held constant at 35° ± 0.5°C. In both systems the wafers were first inserted into the oxidation furnace in the presence of nitrogen for 5 min. In the TCE system, a dry O₂ oxide layer was grown for 1 min prior to the addition of TCE/N₂. This process technique was necessary in order to obtain good quality oxides. Wafers which were fabricated without the 1 min dry O₂ oxide layer were found to produce pitted oxides.

For this study, MOS capacitors were fabricated on <100> oriented, n-type silicon wafers, having a bulk resistivity of 7-8 Ωcm. The wafers were chemically cleaned using both high and low pH peroxide solutions. The wafers were then oxidized using the additions of 0, 5, 10, 30, 60, and 120 cm³/min of both HCl and TCE/N₂, while maintaining a constant flow rate of 1.0 l/min of dry O₂ in each system. Oxidation times were varied to result in an oxide thickness of approximately 1000Å for each of the various flow rates of HCl and TCE/N₂. Wafers were given a high temperature anneal in N₂ for 5-10 min, following the oxidation sequence, and a slow pull of the wafers from the furnace tube was used in order to avoid interface and lattice stresses. The aluminum dots were then E-gun evaporated through a metal mask. The oxide was etched from the back of the wafers, and then metallized to ensure a good back-side contact. The MOS test structures were annealed at 500°C for 5 min in nitrogen to remove radiation damage which resulted from the E-gun evaporation technique.

In addition to these test structures, a similar process was used to produce the oxide-growth kinetics in both systems for each flow rate of HCl and TCE/N₂. Wafers were cleaned and inserted into the oxidation system as mentioned previously. Oxide growth times of 10, 20, 30, and 60 min were used at each flow rate of HCl and TCE/N₂, followed by 5 min anneal in N₂. Wafers were then removed from the oxidation furnace for thickness measurements using the ellipsometric technique.

Results and Discussion

Thermodynamic analysis.—The SOLGAS computer program (7) was used to obtain the equilibrium partial pressures of the chemical species present in the HCl and TCE systems at an oxidation temperature of 1150°C. The data input to this program requires the thermodynamic properties of all possible species in the system, as well as the input concentrations of the chemical elements contained in each of these two systems, for each flow rate of both HCl and TCE/N₂. The program is designed to use an iterative procedure to

* Electrochemical Society Active Member.

minimize the Gibbs free energy of the specific system in order to calculate the equilibrium partial pressures of the chemical species.

In the TCE system, the actual concentration of TCE introduced into this system is limited by the vapor pressure of TCE at the bubbler temperature. Using a bubbler temperature of 35°C, the gram-atoms of each element may be determined at each of the various flow rates.

The most significant species to be found in these two systems are shown in Fig. 1 and 2. These two figures represent the partial pressure data of the chemical species in each system, plotted at the various added flow rates of HCl and TCE/N₂. In the HCl system it was found that the partial pressures of H₂O and Cl₂ are equal. A similar plot for the TCE system indicates that the partial pressure of H₂O is more than one order of magnitude lower than the partial pressure of Cl₂.

A further comparison of these two systems, based on the SOLGAS data, indicates that the partial pressure of H₂O in the HCl system is higher than in the TCE/N₂ system, whereas the partial pressure of Cl₂ is nearly the same in each system, when compared at similar flow rates of HCl and TCE/N₂. Note that the HCl partial pressure in the HCl-O₂ system is nearly an order of magnitude larger than the HCl partial pressure in the TCE/N₂-O₂ system at the same input flow rates. Further reference to these curves reveals the presence of HOCl, ClO, and HO at much lower levels in each system.

Oxide growth kinetics.—The oxide-growth curve for the HCl system and the TCE/N₂ system are presented in Fig. 3 and 4, respectively. An analysis of these two sets of curves clearly indicates that the oxidation rate of silicon increases as the input concentration of HCl and TCE in the oxidizing ambient is increased.

The parabolic rate constants for these two systems have been derived from these two sets of curves using the general relationship for the oxidation of silicon (9)

$$x_0^2 + Ax_0 = B(t + r) \quad [1]$$

Fig. 1. Partial pressure vs. added cm²/min of HCl for the chemical species of the HCl system.

Fig. 2. Partial pressure vs. added cm²/min of TCE/N₂ for the chemical species of the TCE system.

Fig. 3. Oxide growth rate for the HCl system

Fig. 4. Oxide growth rate for the TCE system

Table I. The parabolic rate constants of the HCl and TCE systems

Flow rate cm/min	HCl ($\times 10^{-4} \mu^2/\text{min}$)	TCE ($\times 10^{-4} \mu^2/\text{min}$)
0	4.09	4.12
5	5.44	5.19
10	5.74	5.43
30	6.23	6.06
60	7.10	6.64
120	7.98	7.09

For large times, this equation reduces to the parabolic relationship

$$x_0^2 = Bt \quad [2]$$

where x_0 is the oxide thickness (μm), B is the parabolic rate constant ($\mu\text{m}^2/\text{min}$), and t is the oxide growth time (min). The oxide thickness data was fitted to this equation using the least squares method in order to determine the B constants at each flow rate of HCl and TCE/N₂.

The values of the parabolic rate constants in these two systems are quite comparable at the same input rate of HCl and TCE/N₂, as shown in Table I. Note that of the major species in the oxidizing ambients, the chlorine is the only one which is present in approximately the same composition in both ambients. In the HCl-O₂, ambients both HCl and H₂O are present in levels nearly an order of magnitude greater than in the TCE/N₂ ambients. This result further supports the hypothesis of Tressler *et al.* (10) that the active gaseous species with regard to kinetics of oxidation and passivation in chlorine bearing oxidizing ambients is Cl₂. The slightly lower values of the parabolic rate constants for the TCE/N₂-O₂ ambients may be due to the second-order effect of the reduced H₂O concentration.

Minority carrier lifetime.—In order to determine the effects of HCl and TCE/N₂ on the bulk lifetime of carriers in the MOS test structures, oxides were grown in the presence of various concentrations of these two chlorine species, as mentioned previously. The measurement technique consists of applying a deep depletion voltage step to the metal electrode, after initially biasing the devices into the accumulation mode. A typical capacitance *vs.* time (*C-t*) curve is shown in Fig. 5. The lifetime of carriers may be derived from the slope of this curve using a technique which has been described by Heiman (11). For this study, the inversion time (t_i) (4), defined as the time required for the *C-t* curve to go from the deep depletion to the

Fig. 5. Experimental *C-t* curve of the pulsed MOS capacitorFig. 6. Inversion time vs. HCl and TCE/N₂ flows using a 10 min high temperature anneal and a slow pull in both systems.

inversion mode, has been used to compare the effects of adding various concentrations of HCl or TCE to the oxidizing ambient.

Figure 6 represents a graphic analysis of the data derived from these test structures. It is apparent that the shapes of these two curves are similar and that the addition of 5 cm³/min of HCl or TCE/N₂ results in longer inversion times than the measured values for dry O₂-grown oxides. The largest values of t_i occurred at added flow rates of 60-120 cm³/min of HCl or TCE/N₂. A reduction in inversion time was found at additions of 30 cm³/min of HCl or TCE/N₂. Similar findings have been reported by Declerck *et al.* (4) for the TCE system. A viable explanation for the reduction in t_i at these flow rates has not been determined, but the occurrence of these lower values has been found to be reproducible.

Conclusions

The equilibrium partial pressures of the possible chemical species in the HCl and TCE oxidation systems have been calculated at 1150°C. At nearly equal partial pressures of chlorine in the two systems, for a given flow rate of HCl or TCE/N₂, the partial pressures of H₂O and HCl were found to be approximately an order of magnitude lower in the TCE system.

The kinetics of thermal oxidation at 1150°C in the presence of HCl and TCE are similar at approximately the same partial pressure of Cl₂, although the H₂O and HCl partial pressures are much lower in the TCE system. These results lend support to an earlier hypothesis that Cl₂ is the important active species in the thermal oxidation of silicon with reference to the growth kinetics and passivation.

The measurement of the capacitance *vs.* time curve of the pulsed MOS capacitor has been found to be a convenient method of determining the inversion time of carriers in devices fabricated using various processing constraints. The addition of HCl and TCE were found to result in a significant increase in inversion times (up to a factor of 30 times greater) when compared to values derived from test structures which were fabricated in the presence of dry O₂.

The Relation Between Two-Probe and Four-Probe Resistances on Nonuniform Structures

John Albers

ABSTRACT

A general relation between the two-probe resistance (spreading resistance) and the four-probe resistance on nonuniform resistivity structures is derived. Numerical techniques are presented and discussed for the evaluation of these equations for nonuniform structures. The relation between the four-probe resistance, $Z(x, S)$, and the incremental sheet resistance, $\mathcal{R}(x)$, is shown to arise in the limit as the probe spacing becomes large compared to the distance to an insulating boundary. Specific examples are drawn from calculations on implant-type structures into substrates having insulating boundaries near the end of the implanted region (junction isolation), as well as those where the insulating boundary is far from the implanted region (emulating the back surface of a same conductivity-type substrate). Also presented is a method for the self-consistent calibration of spreading resistance profiles utilizing $Z(x, S)$.

Recently, Dickey (1) has proposed that the two-probe spreading resistance measured on the surface of a thin, nonuniform resistivity, junction-isolated layer is a linear function of the logarithm of the probe spacing (S) with a slope proportional to the four-probe sheet resistance and an intercept which may be related to the probe radius. The basis of the conjecture is an image calculation of the spreading resistance of a thin layer of uniform resistivity over an insulator. For this case, the spreading resistance (R) is of the form

$$R = \frac{\rho}{\pi t} \ln(S/a) \quad [1]$$

where ρ is the resistivity of the layer, t is the thickness of the layer, S is the spacing between the probes, and a is the electrical probe radius. As the sheet resistance of the layer is just ρ/t , Eq. [1] would suggest that the spreading resistance is linear in the logarithm of the probe spacing ($\ln S$) with a slope proportional to the sheet resistance. For layers of nonuniform resistivity formed by junction-isolated boron diffusions with junction depths up to 4.3 μm , this conjecture has been shown to be valid (to within a few percent) when the probe spacing experiment is performed and the results compared with the sheet resistance obtained by means of four-probe measurements (1).

As the applicability of this conjecture to general classes of structures was unknown, several investigations (2, 3) were previously undertaken making use of model spreading resistance data (4). These probe spacing experiment simulations indicated that the probe

spacing experiment would give the correct incremental sheet resistance in the surface region of junction type as well as heavily doped implant and diffusion structures. This conclusion was obtained by comparing the incremental sheet resistance obtained from the probe spacing experiment simulation to that obtained from direct calculation of the resistivity profile. This conclusion was not altered when several forms of the probe-current density (5) were used in the calculations. For lightly to moderately doped layers over substrates of the same conductivity type, the conjecture was found not to hold. In addition, deep layers, typical of power device structures, were found to present what appears to be a breakdown of the conjecture. Also, these investigations showed that the interpretation of the intercept in terms of a probe radius was not well founded. Hence, the use of the probe spacing experiment as a way of obtaining the probe radius is not warranted.

The purpose of this paper is to derive a general relation between the four-probe resistance and the two-probe spreading resistance. It is of utmost importance to emphasize that the four-probe resistance is not necessarily the sheet resistance, but is rather a generalized four-probe resistance. In the discussion which follows, the four-probe resistance refers to the generalized four-probe resistance, the two-probe resistance is the two-probe spreading resistance, and the incremental sheet resistance is referred to as the sheet resistance. All of these quantities are functions of depth. It will be shown that the four-probe resistance is related, in certain well-defined limits, to the sheet resistance. In addition, it will be shown that the four-probe resistance can always be obtained from measurements of the spreading resistance. The latter provides for a simple relation between the two-probe and the four-probe re-

* Electrochemical Society Active Member.

Key words: four-probe resistance, probe-current density, probe radius, probe separation, profile analysis, resistivity, sheet resistance, spreading resistance.

sistances. In addition, the relation between the four-probe resistance and the Dickey conjecture is elucidated. Finally, a self-consistent procedure for determining the probe radius parameter used in spreading resistance profile analysis is developed. Throughout the paper, the symbol "ln" is used to refer to the natural or Naparian logarithm, and the symbol "log" is used for the base-10 logarithm.

Derivation of Relation Between Two-Probe and Four-Probe Resistances

Consider a material of nonuniform resistivity. Four probes are placed on the surface of the material in an in-line configuration with adjacent probes separated by a distance S . The outer two probes are the source-sink combination for the current, while the inner two probes are the voltage sensing probes. It is important to emphasize that value of S is arbitrary and need not be in the range of values usually used for traditional four-probe sheet resistance measurements. Following the general development associated with the Laplace equation multilayer analysis (6, 7), the $\Delta V/I$ or resistance between the inner two probes, denoted by $Z(x, S)$, is given by

$$Z(x, S) = 2\rho(x) \int_0^\infty A(x, \lambda) \{J_0(\lambda S) - J_0(2\lambda S)\} I_\nu(\lambda a) d\lambda \quad [2]$$

where x is the depth, $\rho(x)$ is the nonuniform resistivity, $J_0(\lambda S)$ is the first-order Bessel function, $A(x, \lambda)$ is the kernel of the integral and is related to the details of the underlying resistivity structure, $I_\nu(\lambda a)$ is the Hankel transform of the generalized probe-current density normalized to unit current (5), ν in $I_\nu(\lambda a)$ is an index which refers to the specific form of the current density (3, 5), and λ is the integration variable. As will be shown in the subsequent development, $\pi Z(x, S)/\ln 2$ approaches the sheet resistance as the separation between the probes becomes large compared to the distance to an insulating boundary.

Next, consider the same material contacted by a two-probe configuration typical of spreading resistance measurements. The two-probe spreading resistance at the probe spacing equal to S is given by

$$R(x, S) = 4\rho(x) \int_0^\infty A(x, \lambda) \left\{ \frac{J_1(\lambda a)}{\lambda a} - \frac{J_0(\lambda S)}{2} \right\} I_\nu(\lambda a) d\lambda \quad [3]$$

while the two-probe spreading resistance at the probe spacing equal to $2S$ is given by

$$R(x, 2S) = 4\rho(x) \int_0^\infty A(x, \lambda) \left\{ \frac{J_1(\lambda a)}{\lambda a} - \frac{J_0(2\lambda S)}{2} \right\} I_\nu(\lambda a) d\lambda \quad [4]$$

By subtracting Eq. [3] from Eq. [4], it is easy to show that the four-probe resistance given by Eq. [2] may be simply written as

$$Z(x, S) = R(x, 2S) - R(x, S) \quad [5]$$

Equation [5], which is the desired relation between the two-probe and four-probe resistances, states that the four-probe resistance at a given value of the separation, S , may be simply obtained from the two-probe spreading resistance by taking the difference between the spreading resistance evaluated at $2S$ and the spreading resistance evaluated at S . The central point of the present work is to calculate the four-probe resistance by means of Eq. [2] and to investigate the behavior of the function for various structures and as a function of the probe separation.

In order to complete this section, consider the implications of the Dickey conjecture, *i.e.*, that the spreading resistance is linear in the logarithm of the probe spacing $\ln S$, with a slope proportional to the sheet resistance. If this is the case, the derivative of the spreading resistance with respect to $\ln S$ should under certain well-defined conditions be related to the sheet resistance. Hence, it is quite natural to consider the derivative of the two-probe spreading resistance (as given by Eq. [3]) with respect to $\ln S$. By making use of the chain rule, this derivative, denoted by $D(x, S)$, may be written as

$$D(x, S) = \frac{dR(x, S)}{d \ln S} = S \frac{dR(x, S)}{dS} \quad [6]$$

Substituting Eq. [3] into Eq. [6] and carrying out the derivative of the $J_0(\lambda S)$ Bessel function inside the integral (8) yields

$$D(x, S) = 2\rho(x) \int_0^\infty A(x, \lambda) \lambda S J_1(\lambda S) I_\nu(\lambda a) d\lambda \quad [7]$$

The focal point of the calculations presented here is to consider the functions $Z(x, S)$ and $D(x, S)$ as defined by Eq. [2] and [7], respectively and to show how they are related to the sheet resistance defined as

$$R(x) = \frac{1}{\int_0^x \frac{1}{\rho(x')} dx'} \quad [8]$$

Numerical Evaluation of $Z(x, S)$ and $D(x, S)$

For a particular resistivity structure, the sheet resistance defined by Eq. [8] may be obtained by direct numerical summation or integration. The four-probe resistance and the derivative function were evaluated by making use of the recursion relation for the kernel, *i.e.*

$$A(x, \lambda) = \frac{A(x-d, \lambda)\sigma(x) + \sigma(x-d) \tanh(\lambda d)}{\sigma(x-d) + \sigma(x)A(x-d, \lambda) \tanh(\lambda d)} \quad [9]$$

where d is the sublayer thickness and $\sigma(x)$ is the conductivity. The above form is from Berkowitz and Lux (9) and is fully equivalent to the original form of the recursion relation presented by Choo *et al.* (10). A useful feature of the recursion relation as given by Eq. [9] is that it is easy to obtain the form of $A(x, \lambda)$ for a uniform layer over an insulating boundary, a conducting boundary, or no boundary. By making use of the resistivity structure along with the appropriate boundary condition, it is possible to construct the kernel of the integrals involved in the functions $Z(x, S)$ and $D(x, S)$. Evaluation of the resulting integrals has been accomplished by means of two numerical integration techniques. The first is the trapezoidal-Romberg technique first used by D'Avanzo *et al.* (11, 12) in the evaluation of the arrays of partial integrals involved in the implementation of spreading resistance correction factor integrals. This technique has also been used to generate model spreading resistance data (Eq. [4]). The second technique makes use of a 1250-point integrator.

