might expect that the total positive charge at chain ends would increase and that Q_f should increase also. However, n_{I2} increases only very slightly as T increases but, because the system flows more easily at the higher temperatures, the oxidation should be more complete, the number of oxy-silicon chain ends should decrease, and Q_f should decrease in accord with the results of Deal (8). At the higher T, the reaction between the Si atoms at the ends of the extra half-planes and oxygen will be more rapid and, thus, more complete so that N_{it} should also decrease as T increases. Of course, the reactivity of minor constituents like H or C should also be altered, which will, in turn, alter the observable N_{it} (21).

Orientation dependence.—We assume the same epitaxial match, $(100)Si//(100)SiO_2$, but now we focus attention on the (111) plane of Si as the interfacial plane and notice that it is lined up with the (120) plane of the pseudo-diamond cubic cell of α-cristobalite (see Fig. 1). As Herman *et al.* (22) have noted, the interface model of (100)Si parallel to (100)β-cristobalite, with this latter rotated by 45°, is the simplest interface model constructable between these two phases. In our case, the (100)Si//(100)α-cristobalite with parallel $\langle 100 \rangle$ directions gives almost exactly the result of Herman *et al.* (22). If we look into the α-cristobalite pseudo cube along the $\langle 120 \rangle$ or into the β-cristobalite along this direction, we note easy access to the $\langle 110 \rangle$ tunnels through the diamond cubic structure.

Thus, for this direction, the second term of Eq. [13c] may be larger than for Si orientations where the interface normal is not lined up with the tunnel direction. If this is so, then $n_{I1}(O)$ will be reduced and so will the OED and the OISF. We are not yet in a position to evaluate the magnitude of this effect. The dominant orientation effect, however, is expected to arise as a consequence of its influence on the magnitude of β. As V increases at fixed $n_{I2}(O)$, J_{I1} is fixed; however, for fixed oxide thickness, $\bar{n}_{I1}$ is reduced because it takes less time to form this layer and thus t, in Eq. [14], is smaller. For constant diffusive transport rate in the oxide, $n_{I2}(O)$ should increase as V increases (less transported away per unit film thickness). Thus, $\bar{n}_{I1}$ should decrease as V increases, but a little less than

linearly with V. Since V increases as p_{O_2} increases, a similar change in $n_{II}(O)$ should develop for increasing p_{O_2}. In changing the Si wafer orientation from (100) to (111), the change in $n_{II}(O)$ arises from the fact that $V_{(111)} > V_{(100)}$. Thus, this effect is expected to lower $n_{II}(O)$ for the (111)Si wafers compared to the (100)Si wafers for fixed oxide thickness, in accord with observations.

Because of the increase of k_I for the (111)Si compared to the (100), Q_f will increase, OED will decrease, and OISF will decrease. Since larger k_I means more I-defects in the SiO_2, this means greater lateral swelling stresses as the interstitial Si becomes oxidized. The increased lateral swelling stresses are expected to cause the SiO_2 at the interface to relax to a larger average spacing and leave more Si half-planes per unit interface area on the Si side terminating at the interface. Thus, we also expect N_{it} to increase for the (111) over that for the (100).

Oxidation velocity.—Because the number of I-defects in Si is greater for the (100) orientation than for the (111) orientation, the reverse situation holds for the SiO_2 phase. The greater Q_f for the (111) orientation means an enhanced electric field in the oxide for this orientation. Since the Q_f is associated with positive charge, the interface region will be more positive for the (111) orientation than for the (100). This means that the diffusion rate of $O^=$ ions through the oxide will be enhanced for the (111) oxidation compared to the (100) so the oxidation velocity for (111) oxidation will be greater than for the (100) oxidation. As shown in Part II (2), the field effects enter both the linear and parabolic rate coefficients so both the short-time and the long-time oxidation rates should be affected by this mechanism. Of course, as the temperature is increased, the enhanced flow process allows almost all of the I-defects to enter the SiO_2 phase and differences in the field-driven diffusion for the two orientations disappear. Thus, the oxidation velocities for the (111) and the (100) become almost equal at high temperatures.

Discussion

The most important concept of this paper is the formation of a transitory crystalline SiO_2 layer containing interstitial species. The utilization of this concept allows one to see how a host of ancillary phenomena can occur and be associated with the oxidation process. Consideration of a direct transition to vitreous SiO_2 without interstitial species leaves one with no ready pathway to simply account for these other phenomena. Certainly there is no apparent way to see their interconnectedness. Since the free energy difference between any one SiO_2 phase and another is only $\sim$ 2 kcal/mole, which is $\sim$ 1%-2% of the total free energy available for the reaction, the choice of specific interface SiO_2 structure is of second order to the overall process. In this paper, the slight favorite has been α-cristobalite.

The paper has, for reasons of simplicity, considered that the Si atoms at the ends of the extra half-planes remain unoxidized until after they jump into SiO_2 interstitial positions. In actual fact, many of these atoms will have formed a single Si-O bond and some may have formed O-Si-O bonds. Thus, not only will we have Si interstitials being generated from this interface source but SiO interstitials and some O-Si-O interstitials as well. Of course, this will increase the interface density and the value of x somewhat in the overall interface stoichiometry, SiO_x. We would expect that, in the interface reaction control regime at low temperatures or high O_2 pressures, the oxygen supersaturation at the interface would be greatest, so more of the terminating Si atoms would be partially oxidized, more SiO interstitials would enter the SiO_2, and x would be larger for SiO_x at the interface. At the other extreme, for thick oxides where diffusion control is dominant, the interface oxygen supersaturation will be small and most of the terminating Si atoms will be bare and will enter the SiO_2 interstitial positions as bare Si. Of course, during cooling to room temperature, the excess oxygen in the SiO_2 will move to the interface and partially oxidize these terminating Si species.

For the bare Si atoms in terminal positions at the interface, one might picture them with dangling bonds; however, it is more likely that bond reconstruction will occur and only a few dangling bonds will exist. The density of these dangling bonds is likely to be much lower at room temperature than at oxidation temperatures and to depend on both the quenching rate from high temperature and the quenching environment. This should be governed by the natural bond reconstruction rate which is expected to be a function of the orientation of the extra half-planes terminating at the interface; *i.e.*, it should be a function of interface orientation. We should always expect some bare dangling bonds, even in the equilibrium reconstructed state, for entropic reasons. Given the difference in bond energy, ΔE^*, between the dangling and reconstructed states, the fraction of dangling bond sites, x_{db}, in the equilibrium reconstructed state is simply

$$x_{db} \sim e^{-\Delta E^*/kT} \quad [21a]$$

When some of these terminal atoms are partially oxidized, we must mix the three unique species (dangling bonds, reconstructed bonds, and oxygenated bonds) among these available terminating atoms. For a fixed fraction x_o of oxygenated terminal Si species, Eq. [21a] becomes

$$x_{db} = (1 - x_o)\, e^{-\Delta E^*/kT} \quad [21b]$$

As x_o approaches unity, it can no longer be held fixed in the calculation and we return to a result like Eq. [21a], but with ΔE^* replaced by $\Delta E^* + \Delta E_B$ where ΔE_B is the decrease in bond energy in going from a bare reconstructed bond to a singly oxidized bond.

The conceptual features of this overall model are expected to be fairly representative of the experimental reality for the thermal oxidation of Si. However, much fine tuning of the model is still needed to produce the desired quantitative match with experiment. Many significant theoretical hurdles still stand in the way of this goal.

Conclusions

A qualitative model has been proposed based on the initial transformation of silicon to α-cristobalite plus almost 4 interstitial Si ions per unit cell of Si transformed, with the remainder interstitial Si ions rejected into the bulk silicon phase. Subsequent oxidation of the interstitial Si ions in the SiO_2 matrix produces rapid distortion and transformation of the structure to the vitreous form. The following are the qualitative predictions of the model:

1. OED, OISF, N_{it}, and Q_f can be accounted for.
2. The orientation dependence gives, in accordance with experiment

$$k_{I(100)} < k_{I(111)}$$

$$\mathrm{OED}_{(100)} > \mathrm{OED}_{(111)}$$

$$\mathrm{OISF}_{(100)} > \mathrm{OISF}_{(111)}$$

$$Q_{f(100)} < Q_{f(111)}$$

$$N_{it(100)} < N_{it(111)}$$

$$V_{(111)} > V_{(100)}$$

3. The temperature dependence gives k_I increasing as T increases above $\sim$950°C so that all the orientation dependences tend to decrease.
4. At the lower growth temperatures, a layer of increased density SiO_2 will exist at the Si interface which will yield an increased index of refraction for the layer in accordance with experiment (17). The chemical stoichiometry of the layer will range from almost SiO

(slightly Si deficient) at the interface with Si to almost SiO_2 (slightly O deficient) at the transition with bulk density vitreous SiO_2 which occurs within ~3-5 unit cell distances of the interface.

In addition, a quantitative expression for k_I has been derived and the I-defect content in the Si is predicted to increase for short times as t^p, where $p < 0.5$.

APPENDIX A

Neutral Interstitial Partition Coefficient at the Si/SiO₂ Interface

Let the neutral interstitial enthalpy of formation in Si and in SiO_2 be given by ΔH_{I1} and ΔH_{I2}, respectively. In each phase, the entropy of the I-species, S_p, permuted amongst the mn_s available interstitial sites for m unit cells, is given by

$$S_p = k \ln [(mn_s)!/(mn_I)!(mn_s - mn_I)!] \quad \text{[A-1]}$$

Here, $n_s = 5$ for diamond cubic with one atom or ion per site. However, in SiO_2 it may be possible to have more than one I-species per interstitial site because the sites are so large. Thus, $n_s^{SiO_2}$ is not fully specifiable at this time.

The equilibrium number of interstitials per unit cell, n_I^*, in each phase is given by

$$\frac{n_{Ij}^*}{n_{sj} - n_{Ij}^*} = e^{\Delta s_j^v/k}\, e^{-\Delta H_{Ij}/kT} \quad j = 1, 2 \quad \text{[A-2]}$$

where ΔS^v is the vibrational entropy contribution of the I-defects. Both n_{I1}^* and n_{I2}^* are expected to be small relative to n_{s1} and n_{s2} and $n_{I1}^* << n_{I2}^*$ is also expected. In our area of interest, large values of n_I are being generated at the Si/SiO_2 interface and the excess free energy of each phase for $n_{Ij} >> n_{Ij}^*$ is given by (9)

$$\Delta G_{ex\,j} = mkT \left\{ n_{Ij} \ln \left[\frac{n_{Ij}(n_{sj} - n_{Ij}^*)}{n_{Ij}^* n_{sj}} \right] + (n_{sj} - n_{Ij}) \ln \left[\frac{n_{sj} - n_{Ij}}{n_{sj}} \right] \right\} \quad j = 1, 2 \quad \text{[A-3]}$$

for the m unit cells ($m = N/8$ for a mole of Si or α-cristobalite where N = Avogadro's number). The chemical potentials of the interstitials at these excess concentrations are, in turn, given by

$$\mu_{Ij} = \frac{\partial G_{ex\,j}}{\partial n_j} = kT \ln \left[\frac{n_{Ij}(n_{sj} - n_{Ij}^*)}{n_{Ij}^*(n_{sj} - n_{Ij})} \right] \quad j = 1, 2 \quad \text{[A-4]}$$

APPENDIX B

Interstitial Partitioning of Si

One-step process.—Consider unit area of interface where the environment for Si I-defects is like that in Fig. 4. The concentration of the I-defects in SiO_2 is such that a chemical potential difference, $\Delta\mu_o$, exists between SiO_2 and Si for this species. The number of Si atoms jumping out of the interface layer per unit time into interstitial sites in Si ≡ 1 and SiO_2 ≡ 2 is given by

$$R_{out} = \frac{N_s(\theta)}{2} \frac{\nu}{6} (e^{-Q_2^*/kT} + e^{-Q_1^*/kT}) \quad \text{[B-1]}$$

where $N_s(\theta)$ is the average number of atoms per unit area of the interface and ν is the vibrational frequency. The number jumping back into the interface layer per unit time from these phases is

$$R_{in} = N_{I2} \frac{\nu'}{6} e^{-[Q_1^* - (\Delta H_{I2} + \Delta\mu)]/kT} + N_{I1} \frac{\nu''}{6} e^{-[Q_1^* - \Delta H_{I1}]/kT} \quad \text{[B-2]}$$

The net result arising as a result of interface motion is

$$R_{out} - R_{in} = \frac{4V(\theta)}{\lambda_o^3} \quad \text{[B-3]}$$

where λ_o is the Si unit cell size and V is the interface velocity. Placing Eq. [B-1] and [B-2] into [B-3] leads to

$$\frac{4V(\theta)}{\lambda_o^3} = \left[\frac{N_s(\theta)\nu}{12} - \frac{N_{I2}\nu'}{6} e^{(\Delta H_{I2} + \Delta\mu)/kT} \right] e^{-Q_2^*/kT} + \left[\frac{N_s(\theta)\nu}{12} - \frac{N_{I1}\nu''}{6} e^{\Delta H_{I1}/kT} \right] e^{-Q_1^*/kT} \quad \text{[B-4]}$$

At $V = 0$, $\Delta\mu = 0$ and $N_{I2} = k_I^* N_{I1}$, so a relationship between some of the parameters is possible; however, it is essentially too complex to be readily useful.

Two-step process.—Let all of the I-defects first be liberated into the SiO_2 (with an activation energy that requires Si-Si bond breaking). Then, some of the I-defects are partitioned into the Si interstitial spaces. For this second step, we have

$$R_L = N_{I2} \frac{\nu}{6} e^{(Q^* - \Delta\mu)/kT} \quad \text{[B-5]}$$

and

$$R_R = N_{II} \frac{\nu}{6} e^{-Q^*/kT} \quad \text{[B-6]}$$

where R_L means from the SiO_2 to the Si, while R_R is from the Si to the SiO_2. Therefore, the number of I-defects entering the Si per unit time, J_1, is given by

$$J_1 = R_L - R_R = N_{I2} \frac{\nu}{6} e^{-Q^*/kT} \left(e^{\Delta\mu/kT} - \frac{1}{k_I} \right) \quad \text{[B-7a]}$$

$$\approx \frac{N_{I2}\nu}{6} e^{-Q^*/kT} e^{\Delta\mu/kT} \quad \text{[B-7b]}$$

since k_I^{-1} is very small and $\Delta\mu/kT >> 1$ generally. It should also be noted that J_1 is somewhat proportional to V since the interface conservation condition is

$$\frac{4V}{\lambda_o^3} = J_1 - J_2 \quad \text{[B-8]}$$

and the minus sign is used because J_2 is in the opposite direction to J_1.

Technical Notes

Formation of Recombination Centers in Epitaxial GaAs due to Rapid Changes of the Growth Velocity

L. Jastrzebski
RCA Laboratories, Princeton, New Jersey 08540

and J. Lagowski and H. C. Gatos*
Department of Materials Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

It was established that recombination centers in epitaxial GaAs are formed upon abrupt acceleration of the growth. The corresponding effect of abrupt deceleration of the growth is only minor. In the case of backmelting, recombination centers are also introduced, however, not due to backmelting itself, but rather due to the subsequent acceleration of the growth. The abrupt changes in growth velocity were achieved by corresponding changes in the current density during electroepitaxial growth.

It has been recently demonstrated experimentally and theoretically that liquid phase electroepitaxy provides a unique means for achieving essentially independent control of the interface temperature and the growth velocity (1, 2). In the present study we have utilized this feature of electroepitaxy in the growth of GaAs with intentionally imposed controlled changes of the growth velocity in order to study the role of growth dynamics in the formation of recombination centers.

In electroepitaxy growth is initiated and sustained by passing an electric current through the solution-substrate interface. An electric field, $E = \rho J$, (ρ is the resistivity and J is the current density) in the solution (GaAs in the present case) causes electromigration of solute species (As in the present case) to the interface providing an effective means for the mass transport required for epitaxial growth (1). In addition, electric current flow leads to a change, ΔT_p, of the interface temperature due to the Peltier effect; $\Delta T_p \sim \pi J d$ where π is the Peltier coefficient with a sign depending on the conductivity type of the substrate (n or p) and d is the thickness of the substrate. It is apparent that by using thin substrates, current-induced change of the interface temperature can be minimized (down to a fraction of 1°C) and thus growth can be controlled by electromigration. The velocity (1, 2), $v_E = C_o \mu E J/(C_s - C_o)$, (where C_o and C_s are the equilibrium solute concentration in the solution and in the solid, respectively, and μ is the mobility of solute species) can be programmed by programming the current density as a function of time. The electromigration flux adjusts instantaneously to changes in electric current density and thus the time-lag between rapid changes of J and of the growth velocity, v_E, is negligible. For thick substrates, ΔT_p becomes of significance (of the order of a few degrees C). However, the thermal relaxation time of the interface temperature is typically of the order of 0.1 sec, which is much longer than the relaxation time of the growth velocity associated with solute electromigration changes.

In the present study controlled growth velocity changes were introduced during electroepitaxial growth of Sn-doped ($n \simeq 6 \times 10^{16} cm^{-3}$) GaAs from Ga-rich solution at 950°C with an apparatus described elsewhere (3). The minority carrier lifetime microprofiling in the grown layers was performed utilizing SEM-electron beam-induced current (EBIC).

A current collecting Schottky barrier was formed by evaporating gold on the surface of the epitaxial layer cleaved parallel to growth direction. As shown in Fig. 1, the collection efficiency of the electron beam-induced current was measured while scanning the beam across the regions subjected to changes of growth velocity. The position of these regions (and thus the corresponding values of growth velocity) was determined with differential etching (AB etchant).

EBIC measurements were carried out under plasma generation conditions so that the observed changes of collection efficiency reflect primarily the changes of minority carrier lifetime and thus the concentration of recombination centers (a decrease in collection efficiency corresponds to an increase in the concentration of recombination centers). The experimental results showing the effect of growth velocity changes on the formation of recombination centers are shown in Fig. 2 and 3.

It is evident from Fig. 2a that an abrupt increase of growth velocity[1] from 2 to 4 μm/min produces a pronounced minimum in collection efficiency in the corre-

* Electrochemical Society Active Member.
Key words: growth, electroepitaxy, current.

[1] The change of the current level was brought about in 1 msec; it is believed that the corresponding change of growth velocity took place in approximately the same period of time.

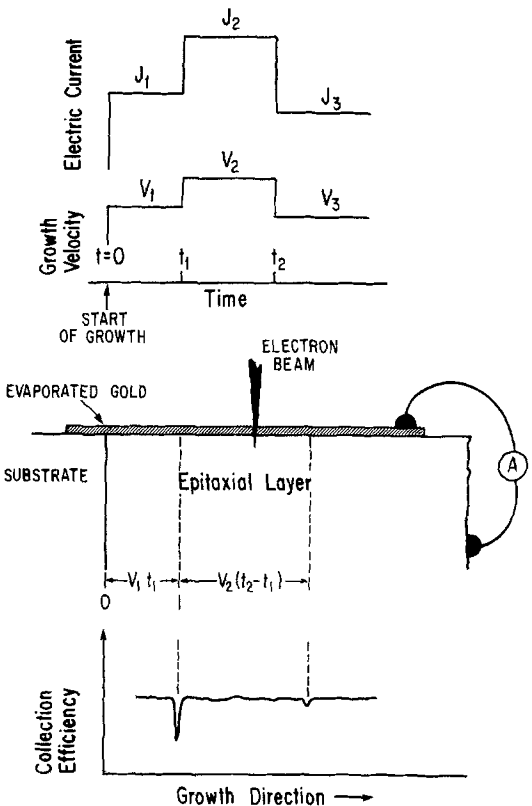

Fig. 1. Schematic representation of current-controlled changes of the growth velocity (upper portion) and corresponding configuration employed in SEM-electron beam-induced current (EBIC) measurements.

sponding transition region. Higher growth velocity changes (from 2 to 14 μm/min; or from 8 to 20 μm/min) reduce the collection efficiency by as much as 30%. It should be pointed out that the recovery of the

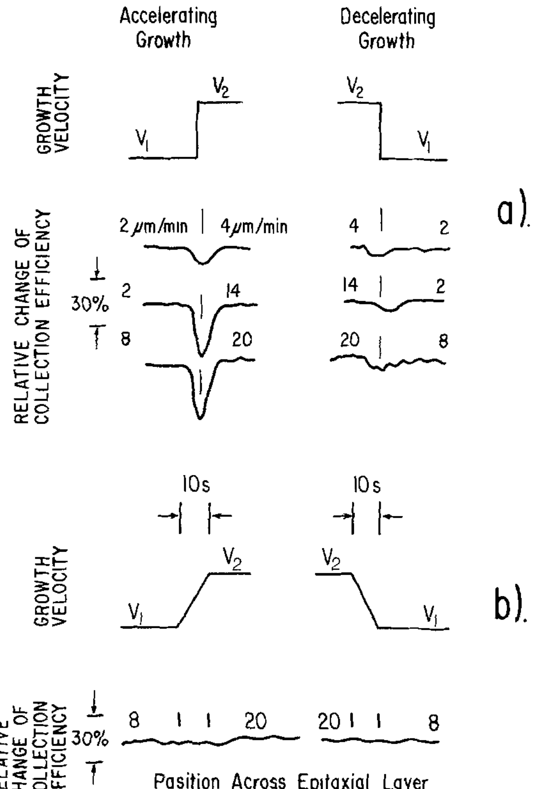

Fig. 2. EBIC microprofiles reflecting formation of recombination centers upon abrupt changes of growth velocity (a) and upon similar changes spread over a period of 10 sec (b).

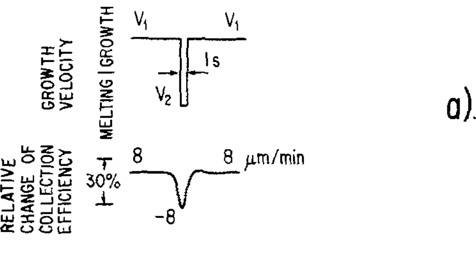

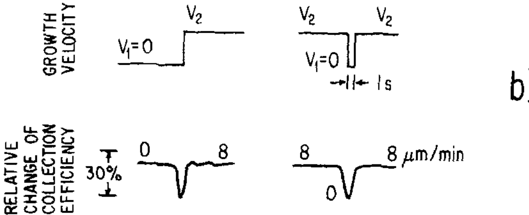

Fig. 3. EBIC microprofiles corresponding to backmelting (a) and to abrupt changes of growth velocity without backmelting (b). (See text.)

collection efficiency (concentration of recombination centers) following the step-like change in growth velocity indicates that the acceleration of the growth (dV/dt) rather than the absolute value of growth velocity (V) is responsible for the formation of recombination centers. This conclusion is confirmed by the results of Fig. 2b, whereby the growth velocity was changed from 8 to 20 μm/min, however, not instantaneously but during a period of 10 sec. In this case no noticeable amount of recombination centers was introduced.

The results shown on the right-hand side of Fig. 2(a, b) indicate that the effect of deceleration of the growth on recombination centers is about one order of magnitude smaller than that of acceleration of the growth.

Experiments, as discussed above, were also carried out with substrates of different thickness, and thus under different current-induced changes of the interface temperature. No significant differences were observed from the results of Fig. 2 obtained with thin substrates. Apparently, changes in interface temperature are of secondary importance compared to changes in growth velocity.

Typical results regarding the effect of backmelting on the formation of recombination centers are shown in Fig. 3. In the upper portion of Fig. 3 backmelting is introduced with 1 sec electric current pulse of polarity opposite than required for growth. It is seen that a minimum in collection efficiency is introduced by this pulse.

In order to verify whether the observed increase in concentration of recombination centers is caused by phenomena taking place during backmelting of the grown crystal or by the subsequent increase of the growth velocity to the original value of 8 μm/min, the following experiments were carried out. Growth was arrested for an extended period and then it was abruptly increased to 8 μm/min. In addition, the growth was interrupted for 1 sec and then restored abruptly to its original value of 8 μm/min. As seen in the lower part of Fig. 3, the results are the same as those obtained for backmelting (upper part of Fig. 3). Thus, it is concluded that the recombination centers introduced into the epitaxial layer during backmelting are formed primarily by the acceleration of the growth following backmelting.

In summary, we have demonstrated the importance of growth dynamics, and in particular, the importance of the acceleration of growth in the formation of re-

combination centers during liquid phase epitaxy. It is likely that these recombination centers originate from point defects generated at the growth interface in response to abrupt increases in growth velocity (abrupt deviations from steady-state growth conditions). It is apparent that surface nucleation effects commonly considered of no significance in the LPE process with slowly varying growth velocity can in fact be of primary importance in the case of abrupt increases in growth velocity. The limited framework of existing theoretical treatments of point defect formation on growth interfaces (4-7) does not provide an adequate basis for further, even qualitative explanation of the present findings.

The Archival Stability of Tellurium Films for Optical Information Storage

David Y. Lou

Philips Laboratories, Briarcliff Manor, New York 10510

Optical storage of information by means of laser micromachining of thin metal films is currently the subject of a great deal of interest (1-3). One of the major potential applications of this technology is the high density, low cost archival storage of information. Thus, the archival properties of the recording medium are examined. We report in this paper data obtained for tellurium films deposited on polymethyl methacrylate (PMMA) substrates, where the recording medium is fabricated into a protective air sandwich structure (2, 3).

Experimental Procedure

Several options exist in the choice of parameters to monitor the degradation of optical disks. One possibility is to monitor the degradation in the recording characteristics of the disk, such as the sensitivity to laser machining and the recovered bit error rate. This would yield information about the shelf life of the optical disk (4). Another important parameter concerns the degradation in the characteristics of a recorded disk, which gives us the archival life of stored information. Obviously, a complete map of errors over the entire disk gives the most information. Such data are, however, also most expensive to come by. Measurements of the fundamental optical properties of the film material, such as reflection, transmission, or subjective appearance, undoubtedly give information directly related to film degradation, and are much easier to perform (5). However, the translation of these properties into degradation characteristics of digital information is problematic, especially when the degradation is nonuniform over the disk surface. The most representative description of the degradation of recorded digital information is the bit error rate, averaged over a meaningful portion of the recordable disk surface area. This is the parameter we have chosen to measure.

Figure 1 shows the electronic instrumentation that was used to measure the bit error rate. The clock for the pattern generator section of the HP 3780A was derived from a Syntest frequency synthesizer for a data rate of 1.85 Mbits/sec. Two bit patterns were used for testing, a 16 bit word, 1010 1010 1010 1010 (1010//4) and a pseudorandom bit sequence 2^{15}-1 bits long (PRBS-15). The Miller modulated version of these bit sequences were used to drive the acousto-optic modulator in the recorder.

The experiments were carried out on air sandwiches (2) assembled from two tellurium-coated disks. The recorder used in this series of experiments was of fairly standard design. Laser radiation of 633 nm was obtained from an He-Ne laser and modulated by an

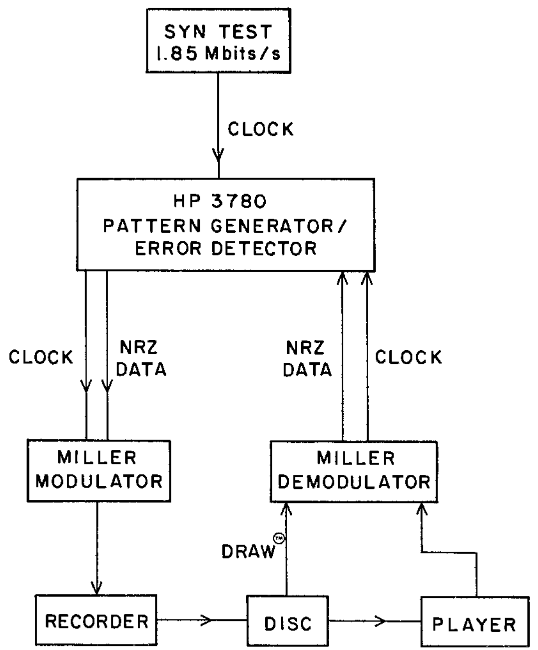

Fig. 1. Electronic system

Key words: aging, humidity, metals.

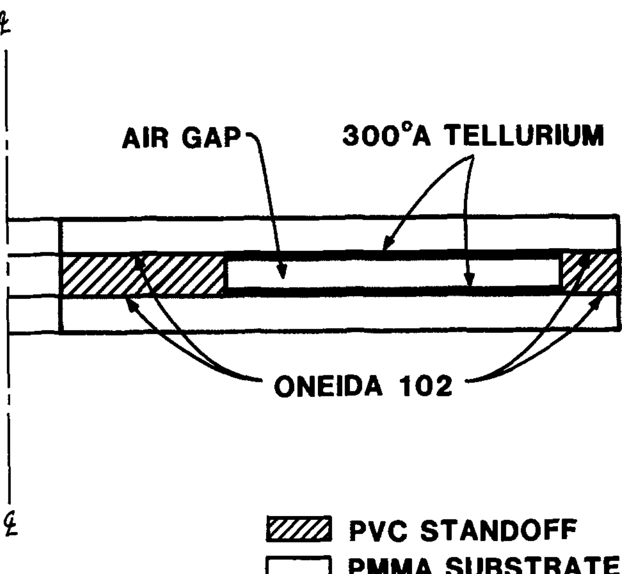

Fig. 2. The air sandwich™ structure

acousto-optic modulator. The sandwiches were mounted on an air-bearing spindle driven by a pancake motor. The focusing lens was a 0.45 N.A. Zeiss objective designed for the Philips Videodisc player. The calculated spot size of the recording beam is 0.7 μm FWHM. Active focusing was obtained by sensing the error signal with an infrared side beam system, and driving the objective with a standard Videodisc type voice coil. The entire focusing optics assembly was mounted on a rectangular Dover air-bearing sled and driven by a linear motor. The readout signal was obtained by splitting off a portion of the laser beam before modulation and aligning it to trail the main recording beam by a few microns on the recorded track.

Typically, each disk has four recorded bands of information, each approximately 2 mm wide, 120 sec long. Recordings of the 1010//4 pattern were made at the inner (75 mm), middle, and outer (95 mm) radii of the disk, together with a PRB5-15 pattern somewhere in between. For each recorded band, the recording parameters were adjusted to minimize the bit error rate of the readout signal.

After recording, the disks were stress aged in a temperature humidity oven at 45°C 95% relative humidity. Periodically, the disks were taken out, and the bit error rates were measured. Playback was on a modified version of the standard Philips Videodisk player. The Miller output from the player preamplifier was demodulated. The bit error rate of the recorded data was measured in the error detector section of the HP 3780A over data segments 10^6 bits in length. With a gating time of 1 sec on the HP 3780A, each recorded band contains approximately 100 readings. The average and standard deviation of these bit error rate readings are taken as the descriptor for the condition of the disk.

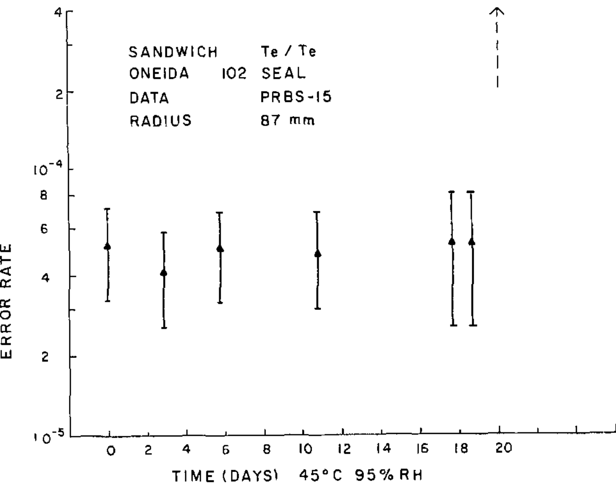

Fig. 4. Error rate degradation for double-sided tellurium air sandwich™, middle radius.

Results

Figures 3-5 show the data obtained for a double-sided sandwich, which has 300Å Te coated on both recordable surfaces. Standard Glasflex PMMA disks were cleaned by an acetone/alcohol rinse, immersion in an ultrasonic detergent bath, and deionized water rinse. The sandwich was bonded together with a polyvinyl chloride standoff using Oneida 102 cyanoacrylate as a seal (Fig. 2). Figure 3 gives the behavior for a 1010//4 pattern recorded at a radius of 80 mm. The recorded data show an initial error rate in the mid 10^{-5} range and are stable at 45°C 95% relative humidity for up to 18 days, after which it rapidly deteriorates. Figure 4 shows the behavior of PRB5-15 data at 87 mm, and Fig. 5 shows the behavior of 1010//4 data at 95 mm, on the same disk. The degradation in the fundamental signal characteristics, as measured by the carrier to noise ratio and carrier to second harmonic ratio, is given in Fig. 6. Figure 7 gives the data for a 1010//4 pattern on a double-sided sandwich which has extensive recordings made on the opposite recordable

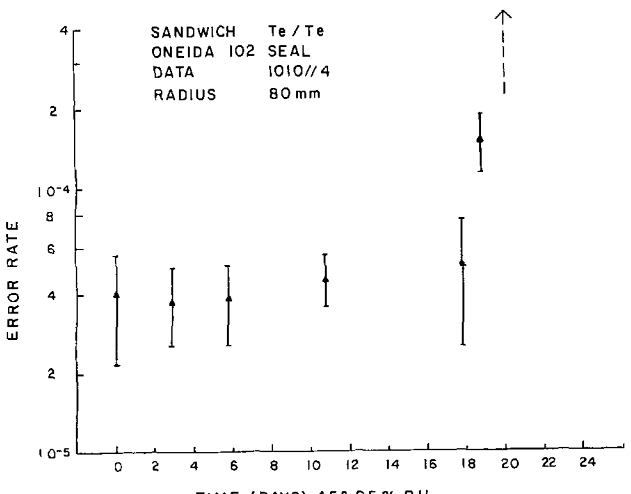

Fig. 3. Error rate degradation for double-sided tellurium air sandwich™, inner radius.

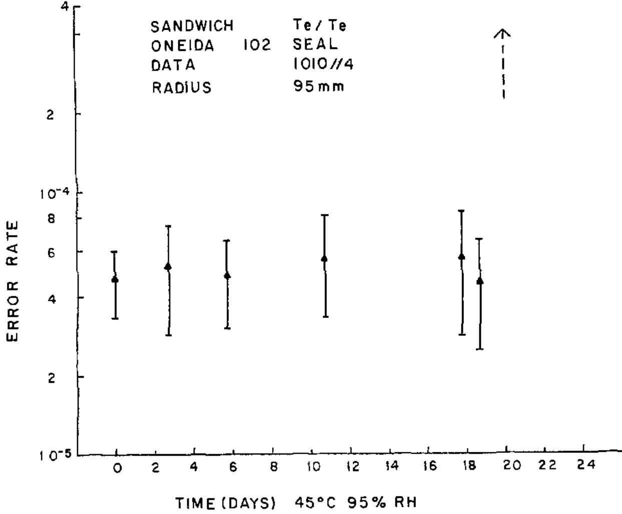

Fig. 5. Error rate degradation for double-sided tellurium air sandwich™, outer radius.

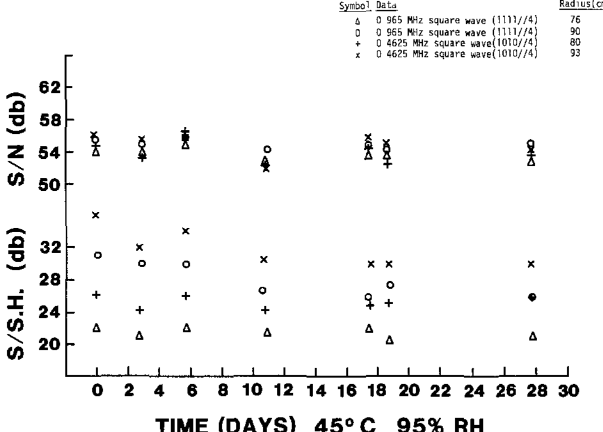

Fig. 6. Signal-to-noise and signal-to-second-harmonic degradation for double-sided tellurium air sandwich™.

surface. The results are typical of the behavior of tellurium air sandwiches.

Conclusions

Recorded data on these tellurium sandwich disks will remain stable in a 45°C and 95% relative humidity environment for at least 15 days. Stability is independent of recording radius, recorded data patterns, and whether recordings have been made on the opposite side. At present, extrapolation of these data to room ambient is uncertain. If one were to adopt the model proposed by Milch and Tasaico (4), developed

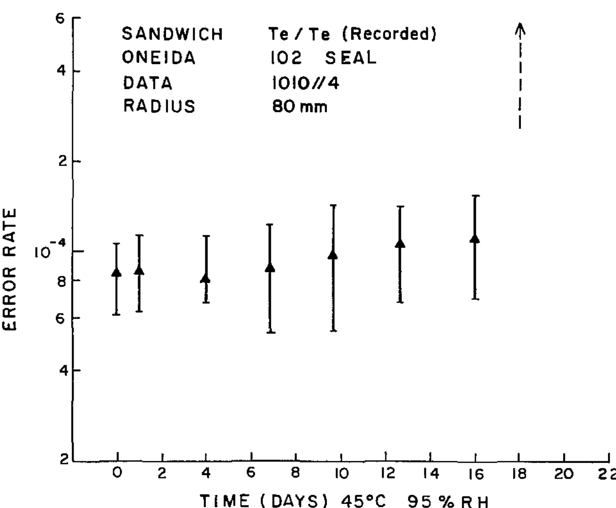

Fig. 7. Error rate degradation for double-sided tellurium air sandwich™ with recordings on opposite side.

for the extrapolation of shelf-life data, these results imply an archival life of at least 10 years for tellurium sandwiches at room ambient (25°C, 50% relative humidity). Failure of the air sandwich consists of a dramatic increase (several orders of magnitude) in the error rate, developing over a comparatively short time (a day or so). The direct cause of failure is apparently the development of localized defects on the disk. The catastrophic failure was not observed in the macroscopic signal characteristics, the film properties, or the integrity of the air sandwich structure. Lifetime data based on macroscopic optical measurements of transmission and reflection may well give overly optimistic results. Analogue information storage based on these macroscopic signal characteristics will probably have substantially longer lifetimes than 14 days at high humidity.

Several possible pathways exist for improving the archival life of the tellurium sandwich. The degradation is primarily associated with humidity. Hermetic sealing of the sandwich (6), or storage at elevated temperatures (4), have been used successfully. Substantially improved stability has also been observed by introducing appropriate impurities in the tellurium film. These results will be reported in a subsequent paper.

Acknowledgments

We would like to thank A. Chan and J. Nadan for the electronics instrumentation used in these experiments, and F. Zernike for the recorder. Sandwiches were fabricated by A. Weeks and M. Jaso, and S. Tan carried out the data analysis. We would also like to acknowledge G. Blom and G. Kenney for reviewing the manuscript.

Manuscript submitted June 24, 1980; revised manuscript received Sept. 15, 1980.

Tarnishing of Silver by Sulfur Vapor: Film Characteristics and Humidity Effects

B. T. Reagor* and J. D. Sinclair*

Bell Laboratories, Holmdel, New Jersey 07733

In laboratory and field studies over the past several years, we have noted that in some environments the average tarnishing rate of silver seemed to be less dependent on relative humidity (RH) than the dramatic dependence that has commonly been observed in the laboratory with hydrogen sulfide (1-15). We have also noted that the tarnish film thickness was often nonuniform. These effects were especially evident

surface. The results are typical of the behavior of tellurium air sandwiches.

Conclusions

Recorded data on these tellurium sandwich disks will remain stable in a 45°C and 95% relative humidity environment for at least 15 days. Stability is independent of recording radius, recorded data patterns, and whether recordings have been made on the opposite side. At present, extrapolation of these data to room ambient is uncertain. If one were to adopt the model proposed by Milch and Tasaico (4), developed for the extrapolation of shelf-life data, these results imply an archival life of at least 10 years for tellurium sandwiches at room ambient (25°C, 50% relative humidity). Failure of the air sandwich consists of a dramatic increase (several orders of magnitude) in the error rate, developing over a comparatively short time (a day or so). The direct cause of failure is apparently the development of localized defects on the disk. The catastrophic failure was not observed in the macroscopic signal characteristics, the film properties, or the integrity of the air sandwich structure. Lifetime data based on macroscopic optical measurements of transmission and reflection may well give overly optimistic results. Analogue information storage based on these macroscopic signal characteristics will probably have substantially longer lifetimes than 14 days at high humidity.

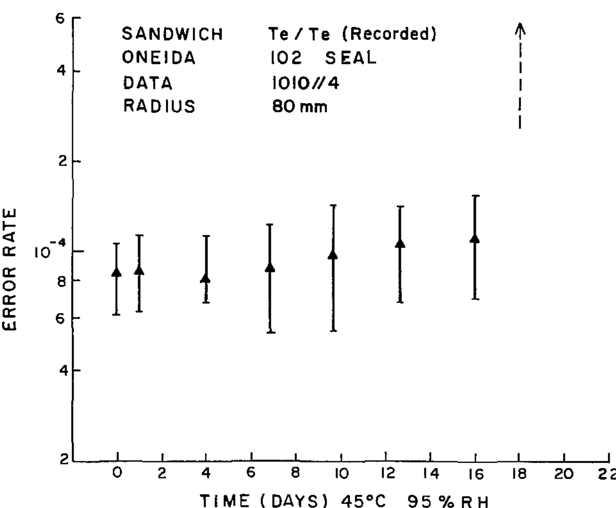

Fig. 7. Error rate degradation for double-sided tellurium air sandwich™ with recordings on opposite side.

Several possible pathways exist for improving the archival life of the tellurium sandwich. The degradation is primarily associated with humidity. Hermetic sealing of the sandwich (6), or storage at elevated temperatures (4), have been used successfully. Substantially improved stability has also been observed by introducing appropriate impurities in the tellurium film. These results will be reported in a subsequent paper.

Acknowledgments

We would like to thank A. Chan and J. Nadan for the electronics instrumentation used in these experiments, and F. Zernike for the recorder. Sandwiches were fabricated by A. Weeks and M. Jaso, and S. Tan carried out the data analysis. We would also like to acknowledge G. Blom and G. Kenney for reviewing the manuscript.

Manuscript submitted June 24, 1980; revised manuscript received Sept. 15, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by Philips Laboratories.

Tarnishing of Silver by Sulfur Vapor: Film Characteristics and Humidity Effects

B. T. Reagor* and J. D. Sinclair*

Bell Laboratories, Holmdel, New Jersey 07733

In laboratory and field studies over the past several years, we have noted that in some environments the average tarnishing rate of silver seemed to be less dependent on relative humidity (RH) than the dramatic dependence that has commonly been observed in the laboratory with hydrogen sulfide (1-15). We have also noted that the tarnish film thickness was often nonuniform. These effects were especially evident

* Electrochemical Society Active Member.
Key words: sulfidation, dendrite, SEM, growth.

in laboratory studies in which sulfur vapor was the tarnishing agent and in field studies at Artesia, New Mexico.

While sulfur vapor is a significant atmospheric tarnishing agent in only a few field environments (16), mercaptans and organic sulfides and disulfides can be more widely found as a result of natural processes and anthropogenic activity. Crossland *et al.* (11) have reported that mercaptans do not tarnish silver, but work in this laboratory indicates that atmospheres generated from organic sulfides and disulfides rapidly tarnish silver, especially in the presence of light (17). Very recently carbonyl sulfide, a major atmospheric sulfur-containing constituent was found to tarnish silver at elevated RH (18). The effect of RH on tarnishing by any of these carbon containing agents is unknown.

In a paper on precious metal alloys, Abbott (19) briefly reported on the tarnishing of silver by sulfur at 30°C in a flowing atmosphere. His data were summarized in a single linear plot that represented all N_2-O_2-SO_2-sulfur-H_2O environments studied. Chiarenzelli (5) claimed tarnishing would not occur in the absence of moisture. We report here the results of a study on sulfide film uniformity and humidity effects, using sulfur vapor as the tarnishing agent for silver coupons exposed in a closed environment at room temperature and 50°C.

Experimental

Tarnish film morphology was studied with an AMR-1000 Scanning Electron Microscope (SEM) in the secondary electron mode using an accelerating voltage of 30 kV. Average sulfide film thickness was measured by cathodic reduction (20). Nonuniformity in film thickness was estimated from sulfur ($K\alpha$) to silver ($L\alpha$) x-ray intensity ratios using a calibration plot based on cathodic reduction measurements. The x-ray intensities were measured with a Princeton Gamma-Tech x-ray detector and Tracor Northern 880 multichannel analyzer in conjunction with the SEM.

Square silver coupons (½ in. on a side) were cut from 0.005 in. thick Sargent-Welch silver foil. The coupons were cleaned and etched by two sets of successive immersions in concentrated nitric acid and then ammonia, the first set involving 10 min immersions and the second set 5 min immersions. Each immersion was followed by multiple rinses in pure water. The coupons were air dried for several hours prior to initiation of the experiments. This procedure produced a uniform and reproducible white matte surface on the coupons.

Sulfide films were grown on coupons suspended individually by glass hooks in bell jars that were approximately 8 cm high with a diameter of 6.5 cm. Sulfur vapors were evolved from a large excess of aged flowers of sulfur spread across a crystallization dish that was placed at the bottom of the bell jar. The vapor pressure of sulfur at room temperature is approximately 0.2 mPa (21), while that at 50°C is approximately 10 mPa (21). The molecular composition of sulfur vapor in equilibrium with the solid is approximately 96% S_8 and 4% S_6 at 50°C (22). A saturated salt solution, pure water, or Drierite, each contained in a 10 ml beaker, was placed at the bottom of the bell jar in the center of the crystallization dish for RH control. The salts used were lithium chloride, calcium nitrate, and ammonium sulfate. A survey of literature data on the vapor pressures of saturated salt solutions (23-32) indicated that the RH over the calcium nitrate solution used at room temperature was approximately 51%, while the RH's over the lithium chloride, ammonium sulfate, and calcium nitrate solutions used at 50°C were 11, 79, and 35-45%, respectively.

Coupon exposures at room temperature (23° ± 2°C) were accomplished on laboratory benches under ordinary fluorescent lighting. Studies at elevated temperatures were carried out in a GCA/Precision Scientific oven that was modified to include a Leeds and Northrup temperature controller. The temperature of the oven was 50° ± 2°C.

Results and Discussion

The sulfide tarnish film thickness on freshly cleaned and etched silver coupons that were exposed for up to 50 and 18 days at room temperature and at 50°C, respectively, is shown in Fig. 1 and 2 as a function of exposure time. The error bars indicate 95% confidence limits. The data confirm that in a closed environment relative humidity does not have an appreciable effect on the average rate of silver sulfide formation in the presence of sulfur vapor either at room temperature or at 50°C. The independence of the rate on relative humidity is further evidence that the probable function of moisture in tarnishing by hydrogen sulfide is to provide a medium for the oxidation of hydrogen sulfide to free sulfur (2, 10).