Extensive testing indicates that the two integration techniques agree well. Because the 1250-point integrator takes far less CPU time than the trapezoidal-Romberg technique, most of the calculations presented here were obtained by means of that technique. For certain situations, a 10,000-point integrator was used. This form allows for evaluation of the integrals over an interval much larger than the one used in the 1250-point scheme. Evaluation of the derivative function, $D(x, S)$, using these latter two techniques sometimes leads to convergence problems. This is due to the large value of the upper limit required in the evaluation of the integral for the case of large probe spacing and thick, same-conductivity type substrates. For these situations, the integrand of $D(x, S)$ decays to zero very

slowly, and the trapezoidal-Romberg technique was used to ensure the convergence of the integrals. For the cases which were investigated, this technique (with an adjustable upper limit) led to convergence. This convergence problem was not seen in the calculation of the four-probe resistance. This is due to the more rapid decay of the integrand of the four-probe resistance integral.

A listing of the Fortran programs used in the 1250-point and 10,000-point schemes may be obtained from either of the authors upon request.

Calculation of $Z(x,S)$ for Two-Layer Structure

These integration techniques were extensively tested on varying thickness uniform layers over an infinite substrate of constant resistivity, and it was found that the four-probe resistance, the derivative function, and the sheet resistance were related by

$$Z(x, S) = \frac{\ln 2}{\pi} R(x) \quad [10]$$

$$D(x, S) = \frac{1}{\pi} R(x) \quad [11]$$

The above results were obtained provided that the substrate resistivity was large compared to the resistivity of the top layer (i.e., for a uniform layer over an insulator), and that x/S is small. For the situation where x/S was comparable to or larger than unity, the relations given by Eq. [10] and [11] did not hold. This is to be expected, since the traditional sheet resistance model (embodied in Eq. [8]) is obtained for the situation where the probes are spaced widely relative to the layer thickness and where the assumption of parallel conduction in the layer holds as a result. For $x/S \geq 1$, $Z(x, S)$ represents the $\Delta V/I$ measured between the two voltage-sensing probes. However, for $x/S \geq 1$, the function $D(x, S)$ cannot be related in a meaningful way to a measurable physical quantity. The behavior of the surface value of $Z(x, S)$ as a function of the ratio of the probe separation and the layer thickness (S/t) is presented in Fig. 1. The specific structure is a variable thickness, $1 \Omega \cdot \text{cm}$, layer over an insulating boundary.

The function $Z(x, S)$ was also evaluated for a general two-layer structure. The behavior of $Z(x, S)$ for a wide range of t/S (for fixed probe spacing) and layer resistivity is presented in Fig. 2. The substrate is infinitely thick and has a resistivity of $1 \Omega \cdot \text{cm}$. The re-

Fig. 1. The behavior of the surface value of $Z(x,S)$ as a function of the ratio of the probe spacing and the layer thickness. The specific structure is that of a varying thickness, $1 \Omega \cdot \text{cm}$, layer over an insulating boundary. If the ratio S/t is greater than 1.67, the four-probe resistance deviates from $\ln(2)/(\pi t)$ by less than 1%.

Fig. 2. The four-probe resistance of a uniform layer over an infinitely thick substrate of $1 \Omega \cdot \text{cm}$ resistivity for a wide range of layer resistivity and layer thickness to probe spacing ratio. The data are for a fixed value of probe spacing and represent the dependence of the four-probe resistance on layer thickness and top layer resistivity. The region in which the Dickey conjecture has validity and utility immediately adjoins the square marked I. In this region, the linear dependence of $\log(\Delta V/I)$ on the resistivity indicates that the shorting effects of the substrate are not severe, and the negative slope $\Delta(\log[\Delta V/I])/\Delta \log[t/S]$, indicates that the four-probe resistance varies inversely with layer thickness and that therefore the sheet resistance is a physically meaningful quantity. In the region to the left of II, the four-probe resistance shows too little dependence on the layer resistivity to be of interest. The region marked III is not generally considered for the use of four-probe measurements. However, it is clear from the linear dependence of $\log(\Delta V/I)$ on $\log(\rho)$ that the sensitivity of the four-probe measurement to the layer resistivity is actually greater here than anywhere else on the surface displayed.

sults were also compared with those obtained from a point-source image simulation of the four-probe resistance. A comparison of the results for these two computational schemes is presented in Fig. 3. The calculation of $Z(x, S)$ agreed with the image solution to the full accuracy expected from the integration technique. This is true even though the probe radius and the variable ν in Eq. [2] were varied over wide limits. This confirms the independence of the four-probe resistance to details of the current injection process, i.e.,

Fig. 3. The results obtained by combining the four-probe resistance shown in Fig. 2 in parallel with $1/(2\pi S)$, the four-probe resistance of an infinite uniform substrate of $1 \Omega \cdot \text{cm}$ resistivity, for $S = 100 \mu\text{m}$. The dashed surface is the one shown in Fig. 2. The relative deviation in the four-probe resistances calculated by the respective methods for the point at the lower right corner is about 10%.

to the probe current density. The surface in Fig. 2 has been subdivided into three regions, denoted by I, II, and III. It is important to note that distinct boundaries of these three regions are not possible, as there is a continuous change from one region to the next. The region denoted by I is that of small top layer resistivity and a large spacing to thickness ratio ($S/t > 1$). In this region, the sheet resistance is a well-defined quantity and the Dickey conjecture is valid. In region II, the probe spacing is still large compared to the top layer thickness ($S/t > 1$), but the top layer resistivity is increasing. Note that the slope of the surface in this region decreases, indicating that the substrate resistivity is dominating the four-probe resistance. Consequently, the four-probe resistance may not be used to obtain information about the layer resistivity. Finally, the region III is that in which the layer thickness is a sizable fraction of, or greater than, the probe spacing. This is a nonstandard region for the operation of a four-point probe in as much as the sheet resistance is not a well-defined quantity here. However, since the $\Delta V/I$ is a linear function of the layer resistivity, the four-probe resistance is a useful measure of layer resistivity.

Calculation of $Z(x,S)$ for Nonuniform Layers

Model resistivity data corresponding to a shallow Gaussian implant into varying resistivity same-conductivity-type substrates were used in these calculations. The substrate resistivities which were used were 126.46, 12.82, and 1.38 $\Omega \cdot \text{cm}$, respectively. These correspond to substrate doping levels of 10^{14} , 10^{15} , and 10^{16} cm^{-3} , respectively. In all cases, the substrate thickness was taken as 350 μm , the approximate thickness of a standard silicon wafer. A typical example of the resistivity data which was used in the calculations is presented in Fig. 4.

The results of these calculations of $Z(x,S)$ and $\mathcal{R}(x)$ are contained in Fig. 5-7. For the case of the 126 $\Omega \cdot \text{cm}$ substrate, the behavior of $Z(x,S)$ as a function of S in the surface region is dominated by the resistivity of the implanted layer. $Z(x,S)$ in this region

is almost independent of the probe spacing, indicating that the sheet resistance is well defined in this region. For substrate resistivities larger than 126 $\Omega \cdot \text{cm}$, the

Fig. 5. The behavior of $\pi Z(x,S)/\ln(2)$ for the shallow implant into a 126.46 $\Omega \cdot \text{cm}$ substrate. The substrate is 350 μm thick. The values of S and the corresponding curves are: A = 25 μm , B = 50 μm , C = 100 μm , D = 200 μm , and E = 500 μm . The curve denoted by F is the corresponding four-probe sheet resistance calculated according to Eq. [8].

Fig. 4. Typical plot of the resistivity profile used in the calculations of the text. The specific structure is that of a shallow implant into a 126.46 $\Omega \cdot \text{cm}$ substrate.

Fig. 6. The S -behavior of $\pi Z(x,S)/\ln(2)$ for a shallow implant into a 12.82 $\Omega \cdot \text{cm}$ substrate. The notation as to the S values and the corresponding curves follows that of Fig. 5.

Fig. 7. The S behavior of $\pi Z(x,S)/\ln(2)$ for a shallow implant into a $1.38 \Omega \cdot \text{cm}$ substrate. The notation follows that of Fig. 5 and 6.

Dickey conjecture will hold. As the substrate resistivity decreases from 126 to $12.82 \Omega \cdot \text{cm}$ (from Fig. 5 to Fig. 6), the effects of substrate shorting are clearly evident. In Fig. 6, the dependence of $Z(x,S)$ on S in the surface region has much the same behavior as is observed in the substrate region. There is a distinct advantage in using a small probe spacing; there is more information about the layer in $Z(x,S)$ for small values of S . Finally, as the substrate resistivity is further decreased from 12.82 to $1.38 \Omega \cdot \text{cm}$ (from Fig. 6 to Fig. 7), the effects of substrate shorting are so severe that it is doubtful that even at the smallest spacing that there would be sufficient resolution in $Z(x,S)$ to recover much information about the implanted surface layer.

For the intermediate substrate resistivity case, *i.e.*, for those cases where the substrate value of $Z(x,S)$ minus the surface value of $Z(x,S)$ is significant, the effect of the substrate can be eliminated. This may be done by using the equation

$$Z_{\text{eff}} = \frac{Z_S Z}{Z_S - Z} \quad [12]$$

where Z_{eff} is the value of Z expected at the surface for an insulating substrate and Z_S is the substrate value of $Z(x,S)$. This formula assumes that the layer four-probe resistance can be added in parallel.

For all of the cases considered, the four-probe resistance was found to be independent of the probe-current density and the probe radius used in the calculations. The four-probe resistance was found to depend only upon the resistivity profile. This forms the basis of the calibration procedure presented below.

Calibration of Spreading Resistance Profile Data

A common difficulty associated with the analysis of spreading resistance profile data arises from the fact that the classical relation between the spreading resistance and the resistivity for a uniform material, *i.e.*

$$R = \frac{\rho}{2a} \quad [13]$$

is, in general, not adequate, in that the probe radius (a) may be a function of the resistivity of the material. There are a number of methods which are currently used to account for this difficulty. First, there is the suggestion that a series surface barrier resistance must be included. Second, on purely arbitrary grounds, the empirical formula (11)

$$R = \frac{\rho^m}{2a} \quad [14]$$

is used with the value of a determined from the fit of the curve evaluated at $1 \Omega \cdot \text{cm}$. Third, the probe radius is assumed to be a function of the resistivity, and the form of the function should be obtained from measurements on a series of uniform calibration samples. However, the point of view which is adopted here is that the so-called probe radius (a) is merely a model-dependent parameter to account for the fact that the current density near the pressure contact of a spreading resistance probe is, in general, not known. Inasmuch as the analysis techniques currently used assume a single form of the probe current density, regardless of the details of the resistivity profile in the material, it is clear that the entire idea of a probe radius as a physically measurable quantity must be abandoned. In its place, a self-consistent technique for obtaining the adjustable parameter (a) which makes no assumptions about the physical interpretation of the parameter is proposed. The basis of the technique being proposed is founded in the fact that the function $Z(x,S)$ is independent of the parameter a as well as the details of the current injection process, *i.e.*, the probe-current density. It depends only upon the resistivity profile. The resistivity profile obtained from spreading resistance data analysis is, however, dependent upon the choice of the parameter a . Hence, the four-probe resistance obtained from resistivity profiles interpreted from spreading resistance data will depend indirectly upon the choice of a used in the spreading resistance data analysis.

In this section, the rationale for such a self-consistent calibration scheme and a detailed description of the procedure to be used are presented. It is important to note that this method is based upon the four-probe resistance rather than the sheet resistance. The former quantity has more general significance, and there is no necessity to restrict the application to junction-isolated structures.

An outline of this method is as follows. First, the spreading resistance is measured as a function of the probe spacing on the top surface of the sample being profiled and is fit (using polynomial regression analysis, for example) to a curve representing the spreading resistance as a function of probe spacing. Then, by using a value of the probe spacing which affords maximum sensitivity to the interesting portion of the dopant profile (by choosing the region of Fig. 3 where the function $Z(x,S)$ is proportional to ρ), $Z(x,S)$ is calculated from $R(x,S)$ and $R(x,2S)$ according to Eq. [5]. Second, the sample is beveled, and the spreading resistance is measured as a function of depth (*i.e.*, along the bevelled surface) for the same value of S used to calculate $Z(x,S)$. Third, using a multilayer analysis scheme, the resistivity profile is calculated from the spreading resistance profile for several values of the parameter a . Of course, these should be in a range of values which would be considered to be reasonable. Fifth, these resistivity profiles (which depend parametrically upon the set of a values) are used to determine $Z(S;a)$ according to Eq. [2]. The notation $Z(S;a)$ is used to denote the calculated four-probe resistance which depends indirectly upon a through the interpreted resistivity profiles. Sixth, by interpolation, the calculated $Z(S;a)$ which agrees with the measured four-probe resistance (from the first step) is found. The value of a thus determined represents

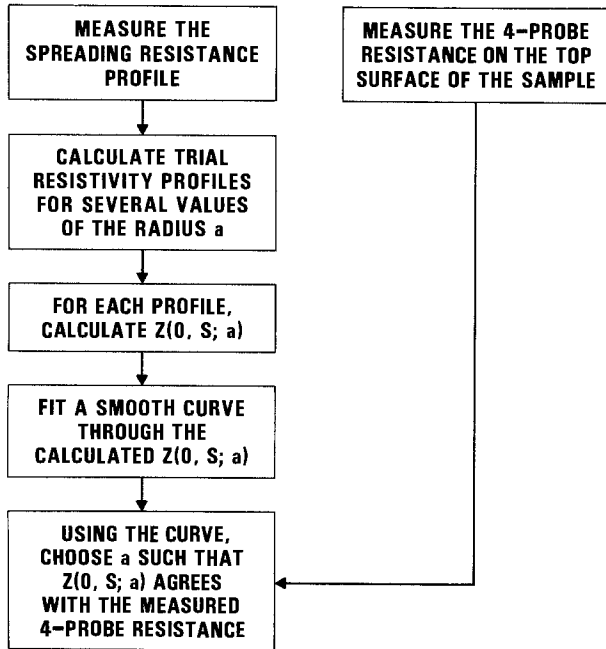

Fig. 8. Schematic diagram of calibration procedure

the self-consistent value of a for the profile in question. This calibration procedure is graphically summarized in Fig. 8.

To determine the sensitivity of this procedure in the evaluation of the probe radius parameter, this method was tested on model spreading resistance data. The model data were generated from the resistivity profiles employed to calculate the $Z(x, S)$ data presented in Fig. 5-7. In all cases, the Choo uniform current density was used along with a probe radius of $a = 2 \mu\text{m}$. The surface values of the spreading resistance, $R(0, S)$, was expressed in terms of a polynomial in S by means of a standard polynomial least-squares fitting routine. A typical plot of $R(0, S)$ vs. S is given in Fig. 9. The spreading resistance as a function of depth and for a fixed value of the probe spacing was then analyzed according to the Berkowitz-Lux correction factor scheme (9) as well as the Dickey local-slope technique (1). This analysis was carried out for a values over the range of 1 to $3 \mu\text{m}$. Typical

Fig. 9. The surface value of the calculated spreading resistance as a function of the probe separation. The specific structure is that of the shallow implant into a $126.46 \Omega \cdot \text{cm}$ substrate. It is this curve which is fitted by means of a polynomial fit and used to calculate the surface value of $Z(x, S)$ according to Eq. [5].

Fig. 10. The effect of the choice of the value of a upon the interpreted resistivity profile. The specific structure is that of the shallow implant into a $126.46 \Omega \cdot \text{cm}$ substrate. The values for a are $A = 3 \mu\text{m}$, $B = 2 \mu\text{m}$, and $C = 1 \mu\text{m}$. The probe spacing is $25 \mu\text{m}$. It should be noted that the qualitative features of the profiles are not sensitive to the choice of a and that variation of a has the effect of shifting the profiles up and/or down. The Berkowitz-Lux correction factor scheme has been used to obtain these resistivity profiles.

resistivity profiles which depend parametrically upon the choice of the value of a are shown in Fig. 10. The corresponding resistivity arrays, $\rho(x; a)$, which depend parametrically upon the choice of a value, were used in the 1250-point integration scheme to obtain the corresponding four-probe resistance denoted by $Z(x, S; \rho[x; a])$. The surface values of these four-probe resistances were then graphically compared with the surface four-probe value determined from the polynomial-fitted $R(0, 2S)$ and $R(0, S)$. Figure 11 contains the results of a typical plot of the surface value of the four-probe resistance against the assumed value of the probe-radius parameter for the case of $S = 25 \mu\text{m}$. From the plot, it is clear that the curvature is

Fig. 11. Typical plot of the dependence of the surface four-probe resistance on the probe radius used in the analysis of the model spreading resistance data. Curve A is that obtained from the Berkowitz-Lux correction factor scheme, while curve B is that obtained from the Dickey local slope technique. The former yields $a = 2 \mu\text{m}$, while the latter yields $a = 1.7 \mu\text{m}$. The value of the probe spacing is $S = 25 \mu\text{m}$.

Fig. 12. A series of plots of the results of the calibration investigation for several values of the probe spacing. The values of the probe spacings and the corresponding curves are: $S = 25 \mu\text{m}$ (A), $S = 50 \mu\text{m}$ (B), $S = 75 \mu\text{m}$ (C), and $S = 100 \mu\text{m}$ (D). In all cases, the Berkowitz-Lux correction factor scheme was used.

sufficient to provide sensitivity and yield the value of $a = 2 \mu\text{m}$, which was originally used in the generation of the spreading resistance. In addition, to show that the sensitivity is not degraded by variation of the probe spacing, the results of the analysis for several values of the probe spacing are presented in Fig. 12. It is important to emphasize that the curvature must be sufficient to provide for the evaluation of the value of a . Should the curve be found to be flat, this would preclude the use of this procedure.

Conclusions

A derivation for the four-probe resistance $Z(x, S)$ and its relation to the two-probe spreading resistance $R(x, S)$ has been presented. The calculation of $Z(x, S)$ for a wide range of resistivity structures and probe

separation has been presented and discussed. It was shown that the sheet resistance, $R(x)$, is obtained from $Z(x, S)$ for isolated structures with $S/x > 1$. In addition, it was shown that the function $Z(x, S)$ can be used to self-consistently obtain the probe radius parameter (a) used in spreading resistance profile analysis.

Defect Characterization in Monocrystalline Silicon Grown Over SiO_2

J. T. McGinn,* L. Jastrzebski,* and J. F. Corboy

RCA Laboratories, Princeton, New Jersey 08540

ABSTRACT

Crystallographic defect structures in monocrystalline silicon films grown over SiO_2 layers have been characterized by cross-section and planar transmission electron microscopy. Overgrowths of epitaxial silicon films on SiO_2 layers have been seeded from single crystal substrates through openings in the SiO_2 layers. Defect structures have been studied as a function of substrate orientation, seeding procedure, and growth temperature. Defect densities have been dramatically reduced through first-order optimization of the above parameters.

Single crystal growth over amorphous substrates has received considerable attention recently (1-8). Such structures are potentially useful in the area of solid-state device fabrication. Successive overgrowth of silicon above silicon oxide may make possible the fabrication of three-dimensional devices. A number of approaches have been attempted in an effort to achieve a uniform, defect-free overgrowth of monocrystalline silicon above an amorphous insulator such as SiO_2 . These approaches may be divided into the two general categories of seeded (5-8) and unseeded (1-4) growth. In the case of the seeded growth, a single crystal seed

* Electrochemical Society Active Member.

of the desired orientation is in contact with an amorphous or polycrystalline silicon film which has been deposited upon an amorphous, insulating layer. If it is possible to preferentially melt the deposited silicon film in the vicinity of the single crystal seed, crystallization of the melt from the seed can occur via liquid phase epitaxy. Various techniques have been adopted to optimize the crystallization process. The most successful have been the scanning laser technique (5, 6) and the strip heater method (7, 8). Large grains of unseeded silicon have been shown to spontaneously result from the laser annealing of amorphous or polycrystalline films on SiO_2 subbing layers (4). The un-

seeded technique for producing monocrystalline films over amorphous layers is referred to as graphoepitaxy (1-3). In this technique, the surface of the amorphous layer is patterned with a series of grooves. The groove morphology and the pattern geometry are specifically tailored to induce nucleation of a deposited silicon film with a specific orientation (2).

The seeded technique mentioned above requires that the silicon films be elevated to a temperature above their melting point. If it is desired to fabricate three-dimensional device structures, such high temperatures could produce an undesirable redistribution of impurities in those devices which had been buried below the insulating layer. In the unseeded technique, graphoepitaxy, considerable difficulty has been encountered in attempts to produce high-quality silicon films.

Due to the difficulties inherent in the above techniques, an alternative approach of producing single crystal silicon overgrowths via seeded chemical vapor deposition (CVD) has been attempted by Jastrzebski *et al.* (9) and McGinn *et al.* (10). Similar work has been done with GaAs overgrowth by Mellend *et al.* (11). This paper reports the findings of a TEM examination of the microstructure of seeded silicon films grown over SiO₂ strips via a chemical vapor deposition technique.

Experimental

Samples were prepared by thermally oxidizing the surface of either (100) or (111) silicon wafers. Parallel, periodic channels were etched through the oxide exposing the underlying Si surface. The repeat distance of the remaining strips of SiO₂ was 26 μm. Samples with oxide strip widths of either 6 or 20 μm were prepared. The edge of the oxide strip was aligned along either the [01 $\bar{1}$] or [2 $\bar{1}\bar{1}$] directions on the (111) wafers and along either the [001] or [011] directions on the (100) wafers. These structures will be referred to as (hkl)-[uvw] structures indicating the (hkl) plane of the substrate and the [uvw] direction of the edge of the oxide strip. The films were grown in a radiant-heated barrel reactor. The silicon films were deposited in a series of growth-etch steps using a mixture of SiH₂Cl₂, H₂, and HCl. The gas flow rates were 0.75, 82, and 2 liters/min, respectively. Each growth step was followed by an etching step using an HCl, H₂ mixture with the same gas flow as in the growth step (9). These growth conditions were designed to suppress the growth of polycrystalline silicon over the oxide while permitting the growth of single crystal epitaxial silicon. The epitaxial Si grew up through the channel openings and then proceeded to expand laterally across the surface of the SiO₂. Cross sections for TEM studies were cut either normal to the substrate surface or along a {111} plane inclined to both the substrate surface and the oxide strip in order to enhance the visibility of certain crystallographic defects. Shear stress measurements taken in the silicon overgrowth were accomplished by measuring the deviation from orthogonality in a symmetric 001 selected area transmission electron diffraction pattern (14).

Observations

In samples prepared from (111) Si wafers, the channels in the SiO₂ layer were etched along either [01 $\bar{1}$] or [2 $\bar{1}\bar{1}$] directions. Defects in the silicon overgrowth were observed for all strip width and channel orientations. When the channels were etched along [01 $\bar{1}$] directions, an asymmetry in the fault structure about the center of the SiO₂ strips was observed as shown in Fig. 1. In this configuration, the overgrowth above the left side of the oxide strip was twin related to the substrate while the overgrowth above the right side retained the substrate orientation. Beyond the right edge of the oxide strip, irregular twins formed pockets

Fig. 1. Lateral overgrowth viewed in cross section above a (111) silicon wafer. The oxide strip runs along the [011] direction. The fault structure is unsymmetrically distributed about the center plane of the oxide strip. A (111)-[01 $\bar{1}$] structure.

in the epitaxial silicon extending from the surface to the substrate overgrowth interface.

When the channels were etched along [2 $\bar{1}\bar{1}$] directions over (111) wafers, the defect structure did not display the asymmetry of the (111)-[01 $\bar{1}$] samples. Figure 2 shows an incomplete overgrowth of a (111)-[2 $\bar{1}\bar{1}$] sample. Here the growth was stopped just as the two growth fronts met above the center of the oxide strip. The overgrowth in this case retained the orientation of the substrate above both sides of the oxide strip. Numerous microtwins are present within the overgrowth as are bands of dislocations, but the asymmetry in twin structures observed in the (111)-[01 $\bar{1}$] sample is absent.

In samples prepared from (100) silicon wafers, the channels in the SiO₂ layer were etched along either [011] or [001] direction. When channels were etched along [011] directions, the silicon which overgrew the SiO₂ was highly defective (Fig. 3). This defect region was bounded below by the oxide strip, above by the free surface, and laterally by the (1 $\bar{1}\bar{1}$) and ($\bar{1}\bar{1}\bar{1}$) planes. The predominant defect feature observed within this volume was macrotwins. Commonly 70-

Fig. 2. Lateral overgrowth viewed in cross section above a (111) silicon wafer. The oxide strip runs along a [2 $\bar{1}\bar{1}$] direction. A (111)-[2 $\bar{1}\bar{1}$] structure.

90% of the volume of the defective region was twin related to the substrate. Microtwins over the oxide were also observed. Above the center of the oxide strip, an incoherent grain boundary extended from the sample's surface to the base of the overgrowth. The boundary was presumably formed when the silicon growth fronts emanating from the two edges of the SiO_2 joined above the center of the oxide strip.

When channels in the SiO_2 layer were etched along [001] directions on (100) wafers, a dramatic improvement in the quality of the overgrowth was achieved. Above $6 \mu\text{m}$ wide oxide strips, high quality silicon was grown as in Fig. 4. A void at the base of the overgrowth above the center of the oxide strip was the only commonly observed defect. Occasionally, isolated stacking faults or microtwins were observed in the overgrowth. A grain boundary above the void where the growth fronts joined was not observed.

Silicon (100) overgrowths above $20 \mu\text{m}$ wide, [001] oxide strips displayed a wide variation in defect structures (Fig. 5¹ and 6). In highly defective samples, stacking faults lying along {111} planes, the central void and associated grain boundary and dislocation networks emanating from the edges of the oxide strip (Fig. 5) were all present. In low defect density samples, as seen in Fig. 6, only scattered dislocations and the central void were observed. On a given side of the central boundary, only two of the four possible {111} stacking fault planes were active. Across the boundary, only the remaining two {111} stacking fault planes were active. The normals to the stacking fault planes comprising an active pair are symmetrically disposed about the [001] direction (i.e., the edge of the oxide strip). On a given side of the central grain boundary, only that pair of {111} planes which forms a closed tetrahedron with the central grain boundary and the overgrowth-oxide interface was found to be active. The active pair of stacking faults to one side of the oxide are clearly displayed in Fig. 7 which was cut from a (100)-[001] sample so that the face of the cross section was a {111} plane. By imaging the region of the fault under various diffraction conditions which render the fault invisible (12, 13) it is possible to observe the dislocations in the fault plane. Applying the $\vec{g} \cdot \vec{b} = 0$ invisibility criterion, where \vec{b} is the Burgers

vector of the dislocation and \vec{g} is the diffraction vector, it was determined that the bounding dislocations and therefore the stacking faults were of the $a/6 \langle 211 \rangle$ type. Figure 8 is a planar view of the overgrowth- SiO_2 interface. The stacking faults and microtwins (presumably caused by the formation of $a/6 \langle 211 \rangle$ faults upon successive planes) are seen to have formed in pairs along two intersecting {111} planes. The line of intersection extended from the edge of the oxide through the remaining overgrowth. Each of the stacking faults extended from this line of intersection to the central void along its respective {111} plane. Also in Fig. 8, a periodic set of dislocations is seen edge on along the edges of the oxide strip. Irregularities in the interface between the overgrowth and the oxide were often visible. Occasionally, the center void was absent and an oscillatory interface was observed above the center of the oxide strip, not shown in this work. A second set of oscillations in the Si- SiO_2 interface was observed further away from the central void. These oscillations were observed as parallel contrast bands when a planar sample containing the interface was

¹ Care must be taken in analyzing Fig. 5. The plane of the cross section is a (001). The sample has been rotated in the microscope about the [100] direction to obtain the [011] view shown in Fig. 5. Under these conditions, the pairs of stacking faults to one side of the oxide will intersect the sample's surface in parallel traces. The two members of the right-side pair can be distinguished in Fig. 5 by the narrow, (111), and the broad, (111), projections they make onto the (011) plane of the micrograph. To the left of the figure the stacking faults overlap and are not individually resolvable.

imaged under dynamic conditions as in Fig. 8. These oscillations correspond in number and spacing to the

growth-etch cycles which occurred during the ELO deposition.

A void on the underside of the oxide strip approximately 1-3 μm from the edge of the oxide was commonly observed in the (100) samples. The voids were typically irregular in shape, but confined to the bottom of the oxide strip tending not to extend into the single crystal silicon region of the substrate (Fig. 6).

Shear stress measurements (14) were taken along the overgrowth-oxide interface in both high and low defect density samples. In the high defect density samples, the shear stress was below the detectable levels. In the low defect density samples, shear stresses of 3.6×10^9 dyn/cm² which changed sign symmetrically across the center of the oxide strips were measured.

Discussion

The specific nature of the defect generation in the overgrowth film has been shown to be highly sensitive to the crystallographic orientation of both the substrate and the edge of the oxide strip. This may be understood in the case of the ELO films grown on (100) wafers if these orientations are considered relative to the slip planes in silicon as well as the directions in which a dislocation must run in order to be in a minimum energy configuration.

A number of mechanisms may induce stress in the overgrowth: (i) A slight misalignment of the ELO film as it expands over the oxide layer would prevent perfect atomic bonding of the two growth fronts as coalescence occurs. Such misalignments whether leading to distorted atomic bonds or to a low angle grain boundary at the point of coalescence would inevitably result in internal stresses. (ii) Stress may result from

Fig. 7. The two active sets of stacking faults to one side of the oxide strip are observable. This sample is an inclined cross section of a (100)-[001] specimen. The faces of the cross section were cut along the (111) plane,

thermal gradients during cooling, or (iii) to differences in the thermal coefficients of expansion between silicon and SiO₂. The disposition of these internal stresses relative to the {111} slip planes and the <110> directions will strongly influence the deformation mechanisms available for the relaxation of the crystal.

In samples prepared on (111) wafers with the oxide running along a [011̄] direction, the microstructure was asymmetric about the center of the SiO₂ strip. The fabricated structure, consisting of the oxide strip and the neighboring channels, contained a plane of mirror symmetry which is perpendicular to the plane of the substrate and passes through the center line of the

Fig. 8. Planar view of the overgrowth-oxide interface in a (100)-[001] sample.

oxide strip. This is a $(2\bar{1}\bar{1})$ plane in the silicon. Since the $(2\bar{1}\bar{1})$ plane is not crystallographically a mirror plane, symmetric stresses imposed on the two sides of the oxide strip would not be expected to be relieved by identical processes. Extensive evaluation of the ELO films on (111) silicon have not been carried out due to the poor prospects for achieving defect-free material. No attempt has been made to formulate a mechanism for fault formation within the ELO layers grown over (111) substrates. It is simply noted that the observed faults were consistent with the symmetries imposed by the crystallography and the fabricated structures.

In samples grown over (100) wafers with the oxide strips along [011] directions, internal stresses which occurred during growth or subsequent cooling were ideally situated to nucleate dislocations. Internal stress risers, such as the edges of the oxide strip, oscillations in the silicon-SiO₂ interface, the central grain boundary and associated void, all ran along the [011] direction and were possible sites for nucleation of perfect, low-energy dislocations. Once nucleated, these dislocations would have been free to glide along either the $(11\bar{1})$ or $(\bar{1}\bar{1}1)$ planes.