The average rate of silver sulfide film formation (at all humidities) was 0.5 Å/hr at room temperature and 13.3 Å/hr at 50°C. Similar to previous work, the observed linearity of the sulfiding rate at the conditions of this study indicates that the process is controlled by the arrival of sulfur at the silver surface (12, 19, 33, 34). An approximation for the rate of arrival of S_8 vapor to the coupon surface was calculated with the equation

$$S/t = DqCe/l$$

from the cylindrical model of Jost (35), where S is the quantity of S_8 arriving in time t, D is the diffusivity of S_8 in air, l is the distance from the sulfur source to the center of the coupon (5 cm), q is the cross-sectional

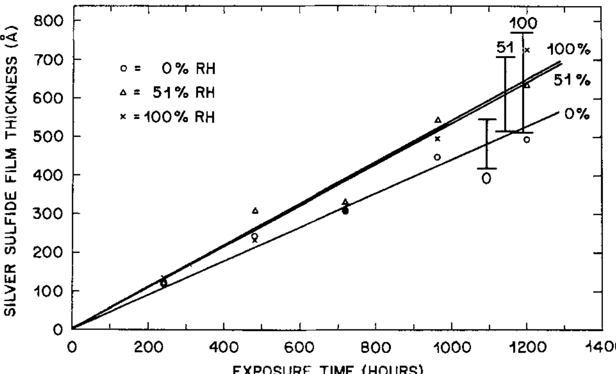

Fig. 1. Sulfide tarnish film formation on silver by sulfur vapor at room temperature.

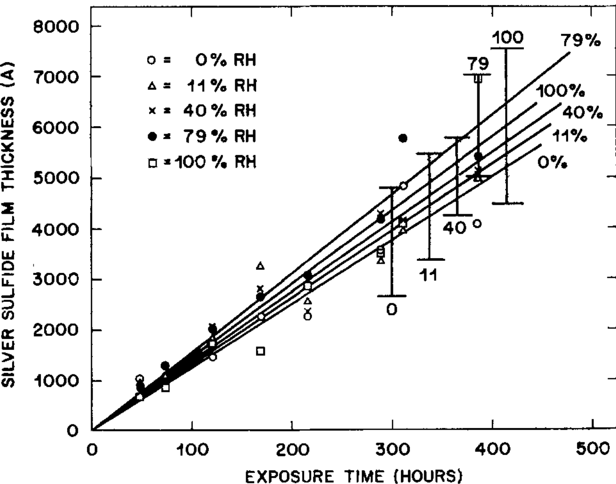

Fig. 2. Sulfide tarnish film formation on silver by sulfur vapor at 50°C.

area of the bell jar, and Ce is the equilibrium concentration of S_8 obtained from the vapor pressure above the solid. The model assumes an S_8 concentration of zero at the silver surface, *i.e.*, all S_8 striking the coupon surface is consumed by silver. The diffusivity of S_8 at room temperature was estimated from the diffusivity of air and the relationship

$$\frac{D_{\text{sulfur}}}{D_{\text{air}}} = \sqrt{\frac{MW_{\text{air}}}{MW_{\text{sulfur}}}}$$

to be 0.036 cm^2/sec. With this model the calculated rate of silver sulfide formation at room temperature was 0.7 Å/hr in reasonable agreement with the experimental rate. Unfortunately the diffusivity of silver in silver sulfide is not well known below 90°C, which prohibits calculating a silver diffusion limited tarnishing rate. Parabolic kinetics have been observed at considerably higher tarnishing agent concentrations (> 1 ppm hydrogen sulfide) (6). For initial film formation rates in excess of approximately 10 Å/hr at room temperature, the diffusivity of silver in silver sulfide appears to be rate controlling.

The morphology of the tarnish films formed at 50°C under the conditions of this study was not appreciably affected by the relative humidity, as the micrographs in Fig. 3 and 4 indicate. The high magnification micrographs in Fig. 3 of approximately 5000Å sulfide films exhibit the crystallinity in the surface film that was observed on the tarnished coupons. The apparent greater crystallinity seen in micrograph d relative to that in micrographs b and c is a result of random variations across the coupon surfaces.

In all cases examined, the tarnish film thickness at the coupon edges was greater than the thickness at the center. The micrographs in Fig. 4 show the extensive dendritic growths observed at the coupon edges and a rapid drop in dendrite density immediately interior to the edges. The tarnish film thickness variations on these coupons, as determined by the SEM/x-ray method, are summarized in Table I. The tarnish film thickness at the coupon centers is from 1240 to 2940Å less than the average thickness at the corners. The trend toward increasing thickness away from the center can be attributed to the statistical distribution of the sulfur diffusion paths as affected by convection currents from the sulfur source to the coupon surface. Most of the film thickness measurements for the four corners are within 200Å of the average of the corners and can be considered essentially identical. However, the corners of the coupons exposed at 0 and 100% RH that exhibited thicknesses of 6500 and 5180Å, respectively, are significantly different from the average.

Table I. Silver sulfide tarnish film thicknesses by S/Ag x-ray intensity ratio (18 day exposure at 50°C)

Percent RH of test atmosphere	Thickness (A)		
	Four corners of coupon	Average of the corners	Coupon center
0	5770, 5770, 6500, 5710	5940	3000
51	5120, 5250, 5180, 5370	5230	3990
100	5180, 5960, 5820, 5770	5680	4020

These nonuniformities indicate that the wide scatter in tarnish rate data found for films analyzed by cathodic reduction in this study and in others could be at least partially caused by random fluctuations in the surface condition prior to tarnishing that may be experimentally caused but that would be most difficult if not impossible to avoid. They could also relate, in part, to convective effects on the sulfur arrival rates. Mechanistic interpretations utilizing film thickness data based on cathodic reduction or other averaging techniques may not always be as straightforward as is often thought. In some cases, for example the mixed oxide, sulfide films that usually form on copper, regional fluctuations in the rates of competing reactions may occur across the surface of test coupons. For silver, the variations in sulfide thickness could result in or be caused by localized mechanistic differences or nonuniform surface energetics but do not appear to influence the average rate of the sulfur limited reaction.

Some of the previous studies of sulfidation of silver have documented the growth of dendrites, whiskers, or platelets. Drott (3), using 2% hydrogen sulfide in water saturated air at room temperature, noted that the appearance of whiskers occurred simultaneously with a sudden increase of the reaction rate. The whisker growth was uniformly distributed and oc-

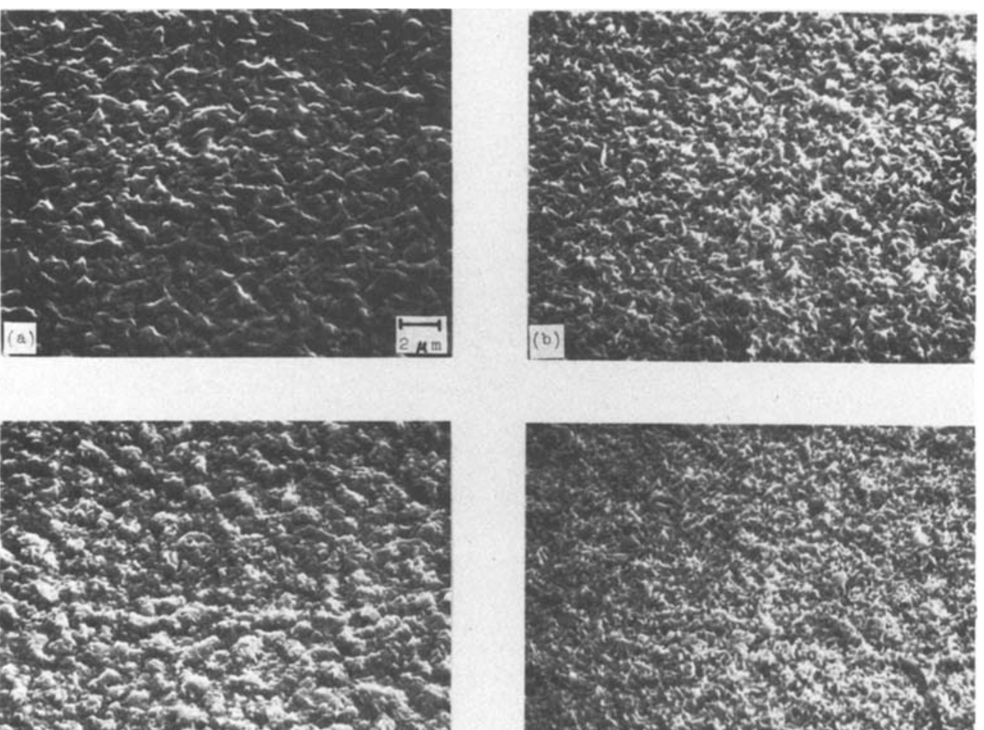

Fig. 3. Morphology of the interior surfaces of silver coupons: (a) untarnished coupon; (b-d) coupons tarnished to a sulfide film thickness of approximately 5000Å at 0, 51, and 100% RH, respectively.

Fig. 4. Dendritic growths at the corners of silver coupons: (a) untarnished coupon; (b-d) coupons tarnished to a sulfide film thickness of approximately 5000Å at 0, 51, and 100% RH, respectively.

curred after the formation of discrete mounds whose distribution was unrelated to the grain structure of the metal. It was suggested that whiskers sprouted when critical mound conditions existed that were brought about by mechanical tension due to rapid growth. Backland *et al.* (4) and Bennett *et al.* (9) reported similar findings.

At the very high tarnishing agent concentrations of Drott the increase in tarnishing rate coincident with whisker growth can be attributed to the sudden availability of silver in a silver-limited environment. In the sulfur limited environment of this study an increased growth rate coincident with whisker growth would not occur. The preferential growth of dendrites at the edges indicates that the rate of arrival of sulfur there was sufficiently large to create a mechanically stressed surface. The surplus silver available at the outer ends of the easy diffusion paths apparently allows whisker growth to start. After initiation, the sulfur arrival process and the surface diffusion paths available on the dendrites would probably be expected to produce preferential growth on the whiskers. The average growth rate would remain linear.

Niobium Triselenide in a Lithium Dioxolane Cell

M. Stanley Whittingham*[,1] and Gerald H. Newman*

Exxon Research and Engineering Company, Linden, New Jersey 07036

For many applications there is a need for a secondary battery with a high volumetric energy density. Although the lithium titanium disulfide cell has very good rechargeability and gravimetric energy density, it has a rather low volumetric energy density compared with some primary cathodes such as MnO_2 and FeS_2. The oxide has a higher potential and the sulfide reacts with about two lithium:

$$Li + MnO_2 \rightarrow LiMnO_2 \quad 2.8 \text{ volts}$$

$$Li + TiS_2 \rightarrow LiTiS_2 \quad \sim 2.1 \text{ volts}$$

$$2Li + FeS_2 \rightarrow Li_2FeS_2 \quad \sim 1.5 \text{ volts}$$

In contrast to the disulfide, titanium trisulfide will react with three lithium to give the compound Li_3TiS_3. However, this compound shows very poor reversibility, less than one lithium being discharged on the 2nd cycle, because of structural changes (1). Niobium triselenide is much more reversible (2), but even here the best reported cycling showed a 60% loss in capacity in going from the first to the third cycle (3). The capacity then fell in the range 26-30% of the first cycle capacity for the next sixty cycles.

The reversibility of the Li/TiS_2 cell was maximized when dioxolane was used as the electrolyte solvent (4). We therefore conducted experiments on the trichalcogenides using dioxolane as the solvent. The cells were constructed as described earlier (5), using as electrolyte a 2.5 molar solution of lithium perchlorate in dioxolane. They were then cycled (6) continuously at 2 ma/cm^2 between voltage limits of 2.65 and 1.45 volts. On the first discharge 2.33 lithium were incorporated into the niobium triselenide lattice, 78% of the theoretical value. This decayed slowly on cycling as shown in Fig. 1. This figure also compares the data in the dioxolane solvent with that obtained (3) in a $LiClO_4$/propylene carbonate cell to which 3 wt.% of an ether additive, tetraglyme, has been added. The latter in turn was much improved over a pure propylene carbonate solvent (3). Just as for titanium disulfide, dioxolane gives the best cycling performance for niobium triselenide. The reason for this is not clear but is related to a number of factors, probably including its lithium plating capability which minimizes formation of lithium "sludge", its greater resistance than propylene carbonate to react at the cathodic lithium potentials and better wetting of the cathode and separators.

The experiments were extended to two other trichalcogenides, NbS_3 and TiS_3, to see whether their cycling could also be improved. The NbS_3 was discharged at 2 ma/cm^2 for the first two cycles and then at 1 ma/cm^2 thereafter; charging throughout was at 1 ma/cm^2. The TiS_3 cathode was discharged at 2 ma/cm^2 but due to the very low capacities the charge rate was only 0.5 ma/cm^2; this was further reduced to 0.25 ma/cm^2 after the 27th discharge. The cycling behavior of these two cathodes are compared with despite the less demanding cycling regime. Thus on the 20th cycle, the capacities are 66%, 30% and 2.6% for $NbSe_3$, NbS_3 and TiS_3 respectively. This behavior is probably a result of an inherent irreversibility of at least part of the lithium in the two sulfides, rather than a function of the electrolyte, as described elsewhere (1,5,7-9). When TiS_2 cells are cycled under similar conditions the loss of capacity over 60 cycles is about 20%. This was reduced to about 0.1%/cycle by applying pressure to the cells (10), and it is anticipated that the capacity of $NbSe_3$ cells would be similarly improved as Jacobson (11) has shown in very slow cycling tests that $NbSe_3$ is inherently totally reversible. In addition, a low capacity, 4 mAHr, $NbSe_3$ cell has recently been cycled to over 80% of 3 Li/Nb sixty times (12).

Low Pressure Deposition of Silicon Nitride by $SiCl_4$ and NH_3 Reaction

I. Szendro and E. Marton
TUNGSRAM, H-1340, Budapest, Hungary

Low pressure deposition processes utilizing SiH_4-NH_3 and SiH_2Cl_2-NH_3 have been reported. The former reaction is extremely sensitive to wafer spacings and system configurations /1.,2./. The SiH_2Cl_2-NH_3/1.,3./ reaction yields excellent film uniformities and reproducibilities. However, to achieve this, care should be taken of the control of temperature and pressure, and at 9oo^{o}C it requires a rather high capacity vacuum system /1./.

In our study we have applied the $SiCl_4$-NH_3 reaction /which is well known at atmospheric, cold wall conditions/ to a low pressure hot wall system as this nitride forming process was expected to be less sensitive to process variations.

Experiments. -- The LPCVD system consisted of a normal resistance heated furnace and a quartz tube /80/74 mm/ without any special tube inserts. The 2 inch diameter wafers were held in four basket type quartz carrier with wafer plane perpendicular to the tube axis. One wafer carrier consisted 25 slots with 3,2 mm spacings. The vacuum exhaust system was based on a LN_2 trap followed by a mechanical vacuum pump of 585 l/min capacity. The pressure could be independently controlled by introducing N_2 gas directly into to vacuum inlet line of the pump. Pressure was measured at the front of the tube by a Baratron 221 type capacitance manometer, temperatures reported here were measured in the subatmospheric reaction zone.

Gases were controlled by taper tube flowmeters /Matheson Gas Prod./, the $SiCl_4$/Merck, zur Synthese/ was held in a stainless steel reservoir, and its vapour was introduced into the reactor zone by N_2 carrier gas. In some experiments undiluted, pure $SiCl_4$ vapour was introduced into the reactor with the help of a mass flow controller, connected between the outlet of the reservoir and the inlet of the reactor quartz tube. In those cases, the N_2 gas inlet of the $SiCl_4$ reservoir was closed and only the $SiCl_4$ vapour / $\sim$260 mbar at 20°C/ feeded the MFC inlet. This set up is useful if one needs a high $SiCl_4$ partial pressure in the reactor, because no N_2 carrier is needed. The E.G. ammonia and diclorosilane /for comparative nitride depositions/ was supplied by Matheson Gas Prod., the N_2 was obtained from liquid nitrogen source and after purification its oxygen and water concentration was less than 2 ppm. All thickness and refractive index measurements were made with a laser ellipsometer.

Results.-- The deposition rate was studied as a function of temperature and the results are plotted in Fig. 1. The Arrhenius curves show that the $SiCl_4$-NH_3-N_2 process is about half as sensitive to temperature change / $\sim$0,9 %/^{o}C/ as the SiH_2Cl_2-NH_3 process /$\sim$1,7 %/^{o}C/. On Fig.2. the $SiCl_4$ and SiH_2Cl_2 partial pressure effect on the nitride growth rate is shown and the advantages of $SiCl_4$ over SiH_2Cl_2 are significant as to deposition rate change versus pressure change. Deposition rate versus wafer spacing was determined for several system pressures and there was no difference between the two nitride forming process.

Film uniformity within a wafer and

Key words: LPCVD, silicon nitride

within wafer to wafer in a 100 wafers load was studied as a function of pressure and temperature slope. In order to get a better uniformity within a wafer than ± 2,5 % and a better than ± 4 % within wafer to wafer the pressure must be below 1,1 mbar, wafer spacings 3,2 mm, and as high as 1,5°C/cm temperature slope should be achieved in the reactor zone declining towards the gas inlet.

The physical and chemical properties of the silicon nitride layers produced by the $SiCl_4$-NH_3 LPCVD process was found to be similar to those deposited by the $SiCl_4$-NH_3 reaction at atmospheric conditions /4./ or by the SiH_2Cl_2 - NH_3 LPCVD process /1./. The refractive index is 1,98 ±0,01, the etch rate in 40 % HF at 25°C is 11 nm/min, the i.r. absorption maximum is at 830 cm^{-1}.

It is known that at atmospheric deposition conditions trace amounts of oxygen and water can cause off stoichiometric silicon nitride layers /5./. We have carried out some experiments to see how the gas phase O_2 and H_2O contamination affects the LPCVD silicon nitride film properties. The preliminary results are suprising and futher experiments have to be made. It is found that up to 50 ppm O_2 concentration in the SiH_2Cl_2-NH_3 process and 50 ppm H_2O in the $SiCl_4$-NH_3 process has no effect on such nitride properties as refractive index, etch rate, i.r. absorption. The possible explanation is that in the hot wall reactors the O_2 and H_2O can not reach the wafers surface because they react in the hot gas phase much faster with SiH_2Cl_2 and $SiCl_4$ than NH_3 does, and the oxide forming reaction is finished already in the colder inlet side of the reactor.

Al/FeS_2 Secondary Cells Using Organic Electrolytes

Setsuko Takahashi and Nobuyuki Koura*

Department of Industrial Chemistry, Faculty of Science and Technology, Tokyo University of Science, 2641 Yamazaki, Noda Chiba 278, Japan

Aluminum is a common and inexpensive metal with a high theoretical capacity and a negative potential, but for use as the negative electrode of cells, it has some drawbacks, oxide film formation, self corrosion, and dendritic deposit. Therefore, there are few practical cells with an Al electrode (1).

It is considered that if the above drawbacks can be overcome, aluminum is highly promising as the active material for the negative electrode of advanced secondary cells. We have investigated Al/$AlCl_3$-NaCl-MCl_x/FeS_2 cells for load-leveling applications and in electric vehicles (2), and there are many other investigations (1) showing that a smooth, dense aluminum deposit forms in organic electrolytes. For this reason, Al/$AlCl_3$-organic solvent/FeS_2 cells have been developed. It was expected that these cells will offer a long service life and high terminal voltage at around room temperature.

The Al electrodes were spiraled rods (ϕ5 mm, 99.99% purity) with areas five to seven times the areas of the FeS_2 electrodes. Details of the FeS_2 electrode are given elsewhere (2). The FeS_2 electrode (7 mm thick, ϕ25 mm) was degassed and immersed in the organic bath in vacuo to wet both the FeS_2 powder and the current collector completely with the electrolyte.

$AlCl_3$ and lauryl pyridinium chloride (LPC) were dried at 80°C for 10 h in vacuo. In tetrahydrofuran (THF) system, $LiAlH_4$ was added to the THF, the solution was refluxed at 70°C for 6 h, and the $AlCl_3$ was put in a THF-benzene or a THF solution to which was added the THF-$LiAlH_4$ solution. Electrolyte preparation was done under a dry N_2 atmosphere. The cell comprises an upper Al electrode and a lower FeS_2 electrode (distance: 5 ∿ 10 mm). Cell performance was observed during about 30 repetitions (1 ∿ 2 months) of the discharge (cutoff: 0.5 V) - charge (cutoff: 2.1 ∿ 3.0 V) cycle under the N_2 atmosphere. The ohmic drop (IR drop) was checked once every 30 minutes with a relay. Potential-current curves were given potentiostatically.

After several cycles the cell performance was steady, therefore, the data (IR-free) of each 10th cycle are presented. Although charge curves are not shown, the coulombic efficiencies were from 80 to 100%. Discharge curves for the LPC systems are shown in Fig. 1. In the case of a 63.0 mol% $AlCl_3$ - 37.0 mol% LPC bath, in which the current density at the FeS_2 electrode was 3 mA/cm^2 and bath temperature was 125 °C, although the discharge capacity was only 0.03 Ah and the IR drop was large (0.5 V), the open circuit voltage (OCV) was 1.50 V. When toluene was added to the bath to lower its temperature, discharge capacity fell to 0.02 Ah at 100°C. For an FeS_2 electrode with a 38% graphite additive, however, discharge capacity for the above bath rose to 0.07 Ah at 60°C and 0.1 Ah at 100°C. The additive had no pronounced effect either on OCV or IR drop. Since THF baths are very favorable to Al deposition, and can be operated at relatively low temperatures, it was decided to test this system (Fig. 2). The discharge capacity rose no higher than 0.32 Ah (ca. 20% of the theoretical capacity). However at room temperature and 5 mA/cm^2, the discharge curve showed a high voltage plateau of about 2.3 V and a low voltage plateau of about 1.0 V. Moreover, in the case of a vitreous carbon current collector, the high voltage plateau capacity increased significantly. These facts indicate that THF systems are very promising.

Potential-current curves for Al

Key words: aluminum, FeS_2, secondary cell, organic electrolyte

anode in LPC and THF systems showed the limiting current of 0.7 mA/cm^2 for the LPC systems and 7 mA/cm^2 for the THF systems. In THF systems the reactions are considered to be as follows:

$AlCl_3+LiAlH_4 \rightleftharpoons 2AlH_2Cl+LiCl$,

$AlH_2Cl+LiCl \rightleftharpoons LiAlH_2Cl_2 \rightleftharpoons Li^+ + AlH_2Cl_2^-$

It is also known that the lower the concentration of $LiAlH_4$, the smaller is the conductivity of the electrolyte (3). In the case of the bath B in Fig. 2, the conductivity was 5.47×10^{-3} Ω^{-1}/cm. We suggest that ionic species ($AlH_2Cl_2^-$, etc.) may be present in insufficient quantities in the electrolyte, and that this is the reason why this cell has a big IR drop and a small discharge capacity. Thus the immediate need is to improve the electrolyte. The fact that the addition of graphite greatly raised the discharge capacity but had little effect on IR drop further corroborate the above reasoning. In a molten-salt cell (Li-Al/LiCl-KCl/FeS_2), it is known that the problem of FeS_2 electrode conductivity is not so severe, due to the existence of certain phases (4), while in the organic solvent cells studied, such phases were not detected by X-ray analysis. Therefore, it is considered that a conductive material should be added to the FeS_2 electrode of organic cells in order to raise the discharge capacity. Since the graphite did not affect the OCV, it would seem that there can have been no effect from a 'carbon-metal complex' (5).

If the cell reactions are:

$(2/3)Al+FeS_2 \rightleftharpoons FeS+(1/3)Al_2S_3$,

$(2/3)Al+FeS \rightleftharpoons Fe+(1/3)Al_2S_3$,

two plateaus should appear in the discharge curve as seen in Fig. 2. FeS and Al_2S_3 were detected by X-ray analysis of a discharged FeS_2 electrode. But the e.m.f. values calculated from free energy values for the above reactions do not correspond to those observed. It should be considered that some complex compounds may be formed in the FeS_2 electrode by the interaction of Al_2S_3 with iron-sulfur compounds such as in the Li-Al/FeS_2 cell (4).

It is suggested that through improvement of the electrolyte and investigation of suitable additives for the FeS_2 electrode, the promise of this cell can be realized in the development of an advanced, high-capacity secondary cell.

Surface Treatment Induced Sub-Band Gap Photoresponse of GaP Photoelectrodes

M. A. Butler* and D. S. Ginley*
Sandia National Laboratories, Albuquerque, New Mexico 87185

The efficiency and behavior of most photoelectrodes depend strongly on the nature of the surface and near surface region of the semiconductor. Thus it is to be expected that the electrodes are sensitive to surface treatment.(1) The predominant mechanism is thought to be the introduction or removal of localized states near the surfaces which can act as recombination centers or can modify the kinetics of the redox reaction. Such localized states, which may be in the band gap of the semiconductor, can provide a mechanism for a photoresponse at energies below the band gap.(2) In this paper we demonstrate that such a sub-band gap photoresponse can be generated in GaP photoelectrodes either by mechanically damaging the surface or by cathodic aging of the electrode.

The p-GaP samples were single crystal wafers cut perpendicular to the [111] axis and Zn doped to a density of $5 \times 10^{17} cm^{-3}$. The contacts were made by sputtering In:Zn alloy and then annealing in vacuum. A conventional 3-electrode electrochemical cell was used with a PAR 173 potentiostat and a saturated calomel reference electrode. The illumination was by a quartz iodine lamp with a Schoeffel grating monochromator. Unless specified otherwise all experiments were run in 0.1M $HClO_4$ electrolyte. Typical sub-band gap spectra for various surface treatments are shown in Figure 1.

Figure 1a shows that etching of the photoelectrodes ~4 μm with a specific GaP etchant(3) removes any sub-band photoresponse that may have existed.

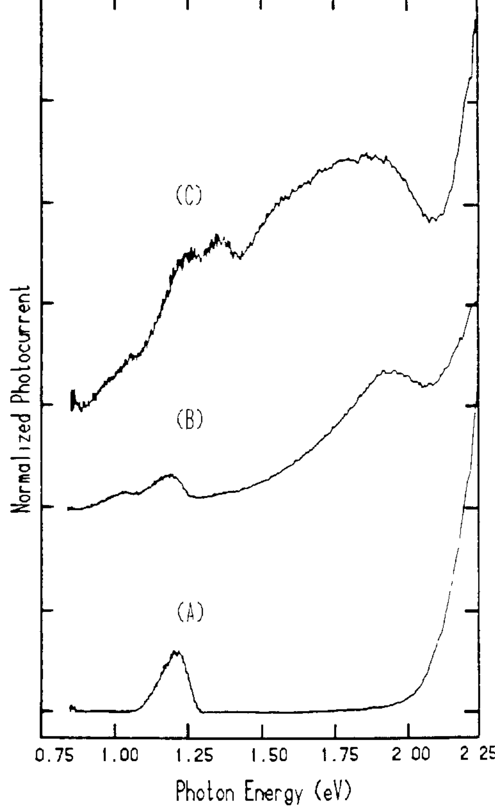

Figure 1. The sub-band-gap photoresponse of p-GaP with various surface treatments. The spectra are normalized to light intensity and the zero level is offset for (b) and (c) by an amount indicated by the left side of the spectra. All measurements were made at -2.0 V(SCE) in 0.1M $HClO_4$ using a filter to cut off the optical response above ~2.5 eV. (a) Polished surface etched 4 μ. (b) Surface mechanically polished using 1/4 μ diamond paste. (c) Cathodic aging under constant current conditions 5 mA for 1 hr. The peak at 1.2 eV is due to the second order reflection of the grating.

*Electrochemical Society Active Member.

Polishing the surface either wet or dry using various materials including diamond paste, aluminum oxide and SiC produces a sub-band gap response such as shown in Figure 1b. Similar behavior but with somewhat broader spectral features is produced by cathodic aging of the sample as shown in Figure 1c.

A sub-band gap response has also been observed in an n-GaP photoanode which was doped with sulfur to a density of $2x10^{18}$ cm^{-3}. The general features were the same as observed in p-GaP although a complete set of experiments on this sample have not been performed.

Etching for fixed time periods to profile the surface treatment effects shows that both polishing and cathodic aging produce damage extending ~1500Å into the surface. These results are confirmed by the potential behavior of the photocurrent shown in Figure 2. For a small optical absorption coefficient α it has been shown[4] that the photocurrent is:

$$J = \phi\alpha\left(\frac{2\varepsilon q}{N_D}\right)^{1/2} \left(V - V_{fb}\right)^{1/2} \quad [1]$$

where ϕ is the photon flux, ε the dielectric constant, q the electronic charge, N_D the dopant density and V the applied potential. Since the width of the depletion layer is given by:

$$W = \left(\frac{2\varepsilon}{qN_D}\right)^{1/2} \left(V - V_{fb}\right)^{1/2} \quad [2]$$

the linear relationship between J^2 and V shown in Figure 2 means that $J \propto W$. The observed photoresponse is a bulk effect arising throughout the depletion layer region. The maximum applied potential, - 4V(SCE), corresponds to a depletion layer thickness of ~0.09 μm. Thus, the linear region in Figure 2 indicates that the surface treatment effects are uniform between ~0.06 μm and ~0.09 μm. The deviation from linearity between 0 and -1V has been shown to arise from recombination in the near-surface region[5].

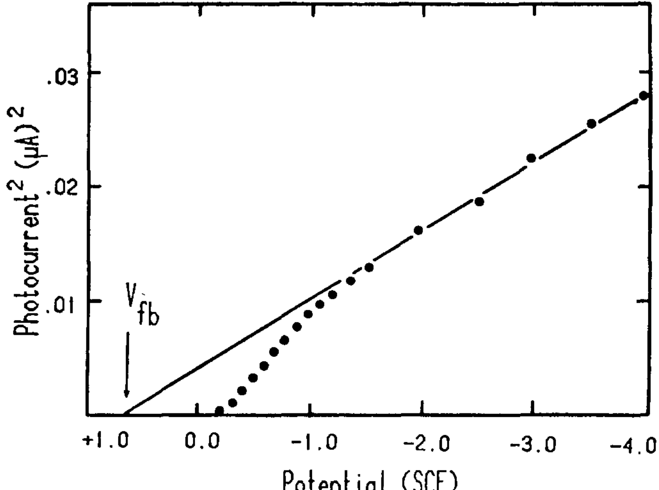

Figure 2. Potential behavior of the photoresponse at 1.75 eV of a polished sample taken in 0.1M $HClO_4$. Note the difference between photocurrent onset and flatband potential (V_{fb}) as determined by capacitance measurements.

In addition to etching, which removes the damaged near surface region, the sub-band gap photoresponse can be removed by anodic aging or by heat treating the sample. Treatment at 800°C for 1 hr. in vacuum totally removes the effect. Since at this temperature the partial pressure of P is higher than the partial pressure of Ga,[6] the heat treatment should change the stoichiometry of the near surface region by lowering the P/Ga ratio. Thus the sub-band gap response may arise from Ga vacancy related defects.

This idea is consistent with the production of a sub-band gap response by cathodic aging and its removal by anodic aging. These two bias conditions represent reductive and oxidative surface conditions which tend to remove Ga and P respectively from the sruface.[5] The exact nature of the defects responsible for the states in the gap is not known.

While the sub-band gap photoresponse induced by mechanical damage or cathodic aging can be removed by similar means, there are differences in such treated electrodes other than the obvious spectral differences

which can be observed. Simultaneously with the sub-band gap photoresponse measurements the capacitance of the interface and the photoresponse above the band gap were measured. Both of these measurements provide further information concerning the nature of the induced electronic states.

For a freshly etched surface in a 0.1M $HClO_4$ electrolyte a Mott-Schottky plot gives a straight line with an intercept of ~ + 0.7 V(SCE) and a slope indicative of a donor density of ~ $7x10^{17}cm^{-3}$. The flat band potential is in good agreement with previously reported values[5] and the donor density is in agreement with the known bulk value of $5x10^{17}cm^{-3}$. Anodic or cathodic aging of the sample does not significantly change either slope or intercept of the Mott-Schottky plot even though the cathodic aging induces a sub-band gap photoresponse. The photoresponse in 0.1M $HClO_4$ at 500nm (2.48eV) of a freshly etched surface has an onset at ~ 0.0V(SCE) again consistent with previously reported results. The discrepancy between the photocurrent onset and the flatband potential arises from recombination at bulk states in the band gap.[5] This behavior is also observed for anodically and cathodically aged samples.

For the mechanically damaged (polished) samples considerable changes are observed. The capacitance is drastically reduced although the intercept remains the same. The slope of the linear part of the Mott-Schottky plot suggests a reduction of the doping density by an order of magnitude with some variation from sample to sample. This interpretation is supported by the photoresponse at 500nm (2.48eV) which shows that the photocurrent increases by approximately a factor of three as would be expected for a lower doping levels and consequently increased depletion layer widths.

Thus it seems that the two processes which produce a sub-band gap photoresponse induce states of considerably different character. Cathodic aging produces states which do not change the overall doping level while polishing results in states which seem to compensate the p-type GaP samples. Both of these processes produce sub-band gap responses which are similar in spectral dependence.

Transference Number Measurements for the Polymer Electrolyte Poly(ethylene oxide) NaSCN

R. Dupon, D. H. Whitmore,* and D. F. Shriver

Departments of Chemistry and Materials Sciences, and Materials Research Center, Northwestern University, Evanston, Illinois 60201

Current interest in the development of high energy density batteries has focused considerable attention on solid electrolytes. The leading solid electrolytes in developmental batteries are hard ceramic materials, which usually are employed at elevated temperatures with liquid electrodes. A more compliant solid electrolyte, such as a polymer electrolyte, should enable contact to be maintained at the electrode-electrolyte interfaces in an all solid state battery and lower operating temperatures might be facilitated. Potential application of ion-containing polymers as battery electrolytes, and electrical measurements on salt complexes with poly(ethylene oxide) and with poly(propylene oxide) have been presented by Armand (1,2), and structural studies of poly(ethylene oxide) salt complexes have been reported from our laboratory (3). The original synthesis and characterization of these materials was reported by Wright (4,5) and extended by James (6).

A fundamental parameter in the characterization of any solid electrolyte is the fraction of the total current which is carried by the mobile ion, i.e. the transference number. Prior to the present work, a rigorous determination of the transference number for poly(ethylene oxide) based electrolytes was not available. The present study is based on the measurement of emf between ion reversible amalgam electrodes which are separated by the solid electrolyte in a concentration cell (7,8).

Experimental Procedure. -- Poly(ethylene oxide) with an average molecular weight 600,000 was obtained from Aldrich. The polymer was purified by ion-exchange of an aqueous solution and the solvent was subsequently removed under high vacuum. Reagent grade NaSCN (B & A) was recrystallized from methanol and dried under high vacuum. Reagent grade methanol (MCB) was dried by distillation from iodine-activated magnesium under a nitrogen atmosphere.

A PEO·NaSCN complex, 4.5:1 mole ratio of polymer repeat unit to salt, was prepared from stoichiometric quantities of the polymer and salt in anhydrous methanol. Following complete dissolution of the two solids, the methanol was removed under vacuum. All manipulations were carried out using standard inert atmosphere techniques (9). The identity of the PEO·NaSCN complex was confirmed by infrared spectroscopy and differential scanning calorimetry, and in previous research the material prepared by this same procedure has been characterized by optical microscopy and x-ray diffraction, which demonstrate the absence of free NaSCN.

Amalgams were prepared with triple distilled mercury and reagent grade sodium (MCB). Molten sodium was filtered through fritted glass to remove sodium oxide. The concentration of the stock amalgam, solution No. 1, Table I, was determined gravimetrically and checked by the gasometric method based on the amount of hydrogen evolved from the reaction of the sodium amalgam with hydrochloric acid. Concentrations of the remaining solutions were determined gravimetrically by successive dilution of the stock amalgam.

The sample and amalgams were placed in a cell which permitted exclusion of the atmosphere, Fig. 1. A pressed pellet of the PEO·NaSCN complex, 4.5:1, was fitted into an o-ring which was then clamped between the side arms. All loading of the polymer complex was carried out in a nitrogen filled dry box. One side arm was filled with the stock amalgam solution while the other was successively filled with the dilutions of the stock. Introduction of amalgam solutions was done with a gas-tight syringe under a flush of dry nitrogen.

Key words: Solid electrolyte, polymer electrolyte, transference number, poly(ethylene oxide).

*Electrochemical Society Active Member.

The potentials of the cell were measured using a Keithley 177 multimeter together with an electrometer containing an RCA CA3140 E MOS/FET operational amplifier designed to increase the input impedance of the measuring device to 10^{12} ohms. All measurements were made at room temperature, 23.5 ± 0.2 °C, which was monitored using an iron-constantan thermocouple and millivolt meter. The cell and connecting leads were placed in an aluminum box designed to shield the system from extraneous radiation. Reversing the cell polarity produced insignificant changes in the magnitude of the observed potentials. The emf was read after the potential had maintained a stable (± 0.3 mV) value over a period of one hour. Typical stabilizaton times were of the order of one to two hours. The measured results are given in Table I. As a check on these measurements, emf values were determined on a different batch of the polymer electrolyte using different amalgam preparations. Agreement between the data sets was good.

A value of the cell impedance was obtained by loading standard resistors in parallel with the cell and observing the change in emf. The observed room temperature cell impedance of 3.9×10^6 Ω was well within the capability of the measuring device and yielded a D.C. conductivity of 6.3×10^{-8} $(\Omega\ \mathrm{cm})^{-1}$, which is in general agreement with the A.C. value shown by Armand (2).

The emf of the concentration cell Hg-Na(x_1) | PEO·NaSCN | Hg-Na(x_2) is expressed by (8):

$$E_{obs} = (1 - t_e)E_{id} = (1 - t_e)\frac{RT}{nF}\ln\frac{a_1}{a_2} =$$

$$(1 - t_e)\frac{RT}{nF}\ln\frac{\gamma_1 x_1}{\gamma_2 x_2}$$

The activity coefficients for dilute amalgams (present case) may be calculated from the relationship (10):

$$\text{Log } \gamma = Qx$$

where

$$Q = 18.720 - 8.00 \times 10^{-3}\ T$$

From this, E_{id} may be calculated:

$$E_{id} = \frac{RT}{F} 2.303 \log\frac{x_1}{x_2} + \frac{RT}{F} 2.303\ Q(x_1 - x_2)$$

A plot of E_{obs} vs. E_{id} for each x_2 (x_1 being fixed as the stock amalgam, solution No. 1) yields a straight line (Fig. 2) of slope $(1-t_e)$.

Results and Discussion. -- For a purely ionic conductor the value of $(1 - t_e)$ should be unity. Least squares treatment of E_{obs} vs. E_{id} produced slope 1.005 ± 0.005, Fig. 2. This result establishes that the electronic contribution to the total electrical conductivity of PEO·NaSCN is negligible and that the ionic component is responsible for the conduction. Since sodium-reversible electrodes were employed and since the conductivity is close to the published A.C. data, the sodium ion is implicated as the major charge carrier in the PEO·NaSCN complex.

Table I. Ideal and observed emf's of concentration cell at room temperature.

Solution No.	x_{Na}	E_{id} (mV)	E_{obs} (mV)
1	0.04103	-	-
2	0.03426	11.13	10.98
3	0.02944	19.64	19.47
4	0.02406	29.99	29.11
5	0.01928	40.25	40.89
6	0.01440	52.36	52.10
7	0.009477	67.84	68.34

E_{obs} = the measured emf
t_e = electronic transference number
E_{id} = ideal emf, value of E_{obs} when $t_e = 0$
R = universal gas constant
T = absolute temperature
n = number of electrons transferred
F = Faraday constant
a_1, a_2 = activities of sodium in the amalgams
γ_1, γ_2 = activity coefficients of sodium in the amalgams

Formation of Tetrabasic Lead Sulfate at Room Temperature

T. G. Chang* and M. M. Wright*

Cominco Limited, Product Research Centre, Sheridan Park, Mississauga, Ontario, Canada L5K 1B4

ABSTRACT

A study was made of the formation of tetrabasic lead sulfate, $4PbO \cdot PbSO_4$, in oxide-sulfate mixtures between room temperature and 80°C for reaction times of up to 4 weeks. Under certain conditions it is a reaction product at room temperature, a finding contrary to the generally held view that this compound can form only above 70°C.

Tetrabasic lead sulfate, $4PbO \cdot PbSO_4$, is, in some cases, a major component in the cured paste of a lead-acid battery plate. In our experience its presence enhances the mechanical strength of the paste, perhaps due to the interlocking of its rodlike crystals. This would not only better preserve the integrity of the plate during the manufacturing process, but it might contribute to a longer cycle life in battery service. Thus, according to Burbank (1), the transformation of $4PbO \cdot PbSO_4$ to PbO_2 during electrochemical formation is largely metasomatic after the original crystals, and Bell Telephone Laboratories (2-6), who have been engaged for years in research on the direct use of $4PbO \cdot PbSO_4$ in battery pastes, have reported that such batteries have a longer cycle life. Although the formation of this compound has been much investigated, there is still uncertainty as to the necessary conditions. It is generally accepted that an elevated temperature (>70°C) is required (2, 7, 8-13). On the other hand, Mrgudich (14), and Bode and Voss (7) have reported that $4PbO \cdot PbSO_4$ was found in pastes cured at room temperature. There is also disagreement in the literature as to whether or not the tetragonal form of PbO can react with sulfates to produce $4PbO \cdot PbSO_4$ (2, 8, 12-14).

The present investigation was carried out to elucidate the effects of temperatures and lead monoxide morphology on the formation of $4PbO \cdot PbSO_4$ in lead-acid battery pastes.

Experimental

Lead monoxide.—Several commercially available lead monoxides were used in this investigation. They are listed in Table I together with data on specific surface area, particle size distribution, and composition. The surface area data were obtained by a 4-point BET method on a Micromeritics Model 2100 surface area instrument and the particle size distribution data by the x-ray sedimentation method on a Micromeritics Sedigraph 500 using Sedisperse as dispersing medium. The proportions of orthorhombic and tetragonal lead monoxide, PbO(o) and PbO(t), were determined by x-ray diffractometry and the metallic lead content by chemical analysis (15). Tetragonal lead monoxide, PbO(t), was prepared by conversion from the orthorhombic form by suspension in boiling water for 1 hr. Reference will be made to these oxides by name of supplier and number, as given in Table I.

Sulfate reagent.—In addition to sulfuric acid the following lead sulfates were used as sources of sulfate ion: normal lead sulfate, $PbSO_4$ (of reagent grade, from Anachemia Chemical Products Limited), monobasic lead sulfate, $PbO \cdot PbSO_4$, and tribasic lead sulfate, $3PbO \cdot PbSO_4 \cdot H_2O$. The latter two compounds were synthesized in this laboratory using the slurry method (1).

The reaction of lead monoxide with a sulfate was studied under three different conditions, as described below. In each case the mole ratio, PbO/SO_3, was 10/1.

Slurries.—Lead monoxide (10g) and the sulfate were reacted as a stirred suspension in 200 ml of water.

Pastes.—For reaction with sulfuric acid, lead monoxide was first mixed with water and then the acid (1.325 sp gr) added, with mixing, over a period of 5-10 min. Mixing was then continued for an additional 5 min. When using the normal and basic lead sulfates, the solids were first mixed together by grinding, packed into a plastic Petri dish, and then water added dropwise without further mixing. In a few cases (which will be indicated) there was further mixing during the addition of water. In all cases the water content was such as to give a wet paste density of 4.0 g/cm^3. All pastes were cured at room temperature in air at 100% relative humidity.

Sediments.—This refers to the reaction in the settled solids of a slurry following a stirring period of a few seconds for its preparation. When sulfuric acid was used, lead monoxide (30g) was first mixed with 50 ml of water and then acid (4.2M, 3.2 ml) added. When a lead sulfate was used, the solids were first ground together and then the water (50 ml) added. After settling, the volume was adjusted to 80 ml by adding water slowly without disturbing the sediments. After a given reaction time, during which the sediments remained undisturbed, the samples were taken out and dried *in vacuo* at room temperature.

X-ray diffraction patterns were recorded on a Philips diffractometer which was equipped with a graphite monochromator (PW 1152) and a pulse height analyzer (PHA, PW 4620). A PW 2113/00 diffraction tube (1.2 kW) with a copper target was employed. The samples were packed in a flat rotating specimen holder (PW 1064/100).

The morphology of the starting materials and products was also studied on a scanning electron microscope, the Etec Autoscan.

Results

Morphology of lead monoxides.—Figure 1 gives the scanning electron micrographs of four commercial lead monoxides: Baker (No. 1a), Anachemia (No. 2a), Fisher, and BDH (No. 4a). Baker oxide No. 1a is very

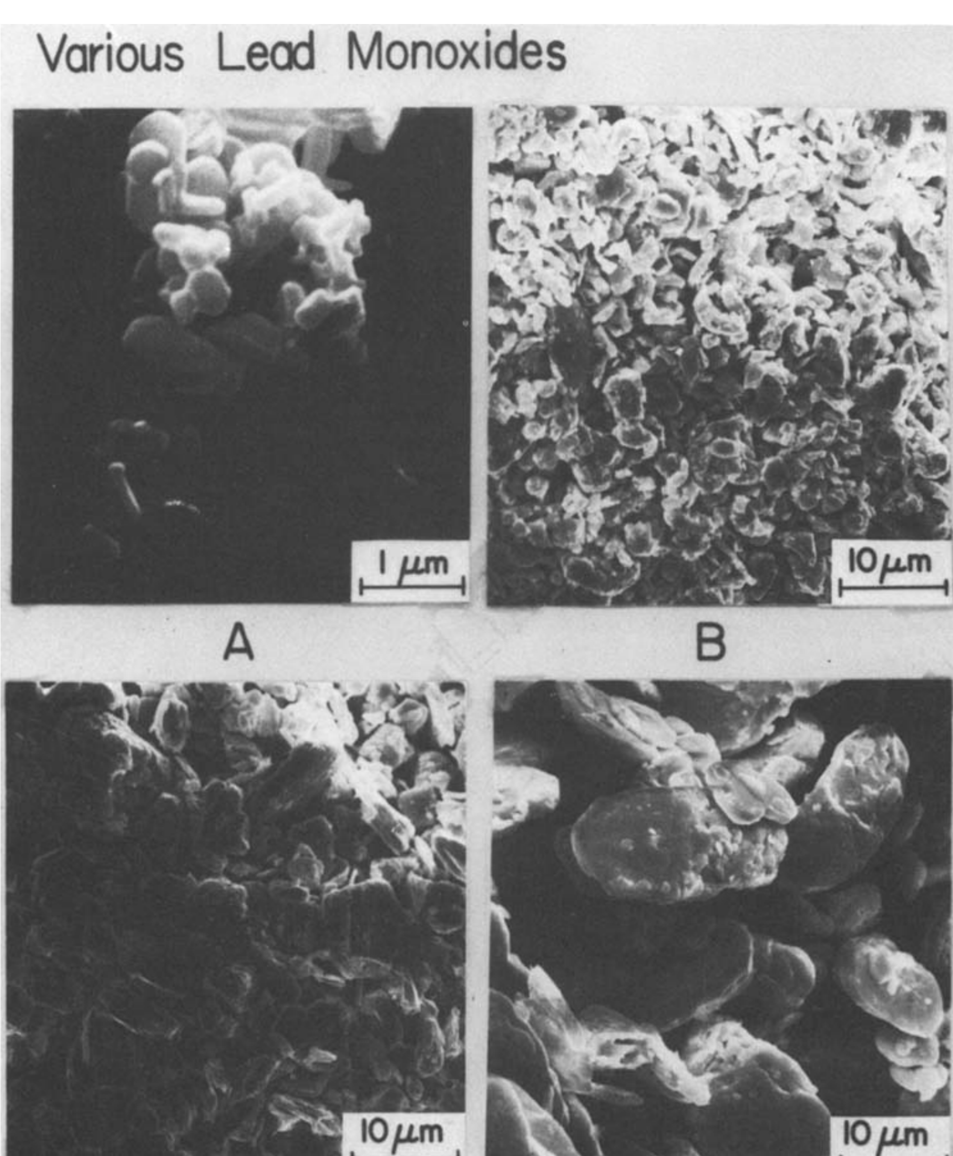

Fig. 1. Electron micrographs of commercial lead monoxides (see also Table I): A. Baker (No. 1a); B. Anachemia (No. 2a); C. Fisher (No. 3); and D. BDH (No. 4a).

fine and well crystallized. X-ray diffractometry showed it to be a pure PbO(o) of high crystallinity. Baker oxides No. 1b and No. 1c of Table I, though of different lot numbers, have the same morphology as No. 1a. Anachemia PbO has particles of nondescript irregular form. Each particle appears to be an agglomerate of numerous small particles. Fisher and BDH No. 4a are similar to the Anachemia oxide, but larger in particle size, especially the latter. However, BDH No. 4b (see Table I; not shown in Fig. 1) is quite different; it is identical in particle size and appearance to the Baker oxides. These latter oxides are believed to be fume oxides (16), prepared by burning a stream of finely divided molten lead. The other oxides are thought to have been made by further processing of a Barton Pot oxide.