When the oxide strip ran along a [001] direction on a (100) substrate, the lines of high internal stress did not coincide with a direction along which dislocations could be easily nucleated. Any dislocation lying along a [001] direction would have been in a high-energy state and thus would have required a high internal stress for nucleation. In cases where sufficient internal stress existed for dislocation nucleation, along an edge, the experimental results suggest that these dislocations were the source of the active pair of stacking faults which originate at the edge. If these dislocations were to act as a source of the pairs of stacking fault which are shown in Fig. 7 and 8, the Burgers vector of the dislocation would by necessity be limited to that direction which could slip in both of the active stacking fault planes.

The proposed model for stacking fault generation is consistent with the nature of the stacking faults observed above the oxide on (100) samples with [001] oxide strips. Shear strain measurements made in the overgrowth indicated that samples with low stacking fault densities had shear strains of 3.6×10^9 dyn/cm² while the shear strain in highly faulted samples was below detectable limits. This suggests that the stacking faults are generated as a strain relief mechanism. Stacking faults may originate at a number of locations where the local strain would be expected to be high. Namely, the overgrowth-oxide interface and the grain boundary above the center of the oxide strip would be points of high internal strain. The model for stacking fault generation given above has used the edge of the Si/SiO₂ interface as the site of nucleation. At the Si/SiO₂ interface, strain is generated due to the differences in the thermal expansion coefficients across that interface. In addition, the edges of the oxide as well as the undulations in the Si/SiO₂ interface may act as stress risers.

Another possible model is that along the central grain boundary, local atomic rearrangements necessary to accommodate the lattice mismatch between the coalesced growth fronts produced strains sufficient to nucleate stacking faults. If stacking fault nucleation were to occur along the central grain boundary at a height of more than half the width of the oxide, the resulting stacking fault would then be free to extend beyond the edge of the oxide strip. This is a consequence of the fact that the apex formed by the pair of active stacking faults lies along a $\langle 101 \rangle$ direction which is inclined at 45° to the surface of the oxide. It should be noted that a stacking fault extending beyond the edge of the oxide has never been observed. The

major stacking faults emerge from a narrow region near the edge of the oxide strip. In addition, stacking faults have been observed in overgrowths which do not contain central grain boundaries. These observations suggest that a heterogeneous nucleation along a line at the edge of the oxide was the active mechanism for fault formation rather than the homogeneous nucleation of the faults over the face of the central grain boundary. The origin of the grain boundary is unclear. The boundary may have been formed due to a misalignment of the two coalescing growth fronts or as a result of plastic deformation after a continuous overgrowth had formed.

A central void is found above the middle of the oxide strip and coincides with the bottom of the grain boundary discussed above in (100) [001] samples. The origin of the void is presumably related to the inhibition of the transport of the silicon bearing species, in the gas phase, to the surface of the oxide strip just prior to the coalescence of the advancing growth fronts. The shape of the growth fronts will depend upon the growth conditions of the CVD process as well as the crystallographic orientation of the advancing faces. Presumably, the growth fronts in the (100)-[001] samples form almost vertical walls (15) which inhibit the transport of the silicon species to the bottom of the canyon formed by these walls just prior to coalescence. This reduced access of the silicon species, in the gas phase, to the oxide surface may account for the decrease in the separation of the growth striations as the center of the oxide strip is approached in Fig. 8.

Conclusions

The seeded overgrowth of Si via CVD on strips of SiO₂ above single crystal Si substrates has been shown to be a viable process for the production of device grade Si films. The fault structures of the Si overgrowth can be strongly influenced by the choice of a number of crystallographic parameters such as substrate and oxide strip edge orientation.

The stacking faults which are generated in the overgrowth of (100) substrates with the oxide strips along [001] directions appear to arise as mechanisms of strain reduction. The strain is presumably introduced as a result of the differences in the thermal coefficients of expansion between the Si overgrowth and the SiO₂ strips. It is suspected that the faults are generated during the cooling of the structures after the overgrowths are formed. A number of practical steps may be taken in order to further reduce the internal strain experienced by the Si overgrowth. These include the following: (i) use of thinner insulating films, (ii) tailoring the edges of the insulating film to reduce the local strains at those points, (iii) matching the thermal expansion coefficients of the insulating layer more closely to that of the Si overgrowth, and (iv) reduction of the growth temperature to minimize the differences in thermal expansion between the overgrowth and the encapsulated oxide.

Void Formation in Phosphosilicate Glass Film with Heat-Treatment in H₂ Atmosphere

Hideaki Takeuchi and Junichi Murota

Nippon Telegraph and Telephone Public Corporation, Musashino Electrical Communication Laboratory, Musashino, Tokyo, 180 Japan

ABSTRACT

The void formation process and phosphorus behavior in phosphosilicate glass film deposited by chemical vapor deposition techniques were investigated. The films were heat-treated three times, first in N₂ atmosphere for densification, then in H₂ or N₂ atmosphere, and after that in N₂ atmosphere. It was found that (i) void formation takes place with the third heat-treatment in N₂ atmosphere, (ii) with the second heat-treatment in H₂ atmosphere, absorbance of P=O band at 1330 cm⁻¹ decreases and absorbance of band at 1250 cm⁻¹ increases, but further absorbance change does not take place with the third heat-treatment. The gain in absorbance of the band at 1250 cm⁻¹ is proportional to the loss in absorbance of the P=O band at 1330 cm⁻¹. The quantity of phosphorus products formed with heat-treatment in H₂ atmosphere was estimated from the absorbance change of the P=O band at 1330 cm⁻¹. Comparing the quantity of the phosphorus products with the void size and number, it was proposed that the phosphorus products are gaseous species at high temperature, and the quantity of the gaseous species determines the product of the void number in the PSG film and square of the void size.

Phosphosilicate glass (PSG) films deposited by chemical vapor deposition (CVD) techniques are important materials for insulation layers in MOSLSI (1). To design a suitable MOSLSI fabrication process using the PSG film, it is necessary to clarify the structural change of the PSG film with heat-treatment in various kinds of atmosphere, because the PSG films are heat-treated under a variety of conditions for such purposes as glass flow (2), densification of the films (3), or stabilization of MOS devices (4). In a previous work (5), it was found that void formation in the PSG film and decreasing of P=O band absorbance take place simultaneously with heat-treatment in H₂ atmosphere above 1000°C. However, the causes of the void formation and the phosphorus behavior in the PSG film with the heat-treatment in H₂ atmosphere have not been clarified.

In the present work, the PSG films were heat-treated under various conditions three times to obtain an accurate relationship between the void formation and the infrared (IR) spectrum change. It was found that the void formation and IR spectrum change take place separately with sequential heat-treatment in H₂ and N₂ atmospheres. For the PSG film heat-treated in H₂ atmosphere, the void formation takes place under the subsequent heat-treatment in N₂ atmosphere. Absorbance of P=O band at 1330 cm⁻¹ decreases, and absorbance of band at 1250 cm⁻¹ increases, indicating formation of phosphorus products with the heat-treatment in H₂ atmosphere. However, further absorbance change does not take place with the subsequent heat-treatment in N₂ atmosphere. Void size and number are compared with a gain in the phosphorus product

quantity, and the void formation mechanism in the PSG films is discussed.

Experimental

The PSG films were deposited at 420°C in a horizontal reactor using a SiH₄-PH₃-O₂-N₂ gas system and then densified with the first heat-treatment in N₂ atmosphere at 1000°C. The film thickness (T_{PSG}) was about 5600Å after the densification. The substrates used were p-type Si wafers of 30-50 Ω cm with mirror-polished (100) surfaces. The substrates were thermally oxidized before the PSG film deposition in order to prevent phosphorus diffusion into the substrate from the PSG film (6).

After the first heat-treatment in N₂ atmosphere at 1000°C, the PSG films were heat-treated in H₂ or N₂ atmosphere at various temperatures. Then the films were heat-treated in N₂ atmosphere at temperatures higher than that of the second heat-treatment. Under these conditions, it was confirmed using x-ray fluorescence technique that the fraction of phosphorus lost is less than 3% and weight loss of the PSG film is not detected within experimental error. T_{PSG} was measured with a Taylor Hobson Talystep. The normal IR spectrum and the differential IR (DIR) spectrum of the PSG films were measured with a double-beam IR spectrophotometer. To obtain the depth profiles of absorption coefficients due to P=O bonds and Si—O bonds, measurements of the normal IR absorbance and etching of the PSG film in HF solution were repeated. The phosphorus concentration of the PSG film was determined by x-ray fluorescence techniques and neutron activation analysis. The size and the number of the void in the PSG film were obtained from observa-

tion of the PSG film cross section using a scanning electron microscope.

Results and Discussion

T_{PSG} and IR spectrum changes.—The PSG films heat-treated in H₂ or N₂ atmosphere at 900°C were next heat-treated in N₂ atmosphere for 40 min at various temperatures. Figure 1 shows the change of T_{PSG} with the third heat-treatment for the PSG film containing 9.5 weight percent (w/o) phosphorus. T_{PSG} increases with increasing the third heat-treatment temperature for the PSG film second heat-treated in H₂ atmosphere, but does not increase for the PSG film second heat-treated in N₂ atmosphere. From these results, it is expected that the second heat-treatment in H₂ atmosphere contributes to void formation in the PSG film with the third heat-treatment in N₂ atmosphere, because T_{PSG} increase is caused by the void formation (5).

The IR spectra of the PSG films were measured after the second heat-treatment in H₂ or N₂ atmosphere. No IR spectrum change was found for the PSG film heat-treated in N₂ atmosphere. The typical IR spectra of the PSG films before and after the heat-treatment in H₂ atmosphere are shown in Fig. 2. It is found that with the heat-treatment in H₂ atmosphere the absorbance of the P—O band at 1330 cm⁻¹ decreases and the absorbance of the Si—OH band at 3700 cm⁻¹ increases. The DIR spectrum was measured by placing the PSG film second heat-treated in H₂ atmosphere in the sample beam in the spectrophotometer and placing the PSG film second heat-treated in N₂ atmosphere in the reference beam of the spectrophotometer (shown in Fig. 2). Four peaks are found in the DIR spectrum: a concave peak at 1250 cm⁻¹, indicating an appearance of a new band; convex peaks at 1100 cm⁻¹ and 1000 cm⁻¹, indicating a decrease in P—O band vibration absorbance; and convex peak at 1330 cm⁻¹, indicating a decrease in vibration absorbance of P=O bond connected with three bridging oxygen atoms. Further IR spectrum change did not take place with the third heat-treatment in N₂ atmosphere at higher temperature.

From these results, it is suggested that structural change with the second heat-treatment in H₂ atmosphere causes the void formation with third heat-treatment in N₂ atmosphere at higher temperature.

Structural change in the PSG film.—To clarify the structural change in the PSG film with heat-treatment in H₂ atmosphere, a quantitative study was made of the absorbance changes of P=O band at 1330 cm⁻¹,

Fig. 1. Change of T_{PSG} with the third heat-treatment in N₂ atmosphere for 40 min. Open circles and closed circles are results for the PSG film second heat-treated in H₂ atmosphere and N₂ atmosphere at 900°C for 160 min, respectively. The PSG film phosphorus concentration is 9.5 w/o.

Fig. 2. IR and DIR spectra of the PSG film heat-treated in H₂ atmosphere. (a) and (b) are IR spectra of the PSG film before and after heat-treatment in H₂ atmosphere at 900°C for 160 min, respectively. (c) is DIR spectrum measured by placing the PSG film which is second heat-treated in N₂ atmosphere in the reference beam of the spectrophotometer. (1), (2), and (3) point to convex peaks at 1330, 1100, and 1000 cm⁻¹, respectively. (4) points to concave peak at 1250 cm⁻¹. The PSG film phosphorus concentration is 9.5 w/o.

P—O band at 1000 cm⁻¹, Si—OH band at 3700 cm⁻¹, and band at 1250 cm⁻¹ with heat-treatment in H₂ atmosphere. Figure 3 shows the relationship between P=O band absorbance at 1330 cm⁻¹ (*I_{P=O}*) and P—O band absorbance at 1000 cm⁻¹ (*I_{P-O}*) for the PSG film with heat-treatment in H₂ atmosphere at various temperatures. Here, the plots for the same phosphorus concentration and heat-treatment temperature were obtained for various heat-treatment times. *I_{P-O}* is proportional to *I_{P=O}*. This means that the quantity of phosphorus atoms whose bonding configuration is changed with the heat-treatment in H₂ atmosphere can be evaluated from a change in either *I_{P-O}* or *I_{P=O}*.

Fig. 3. Relationship between *I_{P=O}* and *I_{P-O}* with heat-treatment at various temperatures in H₂ atmosphere for various phosphorus concentrations.

Figure 4 shows the band absorbance gain at 1250 cm^{-1} (ΔI_{1250}) with heat-treatment in H_2 atmosphere as a function of the P=O band absorbance loss at 1330 cm^{-1} ($-\Delta I_{P=O}$). It is found that ΔI_{1250} is proportional to $-\Delta I_{P=O}$. Figure 4 shows Si-OH band absorbance gain ($\Delta I_{\text{Si-OH}}$) with the heat-treatment in H_2 atmosphere at 850°C for the PSG film containing 9.5 w/o phosphorus. $\Delta I_{\text{Si-OH}}$ increases with increasing $-\Delta I_{P=O}$ and then is saturated. The Si-OH bond numbers per unit volume (N_{OH}) for the PSG film with $-\Delta I_{P=O}$ of 1×10^{-1} , before and after the heat-treatment in H_2 atmosphere, are 3×10^{19} and $6 \times 10^{19} \text{ cm}^{-3}$, respectively. This is calculated from the relationship obtained by Moulson *et al.* (7) between the Si-OH band absorbance at 3700 cm^{-1} and the Si-OH bond concentration. The N_{OH} gain is $3 \times 10^{19} \text{ cm}^{-3}$ with the heat-treatment in H_2 atmosphere. This is negligibly small compared with the quantity of phosphorus atoms whose bonding configuration was changed (about 1×10^{21} , because the $-\Delta I_{P=O}$ change [1×10^{-1}] corresponds to one quarter of total phosphorus atoms [$4 \times 10^{21} \text{ cm}^{-3}$]) with the heat-treatment in H_2 atmosphere.

From these results, it is proposed that the dominant products formed in the PSG film with the heat-treatment in H_2 atmosphere are phosphorus species which have an IR absorption band at 1250 cm^{-1} . The phosphorus species may consist of a P=O bond connected with OH or H atoms, because the absorption band of P=O bond vibration shifts toward a lower frequency from 1330 cm^{-1} when bridging oxygen connected with the phosphorus in the PSG film is replaced by OH or H atoms (8). Further investigation, such as direct analysis of gaseous species in the void, is necessary to clarify the construction of the phosphorus species at high temperature.

Next, the product quantity was estimated from the P=O band absorbance loss at 1330 cm^{-1} in place of using absorption band gain at 1250 cm^{-1} in order to avoid measurement error due to the effect of other bands around the band at 1250 cm^{-1} . Figure 5 shows the heat-treatment time dependence of $I_{P=O}/I_{(P=O)_0}$ with heat-treatment in H_2 atmosphere for various phosphorus concentrations ($I_{(P=O)_0}$ is $I_{P=O}$ for the PSG film before the heat-treatment in H_2 atmosphere).

Fig. 4. $-\Delta I_{P=O}$ dependences of ΔI_{1250} and $\Delta I_{\text{Si-OH}}$ with heat-treatment at various temperatures in H_2 atmosphere for various phosphorus concentrations.

Fig. 5. Heat-treatment time dependence of $I_{P=O}/I_{(P=O)_0}$ in H_2 atmosphere for various temperatures.