X-ray diffractometry showed that Anachemia (No. 2a-e), Fisher, and BDH No. 4a are oxides of low crystallinity, especially Anachemia No. 2a, and the latter two.

Scanning electron micrographs of tetragonal lead monoxide, No. 5 and No. 6, prepared from Baker No. 1a and Anachemia No. 2a (see Table I), are shown in Fig. 2. The particles are small and tabular in form. Many of the crystals of oxide No. 5 appear as regular octahedral platelets.

Production of $4PbO \cdot PbSO_4$.—Slurries.—At room temperature no $4PbO \cdot PbSO_4$ was produced in an agitated slurry within up to 28 days. The result was the same no matter which polymorph of PbO or which form of sulfate (H_2SO_4, $PbSO_4$, $PbO \cdot PbSO_4$, or $3PbO \cdot PbSO_4 \cdot H_2O$) was used in the reaction. The products were found to be, invariably, a mixture of $3PbO \cdot PbSO_4 \cdot H_2O$ and unreacted PbO. When the temperature was raised to 85°C, PbO(o) reacted quickly with each of the sulfates to form $4PbO \cdot PbSO_4$. However, no $4PbO \cdot PbSO_4$ was produced from PbO(t) even at 85°C.

Pastes.—The finely divided and well-crystallized oxides, Baker No. 1a and BDH No. 4b, as shown in Table II, produced no $4PbO \cdot PbSO_4$ at room temperature, even after 28 days. However, the coarser and less well-crystallized Anachemia No. 2a produced some $4PbO \cdot PbSO_4$ after as little as 7 days. The x-ray diffraction patterns of Fig. 3 and 4 show the progress of this reaction. Thus, Fig. 3A shows that in the reaction with H_2SO_4 the only product after 2 weeks is $3PbO \cdot PbSO_4$, as indicated by the peak at 27.3° 2θ. However, after 4 weeks the presence of $4PbO \cdot PbSO_4$ is clearly indicated by the peak at 27.7° 2θ. Figure 3B shows that in the reaction with $PbSO_4$ the peak at 27.7° 2θ is detectable after 2 weeks, and very prominent after 4 weeks. Figure 4 shows that the reaction is faster still between this oxide and $PbO \cdot PbSO_4$; the peak at 27.7° 2θ is observable after only 1 week. The growth of the $4PbO \cdot PbSO_4$ peak at 10.8° 2θ is also shown in Fig. 4. Of the five lots of Anachemia PbO (No. 2a-e), No. 2a was the most reactive; three lots produced no detectable $4PbO \cdot PbSO_4$ even after 4 weeks. The still coarser and less well-crystallized BDH No. 4a was more active yet in the formation of $4PbO \cdot PbSO_4$. Its reaction with $PbSO_4$ is shown in Fig. 5, and the scanning electron micrographs of the products after 2 and 4 weeks are shown in Fig. 6.

The two samples of PbO(t), oxides 5 and 6, produced no $4PbO \cdot PbSO_4$ at room temperature.

When the temperature was raised to 40°C, Baker No. 1a and Anachemia No. 2d, both inactive at room temperature, now gave substantial yields of $4PbO \cdot PbSO_4$, in some cases, in as little as 3 days, as shown in Table II. When the temperature was increased further to 60°C, the only measurable product for these oxides was $4PbO \cdot PbSO_4$. On the other hand, PbO(t) (oxides 5 and 6) was inactive at 40°C; it became active at 60°C, but gave a much lower yield than did lead oxide in the orthorhombic form.

Table II also shows that when $3PbO \cdot PbSO_4 \cdot H_2O$ was used as the sulfate reactant there was no yield of $4PbO \cdot PbSO_4$ at room temperature in any case. Some $4PbO \cdot PbSO_4$ was produced when the temperature was raised to 40°C, but the yield was much lower than when other sulfate compounds were used.

Sediments.—The formation of $4PbO \cdot PbSO_4$ by reaction in sediments over a 28-day period at room temperature is reported in Table III, and x-ray patterns for selected cases are shown in Fig. 7. The results are similar to those for reaction in pastes. The oxides of very

small particle size (*ca.* 1 μm) and high crystallinity (*i.e.*, Baker oxides and BDH No. 4b) produced only $3PbO \cdot PbSO_4 \cdot H_2O$, while the coarsest oxide, BDH No. 4a, gave only $4PbO \cdot PbSO_4$. In general, the yield of $4PbO \cdot PbSO_4$ increased with increase in oxide particle size and decrease in oxide crystallinity.

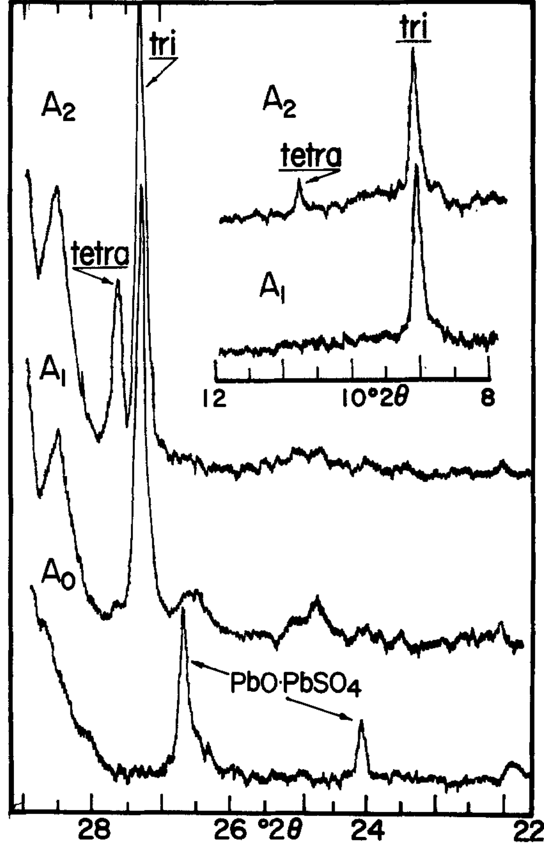

Fig. 4. X-ray diffraction patterns for the reaction of Anachemia PbO (No. 2a) in a paste with $PbO \cdot PbSO_4$, cured at room temperature for 1 week (A_1) and four weeks (A_2). A_0 is the mixture before the addition of water.

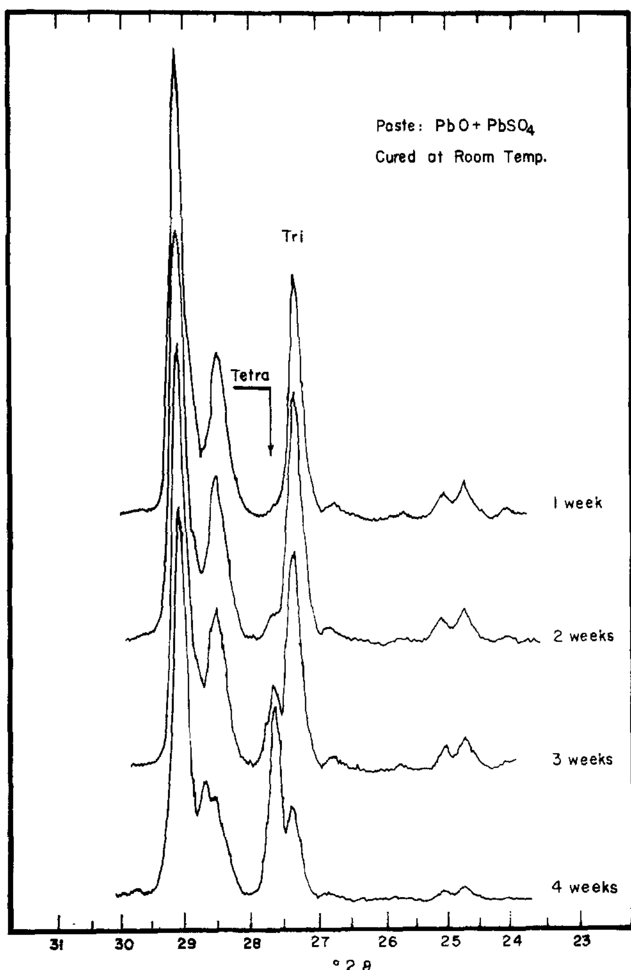

Fig. 5. X-ray diffraction patterns for the reaction products of BDH PbO (No. 4a) in a paste with $PbSO_4$.

Stability of 4PbO·PbSO₄.—When a cured paste is ground and suspended in water, further phase changes usually occur over time. Two examples, A and B (replicates), are shown in Fig. 8. Both pastes were prepared from Anachemia No. 2a and $PbSO_4$ and cured for 4 weeks at room temperature. They were then ground and suspended in water. Figure 8 shows that the ratio of tetrabasic to tribasic sulfate increased with time from 0.6 and 0.3 to 0.9 and 2.4, for pastes A and B, respectively, after 10 days. The amount of tribasic increased after 1 day, thereafter remaining approximately constant for paste A, and decreasing for paste B. In case B the increase in tetrabasic content was obviously at the expense of tribasic.

Discussion

These experiments show that $4PbO \cdot PbSO_4$ can form at room temperature, although the formation rate is low. Given the necessary conditions and sufficient time, $4PbO \cdot PbSO_4$ can be the only sulfate in the product. The necessary conditions are evidently that PbO be in the orthorhombic form and of large particle size and low crystallinity and that the reaction mixture be quiescent. Also associated with the reaction is a long induction period. Thus, Table II and Fig. 3-5 all show that the rate increases markedly beyond the initial 2 weeks. This may be a nucleation period for $4PbO \cdot PbSO_4$.

Some information on the way in which $4PbO \cdot PbSO_4$ forms is revealed by scanning electron microscopy. Thus, in the 2-week paste of Fig. 6, small crystals of $3PbO \cdot PbSO_4 \cdot H_2O$, about 2-4 μm long and 0.5 μm wide, can be seen to lie lengthwise on the surface of large PbO particles, irregular platelike forms about 10 μm in diameter (see Fig. 1D), and completely cover them so that only their outlines show. The few large elongated crystals, 20 μm long and 2 μm wide, are $4PbO \cdot PbSO_4$. It can be seen that one end of these large crystals is almost always attached to a PbO particle. The 4-week paste is different. There is, now, a large number of $4PbO \cdot PbSO_4$ crystals, again, most of them attached to a PbO particle. Some appear to have their ends submerged in a PbO particle, and some to be just emerging from one. It appears, therefore, that the growth of a $4PbO \cdot PbSO_4$ crystal originates at the surface of a PbO particle and that this point of attachment is retained.

* Source of sulfate: A = H_2SO_4, B = $PbSO_4$, and C = $PbO \cdot PbSO_4$.
** W_{tet}/W_{tri} = weight ratio of tetrabasic to tribasic lead sulfate. H = $W_{tet}/W_{tri} > 50$.

Based on these observations the formation of $4PbO \cdot PbSO_4$ may be described as follows. Sulfate ions, SO_4^{2-}, derived from the sulfate reagent, diffuse to the surface of a PbO particle and assimilate into the oxide lattice without precipitation of any known stoichiometric compound (14). (We have found, in agreement with this concept, that with the uptake of sulfate in a paste there is less than the equivalent increase in crystalline sulfate compounds.) An imperfection in the oxide crystal structure may facilitate this process. When the reaction mixture is not stirred the sole means of mass transport is diffusion, which is slow. Therefore, the pH at the surface of the PbO particle can approach its maximum value. A greater solubility and, hence, a higher pH may also be expected if the crystallinity of the PbO particle is low. Moreover, because large particles of PbO are agglomerates of smaller particles, which, in most cases, appear to be fused together, the resultant tiny crevices and holes would also contribute to regions of high pH. Therefore, nuclei of $4PbO \cdot PbSO_4$ may now form on PbO particles, due to the presence of sulfate ion in regions of high pH. This is the induction period. Once the nuclei are formed their growth rate appears to be quite high. If, however, the reaction mixture is stirred the rate of mass transport is greater; the local pH is therefore not as high and conditions for nucleation are less favorable.

PbO(t) has a much lower activity for $4PbO \cdot PbSO_4$ formation than has PbO(o); thus, none is formed below 40°C and, with agitation, none below 85°C. This may be due to its lower solubility (16) and, hence, lower pH, or to a higher energy barrier in the initial absorption or assimilation of sulfate ion. Iliev and Pavlov (13) reported that when the initial reaction mixture contained 30%-60% PbO(t), the rate of formation of $4PbO \cdot PbSO_4$ was highest. They also reported (12, 13) that the polymorphic transformation of PbO(o) to PbO(t), or vice versa, took place during the paste reaction at 35° and 80°C. We have found, however, that the extent of the polymorphic transformation in either direction is negligible. Even when the orthorhombic form, PbO(o), which is unstable under 390°C (16), was used as the starting material, no ap-

Pastes($PbO+PbSO_4$) Cured at Room Temperature

I. Cured for 2 Weeks.

II. Cured for 4 Weeks.

Fig. 6. Electron micrographs of pastes made from BDH (No. 4a) and $PbSO_4$ after being cured at room temperature for, I, 2 weeks and II, 4 weeks. (a, b, and c show different fields in the same sample).

preciable amount of PbO(t) was found in reactions at temperatures up to 85°C, with or without agitation. It appears that the presence of sulfates in the mixture inhibits the transformation.

When crystalline $3PbO \cdot PbSO_4 \cdot H_2O$ is the source of sulfate ion the formation of $4PbO \cdot PbSO_4$ is not observed at room temperature. However, the reaction does occur after the induction period, as shown in Fig.

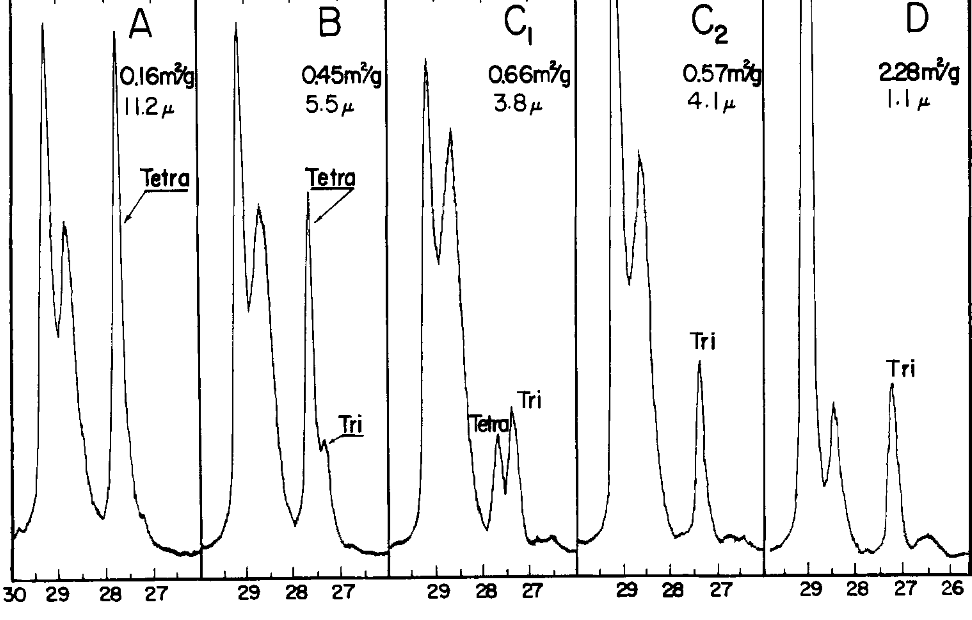

Fig. 7. X-ray diffraction patterns of products in the sediments from the reaction of $PbSO_4$ with oxides: A, BDH (No. 4a); B, Fisher (No. 3); C_1, Anachemia (No. 2a); C_2, Anachemia (No. 2d); D, Baker (No. 1a). The values in the upper right corner of each section are the specific surface area and median particle size of the oxide.

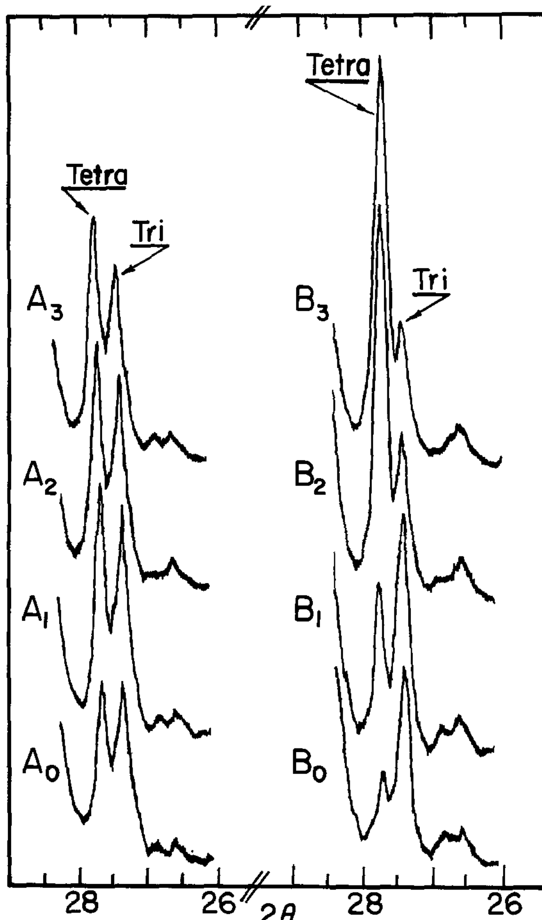

Fig. 8. X-ray diffraction patterns of two examples (A_0 and B_0) of pastes prepared from Anachemia PbO (No. 2a) and $PbSO_4$, and cured at room temperature for 4 weeks. They were then ground and suspended in water at room temperature for 1 day (A_1 and B_1), 4 days (A_2 and B_2), and 10 days (A_3 and B_3).

5 and 8. The nucleation process is evidently much slower for the reaction with crystalline $3PbO \cdot PbSO_4 \cdot H_2O$. This suggests that the nucleation site is the ternary interface between the aqueous phase, a growing structure energetically close to tribasic sulfate and the PbO surface, one that, in a quiescent state, would be well established and have a high pH. With tribasic sulfate as the added reactant, and in a well-crystallized form, such an interface may not readily be formed.

All the evidence seems to suggest that, in the presence of excess PbO, $4PbO \cdot PbSO_4$ is the stable sulfate at room temperature. If so, further studies on the $PbO-SO_3-H_2O$ system, its thermodynamic aspects and potential-pH diagram, are warranted.

All-Solid Lithium Electrodes with Mixed-Conductor Matrix

B. A. Boukamp,* G. C. Lesh, and R. A. Huggins*

Department of Materials Science and Engineering, Stanford University, Stanford California 94305

ABSTRACT

The concept of a novel all-solid composite electrode is presented. One example of such a composite contains a finely dispersed reactant, Li_ySi, in a solid mixed-conducting matrix, $Li_{2.6}Sn$. Repeated charging and discharging of such electrodes without appreciable loss of capacity has been demonstrated. The polarization is found to be comparable to values typical of highly porous electrode systems in molten salt electrolytes.

The use of elemental lithium electrodes in high temperature lithium/metal sulfide battery systems presents serious problems, as it is highly corrosive, difficult to contain, and dissolves in the molten salt electrolyte causing severe self-discharge. These problems can be reduced by using solid lithium-metal alloys which have a lower lithium activity. In order to provide high current densities, these electrodes are typically made as a highly porous salt-filled sponge [Li-Al

* Electrochemical Society Active Member.

Key words: composite, battery electrodes, chemical diffusion, lithium-silicon, lithium-tin.

system (1, 2)], or as a powder contained in a mesh cage [Li-Si system (3, 4)]. Such lithium-metal alloys are often found to lose capacity with cycling.

A different approach, an all-solid composite electrode, which has the potential of being an attractive alternative is presented here. This composite has a microstructure in which a reactant, (*e.g.*, Li_yAl or Li_ySi) is finely dispersed in a solid mixed-conducting matrix, so that there is a large (internal) reactant surface area. The compound that is used as the matrix phase should be a good electronic conductor, should have a high diffusion constant for the electroactive species (*e.g.*, Li), and except for the transfer of the electroactive species, should not react with the reactant phase. It must also be stable over the range of potential at which the reactant is operated. The matrix phase determines and maintains the microstructural morphology of the dispersed reactant, is the current collector, and is also a fast transport medium for the electroactive species, while the reactant acts as the storage system.

While some preliminary experiments have been performed with different combinations of reactants and matrix compositions, the data presented here, showing the feasibility of this concept, deal with experiments done on the $Li_ySi/Li_{2.6}Sn$ system. The important electrochemical and structural parameters are given in the next two paragraphs.

A number of phases exist in the Li-Sn system (5-11). They all exhibit rather high chemical diffusion for Li (12). The $Li_{2.6}Sn$ (or $Li_{13}Sn_5$) phase has the highest chemical diffusion constant, with $\tilde{D}_{Li} = 5 \times 10^{-5}$ increasing to 7.6×10^{-4} cm²/sec with increasing lithium activity at 415°C, which is even greater than typical molten salt values of $1\text{-}5 \times 10^{-5}$ cm²/sec. The stability range of this phase is between 0.390 and 0.286V with respect to lithium at 415°C (5) (for increasing a_{Li}). The position of all Li-Sn phases and two-phase voltage plateaus is given in Fig. 1, together with those for the reactant, Li_ySi. The variation in stoichiometry, δ, for $Li_{13+\delta}Sn_5$, is small, ranging from -0.04 to $+0.025$ with increasing a_{Li} (12). The volume per Sn atom varies with increasing Li content, in some cases causing appreciable volume changes upon the conversion of one Li-Sn phase into the next. The important parameters pertaining to this are given in Table I.

Much doubt has existed about the true compositions of the Li-Si phases. Recent electrochemical measurements in our laboratory (13, 14) and careful x-ray analysis elsewhere (11, 15-18) have shown that the phases in the Li-Si system are $Li_{1.71}Si$ (or $Li_{12}Si_7$) (15), $Li_{2.33}Si$ (or $Li_{14}Si_6$) (16), $Li_{3.25}Si$ (or $Li_{13}Si_4$) (17), and $Li_{4.4}Si$, (or $Li_{22}Si_5$). The stability ranges of these phases with respect to the lithium activity, and the two-phase voltage plateaus according to Ref. (13) and (19-21) are given in Fig. 1. From this figure it is clearly seen that the Si-$Li_{1.71}Si$ two-phase plateau voltage is positioned in the middle of the stability range of the matrix phase $Li_{2.6}Sn$.

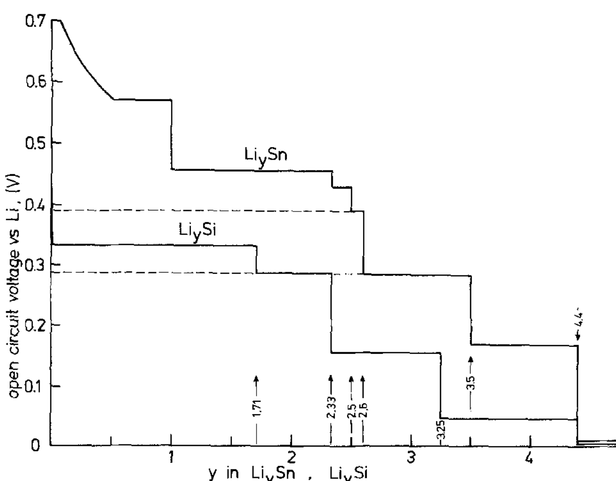

Fig. 1. Coulometric titration curve showing two-phase plateaus and ranges of stability of single phases for the Li-Sn (5) and Li-Si (13, 19-21) systems.

Table I. Crystal structure, unit cell volume, number of formula units per unit cell, crystal volume per Sn atom, and theoretical density for the Li-Sn system

Compound and crystal structure	Unit cell volume (Å³)	Formula units per unit cell	Volume per Sn atom (Å³)	Theoretical density (g/cm³)	Ref.
LiSn Monoclinic	132.2	3	41.1	5.07	(6, 7)
Li_7Sn_3, ($Li_{2.33}Sn$) Monoclinic	367.1	2	61.2	3.66	(8)

$Li_{22}Sn_5$, ($Li_{4.4}Sn$) Cubic	773.9	16	96.7	2.56	(11)

For the Li-Si system the volume per Si atom also varies appreciably among the phases encountered upon increasing the Li content. The volume per Si and the theoretical densities for all Li-Si phases are given in Table II.

Experimental Procedures

The matrix, Li_ySn, was prepared by the careful addition of lithium (99.9%, Alfa) to molten tin (99.9%, Baker) in a molybdenum crucible at ~ 400°C followed by heating to 600°C for 20-30 min. The crucible was closed, but not tightly sealed, with a molybdenum lid. After rapid cooling by removal of the crucible from the furnace, the metallic gray product was broken in a mortar and milled to a fine powder in a ball mill. All handling was done in a helium atmosphere glove box, or in a protective, leak-tight enclosure. No chemical analysis was necessary, as the composition could be readily determined by electrochemical titration.

The matrix material was then mixed and ground with Si powder (99.95%, Alfa) in a mortar, the Si/Sn ratio being 0.617. The particle size of 90% of the powder mixture was smaller than 45 micron. Pellets were pressed from this mixture in either 3/8 in. (0.93 cm) or 5/16 in. (0.794 cm) diameter evacuated steel dies at a pressure of 2700 kg/cm². This resulted in an overall density over 80% of the theoretical value. This is considerably greater than that typically found in finely divided porous electrodes. The pellets were then placed in a molybdenum holder which was tightened around the cylindrical edge of the sample, exposing the flat planparallel surfaces to the molten electrolyte.

Reference and counterelectrodes were prepared in the same manner using an Al/LiAl mixture of nominal

overall composition $Li_{0.82}Al$. The three electrode system (LiAl/Al counter and reference; Li-Sn-Si working electrode) was then placed in the molten LiCl-KCl electrolyte (Lithcoa), contained in an Al_2O_3 crucible in a furnace, the temperature being maintained at ~ 410°C. The electrochemical experiments also were carried out in a helium atmosphere glove box.

Experiments were performed using an Aardvark Model V potentiostat/galvanostat, an Aardvark Model BA-1 buffer amplifier, and a Model 379 PAR digital coulometer. Voltages were measured using a Keithley digital multimeter and a stripchart recorder. Experiments were either performed potentiostatically or galvanostatically.

Experiments and Results

Experiments were performed on electrode systems in which the starting composition of the matrix was $Li_{1.56}Sn$, (or LiSn + 0.74 $Li_{2.33}Sn$). Lithium was added electrochemically to the sample until its potential reached 0.350V with respect to lithium. At this point virtually no lithium has been incorporated in the single-phase Si reactant, as the solubility of Li in silicon has been estimated to be less than 0.36 atomic percent (a/o) at 415°C (13). The matrix then goes through two phases, $Li_{2.33}Sn$ and $Li_{2.5}Sn$, before arriving at the equilibrium composition $Li_{2.6}Sn$. The influence of this recrystallization process upon the mechanical strength of the sample is still under investigation.

The first few charging (adding lithium to the reactant) and discharging (removing lithium from the reactant) cycles were performed potentiostatically, the charging potential being set at 0.300V *vs.* Li and the discharging potential at 0.375 *vs.* Li. The current was integrated by a coulometer and recorded on a stripchart recorder. In this way the capacity of the reactant could be measured. The coulombic capacity was found to be within the experimental error of the calculated value for the Si-$Li_{1.71}Si$ plateau. During the course of the experiment potentiostatic cycles were run in order to monitor the coulombic capacity. It was found that it remained virtually constant over the duration of the experiments (16-20 cycles, one charge and discharge counted as one cycle) indicating negligible capacity loss on cycling.

During this potentiostatic cycling possible slow second phase nucleation was observed for the reactant. At the onset of the charge or discharge cycle the current had an initial high value, which decreased rapidly due to the small change in stoichiometry of the matrix phase which is associated with the instantaneous change in lithium activity. The current then went through a minimum which is probably associated with the slow nucleation of the second phase ($Li_{1.71}Si$ for the charge and Li-saturated Si for the discharge cycle) as under this potentiostatic cycling the reactant is driven into its single-phase regime.

A number of cycles were performed galvanostatically in order to establish the polarization characteristics of the mixed-conducting matrix electrodes. No special precaution was taken with respect to the placement of the electrodes; a simple triangular arrangement was used. In order to start from the same composition, or lithium activity, the electrodes were equilibrated potentiostatically at 0.375V *vs.* Li before charge, and 0.300V before discharge. Thus, as each cycle started with a single-phase reactant, what appeared to be slow second-phase nucleation again was observed as a voltage dip in the polarization at the onset of the charge cycle, and a voltage peak at the onset of the discharge cycle, as shown in Fig. 2.

When the galvanostatic charge and discharge cycles were terminated before reaching the ends of the two-phase plateau, this slow second-phase nucleation was not observed, as both phases were then always present in the reactant (see Fig. 3).

The overpotential as a function of the current density (taking both sides of the sample into account) is shown for a 50% state of charge in Fig. 4. The overpotential was found to be small, of the order of 1 mV per mA per cm² of macroscopic surface area, being slightly larger near the end of the charge or discharge cycle.

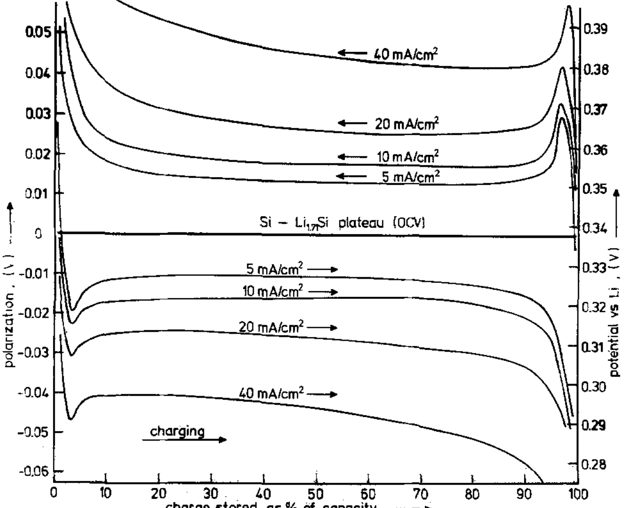

Fig. 2. Electrode polarization as function of the state of charge for several current densities.

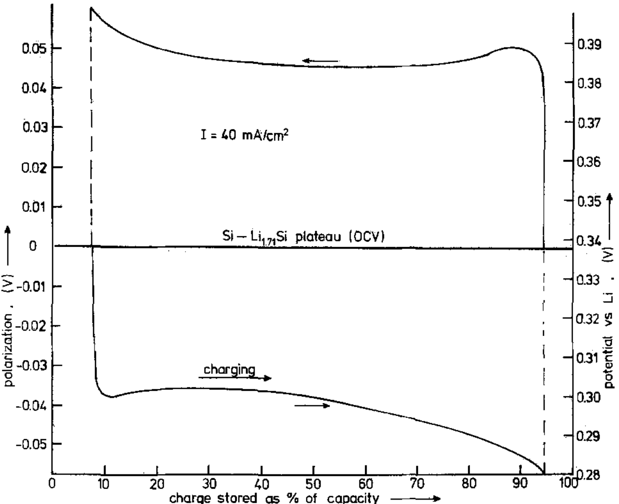

Fig. 3. Electrode polarization as function of the state of charge demonstrating the disappearance of the nucleation related dips and peaks when not cycled to the ends of the plateau.

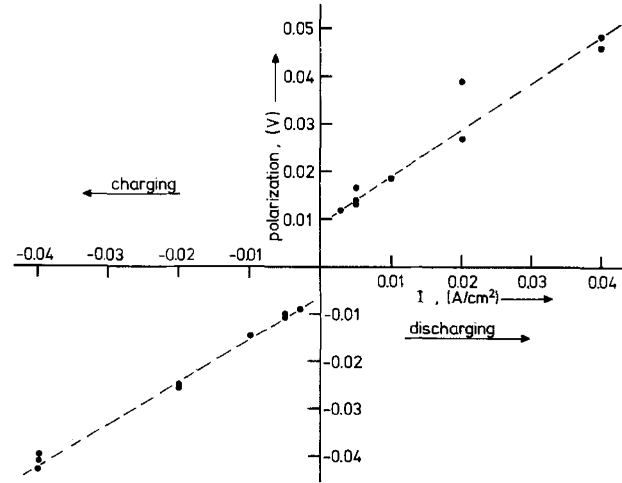

Fig. 4. Electrode polarization as function of the current density for a state of 50% charge stored.

If the matrix electrode is charged with more lithium the potential falls to that of the next two-phase plateau where $Li_{2.33}Si$ begins to form. The matrix could also enter a two-phase region with the formation of $Li_{3.5}Sn$ at about the same potential [0.282V *vs.* Li for $Li_{1.71}Si/Li_{2.33}Si$ (19-21) and 0.286V *vs.* Li for $Li_{2.6}Sn/Li_{3.5}Sn$ (5)].

Figure 5 shows a complete galvanostatic cycle, measured at a current density of 5 mA/cm^2 in which the two additional plateaus can be observed. From the length of these plateaus it follows that the first additional plateau is the $Li_{1.71}Si/Li_{2.33}Si$ two-phase region, as its length is $\sim$ 0.3 times the length of the first, *i.e.*, $Si-Li_{1.71}Si$, plateau. The OCV was measured to be 0.288V at 410°C, the same as found by Ref. (13), but slightly higher than reported by Ref. (19-21). The second additional plateau is associated with the $Li_{2.6}Sn/Li_{3.5}Sn$ two-phase region. Its length was equivalent to about 0.9 times the amount of Sn in the sample. The OCV for this plateau was measured to be 0.276V *vs.* Li, (at 410°C) which is 10 mV lower than reported by (5).

These extended charging and subsequent discharging did not seem to affect the integrity of the sample, or the overall kinetic behavior of the electrode. The coulombic capacity of the first plateau remained virtually unchanged.

Discussion

In the preceding section the feasibility of this mixed conducting matrix electrode concept has been clearly demonstrated. It is, however, important to discuss its merits with regard to the conventional porous, salt-filled electrodes. The solid matrix phase is obviously heavier than the chloride molten salt which typically exists in the pores of electrode structures prepared by the consolidation, or mechanical containment, of powders (the density of $Li_{2.6}Sn$ is 3.47 g/cm^3, whereas the density of the eutectic composition of the LiCl-KCl salt is 1.66 g/cm^3). The matrix phase acts, on the other hand, simultaneously as the current collector, so no additional material needs to be included for that purpose. Nor is a metallic (*e.g.*, nickel, which has a density of 8.90 g/cm^3) sponge necessary to hold the reactant powder in place.

While this may lead to a slight loss of weight efficiency in this approach, there could be kinetic advantages, as the chemical diffusion coefficient is greater in this metallic matrix than the typical value of about 10^{-5} cm^2/sec for molten salts. In this way the possibility of electrolyte freezing inside the pores of the salt-filled electrodes, due to a local depletion or enrichment of Li in the eutectic electrolyte (22) is avoided.

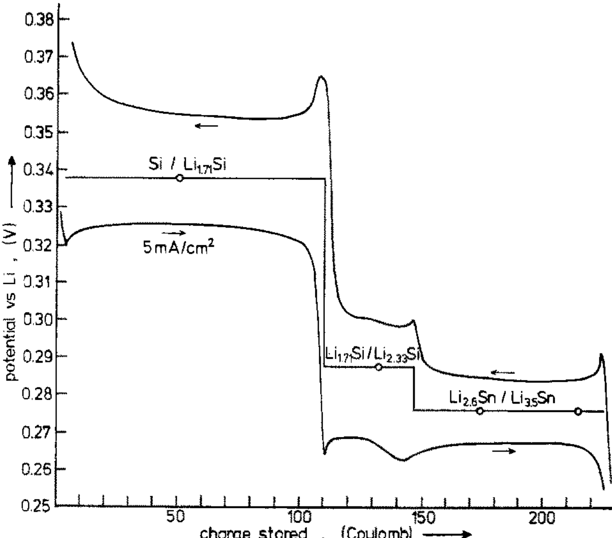

Fig. 5. Electrode polarization at 5 mA/cm^2 as function of the charge stored during a complete charge-discharge cycle to lower voltages. The circles represent measured open-circuit voltages.

The theoretical coulombic capacity of such an electrode with an Si/Sn atom ratio of 0.62, operated only within the first Li-Si two-phase region is 0.46 A-hr/cm^3. In comparison, the "contained powder" Li-Si electrode of Seefurth and Sharma (3, 4) contained 0.68 A-hr/cm^3 when charged to the same Li/Si atom ratio. If the composite electrode were utilized to higher Li contents, *i.e.*, to $Li_{3.5}Sn$ and $Li_{2.33}Si$, which involved reaction with both the silicon and the tin, the capacity increases to 0.93 A-hr/cm^3. Under these conditions, the pure Li-Si electrode of Seefurth and Sharma also has 0.93 A-hr/cm^3. The measured overvoltages were somewhat larger than those measured by Seefurth and Sharma (3, 4) although no corrections for electrolyte resistance were applied.

Although there have not been very many experiments to data, present indications are that there is negligible loss of capacity upon cycling electrodes with this type of composite structure. This is what would be expected if the microstructure returned to its original state after the completion of each full cycle.

This approach avoids the typical problems of densification and particle growth which often play a role in decreasing the useful capacity in conventional liquid-permeated electrode structures.

Further work is being undertaken to investigate the microstructural features of the operation of such composite electrodes as well as their range of applicability.

Influence of the Growth Conditions of Al_2O_3 Passivating Layers on the Corrosion of Aluminum Films in Water

J. Grimblot[1] and J. M. Eldridge

IBM Research Laboratory, San Jose, California 95193

ABSTRACT

The effects of water vapor on the oxidation kinetics of UHV-deposited Al films have been investigated using *in situ* ellipsometric measurements. For a given exposure time, the presence of ~33% H_2O increases the Al_2O_3 thickness by ~50% and roughly doubles the extinction coefficient of the oxide. We attribute the nonzero extinction coefficients (with a range in values from 0.05 to 0.18) as being due to the presence of excess Al in the oxide. The "wet"-grown Al_2O_3 layers oxidize at least twice as fast as "dry"-grown layers on storing of samples in a normal laboratory environment. Furthermore, the relative effectiveness of the passivation provided to the underlying Al is greater for the "dry"- than the "wet"-grown Al_2O_3 layers. Gravimetric and electrical resistance data from samples exposed to an aqueous corrosion test are given to support this.

The lifetimes of Al conductor lines in integrated circuits is highly dependent on the quality of the thin (~20Å) air-formed Al_2O_3 layer. In an effort to better understand processing effects on Al_2O_3 quality as a passivant, *in situ* ellipsometry studies have been used to evaluate the growth and optical properties of oxide layers grown in dry O_2 on UHV-deposited Al films (1). The sensitivity afforded by this approach has clearly shown that the reaction rate is not significantly pressure sensitive and only moderately temperature dependent.

In this paper we report on the effects of water vapor on the oxide growth and properties, as determined by *in situ* ellipsometric measurements. Electrical resistance and weight change determinations were carried out *ex situ* to compare the passivating characteristics of "dry" and "wet" grown Al_2O_3.

Al films (2000Å thick) were deposited under UHV conditions as described elsewhere (1), and exhibited a very strong (111) preferred orientation. The effects of moisture [up to 33 volume percent (v/o)] on Al oxidation at 274°C is shown in Fig. 1. The data are presented according to a direct logarithmic growth law, although our earlier analysis (1) suggests the well-known Mott-Cabrera inverse log law is probably more correct. Note that the presence of 33% water increases the oxide thickness by roughly 50%.

As reported for the Al-dry O_2 reaction (2), the oxide layer is slightly light-absorbing at $\lambda = 5461$Å. For dry O_2, the optical extinction coefficient (k) of thin Al_2O_3 layers varies from 0.07 to 0.05 as the oxide grows from roughly 20 to 30Å. For "wet" grown oxides, k varies from ~0.18 to 0.10 for the same thickness range. We attribute the small light absorption as being due to the presence of a very small (~10^{19}/cm³) concentration of Al atoms in excess of the stoichiometric ratio. Similar effects have been seen in the In_2O_3-In system (2).

We have attempted to use *ex situ* ellipsometric measurements in an effort to compare the relative passivities provided by the "dry" and "wet" Al_2O_3 layers. However, the results were quite difficult to interpret, perhaps owing to the formation of quite discontinuous islands of hydroxide, pits, blisters, etc. Indeed, it may only be possible to study the very initial reaction of materials in corrosive solutions via ellipsometry (3). Accordingly, we used ellipsometry here to measure thickness increases of the above oxides due to prolonged exposure to laboratory air (*i.e.*, ~25°C, 40-50% RH, and some unknown levels of corrosive pollutants). For periods up to roughly 40 days, we found the "wet" Al_2O_3 layers continued to grow in ambient air at ~1 Å/day, whereas "dry" Al_2O_3 grew at ~0.4 Å/day.

In an effort to better differentiate between the reactivity of these oxides, more extensive tests were conducted using various aqueous reactive ambients. We regard the aqueous test results as significant because: DI-water rinses are integral to all IC processing (4);

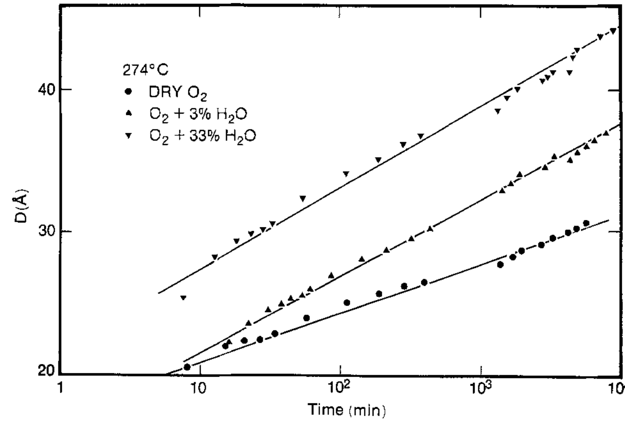

Fig. 1. Plot of the thickness as a function of log time (min). ● Dry O_2 (50 Torr) at 274°C; ▲ O_2 + 3% H_2O (50 Torr total pressure) at 274°C; ▼ O_2 + 33% H_2O (100 Torr total pressure) at 274°C.

and, adsorbed water layers lead to Al corrosion in electronic circuits of all types (5). For this purpose, weight change and resistance increase measurements were used to monitor the effects of exposure of films to various aqueous solutions. In each case, three nominally identical samples were used to minimize effects of specimen inhomogeneities. Experiments were conducted using samples with roughly the same Al_2O_3 thickness: 30Å for "dry" oxide (formed in 4200 min at 274°C); and, 35Å for "wet" oxide (grown in 200 min at 274°C with 33% H_2O in O_2).

Figure 2 shows weight losses of various samples due to immersion in different solutions at room temperature. The NaF solution is too corrosive, removing entire 2000Å thick Al films (*i.e.*, ~230 μg) in 3-20 hr depending on concentration. The KCl solutions are less corrosive but still sufficiently large as to mask significant differences amongst the oxide layers.

For our comparisons, we finally decided to use a DI H_2O solution containing Al^{+3} ions (obtained by boiling the water with an excess of ultrapure Al slugs). In this way, we hoped to minimize effects due to dissolution-precipitation processes, even though the solubility product of $Al(OH)_3$ in water is very low (6) at room temperature. The weight change *vs.* time curves in Fig. 2 for this solution are quite complex and beyond our total understanding at this time. This is not unexpected in view of the well-known complexities of the $Al\text{-}H_2O$ interactions (7-8). However, two well-defined regions emerge here. In the first, an incubation period (IP) appears with no noticeable weight loss. We attribute the IP to the time needed to hydroxylate the Al_2O_3 since this period is smaller for the "wet" oxide. The IP characteristics of Table I show this value decreases with storage of "dry" grown Al_2O_3 samples, becoming essentially identical to freshly prepared "wet" oxide after roughly 25 days. Since hydroxylated Al_2O_3 layers have a more open structure wherein corrosive species diffuse more readily, the above observations may have an important practical aspect. Namely, so-called "dry" processing and subsequent storage in inert ambients should enhance the passivity of Al conductor lines. Such effects are likely to become more important as VLSI technologies are developed where all reasonable precautions should be taken to prevent metal corrosion with attendant yield loss, etc.

The second stage of the result in Fig. 2 is characterized either by weight loss and/or small hole formation

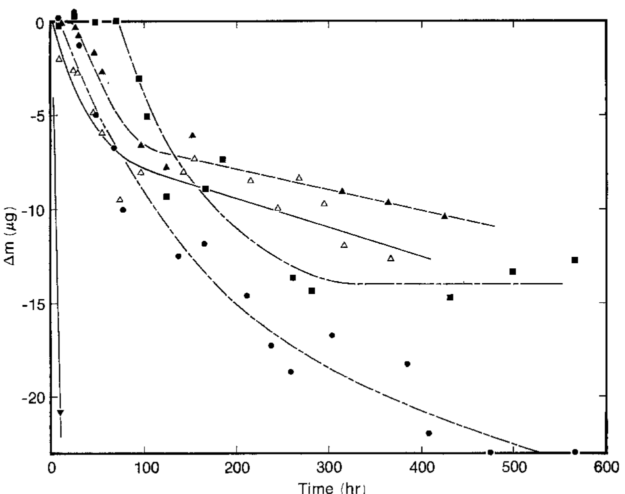

Fig. 2. Plot of weight change in μg (averaged over 3 identical samples) as a function of time (hr). ▽ "Dry" oxide in NaF (0.01m); ● "dry" oxide in KCl (0.1m)—5 days between preparation and corrosion test; ■ "dry" oxide in water—4 days between preparation and corrosion test; ▲ "dry" oxide in water—25 days between preparation and corrosion test; △ "wet" oxide in water—21 days between preparation and corrosion test.

Table I. Characteristics of the incubation period

Sample	Time between preparation and corrosion test (days)	Solution	Incubation period (hr)	Symbol used in Fig. 2
Dry	5	KCl (0.1m)	≃20	●
Dry	4	Water ($+Al^{3+}$)	≃75	■
	12	Water ($+Al^{3+}$)	≃60	
	25	Water ($+Al^{3+}$)	≃15	▲
Wet	1	Water ($+Al^{3+}$)	≃25	
Wet	21	Water ($+Al^{3+}$)	0	△

through the films. We then expect that adhesion of some corrosive products is poor to the glass substrate. It is probably one of the reasons why our findings disagree with previous results (7) indicating weight gain by immersion of bulk Al sheets in water (from 20° to 80°C). Since hole formation seems to occur randomly, it is difficult to compare absolute weight losses from different samples.

Probably similar effects have to be invoked to explain the resistance variations of typical "dry" and "wet" samples when immersed in the test solution (Fig. 3). Hole formations in the aluminum film and insulator produce growth that can give acceptable explanations of the observed resistance increases, but the presence of a sharp maximum after ≃40 hr of immersion is still unclear. Note also that the "wet" oxide samples exhibit a larger resistance increase with time, similar to the weight change results of Fig. 2. In addition, the "wet" oxides exhibit much smaller IP values, as expected.

In conclusion, this paper clearly shows that introduction of water vapor in O_2 modifies unambiguously the kinetics of aluminum film oxidation. Moreover, the "wet"-formed oxide is less stochiometric because its extinction coefficient is relatively higher. Secondly, the "wet" Al_2O_3 layers are less effective as passivants on storing Al films in a normal laboratory environment. Thirdly, immersion of the samples in DI water yields an incubation period which can be observed gravimetrically and electrically. Both techniques show that IP is higher for the "dry" compared to the "wet" oxide. Since significant corrosion only starts after the completion of this IP, we conclude that the fresh "dry" oxide is more protective than the "wet" oxide.

High Rate Electrodeposition of Niobium from Molten Fluorides Using Periodic Reversal Steps and the Effects on Grain Size

Uri Cohen[1]

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

Application of periodic reversal (PR) technique, in which a cathodic (depositing) step is followed by an anodic (polishing) step, was found very beneficial to the increase of electroplating rate of coherent niobium. With no mechanical agitation, the application of the PR technique facilitated an electroplating rate increase by a factor of about 10 over the direct current method. The morphology of the deposits was found to be of the columnar structure. The columns became more oriented along the [100] direction, and of smaller diameters as the rate of electrodeposition increased. Unexpectedly, beyond a certain rate and under certain conditions, the columnar grains became large once again. Under such conditions a pronounced heteroepitaxial effect of the substrate (Cu) grains on the deposit grain size and orientation was observed.

Niobium (1, 2), as well as other refractory metals (2-7), were first demonstrated by Senderoff and Mellors to be capable of electroplating in coherent and dense coatings from molten alkali fluoride solvents. In addition, Senderoff and Mellors also investigated the electrode reactions of niobium (8) and the other refractory metals (3, 5) by chronopotentiometry. They reported three steps in the reduction of Nb(V) (which is used as the solute source): $Nb(V) \xrightarrow{e^-} Nb(IV) \xrightarrow{3e^-} Nb(I) \xrightarrow{e^-} Nb$. They also investigated its anodic oxidation to the hexavalent state on inert anodes (9). The decomposition potentials of the solute salt K_2NbF_7 in the molten alkali fluoride solvent, as well as those of several other metal salts, were measured by Cohen (10, 11). In addition, Cohen also studied the behavior of niobium electrode by slow cyclic voltammetry and by a newly developed technique, reversal current step voltammetry (RCSV) (10). The latter technique provides steady-state polarization curves while greatly eliminating the deleterious effects (13-15) associated with prolonged electrodeposition at high rates onto solid electrodes. These studies showed that niobium is capable of both electrodeposition and electropolishing in the same molten fluoride electrolyte.

Molten alkali fluorides, due to their high decomposition potentials (>3V) (10, 11), provide inert media from which many metals and alloys can be readily deposited. Some of these metals and alloys cannot be deposited from other solvents with smaller decomposition ranges (such as water) due to the latter decomposition. This advantage, as well as several other attractive features of the alkali fluoride solvents (such as the fluxing effect of metal surface oxides, the complex ion stability, the high ionic conductivity, and the low melting point eutectics) have been discussed previously (10, 12).

Electrodeposition with the periodic reversal (PR) current was first developed by Jernstedt (16, 17). The technique was originally applied to the plating of Cu, Ag, and brass from their aqueous cyanide baths. It was further investigated by other workers (18-25). Several review papers are now available (26-28). The technique was shown to be particularly useful for coating properties such as coherency, density, smoothness, brightness, uniformity, and the reduction of internal stresses. Very low frequencies, typically in the range of few cycles per minute, have been found most beneficial. The anodic current magnitude has not, in general, exceeded the cathodic current magnitude. The average PR plating rate has been, in general, about the same or somewhat higher than the conventional direct current (d-c) plating. The PR method was reported to be very beneficial to copper plating from its cyanide bath (27, 29), but to have no such effects when applied to the acid copper sulfate bath (30). Despic and Popov (31) related the positive PR effects to systems operating under diffusional control of the deposition process, but to have no such effects with systems operating under activation-controlled deposition process.

In the present work, much larger anodic than cathodic current magnitudes were employed, and the anodic periods were shorter than the cathodic periods.

[1] Present address: Department of Materials Engineering, Technion, Haifa, Israel.

Key words: fused salts, electrode, current density, electrodeposition.

The larger anodic current magnitude ensured polishing rather than etching. The large current magnitudes were facilitated by the large decomposition potential range of the alkali fluoride solvent.

Recently, Jackson and Miller (32) described a new method of thermal cycles for remelting and regrowth. Utilizing *in situ* microscopic observations of the growing crystals, they reported significant improvements in the crystal perfection and grain size increase. Several mechanisms which they suggested for the cyclic thermal growth seem to be also valid for some observations made in the present study.

The basic principles of the PR steps technique, utilized in this study, are schematically illustrated in Fig. 1. Figure 1(a) defines the operating parameters of a PR-current signal. Similar parameters are likewise defined for PR-potential signal. Figure 1(b) shows the effect of a PR cycle. The original flatness of the solid-liquid interface prior to the cycle ($t = 0$) is restored at the end of the cycle ($t = t_C + t_A$). Thus, although the cathodic pulse may drive into the diffusion-controlled regime, giving rise to interface protrusions forming after some initiation period (31, 33, 34), the latter may then be taken off during the following anodic polishing pulse. The next cathodic deposition step will start again with a fresh smooth and flat interface.

Experimental

The experimental setup has been described in detail elsewhere (10). An inert atmosphere of purified helium was maintained in the vacuum-tight chamber (with a slow flow rate). Three electrodes insulated from each other and from the chamber, could be replaced through special "rescue chambers" without having to open the main chamber. The latter consisted of an Inconel can fitted with an O-ring seal and a water cooled top flange. The Inconel can was inserted into an electrically heated tube furnace. The crucible was typically made of Ni or Mo metals, and was protected from contamination originating on the Inconel walls by an Mo liner.

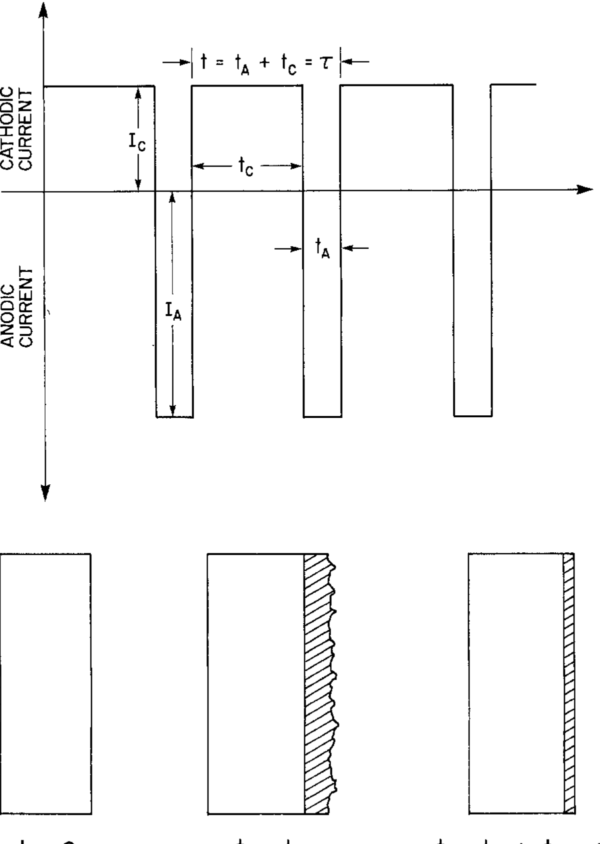

Fig. 1. (a, top) PR-current (PRC) signal and its parameters, (b, bottom) schematic profile cross section of the cathode and its coating during a PR cycle.

A convenient salt mixture containing 6 mole percent (m/o) K_2NbF_7, 10 m/o KHF_2, and balance LiF:KF (47:37 m/o), was first melted in a manner which was described elsewhere (10, 35). A niobium anode piece was then immersed in the melt in order to equilibrate the niobium valences (1)

$$Nb + 4Nb(V) = 5Nb(IV) \qquad [1]$$

A pre-electrolysis run was then performed with a copper strip cathode. This pre-electrolysis substantially reduced the more noble metal impurities. Thus, an initial contamination of the niobium deposit with 0.2 weight percent (w/o) Fe, dropped to below 0.05 w/o Fe after an overnight electrolysis at 10 mA (total bath of 3 moles).

A practical quasi-reference electrode[2] was the redox couple electrode Cu/Nb(V), Nb(IV). The reaction [1] was shown (1) to reach equilibrium at a mean valence of 4.5. The ratio of $[Nb(V)]/[Nb(IV)] \simeq 1$ suggests a stable redox potential since concentration fluctuations will only slightly affect the redox potential. The anode was always a dissolving niobium sheet, and both copper and molybdenum strips were used as substrates.

The electrical signals for both electrodeposition and voltammetric studies were produced by the combination of a potentiostat and a signal programmer PAR 173/PAR 175.

The samples were analyzed by x-ray diffraction (XRD) for preferred orientation. Scanning electron microscopy (SEM), and sample sectioning and metallography were used to study the morphology. The sectioned samples were mounted in a plastic mold and ground and polished. They were then etched in a solution which contained H_2O (50 ml), HF (20 ml), HNO_3 (10 ml), and H_2SO_4 (15 ml). Superconducting transition temperature measurements were performed by Professor Geballe's Cryogenic Group at Stanford University.

Results

Electrodeposition at constant current.—Constant current electrodeposition experiments were done at 750° ± 5°C, from a solution of 6 m/o K_2NbF_7. No mechanical agitation was used. Figure 2 shows a sample which was prepared during the pre-electrolysis purification stage. A constant current density of 3.3 mA/cm^2 was applied. The deposit was dense and coherent. Its cross section reveals a columnar microstructure, and XRD analysis of the as-deposited sample indicated strong preferred orientation along the [100] direction. The deposit had a light gray matte color, and was of dull appearance due to its surface roughness. The unusual pyramidal morphology is believed to be due to the adsorption of impurities. Following the purification stages, the application of a constant current density of 5 mA/cm^2 to the pure solution yielded the sample shown in Fig. 3. This deposit was of high quality but had also a dull appearance. Application of a constant current density of 25 mA/cm^2 resulted in a deposit revealing the onset of deterioration beyond a thickness of about 100 μm. The deposit is shown in Fig. 4. An upper limit of about 25 mA/cm^2 on the useful range of constant current was thus established.

Electrodeposition with periodic reversal (PR) pulses.—Experiments with PR were also performed with a solution of 6 m/o K_2NbF_7, and at 750° ± 5°C. Cu and Mo strips of 1 cm width were used as cathodes, and

[2] The potential of immersed metal Cu in this melt is not well defined. The slightly soluble (8) species Nb(I) may greatly affect it. However, the potential of this electrode reaches a steady-state value after a few minutes of immersion. That potential is stable (within about ±1 mV) over periods of several days. As this quasi-reference electrode was only used to monitor variations in the working electrode potential over short durations, its actual potential was considered of secondary importance.

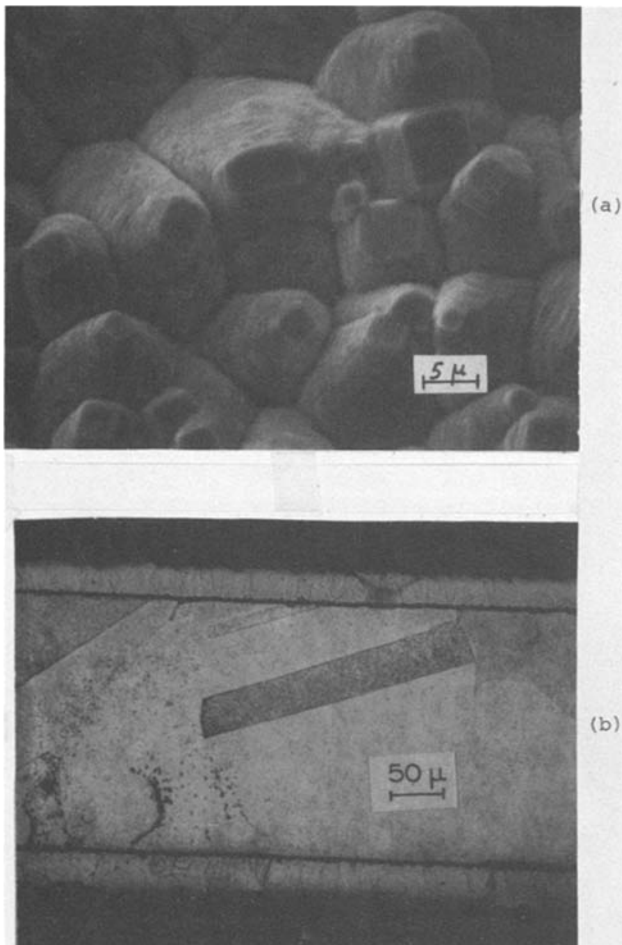

Fig. 2. Nb deposit obtained by constant current (d-c) pre-electrolysis at $i_C = 3.3$ mA/cm^2. (a) SEM photograph of the coating surface, (b) optical micrograph of a vertical cross section.

a niobium sheet was used as a dissolving anode. Cu/Nb(IV), Nb(V) was used as a quasi-reference electrode. No mechanical agitation was used. Both methods of PR-potential (PRP) and PR-current (PRC) were examined. Figure 5 shows the traces of a PRP controlling signal and the current response with time. Figure 6 shows the traces of a PRC controlling signal and the potential response with time. The deposit shown in Fig. 7 was obtained from the application of the PRP signal of Fig. 5. The deposit was of high quality with a very smooth, polished, and shiny appearance, but had etch pits on the surface. The average cathodic current density on this sample was about 90 mA/cm^2. The average anodic dissolution current density was about 110 mA/cm^2. The Q-ratio for this sample was about 4.1, where Q is defined by

$$Q = |Q_C/Q_A| = |t_C i_C/t_A i_A| \quad [2]$$

The signal parameters are defined in Fig. 1.

Figure 8 shows another sample which was grown by PRP. For this sample, however, the average deposition current density was 300 mA/cm^2, and the Q-ratio was about 8.0. The bad morphology of this deposit is seen in the poor filling and coherency. The more the deposit grows, the worse its quality becomes.

PRC offers a better control of the Q-ratio as the currents do not drift during the deposition run. Figures 9 and 10 show the effect of reducing the Q-ratio when PRC steps were applied. The sample shown in Fig. 9 was grown by the PRC signal of Fig. 6 with $Q = 4.0$. The sample shown in Fig. 10 had $Q = 2.0$. Both samples were grown with identical cathodic current density, $i_C = 300$ mA/cm^2.

Increasing the frequency showed a slight improvement of the deposit brightness, but decreased uniformity. A sample which was prepared under similar conditions to those of Fig. 10, but at a ten times higher frequency, yielded a somewhat brighter deposit on the flat surface. However, large dendrites were found on the strip edges, due to the higher local current density there.

Concentration effects.—A mixture containing 0.8 mole K_2NbF_7, 0.1 mole KHF_2, and 0.1 mole LiF (total of 1 mole) was heated and melted according to a procedure previously described (10, 35) (on cooling, the first freezing was observed at 705° ± 5°C). The niobium valences were then equilibrated with niobium metal according to (1). A dissolving Nb anode was used and the cathodes were either Cu or Mo strips.

Using a PRC signal to deposit Nb from the 80 m/o K_2NbF_7 solution was less favorable than from the 6 m/o solution. Figure 11 shows samples which were grown with $i_C = 50$ mA/cm^2 and $Q = 2.0$ from the 80 m/o solution. The deposit was shiny and of high quality and coherence. However, at higher PRC cathodic current densities, large dendrites began to appear on the substrate edges, and an "umbrella" of deposit rapidly grew at the liquid surface perpendicular to the substrate surface. Thus the maximum deposition rate obtainable from the highly concentrated solution is significantly lower than from the 6 m/o solution. The Nb dissolving anode, after operation in the 80 m/o solution, is shown in Fig. 12. Notice the highly polished appearance of this anode.

Superconductivity tests.—Superconducting transition temperature, T_c, was measured by magnetic suscepti-

bility. Both frequency shift and oscillation amplitude methods were utilized (36).

Strongly oriented deposits along the [100] direction with fine columnar grain structure, such as seen in Fig. 7, revealed wide transition temperature interval, $\Delta T_c = 5.2\text{-}9.1$ K. The interval decreased as the grains became larger, less oriented, and less coherent. Thus, the deposit shown in Fig. 10 had $\Delta T_c = 8.3\text{-}9.1$ K, and the one shown in Fig. 4 had $\Delta T_c = 8.8\text{-}9.15$ K. The high transition limits indicate that the deposits were very pure. For a comparison, the impure Nb deposit which was obtained during the pre-electrolysis stage (shown in Fig. 2), had only $\Delta T_c = 7.9\text{-}8.4$ K. The latter contained between 0.2-0.05 w/o of Fe, as revealed by electron microprobe analyses before and after the deposition, respectively. Analysis by electron microprobe of Nb deposits with high T_c failed to reveal any impurities (detection limit of about 0.01 w/o).

The superconducting transition temperature ranges, along with other relevant properties and preparative parameters of representative samples, are summarized in Table I.

Discussion

Anodic dissolution of niobium.—Anodic and cathodic polarization curves of niobium electrode in molten fluorides were described elsewhere (10). The anodic curve was nearly linear for current densities below about 5 A/cm². The etch pits observed in Fig. 7(b) are believed to be due to an insufficient anodic current density pulse (110 mA/cm²). This sample was prepared from a 6 m/o K_2NbF_7 solution in which the rate of the anodic dissolution was probably insufficient to reach a level of saturation and passivity. The dissolution was therefore of a discriminative etching nature. Such pitting was not observed when higher anodic current densities were used. The samples shown in Fig. 9-10 were prepared with anodic current pulses of 375 mA/cm². It is of interest to note in this context that the niobium anode of Fig. 12, which was used in the 80 m/o solution of K_2NbF_7, was very smooth and shiny. Relatively low anodic current pulses were applied to this anode (75 mA/cm²). However, grain boundaries and other features (dislocations?) related to preferred dissolution are clearly observed. The very concentrated solution is expected to enhance passivity due to saturation of anodic products. An insoluble salt film covered this anode when it was removed from the molten bath. When immersed in a dilute HCl solution, the film dissolved with a vigorous hydrogen liberation. It is believed that a lower niobium valence salt such as NbF (8) constituted the film. Hydrogen evolution was then a result of the reaction $Nb(I) + 4H^- = Nb(V) + 2H_2$. Anodic current densities in excess of 100 mA/cm² are believed to be essential for successful electropolishing.

Effects of PR plating on the deposition rate.—The definition of the plating limiting current density (not to be confused with the diffusion-limited current) is not unambiguous. It is based on the surface roughening which is also a function of the deposit thickness. Thus, for a very thin deposit, very high current densities might be used without appreciable surface deterioration. On the other hand, for very thick coatings, much lower current densities may cause severe surface roughening. Ideally, the limiting current density should be determined only for well-defined surface roughness and thickness of the deposit. Many other parameters, such as substrate surface preparation and composition,

Fig. 5. PR-potential (PRP) for the deposition of Nb from 6 m/o K_2NbF_7. $\eta_C = -70$ mV; $t_C = 50$ sec; $\eta_A = 50$ mV; $t_A = 10$ sec; $Q \cong 4.1$.

temperature, bath concentration and purity, and mechanical agitation may appreciably affect the deposit character and vary this definition, accordingly.

Senderoff and Mellors (1) reported a constant current density range of 5-125 mA/cm² for the electrodeposition of coherent niobium. However, they did not report some important parameters such as the mechanical agitation. In this work, under the stated operating variables, the limiting constant current density was found to be between 5-25 mA/cm². This definition is specified as follows: no mechanical agitation, copper strip substrate which was chemically polished in HNO_3/HF mixture (7:3), 750°C, and 6 m/o K_2NbF_7 in the KF-LiF solvent. A deposit thickness of at least 100 μm, and the appearance of local macrodeterioration were used as criteria. Thus, Fig. 3 shows a stable growth at 5 mA/cm², whereas the onset of surface deterioration is observed in Fig. 4 of a sample which was grown at 25 mA/cm².

The effects of the PR variables were not comprehensively investigated. Several trends, however, were clearly observed. It was found that the most important parameter was the Q-ratio (defined by [2]). The closer was Q to unity, the better were the coherency and smoothness of the deposits. The PR-potential (PRP) method was found hard to control since the currents varied in time and, as a result, the Q-ratio varied too. It was found desirable to use anodic pulse amplitudes as high as possible to ensure electropolishing rather than electroetching. Anodic current densities of $i_A >$ 100 mA/cm² were found essential for successful electropolishing. The pulse periods, t_C and t_A, were found to have influence on the Q-ratio mostly through their ratio t_C/t_A. Very long periods, $t_C \geqq 1$ min, were found to be deleterious due to the formation of large protrusions which could not be completely removed by electropolishing. Frequencies from about 1 cycle per minute to about 1 cycle per second were investigated. The increase of the frequency showed some improvement in the brightness and coherency, but fast deterioration

at the edges (with higher local current density) was also observed. The diminution of the beneficial effects of the PR technique with the increase of the frequency is believed to be due to the growing share of the nonfaradaic currents (*e.g.*, double layer charging) with the frequency increase. The current spikes of Fig. 5 are probably due to such currents. The net result is the lessening of the available current to remove the interface protrusions during the anodic pulses. It may be noted that the high values of these current spikes do not appear to adversely affect the deposit morphology. It is possible, however, that they facilitate nucleation and thus finer grain size. The best results were obtained with cycles of periods in the range of 3-50 sec.

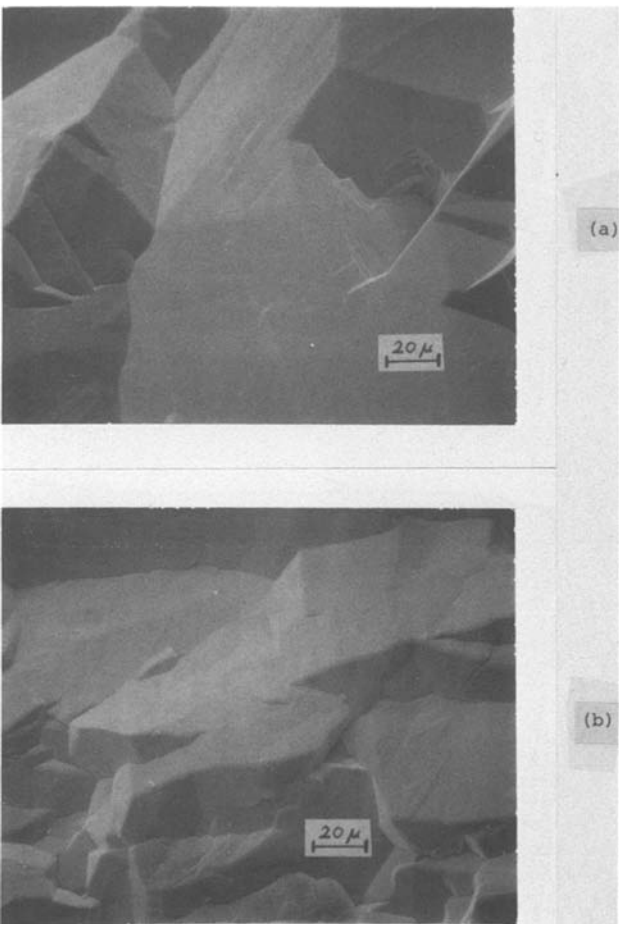

Fig. 11. SEM of Nb deposit surface. 80 m/o K_2NbF_7 solution; $i_C = 50$ mA/cm^2; $t_C = 10$ sec; $i_A = 250$ mA/cm^2; $t_A = 1$ sec; $Q = 2.0$. (a) Cu substrate, (b) Mo substrate.

With PRC plating, cathodic current densities of 300 mA/cm^2 (corresponding to an instantaneous growth rate of about 5 μm/min) were successfully achieved. The average current density is, of course, lower. For $i_C = 300$ mA/cm^2 and $Q = 4.0$, the average current density is 187.5 mA/cm^2. The latter is only 107.1 mA/cm^2 for $Q = 2.0$. The present study, which is only preliminary, already demonstrates that the application of the PR technique can facilitate increase of the useful plating rate by about an order of magnitude over the constant (d-c) current technique, under otherwise identical condititons.

Effects of concentration.—Low concentrations usually reduce the limiting current density. On the other hand, the increase of solute concentration (in the present system) raises the liquidus temperature so that higher operating temperatures are necessary. The higher temperatures cause coherence deterioration, probably due to the dissociation of the complex ionic species present (1), and higher volatility of the solute and rapid bath depletion. For the eutectic LiF-NaF-KF (Flinak) solvent, a limit of about 7.5 m/o K_2NbF_7 was cited (1). The system KF-K_2NbF_7 was found (37) to have low eutectics at 20 m/o K_2NbF_7 (723°C), and at 80 m/o (706°C). In this work, a solution of 80 m/o K_2NbF_7 in the "solvent" KF (10 m/o)-LiF (10 m/o) was found to freeze at 705° ± 5°C; the effect of substituting LiF for part of KF being very small. The very concentrated solution was found to offer no advantage for the electrodeposition of niobium. A lower electrodeposition rate, by at least a factor of 3 compared with the 6 m/o solution, was found. This is believed to

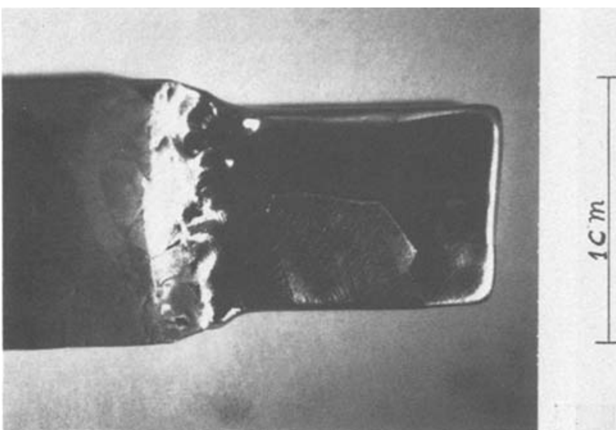

Fig. 12. Nb dissolving anode which was used in the 80 m/o K_2NbF_7 solution. $i_C = 375$ mA/cm²; $t_C = 1$ sec; $i_A = 75$ mA/cm²; $t_A = 10$ sec; $Q = 0.5$.

be due to a higher viscosity which lowers the ionic conductivity and diffusion rates. In addition, the highly concentrated solution had high vapor pressure of NbF_5 over the melt, resulting in excessive volatilization and bath depletion. The concentrated solution, however, may prove to be more useful for electropolishing of niobium.

Grain size control.—The columnar grains of the niobium deposits become more oriented and of smaller columnar diameter as the rate of plating is increased. Unexpectedly, it was found that, beyond a certain PR plating rate and appropriate Q-ratio, the columns become very large. This is demonstrated in the series of experiments shown in Fig. 2(b), 4(d), 7(c), and 10(c). These figures show vertical cross sections of samples which were grown at various cathodic currents and modes. A gradual decrease in the columnar diameter is seen through Fig. 2(b) (d-c plating at 3.3 mA/cm²), 4(d) (d-c plating at 25 mA/cm²), and 7(c) (PRP plating at 90 mA/cm²). Figure 10(c) (PRC plating at 300 mA/cm²), however, shows large columnar grains with an apparent heteroepitaxial correlation with the copper substrate grains. Such a correlation is not observed at the lower current densities.

It is believed that the anodic pulses, in addition to removing the solid interface protrusions, may also act to remove precursory defective solid material. Thus, adsorption of foreign species may gradually hinder the normal crystallization process, eventually leading to nucleation and growth of new grains. The periodic regression of the solid interface removes the blocking species at the interface along with the solid material. It thus yields fresh, adsorption-free, crystalline interface for the next growth cycle. Such mechanism may avoid secondary nucleation, and result in much larger grains. Other defects may similarly be avoided. Jackson and Miller (32), utilizing thermal cycles for remelting and regrowth, observed significant increase of grain size and improvement of crystal perfection. They forwarded a mechanism by which the slow-growing crystals (or grains) with low index plane parallel to the interface, are preferentially selected, yielding large grains with flat interface. They also reported the removal of inclusions and gas bubbles by the process. In addition to the above mechanisms, it is conceivable that the large amplitude current pulses applied in the PR technique, may cause additional convection mode in the liquid interface. This may significantly reduce the effective diffusion layer thickness, thereby eliminating much of the deleterious effects caused by concentration polarization. The simple method of controlling the columnar grain size may be of considerable practical significance. Mechanical properties as well as superconducting properties depend on the grain size. A smaller grain size generally results in harder materials and, for superconductors, this means stronger magnetic flux pinning, and therefore larger critical current densities. The superconducting transition temperature, T_c, with no magnetic field applied, is not expected to be affected by the grain size (38). The latter was verified by the T_c measurements, as described above. Applications of niobium superconductors requiring high pinning capability along a certain direction may find the PR plating technique, with its easy grain control, very attractive.

Conclusions

The results of the present preliminary study indicate that electroplating with the PR technique is very beneficial to the increase of plating rate of coherent niobium. With no mechanical agitation, the rate could be increased by about an order of magnitude over d-c plating.

Beyond a certain rate, and under certain conditions of PR plating, the columnar grains of the Nb deposit become very large, revealing a clear heteroepitaxial correlation with the substrate grains.

The simplicity of the PR technique, and the already achieved high rate of deposition of Nb, combined with the high purity and quality of the coatings, may very likely find ready future applications in the production of superconducting and refractory metal coatings. The PR technique is also likely to be beneficial in the electrodeposition of other refractory metals such as Ta, Mo, W, V, Cr, and perhaps Zr from molten fluoride electrolytes.

Acknowledgments

The author wishes to express his gratitude to Professor W. A. Tiller for his comments, suggestions, and discussions. He is also indebted to Dr. K. A. Jackson for reviewing the manuscript and his many helpful comments. The technical assistance of R. Koch, L. J. Anderson, and Professor Geballe's Cryogenic Group, from Stanford-CMR, is gratefully acknowledged. This paper is based on the author's Ph.D. thesis [Ref. (10)]. The research was supported, in part, by the Center for Materials Research at Stanford University under the NSF-MRL Program.

Manuscript submitted June 25, 1979; revised manuscript received Sept. 2, 1980. This was Paper 147 presented at the Dallas, Texas, Meeting of the Society, Oct. 5-9, 1975.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Electrodes for Alkaline Water Electrolysis

D. E. Hall*

Inco Research & Development Center, Incorporated, Sterling Forest, Suffern, New York 10901

ABSTRACT

Electrodes for alkaline water electrolysis have been made by applying high specific surface area coatings of nickel or nickel-iron alloy to steel or nickel substrates. The coatings are applied as polysilicate-based paints containing particles of the desired metals. The coating is sintered into a porous structure which is bonded firmly to the substrate. The present electrode preparation method has been used to coat a variety of substrate forms, such as flat plates or wire screens, and is compatible with commercial alkaline electrolysis equipment. The resulting electrodes were found to be particularly effective as anodes for oxygen evolution. The efficiency of the electrodes was greatly influenced by coating microstructure. This microstructure, in turn, could be controlled by adjusting the sintering conditions. Electrochemical operating characteristics of the electrodes in 30 w/o KOH at 80°C were determined. Comparable oxygen evolution efficiencies were obtained with coatings made from nickel powders, nickel flake, and nickel-iron alloy powder.

Hydrogen has been produced commercially by alkaline water electrolysis for many years. Recent indications are that significant improvements can be made in the electrolysis efficiency of practical cells (1). Thus, despite advances in other electrochemical hydrogen production methods (2), much research continues to be done in alkaline water electrolysis to improve efficiency and develop more durable cell materials (3).

There are several approaches to improving the efficiency of alkaline water electrolysis. Raising the electrolysis temperature, for example, lowers the voltage required to maintain a given cell current density (4). Improvements in cell design, separator structures, and materials, etc., will also contribute to better cell performance. Whatever advances are made, it will remain necessary to develop electrodes, compatible with the system design and operating conditions, which will give the lowest possible overpotentials. This can be achieved by two methods, which can sometimes be combined for maximum benefit. In the first, catalytically active materials such as $NiCo_2O_4$ (5) are applied to the electrode surface. The second method involves greatly increasing the electrode surface area (*i.e.*, its "roughness factor," defined as the ratio of its real surface area to its apparent, or geometric, area), thereby lowering the real current density and the associated activation overpotential.

Efficiency gains, as a rule, must be balanced against the additional capital cost incurred (6). For this reason, work continues to be done to minimize oxygen and hydrogen overpotentials on inexpensive electrode materials such as nickel (7) and nickel alloys (8, 9), which are the least expensive electrode materials currently known that can be used as both anodes and cathodes. These materials function most efficiently when fabricated as high surface area electrode forms.

Because the electrode structures used in commercial alkaline electrolyzers vary, it is desirable to have a method of increasing the surface area without regard to whether the electrode is a corrugated or flat plate, wire cloth, or a combination of these or other structures. This paper reports the development of such electrodes, in which a high surface area coating is applied to metal substrates, using a paint containing particulate nickel or nickel-iron alloys. Although nickel, nickel-iron alloy, and steel substrates have all been used to prepare electrodes, the present paper is concerned mainly with coatings on steel sheets and nickel screen.

* Electrochemical Society Active Member.
Key words: alkaline water electrolysis, electrodes.

The coated steel sheets are intended for use primarily in low temperature ($T \leq 80°C$) electrolysis characteristic of today's commercial practice.

Experimental

Electrode coatings were prepared using polysilicate-based paints, in which the metal particles described below were suspended. The parent nickel powders, known commercially as Inco Type 123 and Inco Type 287, are high purity powders prepared by the thermal decomposition of nickel tetracarbonyl (10). These powders are referred to in this paper as "Ni 123" and "Ni 287," respectively. Their surfaces are highly spiky and angular. The specific surface area of Ni 123 is ~0.4 m^2/g and that of Ni 287 is ~0.6 m^2/g. Using these values, a typical Ni 123 coating 50% dense and 100 μm thick would provide a maximum surface roughness factor of about 180 to a coated electrode. A nickel-iron alloy powder (37% Ni), similar in structure to Ni 123, and a nickel flake produced by ballmilling Ni 123 powder were also used.

The coatings were applied to flat panels of AISI 1008 steel which had been sandblasted to improve coating adhesion. The metal-containing paints were spread over the steel surfaces with drawbars; coating thickness was varied by using drawbars with different gauge wire wrappings. Coatings were also applied to nickel wire screen, an electrode form found in some commercial electrolysis units. The nickel screen was 20 mesh, with a wire diameter of 0.38 millimeters. Screens were immersed in the polysilicate paint and then shaken to remove any excess paint which filled the spaces between adjacent wires. Roller- and spray-coating of screens were also used.

The coatings were dried and then sintered in a cracked ammonia atmosphere at selected temperatures between 760° and 980°C for 5-60 min. Exact sintering conditions for particular electrodes are given in the text. Coating thicknesses were determined from photomicrographs of polished electrode cross sections. Coatings less than ~125 μm thick were uniform; thicker coatings on the flat steel panels showed broad, shallow striations caused by the wire wrappings on the drawbars. The average thickness was used for analysis of the experimental results.

Electrodes were made from the coated steel panels and nickel screens by cutting them to appropriate size and tack-welding a nickel wire to each. The wire was insulated with epoxy resin. The back and edges of each coated steel panel were also coated, with epoxy lapped over the front (coated) side of the panel to prevent direct contact of the uncoated steel with the electrolyte solution during electrochemical experiments. The geometric areas of finished electrodes were typically 3-7 cm^2.

The structures of the electrode coatings were examined using photomicrographs of polished electrode cross sections. In addition, the coating surface structure and the morphologies of individual coating particles were characterized by scanning electron microscopy.

Electrochemical measurements.—The electrochemical cell used for current *vs.* potential measurements was a straight-walled cylindrical polypropylene beaker with a Teflon cover machined to fit. The cell, containing 30 weight percent (w/o) KOH electrolyte, was immersed in a water bath which maintained the cell temperature at 80° ± 0.5°C. A large planar nickel counterelectrode was positioned facing the working electrode, at a distance of about 3 cm from it. A saturated calomel electrode (SCE) was used as the reference electrode. The SCE was inserted into a Luggin probe, the tip of which was positioned at the center of the working electrode. Overpotentials were determined from current *vs.* potential data using the reversible hydrogen electrode potential *vs.* SCE in 30 w/o KOH at 80°C (9) and the theoretical water electrolysis voltage at 80°C (11).

The experimental current density *vs.* overpotential data were then corrected for the effects of ohmic resistance using a computer method developed by LeRoy *et al.* (12). The Tafel slopes and exchange current densities reported below are based on the resistance-corrected data. The overpotential corrections produced by the program were typically 10-20 mV at current densities of 200 mA cm^{-2}.

Current density *vs.* electrode potential measurements were made galvanostatically. A constant current density of 200 mA cm^{-2} was imposed on each electrode for ~6 hr. At roughly 1 hr intervals, electrode potentials were measured at several current densities from 600 to 0.5 mA cm^{-2} in descending order. The last set of measurements from each electrode was used for the data analysis given in this paper. Potentiostatic measurements of log *i vs. E* were also made for several 2.0 cm^2 electrodes, in slow potential-sweep experiments. Because of the similarities of results from the galvanostatic and potentiostatic experiments, only the former are discussed here.

Results

Nickel and Nickel-Iron Alloy Anode Coatings

Coating structure.—The coatings prepared from Ni 123, Ni 287, and nickel-iron alloy powders consist of porous networks with unit particle diameters characteristic of the powders used to make them. Figure 1a shows the surface structure of a typical coating on a mild steel sheet. The cross section of this coating, shown in Fig. 1b, indicates that the structure is quite uniform from the base of the coating to its surface. Porosity pockets with diameters several times larger than the particles themselves are spread evenly through the coatings.

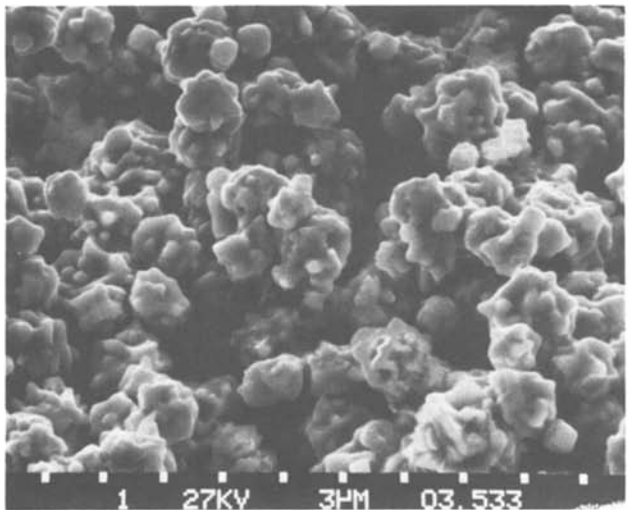
Nickel flake coatings, applied to mild steel panels, have a laminar structure in which the flakes and the porous channels between them are preferentially oriented parallel to the steel base. This structure is shown in Fig. 1c.

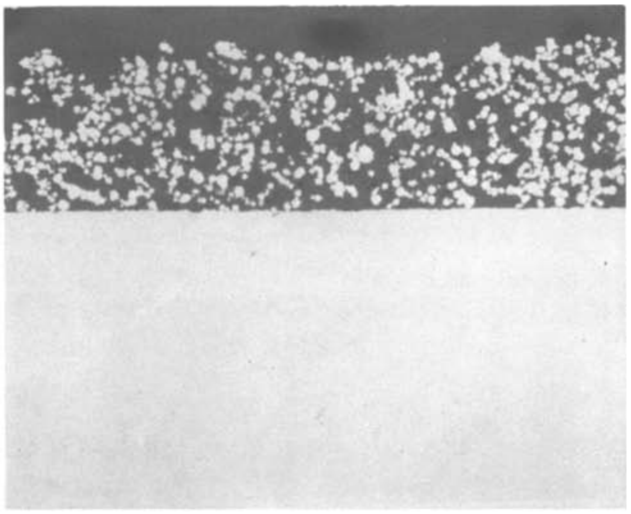
Electrochemical characteristics.—Overpotentials for oxygen evolution (η_{O_2}) at the high surface area nickel anode coatings on steel sheets are less than or equal to those at nickel anode forms such as nickel-plated steel (13), nickel cloth, and nickel sinter (7). Typical current density *vs.* overpotential data for the oxygen evolution reaction (OER) at two types of nickel powder-coated steel electrodes are plotted in Fig. 2. Tafel slopes of η_{O_2} *vs.* log *i* plots were generally 30-40 mV/decade for the electrodes studied in this work; slopes greater than 40 mV/decade were, however, obtained at some electrode coatings sintered at the higher end of the 760°-980°C temperature range used. The average slope of ~35 mV/decade is considerably lower than Lu and Srinivasan's value of 62 mV/decade at smooth nickel electrodes tested under identical conditions (14).

The efficiency of nickel screen anodes was also improved significantly by the nickel powder coatings. For example, a coating ~40 μm thick was sintered onto nickel screen at 760°C for 30 min. The oxygen evolution overpotentials at current densities of 100 and 200 mA cm^{-2} were about 80 mV lower than on uncoated nickel screen anodes.

Nickel flake coatings, sintered at 760°C for 60 min onto mild steel sheets had a laminar structure, as described above and shown in Fig. 1c. Despite this preferred orientation of pore channels perpendicular to the direction of electrolyte penetration and gas evolution, the nickel flake anode coating performed well. The Tafel slope was 33 mV/decade and overpotentials were comparable to those obtained at Ni 123 (Table I) and Ni 287 powder coatings.

Nickel-iron alloy anode coatings on mild steel sheets, sintered at 760°C for 60 min, had current density *vs.* overpotential characteristics which were nearly equal





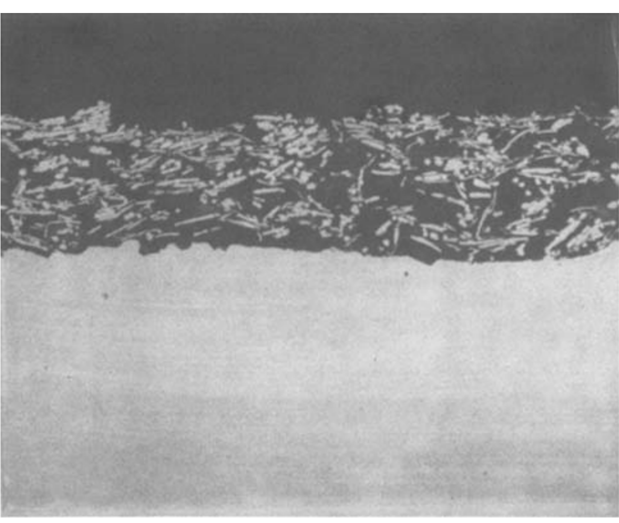


Fig. 1. (a, top left) Ni 123 coating on mild steel, sintered at 760°C for 60 min (Fischer subsieve of Ni 123 powder = 3-7 μm) 3000×; (b, top right) cross section of same coating, 300×; (c, bottom left) cross section of Ni flake coating, 300×.

to those obtained with similar Ni 123 coatings, as shown in Table I.

Effect of sintering conditions on coating microstructure and anode efficiency.—The sintering conditions of the electrode coatings, as expected, were found to have a significant effect on their oxygen evolution efficiencies and microstructures. The overall structure of the porous network, shown in Fig. 1a and 1b, is not greatly changed over a broad range of sintering times and temperatures. However, the coating microstructure, *i.e.*, the morphology of the individual particles which make up the coating network, is sensitive to sintering conditions. At low sintering temperatures, much of the particle morphology is preserved; however, as one would expect, as the sintering temperature is raised or the sintering time is increased, the particle surfaces tend to spheroidize and the contact areas between adjacent particles increase. The result is a reduction in electrode surface area. This can be seen by comparing the coating structures in Fig. 3.

To determine the effects of coating microstructure on the efficiency of oxygen evolution, nine Ni 123 electrode coatings on mild steel panels were prepared as described in Table II. Coatings were all applied using the same drawbar; the average thickness was ~60 μm. After sintering and prior to electrode fabrication, a portion of each coating was tested for adhesion with a simple tape test, in which cellophane tape was applied firmly to the coating and then pulled away. Coatings 5-9 successfully resisted the test, but succes-

Table II. Sintering conditions of Ni 123 electrode coatings on mild steel sheets used to determine the effect of coating microstructure on electrocatalytic efficiency

Electrode	Temp, °C	Time, min	Microstructure (by SEM)
1	760	5	Most of Ni 123 structure preserved. Some rounding of surface spikes.
2	760	10	
3	760	30	Substantial rounding of spikes.
4	870	5	Spikes lost, but particles are still angular.
5	870	10	
6	870	30	Ni 123 structure lost. Particles are rounded, indistinct; interparticle contact areas are large.
7	980	5	
8	980	10	
9	980	30	

sively increasing amounts of nickel powder were removed from coatings 4 (minimal) through 1 (substantial). Because the relationship of this test to the mechanical stability requirements for practical electrolyzer anodes was not known, all coatings were used as anodes. A clear relationship between coating microstructure and overpotential at a constant current density was obtained (Fig. 4). Increasing the temperature and/or time of the sintering operation, *i.e.*, reducing the effective anode surface area, caused a greater than 70 mV overpotential increase at 200 mA cm^{-2} and an associated increase in Tafel slope between coatings 2 and 9. Anode 1 was an exception; it was mechanically unstable under conditions of vigorous oxygen evolution. Thus some coating material was lost, causing a reduction in surface area and a consequent increase in overpotential.