$I_{P=O}/I_{(P=O)_0}$ decreases exponentially with an increase in heat-treatment time (t). Disregarding phosphorus concentration, $I_{P=O}/I_{(P=O)_0}$ is approximated by

$$I_{P=O}/I_{(P=O)_0} = \exp(-kt) \quad [1]$$

where $k = 110 \exp(-3.5 \times 10^4 \text{ cal/mol}/RT) \text{ s}^{-1}$. The absorption coefficients of the P=O band are distributed uniformly throughout the PSG film for the film heat-treated in H_2 atmosphere, as shown in Fig. 6. Therefore, the number of the products (N_P) per unit volume in the PSG film which have the absorption band at 1250 cm^{-1} , is expressed by

Fig. 6. Depth profiles of P=O band and Si-O band absorption coefficients ($A_{P=O}$ and $A_{\text{Si-O}}$) for the PSG film heat-treated in H_2 atmosphere at 900°C.

$$N_P = M_{(P=O)_0}(1 - \exp[-kt]) \quad [2]$$

where $M_{(P=O)_0}$ is the number of P=O bonds in the unit volume of the PSG film which is not heat-treated in H_2 atmosphere.

Relationship between void size and product quantity.

—From the results described in the previous section, it is obvious that the phosphorus product quantity is proportional to $-\Delta I_{P=O}$. In this section, $-\Delta I_{P=O}$ is compared with the size and number of voids formed with the third heat-treatment in N_2 atmosphere. The void formation mechanism is also discussed.

Figure 7 shows T_{PSG} after the third heat-treatment as a function of $-\Delta I_{P=O}$ for the PSG film containing 4.5–9.5 w/o phosphorus. T_{PSG} increases with an increase in $-\Delta I_{P=O}$ for the PSG film containing 9.5 w/o phosphorus, but T_{PSG} scarcely increases for the PSG film containing less than 7.0 w/o phosphorus. It seems that T_{PSG} increase, i.e., void formation, is inhibited by an increase in PSG-film viscosity due to reduction in phosphorus concentration. Therefore, the dependence of void size and number on $-\Delta I_{P=O}$ was investigated for the PSG film containing 9.5 w/o phosphorus, so that the effect of PSG film viscosity on void size could be neglected.

First, the variations of the void size and number with the heat-treatment in N_2 atmosphere were investigated for the PSG film whose $-\Delta I_{P=O}$ is constant. Figure 8a shows cross-sectional views of the PSG film heat-treated in N_2 atmosphere at $950^\circ C$ for various periods of time after the heat-treatment in H_2 atmosphere at $900^\circ C$ for 240 min. Many small voids are formed at the first step in the heat-treatment in N_2 atmosphere, and the voids tend to gather locally. As a result, they become larger, and T_{PSG} increases. Mean void size (L) and total void number per square centimeter (N_V) in 5600Å-thick PSG film can be obtained from Fig. 8a. The results are shown in Fig. 8b. As heat-treatment time in N_2 atmosphere increases, L increases and is saturated, and N_V decreases and becomes constant. Figure 9 shows the L dependence on N_V . It is found that L is proportional to $N_V^{-1/2}$.

Next, the L and N_V dependences on $-\Delta I_{P=O}$ were obtained for the PSG film with saturated L growth. Figure 10 shows the results with the heat-treatment in N_2 atmosphere at $950^\circ C$ for 360 min for the PSG film second heat-treated for various periods of time in H_2 atmosphere at $900^\circ C$. N_V is proportional to $-\Delta I_{P=O}$, and L is constant in spite of $-\Delta I_{P=O}$.

The relationship between L and pressure in the void

Fig. 7. Change of T_{PSG} with the second heat-treatment in N_2 atmosphere at $1000^\circ C$ for 40 min for various $-\Delta I_{P=O}$. $-\Delta I_{P=O}$ was changed with heat-treatment in H_2 atmosphere at $900^\circ C$ for various periods of time.

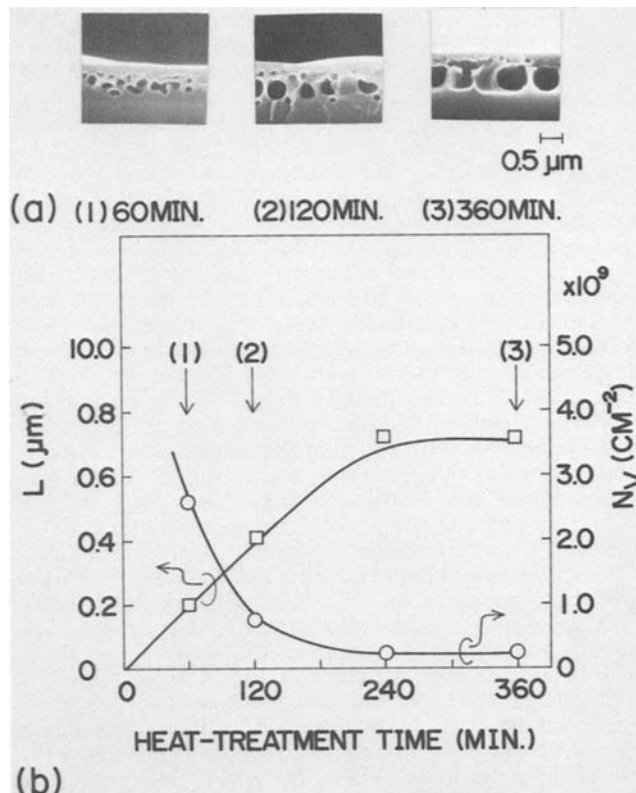

Fig. 8. Change of r and N_V with the third heat-treatment in N_2 atmosphere at $950^\circ C$ for the PSG film heat-treated in H_2 atmosphere at $900^\circ C$ for 240 min. (a) is scanning electron micrograph showing cross sections of the PSG film after the second heat-treatment and (b) is heat-treatment time dependence of r and N_V . The PSG film phosphorus concentration is 9.5 w/o.

is discussed below to explain the effect of the quantity of phosphorus products on void formation. Assuming that the voids are spherical (the radius $[r]$ is defined as $r = L/2$) and L is determined by the pressure in the void and surface energy of the PSG film, the gaseous pressure (P) in a void, the void volume (V) and r can be described by

Fig. 9. Relationship between r and N_V for the PSG film second heat-treated in H_2 atmosphere at $900^\circ C$ for 240 min followed by heat-treatment in N_2 atmosphere at $950^\circ C$ for various periods of time. The PSG film phosphorus concentration is 9.5 w/o.

Fig. 10. $-\Delta I_{P=O}$ dependence of r and N_V for the PSG second heat-treated in H_2 atmosphere at $900^\circ C$ for various periods of time and third heat-treated in N_2 atmosphere at $950^\circ C$ for 360 min. The PSG film phosphorus concentration is 9.5 w/o.

$$PV = nRT \quad [3]$$

and

$$P = \frac{2\gamma}{r} \quad [4]$$

where γ is surface energy of the PSG film, R is ideal gas constant, n is the quantity of gaseous species in a void, and T is absolute temperature. Since n is M_P/N_V (M_P is total quantity of the gaseous species per square centimeter in 5600Å-thick PSG film and $V = 4/3 \pi r^3$), M_P can be obtained from Eq. [4] and [3] as follows

$$M_P = r^2 \left(\frac{8\pi\gamma}{3RT} \right) N_V \quad [5]$$

The product of r^2 and N_V is constant under the condition that $-\Delta I_{P=O}$ is constant, as shown in Fig. 9. Therefore, from Eq. [5], it is considered that M_P is constant regardless of the third heat-treatment time in N_2 atmosphere, assuming that γ change is negligibly small. On the other hand, N_V is proportional to $-\Delta I_{P=O}$ when L is independent of $-\Delta I_{P=O}$, as shown in Fig. 10. This means that M_P is proportional to

$-\Delta I_{P=O}$, i.e., the quantity of the phosphorus products formed with the heat-treatment in H_2 atmosphere.

Therefore, it is proposed that the phosphorus products formed with the heat-treatment in H_2 atmosphere are gaseous species at high temperature, and the quantity of the gaseous species determines the product of L^2 and N_V .

Conclusion

The PSG films were heat-treated sequentially three times in N_2 , H_2 , and N_2 atmosphere. It was found that the void formation takes place with the third heat-treatment in N_2 atmosphere. The absorbances of $P=O$ band at 1330 cm^{-1} , and $P-O$ bands at 1100 and 1000 cm^{-1} decrease, and the absorbance of the band at 1250 cm^{-1} increases with the second heat-treatment in H_2 atmosphere. However, no further absorbance change takes place with the third heat-treatment in N_2 atmosphere. The quantity of the phosphorus products formed with the heat-treatment in H_2 atmosphere was estimated from the absorbance change of the $P=O$ band. Comparing the quantity of the phosphorus products formed with the second heat-treatment in H_2 atmosphere with the void size and number, it is proposed that the phosphorus products formed with the second heat-treatment in H_2 atmosphere are gaseous species at high temperature, and the quantity of the gaseous species determines the product of the void number in the PSG film and square of the void size.

Acknowledgments

Passivation and Maskless Processing with Anisotropic Etches in Silicon

D. J. Day, G. W. R. Middleton, T. W. Janes, J. C. White,* and V. J. Mifsud

Royal Signals and Radar Establishment, Great Malvern, Worcestershire, England

ABSTRACT

The passivation of silicon surfaces to anisotropic etches by ion and electron beams is demonstrated. The mechanisms for passivation is attributed to oxide growth induced by lattice damage and strain. Its application as a maskless etch process or etch stop for fabrication of nonplanar microstructures is discussed.

Anisotropic or preferential etching of different crystal planes in silicon has been exploited widely for

* Electrochemical Society Active Member.

Key words: ion and electron beams, etch-stop.

microengineering of mechanical (1) and electrical (2) structures. In such applications conventional masking techniques employing etch-resistant materials are used to define an etch surface with edges aligned to planes

of lower etch rate. By suitable choice of crystal orientation and mask shape, fine geometries of grooves, holes, and points can be obtained.

It has been found that these etches are not only anisotropic but can also be selective in that etching is inhibited in highly doped ($>10^{19} \text{ cm}^{-3}$) silicon (3). This has prompted the use of heavily doped buried layers as etch stops (4, 7), to give self-stopping control on etch depth. An apparently different form of selectivity has been reported employing electrochemical etching (5) where the surface potential is held so that etching occurs for material of one doping level but cause passivation to etching in material of another doping level or type (6). The electrochemical cell employed and pen recorder traces of the cell currents during etching of a p-type crystal and a diode layer of Janes (6) are shown in Fig. 1 and 2. The passivation of the p-type surface was identified with an oxide film since the surface could be restored by a short oxide etch (10:1 buffered HF). This surface passivation by an oxide has also been attributed as the mechanism for etch-stop layers (7). The competition between surface reactions would therefore seem to be the common mechanism for selectivity of these etches, with doping or cell potential as the external means of influence. It is influence rather than control, however, that is usually obtained by these techniques since spontaneous passivation can occur because of a variety of experimental conditions, and an element of nonreproducibility easily arises if surface history is not controlled.

It is the purpose of this paper to report a new passivation process associated with ion implantation that affords far better control over surface etching. The reproducibility obtained with this technique makes it potentially useful in defining a self-aligned mask or etch stop for fabrication of nonplanar microstructures (8).

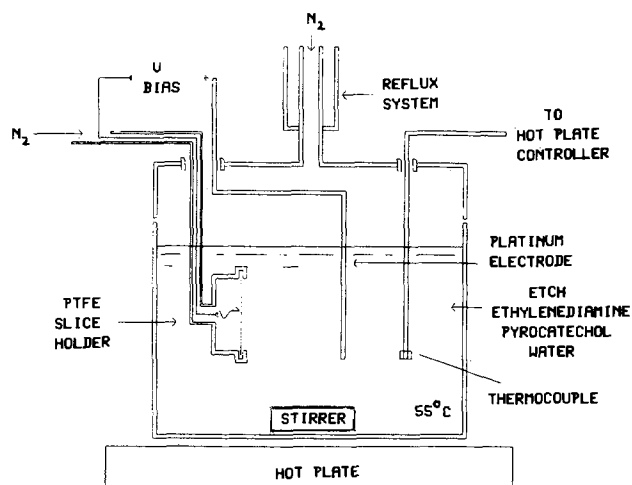

Fig. 1. Anisotropic etching system

Fig. 2. Cell currents vs. time

Observation

It is observed that ion implanted silicon surfaces are passivated to anisotropic etches, e.g., ethylenediamine or potassium hydroxide. Implanted patterns are therefore left in relief by those etches. This is shown in Fig. 3, which shows an unannealed arsenic implant (10^{14} cm^{-2} at 80 keV) with 1μ line width, relief etched to 0.6μ . This passivation is spontaneous for unannealed implants and persists even after extended annealing, e.g., 1.5h at 1000°C . Its occurrence seems to be determined by the surface concentration of implanted species and can be observed in both directly implanted surfaces as well as those implanted through thin films of oxide or resist, provided a threshold surface concentration is exceeded. The threshold for passivation, however, varies with both implant species and etch conditions, but is generally found to be of the order 10^{17} cm^{-3} . For example, an arsenic-implanted surface of 10^{13} cm^{-2} at 80 keV can be readily relief etched (e.g., 3 min in ethylene diamine at 50°C), while a similar boron implant will etch under the same conditions to a depth of nearly 2000 \AA before passivation is observed. Threshold concentrations for implants are significantly different from that reported for etch stops in bulk silicon ($>10^{19} \text{ cm}^{-3}$).

The threshold for occurrence, however, is less important for device processing than the stability of the passivated surface. It is found that passivation breaks down after prolonged exposure to etches. This breakdown is complicated by a dependence on implanted species, dose, and area, as well as etch temperature and electrode bias. Line widths of 1μ have been relief etched to several microns for an implant dose of 10^{14} cm^{-2} . Freely suspended slices will break down before those held at a surface potential in an electrochemical cell. No electrochemical etching of the unpassivated surface seems to take place; it is found to be a predominantly chemical process. Unimplanted regions, however, can be passivated electrochemically. Moreover, although the stability of the implanted surfaces increases with dose, the differential etch rate of the unimplanted regions is observed to decrease. Typical rates would be $0.25 \mu/\text{min}$ at 10^{13} cm^{-2} down to $0.1 \mu/\text{min}$ at 10^{15} cm^{-2} for ethylenediamine at 50°C .

Discussion

The simplest interpretation of these observations is to regard them as an extension of the etch-stop mechanism for the case of doping by ion implantation. The high peak concentration and finite range of an implanted profile combine with an easily verified requirement for oxide to etch at a slow rate to give a simple model for passivation breakdown and stability. The questions this interpretation raises are then directed toward the differences in the reported behavior of bulk

Fig. 3. Unannealed arsenic implant, 0.6μ relief

and implanted surfaces and what new aspects of the mechanism of passivation these illuminate.

It is not only the significant decrease in observed threshold for detectable passivation that is unexpected in this work, but also the fact that these impurities need not be electrically active. To confirm if the electronic or ionic nature of the implanted species made any significant contribution to the surface condition, implantation of silicon in silicon was investigated to emulate the contribution of residual crystal damage and strain. Figure 4 shows a cross section of an unannealed silicon implant (10^{14} cm^{-2} at 80 keV), indicating that no difference could be found in the passivation characteristics of these unannealed implants. In this case, annealing caused passivation to appear preferentially at the periphery of the implant. This suggests that lattice damage or strain makes a considerable contribution to the free energy of the surface. Implanted surfaces having a high free energy due to crystal damage will oxidize more readily under conditions of normal surface oxidation (9). It is reasonable to expect a similar association with passivation. There is one inconsistency with this strain argument: anisotropic etches are used for microfabrication of silicon on sapphire (SOS) wafers with little comment on nonuniformity or passivation, lattice mismatch in this case being a known source of strain in the thin silicon layers. Implantation and relief etching were attempted in both SOS and polysilicon with equal success. Thus lattice strain that has achieved some form of thermodynamic equilibrium or relaxation does not seem to influence surface reactions in the same way as nonequilibrium processes such as implantation.

To pursue this point further, nonequilibrium energy deposition associated with an electron beam was investigated. The different energy-loss mechanisms appropriate to electrons and ions, discernable from their diverse ranges of penetration, will also determine the nature and distribution of crystal damage they produce. It is questionable, therefore, if an electron beam would also induce passivation to these etches and allow direct writing of patterns for relief etching. A lithographic electron beam system with a beam width of 0.2μ at 20 keV and capable of $5 \times 10^{-3} \text{ C/cm}^2$ dose was used to write a test pattern.¹ Only weak images of small relief and poor uniformity could be produced (see Fig. 5). These were readily over etched to leave a persistent silhouette (Fig. 6). The image was enhanced by decreasing the etch temperature (ethylenediamine) from 50°C to room temperature. Local en-

¹ The pattern consisted of 100μ -square fields containing 20 lines varying in width between 0.06 and 1.25μ .

hancement also occurred at sites where mask overlap occurred giving double exposure (see Fig. 5) or other surface damage occurred, *e.g.*, tweezer marks, as shown in Fig. 7. All of this lends support to the role of lattice damage and strain in favoring passivation.