Effect of coating thickness on anode efficiency.—The porous, open structure of the nickel coatings suggests the likelihood that the interior surfaces of the anode coatings catalyze the oxygen evolution reaction to some extent. This was investigated using Ni 123 and Ni 287 coatings covering a wide range of thicknesses. The coatings were prepared on mild steel panels using identical sintering conditions (760°C, 60 min). Despite some fluctuations in the data, Fig. 5A shows that an increase in Ni 123 coating thickness from 23 to 150 μm causes some reduction in η_{O_2} at a given current density. For Ni 287 coatings (Fig. 5B), the change in η_{O_2} with thickness is somewhat smaller.

An increase in coating thickness also causes an increase in the exchange current density. At the Ni 123 coated anodes described in Fig. 5A, for example, i_o ranged from 2.8×10^{-8} A cm^{-2} at the 23 μm thick coating to 1.9×10^{-7} A cm^{-2} at the 150 μm thick coating. The data from these experiments were compared to the behavior expected assuming that the entire coating thickness had equal electrocatalytic activity, which was determined as follows.

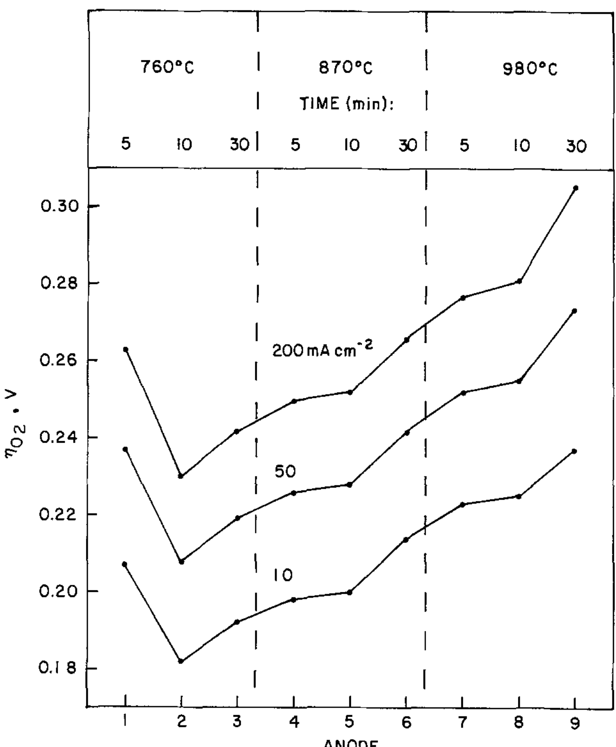

Fig. 4. η_{O_2} at selected current densities, for Ni 123 coatings on mild steel (from Table II). Effect of coating microstructure changes caused by variation of sintering conditions.

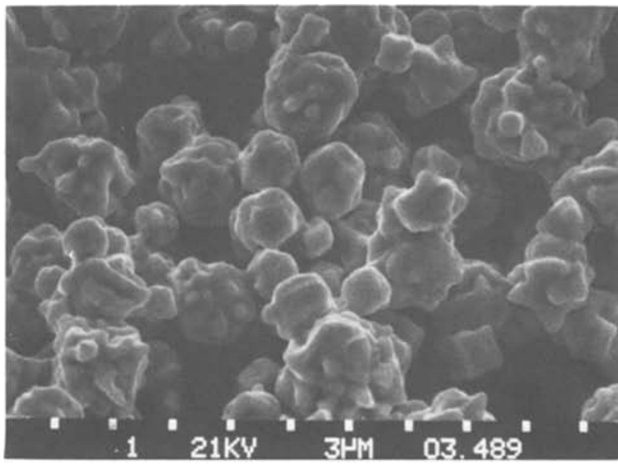
If the entire microstructural surface of the coating catalyzes the OER with equal effectiveness, the effective surface area of the electrode, A_{eff}, is proportional to the coating thickness. The exchange current density per unit effective surface area is a constant, characteristic of the electrode material and the reaction which takes place. Thus, the experimentally measured exchange current will be proportional to coating thickness (x)

$$i_o = Mx + B \quad [1]$$

M is the slope of a plot of exchange current density *vs.* coating thickness. The B term includes exchange current on accessible portions of the substrate surface (if any) and on the extra microstructural area available in the top layer of sintered particles; at large x (compared to the surface roughness of the substrate and the coating unit particle diameter), B should be much less than Mx.

Under conditions of net current flow, the Tafel relationship $\eta = a + b \log i$ obtains. Strictly, the current density in this equation is based on effective surface area, and thus $\eta \propto \log (I/A_{eff})$, where I is the total



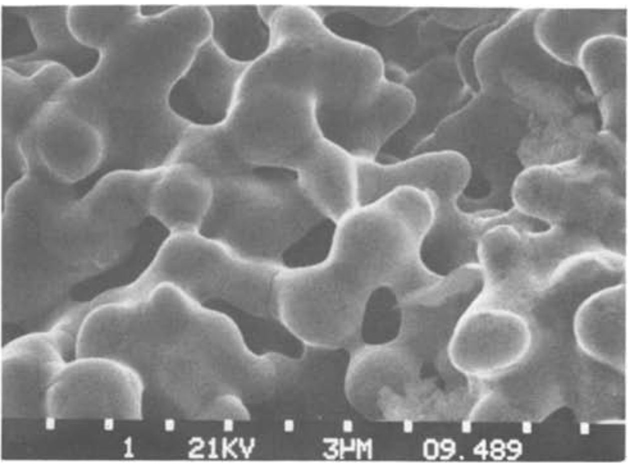


Fig. 3. Ni 123 coatings on mild steel, sintered for 30 min at (a, left) 760°C and (b, right) 980°C. 3000×

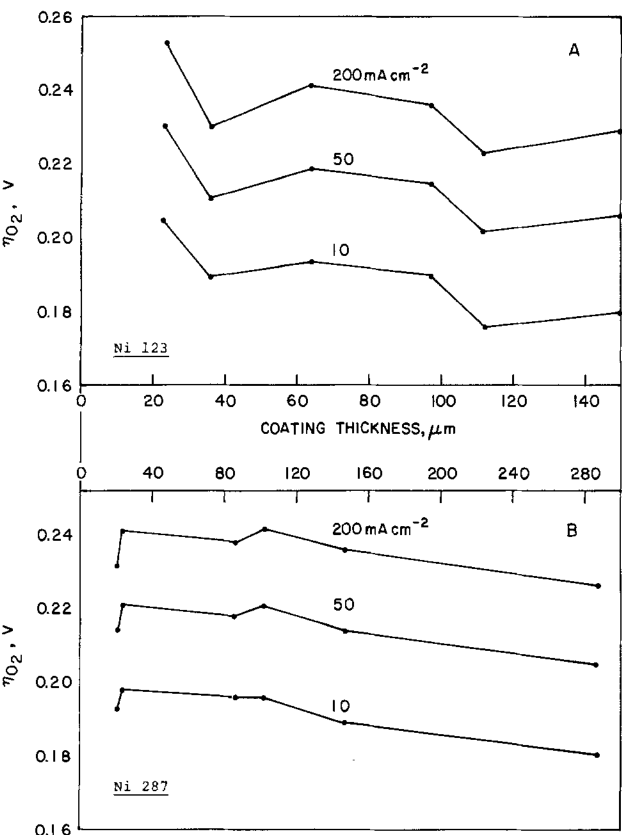

Fig. 5. η_{O_2} at selected current densities: effect of coating thickness. All coatings sintered at 760°C for 60 min. (A) Ni 123 coatings on mild steel sheets, (B) Ni 287 coatings on mild steel sheets.

current. A_{eff} is proportional to coating thickness, and thus

$$\eta_{O_2} = C - D \log x \quad [2]$$

where D is the slope of a plot of η_{O_2} *vs.* $-\log x$, and C is a constant. This equation, like Eq. [1], will be valid for coating thicknesses greater than several unit particle diameters.

Regression fits of experimental data from the anodes of Fig. 5 to Eq. [1] and [2] were used to determine how effectively the coating interiors were utilized. For Eq. [1], the "goodness-of-fit" (F value) indicated that the regressions were significant at the 99% level for both Ni 123- and Ni 287-coated anodes. At Ni 123-coated anodes, an increase of 10 μm in the coating thickness produced an average 1.4×10^{-8} A cm^{-2} increase in i_o (Fig. 6); for Ni 287 anode coatings, the corresponding i_o increase was smaller, about 3.5×10^{-9} A cm^{-2}.

It is interesting to compare the above results with data from Appleby *et al.*, who found [Fig. 7 of Ref. (7)] that i_o at 90°C was ~55 times higher on a 150 μm thick sintered nickel plaque than on a smooth nickel surface. Using the i_o value at smooth nickel obtained by those authors (~7×10^{-10} A cm^{-2}), this increase is then about 3.8×10^{-8} A cm^{-2}, or roughly 2.6×10^{-9} A cm^{-2} for each 10 μm of sintered nickel thickness. This value is comparable to that reported above for Ni 287 coatings.

The nickel sinter used by Appleby *et al.* had an available electrode surface area, according to BET measurements, of 140 cm^2 per square centimeter of the sintered plaque. If all of this area were electrochemically active, one would expect the exchange current density measured on the plaque to be 140 times higher than on the smooth nickel electrode. It is noteworthy that this is nearly three times higher than the ~55-fold increase in i_o actually obtained, indicating that the BET surface area may substantially overestimate the effective surface area of a particular electrode with a high roughness factor. This would, of course be expected under conditions of copious gas evolution, resulting in areas where electrode-electrolyte contact is lost. However, it is apparently also true when gas blockage is not a major consideration, *i.e.*, when the current density is low: the linear region of the Tafel plot extrapolated to obtain the i_o value at the sintered nickel plaque anode extended from 10^{-2} A cm^{-2} down to almost 10^{-6} A cm^{-2} [Fig. 6 of Ref. (7)].

Overpotentials at 200 mA cm^{-2} were used in Eq. [2], to assess coating interior participation in the oxygen evolution reaction during copious gas formation. Goodness-of-fit was less satisfactory than with Eq. [1]; correlation of Ni 287 coating data with Eq. [2] was poor. For Ni 123 coatings, the regression was significant at about the 90% level; the coefficient D was 24 mV/decade. If the entire coating microstructure participated equally in the oxygen evolution reaction, the expected decrease in η_{O_2} would be equal to the Tafel slope at Ni 123 anode coatings, or ~35 mV/decade. Thus, there is probably some pore blockage by evolved gas, which increases the observed overpotential by reducing the active anode surface area and increasing the resistance loss within the coating pores. This problem is apparently more severe with the Ni 287 coatings examined, and may be due to the chainlike structure of Ni 287 powder, although this was not evident from SEM photomicrographs of the coatings.

Nickel Powder Cathode Coatings

The electrochemical behavior of nickel cathode coatings on mild steel sheets was interpreted using criteria similar to those applied to anodes in the preceding sections. At normal operating current densities (200 mA cm^{-2}), cathode overpotentials were 0.1-0.2V higher than corresponding anode overpotentials for the same coatings. Tafel slopes on Ni 123 cathode coatings were 130-175 mV/decade, while i_o varied from 1.6×10^{-4} to 3.4×10^{-4} A cm^{-2}. On Ni 287 coatings, Tafel slopes ranged from 134 to 167 mV/decade, with most between 134-144 mV/decade. The exchange current density varied from 8.8×10^{-5} to 4.2×10^{-4} A cm^{-2}. The higher exchange current densities are com-

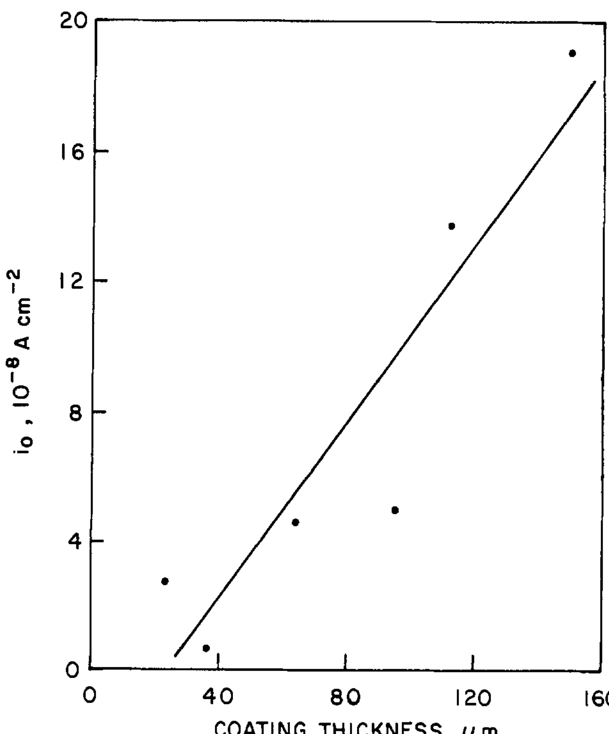

Fig. 6. Exchange current densities vs. thickness of Ni 123 coatings on mild steel. Points: experimental. Line: best fit of Eq. [1].

parable to those observed by Appleby *et al.* (7) on screen-reinforced sintered nickel under similar conditions. However, the hydrogen evolution overpotentials at higher current densities reported by those authors are significantly lower (by >70 mV at 10 mA cm^{-2}) than observed on high surface nickel coatings in the present work. The explanation for this behavior may lie in the fact that gas may exit only from the front face of the coatings on steel sheets rather than from both faces in the case of porous sintered nickel. This should be relatively more important in H_2 evolution than in O_2 evolution, due to the twofold difference in gas volume produced at equal current densities. However, when Ni 123 coatings were applied to Ni cathode screens, no significant overpotential reduction was obtained.

There is a trend toward higher overpotentials at coatings with reduced microstructural surface area, caused by more severe sintering conditions, as shown in Fig. 7. However, this trend did not include the most highly sintered cathode (No. 9), which showed an unexpected decrease in η_{H_2}. No explanation for this behavior was evident from photomicrographs of the coatings. It is possible that this increase in efficiency at the nickel coating with the smoothest surface morphology is a result of easier gas release from coating pores; the fact that similar behavior was not observed for O_2 evolution may be due to the smaller size of evolving H_2 gas bubbles. It is also noteworthy that coating No. 1 failed in anodic operation but not as a cathode. This indicates that cavitation forces which may rupture the sintered coating structure may be more dependent on gas bubble size (larger for O_2) than on total gas volume (larger for H_2).

Appleby and co-workers (7) suggested that the interior of screen-reinforced sintered nickel was largely accessible for the hydrogen evolution reaction, as a

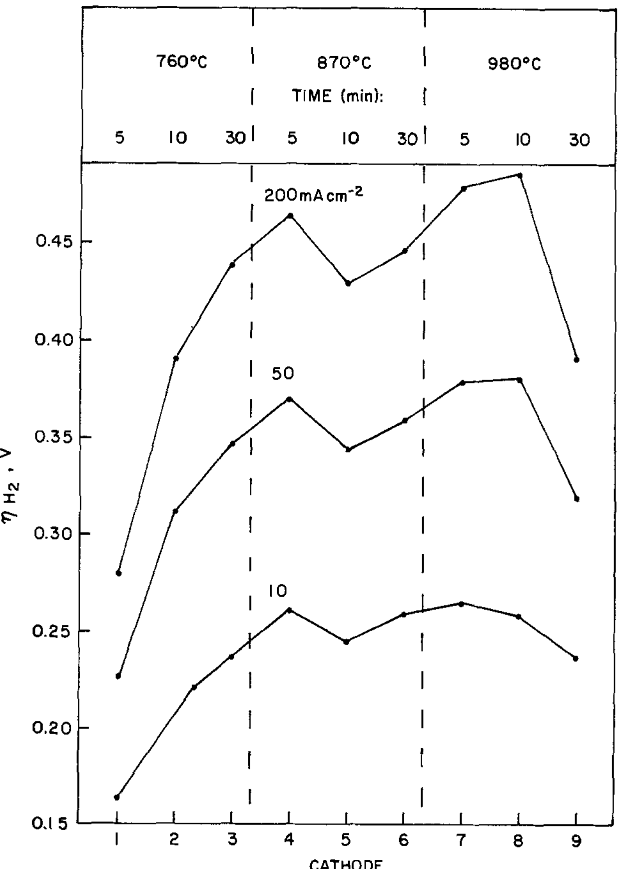

Fig. 7. η_{H_2} **at selected current densities, for Ni 123 coatings on mild steel (from Table II). Effect of coating microstructure changes caused by variation of sintering conditions.**

consequence of the small bubble size of evolved H_2. Using the technique applied above to anode coatings, the electrochemical activity of the inner surfaces of Ni 287 cathode coatings was investigated as part of the present work. A regression analysis of the hydrogen evolution data for Ni 287 coatings from ~20 to 290 μm thick showed that each 10 μm increase in coating thickness produced a 1.1×10^{-5} A cm^{-2} increase in i_o. For one decade of increase in coating thickness, η_{H_2} at 200 mA cm^{-2} was reduced by 55 mV. This is less than half of the overpotential reduction expected if the entire surface of the coating were catalyzing the reaction equally. Similarly, Appleby *et al.* (7) point out that the apparent exchange current density for the hydrogen evolution reaction at their sintered nickel electrode was only 30 times higher than at smooth nickel. This is substantially below its roughness factor of 140, as measured by the BET technique.

Discussion

The electrodes described in the present paper are prepared by applying particulate metal coatings to metal substrates. The use of a paint-like suspension of the metal particles makes it possible to achieve uniform coatings of controlled thickness using a variety of coating techniques. This electrode fabrication method, which appears to be well suited for preparing anodes for alkaline water electrolysis, has two main advantages: (*i*) the coating technique can be used to add considerable surface roughness to existing electrode structures of many kinds; (*ii*) the materials and procedures used to prepare the electrodes are relatively inexpensive. Both of these factors are in keeping with the capital cost restraints on commercial alkaline electrolysis equipment.

The efficiencies of the coated electrodes and their microstructures, can be varied significantly by changing the coating preparation conditions. The interior surfaces of both anode and cathode coatings participate in the electrode reactions to some extent; thus, overpotentials can be reduced by increasing the electrode coating thickness. However, the use of thick anode coatings to improve electrolysis efficiency is of doubtful value on economic grounds, since the overpotential reduction obtained is small. This would be true even under ideal conditions, in which the overpotential reduction for a tenfold increase in coating thickness is given by the Tafel slope, which is only ~35 mV, as shown earlier.

Although the electrode structure developed in the present work is less suitable for hydrogen evolution than for oxygen evolution, the cathode overpotential reduction with increased coating thickness is larger. This is not due to the more effective utilization of the electrode coating interior for hydrogen evolution than for oxygen evolution, but is rather a consequence of the difference in Tafel slopes for the two processes.

The optimum electrode coating microstructure, for any given cell and set of operating conditions, is that which gives adequate strength and stability while maintaining the highest possible surface roughness factor. The present work indicates that different coating strengths are necessary, depending on whether the coated electrodes are used as anodes or cathodes. The efficiency improvements which can result from choosing proper sintering conditions are large enough to be significant. In addition, sintering no more than necessary for adequate mechanical integrity of the coating minimizes sintering costs.

The use of steel substrates with porous coatings as anodes in alkaline electrolysis raises questions regarding their durability, since unprotected mild steel corrodes rapidly under anodic service. None of the electrodes used in this work showed evidence of corrosive failure in six-hour electrolyses. A report of the operating characteristics and corrosion resistance of nickel

powder-coated mild steel-based anodes in 1200 hr tests will be made in a future publication.

An SEM Study of the Nature of the Electrochemical Deposit in Reversible Electrodeposition Displays

H. J. Stocker, L. G. VanUitert, T. C. Loomis, and F. B. Koch*

Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

SEM-x-ray spectroscopic studies of display cells based on reversible electrodeposition (RED's) conclusively show that the deposit is composed of elemental silver, regardless of its color (gold, gray, black, red-brown, etc.) A gold deposit is shown to consist of finely dispersed (colloidal) silver particles, while the black deposit consists of a spongy type of deposit of elemental silver. This fact means that the mechanism of operation of these dispersive displays is due to collective electromagnetic scattering effects of colloidal silver. Confirming evidence that TiO_2 particles form in-depth contacts is also presented.

Display cells based on reversible electrodeposition (RED's) are under active study (1, 2).

Experimental cells are constructed of two parallel plates of indium-tin oxide (ITO) coated glass. The intervening space is filled with a paste electrolyte consisting of silver iodide (AgI), tetralkylammonium iodide (RN_4I), and a solvent (dimethylformamide or DMF). The use of the tetralkylammonium iodide permits the use of high silver concentrations in organic solvent based electrolytes (2). Sometimes a mixture of TiO_2 powder and fine ZEOLITE particles (molecular SIEVE) is added to the mixture. The function of the TiO_2 is twofold: one, it serves as an opacifier (white background) and second it extends the electrical contact into the interior of the cell, thus enlarging the volume in which the electrochemical reactions take place. The molecular sieve is added in an empirically determined proportion to adjust the conductivity of the mixture for maximum contrast. The functions of these components are more fully described in Ref. (2). Upon application of voltage pulses of 1-2V magnitude and several hundred millisecond durations, coloration is observed at the cathode. A variety of colors, including gray, black, gold, green-gold, red, red-brown, light-blue, and navy blue reproducibly result from plating in these experimental display cells. Several colors may be observed in the same display cell, depending on driving conditions. For instance, a brief high amplitude pulse (duration 0.1 sec) in a DMF/AgI/TBAI/TiO_2-SIEVE cell (TBAI is tetrabutyl ammonium iodide) produces a bright red color, while a low amplitude pulse of 1 sec duration produces a dark gray color. Similarly, in cells without the TiO_2/SIEVE filler, a golden color can often be observed with a low driving current, while a gray to black deposit develops if the cell is driven harder.

(b)

Fig. 1. (a) A 5000× picture of the gold-colored deposit showing clearly the finely dispersed particles. (b) X-ray energy spectrum belonging to Fig. 1a. Si and In are due the substrate. Ag is clearly present but there is no I peak, supporting the conclusion that the deposit consists of colloidal silver.

These puzzling coloration effects cannot be understood as a straightforward electroplating of silver, which had been the basis of earlier work in aqueous solutions by Zaromb (3, 4).

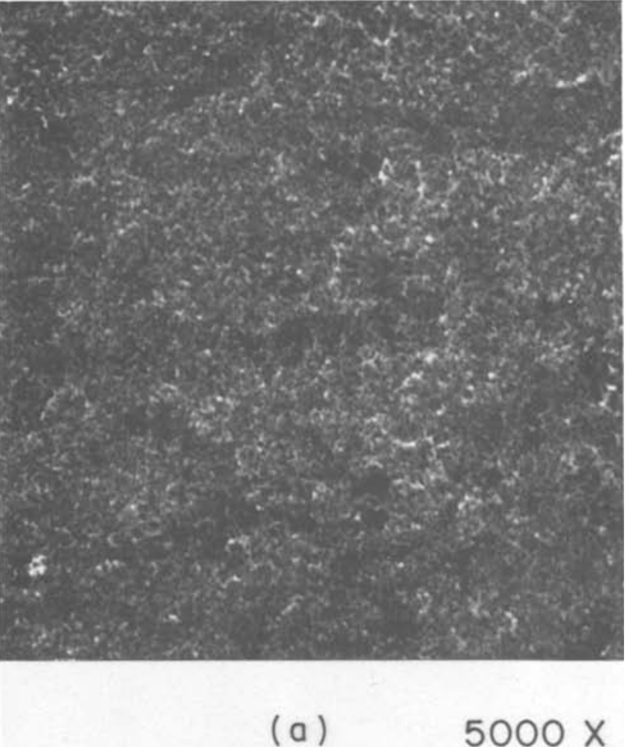
We will consider two fundamentally different hypotheses, namely, (*i*) that the different colors correspond to the different electrochemical reaction products (*e.g.*, Ag, $Ag_0(AgI)_x$, etc.) or (*ii*) that only Ag is deposited and the different colors result from collective electromagnetic scattering effect of a collection of colloidal silver particles. The latter effects, first studied by Carey-Lea in 1889 (5) in silver electrolytes cause many fascinating colors, including most of the colors seen in display cells. The particular colors observed correlate with the size of the colloidal silver particles. A summary of such phenomena is given in Gmelin's handbook (6). It is this key question of the physical and chemical nature of the deposit to which our SEM-x-ray spectroscopic study was addressed in experiments A and B, described below.

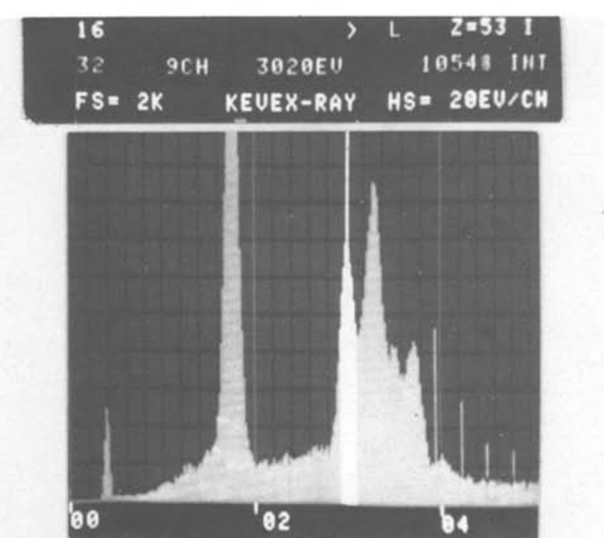
Experiment C clarifies the role of the TiO_2 particles sometimes used in the pastes. The working hypothesis that the TiO_2, by virtue of its conductivity, allows plating to occur throughout the volume of the paste rather than just on the planar electrode is confirmed by this experiment.

Results

In experiment A, a cell containing an $NR_4I/AgI/DMF$ solution but no filler was cycled with 1 Hz square waves of 2.5V amplitude so that a gold color developed. With the gold color remaining on the first electrode, the cell was opened and the deposit washed with acetone and then subjected to SEM analysis.

The SEM examination revealed both a submicron structure of finely dispersed particles and a large number of Maltese-cross and bar-shaped crystals. There is strong evidence that these crystals are an experimental





(b)

Fig. 2. (a) SEM picture at 5000× of a black deposit, showing a dense spongy structure. (b) X-ray energy spectrum showing the presence of Si, Ag, and In but no I.

artifact in the form of AgI precipitated from a supersaturated solution when the cell was opened and the solvent evaporated. The elemental ratios, found using energy dispersive x-ray analysis correspond to the ratios obtained from an AgI standard. Also, the growth of similar crystals could be observed directly with an optical microscope as the solvent evaporated. The gold color seen in an unopened cell thus must be attributed to light scattering from the submicron structure rather than the AgI-salt crystals.

Figure 1(a) shows a detail of the gold-colored deposit in an area free of AgI crystals at a magnification of 5000×, where the morphology of the finely dispersed particles can clearly be resolved. Their size is approximately 50 nm. The corresponding x-ray energy spectrum in Fig. 1(b) shows only the presence of Ag from the particles, In from the transparent conductive coating, and Si from the substrate. We therefore conclude that silver is present in colloidal form in this area.

In experiment B, a cell containing ASI/TBAI/DMF (ASI is ammonium silver iodide) was colored with several 1 sec, 2V d-c pulses until a dark gray to blackish deposit had formed. The cell was then opened and the deposit carefully washed with acetone and distilled water. The deposit has a spongy form as indicated in Fig. 2(a) (5000×). The composition is again entirely elemental silver, with no iodine present [Fig. 2(b)]. This experiment thus conclusively shows that the deposit, when driven hard enough to produce black color, is entirely elemental silver, and furthermore is of a spongy, loose structure. The only difference between the black deposits [Fig. 2(a)] and the golden deposit formed at lower driving currents [Fig. 1(a)] is that the silver particles which were isolated in the golden deposit have been agglomerated into a deep spongy form in the black deposit.

In experiment C, an ASI/TBAI/DMF/TiO_2/SIEVE cell was colored to a red-brown color with a d-c pulse of 300 msec duration and 2V amplitude. The cell was then taken apart carefully and the paste near the electrode examined under the SEM. Figure 3 is a 5000× SEM picture of the paste together with elemental distribution maps for Al, Ti, and Ag. The Al map indicates the position of the zeolite ($NaAlSi_2O_6$) particles, the Ti map the position of the TiO_2 particles. A careful comparison of the elemental maps lead to the conclusion that the Ag is indeed distributed predominantly on the TiO_2 particles. This confirms the hypothesis that the TiO_2 acts as an in-depth-contact, so that dispersed silver is formed within much of the volume of the paste.

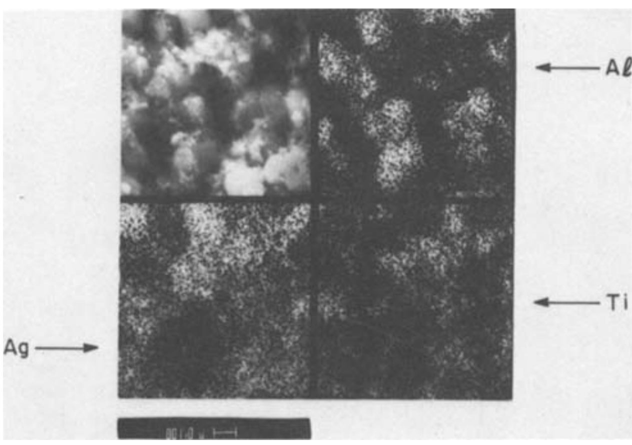


Fig. 3. SEM picture and elemental distribution maps of the TiO_2/SIEVE paste mixture, after cell had been colored red-brown. The preferential occurrence of Ag on the TiO_2-particles confirms their role as an in-depth contact.

A cell which appears red-brown when viewed normally (*i.e.*, perpendicular to the electrode plane) may appear greenish when viewed at a ~75° angle. We have not studied these complicated effects in detail but we believe they are consistent with the hypothesis of formation of a silver colloid, in fact provide further evidence for it. Theoretically (7), one expects different colors to be seen at different angles in a colloid of silver particles, because the light scattering efficiency, as calculated for uniform particle size in Mie's theory, predicts dependence on both the angle ϕ and the wavelength λ. The resulting array of colors is known as higher order Tyndall spectra (7).

Conclusions

The major conclusion of this study is that the chemical composition of the deposit in dispersive RED display cells is elemental silver for both the dispersive colors and the more conventional electroplated deposit at the cathode. This conclusion is consistent with studies of the cyclic voltammograms of such cells which show a smooth behavior consistent with the electrochemical reaction $Ag^+ + e \leftrightarrow Ag\cdot$ but no structure which would indicate the electrodeposition of other reaction products.

As larger amounts of currents are passed through the cell, the colloidal particles (gold color) apparently agglomerate to larger structures whose optical properties make them look black.

A second result of our study is confirmation that the TiO_2 particles indeed do form in-depth contacts and therefore act as a dispersing agent. This effect is believed to enhance the electromagnetic scattering effects attributable to a colloid vis-a-vis the more conventional electroplating effects at the electrode.

Electroluminescence during the Anodic Growth of Tantalum Pentoxide

V. Kadary[1] and N. Klein

Department of Electrical Engineering, Technion, Israel Institute of Technology, Haifa, Israel

ABSTRACT

Light emission during the anodic growth of tantalum pentoxide was found to grow quasi-exponentially with electric field and oxide thickness. Data on the spectrum were obtained with six narrow bandpass filters. Largest light output was found for 4.8 eV photons. This light component was strongly absorbed in the oxide, since its bandgap is 4.6 eV. The light emission was interpreted as an electroluminescent (EL) effect due to electron avalanching and to recombination of hot electrons with trapped holes for most of the light components. The nonabsorbed light components could in part be due also to first-order kinetics EL processes. Relations derived for the EL output fitted experimental results well, giving $\alpha = 1.12 \times 10^5$/cm for the coefficient of impact ionization at a field of 6.26 MV/cm. Earlier breakdown investigations resulted in $\alpha = 1.4 \times 10^5 \pm 10\%$/cm. The difference in α values can be due to approximations made in deriving relations for the two phenomena. Since both breakdown and EL theories were developed with the same avalanche model, independent evidence was obtained on impact ionization in tantalum pentoxide from two phenomena.

It has been known since the end of the last century that a steady light emission accompanies the anodic growth of oxides. The effect was termed galvanoluminescence (1) and surveyed in an excellent review article by Ikonopisov (2). The survey shows that this luminescence is not well understood and that there are many contradictions in observations and insufficiencies in interpretations.

Light output during the growth of aluminum oxide was found to increase quasi-exponentially with the electric field in the oxide and also with thickness (3). This thickness dependence could not be explained by chemiluminescence due to electrochemical reactions at the electrolyte interface (4), or at flaws (5). Many investigators assume that the light emission is an electroluminescent (EL) effect (2).

A mechanism for the EL in aluminum oxide was proposed by van Geel *et al.* (3), assuming that impact ionization by electrons and avalanching take place during anodization at a field of nearly 9 MV/cm in the oxide. EL was ascribed to excitation of impurities by hot electrons and subsequent radiative de-excitation. The thickness dependence of EL was explained with the exponential increase of hot electrons with thickness by avalanching. The luminescent impurity centers were thought to be metallic (6), or organic ions (5), and addition of manganese to aluminum was found to enhance the EL manifold (7). Anderson suggested radiative hole-electron recombination as an alternative EL mechanism (8).

Most of the EL investigations were confined to aluminum oxide (2). Publications on light emission during the anodic growth of tantalum pentoxide were fewer and less detailed (4, 7-10). Investigating electrical breakdown processes during the anodic growth of oxides on tantalum (11) and aluminum (12), we found that breakdown events could be well explained by the succession of avalanches breakdown model (13). The question arose whether the light emission is also connected with avalanching processes in tantalum pentoxide and whether light emission observations could provide independent data on avalanching. We therefore investigated light emission in parallel with electrical breakdown during anodic growth.

[1] Present address: Israel Aircraft Industries, Yahud, Israel.

Key words: electroluminescence, insulator, anodization, breakdown.

We describe below results of light emission observations in tantalum pentoxide. It is shown that most of the light emission is an EL process, explained by the effects of avalanching and by radiative hole-electron recombinations. The magnitude of the coefficient of impact ionization, α, is derived from EL data and found to be in reasonable agreement with α obtained from breakdown experiments.

Samples and Experimental System

The sample and experimental system were described in the publication on breakdown in tantalum pentoxide (11) and we recapitulate here the main features. Figure 1 illustrates the sample. The anodizations were carried out on 500 nm thick, sputtered, lightly nitrogen-doped, β tantalum films. The sample was placed horizontally in the electrolytic bath. This was an aqueous solution of citric acid with a range of concentrations from 2.5×10^{-3} to 1.8 weight percent (w/o), the corresponding electrolyte resistivities varying from 21,000 to 260 Ω-cm at 1 kHz. Anodizations were carried out at constant current densities of 0.5, 1.0, 5.0, or 10.0 mA/cm^2. The corresponding mean electric fields in the oxide were 6.14, 6.26, 6.56, and 6.7 MV/cm, respectively

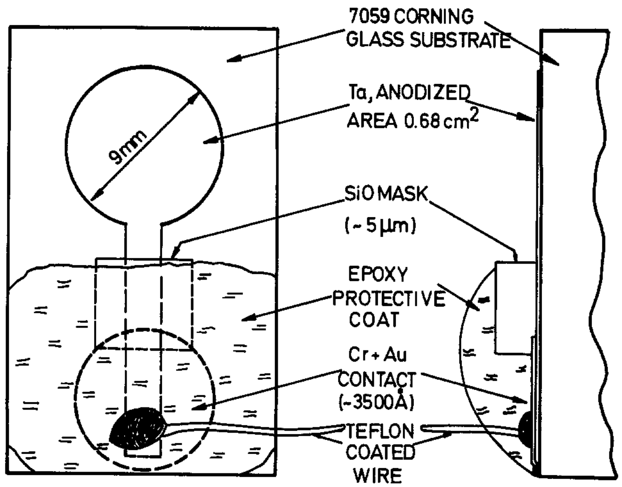

Fig. 1. Tantalum sample for anodization

(11). Magnetic stirring of the bath reduced temperature rises to less than 1°C in the sample for a current density of 1 mA/cm^2 and oxide thickness of about 500 nm.

Light emitted from the sample was collected with a vertical 100 mm long, 10 mm diam quartz light guide. The collecting face of the light guide was concentric with and 10 mm above the sample in all experiments. The light guide was coupled to an RCA Type 1P28 photomultiplier, sensitive over the spectral range of 220-620 nm, with a maximum sensitivity close to 330 nm. The photomultiplier had potted leads and was cooled with solid CO_2. Electrolytic bath, light guide, and photomultiplier were enclosed in an aluminum box, impervious to external light.

Measurements recorded light emission and voltage across the oxide *vs.* time of anodization. The output of the photomultiplier was amplified and the light emission was plotted on a Hewlett Packard strip chart recorder. Voltage was measured across a capacitor connected in parallel with the electrolytic bath. The voltage across the oxide layer was obtained by subtracting voltage drops in the electrolyte and in a series resistor. Light emission observations extended from the smallest to close to the breakdown voltages. Breakdown sparks foiled observations in the breakdown range of voltages.

Experimental Results

Results were presented in plots of light emission during anodic growth *vs.* voltage across the oxide, or *vs.* the oxide thickness, w. The oxide thickness was calculated from the voltage and the oxide field data given above.

The field dependence of the light emission *vs.* thickness is presented in Fig. 2, with mean field in the oxide as parameter. The solid line results were obtained with continuous anodic growth experiments and the broken line results at fields lower than applied for anodizations. The latter results were obtained from sequences of light emission measurements indicated by arrows in Fig. 3. The anodic growth was interrupted in this experiment near 100, 150, and 200V and light emission was measured rapidly at decreasing and again at increasing voltages, followed by resumption of anodic growth. We estimated that the growth in the thickness of the oxide film was insignificant during a voltage decrease period, owing to the rapidity of voltage decrease and due to the quick decrease in ionic current density with field reduction. We obtained thus approximate field-dependent data on light emission below fields for anodic growth.

The data of Fig. 2 were replotted and showed that (*i*) the light emission grows in a superlinear manner with current density of anodization and (*ii*) the light emission grows exponentially with oxide field at a given oxide thickness. A semilogarithmic plot of emission consists of two ranges, one with a relatively low slope at lower fields and one with a relatively large slope at fields of anodic growth.

The effect of the electrolyte resistivity, ρ_e, on the light emission is illustrated by Fig. 4. An increase of ρ_e from 285 to 21,000 Ω-cm produced no significant change in the light emission; observations of this nature were made earlier also with aluminum oxide (7, 10). The effect of temperature on light emission was found to be small in the range of 3°-50°C as is indicated by the curves in Fig. 5. In contrast, the light emission of aluminum oxide was found to change and increase with temperature in an inorganic electrolyte, but decrease with temperature in an organic electrolyte (5).

Data on the spectrum of the light emission were obtained by a series of anodizations performed under identical conditions at a current density of 1 mA/cm^2. The light emission was measured through a different narrow bandpass interference filter on each of the anodization runs. Balzer filters of a half-bandwidth of about 10 nm were used, of wavelengths 259, 313, 366, 408, 434, and 545 nm at their maximum transmittance. The peak transmittance of the filters varied between 20% and 30%.

Fig. 2. Light emission vs. thickness with field as parameter. Electrolyte resistivity 7000 Ω-cm.

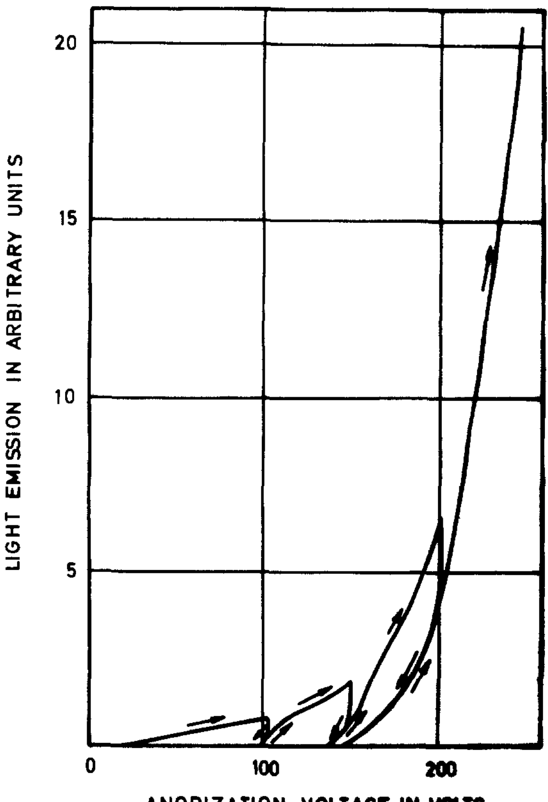

Fig. 3. Light emission vs. voltage with interruptions of anodic growth near 100, 150, and 200V. Current density 0.5 mA/cm^2, electrolyte resistivity 7000 Ω-cm.

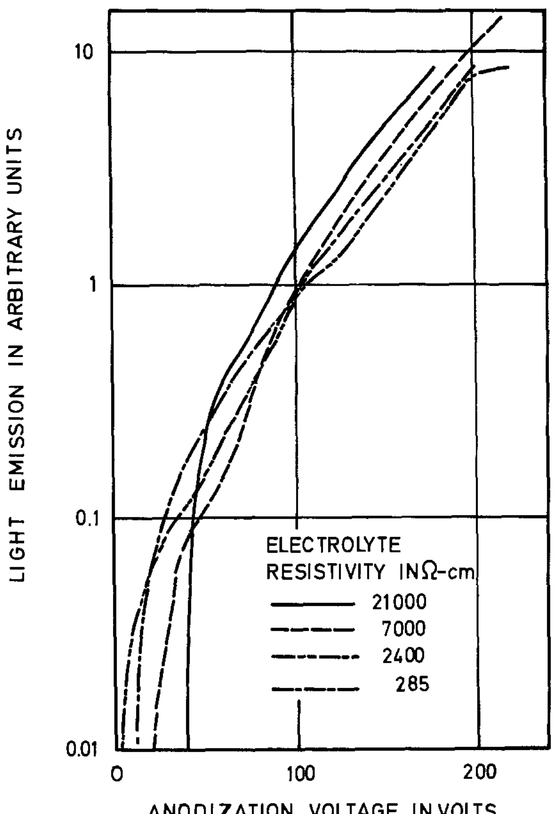

Fig. 4. Light emission *vs.* voltage with electrolyte resistivity as parameter. Current density 1 mA/cm^2.

For the evaluation of the light measurements, the transmission of the filters and the quartz light guide was determined with a Cary 14 type spectrometer and the photomultiplier spectral response was calibrated using a Jarrel-Ash monochromator Model 83-410 and an Eppley thermopile. Light readings were corrected for transmission losses in the system and for differences in the photomultiplier spectral response.

Results are shown in Fig. 6, where the narrow-band light emission, L, is plotted in relative units *vs.* anodization voltage with wavelength as parameter. The light emission component at 259 nm is of special interest with photon energies centered at 4.8 eV. The bandgap of anodically grown tantalum pentoxide was found to be smaller by photoconduction, 4.6 eV (14). Thus the 259 nm light emission was expected to be affected by light absorption in the oxide. Spectrophotometrical measurements showed that the coefficient of absorption K has a value between 1.8 and 2.0×10^5/cm at 259 nm in good agreement with earlier results of Bray *et al.* (15). A slight absorption was found at 313 nm wavelength with $K < 5 \times 10^3$/cm.

Mechanisms of Electroluminescence

Avalanching.—The near-exponential increase of light emission with thickness in Fig. 2, 4-6 suggests that the light emission is connected with avalanching, as found by van Geel *et al.* (3) for aluminum oxide. Since electrical breakdown investigations confirmed that impact ionization and avalanching accompany the anodic growth of tantalum pentoxide (11), we proceed examining avalanche models for the interpretation of light emission. The properties of impact ionization and avalanching are recapitulated first.

Fitting experimental data to breakdown theory it was found that the coefficient of impact ionization, α, is related to the field by $\alpha = 4.4 \times 10^6 \exp(-21.5/F)$/cm in the range of fields, F, 6.1-6.7 MV/cm with F given in MV/cm. The current density, j, of most anodizations was 1 mA/cm^2 at a field of 6.26 MV/cm and the corresponding value of α was 1.4×10^5/cm with an estimated uncertainty of $\pm 10\%$.

Electrons injected into the oxide produce avalanches by impact ionization. Electrons are little affected by trapping and traverse the oxide in the order of picoseconds. In contrast, holes produced on impact are deeply trapped, drift slowly toward the electrolyte,

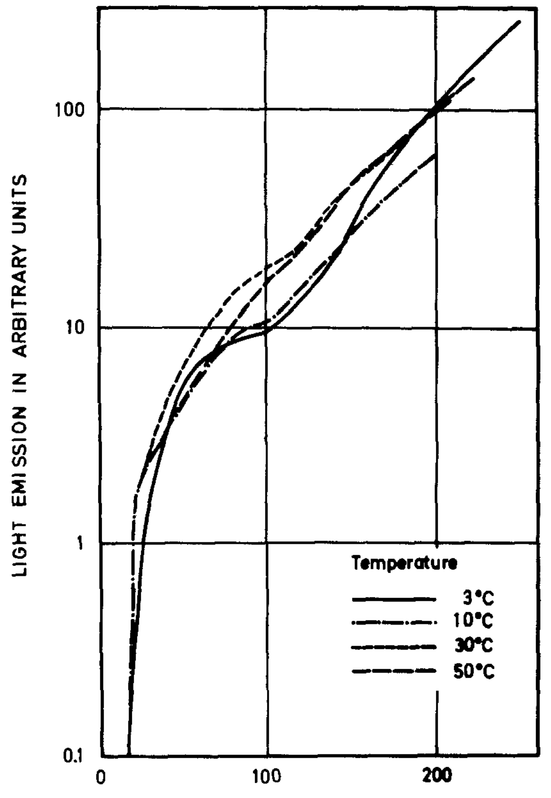

Fig. 5. Light emission *vs.* voltage with temperature as parameter. Current density 1 mA/cm^2, electrolyte resistivity 7000 Ω-cm.

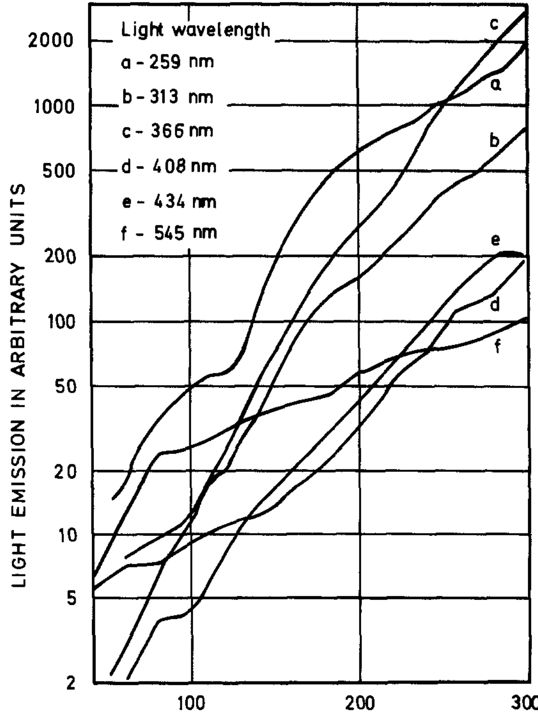

Fig. 6. Light emission through narrow bandpass filters *vs.* voltage. Parameter wavelength at maximum transmittance of filters. Current density 1 mA/cm^2, electrolyte resistivity 7000 Ω-cm.

and traverse the oxide in the order of micro- to milliseconds. Figure 7a shows a schematic oxide cross section with avalanche cones of holes at various stages of drift through the oxide. Most positive charge clusters drift out of the insulator. There is, however, some probability that a drifting cluster is hit by an electron injected from the electrolyte. Such an electron produces a second avalanche and a succession of avalanches at one spot produces breakdown (11).

The average number N, of electrons in an avalanche, as a function of distance x from the electrolyte interface is (11)

$$N = \exp\left(\int_0^x \alpha dx'\right) \quad [1]$$

There is an upper limit to the avalanche size, since positive charges produced and left behind keep decreasing the field at the propagating front of the avalanche until impact ionization stops (16, 13). The limiting avalanche size N_1 was found to produce about 2000 carriers of each sign in tantalum pentoxide (11). Since the avalanche size is an exponential function of x, the effect of positive charges becomes significant only in the last few ionizing steps of an N_1 size avalanche. The avalanche sizes were limited by oxide thickness in the light emission experiments, so that usually $N << N_1$ and N could be approximated by

$$N \simeq \exp(\alpha x) \quad [1a]$$

The number of holes produced in an avalanche $P = N - 1$. Figure 7b presents a second illustration of hole clusters drifting toward the electrolyte. The hole cones are not limited in this sketch by spatial extension in the electrode direction, but by curves approximating the hole density as function of x.

First-order kinetic processes.—The light emission can be examined by processes of first- and of second-order kinetics and we start with first-order processes. These produce light in proportion to the electron current. Photon emissions are due to events such as de-excitation of impurities, radiative trapping, geminate recombination, or de-excitation of excitons.

We assume that the rate of light emission by these processes dL from the wavelength band $\Delta\lambda$ and from the space between x and $x + dx$ is proportional to exp (αx), and to the rate of electrons injected, I_e/q, and

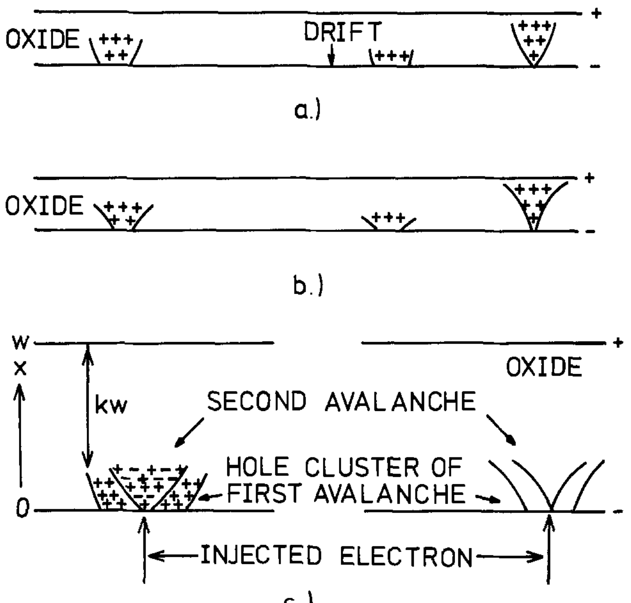

Fig. 7. Sketches showing (a) space occupied by avalanche hole clusters drifting through oxide; (b) hole density of drifting clusters as function of x; (c) EL event, left, spatial extensions and, right, hole density of overlapping avalanche clusters.

$$dL = A_\lambda I_e \exp(\alpha x) dx/q$$

I_e is the electron current, q the electronic charge, and A_λ is a constant dependent on the wavelength λ. Integrating between the limits 0 and w, the oxide thickness, the relation for light emission L is obtained in the absence of light absorption, $K = 0$, and

$$L = \frac{A_\lambda I_e}{\alpha q}[\exp(\alpha w) - 1] \quad [2]$$

This relation was derived by van Geel *et al.* (3). When account has to be taken of light absorption

$$dL = A_\lambda I_e \exp(\alpha x) \exp(-Kx) dx/q$$

and integration over the oxide thickness gives

$$L = \frac{A_\lambda I_e}{q(\alpha - K)}[\exp(\alpha - K)x - 1] \quad \text{for} \quad \alpha > K \quad [3a]$$

and

$$L = \frac{A_\lambda I_e}{q(K - \alpha)}\{1 - \exp[-(K - \alpha)x]\} \quad \text{for} \quad K > \alpha \quad [3b]$$

It is important to differentiate between the two cases: L grows quasi-exponentially with w, when $\alpha > K$. L saturates with w when $K > \alpha$, because light is detected only from a roughly $1/(K - \alpha)$ thick layer adjacent to the electrolyte.

The spectral data of Fig. 6 were examined with Eq. [2] first. Some difficulties were experienced in fitting results to Eq. [2] owing to a wavy structure superposed on the curves, which may perhaps be due to interference effects. We fitted by the least squares method and derived values for the coefficient of impact ionization α. These were tabulated for four wavelengths in Table I.

The results for the wavelengths 313 and 366 nm are remarkable, since they coincide closely with $\alpha = 1.4 \times 10^5$/cm obtained from breakdown observations (11). The agreement is less good for the 408 and 434 nm minor light components. Another minor component at 545 nm does not fit Eq. [2] and increases roughly in a linear manner with thickness.

The light emission at 259 nm is subject to light absorption. It could be fitted to Eq. [3a] resulting in $\alpha - K = 1.1 \times 10^5$/cm. Since the coefficient of absorption $K \simeq 2.0 \times 10^5$/cm, $\alpha = 3.1 \times 10^5$/cm results. This contradicts the values obtained at longer wavelengths and on breakdown (11). Alternatively we can use $\alpha = 1.4 \times 10^5$/cm and $K = 2.0 \times 10^5$/cm to describe the dependence $L(w)$ with Eq. [3b]. This equation predicts saturation in L which is not found with the exponentially rising 259 nm curve in Fig. 6. Thus first-order kinetics cannot explain the light emission at 259 nm.

Second-order kinetics processes.—We continue examining a second-order kinetics model for radiative hole-electron recombinations. These can take place on the chance event of an injected electron hitting an avalanche cluster of holes. A second avalanche is produced and recombination of holes of the first and electrons of the second avalanche can result in light emission. The probability of such an event, s, is $j_e(F_c)A_v t_t/q$ (13), $j_e(F_c)$ is the electron current density and F_c the cathode field at a hole cluster, A_v is the cross section of an average avalanche at the tantalum electrode, t_t the hole cluster transit time, and q the electronic charge. When electron injection takes place by tunneling, $j_e(F_c) \propto \exp(-B/F_c)$. The cathode field $F_c = \beta F$,

Table I. The coefficient of impact ionization, α from first-order kinetics processes

Wavelength, nm	259	313	366	408	434	545
Photon energy, eV	4.8	4.0	3.4	3.0	2.85	2.3
α, 10^5/cm		1.38	1.36	1.04	1.15	

where $\beta > 1$ is the field enhancement factor at a hole cluster.

The cathode field F_c keeps increasing during the drift of an avalanche cluster toward the cathode because most holes were produced near the anode. Increase of F_c increases $j_e(F_c)$ and s exponentially with $1/F_c$. The probability s will thus be largest in the vicinity of the cathode.

Figure 7c illustrates with two sketches the EL event resulting from hole-electron recombinations. The left-hand sketch shows the spatial extensions of the drifting hole cluster and of the new avalanche produced by a centrally hitting electron. The right-hand sketch indicates hole and electron densities of the first and second avalanche in the manner of Fig. 7b.

A relation for the EL emission can be readily derived with the help of a simplified model. We assume that injection of an electron into a hole cluster and light emission take place when the hole cluster has drifted a fraction kw of the insulator thickness toward the cathode (see Fig. 7c). The recombination light, dL_a, emitted by one avalanche in the wavelength band $\Delta\lambda$ and between x and $x + dx$ is $dL_a = r_\lambda N\ (\partial P/\partial x)\ dx$. Here r_λ is a constant, a function of the wavelength λ. $N = \exp\ (\alpha x)$ is the approximate size of the second electron avalanche crossing the space between x and $x + dx$ and $(\partial P/\partial x)\ dx$ are the holes produced in the space between x and $x + dx$ by the first avalanche.

Since on impact ionization $\partial N/\partial x = \partial P/\partial x$, we find with Eq. [1a] that $(\partial P/\partial x)\ dx = \alpha \exp\ (\alpha x) dx$ at the time of avalanche production. When the hole cluster drifts the distance kw toward the cathode, $(\partial P/\partial x) dx = \alpha \exp \alpha[(x + kw)]dx$ and

$$dL_a = \alpha r_\lambda \exp\ (\alpha x)\ \exp\ [\alpha(x + kw)]dx$$

To account for absorption of light, dL_a is replaced by an expression dL_{aa}

$$dL_{aa} = \exp(-Kx)\ dL_a = \alpha r_\lambda \exp(\alpha kw) \exp[(2\alpha - K)x]dx$$

The EL light emission is obtained by integrating dL_{aa} across the hole cluster from $x = 0$ to $(1 - k)w$ and by multiplying by the rate of light emitting clusters, sI_e/q. The resulting relation for L is

$$L = \frac{sI_e r_\lambda \alpha}{q(2\alpha - K)} \exp(\alpha kw)\{\exp[(2\alpha - K)(1 - k)w] - 1\} \quad [4]$$

When absorption is absent

$$L = \frac{sI_e r_\lambda}{2q} \exp\ (2kw)\{\exp\ [2\alpha(1 - k)w] - 1\} \quad [5]$$

Examination of the expression for dL_a, or of Fig. 7c, quickly reveals that most of the light is produced in a thin layer, a distance $x = (1 - k)w$ from the electrolyte interface.

The simplifications in the derivation of Eq. [4] and [5] are connected with the use of continuum instead of single electron calculations and with the omission of the effect of fluctuations in k and the place of electron injection with respect to the hole cluster. Owing to fluctuations in k and due to hole diffusion, the light emitting layer is expected to be broader than found with Eq. [4] and [5]. A further simplification is the assumption for the expression dL_a that the size of the second avalanche N is $\exp\ (\alpha x)$. Due to a dead space for ionization at the cathode and due to recombinations, N grows slower with x than $\exp\ (\alpha x)$, but faster owing to the increased rate of impact ionization by the enhanced field at the hole cluster.

The applicability of the recombination EL model was examined assuming that the major light components of Fig. 6 at 259, 313, and 366 nm are all due to radiative hole-electron recombinations. Equation [4] was fitted for this purpose to the experimental data at 259 nm and Eq. [5] to the data at 313 and 366 nm, using the same values of k and α. The small absorption at 313 nm was neglected.

The results are presented for better legibility separately, in Fig. 8, where full lines plot experimental data and the dotted line curves fitted with $\alpha = 1.12 \times 10^5$/cm, $k = 0.78$, and $K = 2 \times 10^5$/cm. A slightly better fitting results for nonabsorbing components, when only a pair of components is fitted. Thus if fitting is restricted to the 259 and 313 nm components, $\alpha = 1.105 \times 10^5$/cm and $k = 0.795$ is obtained. The pair of components of 259 and 366 nm gives $\alpha = 1.135 \times 10^5$/cm and $k = 0.765$. Thus the fitting procedure results in fairly precise values for α and k. The influence of the coefficient of absorption is not strong and a decrease of K to 1.8×10^5/cm has but a small effect on the fitting of the 259 nm curve to experimental data.

The breakdown investigations resulted in $\alpha = 1.4 \times 10^5 \pm 10\%$ at a field of 6.26 MV/cm (11). The difference from the α value found here is not unexpected owing to approximations in the models of the phenomena. A further difficulty is added by the lack of assessment of the influence of the wavy superstructure on the emission curves of Fig. 6. It was not thought warranted for this reason to derive EL relations more accurate than Eq. [4] and [5].

The total light production at 259 nm was determined too. Comparison of Eq. [4] and [5] shows that the total light is obtained by multiplying the measured light emission by

$$\frac{2\alpha}{2\alpha - K} \frac{\exp\ [(2\alpha - K)(1 - k)w] - 1}{\exp\ [2\alpha(1 - k)w] - 1} \quad [6]$$

The resulting total light production is plotted as a broken line curve in Fig. 8. The calculated total light emission curves of Fig. 8 show that the ratio of the light emissions L at 259, 313, and 366 nm wavelengths is 1:0.14:0.3.

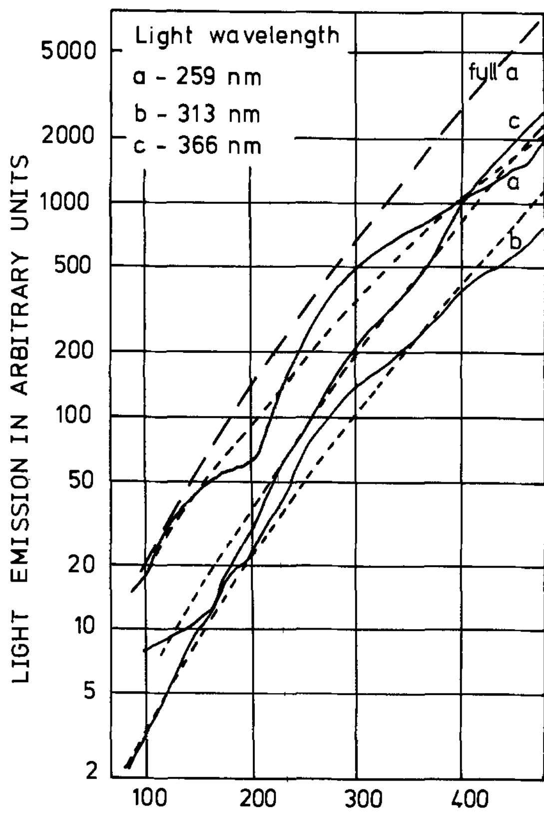

Fig. 8. Solid lines replot light emission curves of Fig. 6 for the wavelength 259, 313, and 366 nm. Dotted lines represent calculated results and the broken line is the full light production at 259 nm.

Discussion of the Luminescence

We first turn our attention to an assessment of the energy levels of the recombining conduction band electrons and trapped holes. Considering that the bandgap is 4.6 eV and using the photon energy data of Table I, we find that the hole traps are at least $q\phi_t = 1.2$ eV above the valence bandedge, if light emission is ascribed to the components 259, 313, and 366 nm only. If the components at 408 and 434 nm are also produced by recombination $q\phi_t = 1.85$ eV at least.

Further indication about the magnitude of $q\phi_t$ can be obtained from results of the breakdown investigations (11). These show that holes must be deeply trapped, since shallow traps would be empty at the fields of anodization larger than 6 MV/cm. There is also an upper limit for $q\phi_t$, since the mobility of trapped holes, μ_t, was estimated to be larger than 10^{-8} cm²/Vsec.

While these data are insufficient to calculate $q\phi_t$ we will attempt assessments of $q\phi_t$ with the help of assumptions. We start with the ratio of the hole density p in the valence band and the trapped hole density p_t. We equate p/p_t with the ratio of hole mobilities μ_t/μ_v, where μ_v is the hole mobility in the valence band. When the oxide thickness and the avalanches are small we assume that $p << p_t << P_t$, where P_t is the hole trap density. Boltzmann statistics apply in this case (17) and

$$\frac{\mu_t}{\mu_v} = \frac{p}{p_t} = \frac{N_v}{P_t} \exp\left\{-\frac{q}{k_T T}\left[\phi_t - \left(\frac{qF}{\pi\epsilon_0\epsilon}\right)^{1/2}\right]\right\} \quad [7]$$

Equation [7] permits one to calculate $q\phi_t$. N_v is the equivalent density of states in the valence band, k_T the Boltzmann constant, T the temperature, ϵ_0 the permittivity of empty space, and ϵ the relative permittivity of the oxide. We assume that $\mu_t = 10^{-8}$ cm²/Vsec, $\mu_v = 10$ cm²/Vsec, $N_v/P_t = 10^5$, $T = 300$ K, and $F = 6.26$ MV/cm. The magnitude of ϵ lies for Eq. [7] between the static value 25 and the optical value 4.5. We assumed first $\epsilon = 5$ and calculation with Eq. [7] resulted in $q\phi_t = 1.6$ eV. The calculation with $\epsilon = 15$ resulted in $q\phi_t = 1.24$ eV.

Avalanches grow to large sizes when the oxide thickness is large; p_t may reach values of 10^{18}/cm³ (11) and may be close to the magnitude of P_t then. We assessed $q\phi_t$ in these cases too, obtaining values slightly larger than when p_t is small. Examination of these results indicates that the hole trap level, or possibly levels, are situated approximately 1.5 eV above the valence bandedge. Addition of the photon energies of Table I to the hole energy level gives the energy level of the recombining electrons; for the 259, 313, and 366 nm light components these are 1.7, 0.9, and 0.3 eV above the conduction bandedge, respectively. These energy levels and recombination processes are illustrated with the schematic energy band diagram of Fig. 9.

The minor light components at 408 and 434 nm could also be ascribed to hole-electron recombination processes. Equation [5] would then apply to the light components 408 and 434 nm with the same constants α and k as to the components 313 and 366 nm. Figure 6 shows that this is not the case, since the slopes of the light emission curves at 408 and 434 nm wavelengths are smaller than at 313 and 366 nm. This discrepancy is expressed also in the difference of the corresponding α values in Table I. The reason for this difference may be indicated by the minor light emission at 545 nm (Fig. 6), which rises with thickness in a linear manner only. This emission cannot be ascribed to an EL process by avalanching and its origin is not known. It is feasible that the light emission at 408 and 434 nm is only in part due to recombination EL but in part due to processes which produce the 545 nm light component.

The discussion shows that radiative hole-electron recombinations can explain most of the spectrum observed. First-order kinetics processes can also interpret

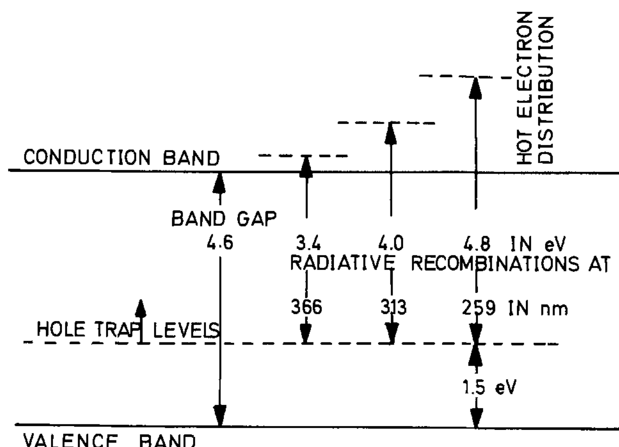

Fig. 9. Schematic band diagram for the illustration of the hole-electron EL recombination mechanism.

the light components not absorbed by the oxide, but not the largest component at 259 nm, partly absorbed by the oxide. Whatever the order of the process, a continuous spectrum is expected, as was observed on the anodic growth of aluminum oxide (18). It appears also that the total light output measured during the anodization of tantalum represents the sum of light emissions by different processes, of which recombination EL is preponderant. Total light output data are presented in Fig. 2, 4, and 5. Owing to differences in EL light processes, the data of Fig. 2, 4, and 5 will be discussed in a qualitative manner only.

We consider first the influence of the electrolyte (Fig. 4), which can affect the EL through the magnitude of the injected electron current, I_e. The light emission is proportional to I_e in first-order processes and to $sI_e \propto I_e^2$ in second-order processes (see Eq. [2]-[5]). Since the results of Fig. 3 show that L is not influenced by changes in the electrolyte, we find that I_e is unaffected by changes ranging from 2.5×10^{-3} to 1.8 w/o in the concentration of the aqueous citric acid electrolyte.

The rapid increase of EL emission with field shown by Fig. 2 is expected with Eq. [2]-[5] owing to exponential field dependences of I_e and α in these equations. The electron current I_e can be proportional to exp $(-B/F)$ and the coefficient of impact ionization is related to F by $\alpha = \alpha_0 \exp(-H/F)$, with α_0 and H constants (11).

Figure 5 illustrates the temperature dependence of light emission observed on anodizations at a current density of 1 mA/cm². Calculating fields of anodization (19), $F = 6.5$ MV/cm is found for the 3°C experiment and 5.8 MV/cm for the 50°C experiment. This decrease in F with increasing temperature implies large decreases in I_e and α, hence also in L according to any of the Eq. [2]-[5]. Figure 5 shows but little change in L between 3° and 50°C indicating the effect of compensating processes, contained perhaps in the temperature variation of the coefficient r_λ in Eq. [4] and [5].

Conclusion

The quasi-exponential increase of light emission with thickness during the anodic growth of Ta_2O_5 suggests that the process is an EL effect connected with avalanching. The light can originate from a number of de-excitation processes. An indication of their nature was found in observations on the largest light component at 259 nm. The light emission of this component increases quasi-exponentially with thickness, in spite of the fact that the component is strongly absorbed by the oxide. This could be well explained by radiative hole-electron recombinations, but not with first-order kinetics processes. Approximate relations derived for the thickness dependence of hole-electron recombination

light could be quite well fitted not only to experimental results of absorbed, but also of nonabsorbed, light components. Thus most of the light can be ascribed to recombination light, although it is feasible that nonabsorbed light components are in part due to first order kinetics EL mechanisms. A minor light component at 545 nm wavelength increased roughly linearly with thickness. This component cannot be explained with an EL mechanism connected with avalanching.

Fitting of experimental data on the major light components to theory resulted in fairly precise value for the coefficient of impact ionization, $\alpha = 1.12 \times 10^5$/cm at a field of 6.26 MV/cm. Comparison of electrical breakdown observations with theory gave $\alpha = 1.4 \times 10^5 \pm 10$ %/cm at this field. The difference in the α values was not unexpected, owing to the approximations made in deriving relations for the two phenomena. A further difficulty in the determination of α by EL was due to a wavy superstructure on the EL observations. The influence of this structure on the emission curves could not be assessed.

We used the same avalanche model in the development of theory for light emission and electrical breakdown. Theories could be well fitted to experimental observations and the magnitudes of the coefficient of impact ionization derived from EL and breakdown data were in fair agreement. Thus independent evidence was obtained on avalanching processes in tantalum pentoxide from two phenomena.

Acknowledgment

We gratefully acknowledge the help of Dr. M. Basseches of the Bell Laboratories, who supplied the tantalum-coated substrates. Thanks are due to Professor M. Auwärter, Balzers for the loan of optical filters and to Dr. E. Finkman for the measurements of optical constants. This work was submitted by V. K. in partial fulfillment of requirements for the D.Sc. degree to Technion.

Manuscript submitted Oct. 7, 1980; revised manuscript received Nov. 20, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Electrochemical and *In Situ* Laser Raman Spectroscopy Studies on Carbon-Supported Iron Phthalocyanine Electrodes

C. A. Melendres* and F. A. Cafasso

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

Cyclic voltammetry has been used to characterize the electrochemical behavior of iron phthalocyanine (FePc) films on glassy carbon electrodes in 0.05M H_2SO_4 solution. The films were found to catalyze oxygen reduction but deactivate on continuous cyclic scans. Films prepared by evaporation of a solution containing FePc and organic solvents, as well as by immersion in such a solution, showed significantly higher activity than those prepared by vapor deposition. This difference was attributed to the difference in the polymorphic forms of the FePc films. *In situ* laser Raman spectroscopy studies of this film indicated coordination of the FePc with water molecules in solution. The vibrational spectra, however, appear to be independent of potential in the region of 0.4 to -0.9V *vs.* Hg/Hg_2SO_4.

Considerable interest exists in the use of transition-metal macrocyclic compounds as a catalyst for the electrochemical reduction of oxygen (1). Iron phthalocyanine (FePc) and its derivatives, supported on carbon, appear to be among the most promising such catalysts. A number of electrochemical studies of this material both as an adsorbed layer or thick films on carbon have been reported in the literature (2-6). Spectroscopic studies have also been undertaken to

* Electrochemical Society Active Member.
Key words: electrocatalysis, iron phthalocyanine, Raman spectroscopy.

characterize the physicochemical properties of FePc (6-9). Despite these investigations, our understanding of the mechanism of O_2 electrocatalysis by FePc is far from complete. For example, little information exists concerning the molecular electronic structure of FePc on the electrode surface during electrolysis. The electrochemical behavior toward oxygen reduction of FePc films prepared by solution precipitation (2) and those prepared by vapor deposition (3) is apparently different; the reason for this is yet unexplained. Furthermore, the nature of the interaction of FePc with O_2 during electrocatalysis and the structure of a possible FePc-O_2 complex (8) have not been determined. In a program of basic research at Argonne National Laboratory, we are seeking correlations between the structure and intermolecular interactions of transition-metal macrocyclic compounds and their electrocatalyic properties. In this communication, we report some results on the interfacial behavior of carbon-supported FePc films in 0.05M H_2SO_4, as determined by cyclic voltammetry and laser Raman spectroscopy studies.

Experimental

Glassy carbon rods (¼ in. diam, from Fluorocarbon Corporation, Anaheim, California) were cut at an angle of 45°-60° then ground and polished to a mirror finish. These rods were then sheathed in heat shrinkable Teflon, leaving exposed only the elliptical-shaped, polished surface. FePc was obtained from Eastman Kodak Company (Rochester, New York) and used without further purification. Sample purity was established by infrared, Mössbauer, and atomic emission spectroscopy together with elemental (carbon, hydrogen, nitrogen) analysis. The FePc material was supported on the glassy carbon surface in a number of ways: (*i*) the carbon electrode was dipped in a solution of 0.25 weight percent (w/o) FePc in pyridine or 0.1 w/o FePc in dimethyl formamide (DMF) for 30 min to 4 hr, (*ii*) a portion of the same solution was evaporated on the surface, and (*iii*) FePc was vapor deposited onto the surface under vacuum. In all cases, the resulting electrode was washed thoroughly with distilled water before use. The average thickness of the FePc layer was determined from the amount of solution taken for evaporation or vaporization and/or by the use of a Varian Å-scope Interferometer Model 980-4000. A Princeton Applied Research Model 173 Potentiostat and 179 Universal Programmer were used for cyclic voltammetry. Electrode potentials were measured against an Hg/Hg_2SO_4 reference. The 0.05m H_2SO_4 solution was prepared from triply distilled water and deaerated by bubbling through it ultrahigh purity He (which had less than 2 ppm O_2 initially, then passed through molecular sieves at liquid nitrogen temperature). A special H-type, three-compartment cell fitted with a quartz optical window at an angle of 60° from horizontal was constructed for *in situ* measurements using laser Raman spectroscopy. A Spex Model 1401 double monochromator with a photomultiplier tube detector was used for these Raman measurements. Slit widths of 150-250 μm were employed with spectral resolution of 2-4 cm^{-1}. The signal was recorded following the usual d-c amplification. The cell and a diagram of the Raman setup are shown in Fig. 1. Sample excitation was by Ar^+ and/or Kr^+ lasers (Coherent Radiation Model 52G).

Results and Discussion

Electrochemical measurements.—Figure 2 shows typical cyclic voltammograms obtained from the pure glassy carbon electrode (no FePc) in 0.05M H_2SO_4 solution. Figure 3 shows a typical cyclic voltammogram in solution saturated with helium obtained for glassy carbon electrodes with FePc films prepared by methods (*i*) and (*ii*) given in the experimental section. Three cathodic (Ic, IIc, and IIIc) and three anodic waves (Ia, IIa, and IIIa) were observed in the voltage range

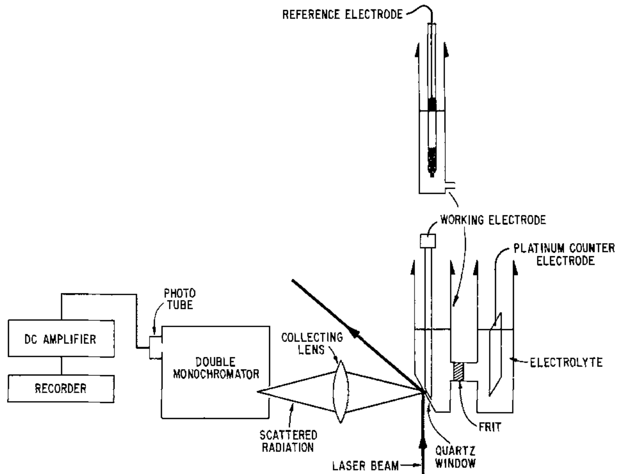

Fig. 1. Experimental setup

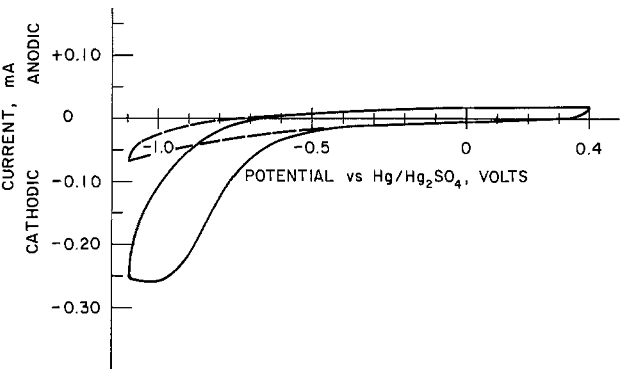

Fig. 2. Cyclic voltammograms of GC electrode: (1) — O_2 saturated, (2) - - - He saturated.

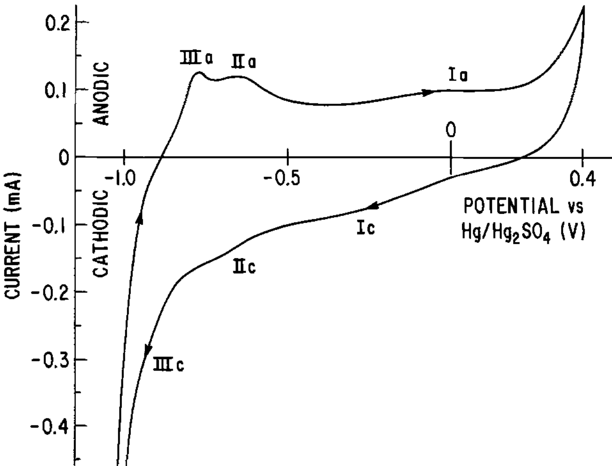

Fig. 3. Cyclic voltammogram of GC with FePc film prepared by solution evaporation: He saturated, avg. film thickness = 11000Å, apparent area = 0.57 cm^2, scan rate = 100 mV/sec.

of 0.4 to −1.0V *vs.* Hg/Hg_2SO_4. Figure 4 shows a number of scans made on the FePc-C electrode in oxygen-saturated solution. In contrast to Fig. 3, waves IIa and IIIa are not evident, while waves Ic and IIIc increase and become the dominant waves. Voltametric peak IIIc appears to coincide with the position of the cathodic peak produced in the reduction of O_2 on pure glassy carbon electrodes (Fig. 2). This suggests that this wave represents the reduction of oxygen on bare carbon surface in the FePc-coated electrode. Optical and electron microscopic examinations of the electrodes showed the existence of bare spots and a rather nonuniform coating distribution for films prepared by evaporation of FePc solutions. Wave Ic appears to be

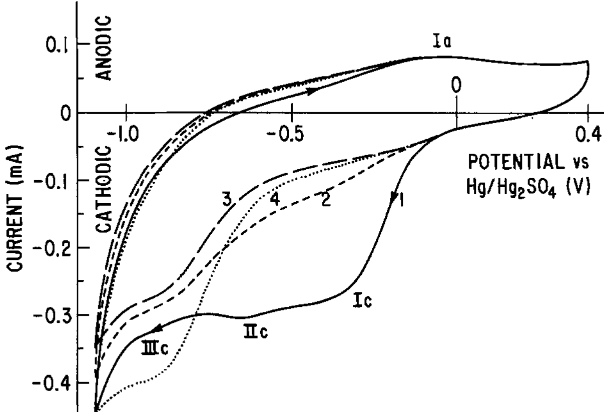

Fig. 4. Cyclic voltammograms of GC with FePc film: O_2 saturated, avg. film thickness ~ 11000Å, apparent area = 0.57 cm^2, scan rate = 100 mV/sec. (1) — first scan, (2) - - - - second scan, (3) —— fifth scan, (4) .... on stirring and bubbling O_2; sixth scan.

associated with the reduction of oxygen on the FePc film. The variation of peak current with the square root of scan rate for this wave is linear (Fig. 5), indicating that the process is diffusion controlled. Furthermore, the peak potential of Ic shifts to more cathodic values as the scan rate increases, implying a slow electron transfer process. This wave persists even after bubbling He through the solution for 2-3 hr, and we have been unable to eliminate it completely. Presumably, some residual oxygen remains in the solution or is adsorbed on the FePc surface.

It is interesting to note here that the well-defined voltammetric wave, Ic, was obtained only on the first scan and its intensity is diminished considerably on continuous scanning (see Fig. 4). By waiting for about 1 hr at open circuit until the initial open-circuit potential of about 0.15V *vs.* Hg/Hg_2SO_4 is reestablished, we are able to retrace the original wave (solid line in Fig. 4). The time to reestablish this open-circuit potential appeared to be independent of whether or not O_2 was present in the solution. This apparent "deactivation" of the electrode for the reduction of oxygen

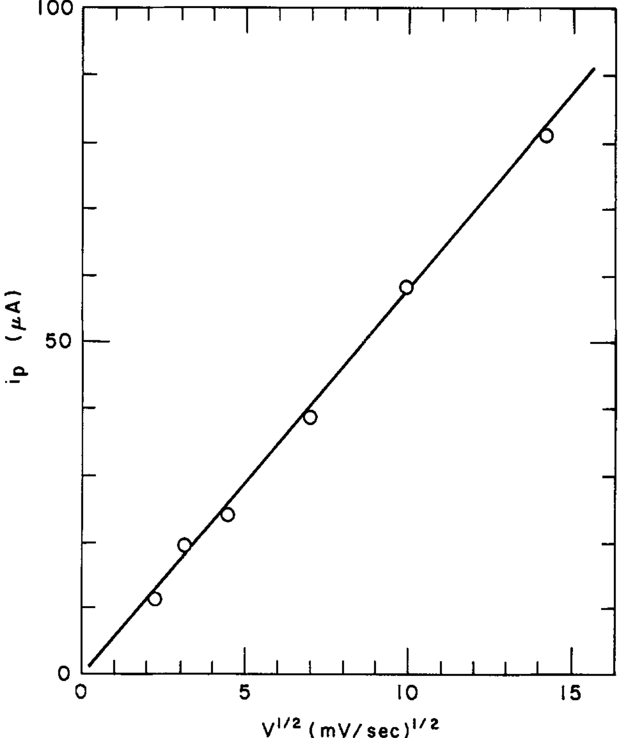

Fig. 5. Scan rate dependence of peak current for Ic

with repeated scanning was first noted by Kozawa *et al.* (2), who thought that it was due to high cathodic potentials (−0.8V *vs.* SCE in acid solutions). Although some loss in activity occurred in our electrodes when cycled to about −1.1V *vs.* Hg/Hg_2SO_4, this loss appears to be primarily due to desorption of the catalyst and/or breakdown of the film, which was brought about by the onset of gas evolution. Even under this condition, wave Ic reappeared when the cell was retained on open circuit for ~ 1 hr. Our electrodes deactivated even when switching potentials of −0.8V were used. Stirring the solution or bubbling O_2 through it during subsequent scans did not increase the cathodic current for Ic, although it increased that for IIIc. We are conducting further investigations to establish the origin of this deactivation phenomenon. Some possible causes are: (*i*) deactivation by peroxide electrogenerated on the bare electrode surface, (*ii*) blockage of active surface sites on the electrodes, or (*iii*) some limitation in the transport of charge carriers within the electrode. The third possible cause might be expected if, in line with Faulkner's hypotheses (5), FePc is considered a p-type semiconductor. Depletion of electrons or limitation in their transport can lead to saturation-type currents, which have been observed with semiconductor electrodes (10).

Electrochemical behavior similar to that of electrodes prepared by method (*ii*) was observed for our electrodes prepared by soaking the glassy carbon in solutions of FePc in pyridine or DMF (method *i*). For such electrodes, the peak current of wave IIIc is, however, often higher, indicating that a larger area of the carbon surface had been exposed. The intensities of the waves vary considerably from electrode to electrode, the efficiency of the dipping process for FePc attachment being facilitated by slightly roughening the glassy carbon surface.

Some difference was observed in the electrochemical behavior of the vapor-deposited FePc films (method *iii*). Figure 6 shows the cyclic voltammogram for an electrode with 3000Å thick FePc film vapor deposited on glassy carbon (0.05M H_2SO_4 electrolyte solution). The absence of wave IIIc is notable in this voltammogram. Coverage by the vapor-deposited film on the electrode appeared uniform and no bare spots were visible microscopically. The absence of IIIc is thus explained. For the case of O_2- saturated solution, waves IIIa and IIa also disappear, while an increase in background current in the region of IIc causes this wave to increase. Only a small peak for Ic is observed. The increase in residual current at −0.35V in the presence of oxygen is slight. This appears to support Tachikawa and Faulkner's (5) claim that O_2 is not significantly reduced on their vapor-deposited film electrodes.

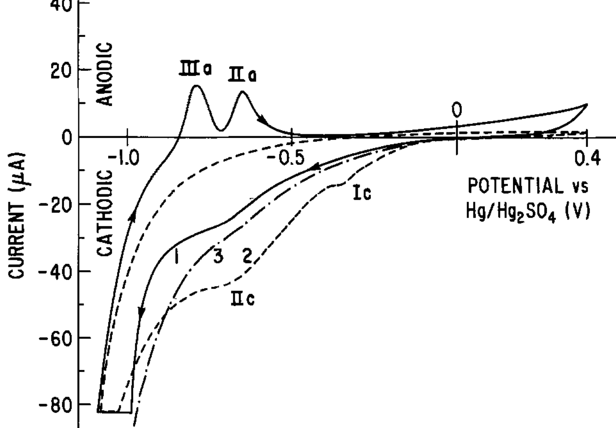

Fig. 6. Cyclic voltammograms of vapor-deposited FePc film on GC electrode: scan rate = 100 mV/sec, apparent area = 0.42 cm^2. (1) — He saturated; (2) - - - - O_2 saturated, first scan; (3) —·— O_2 saturated, second scan.

Table I. Oxygen reduction on FePc-glassy carbon electrodes

Method of electrode preparation*	Avg. film thickness (A)	Cathodic current** ($\mu A/cm^2$)
1) Vapor deposited	3000	17
2) Vapor deposited	1500	23
3) Vapor deposited	500	21
4) Evaporation of 0.1 w/o FePc/DMF solution	2000	145
5) Evaporation of 0.1 w/o FePc/DMF solution	6000	192
6) Same as (4) and (5) but on rough carbon substrate	11,000	354
7) Soaking in 0.25 w/o FePc/pyridine solution (roughened slightly)	—	95
8) Soaking in 0.1 w/o FePc/DMF solution (roughened slightly)	—	296

* Highly polished carbon substrate unless otherwise specified.
** At − 0.35V; scan rate = 100 mV/sec.

In Table I, we present the oxygen reduction currents at about −0.35V for FePc films on carbon prepared by the three methods. It is evident that, while all the films catalyze O_2 reduction, the activity of vapor-deposited FePc films is significantly lower than that of films prepared from pyridine or DMF. It also appears that the activity of the latter film does not depend on the solvent used since the same cathodic current has been observed by Kozawa on films prepared by precipitation of FePc from concentrated H_2SO_4 solutions (2). The difference in electrocatalytic activity of the films is probably attributable to their different structures. Films prepared by vapor deposition (or sublimation) are known to crystallize in the β-polymorphic form of FePc while those precipitated from solution take the α-form (11). The former is more stable, but the latter has higher electrical conductivity and is more active towards the uptake of oxygen. In the β-polymorph, the nitrogen atoms of the neighboring molecules are situated axially above and below the central metal atoms at about 3.38Å. In the α-form, the nitrogen atoms of the nearest molecules are not in axial positions, thereby, allowing access of electronegative ligands (*e.g.*, O_2) to the iron site (6). Our Raman spectroscopy results, described in the next section, provide concrete evidence for the difference in structure of the two types of film.

We feel confident about the assignment of waves Ic and IIIc for films prepared by all 3 methods. Waves IIc, IIIa, and IIa appear to be characteristic of the FePc itself. From their symmetrical shapes, they appear to be surface processes (12). The integrated charges under each wave indicate that the bulk of the FePc film is not involved. Wave Ia has been difficult to characterize owing to the presence of a coincident wave on the pure carbon electrode. This wave may be partially attributable to a surface process on the FePc, with a component also due to the anodic oxidation of the carbon surface. A similar deactivation phenomenon is observed with IIc as with Ic. The possibility that IIc has a component which is a consecutive reaction to Ic cannot be ruled out at this time. The possibility that the voltammetric waves observed here were due to impurities has also been considered. We feel this is unlikely. Analyses of our FePc showed insignificant organic contaminants and only a faint trace (< 10 ppm) of a number of metals. Impurities tend to give rise to a high background residual current rather than well-defined waves. Moreover, the same general voltammetric behavior is observed with different sample preparation procedures which should lead to varying impurity levels in the electrode and solution. Further electrochemical investigations of the redox processes associated with the above voltammetric waves are needed. To help elucidate these phenomena, spectroscopic measurements were undertaken. Some initial results are presented in the following section.

In situ laser Raman spectroscopy studies.—Raman spectroscopic measurements for the FePc films on glassy carbon electrodes in 0.05M H_2SO_4 were conducted *ex situ* and *in situ* as a function of applied potential. Laser excitation with a Kr^+ laser at 647.1 nm was principally employed to take advantage of resonance enhancement of the Raman effect. (FePc has an electronic absorption band in the 600-800 nm region.) Typical spectroscopic results are shown in Fig. 7. Essentially the same spectra are obtained *ex situ* for FePc films on glassy carbon prepared by method (*ii*), solution evaporation, and method (*i*), immersion in solution. Some difference was observed when the film was prepared by method (*iii*), vapor deposition. Bands at 1330 and 1600 cm^{-1} due to the carbon substrate appear for all the electrode specimens; their intensities relative to the FePc bands vary inversely with film thickness. The *in situ* spectra for films prepared from organic solutions appear to be the same as the *ex situ* spectra with the following exceptions: a new band appeared at 1513 cm^{-1} and the 1526 cm^{-1} band increased in intensity following immersion of the electrode in the solution (Fig 8). To ascertain the origin of the 1513 cm^{-1} band, *in situ* spectra were taken in pure water both in the presence and absence of oxygen. The 1513 cm^{-1} band was observed in both cases, indicating that this band is associated with an interaction of the FePc film with water. This band appears to increase with time following immersion of the electrode in water, while the adjacent band at 1500 cm^{-1} decreases proportionately with time. Removal of the electrode from water results in reappearance of the 1500 cm^{-1} band and a proportional decrease in intensity of the 1513 cm^{-1} band. Based mainly on infrared spectral studies on metalloporphins (13, 14) and metal phthalocyanines (15-17) together with a normal coordinate analysis of the vibrational spectra of metalloporphins (19), we have assigned the 1500 cm^{-1} band to the C-N stretching mode. A shift in the frequency of this band to 1515 cm^{-1} is consistent with coordination of water to the bridge nitrogen site in FePc. This assignment is supported by the x-ray and u.v. photoelectron spectroscopy studies of Kawai *et al.* (20) on the adsorption of water on metal phthalocyanines. This last study as well as that of Sidorov (18) indicate adsorption of a hydrogen in the water molecule onto the bridge nitrogen site. Furthermore, from the intensity of the 1530 cm^{-1} band, it can be deduced that the water is incorporated into the bulk of the phthalocyanine film rather than just on the surface layer.

We are as yet unable to assign a mode for the 1526 cm^{-1} band; its intensity change follows closely that of the 1513 cm^{-1} band and can, to a large extent, be accounted for by its partial overlap with this band.

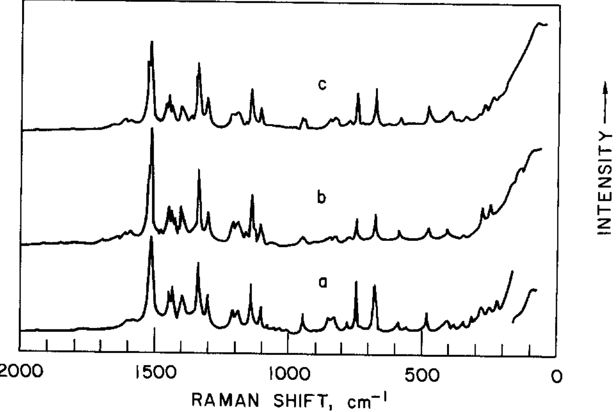

Fig. 7. Raman spectra of FePc film-on-glassy carbon electrode: (a) *ex situ* spectra, (b) *in situ* at $E = 0.4V$, (c) *in situ* at $E = -0.8V$. Avg. film thickness ≈ 500Å, Kr^+ Laser, $\lambda = 647.1$ nm, $P = 140$ mW.

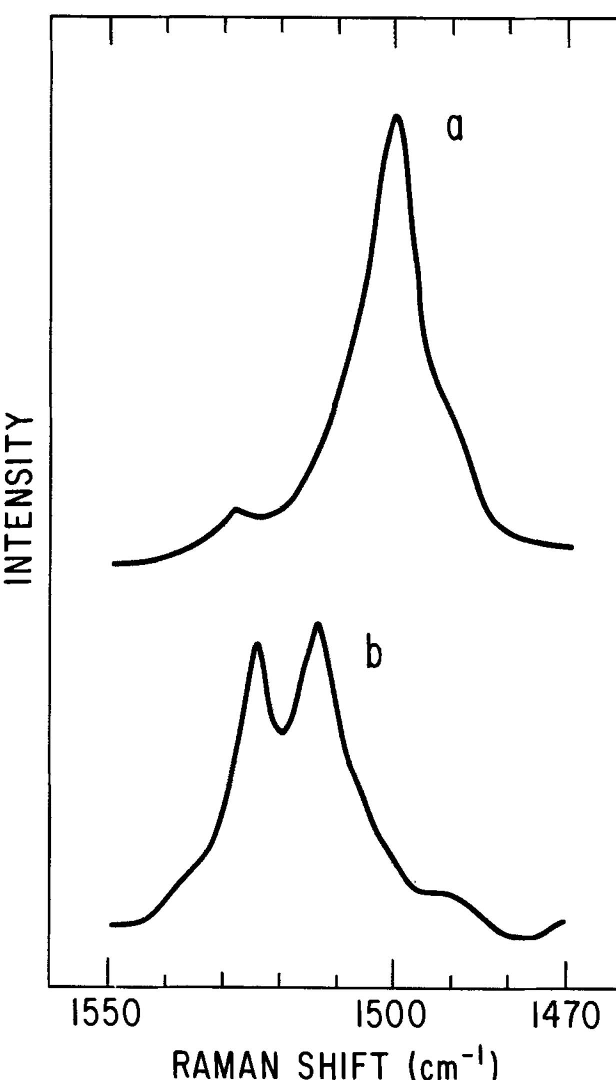

Fig. 8. Raman spectra of FePc-on-glassy carbon electrode (partial). Film prepared by evaporation of DMF solution (α-form). (a) *Ex situ* spectra, (b) *in situ* after 15 min following immersion of electrode in solution. Avg. film thickness ~ 3500Å, Kr^+ Laser, λ = 647.1 nm, P = 95 mW.