Fig. 7. Etch enhancement at surface damage

(a) GROOVED GATE MOS

(b) VERTICAL MOS

Fig. 8. Novel MOS devices

The weak images make it difficult to comment on the resolution obtainable by electron beam passivation. The line widths, however, appear to be similar and not representative of the lithography. This suggests that the variance of the energy loss distribution function (10) is comparable with the largest lithographic line widths, *i.e.*, $\sim 1\mu$. Maskless processing of relief-etched structures would therefore seem possible employing electron beams at high exposures and/or beam currents and limited resolution.

Conclusions

The passivation of silicon surfaces to anisotropic etches by ion and electron beams has been demonstrated. The observation of this passivation has been shown to be limited by the duration or stability of the passivation rather than its occurrence. It has been argued that the occurrence of this passivation is due to surface conditions favoring the formation of an oxide that itself etches relatively slowly. It has also been argued that such surface conditions are induced by nonequilibrium lattice defects and strain produced by the ion or electron energy loss, while the stability reflects the depth over which this oxide growth is favored.

Finally, exploitation of this passivation for processing microstructures would seem to lie with small-scale nonplanar devices or self-aligned isolation. Figure 8 shows two such novel MOS structures that we are investigating. The grooved gate device allows small self-aligned structures that have improved threshold and punch-through characteristics, while the vertical structures allow submicron channel lengths to be defined by etching to deep implant channel stops. If such nonplanar structures are as successful as ultra-small devices, this technique could prove valuable for maskless processing with ion beam lithography.

ABSTRACT

Transmission and analytical electron microscopy, nuclear backscattering, and secondary ion mass spectroscopy have been used to study the incorporation of Cl at the Si/SiO₂ interface during the oxidation of Si. Oxidations were carried out in the range of 1100°-1200°C, for 10-120 min and with HCl additions from 1-13%. It was found that a critical concentration of Cl ($2 \times 10^{15} \text{cm}^{-2}$) is required before a Cl-rich phase is observed. X-ray microanalysis indicates that the matrix in the interfacial region still contains at least about $2 \times 10^{15} \text{cm}^{-2}$ as the Cl-rich phase forms. These two observations suggest that the Cl-rich phase formation takes place in order to reduce the reacted Cl supersaturation in the SiO₂ matrix. Agglomerates, whose growth occurs by thickening and/or coalescence phenomena, are the final morphology observed during the continuing Cl incorporation. Models relating Na-ion passivation to the Cl-rich phase are shown to require modification in terms of the microstructural development.

The oxidation of silicon in chlorine-containing ambients is known to cause chlorine incorporation into the SiO₂ near the Si/SiO₂ interface (1, 2). For several oxidation conditions, phase separated regions have been observed (4-6). It has been asserted that both chlorine incorporation and sodium neutralization are related to the development of the Cl-rich phase formed at the Si/SiO₂ interface (3-5). Recent Cl concentration *vs.* distance profiles through the bulk oxide determined by secondary ion mass spectroscopy (SIMS) were interpreted to be the result of field-aided diffusion (7). The profiles show the chlorine concentration to increase exponentially toward the Si/SiO₂ interface where a peak occurs. Auger analysis-sputter profiles indicate the interface Cl peak is ≤ 3 nm thick (7, 8). This peak is presumably the result of the Si/SiO₂ interface acting as a "sink of the electrochemical potential" for Cl (7). Simple steady-state diffusion models have been proposed to describe the Cl incorporation as a function of oxide thickness (7-9).

To improve the understanding of Cl incorporation, we have carried out detailed determinations of both the Si/SiO₂ interface microstructure and the chlorine concentration and its lateral distribution along the interface. The interface morphology was determined by transmission electron microscopy (TEM). The total Cl content was obtained using nuclear backscattering (NBS) measurements (1, 2). The analytical electron microscope (AEM) [*i.e.* with the microscope operating in scanning transmission (STEM) mode] was used to determine the local Cl concentration at the interface. The Cl concentration profile was investigated in depth on several samples by SIMS. The effect of the initial oxide thickness on the chlorine incorporation process has also been studied. These results will be discussed with the objective of trying to understand the processes controlling chlorine incorporation. The relationship between the Cl-rich phase morphology and the Na-ion passivation models is briefly considered.

Experimental

Samples were prepared by thermal oxidation of (100) silicon (As-doped, 5-10 Ωcm) in ambients containing O₂ and HCl. The oxidation temperature ranged from 1100° to 1200°C and the oxidation time from 10 to 120 min. The HCl volume concentration in the input gas mixture varied from 0 to 13%. Wafers to be oxidized were pushed rapidly into a resistance heated furnace and allowed to stand for 5 min in flowing nitrogen (or argon) for thermal equilibration. Oxidation was started by shutting off the inert

gas and turning on the mixture of HCl and O₂ with a pre-established volume mixing ratio. The total flow rate was kept at 1000 cm³/min. At the end of oxidation, the O₂/HCl flow was stopped, the furnace was purged with nitrogen for 5 min, and the wafers pulled out of the furnace rapidly.

The thickness and refractive index of the oxide films were determined from ellipsometric measurements. For two-step oxidations, the initial dry oxides with thickness ranging from 0 to 80 nm were first grown at 1125°C in the dry O₂ ambient. The subsequent oxidations were carried out at 1125°C with 6% HCl and 1200°C with 3.5% HCl for oxidation times from 10 to 40 min. The thickness of the initial oxide was determined by ellipsometry. The chlorine content of the oxide films was measured by NBS of 2.8 MeV alpha particles using a 3.5 MeV Van de Graaff accelerator. A silicon detector was positioned at a scattering angle of 165°. The Cl content was obtained by comparing the total number of counts above background in the chlorine and oxygen peaks (1, 2). The samples were aligned so that channeling occurred in the (100) Si substrates in order to reduce the background under the Cl peaks.

The chlorine depth profiles were determined by secondary ion mass spectroscopy. The samples were sputtered with an Ne⁺ beam at 5 kV (10). Cl concentrations were determined by use of an ion-implanted standard. The beam was sawtooth-rastered and gated to restrict the detected sample to the central 8% of the sputtered area.

Specimens for examination by electron microscopy were prepared by chemically jet-etching the Si from the back of the wafer using 9HNO₃:1HF solution (6, 11). The etching formed a bowl-shaped depression through the silicon wafer leaving the oxide film supported across a hole in the silicon wafer. Details of the apparatus and methods are given in Ref. (9).

A Philips EM400T TEM/STEM with facilities for x-ray microanalysis was used throughout this study. All micrographs were taken with the microscope operating in the TEM mode at 120 kV. A quantitative metallographic analysis of the microstructures was carried out and the results will be reported in detail elsewhere (16). For x-ray microanalysis, the microscope was operated in the STEM mode using a 10 nm diam electron beam. The x-rays produced by the electron beam-specimen interaction were detected and analyzed by an EDAX energy dispersive spectrometer and a Tracor Northern 2000 minicomputer system. (To avoid blocking the path of the x-rays produced at the Si/SiO₂ interface by the remaining silicon wafer, the oxide layer must face upward after inserting the sample in the microscope.) The chlorine composition averaged through the whole x-ray emitting volume was calculated using the Cliff-Lorimer equation (12).

Key words: oxidation, impurity, analysis.

$$\frac{\bar{C}_{Cl}}{\bar{C}_{Si}} = k_{ClSi} \frac{I_{Cl}}{I_{Si}} \quad [1]$$

where k_{ClSi} = the Cliff-Lorimer factor, which is 1.05 (15) at the operating voltage (120 kV), \bar{C}_{Si} = the average mass composition of silicon in the analyzed region, C_{Cl} = the average mass composition of chlorine in the analyzed region, I_{Cl} = the net total number of chlorine x-ray counts (above background), and I_{Si} = the net total number of silicon x-ray counts. The mass composition ratio of chlorine in the third phase particle and in the matrix can be obtained by the following equation

$$\frac{\bar{C}_{Cl}^P}{\bar{C}_{Cl}^M} = \frac{(I_{Cl}^P/I_{Si}^P) \bar{C}_{Si}^P}{(I_{Cl}^M/I_{Si}^M) \bar{C}_{Si}^M} \quad [2]$$

where superscripts P and M refer to data taken with the electron beam on the particle and in the matrix nearby. The fact that most of chlorine exists in a very thin layer at the SiO₂/Si interface means that $\bar{C}_{Si}^P = \bar{C}_{Si}^M$, if the electron beam is placed at points with the same specimen thickness (13, 15). This condition can be obtained by moving the beam along a thickness (extinction) fringe, due to the thin crystalline silicon layer below the oxide. Under this condition, the equation for the composition ratio becomes

$$\frac{\bar{C}_{Cl}^P}{\bar{C}_{Cl}^M} = \frac{I_{Cl}^P/I_{Si}^P}{I_{Cl}^M/I_{Si}^M} \quad [3]$$

The silicon composition, \bar{C}_{Si} , is composed of contributions from SiO₂ and Si and is obtained from

$$\bar{C}_{Si} = \frac{C_{SiO_2} V_{SiO_2} + C_{Si} V_{Si}}{V_{SiO_2} + V_{Si}} \quad [4]$$

C_{SiO_2} is the silicon composition in SiO₂, which is 0.467, and C_{Si} is the silicon composition in Si, which is 1. V_{SiO_2} and V_{Si} are the respective x-ray emitting volumes after taking into account the beam spreading. The equation used to calculate these volumes (Eq. [7] below) considers the spread beam to be that volume containing 90% of the transmitted electrons (15). A schematic sketch showing the incident electron-beam size d , beam spreading b_1 at the bottom exit of SiO₂, and beam spreading b_2 at the bottom exit of a thin silicon layer is presented in Fig. 1. After integration, the x-ray emitting volumes in the SiO₂ and the Si are, respectively

$$V_{SiO_2} = \frac{\pi t_{SiO_2}}{4} \left(d^2 + b_1 d + \frac{b_1^2}{3} \right) \quad [5]$$

$$V_{Si} = \frac{\pi t_{Si}}{4} \left[(d + b_1)^2 + (d + b_1)b_2 + \frac{b_2^2}{3} \right] \quad [6]$$

The effective beam spreading b_1 and b_2 in SiO₂ and Si can be calculated using the equation

$$b = 625 \frac{Z}{E_0} (\rho/A)^{1/2} t^{3/2} \quad [7]$$

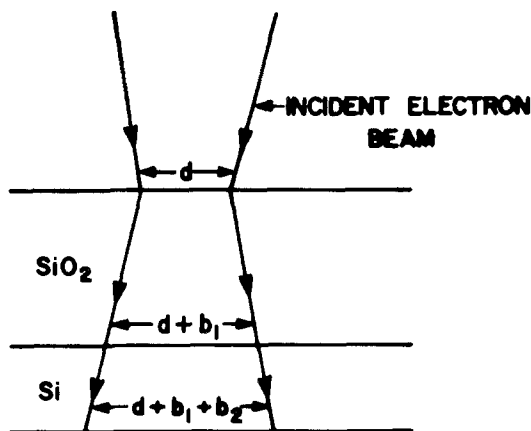

Fig. 1. Schematic representation showing the diameter of the incident electron beam, d , and the beam spreading b_1 and b_2 in the SiO₂ and the Si, respectively.

where b is in cm, Z is the atomic number, A is the atomic weight, E_0 is in keV (=120 keV), ρ is the density in g/cm³, and t is the film thickness in cm. For SiO₂, the average atomic number (10) and atomic weight (20) were used. The oxide thickness is known from the ellipsometry measurements. The silicon layer thickness is either obtained from the known extinction distance in Si or by using contamination spot separation methods (13). The extinction distance for the (220) reflection from Si is 76 nm.

The value of \bar{C}_{Cl} determined using the method described above can be compared with the value calculated independently from NBS. The Cl composition is obtained by averaging the total Cl determined from backscattering measurements throughout the whole x-ray emitting volume. The Cl mass composition is equal to the ratio of the Cl weight to the total weight in the x-ray emitting volume

$$C_{Cl}^{Cal} = \frac{N [\pi(d + b_1)^2/4] w_1}{\rho_1 V_{SiO_2} + \rho_2 V_{Si}} \quad [8]$$

N (Cl/cm²) is the Cl concentration obtained from backscattering measurements, $\pi(d + b_1)^2/4$ is the area excited by the electron beam of size $(d + b_1)$ at the SiO₂/Si interface, w_1 is the weight in grams of one Cl atom. V_{SiO_2} and V_{Si} are the x-ray emitting volumes in SiO₂ and Si. In the above equation, all of the chlorine is assumed to exist in the SiO₂ interface. This is a good approximation as we see from the SIMS profiles presented here and elsewhere (7). Most of the Cl is within 5 nm of the interface for 100-200 nm thick SiO₂ films.

Results

The Si/SiO₂ interfacial morphology was determined as a function of HCl ambient concentration or oxidation time for samples prepared at 1200°, 1170°, 1150°, and 1100°C. We present a few micrographs to show the essential features of the phase development. Detailed studies will be reported separately (16). The line seen in each micrograph corresponds to a length of 0.5 μ m. In agreement with previous work, we have not seen any diffraction effects that would indicate the Cl-rich phase was crystalline.

Figure 2a shows a sample in which no Cl-rich phase could be seen even though it contains Cl. Figures 2b-2d show the phase develop with an increase in number and size of individual particles. The initial stages of agglomeration are seen in Fig. 2d at which point a larger scale lateral nonuniformity appears. Figure 2e shows a typical microstructure of the Cl-rich phase when the agglomeration is more complete. These larger particles are widely spaced, have irregular shape, show increased contrast in the microscope, and are always surrounded by smaller particles.

Figure 3 shows results of the Cl determinations by NBS as a function of the ambient HCl concentration for samples prepared at 1200°, 1150°, and 1100°C with the oxidation times 30, 30, and 60 min, respectively. The three straight lines were drawn to pass through the origin. The Cl contents appear to increase monotonically with increasing HCl concentration. A rapidly increasing region as the third phase particles are developing (2,3) is not obvious in the data presented here. It is possible that this effect may be within the error limits of our data.

Figure 4 is the plot of the chlorine content as a function of the oxidation time for samples prepared at 1200°, 1170°, and 1125°C with various HCl concentrations. All curves appear to follow a similar time-dependent behavior. Again, a rapidly increasing region is not apparent for the oxidation conditions used here, nor has it been reported previously for Cl content as a function of oxidation time.

The Cl concentrations as a function of the initial (dry) oxide thickness are shown in Fig. 5 and 6 for samples prepared at 1125° and 1200°C. The Cl content of the oxide films is seen to decrease as the initial oxide thickness is increased. This decrease is very slight at the lower temperature but becomes more pronounced at higher temperatures and longer times. Figures 7a and 7b are two electron micrographs which indicate that a smaller portion of the interface is covered by the particles (less Cl-incorporated) for a larger initial oxide thickness. TEM observation shows no Cl-rich particles at the SiO₂/Si inter-

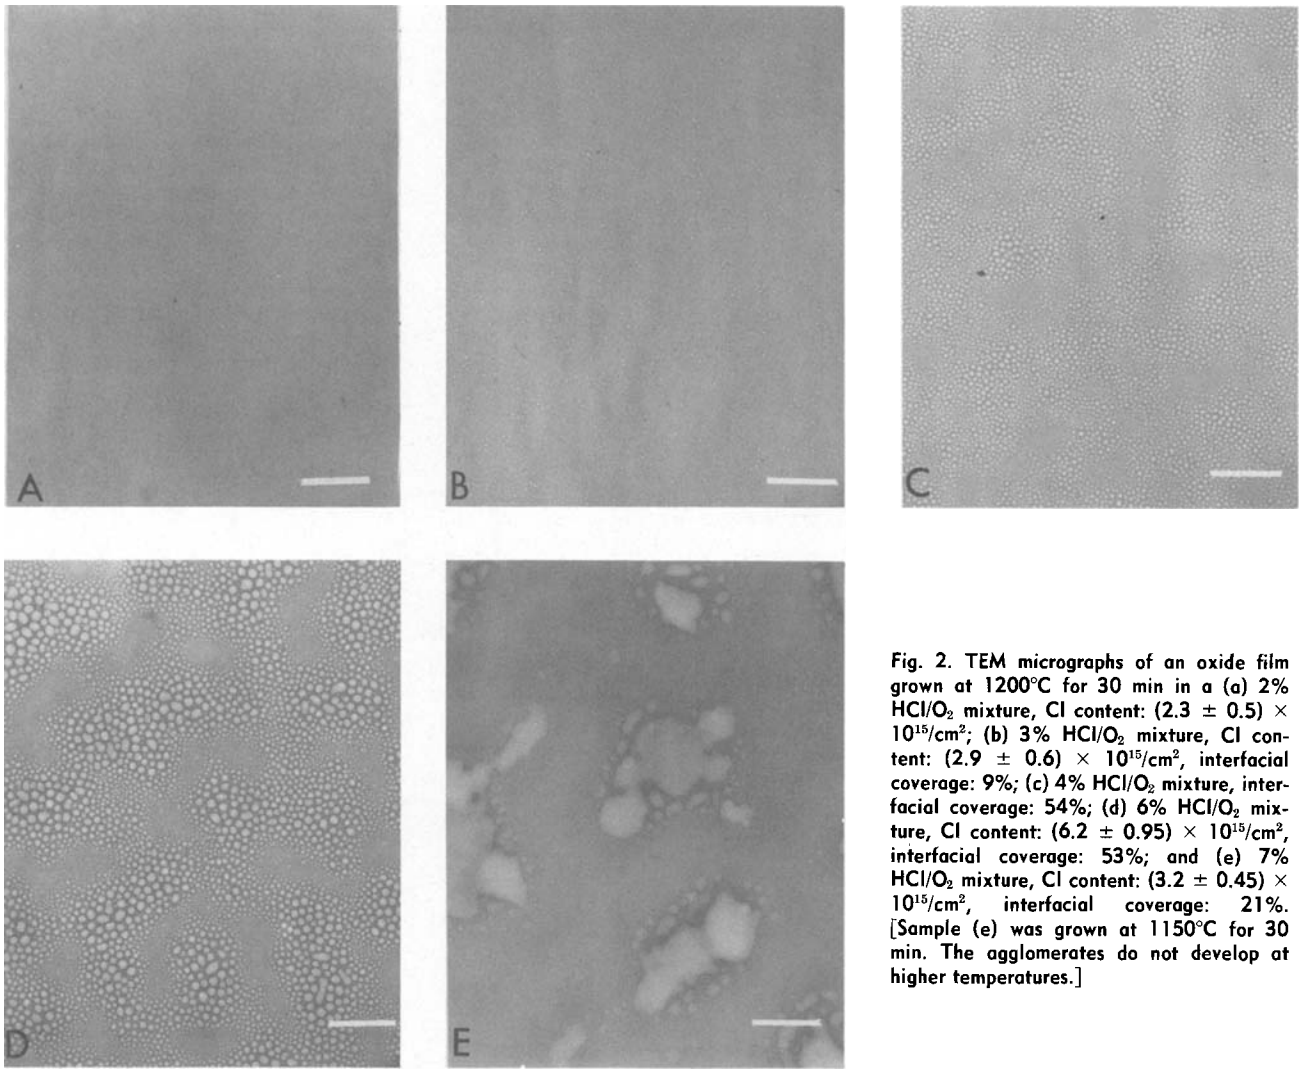

Fig. 2. TEM micrographs of an oxide film grown at 1200°C for 30 min in a (a) 2% HCl/O₂ mixture, Cl content: $(2.3 \pm 0.5) \times 10^{15}/\text{cm}^2$; (b) 3% HCl/O₂ mixture, Cl content: $(2.9 \pm 0.6) \times 10^{15}/\text{cm}^2$, interfacial coverage: 9%; (c) 4% HCl/O₂ mixture, interfacial coverage: 54%; (d) 6% HCl/O₂ mixture, Cl content: $(6.2 \pm 0.95) \times 10^{15}/\text{cm}^2$, interfacial coverage: 53%; and (e) 7% HCl/O₂ mixture, Cl content: $(3.2 \pm 0.45) \times 10^{15}/\text{cm}^2$, interfacial coverage: 21%. [Sample (e) was grown at 1150°C for 30 min. The agglomerates do not develop at higher temperatures.]

face for the samples corresponding to the results shown in Fig. 5. The individual Cl-rich particles were observed (Fig. 7) only for those samples corresponding to the data of Fig. 6 with Cl concentrations $\geq 3.0 \times 10^{15}/\text{cm}^2$.

The local chlorine composition at the SiO₂/Si interface was investigated using x-ray microanalysis with the electron microscope in the STEM mode. Several samples prepared at 1150° and 1200°C were studied. It was found that the electron beam must be focused on the area with a thin silicon layer beneath the oxide, otherwise either very little or no chlorine was detected. Presumably, the HNO₃/HF etchant removes the Cl-containing phase upon contact.

Table I lists the results from x-ray microanalysis. The thicknesses of the SiO₂ film and the silicon layer required for the calculation of the average Si composition in the x-ray emitting volume are shown in Table II. Figure 8 is one example indicating where the x-ray microanalyses were carried out. Before the data acquisition, the specimen was tilted away from the two-beam condition, which eliminates the thickness fringe, makes the particles easier to see, and avoids the possibility of anomalous x-ray generation (14). The specimen was tilted back to the (220) reflection after the data analysis. By observing the carbon contamination spots that form during microanalysis, it was possible to check that the points analyzed were along the same thickness fringe.

For the sample showing no Cl-rich particles, chlorine appears to be uniformly distributed over the interface within the resolution limit of the microscope (Fig. 2a). For oxidation conditions which show isolated particles (Fig. 2b or 2c), the ratio of chlorine concentration in the particle to that in the matrix ranges from 2 to 4. This composition ratio was found to increase slightly with the particle

size. The composition ratio, however, is as high as 7 for a sample showing complex phase-separated regions, *i.e.*, agglomerates (Fig. 2e). SEM observation of the oxide surface of samples with agglomeration are bumpy, presumably due to the thickening of these larger phase-separated regions. The average silicon composition, \bar{C}_{Si} , was determined using Eq. [3]. Equation [1] was then used to calculate the average chlorine composition, \bar{C}_{Cl} . These values of \bar{C}_{Cl} are in reasonable agreement with the nuclear backscattering values of $C_{\text{Cl}}^{\text{cal}}$ calculated in Eq. [8]. Note that the Cl concentration obtained from backscattering measurements is an average value without taking into account the nonuniform distribution of Cl along the SiO₂/Si interface. The beam diameter in the backscattering measurements is 2 mm. The \bar{C}_{Cl} obtained from x-ray microanalysis comes primarily from the chlorine in the interface region. This is due to the fact that the net total number of chlorine x-ray counts from Cl in the bulk oxide (according to the SIMS results) would be below the minimum detectable number of counts calculated by the relation $3(2I_{\text{Cl}}^{\text{b}})^{1/2}$, where I_{Cl}^{b} is the background counts under the chlorine peak (15).

The Cl concentration, after making conversion of \bar{C}_{Cl} weight percent (w/o) to $N(\text{Cl}/\text{cm}^2)$ using Eq. [8], is shown in the last column of Table I. For the three samples with observed Cl-rich phase particles, the matrix contains 2-2.5 $\times 10^{15}$ Cl/cm² independent of the state of agglomeration of the Cl-rich phase.

Figures 9 and 10 show chlorine and hydrogen profiles for samples prepared under conditions where individual particles of the Cl-rich phase are observed (Fig. 2b and 2c). The oxygen data are included to show the uniformity of the ion yield and the sharpness of the Si/SiO₂ interface. Ion implanted standards with Cl in SiO₂ were used to cali-

ground, which limited the minimum detection level to $10^{19}/\text{cm}^3$ vs. $10^{17}/\text{cm}^3$ for the instrument used in this work. The hydrogen profiles are generally similar to that reported by Burkhardt for a steam-grown oxide (18). The large error bar indicated for the hydrogen concentration is due to the fact that we did not use our ion-implanted standard for hydrogen in SiO₂ during this set of measurements. However, it was used during the overall series of measurements so that we have a reasonably accurate calibration for the hydrogen concentration. The very large concentrations near the interface are uncertain since they would not be consistent with the calibrations for a "minor" impurity in an SiO₂ matrix.

Discussion

Phase Development.—The microstructures may be classified into three types, *i.e.*, microstructures with no Cl-rich phase, with individual Cl-rich phase particles with circular cross section, and those in which the Cl-rich phase has a complex shape which we will simply refer to as agglomerates. Figure 11 summarizes this important characteristic of the microstructure as a function of the average chlorine content and oxidation temperature. We have used the total chlorine content as a variable to classify the microstructure development instead of the time and HCl concentration, which are the experimental parameters. The motivation for this choice is that the microstructure is continually changing during the oxidation process because the Si/SiO₂ interface is moving during

Fig. 9. Hydrogen and chlorine profiles as determined by SIMS. Sample prepared at 1150°C, in 5% HCl-O₂ mixture by a 30 min oxidation. A few of the actual data points are shown in the vicinity of the error bar on the hydrogen profile.

Fig. 11. Characterization of principal features of the morphology as a function of oxide chlorine content at various oxidation temperatures.

the oxidation. Therefore, since the chlorine is always found to be primarily segregated to the interface it must also move, and, thus, the Cl-rich phase particles "move." We specifically do not suggest that this is a macroscopic "dragging" motion but rather the result of continuous formation by chemical reactions (growth) at the Cl-rich phase-silicon (Si/SiO₂) interface and decomposition reactions at the Cl-rich phase-oxide interface. In terms of this variable, the necessary condition for the Cl-rich phase to form is that the total Cl content exceeds 2×10^{15} Cl/cm². However, from Fig. 11 we see that this does not appear to be a sufficient condition. This minimum concentration is similar to the solubility limit of a single-phase region. This is a "quasi-thermodynamic" condition and would not be expected to describe the kinetic aspects of the new phase development (31).

Before discussing the kinetic aspects of this phase development, it is worth inquiring as to the nature of the phase. We have noted that from the electron diffraction information the phase is noncrystalline. The x-ray microanalysis found the Cl areal density in the phase of $\sim 4 \times 10^{15}$ Cl/cm². Cl concentration *vs.* depth profiles using SIMS show an interfacial peak 3×10^{-7} cm wide and average volume concentration of $\sim 10^{21}$ Cl/cm³ (7). Since the

area fractions are $\sim 10\%$, we see this average volume concentration is consistent with what one calculates for the particles, *i.e.*, $4 \times 10^{15}/3 \times 10^{-7} \sim 10^{22}$ Cl/cm³ in the Cl-rich phase. However, the micrographs show that the Cl-rich phase is more transparent to the electron beam than SiO₂. Thus, even with the increased concentration of the higher atomic number element, Cl, the overall electron and/or atomic density is less. Calculations assuming elastic scattering show that to a first approximation even if the 3 nm thick "particle" were a void in a 250 nm Si/SiO₂ layer it would have only $\sim 2\%$ increase in transmission, which is close to the limits of contrast visible to the human eye. Thus, we must conclude that we are dealing with a very low density noncrystalline phase. If the density were about half that of SiO₂, it would mean an Si concentration of $\sim 10^{22}$ /cm³ and an oxygen concentration of $\sim 2 \times 10^{22}$ /cm³. This would be consistent with a molecular composition such as Si₂O₃Cl₂ as suggested by several authors (19, 20). Such compounds have been identified in the gas phase (21). Thus we are dealing with a phase-separation process similar to that found in many silicate glasses (22).

In an extensive study of phase separation of Na₂O-CaO-SiO₂ glasses, the process was found to proceed by nucleation and growth with the critical nucleus radius being ~ 2 to 3 nm (23). This small size resulted even though the interfacial energy was found to be only ~ 4 ergs/cm². This compares with solid/liquid interfacial energies (such as one might consider the crystalline Si/glassy SiO₂ interface) ~ 200 ergs/cm² (24). Therefore, since the particles we see are >10 nm, we are probably observing the growth of the phase following nucleation. Also, such low interfacial energies as found in (23) would be consistent with the large number of particles we see in the individual particle interval of the phase development and with the reluctance of the particles to coarsen and agglomerate. It is also likely that the actual nucleation event occurs on the Si/SiO₂ interface, which has been shown to possess monoatomic steps, etc., that would facilitate the nucleation (25,33). Thus the kinetics we are observing are the result of the growth process of the Cl-rich phase. The observation that Cl can segregate laterally over distances much larger than the oxide thickness, *e.g.*, agglomerate spacings, observed in Fig 2e, implies that the Cl diffusivity is large.¹ We agree with the previous suggestion that the growth process is controlled by the interfacial chemical reactions and not by Cl transport (7). We will discuss these reactions shortly. We point out that in no case was the Cl-rich phase seen to cover the interface. When agglomeration occurred, the interfacial coverage decreased significantly, which is consistent with the ability of Cl to diffuse laterally.

Finally, the lack of conventional coarsening as agglomeration occurs (exemplified by the absence of a Cl-depleted zone around the agglomerates) is consistent with a very low interfacial energy between SiO₂ and the Cl-rich phase as suggested above. Since the Cl-rich phase growth is apparently interface-controlled, we would interpret the clustering and agglomeration as follows: if some Si/SiO₂ interfacial feature resulted in an enhanced Cl reaction rate, the new phase would nucleate and grow rapidly in that region. Thus, particles would contact and agglomerate. Yet, the smaller particles nucleating nearby, but not growing as fast, would still be present, as the micrographs show. The rapid lateral Cl diffusion to these enhanced reaction sites would suppress Cl-rich phase formation in between these regions. Thus, the lateral nonuniformity should be more apparent when the agglomerates are seen. At the lower temperatures of 1150° and 1100 °C, we would expect the interfacial reactions to be more sensitive to interfacial nonuniformities. In agreement with this idea, more clustering and agglomeration phenomena are observed *vs.* uniformly distributed particles (9).

Chlorine incorporation.—The results for the total chlorine incorporated as a function of time or HCl concentration are generally consistent with those previously reported (2, 5, 8). However, a rapid increase in the so-called "threshold" region is not apparent as in our earlier results (2). We believe this is more a matter of experi-

¹At least with respect to the O₂ diffusivity which controls the oxidation process in the range of thicknesses obtained here.

mental conditions than of different phenomena. All of the Cl depth profiles reported here and elsewhere show the chlorine to be segregated to the Si/SiO₂ interface. Thus, the Cl must dissolve in the oxide and diffuse to the interface. The Doremus model of molecular solution and diffusion of gases in SiO₂ appears to explain the Si oxidation kinetics as well as more recent isotope redistribution experiments (26, 27). Therefore, if we apply these ideas to the Cl₂ and HCl transport, the concentration of diffusing species would be $\leq 10^{15}$ cm⁻³ and thus undetected by either SIMS or NBS measurements. As previously suggested by Monkowski *et al.* (4), and demonstrated by Sheu *et al.* (28), Cl₂ appears to be the gas phase species controlling Cl incorporation. We then assume Cl₂ arrives at the Si/SiO₂ interface where it reacts and is incorporated into the SiO₂. In the initial stages of incorporation (Cl $\leq 2 \times 10^{15}$ /cm²), this is a laterally uniform process as indicated by the x-ray analyses and absence of Cl-rich particles. The Cl, and apparently hydrogen, are incorporated into the SiO₂ network as the oxide forms at the interface. These reactions will compete with the oxidation reactions and the outcome will be controlled by the local activities at the interface. One factor which could act to favor the interfacial H and/or Cl incorporation is the lowering of the viscosity of the SiO₂ as a result of the inclusion of these network-modifying species (29). This would enhance the viscous flow which has been suggested as one mechanism of accommodating the volume change (volume per Si) upon oxidation (30). As shown by the x-ray microanalysis, this process occurs throughout the entire range of Cl incorporation studied here (Table I). Thus this process is the incorporation mechanism up to total Cl contents of $\sim 2 \times 10^{15}$ cm⁻². The weak dependence of the total Cl/cm² on initial oxide thickness indicates that the Cl₂ transport is not the rate-limiting step in the incorporation process. Also, as noted above, the large lateral distances (~ 1 μ m) over which the Cl segregation takes place (when agglomerates occur) is consistent with a large diffusivity for Cl. Therefore, it appears that the chemical reaction incorporating Cl into the network is the most important step in the kinetics of incorporation. Thus, fitting the steady-state diffusion models for Cl incorporation to the total Cl/cm² should not be a good method for determining the Cl₂ diffusivity (8).