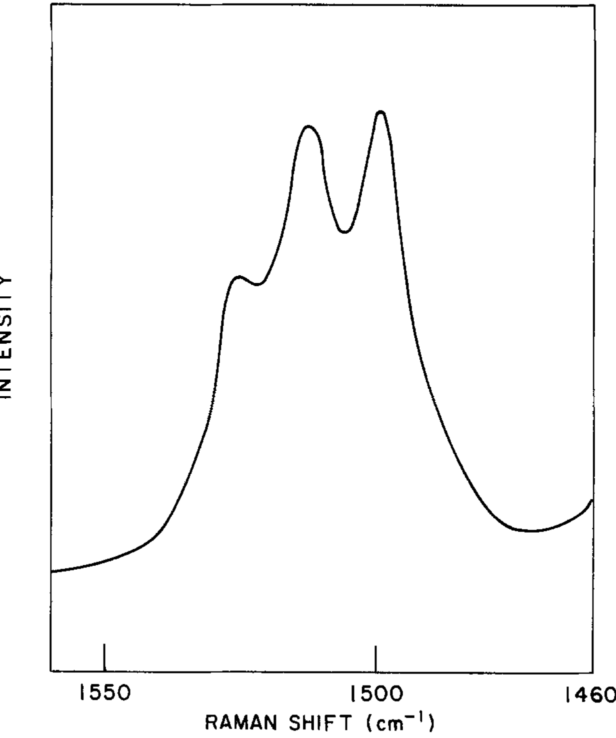

Fig. 9. Raman spectra of vapor-deposited FePc film on GC (β-form). Average thickness = 3000Å.

The difference in *ex situ* spectra of vapor-deposited FePc film and films prepared by methods (*i*) or (*ii*) can be seen by comparison of Fig. 9 and Fig. 8a. In Fig. 9, strong bands at ~ 1513 and ~ 1526 cm^{-1} are observed in addition to the 1500 cm^{-1} band. These two bands again increase in intensity on immersion of the electrode in water or 0.05M H_2SO_4 solution, while the 1500 cm^{-1} band decreases. The appearance of the 1513 cm^{-1} band in the vapor-deposited films, even in the absence of water, can be rationalized in terms of the structure of the β-form of FePc. As previously stated, in this form, the iron is coordinated above and below the bridge nitrogen site, hence the spectrum is similar to that taken *in situ* for the α-form coordinated with water molecules. As a result of this coordination, the C-N stretching frequency shifts. We also find a weak band at ~ 278 cm^{-1} which is specific to the vapor-deposited FePc; this is in addition to all other bands observed for films prepared from solution. This weak band probably involves an iron-ligand vibrational mode, which is expected to occur in the region of 100-300 cm^{-1}.

We have also studied the dependence of the vibrational spectrum of FePc on the applied potential. Starting at an open-circuit potential of about 0.15V *vs.* Hg/Hg_2SO_4, the potential was changed to the desired value and the spectrometer was scanned from 100 to 2000 cm^{-1}. Spectra were obtained at constant potentials from + 0.4 to − 1.0V. Apart from a marked decrease in intensity of the bands with the passage of current, the spectra were essentially the same as the one obtained at open circuit (Fig. 7a and 7b); no significant shift in frequency of the bands occurred and no new bands appeared. The 1513 and 1526 cm^{-1} bands appear unaffected by the applied potential and cycling. A continuous deterioration of the spectra (poor signal-to-noise ratio), however, occurs with time of cathodization and at the more negative potentials. The latter is probably associated with the formation of gas bubbles, which were observed on the electrode surface.

The independence of the vibrational spectra of FePc on applied potential implies either the structure of the FePc film is unaffected by potential or the laser Raman spectroscopic technique is insensitive to any structural changes that are occurring, or both. It is likely that no structural change occurs in the bulk of the FePc film as a function of potential. If the bulk of the film were ionized, frequency shifts of the bands and the appearance of new ones would be expected (22). The laser Raman technique is sensitive to bulk structural changes. Whether it is able to monitor electronic structural changes of the surface layer in the present system was of interest to us. The passage of current certainly indicates the occurrence of electrochemical reactions at the electrode surface. To see if we can follow the structural changes associated with these reactions, *in situ* spectra of FePc on glassy carbon prepared by dipping the electrode in a solution of FePc in pyridine, to obtain monolayer coverage, were obtained. The spectra were not significantly different from those of the thick film as far as can be established. The signal-to-noise ratio, however, was rather poor; in many instances, only the most intense band at about 1500 cm^{-1} was observed. Again, no potential dependence was observed for this band. Initial attempts to obtain spectra *in situ* for FePc adsorbed on high-surface-area carbon electrodes have not been successful.

To recapitulate, we have reported in this publication some results on the interfacial behavior of carbon-supported FePc films in 0.05M H_2SO_4. Our cyclic voltammetry measurements showed similar electrochemical

behavior of FePc films prepared by solution evaporation or dipping and by vapor deposition. The FePc films catalyze the electrochemical reduction of oxygen to varying degrees but deactivate on continued scanning. The mechanism for this deactivation process is not known; it is likely to be associated with the slow transport of charge carriers within the semiconductor film electrode. "*In situ*" laser Raman spectroscopy investigations indicate coordination of the FePc with water molecules in solution. This finding should be considered in any attempt to correlate electrocatalytic activity of FePc films with structural features. The "*in situ*" laser Raman technique can monitor structural changes in the bulk of the FePc film; the α and β forms of FePc can be distinguished. The vibrational modes of the bulk film, however, appear independent of applied potential.

Acknowledgment

The authors are grateful to Dr. J. Unik and Dr. J. Ferraro of the Chemistry Division, ANL, for allowing us the use of their Raman spectrometer, to Al Smirvickas for assistance in its operation, and to Dr. R. Varma for initial introduction to the technique.

This work was carried out under the auspices of the Materials Science Office of the Department of Energy's Division of Basic Energy Sciences.

Reactions of FeS Electrodes in LiCl-KCl Electrolyte

Z. Tomczuk,* S. K. Preto,* and M. F. Roche*

Argonne National Laboratory, Chemical Engineering Division, Argonne, Illinois 60439

ABSTRACT

The reactions of FeS electrodes in LiCl-KCl electrolytes of various compositions were determined by a combination of phase studies, cyclic voltammetry, and emf measurements. The effect of temperature, charge-cutoff voltage, and electrolyte composition on the phases present in the sulfide electrode were determined. Six electrochemical and four chemical reactions can occur. The emf's of three of the six electrochemical reactions were measured over a temperature range of 380°-530°C and were computed for the other three electrochemical reactions. The free energy changes for the chemical reactions were also calculated.

Since the early 1970's Argonne National Laboratory has been developing high-performance batteries for use as power sources for vehicle propulsion and as energy storage devices for electric utilities. In the ongoing development work, the battery cells are operated at 400°-500°C and consist of molten LiCl-KCl electrolyte, Li-Al alloy negative electrodes, and FeS or FeS_2 positive electrodes. The LiAl/FeS cell has received the greatest attention, primarily because an inexpensive current collector (iron) can be used in the FeS electrode and because the capacity retention of this cell is superior to that of the LiAl/FeS_2 cell (1, 2).

The electrochemical properties of the Li-Al alloy have been reported in considerable detail (3-8). The potential of this electrode in LiCl-KCl electrolyte at 400°C is approximately 300 mV less anodic than that of liquid lithium, and the electrode reaction is simply

$$\text{LiAl}(\beta\text{-phase}) \rightleftarrows \text{Li}^+ + \text{Al}(\alpha\text{-phase}) + e^- \quad [1]$$

Some properties of the FeS electrode, which has a voltage of about 1.34V *vs.* Li-Al, have also been reported (9-17). Five phases have been identified: FeS, $LiK_6Fe_{24}S_{26}Cl$ (≡J-phase), Li_2FeS_2 (≡X-phase), Li_2S, and Fe. The FeS phase corresponds to a fully charged electrode, the J- and X-phases are present at intermediate states of discharge or charge, and the Fe and Li_2S phases correspond to the fully discharged electrode. Additional phases are formed when cells are overcharged (12). These higher voltage phases were usually avoided in the present study.

* Electrochemical Society Active Member.

Key words: fused salts, free energy, voltammetry, emf.

The objectives of this study were: (*i*) to determine the sequence of phase transitions that occurs in the FeS electrode during discharge and charge, (*ii*) to obtain information on the effects of electrolyte composition and cell temperature on the electrode reactions, and (*iii*) to determine the thermodynamic properties of the reactions.

Thermodynamic preliminaries.—Because so many phases are involved in the FeS electrode reactions, some thermodynamic preliminaries are useful to outline the relationships among them. The condensed phases in the positive electrode consist of the liquid electrolyte, iron, and the sulfide phases. All of these phases can be prepared from five components: LiCl, KCl, FeS, Li_2S, and Fe. The Gibb's phase rule for condensed systems, in which pressure and the gas phase are ignored, states that six conditions (coexisting phases and defined intensive variables) must be met to define a five-component condensed system at equilibrium (18). Four such conditions for the electrochemical reactions of FeS are: (*i*) iron is present, (*ii*) liquid electrolyte is present, (*iii*) the cell has a known temperature, and (*iv*) the electrolyte has a known ratio of LiCl to KCl. If any two of the sulfide phases are then present, an electrode of fixed potential is defined. Six such combinations of the four known sulfides are possible as shown in Fig. 1. The LiAl/FeS cell discharge reactions that correspond to the arrows in Fig. 1 are as follows

$$6LiAl + 26FeS + 6KCl \rightarrow J + 2Fe + 5LiCl + 6Al \quad [2]$$

$$20\,LiAl + J + 5LiCl \rightarrow 13X + 11Fe + 6KCl + 20\,Al \quad [3]$$

$$46LiAl + J + 5LiCl \rightarrow 26Li_2S + 24Fe + 6KCl + 46Al \quad [4]$$

$$2LiAl + 2FeS \rightarrow X + Fe + 2Al \quad [5]$$

$$2LiAl + FeS \rightarrow Li_2S + Fe + 2Al \quad [6]$$

$$2LiAl + X \rightarrow 2Li_2S + Fe + 2Al \quad [7]$$

The arrows in Fig. 1 are labeled with the free energy change of the electrochemical reaction

$$\Delta G_i = -n_i\mathbf{F}E_i \quad [8]$$

where n_i is the Li-Al coefficient in reaction [i], **F** is the Faraday, and E_i is the emf of reaction [i]. For instance, the free energy change for reaction [2] is given by $\Delta G_2 = -6\mathbf{F}E_2$.

Certain combinations of three E_i define the thermodynamic properties: any three E_i not forming a triangle in Fig. 1 may be selected independently. For instance, the discharge path consisting of reactions [2], [3], and [7] has the net effect of reducing FeS to Fe plus Li_2S and gives one set of three independent voltages from which the other three voltages can be calculated.

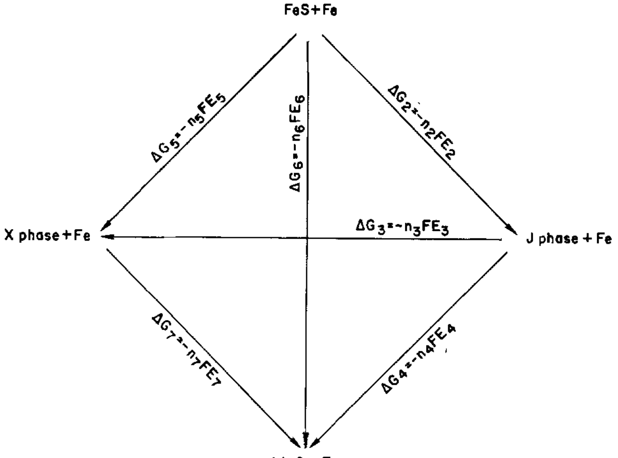

Fig. 1. Electrochemical reactions of the FeS electrode

It will occasionally be necessary to consider mixtures of three sulfide phases with iron. Such mixtures can be at equilibrium in a given electrolyte at only one temperature. At other temperatures in the same electrolyte, the three sulfide phases are not in equilibrium, and a chemical reaction tends to consume one of them. These chemical reactions are derived by eliminating Li-Al (and Al) between any two of the electrochemical reactions [2]-[7]. Four chemical reactions, two of which are independent, are derived in this way. These are

$$23X + Fe + 6KCl \rightarrow J + 20\,Li_2S + 5LiCl \quad [9]$$

$$3X + 20\,FeS + Fe + 6KCl \rightarrow J + 5LiCl \quad [10]$$

$$23FeS + 3Li_2S + Fe + 6KCl \rightarrow J + 5LiCl \quad [11]$$

$$FeS + Li_2S \rightarrow X \quad [12]$$

The free energy changes of these chemical reactions (ΔG_9 to ΔG_{12}, respectively) are related to the emf's of the electrochemical reactions as follows

$$\Delta G_9 = -46\mathrm{F}(E_7 - E_4) = -20\,\mathrm{F}(E_7 - E_3) \quad [13]$$

$$\Delta G_{10} = -20\,\mathrm{F}(E_5 - E_3) = -6\mathrm{F}(E_2 - E_5) \quad [14]$$

$$\Delta G_{11} = -46\mathrm{F}(E_6 - E_4) = -6\mathrm{F}(E_2 - E_6) \quad [15]$$

$$\Delta G_{12} = -2\mathrm{F}(E_5 - E_6) = -\mathrm{F}(E_5 - E_7) \quad [16]$$

Measurement of two of these ΔG_i *vs.* T and one of the E_i *vs.* T is sufficient to describe the system's thermodynamic properties. For example, Saboungi, Marr, and Blander (15) have obtained the ΔG_i at several temperatures through determination of the sulfide-ion activity required to convert FeS to J-phase or J-phase to X-phase in LiCl-KCl eutectic electrolyte. These ΔG's may be combined with E_i data to define the system. In other experiments, Saboungi and Martin (16) have conducted metallographic studies to determine several combinations of temperatures and LiCl-to-KCl ratios that correspond to either $\Delta G_9 = 0$ or $\Delta G_{10} = 0$. Under these $\Delta G = 0$ conditions, three sulfide phases coexist with iron, and, according to Eq. [13] and [14], three of the E_i coincide. These data may also be combined with E_i data to derive the system's thermodynamic properties. Thus, a variety of techniques may be employed to determine the thermodynamic properties of the LiAl/FeS cell.

In this study, we began by establishing the FeS electrode phases under various cycling conditions through metallographic and x-ray examinations. Cyclic voltammetry experiments were then conducted to aid in determining the dominant reaction paths in electrolytes of various compositions and temperatures. Finally emf measurements were combined with other available data to obtain the thermodynamic properties of the electrode.

Experimental

The LiCl-KCl eutectic (mp 352°C) was obtained from Anderson Physics Laboratory and was polarographic grade. It was analyzed to confirm its composition [58 mole percent (m/o) LiCl]. Polarographic grade LiCl was also obtained from the Anderson Physics Laboratory. The KCl was reagent grade (Baker) and had been dried at 100°C under vacuum for about 1 hr. The iron sulfide was stoichiometric FeS, obtained from Great Western Inorganic, that was ground and sieved (either −80, +170 mesh, or −325 mesh). Chemical analysis indicated that the purity was >99% and x-ray diffraction analysis showed that the material was single phase. The iron and lithium sulfide powders were obtained from Cerac/Pure, Incorporated and Foote Minerals, respectively. The stated purity of the iron was 99.9%, and the stated purity of the lithium sulfide was >97%. The purity of both materials was verified by chemical analysis. The Li-Al alloy powder

was obtained from KBI, Incorporated and contained 48 atom percent (a/o) lithium. The aluminum powder was obtained from Alcoa Aluminum Company and was >99% pure.

The cell design is shown in Fig. 2. The cells contained an iron sulfide working electrode and lithium-aluminum counter and reference electrodes. These were immersed in about 80 ml of electrolyte contained in a 250 ml alumina crucible. The Li-Al reference electrode was required only for cyclic voltammetry experiments; the Li-Al counterelectrode served as a reference electrode in the phase studies and emf measurements. In some phase studies, a liquid lithium counterelectrode (9) was used instead of Li-Al. We have converted any voltage data from these cells to the equivalent voltage *vs.* Li-Al. Thus, all cell voltages are given *vs.* an Li-Al reference electrode.

The FeS working electrodes were prepared by loading the FeS (or an equivalent amount of Fe and Li_2S) into the cavity (5 $cm^2 \times 0.6$ cm) of an ATJ[1] graphite cup. A disk of porous graphite (PG-60[1]) was then graphite-cemented to the face of the cup to serve as a particle retainer. Other designs of working electrode were employed in a few experiments. For example, an iron or molybdenum cup (1 $cm^2 \times 0.5$ cm), covered with fine screens and containing FeS with a five-fold excess of iron powder, was used in some of the voltammetry work. Molybdenum cups (2.5 cm diam $\times$ 0.6 cm deep) were also substituted for the graphite cups in a few cell tests. The theoretical capacity of the working electrodes was 0.5-1 A-hr (0.8-1.6g FeS) in the phase studies and emf measurements, but was much smaller in the cyclic voltammetry experiments (20-80 mA-hr).

The Li-Al counterelectrodes (42 a/o Li) were prepared by vibrating a mixture of 6g Li-Al powder (~5 A-hr Li) and 1.5g Al powder into a porous iron Retimet[2] disk (2.5 cm diam $\times$ 1.2 cm thick) which was contained in an iron or nickel cup. Fine stainless steel screens were welded to the face of the cup to retain the powders. The Li-Al reference electrodes (42 a/o Li) were similar in construction to the counterelectrodes, but were smaller (1 cm diam) and contained 1.6g Li-Al and 0.4g Al. These reference electrodes were wrapped in BN fabric so they could be placed close to the working electrodes (within 0.5 cm) without shorting.

Procedures.—The cells were operated at temperatures ranging from 370° to 520°C in a furnace well (7.5 cm ID) which was attached to a helium-atmosphere glove box. The helium was continuously purified

[1] A product of Union Carbide Corporation.
[2] A product of Dunlop Limited, Coventry, England.

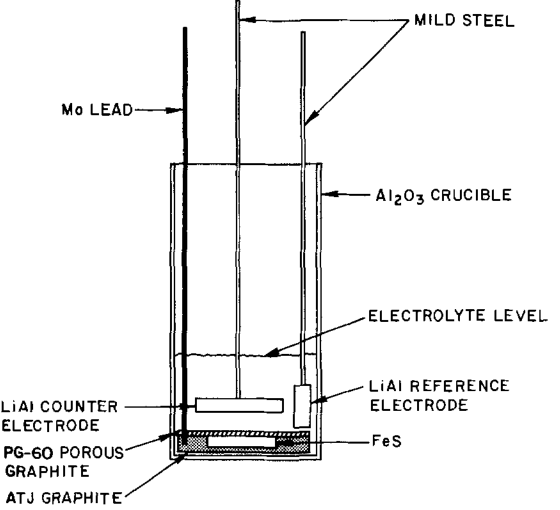

Fig. 2. Design of the LiAl/FeS cell

(<3 ppm O_2 and H_2O) by a combination of molecular sieves and cold traps. The furnace controller maintained the cell temperature within 1°C of the preselected value during cell operation. A sheathed Chromel-Alumel thermocouple that had been calibrated against an NBS standardized thermocouple was used to monitor the temperature of the cell *vs.* an ice point reference.[3] Since the thermocouple was wired to the cell exterior, a correction was required for the temperature drop through the alumina crucible. Interior *vs.* exterior temperature measurements on one cell gave a linear temperature correction ranging from 8° to 13°C for interior temperatures of 370°-520°C. In another cell (operated in a different furnace well), the correction was 2°C over the same temperature range. The reported cell temperatures include this type of temperature correction and are believed to be within 0.5°C of the actual cell temperature.

The cells used for phase studies were cycled at constant charge and discharge current densities of 10-50 mA/cm^2. The cell temperature employed during this cycling ranged from 400° to 490°C. The cycler consisted of a Hewlett-Packard Model 620B constant-current power supply equipped with a voltmeter-controlled relay system that reversed the direction of cell current at charge and discharge cutoff voltages of about 1.6 and 1.0V, respectively.

For the phase studies, some of cell tests were stopped during their initial charge or discharge, and others were stopped after subjecting them to five or more full cycles (generally, the coulombic efficiency was greater than 90% and the utilization of the FeS electrode capacity was greater than 80% in each of these cycles). In most of these tests, the electrodes were removed immediately after interrupting the current, and the electrodes were cooled to ambient temperature in the glove box. However, in some cases, the cells were allowed to approach equilibrium (either on open circuit or at some constant voltage) for several days prior to removal of the electrodes.

The positive-electrode phases were then examined by metallography and x-ray diffraction. The polishing equipment and microscopes for the metallographic work were located in a helium-atmosphere glove box to prevent reactions between the electrode samples and air. The glass capillaries for x-ray diffraction work were filled with electrode samples and were temporarily sealed with Apiezon grease prior to removal from the glove box. Upon removal, a section of the capillary between the sample and grease was fused to form a permanent seal.

For the cyclic voltammetry studies, the three-electrode cells were controlled by a Wenking Model 70HC3 potentiostat and a Wenking Model VG72 voltage scan generator, and the data were recorded on a Hewlett-Packard Model 7045A X-Y recorder. The procedure consisted of repeated cathodic and anodic sweeps to obtain steady-state voltammograms at each electrolyte composition and temperature. The tests were conducted using LiCl-KCl electrolyte (52-75 m/o LiCl) at temperatures of 389°-481°C. To resolve the various electrode-reaction peaks, low scan rates (about 0.02 mV/sec) were usually employed; a typical voltammetry cycle (1200 mV) required ~17 hr. These cycling rates are comparable to the rates at which the LiAl/FeS cells were cycled, and thus the phase data from cells could be related to the voltammetry data. The small capacity and large volume of the cyclic voltammetry electrodes precluded direct phase determinations on them.

For the emf measurements, cells of high coulombic efficiency were selected. These cells were first conditioned by cycling them for at least five full cycles at a current density of 15 mA/cm^2 and a temperature of 420°C. In these cycles, the coulombic efficiencies exceeded 99%, and the utilization of the FeS electrode

[3] A product of J. Kaye Company, Cambridge, Massachusetts.

capacity was greater than 80%. After being cycled, the cells were either discharged or charged to a selected fraction of their capacity and were placed on open circuit. The emf was then measured at the operating temperature of the cell as well as higher and lower temperatures with a Dana Model 5330 digital voltmeter ($10^{10}\Omega$). An emf was recorded only after the open-circuit voltage at each temperature was stable within 0.1 mV for at least 4 hr. Most of the data includes a 16-20 hr check of stability, although the voltage had usually stabilized within 1-2 hr. In some special cases, however, very long relaxation times (in excess of 100 hr) were employed to test for the possible effects of slow chemical reactions.

The cells for the emf measurements employed electrolyte of eutectic composition. However, it was recognized that the J-phase reactions would shift the composition. The maximum shift in composition was computed from the known weights of cell electrolyte and FeS and the stoichiometries of reactions [2], [3], and [4]. It never exceeded 0.3 m/o, and thus could be ignored.

A thermal emf, which resulted from the use of dissimilar metal leads (molybdenum on the positive electrode and iron on the negative electrode), was subtracted from the cell emf data. The thermal emf was measured by shorting the fully discharged electrodes to each other within the cell and reading the residual voltage at various temperatures. The thermal emf varied linearly from 3.3 mV at 370°C to 4.4 mV at 520°C.

Results and Discussion

Electrode phases.—In the first discharge of relatively large FeS particles (~160 μm diam), different surface reactions and core reactions were evident, as shown in Fig. 3. With an equivalent amount of more finely divided FeS particles (<45 μm diam) in the electrode, the surface reactions tended to go to completion, and the cores were then absent in all but a few larger particles. This difference between equivalent amounts of larger and smaller particles indicates that the layering effect in larger particles is caused by limited diffusion within the surface layer. Since the FeS particles in well-cycled electrodes become very fine (<20 μm diam), their discharge reactions are much simpler than those shown in Fig. 3. Nevertheless, an examination of the first discharge of large particles is of interest because the limitations of some of the

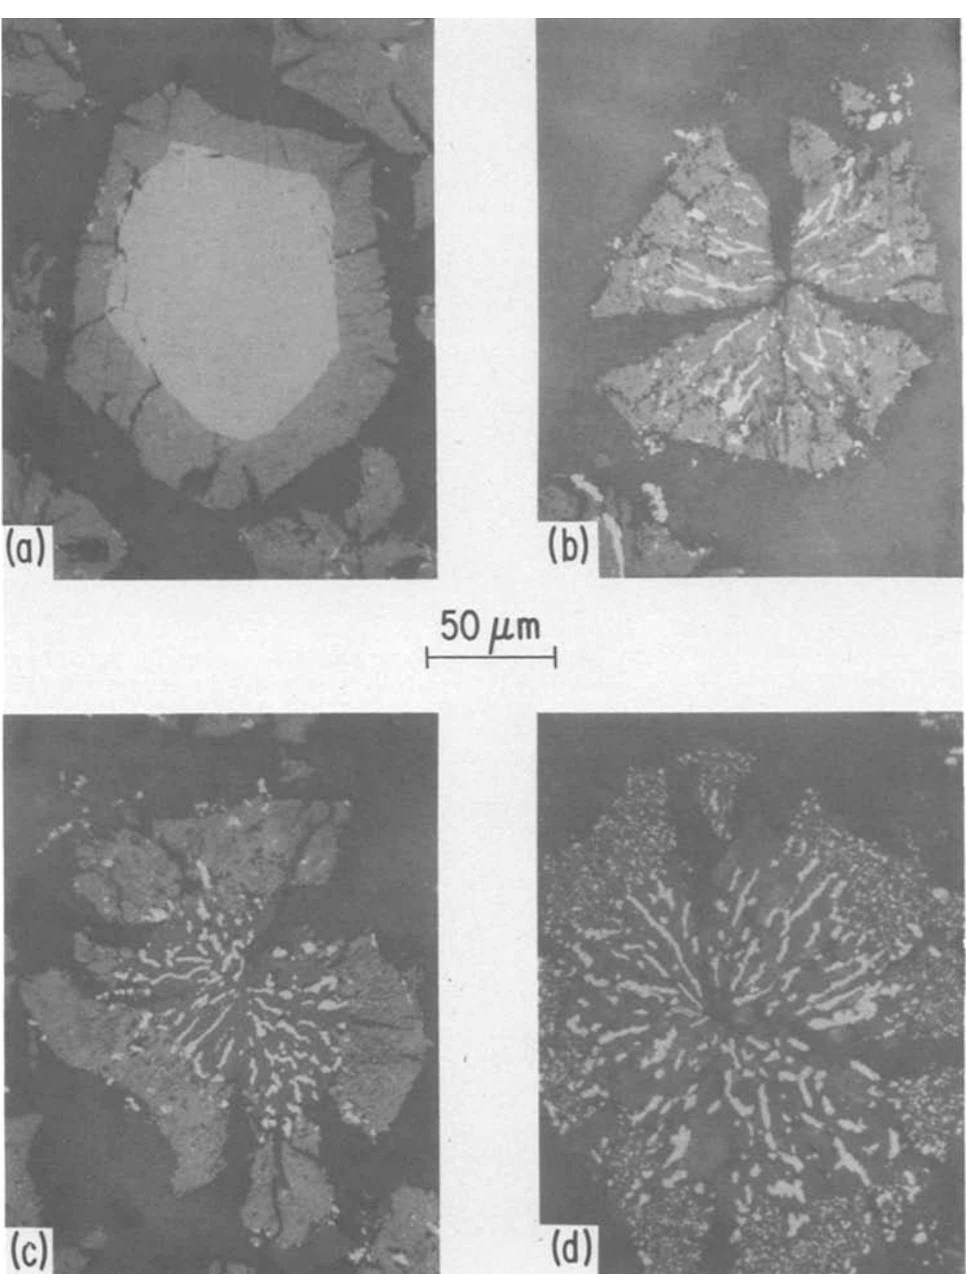

Fig. 3. Phases formed during the first discharge of large FeS particles (matrix phase is electrolyte): (a) core is FeS and surface layer is J-phase plus fine iron particles, (b) core is X-phase (gray) plus iron (white) and surface layer is J-phase plus fine iron particles, (c) core is Li_2S (gray) plus iron (white) and surface layer is J-phase plus fine iron particles, and (d) core and surface are Li_2S and iron.

reactions are readily observed. The first discharge of Cu_2S-modified FeS electrodes (20 m/o Cu_2S) has been reported (14). In that system the first reaction was like that shown in Fig. 3(a), but subsequent reactions also involved the Cu_2S and the distinct surfaces and cores were not as evident.

The particles shown in Fig. 3 came from various electrodes that were 20-100% discharged in eutectic electrolyte at 409°-430°C and were then cooled immediately to room temperature. The state of discharge of each particle can be crudely estimated from the relative areas of the phases and the stoichiometry of discharge reactions [2], [4], [5], and [7]; the particles in Fig. 3 are discharged approximately (a) 8%, (b) 25%, (c) 40%, and (d) 100%. Any one electrode usually contained a variety of such particle types. For instance, an electrode stopped at 20% discharge contained a mixture of unreacted FeS, particles like (a) and (b), and four-phase particles that combined features of (a) and (b). These four-phase particles each had a core of FeS, an intermediate layer of X-phase and Fe, and a surface layer of J-phase and Fe. These mixtures of particle types clearly were not in equilibrium, but the overall reaction sequence could still be deduced by examining the individual particles.

This examination showed that the first discharge of large FeS particles proceeded in four successive stages: I, FeS on the surface discharged to J-phase and iron; II, FeS in the core discharged to X-phase and iron; III, X-phase in the core discharged to Li_2S and iron; and IV, J-phase on the surface discharged to Li_2S and iron. The core reactions (stages II and III) only required Li^+ ions (and electrons) for their completion, while the surface reaction (stage I) also required K^+ and Cl^- to satisfly the stoichiometry of J-phase. Preferential diffusion of Li^+ through the J-phase surface layer was evident from the occurrence of the core reactions. It was also evident that the discharge of J-phase (stage IV) had a relatively low voltage; stages II and III were completed before stage IV occurred. Since the formation of J-phase was diffusion limited and the discharge of J-phase was a lower voltage reaction, suppressing these reactions (and accentuating the X-phase reactions) seemed desirable for high electrode performance.

One possible method of suppressing the J-phase is to employ an electrolyte with a high LiCl-to-KCl ratio, which tends to drive chemical reactions [9]-[11] to the left (15, 16). A first discharge of FeS in LiCl-saturated (68 m/o LiCl) electrolyte at 425°C provided an initial test of this possibility. The J-phase surface layers generated under these conditions were only one-fifth as thick as the surface layers shown in Fig. 3. Subsequent cell tests (19) established the beneficial effects of LiCl-rich electrolytes on cell performance, and such electrolytes are now routinely used in high-performance Li-Al/FeS cells (20).

The phases in well-cycled FeS electrodes and their relationship to cell voltage curves will now be described. Voltage curves for a well-cycled FeS cell are shown in Fig. 4; two voltage regions, A and B, are apparent. A charge cutoff voltage of 1.78V, which is somewhat higher than the normal 1.65V, was used to reveal region A, which corresponds to the J → FeS reaction on charge and the FeS → J reaction on discharge. A reference electrode showed that the higher voltage of region A was caused by shifts in the potential of the FeS electrode. The phase progression in regions A and B during discharge is simpler than that during charge and will be described first.

As noted previously, well-cycled FeS electrodes contain very fine particles ($<20\mu$ m diam) which undergo mainly the surface discharge reactions of larger particles (*i.e.*, stages I and IV). Thus, at least in terms of observed phases, the cell discharge presents a simple, two-stage sequence that can be represented as FeS → J → Li_2S. Early in the discharge (region A of Fig. 4),

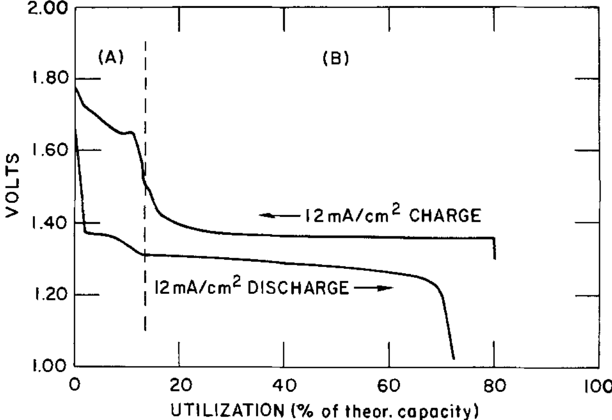

Fig. 4. Voltage curves for an Li-Al/FeS (0.45 A-hr) cell operated at 443°C using electrolyte of eutectic composition.

the phases are FeS, J, and Fe, and, for the remainder of the discharge (region B of Fig. 4), the phases are J, Li_2S, and Fe. Very little X-phase can be found in well-cycled electrodes that are stopped during discharge at normal cell temperatures (450°C or less). These results may be compared with metallographic studies (16) of chemical reactions [9] and [10]. These showed that mixtures of FeS, J-phase, and Fe were more stable than mixtures of FeS, X-phase, and Fe at temperatures up to 623°C in eutectic electrolyte. Similarly, mixtures of J-phase, Li_2S, and Fe were more stable than mixtures of X-phase, Li_2S, and Fe at temperatures up to 455°C in eutectic electrolyte. Thus the phase mixtures found in cycled cells that are discharged at normal temperatures are the equilibrium phase mixtures.

The phase mixtures found in well-cycled FeS electrodes that were stopped on charge were more complex than those on discharge. For example, X-phase was always found in cells stopped during charge anywhere in voltage region B of Fig. 4. In the first charge (5% theoretical) of fine Li_2S and Fe powders (−200 mesh) at 430°C, we found coexisting mixtures of X-phase, J-phase, Li_2S, and Fe. In fact, whenever X-phase was present, J-phase, Li_2S, and Fe were also found in the electrode, with the ratio of X-phase to J-phase being dependent on temperature and state of charge. In cells with eutectic electrolyte, the X-phase was more evident at higher temperatures and lower states of charge.

In spite of the complicated, nonequilibrium phase mixtures, the successive stages of the charge reaction could be outlined by examining contiguous regions of electrodes that were at increasing states of charge. Photomicrographs that illustrate various phase mixtures present in small regions of the electrodes, and that also represent successively higher states of charge, are shown in Fig. 5. From such examinations, we believe that the major stages during charge are as follows: I, Li_2S and Fe charge mainly to X-phase and Fe (with concurrent formation of J-phase tending to obscure this reaction); II, X-phase and Fe charge to J-phase and Fe; and III, J-phase and Fe charge to FeS. These charge stages were not as well defined as the discharge stages because of the involvement of X-phase, which is a nonequilibrium phase at normal cell temperatures.

Stages I and II occurred in region B of the charge curve in Fig. 4, while stage III occurred in region A. The voltage of the charge curve in region A was highly temperature sensitive, ranging from ~1.7V at 390°C to ~1.45V at 480°C; the other portions of the voltage curves varied only slightly with temperature. The difference between the charge and the discharge voltages in region A suggests poorer reversibility at low temperatures (large difference) and better reversibility at high temperatures. To confirm the indications that a

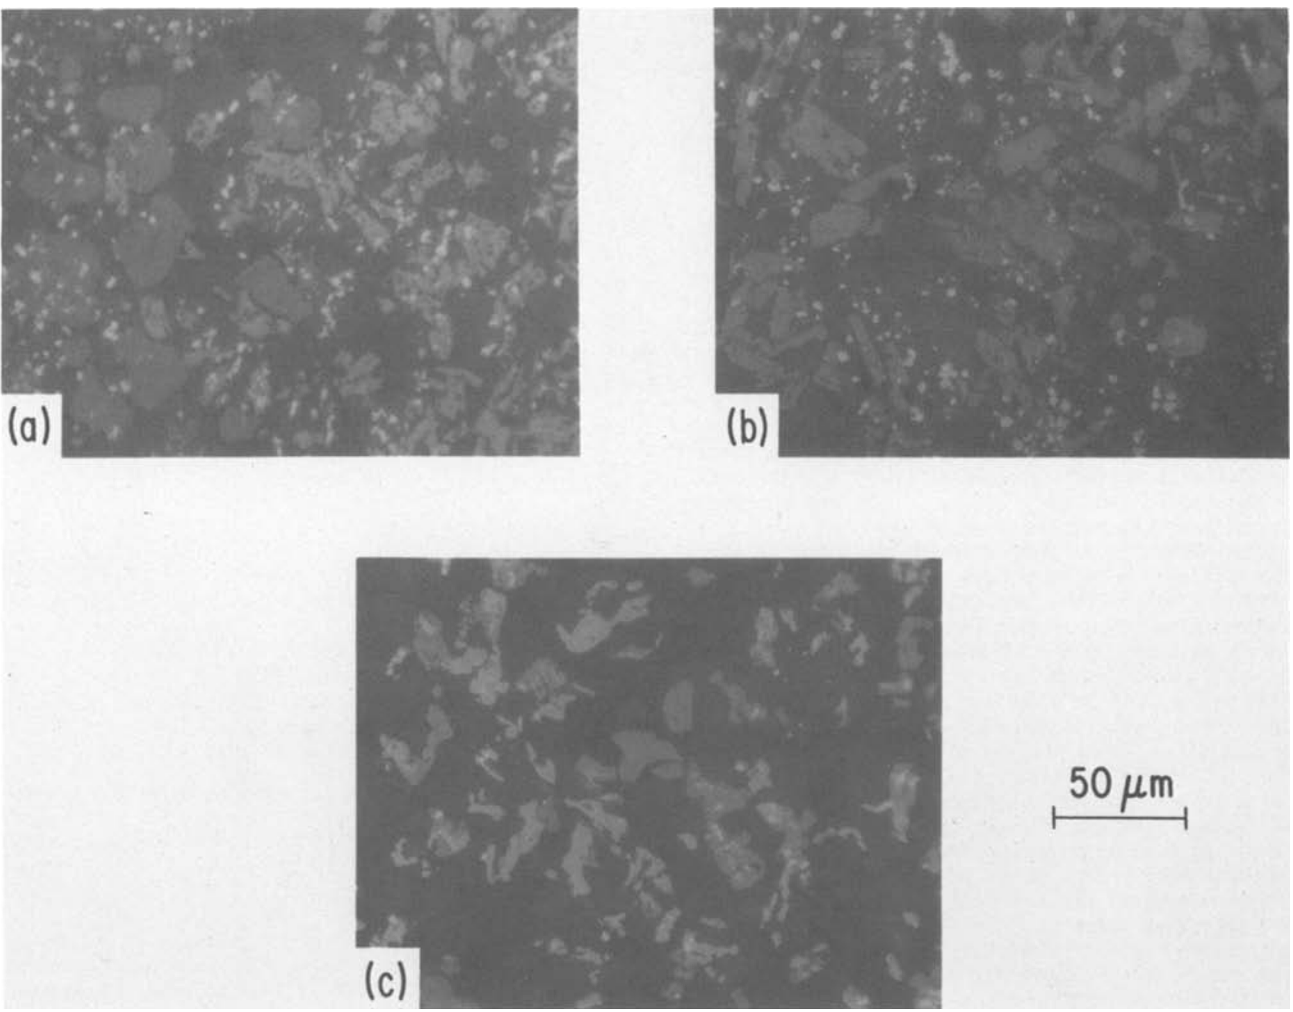

Fig. 5. Phases formed in well-cycled FeS electrodes during charge (matrix phase is electrolyte): (a) conversion of Li_2S and Fe (gray and white particles, respectively, on the left) to X-phase and Fe (gray and white particles, respectively, on the right), (b) conversion of X-phase and Fe (gray and white particles, respectively, on the left) to J-phase and Fe (gray and white particles, respectively, on the right), and (c) conversion of J-phase (darker gray) and Fe to FeS (lighter gray).

high cell voltage is required to drive the stage III reaction, we potentiostated two well-cycled cells at 1.50V for about 100 hr at a cell temperature of 400°C. The positive electrodes taken from these cells contained only J-phase and Fe; no FeS was generated.

From these phase studies, it was evident that well-cycled FeS electrodes had a different phase sequence on charge ($Li_2S \rightarrow X \rightarrow J \rightarrow FeS$) than on discharge ($FeS \rightarrow J \rightarrow Li_2S$) when eutectic electrolyte and cell temperatures less than 450°C were employed. However, one other feature of low-temperature cell operation needs to be considered. In addition to the usual solid phases, KCl or LiCl crystals may also be formed by current-induced shifts in salt composition (21, 22). We have occasionally seen evidence that such crystals were formed in cells operated at high current densities (~50 mA/cm²) and low cell temperatures (~430°C). In qualitative agreement with expectations, excess KCl was found near full discharge and excess LiCl near full charge. Such shifts in electrolyte composition, although not ordinarily detected, are in a direction that would tend to stabilize J-phase relative to X-phase on discharge and, conversely, stabilize X-phase relative to J-phase on charge. Thus, electrolyte composition shifts may partly account for the X-phase being more evident on charge than discharge at lower cell temperatures. However, the electrochemical and chemical reaction sequences are also a factor in accentuating X-phase on charge and suppressing it on discharge, as will be seen in the analysis of cyclic voltammetry data.

A few cells with eutectic electrolyte were tested at temperatures of 480°-500°C during the course of the phase studies. The results of these tests tend to support the chemical-reaction studies (16) which showed X-phase becomes an equilibrium phase at high temperatures in eutectic electrolyte. For example, we found that X-phase was apparently in equilibrium with J-phase and Fe at a temperature of 500°C in a 20% discharged cell that had been placed on open circuit for 50 hr prior to removal of the electrodes. In another cell, operated at ~490°C and stopped at 43% charge, X-phase and iron were dominant; only traces of J-phase were found. In a cell operated at ~490°C and stopped near full charge, FeS, J-phase, and Fe were still the dominant phases. Although these studies of phases present at high temperatures are less extensive than the studies of phases present at low temperatures, the phase sequence seems reasonably certain. Higher temperatures lead to similar sequences of sulfide phases during charge and discharge; namely, $Li_2S \leftrightarrow X \leftrightarrow J \leftrightarrow FeS$. However, the cyclic voltammetry studies indicate that the electrode reactions are not quite as reversible as this simple sequence implies.

It should be noted that no significant variations in either the x-ray diffraction patterns or metallographic characteristics of the electrode phases were detected in the above studies. Furthermore, there were always at least two coexisting sulfides (*e.g.*, FeS and J-phase) during an electrode reaction. Thus each of the reactions is expected to have a fixed emf.

Although we have sometimes used a shorthand notation (*e.g.*, $Li_2S \rightarrow X$) for reactions, we have purposely delayed the assignment of specific reactions (from the list of ten in the first part of the paper) to the observed phase sequences. The problem in making such assignments is that a variety of plausible combinations of electrochemical and chemical steps can lead to the same mixtures of phases. More detailed reaction assignments are given in the discussion below.

Cyclic voltammetry.—Cyclic voltammograms at high scan rates (5-50 mV/sec) for iron immersed in Li_2S-saturated LiCl-KCl eutectic electrolyte have been presented (11, 17). Their interpretation is difficult because the peaks may reflect transient intermediates rather than known electrode phases. In the present study, we concentrated on very low scan rates (0.01-0.02 mV/sec) that were comparable to the cell-cycling rates used in the phase studies. This type of voltammetry is similar to coulometry since the area of a current peak (in coulombs) is approximately the theoretical peak capacity and each peak can be reasonably associated with known electrode phases.

The effects of increasing scan rates are shown in Fig. 6 in which cyclic voltammograms at scan rates of 0.015, 0.1, and 0.2 mV/sec are given. In this case, the electrode consisted of 20 mA-hr of FeS (and a five-fold excess of iron) in a molybdenum housing (1 cm^2 $\times$ 0.5 cm). These voltammograms indicate that the dominant peaks (one on discharge and two on charge) are under ohmic control since the peak currents and peak potentials are both proportional to the square root of the scan rate. This type of ohmic behavior has been noted previously for the discharge peaks (11). Each of the peaks in Fig. 6 seems to exhibit more structure as the scan rate increases. Consequently, we believe that our reaction assignments, which will be based on the lower rates, will not define all the possible reactions at higher rates.

Figures 7 and 8 illustrate some of the effects of changes in cell temperature and electrolyte composition on voltammograms taken at scan rates of 0.01-0.02 mV/sec. The voltammograms in Fig. 7 are for eutectic electrolyte (58 m/o LiCl) at (a) 400°C and (b) 455°C, while those in Fig. 8 are for LiCl-rich electrolyte (67 m/o LiCl) at (a) 453°C and (b) 481°C. Since the mole ratio of electrolyte to FeS was very high (100:1) within the electrode cavity and a very large excess of electrolyte was present in the cell, the effects shown in these figures are not due to shifts in electrolyte composition.

Two general features of these voltammograms are of interest. First, the voltammograms indicate that the discharge electrochemistry is more complex than the charge electrochemistry. The phase studies showed an opposite effect, the phase sequences being more complex during charge. To explain these contrasting effects, a combination of chemical and electrochemical reactions is required. Second, the voltammograms indicate that many of the reactions do not have the sort of ideal reversibility that is desirable for emf measurements; the discharge peaks have different areas than the charge peaks and seem to be located at different potentials.

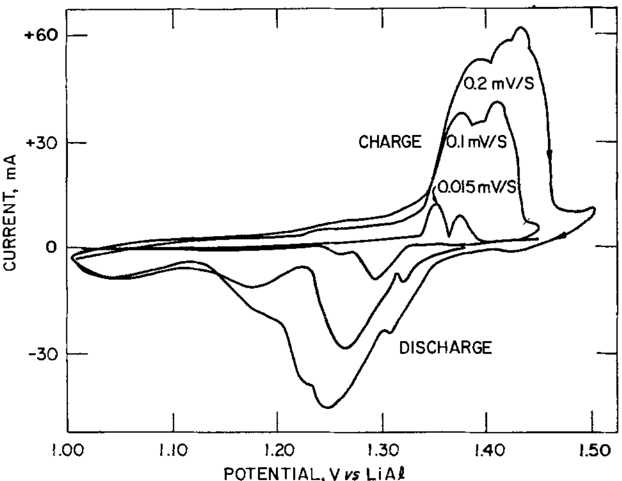

Fig. 6. Effects of increasing scan rates on cyclic voltammetry peaks of FeS electrode (20 mA-hr capacity) operated in eutectic electrolyte at 430°C.

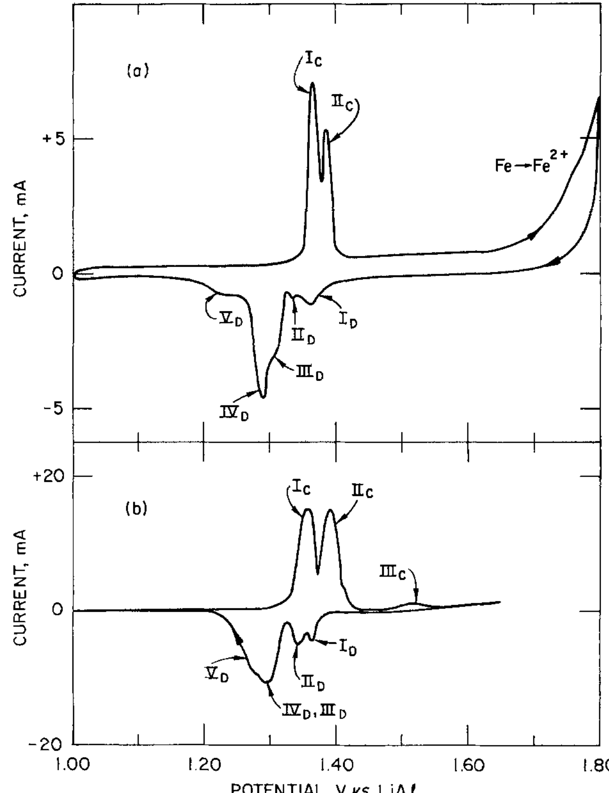

Fig. 7. Voltammograms for FeS electrodes operated in eutectic electrolyte (a) 400°C, 0.015 mV/sec, 18 mA-hr FeS and 90 mg Fe in molybdenum housing, and (b) 455°C, 0.01 mV/sec, 80 mA-hr FeS in graphite housing.

The major reaction paths were derived by combining the data from cyclic voltammetry and the phase studies. An electrochemical reaction (from the list of six in the beginning of the paper) was assigned to each voltammetry peak on the basis of its size, location, and response to changes in electrolyte composition, cell temperature, and charge-cutoff voltage. These assignments were compared with the emf of each reaction (given in the next section) to ensure that the discharge peak was below the emf and the charge peak was above the emf. The chemical reactions were then considered as required to reconcile any differences between the electrochemical assignments and the observed electrode phases. These chemical reaction assignments were also compared with the emf data, using Eq. [13]-[16], to ensure that the reactions were capable of proceeding in the desired direction.

The electrochemical reactions assigned to charge peaks I_c and II_c in Fig. 7 and 8 are, respectively, $Li_2S \rightarrow X$ (E_7) and $X \rightarrow FeS$ (E_5). These assignments are based primarily on the observation that the areas of the two peaks remain nearly equal over a wide range of conditions (see Fig. 7 and 8). However, the assignments are also supported by an analysis of the response of the peak voltages to changes in electrolyte composition and temperature. This analysis is based on the voltage at the leading edge of each peak, which approximates the emf of each reaction. The voltage,

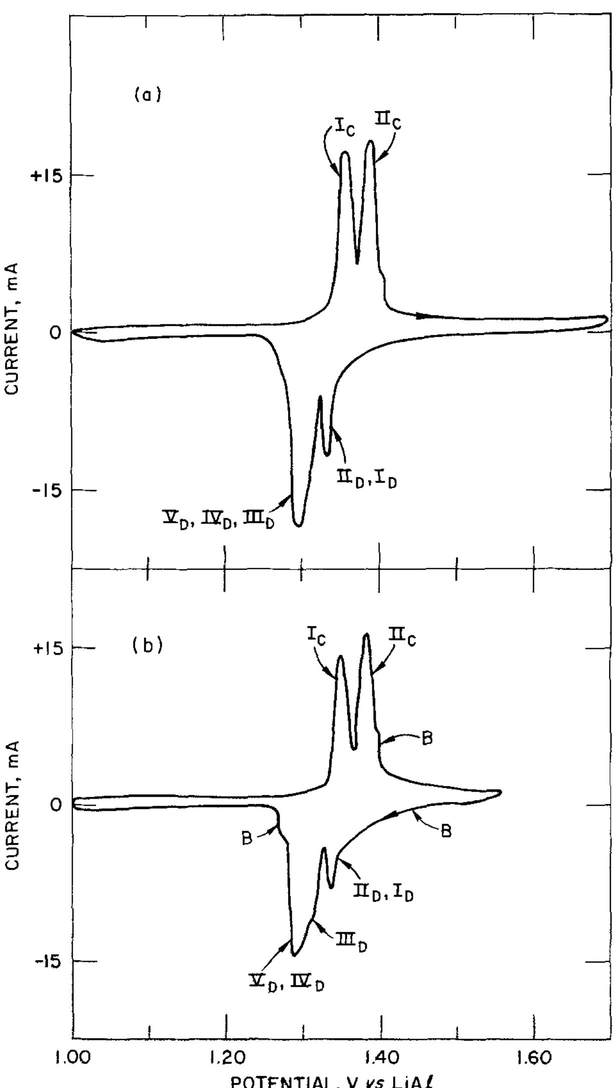

Fig. 8. Voltammograms (0.02 mV/sec) for FeS electrode (40 mA-hr in graphite housing) operated in LiCl-rich electrolyte (67 m/o LiCl) at (a) 453°C and (b) 481°C.

$V(I_c)$, was obtained by linear extrapolation of the left side of peak I_c to zero current, and the voltage, $V(II_c)$, was obtained by adding the peak separation to $V(I_c)$. The voltages obtained in this way for a variety of electrolyte compositions and cell temperatures are presented in Table I and Fig. 9. The voltages in Table I are independent of electrolyte composition, which is in accord with the assigned reactions and excludes J-phase reactions. Furthermore, the voltages have the same temperature dependence as the emf's of the assigned reactions, which are derived in the next section and are also presented in Fig. 9. The slight difference (10-15 mV) in Fig. 9 between the voltages obtained from the voltammograms and the actual emf's

Table I. Voltages of major charge reactions

Temperature (°C)	Electrolyte composition (m/o LiCl)	$V(I_c)$ (V)	$V(II_c)$ (V)
400	58 (eutectic)	1.345	1.366
425	58	1.339	1.364

481	75	1.326	1.359

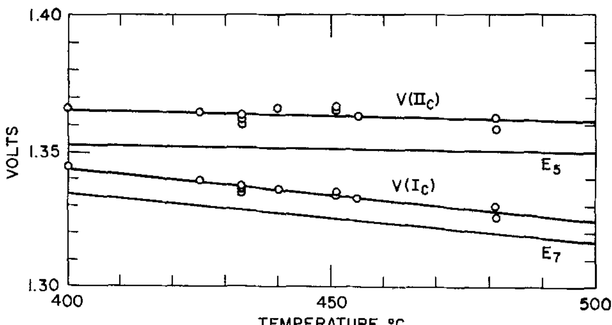

Fig. 9. Comparison of the voltages of the major charge reactions, I_c and II_c, with the emf of the assigned reactions $E_7(X \leftrightarrow Li_2S)$ and $E_5(FeS \leftrightarrow X)$, respectively.

is reasonable; the voltages obtained from the voltammograms may include overpotentials that are not removed by linear extrapolation techniques. Thus, the peak areas and the response of the peaks to changes in electrolyte composition and temperature all tend to support the reaction assignments.

Peaks I_c and II_c are equivalent to charge region B of Fig. 4. According to the phase studies for this region, J-phase is formed to some extent during reaction $I_c(Li_2S \rightarrow X)$ and it is the final product of reaction $II_c(X \rightarrow FeS)$. Thus, chemical reactions [9] $(X \rightarrow J + Li_2S)$ and [10] $(X + FeS \rightarrow J)$ are required to reconcile the differences between the electrochemical assignments and phase studies. These reactions form J-phase at temperatures as high as 455° and 623°C, respectively, in eutectic electrolyte, according to Saboungi and Martin (16). Certain rate conditions are implicit in these assignments (namely, [9] is slow and [10] is fast), but the rates have not been measured.

The J-phase that is formed in the above reactions is equivalent to approximately 90% charge. The remaining 10% of the charge reaction $(J \rightarrow FeS)$ occurred in cell tests on a poorly defined plateau (see Fig. 4) that was temperature sensitive (~1.7V at 390°C; ~1.45V at 480°C). In the cyclic voltammetry, we had great difficulty in locating a corresponding current peak. At low temperatures (400°C), the peak may have been masked by the $Fe \rightarrow Fe^{2+}$ charge reaction, which is shown in Fig. 7(a). When this reaction was avoided by reversing the charge scan at 1.7V instead of 1.8V, the leading discharge peak, I_D, was only 50% as large. This indirect evidence suggests that the conversion of J-phase to FeS occurred in the neighborhood of 1.7V. At a higher temperature of 455°C a small peak (III_c) was barely discernible above the background current in Fig. 7(b). This peak shifted from ~1.5 to ~1.6V when KCl was added to the electrolyte (decreasing the LiCl concentration from 58 to 52 m/o). Such a shift is in the expected direction according to emf calculations which are discussed later. Therefore, we have tentatively assigned the reaction $J \rightarrow FeS(E_2)$ to peak III_c.

In the scans employing LiCl-rich electrolytes (Fig. 8), no high-voltage charge peak for the $J \rightarrow FeS$ reaction could be detected above the background current, but indirect evidence again suggested that a relatively high voltage was required to complete the reaction. For instance, the discharge peak I_D, II_D shown in Fig. 8(a) was only half as large when the charge scan was reversed at 1.56V instead of 1.7V. A peak representing 10%-12% of the charge capacity in Fig. 7 and 8 would have been readily detected if the reaction occurred over a narrow voltage range like peaks I_c and II_c; we believe therefore, that the III_c peak was usually too broad to detect.

In Fig. 8(b), two poorly resolved peaks and much of the high-voltage region are labeled as background B. These features became noticeable only after high-temperature (~450°C) cycles. We concluded that the B-reactions were not associated with the normal FeS re-

actions because they did not decline with cycling as sulfide was lost from the electrode (probably through dissolution of Li_2S in the large volume of cell electrolyte). Over a period of ten cycles of the type shown in Fig. 8(b), the FeS reaction peaks all declined by a factor of three while the background features remained constant. The background peaks and much of the 1-3 mA background current at high voltages may have resulted from intercalation of electrode material in the graphite housing; graphite will intercalate iron chloride and iron sulfides at high temperatures (23). The background problem is also present in the scan shown in Fig. 8(a) (the same electrode, but an earlier cycle), and one of the background peaks seems to be present in Fig. 7(b) to the right of peak II_c (this electrode also employed the graphite housing). With a molybdenum housing, the peaks were absent, but high-voltage background currents were still a problem.

The discharge electrochemistry was very complicated. For example, five discharge peaks are noted in Fig. 7(a), yet only two phase mixtures (FeS, J and Fe or J, Li_2S and Fe) are found on discharge at such low cell temperatures (400°C). Thus, at low temperatures, there are too many electrochemical steps and not enough phase mixtures to account for them. Since X-phase is present in the charge reactions and in the higher temperature discharges, we shall assume that it is also an intermediate in the lower temperature discharges. This situation is basically no different than that with charge peak II_c, where the electrochemical evidence warranted choosing FeS as a charge intermediate even though J-phase was the final product. However, the problem in choosing the intermediate is more obvious on discharge since X-phase will be required for three of the five low-temperature peaks.

The discharge peaks in Fig. 7 and 8 can be divided into two groups using the emf of the J → Li_2S reaction (~1.32V from the emf measurements). From the known phase mixtures above and below this emf, the two higher voltage reactions convert FeS to J-phase and the three lower voltage reactions convert J-phase to Li_2S. As the temperature and LiCl concentration were increased the separate peaks in each region tended to merge; the multiple labels on a peak thus reflect the probable occurrence of more than one reaction.

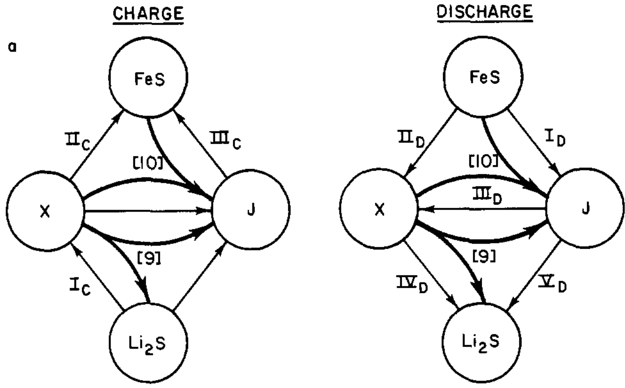
The electrochemical reactions assigned to peaks I_D and II_D are FeS → J(E_2) and FeS → X(E_5), respectively. As with the charge peak II_c (X → FeS), we shall require chemical reaction [10] (X + FeS → J) to occur with the discharge peak II_D (FeS → X). Thus the final product of I_D and II_D is J-phase. The combined areas of these two peaks are consistent with the conversion of FeS to J-phase (~10% of the discharge capacity). At high temperatures and LiCl concentrations, these peaks tended to merge at the location of the II_D peak which is in accord with the assignments since the stability of the X-phase relative to J-phase increases under these conditions.

The electrochemical reactions assigned to peaks III_D, IV_D, and V_D are J → X(E_3), X → Li_2S(E_7), and J → Li_2S(E_4), respectively. These peaks merge in a complex manner as the LiCl concentration and temperature of the cell are raised (compare Fig. 7 and 8). The last of the peaks, V_D, is assigned the J → Li_2S reaction because it is present under conditions of lowest X-phase stability relative to J-phase (lower temperatures and lower LiCl concentrations). The other two peaks, which are poorly resolved, are assigned the J → X (III_D) and X → Li_2S (IV_D) reactions merely because the J → X transition has to precede the X → Li_2S transition. The poor resolution implies that the reactions tend to occur simultaneously. Consequently, X-phase, if it is indeed the intermediate in this doublet, need not appear as a major phase during the J → X → Li_2S sequence. The III_D-IV_D reaction assignments are thus in accord with the phase studies.

With a stoichiometric FeS electrode at a temperature of 400°C, peak V_D was much more prominent than shown in Fig. 7(a). Its area was equivalent to ~50% of the discharge capacity, and it was a more definite, but very broad peak that was centered at ~1.19V and extended from ~1V into the trailing edge of the III_D-IV_D peaks. With a large excess of Fe in the electrode [Fig. 7(a)], this broad V_D peak was partially suppressed and the III_D-IV_D peaks were accentuated. A more efficient method of suppressing V_D is to reverse the direction of chemical reaction [9] (X → J + Li_2S) through the use of higher temperatures and higher LiCl concentrations. These conditions tend to promote the J → X → Li_2S reaction sequence (peaks III_D and IV_D) and diminish the contribution from the direct J → Li_2S reaction (peak V_D). However, from the way in which the peaks merge as the cell temperature and LiCl concentration are increased, we believe all three reactions occur simultaneously and have labeled the voltammograms in Fig. 8 accordingly. The X-phase will tend to appear during these simultaneous reactions since it is an equilibrium phase at higher temperatures and LiCl concentrations.

In the above assignments we have not employed the FeS → Li_2S(E_6) reaction. Although this reaction will no doubt be required to explain high-scan-rate data, it does not represent an equilibrium mixture of cell phases under any of our test conditions.

The reaction assignments are summarized in Fig. 10 for two general cases, (a) lower LiCl concentrations and temperatures, and (b) higher LiCl concentrations and temperatures. The connecting lines are labeled with the assigned peaks (rather than the E_i used in Fig. 1), and the broad arrows show the effects of the chemical reactions [9] and [10]. Note that the X →



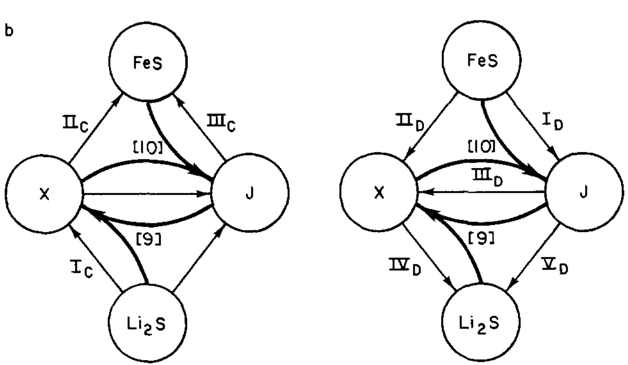


Fig. 10. Summary of reaction assignments for two general cases (a) lower LiCl concentrations and temperatures and (b) higher LiCl concentrations and temperatures. Peak assignments from cyclic voltammetry (roman numerals) and the directions of chemical reactions [9] (X ↔ J + Li_2S) and [10] (X + FeS ↔ J) are shown.

$J(E_3)$ and $Li_2S \rightarrow J(E_4)$ lines have no peak assignments on charge. The results of emf measurements show that E_3 and E_4 are reversible under some conditions. Consequently, these reactions must occur, but may be masked by the other reactions. The only notable difference between cases (a) and (b) in Fig. 10 is that reaction [9] tends to form J-phase in (a) and X-phase in (b). This accentuation of X-phase at higher LiCl concentrations and temperatures leads to greatly improved cell performance (19, 20), without completely eliminating J-phase from the reaction scheme.

Emf measurements and thermodynamic properties.—Voltage *vs.* temperature data are given in Fig. 11 and 12. The data in Fig. 11 are from one cell on which measurements were made at 15%-30% discharge (squares) and at 20% charge (circles). The data in Fig. 12 are from a second cell on which measurements were made at 80% charge. The lines E_3, E_4, and E_7 in these figures are linear regression curves through selected data (the selection process is based on reversibility tests, and is described below). The dashed curves labeled α, β, and γ in the figures pass through data that represent measurements on various nonequilibrium mixtures of electrode phases (see below); the potentials of such mixtures are often called "mixed" potentials.

Other types of voltage *vs.* temperature patterns can be obtained depending on the cell operating temperature, the percent of discharge or charge, and the direction of

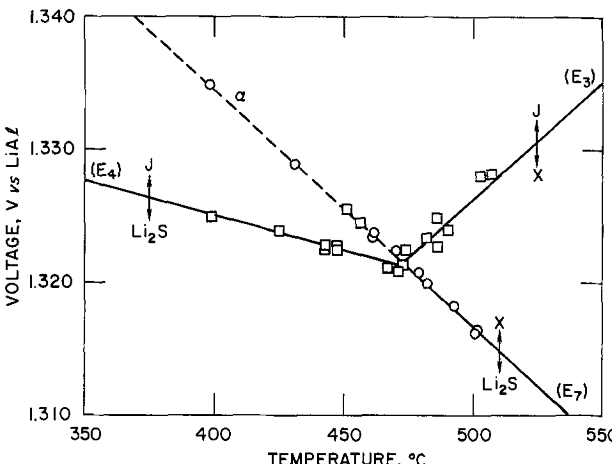

Fig. 11. Voltage measurements on LiAl/FeS cells at 15%-30% discharge (squares) and 20% charge (circles). Emf assignments and a nonequilibrium curve, α, are also shown. Electrolyte is LiCl-KCl eutectic.

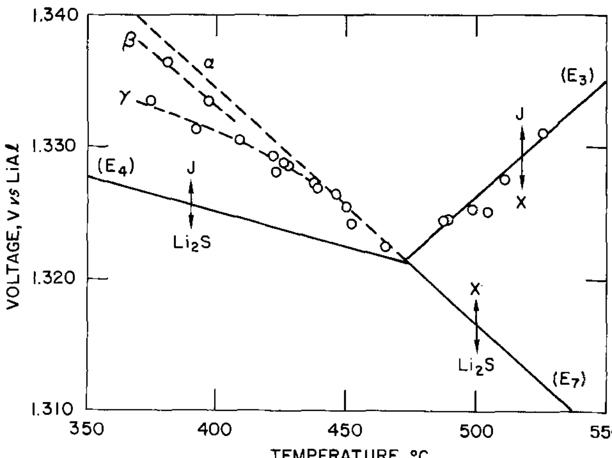

Fig. 12. Voltage measurements on LiAl/FeS cell at 80% charge. Emf assignments and three nonequilibrium curves (α, β, γ) are also shown. Electrolyte is LiCl-KCl eutectic.

temperature change during the voltage measurements. For example, a cell was discharged aout 52% at a temperature of 400°C, and the open-circuit voltages were recorded as the temperature was first increased to 500°C and was subsequently decreased to 400°C. What is expected here is a pattern similar to the 15%-30% discharge data shown in Fig. 11, but the high temperature data should lie on the $X \leftrightarrow Li_2S$ line instead of the $J \leftrightarrow X$ line because, beyond 50% discharge, the high temperature equilibrium phases are X, Li_2S, and Fe. The results when increasing the temperature were in accord with expectations; the data at temperatures below 470°C were near the $J \leftrightarrow Li_2S$ line, and, above 470°C the data were near the $X \leftrightarrow Li_2S$ line. However, when the temperature was then decreased in several stages from 500° to 400°C, in an attempt to retrace the $X \leftrightarrow Li_2S$ and $J \leftrightarrow Li_2S$ lines, the data were near the $X \leftrightarrow Li_2S$ and α-lines. Thus, the voltage patterns can be extremely complex.

An emf may be extracted from such data only when certain reversibility criteria are satisfied. For instance, the $J \leftrightarrow X(E_3)$ data are obtained at both 20% discharge (Fig. 11) and 80% charge (Fig. 12) which are equivalent states of charge approached from different directions. This is an indication of reversibility. In addition, we found the J, X, and Fe phases in apparent equilibrium at this emf by phase determinations on a cell that had been equilibrated for 50 hr at 20% discharge and 500°C. Thus, we consider the $J \leftrightarrow X(E_3)$ line to be well established and have calculated E_3 by a linear-regression analysis of the 480°-525°C data near E_3 in Fig. 11 and 12. This emf[4] is given by

$$E_3(J \leftrightarrow X) = 1238.6 + 0.1753T \qquad [17]$$

The $J \leftrightarrow Li_2S(E_4)$ data in Fig. 11 were collected in several experiments: (*i*) The cell was discharged ~15% at 486°C, and measurements were made on the $J \leftrightarrow X(E_3)$ line prior to lowering the temperature to measure the $J \leftrightarrow Li_2S(E_4)$ line. (*ii*) The cell was discharged ~20% at 400°C, and measurements were made on the $J \leftrightarrow Li_2S(E_4)$ line prior to increasing the temperature to measure the $J \leftrightarrow X(E_3)$ line. The data from (*i*) and (*ii*) coincided, indicating reversibility. (*iii*) The cell was discharged ~30% at 443°C and the procedure described in (*ii*) was repeated, giving the same results. In this case, however, the temperature was lowered again in an attempt to retrace the $J \leftrightarrow Li_2S(E_4)$ line; the data appeared instead on the α-line (the two square symbols on this line in Fig. 11).

From such measurements, we have found that the $J \leftrightarrow Li_2S(E_4)$ line can be observed when the cell is discharged at low temperatures to avoid large amounts of the X-phase. No data for this line were obtained during charge, where the X-phase interferes. Because of the difficulty in establishing reversible behavior, we consider this line to be less well defined than the $J \leftrightarrow X(E_3)$ line. A linear regression analysis of the 400°-450°C data along E_4 in Fig. 11 gives

$$E_4(J \leftrightarrow Li_2S) = 1346.0 - 0.0525T \qquad [18]$$

The $X \leftrightarrow Li_2S(E_7)$ data shown in Fig. 11 are for 20% charge; data near the E_7 line have also been obtained at >50% discharge, indicating reversibility. The persistance of X-phase at low temperatures leads to various nonequilibrium extensions of the E_7 line into the J-phase field. These extensions, which are labeled α, β, and γ in Fig. 11 and 12, would lie on the E_4 line if X-phase were absent. Consider the α-line data in Fig. 11. The data, most of which were obtained at 20% charge, are as much as 10 mV above the $J \leftrightarrow Li_2S$ data, which were obtained near 20% discharge. However, 20% discharge is actually the higher state of charge, being equivalent to 80% charge. Thus, the α-data are definitely for a nonequilibrium state; the emf at 20%

[4] All emf equations are given with the temperature in degrees centigrade and the emf in millivolts.

charge cannot exceed the emf at 20% discharge. Despite the lack of equilibrium, the α-line data represent quite stable voltages; the data at 398° and 431°C showed less than 0.1 mV drift in 100 hr open-circuit measurements. The colinear data along the α-line and E_7 line in Fig. 11 give the following equation for E_7

$$E_7(X \leftrightarrow Li_2S) = 1405.8 - 0.1781T \qquad [19]$$

The data along the γ-line in Fig. 12 were obtained during an attempt to eliminate the X-phase by extended open-circuit relaxations at a high state of charge. (At a high state of charge the ratio of J-phase to X-phase is high.) Eight measurements were made along the γ-line over a 300 hr period as the temperature was lowered. It can be seen that data lying between the lines E_4 and α were obtained, suggesting that traces of X-phase were still affecting the results. The cell was then heated at ~500°C to generate additional X-phase, and two voltage measurements were made over a 90 hr period at low temperatures. The data were on the β-line in Fig. 12, indicating a somewhat higher level of X-phase in these shorter time measurements. It was evident from the above tests that many hundreds of hours would be required to completely eliminate the X-phase at low temperatures.

The J $\leftrightarrow$ Li_2S, J $\leftrightarrow$ X, and X $\leftrightarrow$ Li_2S lines in Fig. 11 and 12 intersect at 473° ± 2°C and 1321.4 ± 0.2 mV. This is a point of four-phase equilibrium (J, X, Li_2S, Fe) at which $\Delta G_9 = 0$ in Eq. [13]. Metallographic studies have indicated temperatures of 455° ± 4°C (16) and 465° ± 7°C (24) for this intersection. Considering the difference in techniques, we believe the measurements are in fair agreement.

One test of the emf equations given for E_3, E_4, and E_7 is provided by Eq. [13] which can be written as follows

$$(E_7 - E_3) = 2.30\ (E_7 - E_4) \qquad [20]$$

This equation can be used to calculate E_4*[5] from the measurements of E_3 (Eq. [17]) and E_7 (Eq. [19])

$$E_4^*(J \leftrightarrow Li_2S) = 1333.0 - 0.0245T \qquad [21]$$

The difference between E_4 (Eq. [18]) and E_4^* is only 1.7 mV at 400°C. In view of the difficulties in establishing the E_4 line, we consider the agreement between E_4 and E_4^* to be acceptable. In fact, we prefer to use E_4^* in our subsequent calculations since E_4 is slightly above E_4^*, which may reflect the presence of some residual X-phase during the E_4 measurements.

Note that only two of the emf equations presented so far are independent; one additional emf is needed to determine the thermodynamic properties of the FeS electrode. We attempted to measure the emf of the FeS $\leftrightarrow$ J(E_2) transition, but could not obtain stable readings. For example, when a cell was charged at 446°C to ~95% of its theoretical capacity, where the FeS $\leftrightarrow$ J transition is known to occur, the open-circuit voltage steadily declined from 1.49V at 1 hr to 1.42V at 24 hr. When the same cell was taken to full charge and then discharged ~5%, the open-circuit voltage rose to 1.43V at 1 hr, but then declined to 1.355V at 24 hr. We will be able to compute the emf of the FeS $\leftrightarrow$ J(E_2) reaction (assuming it has a fixed emf), but we consider the calculated value to be uncertain since direct measurement was not possible.

To obtain the additional emf equation that was required for a complete description of the electrode, we calculated the emf of the FeS $\leftrightarrow$ Li_2S(E_6) reaction from available thermodynamic data (3, 25-27). This emf, which is probably uncertain by ±25 mV, is

$$E_6^*(FeS \leftrightarrow Li_2S) = 1383 - 0.10T \qquad [22]$$

The J $\leftrightarrow$ X, X $\leftrightarrow$ Li_2S, and FeS $\leftrightarrow$ Li_2S equations were then combined with Eq. [13]-[16] to calculate the emf of the FeS $\leftrightarrow$ X reaction and FeS $\leftrightarrow$ J reaction. These calculated emf equations are given by

$$E_5^*(FeS \leftrightarrow X) = 1361 - 0.022T \qquad [23]$$

$$E_2^*(FeS \leftrightarrow J) = 1769 - 0.68T \qquad [24]$$

Five emf equations are plotted in Fig. 13 to show the regions of stability of the various electrode phases in eutectic electrolyte. The equation for E_6^*, which is simply the average of E_5^* and E_7, is omitted. Note the location of an intersection between E_2^*, E_5^*, and E_3 at a temperature of 621°C. This temperature is in excellent agreement with metallographic studies, which have located the intersection at 623° ± 7°C (16) and 624° ± 4°C (24); the four solid phases in equilibrium here are FeS, J, X, and Fe. Because of the excellent agreement with metallographic studies, we believe the E_5^* line is accurate to within a few millivolts. It follows that the E_6^* equation must have a similar accuracy, although the thermodynamic data from which E_6^* was calculated were not that precise.

It will be noted that the FeS $\leftrightarrow$ X(E_5^*), J $\leftrightarrow$ X(E_4^*), and X $\leftrightarrow$ Li_2S(E_7) lines have been extended in Fig. 13 to low temperatures. These extensions were required to treat both the phase data and the cyclic-voltammetry peaks at lower cell temperatures.

The FeS $\leftrightarrow$ J(E_2^*) line in Fig. 13 is located at a relatively high voltage (~1.5V at 400°C; ~1.46V at 450°C). The cyclic voltammetry studies gave lower voltages than E_2^* on discharge (1.4V at 400°C, 1.38V at 450°C), but higher voltages on charge (~1.7V at 400°C, ~1.5V at 455°C). In cells potentiostated at 1.50V for 100 hr at 400°C, no FeS was formed from J-phase. Thus, the proposed emf for the J $\leftrightarrow$ FeS transition is in accord with the experimental data.

The emf's of reactions [2], [3], and [4] depend on the electrolyte composition. The changes in E_2^*, E_3, and E_4^* can be calculated from the reaction stoichiometry and the changes in the activity of LiCl and KCl with electrolyte composition (28). The calculated emf equations for an LiCl-rich electrolyte containing 67 m/o LiCl are as follows

$$E_2^{*\prime} = 1738 - 0.71T \qquad [25]$$

$$E_3' = 1247.8 + 0.1843T \qquad [26]$$

$$E_4^{*\prime} = 1.337.1 - 0.0205T \qquad [27]$$

These equations (and E_5^* and E_7) are plotted in Fig. 14 to show the effects of the LiCl-rich electrolyte on the regions of stability of the various electrode phases. The emf-intersection temperatures decrease from 473° and 621°C in eutectic electrolyte (Fig. 13) to 436° and 549°C, respectively, in the LiCl-rich electrolyte (Fig. 14). These shifts cause the field of J-phase stability to

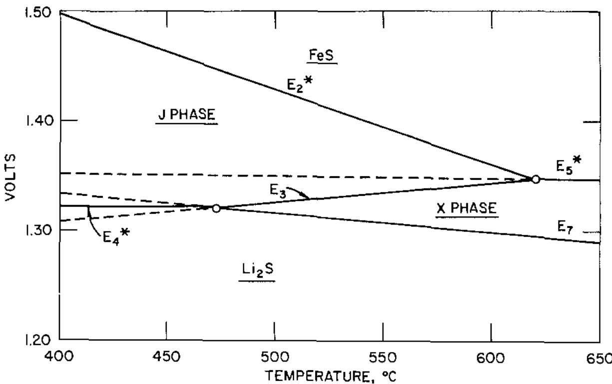

Fig. 13. Regions of stability of FeS, J-phase, X-phase, and Li_2S in LiCl-KCl electrolyte of eutectic composition. Extensions of the FeS $\leftrightarrow$ X(E_5^*), J $\leftrightarrow$ X(E_3), and X $\leftrightarrow$ Li_2S(E_7) reactions into the low temperature region are indicated by dashed lines. An asterisk indicates a calculated emf.

[5] An asterisk on an emf indicates that it has been calculated from other data.

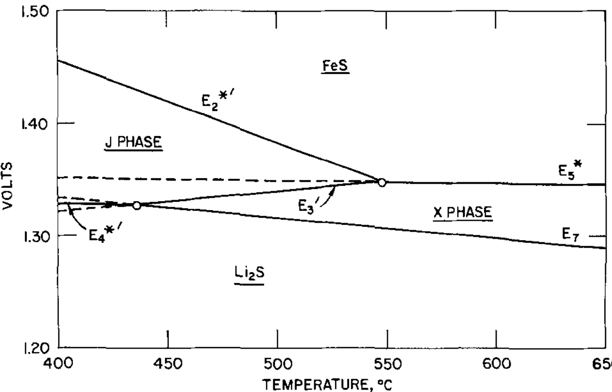

Fig. 14. Regions of stability of FeS, J-phase, X-phase, and Li_2S in LiCl-rich electrolyte (67 m/o LiCl). Extensions of the FeS ↔ X(E_5*), J ↔ X(E_3'), and X ↔ Li_2S(E_7) reactions into the low temperature region are indicated by dashed lines. An asterisk indicates a calculated emf. Note that E_2*', E_3', and E_4*' are shifted from their corresponding values in eutectic electrolyte (E_2*, E_3, E_4*), and the field of J-phase stability is therefore much smaller.

become much smaller. A cell temperature of 460°C and an electrolyte containing ~67 m/o LiCl are known to be sufficient to suppress the harmful effects of the J-phase on electrode performance (19). According to Fig. 14, the reaction sequence under these conditions is FeS ↔ J ↔ X ↔ Li_2S.

Another calculation that can be made from the emf equations and the activities of LiCl and KCl is the emf-intersection temperatures in LiCl-saturated electrolyte. For example, the intersection of E_2*, E_5*, and E_3, which occurs at 621°C in eutectic electrolyte, is calculated to occur at 481°C in electrolyte saturated with LiCl [75.2 m/o LiCl (29)]. This temperature is in excellent agreement with the metallographically determined temperaure of 481° ± 5°C (16). Similar calculations for the intersection of E_3, E_4*, and E_7 (which occurs at 473°C in eutectic electrolyte) give a value of 429°C in LiCl-saturated electrolyte [68.4 m/o LiCl (29)], which is in reasonable agreement with the 419° ± 2°C temperature determined in the metallographic studies (16). The above temperature calculations rely on the reaction stoichiometries and certain emf differences, while the metallographic studies only require the presence or absence of phases. The good agreement between these independent methods tends to confirm the emf equations and the reaction stoichiometries. Therefore, the free energy changes of the chemical reactions can be calculated with a reasonable degree of confidence.

The free energy changes of the chemical reactions [9]-[12] were calculated from the emf equations and Eq. [13]-[16]. For the calculations we selected the eutectic electrolyte as the standard state and used the following relationships

$$\Delta G°_9 = -20\,F(E_7 - E_3) = -322.6 + 0.682T \quad [28]$$

$$\Delta G°_{10} = -20\,F(E_5{}^* - E_3) = -236 + 0.380T \quad [29]$$

$$\Delta G°_{11} = -6F(E_2{}^* - E_6{}^*) = -223 + 0.336T \quad [30]$$

$$\Delta G°_{12} = -F(E_5{}^* - E_7) = 4.32 - 0.015T \quad [31]$$

where the temperatures are in °C and the free energy changes are in kJ. Calculated values are given in Table II for temperatures ranging from 400° to 600°C. This table shows the decreasing stability of J-phase (first three reactions) and increasing stability of X-phase (last reaction) with increasing temperature.

The $\Delta G°_{12}$ values in Table II are in good agreement with an earlier study (15), which gave values of −1.38 ± 0.84 kJ at 450°C and −3.01 ± 0.84 kJ at 500°C. The $\Delta G°_{11}$ values in Table II are more negative than those obtained in the earlier study, which gave values of −25.9 ± 7.5 kJ a 400°C, −25.5 ± 1.2 kJ at 450°C, and −28.9 ± 2.5 kJ at 500°C. These values were obtained by determining the sulfide-ion activity required to cause J-phase formation from FeS in eutectic electrolyte. The method used was equivalent to a cell discharge, and the location of the FeS ↔ J(E_2) discharge peak in the cyclic voltammograms (Fig. 7) is indeed in accord with the earlier measurements. However, we prefer the higher voltage calculated from Eq. [24] for the FeS ↔ J(E_2) reaction since it seems to be more representative of the combined data for discharge and charge.

Table II. Standard free energy changes for the four chemical reactions

$\Delta G°_i$ (reaction)	Standard free energy change (kJ) 400°C	450°C	500°C	550°C	600°C
$\Delta G°_9$ (X → J + Li_2S)	−50	−16	18	52	87
$\Delta G°_{10}$ (X + FeS → J)	−84	−65	−46	−27	−8
$\Delta G°_{11}$ (Li_2S + FeS → J)	−89	−72	−55	−38	−21
$\Delta G°_{12}$ (Li_2S + FeS → X)	−1.7	−2.4	−3.2	−3.9	−4.7

One measure of the uncertainty in the $\Delta G°_{11}$ values given in Table II is provided by an alternative calculation. Note that Eq. [15] gives two methods of calculating $\Delta G°_{11}$, one based on E_2 (which was used for Table II) and another based on E_4, which was both measured (Eq. [18]) and calculated (Eq. [21]). Of course, the value of $\Delta G°_{11}$ that would be obtained from the calculated E_4(E_4*) would agree with the results given in Table II. However, the equation that results from the measured E_4 is

$$\Delta G°_{11} = -164 + 0.211T \quad [32]$$

This equation differs significantly from Eq. [30] and gives values ranging from −80 kJ at 400°C (*vs.* −89 kJ in Table II) to −38 kJ at 600°C (*vs.* −21 kJ in Table II). Clearly, alternative methods of measuring this free energy change are needed. The problem is to find reversible conditions under which the emf of the FeS ↔ J(E_2) reaction can be measured; the use of LiCl-rich electrolytes for this particular emf measurement may be appropriate.

Conclusions

A reasonably complete description of the electrochemistry and chemistry of the FeS electrode in LiCl-KCl electrolytes at low cycling rates was obtained by combining phase studies, cyclic voltammetry data, and emf measurements. In many cases, the measurements are in excellent agreement with other studies, but in one particular area, the thermodynamics of the J-phase ($LiK_6Fe_{24}S_{26}Cl$), more study is needed. The problem with the J-phase is the poor reversibility of its electrochemical reactions, which leads to large uncertainties in the thermodynamic properties.

In agreement with other studies, high LiCl concentrations in the LiCl-KCl electrolyte tend to improve the cell performance by suppressing the adverse effects of the J-phase. The required mole ratio of LiCl to KCl is approximately 2:1. This electrolyte accentuates the reactions of X-phase (Li_2FeS_2), which are more reversible than the J-phase reactions.

To date, emf measurements have been conducted only in the eutectic electrolyte. Measurements will also be needed in LiCl-rich electrolytes and in electrolytes containing only lithium salts (*e.g.*, LiCl-LiBr-LiF) to more firmly establish the thermodynamics of the six electrochemical and four chemical reactions that are required to describe the FeS electrode. Methods of establishing the identity of transient intermediates in the electrode reactions are also desirable; at present, the reactions are understood only at low cycling rates.

The very complex chemistry and electrochemistry of the FeS electrode has not prevented its use in high-performance (>100 W-hr/kg), long-lived (>300

cycles) Li-Al/FeS cells. The performance and cycle life of this cell may be even higher than they are at present once the FeS electrode reactions are fully understood.

Acknowledgments

The authors would like to express their thanks to A. E. Martin and N. C. Otto for their metallographic analyses and to B. S. Tani for his x-ray diffraction studies. The active support and encouragement of D. R. Vissers, R. K. Steunenberg, D. L. Barney, P. A. Nelson, and L. Burris during the course of this study are also appreciated. Discussions with M. Blander and M. L. Saboungi were particularly helpful and are gratefully acknowledged. Special thanks are due to J. Harmon for editorial assistance. This work was conducted under the auspices of the U.S. Department of Energy.

Manuscript submitted June 9, 1980; revised manuscript received Nov. 14, 1980.

Any discussion of this paper will appear in a Discussion Section to be published in the December 1981 JOURNAL. All discussions for the December 1981 Discussion Section should be submitted by Aug. 1, 1981.

Publication costs of this article were assisted by Argonne National Laboratory.

Properties of $LiAlCl_4$-$SOCl_2$ Solutions for $Li/SOCl_2$ Battery

H. V. Venkatasetty* and D. J. Saathoff

Honeywell Corporate Material Sciences Center, Bloomington, Minnesota 55420

ABSTRACT

Conductance and viscosity of $LiAlCl_4$-$SOCl_2$ solutions covering a wide range of concentration (10^{-4}-2.0M) have been measured at 25°C and for concentrated solutions these measurements have been made at several temperatures. Parameters characteristic of ion-ion and ion-solvent interactions and the energy of activation for conductance and for viscous flow have been obtained. Cyclic voltammograms of $LiAlCl_4$-$SOCl_2$ solutions at several concentrations have been obtained and the effect of the additives, such as S_2Cl_2, SCl_2, SO_2, and SO_2Cl_2 on the reduction behavior of $SOCl_2$ has been studied as some of these are reduction products of $SOCl_2$. The implications of these studies on the performance and safety of the lithium-thionyl chloride battery are discussed.

The lithium-thionyl chloride battery system has become technologically important as a high-energy density and high-power density battery with potentially long shelf-life (1-4). In a lithium-thionyl chloride ($Li/SOCl_2$) battery, thionyl chloride serves both as a solvent for the solute and a depolarizer for the cell. The common solute used for primary active cells is lithium aluminum chloride ($LiAlCl_4$) in $SOCl_2$ at fairly high concentration (1.5-1.8M). It is well known that the transport properties and the structure of these solutions play an important role in the performance of the battery. The charge transfer rate is very much influenced by the nature of the electrical double layer at the phase boundary, and the double layer structure is dependent on the properties of the electrolyte solution. Recently the electrical conductance, viscosity, density of $LiAlCl_4$-$SOCl_2$ solutions, and diffusion coefficient of electroactive species, namely, $SOCl_2$, have been reported (5).

A better understanding of the overall reaction mechanism and the reaction products during the discharge of lithium-thionyl chloride battery is necessary to improve the performance and safety of the battery. There is no complete agreement on the lithium thionyl chloride cell reaction and several cell reactions have been proposed (1, 2, 6). It has been reported that the products of electrolysis of $SOCl_2$ above 0°C are SO_2, S_2Cl_2, and Cl_2 (7). This paper reports the results obtained on conductance, viscosity, and density of $LiAlCl_4$-$SOCl_2$ solutions covering a wide range of concentration (10^{-4}-2.0M) and temperature. Parameters characteristic of ion-ion and ion-solvent interactions and the energy of activation for conductance and for viscous flow have been obtained. Cyclic voltammetric studies on $LiAlCl_4$-$SOCl_2$ solutions at several concentrations have been obtained and the effect of additives such as S_2Cl_2, SCl_2, SO_2, and SO_2Cl_2 on the reduction behavior of $LiAlCl_4$-$SOCl_2$ solutions have been examined. The implications of these studies on the performance and safety of lithium-thionyl chloride battery are discussed.

Experimental

Thionyl chloride (MC/B) was mixed with triphenylphosphite (16% by volume) and distilled under a positive pressure of dry nitrogen. The distillate from the first distillation was redistilled with a cut-off point at 80°C, and the middle fraction of the second distillation was used for this study. Anhydrous $LiAlCl_4$ prepared in this laboratory was used. All chemicals were weighed to 0.1 mg inside the dry box which was purged with dry argon. All solutions were prepared in the glove bag under a positive pressure of dry nitrogen. Electrochemical measurements were carried out using different batches of $LiAlCl_4$-$SOCl_2$ solutions and the experimental data were reproducible. Conductance measurements were made using a Jones bridge with accessories and Jones and Bollinger type conductance cells with bright platinum disk electrodes. A constant temperature oil bath with a control of $\mp$0.05°C at 15° and 25°C and $\mp$0.5°C at 40° and 60°C was used. Viscosity was measured using calibrated Cannon-Fenske type viscometer with guard tube attachment to minimize moisture contamination. Densities were measured using a calibrated density bottle. Cyclic voltammetric studies were carried out using Princeton Applied Research Corporation Model 173 potentiostat/galvanostat with a Model 175 universal programmer. A three-electrode cell with compartments separated by a medium porosity fritted disk was used. A glassy carbon electrode was the working electrode, with platinum spiral counterelectrode, and Li/Li^+ with a solution of $LiAlCl_4$ of the same concentration as in the working electrode compartment in $SOCl_2$ in a tube with fritted disk was used as a reference electrode. The glassy carbon electrode was polished to a mirror finish with alumina powder, washed with 0.05M H_2SO_4 and with distilled water. The cyclic voltammograms were run at different scan rates after cleaning the electrode and the voltammograms were reproducible.

Results and Discussion

The basic conductance, viscosity, and density data for $LiAlCl_4$ in $SOCl_2$ solutions covering a wide range of concentrations are given in Tables I and II. The specific conductances of $LiAlCl_4$-$SOCl_2$ solutions measured over a range of concentration (3×10^{-4}-2.0M) show that the conductance increases with concentration and reaches a maximum at about 1.8M. A plot of equivalent conductance (Λ) *vs.* $C^{1/2}$ shows that the value of Λ is high at low concentration, decreases rapidly with increase of concentration, reaches a maximum around 0.8M, and decreases again (Fig. 1). This behavior is characteristic of weak electrolytes in solvents of low dielectric constant (8, 9). The data for dilute solutions ($<$ 0.00544M) were treated theoretically using an equation of a form similar to that of Fuoss-Shedlovsky (10) except for the function $S(Z)$. The equation is

$$\frac{1}{\Lambda} = \frac{1}{\Lambda_o} + \frac{C\Lambda}{Kd(\Lambda_o)^2}$$

where Λ_0 is the limiting equivalent conductance and Kd is the dissociation constant for the ion-pairs. A plot of $1/\Lambda$ *vs.* $C\Lambda$ is linear (Fig. 2), the intercept gives $\Lambda_0 = 16.51$, and the slope gives $Kd = 1.605 \times 10^{-3}$. The data for solutions in the concentration range of 0.005M to about 0.5M were treated by Fuoss and Kraus method (8, 9). The equation is given by

$$\Lambda = \sqrt{\frac{Kd}{C}}\,\Lambda_0 + \frac{\sqrt{KdC}}{k}\,\Lambda_{03}$$

where k is the dissociation constant for triple ions and Λ_{03} is the limiting equivalent conductance for triple ions. A plot of $\Lambda C^{1/2}$ *vs.* concentration gives a linear relationship from which the value of $k/\Lambda_{03} = 1.21 \times 10^{-3}$ is obtained.

The low value for Λ_0 and high value for Kd indicate appreciable amounts of ion-solvent and ion-ion interactions in these solutions. For concentrated solutions, the viscosity plays an important role which is evident from the plot of conductance corrected for