As the Si/SiO₂ interface moves during oxidation, chlorine incorporated in the SiO₂ at the interface ends up in the "bulk" oxide. This Cl is probably unstable due to the increased O₂ or H₂O activity of these indiffusing oxidants. Diffusing O₂ is not found to exchange with network oxygen nearly as much as H₂O (26, 27). Therefore, the likely displacement reaction is that OH replaces Cl in the network, *i.e.*

This would reduce the Cl concentration as the interface moves, or as oxidation proceeds, and we look at a point fixed with respect to the outer oxide surface. This is qualitatively consistent with the Cl depth profiles. The Cl released in the bulk would diffuse back to the interface where it would react again, resulting in a net accumulation process.

When the Cl concentration reaches a value such that the total Cl $> 2 \times 10^{15}$ cm⁻², the Cl-rich phase becomes stable. As noted above, the nucleation stage was not observed and the growth of the particles beyond ~ 30 -40 nm is limited. Instead of more lateral growth, increased numbers of particles are nucleated. As suggested above, this is consistent with several observations. First, interfacial energies between two amorphous phases (phase separation in silicates) can be very low; second, if the incorporation is reaction-controlled, it should only occur at the Si/SiO₂ interface and not on the "lateral" surfaces of the particles; third, the clustering and lateral nonuniformity of the individual particles may indicate "heterogeneous" nucleation on the Si/SiO₂ interface to be rate controlling (especially at lower temperatures). Since the matrix remains saturated at 2×10^{15} Cl/cm² and the Cl-rich phase has about 4×10^{15} Cl/cm², as the interface

becomes increasingly covered by the particles the additional Cl incorporation is due to the new phase forming. This process will be the principal Cl incorporation process above about 25% interfacial coverage. However, we do not find more than 60% of the interface covered for the conditions studied here. As suggested above, the actual value of interfacial coverage at which agglomeration becomes important is not as well defined as the conditions for individual particle formation. It appears to depend on enhanced local reaction rates for Cl, perhaps due to nonuniformities on the interface. It has been suggested that a gaseous phase may be present under these high chlorine incorporation conditions (31). We will not consider this part of the problem any further.

Returning to the question of the Cl incorporation when the Cl-rich phase is present, we must give further consideration to the moving reaction interface aspect of the process. Since the particles always appear to be "at" the interface, they must effectively "move" with the interface. As we noted previously, this must be the result of the Cl-rich phase being converted to SiO₂ by reactions at its interface with the bulk SiO₂. A similar argument has been suggested by Monkowski *et al.* (19). We suggested a composition for the phase of Si₂O₃Cl₂. Thus this reaction involves replacement of 2 Cl by O or possibly by 2 OH. This latter reaction (involving OH) would again seem more likely due to spatial restraint, *i.e.*, the two silicons bonded to the Cl's would not have to be close enough to bond to the single oxygen. This is consistent with the large hydrogen content of the oxide. Also, the considerable Cl concentration in the oxide away from the interface could imply that, in addition to the Cl incorporation into the matrix between the particles, the SiO₂ formed from the Cl-rich phase also contains Cl in its network. Since the Cl-rich phase is of low mass density, transport of the released Cl within the particle back to the Si interface should be very rapid. Again, reaction at this interface would continue to be the rate-controlling step so that similar kinetics should be observed throughout the complete range of Cl incorporation. However, again we note that the simple steady-state diffusion models with a single "incorporation rate constant" should not be a useful way to try to model the incorporation process. For all conditions, at least two chemical reactions are involved in the net Cl incorporation "reaction." It would appear that modeling studies which try to fit the Cl concentration *vs.* depth profiles, as well as the total Cl, could give the additional information needed to understand the overall Cl-incorporation process.

Sodium neutralization.—The fact that complete sodium neutralization is achieved in the samples containing sufficient incorporated Cl (by increasing the oxidation time or the ambient HCl concentration) is, in general, consistent with the evidence for Cl-rich phase development in the temperature range 1100°-1200°C. The model suggested by Stagg and Boudry for Na⁺ neutralization is that the Na⁺ diffuse laterally to the large agglomerate particles where the charge exchange takes place (32). According to these authors, the samples belonging to the agglomerated phase regime contain Cl higher than 3×10^{15} /cm² for all the oxidation temperatures (5). However, in addition to the agglomerates we have observed individual particle microstructures for samples with Cl content higher than 3.0×10^{15} /cm². These individual particles are also seen in samples with Cl content $< 3.0 \times 10^{15}$ /cm². For these samples with relatively low oxide chlorine content, Stagg and Boudry have demonstrated that the sodium ions at the SiO₂/Si interface can only be partially passivated. However, complete passivation should be achieved more quickly in these samples with the more closely spaced individual particles. This situation contradicts their model for neutralization based on the sodium interface diffusion (32). How the individual particles are correlated with the sodium passivation still needs to be resolved by determining both the microstructure and passivation on the same samples. However, we have shown that the lateral diffusion/agglomerate model needs modification when compared to the trends in the microstructure development.

We next consider the implications of the similar trends in the dependence of the microstructure development and the sodium passivation on the so-called ballistic model for neutralization (3). In this model, only the Na^+ ions arriving at the interface which "hit" a Cl-rich phase particle are neutralized. For oxides grown as a function of the HCl concentration at 1150° and 1200°C with the same oxidation time of 30 min, the individual particle microstructure falls in the so-called "threshold" region of Rohatgi's passivation results (3).² The area fraction generally does increase with the passivation, implying qualitative agreement. But instead of the interface becoming covered by the Cl-rich phase above the "threshold" as required by the ballistic model for 100% passivation, we find the areal fraction to remain approximately constant at ~0.5 or to decrease. Thus in spite of qualitative similarities, this model is also inconsistent with the quantitative features of the microstructure development (as well as with Na^+ lateral diffusion.)

Summary

We have presented data on Cl content and Cl segregation as a function of oxidation conditions. There is good agreement between data obtained by NBS and AEM techniques. This data has led us to conclude that chemical reactions at the interface and in the bulk oxide are the processes controlling chlorine incorporation. When the interfacial Cl concentration and the relative Cl and oxygen incorporation rates reach critical values, a Cl-rich phase forms. The phase is amorphous and contains about twice the Cl of the SiO_2 matrix. The development of this phase controls additional Cl incorporation over a range of oxidation conditions. The upper end of this range is reached when complex shape agglomerate particles of a Cl-rich phase appear. We have not attempted to discuss Cl incorporation in the agglomerate regime other than to note that the x-ray microanalysis tells us that agglomerates act as strong sinks for Cl and are apparently substantially thicker than the initial particles.

The Cl-rich phase appears to nucleate on the Si/SiO₂ interface. The phase develops as individual particles with extensive nucleation and limited lateral growth. This and the lack of conventional coarsening phenomena are consistent with a very low interfacial energy between the Cl-rich phase and SiO₂. Similar low energies have been observed in phase separation in silicate glasses. The agglomeration and clustering that then occurs at higher Cl contents is suggested to be due to locally enhanced Cl reaction rates at the Si/SiO₂ interface. This is consistent with the suggestion that the Cl-rich phase formation is an interface reaction controlled process, not Cl transport controlled. Finally, while the Na-ion neutralization is generally consistent with the phase development, a more careful comparison shows that the currently proposed models of the process are incomplete.

Manuscript submitted Jan. 13, 1983; revised manuscript received Sept. 20, 1983. This was Papers 198 and 199 pre-

²The oxide Cl content measured in our samples is systematically higher than that reported by Rohatgi *et al.* under the same oxidation conditions (2). In Rohatgi's work an RF-heated cold wall furnace was used. The incoming gases were preheated by passing through narrow passageways in the Si susceptor. It is possible that the HCl and O₂ may not have reacted completely to form the equilibrium concentration of Cl₂. Since Cl₂ is apparently the important gas phase species controlling Cl incorporation, this lack of equilibrium would result in low Cl content samples (2, 3).

Nippon Telegraph and Telephone Public Corporation, Atsugi Electrical Communication Laboratory, 1839, Ono, Atsugi-shi, Kanagawa 243-01, Japan

ABSTRACT

A surface planarization process for multilevel metallization structure is proposed for higher packing density and higher yields in fabricating LSI's. The technique makes use of the ECR plasma deposition method and a lift-off process. The deposition method is suited for the lift-off process, because of its directional deposition properties and low temperature deposition. The surface planarization process yields a flat surface. Fine patterns in the upper layer are obtained. The potential for using this technology for manufacturing the MOS LSI is verified by the good yield and fine Al patterns for 1 kbyte associative memory fabricated with this process.

For higher packing density in LSI's, a multilevel metallization structure must be improved by miniaturization and by increasing the number of layers. In microfabrication technology, lithographic techniques and dry etching techniques have contributed to the rapid progress in reduction of the lateral dimensions for the patterns. In contrast to such rapid advancement, the thickness of the insulating and conducting films for multilevel interconnection cannot be appreciably reduced, because of wiring resistance and parasitic capacitance. Thus, the LSI surface step height increases compared with the lateral dimensions of the pattern with increasing LSI packing density. In this case, the surface step causes poor step coverage of a deposited thin film, short circuiting, or breakage in conducting lines. In addition, the pattern size uniformity in the lithographic process becomes worse.

In order to solve these problems, planar technology for the interconnection layer has been used. For example, there are several planarization techniques, such as anodic oxidation (1), lift-off (2-4), glass flow (5), surface leveling (6), polymer film coating (7), and etch back employing RIE (8). Anodic oxidation can form completely planar interconnection metallization (1). In this process, the unanodized metal remains in the spaces between the lines, and a reduction in cross-sectional area for the metal line occurs. Thus, it seems that these factors interfere with miniaturizing the LSI's pattern, because it is difficult to further decrease these factors. The lift-off process for surface planarization utilizes Al evaporation on the photoresist without heating the substrate (2, 3). Thus, Al film has a poor step coverage at the sidewall of the through-hole contact or at the surface step of the underlying film pattern edge. Furthermore, the MOS LSI fabrication process utilizes CVD film deposition or H₂ heat-treatment at about 400°C substrate temperature. In these heating processes, hillocks will grow easily for Al film evaporated (9). There is another lift-off process, which can obtain fine-featured smoothly tapered metallization patterns by using a polyimide as the lift-off layer (4). In this process, the remaining surface steps interfere, increasing the number of metallization's levels. The P-glass flow process, which makes the surface smooth (5), requires 1000° to 1200°C heat-treatment and still leaves the surface step. The surface leveling process makes use of organic material flow and its etching, using conditions that etch the photoresist and the underlying P-glass at nearly the same rate (6). Although this process also can obtain a smoothed surface without high temperature heat-treatment, the surface step still remains. There is another process, utilizing a polyimide as an interlevel dielectric (7). Although the film is highly resistant to heat, it seems to be difficult to obtain a uniform miniaturization because of film-thickness variations. The etch-back process, employing RIE, can be used to obtain a smoothed surface (8). In this process also the surface step still remains. There are other planar technologies which have the potential for the application to planar interconnection. For

Key words: multilayer metallization, planar interconnection, lift-off, ECR plasma deposition.

example, there is a technology which employs a low temperature photo-CVD oxide (10) in conjunction with a lift-off. Using this technology, the fabrication of a fully recessed field isolation (11) had been attempted.

This paper introduces a new planar technology for multilevel metallization with a high packing density (12). In this process, surface planarization is carried out employing the lift-off technique. This lift-off utilizes electron cyclotron resonance (ECR) plasma deposition, which has such features as high directionality, high quality, and low temperature deposition (13). Thus, in this lift-off process, the processing ease depends mainly on the deposited film, and not on the stencil. Furthermore, this lift-off utilizes anisotropic dry etching for pattern formation. Therefore, it is suitable for miniaturization and multilevel formation of metallization. In the following sections, a fundamental planar process, ECR plasma deposited film, lift-off yield, and the application to LSI fabrication are described.

Manufacturing Process

The fundamental process steps for making planar interconnections are shown in Fig. 1. Details of these steps are as follows.

Step A.—First Al layer etching with a resist mask using a dry etching technique. Al(Si) film 0.6 μm thick as a first Al layer is deposited by using a magnetron sputter evaporation technique. The substrate temperature is about 300°C. A projection printing technology is used for the photolithography. The photoresist layer is 1.5 μm thick, and the minimum pattern size is a 2 μm lines and spaces. First Al interconnection patterns are etched away in a parallel plate plasma etcher using 0.25 torr CCl₄ gas. All these methods are generally used in the metal interconnection formation.

Step B.—Silicon dioxide (SiO₂) deposition, using the ECR plasma deposition method. The SiO₂ film thickness deposited by the ECR plasma deposition method is the same as in Step A.

Step C.—Sidewall deposited film etching with wet etchant.

Step D.—SiO₂ film lift-off from the resist by resist removing. More details for steps C and D are indicated in Table I. Ammonium fluoride/hydrofluoric acid/ethylene glycol solutions shown in Table I are used to make the SiO₂ and Al etching rate ratio large (14). The lift-off process itself is completed in process 3 of Step D in Table I. But, in case the lifted-off material adheres on the wafer surface again, a high pressure water method is employed, which can remove the adhesive material without giving

any scratch on the wafer surface. Since the strength of the adhesion is too weak to be removed by the high pressure water method, the removal is completed perfectly. 1200 psi water pressure is used.

Step E.—Filling the remaining groove by interlevel insulator deposition. Second Al layer formation on the substrate. CVD SiO₂ 0.8 μm thick is deposited at 400°C substrate temperature. The second Al interconnection 1.0 μm thick is formed by using the above-mentioned method.

Features of this process are as follows. After a pattern having a steep side wall is formed by using parallel plate plasma etching, the sunken place formed by the etching is buried using the ECR plasma deposition. This process is suitable for miniaturization, because it utilizes anisotropic characteristics both in etching method and deposition method. Next, the processes added to the conventional LSI process are only Steps B, C, and D. With regard to photolithography, generally used process conditions are utilized. Thus, this process can be applied easily to the conventional process by adding Steps B, C, and D.

ECR Plasma Deposited Film Properties

The ECR plasma deposition apparatus allows the performance of high quality thin film deposition at room temperature without the need for thermal reaction (13). It does this by enhancing the plasma excitation efficiency

and the bombardment effect of ions with moderate energies on the deposition reactions through using a microwave ECR plasma generation and a plasma extraction by a divergent magnetic field method. SiO₂ film can be deposited by introducing O₂ and SiH₄ into the plasma and specimen chamber, respectively. The deposition rate increases from about 200 to 400 $\text{\AA}/\text{min}$ at the gas flow rates of O₂ 10 cm^3/min and SiH₄ 10 cm^3/min in the microwave power from 50 to 300W. Table II shows the fundamental characteristics of ECR SiO₂ deposition used in this study.

Step coverage.—Figure 2 shows step height and tapered angle dependence on deposited SiO₂ thickness. CVD SiO₂ is also shown for comparison. The substrate is silicon, which is etched away to form lines and spaces 1 μm deep. For CVD SiO₂, the trench becomes filled when the deposited film thickness becomes greater than 2 μm . However, for ECR SiO₂, the trench is not filled yet to the same deposited thickness. The tapered angle for ECR SiO₂ is constant, even when the ECR SiO₂ thickness is 2 μm , while that for CVD SiO₂ increases after decreasing. For CVD SiO₂, with increasing deposited film thickness, the trench is filled when the tapered angle starts increasing. In this way, in the ECR plasma deposition method, the deposited film surface keeps the substrate shape. Film thickness deposited on the sidewall is about a third of that deposited on the flat surface. The reason that the

step coverage of the ECR SiO₂ becomes a characteristic shape (as mentioned above) is the high directionality of the ECR plasma deposition. The directionality is considered to be produced by the following mechanism. After ions are extracted from the plasma chamber by a magnetic field, they are accelerated towards the substrate by the electric field in the plasma stream. In this process, these ions have no collision for the other gas molecules because of the low gas pressure (mean free path is 20 ~ 30 cm). In addition, the neutral species having no directionality scarcely deposit on the specimen (13).

Film etching rate and other properties.—The etching rate for the ECR SiO₂ deposited on the flat surface was examined using buffered solution containing 10% HF as a function of the solution temperature (10° ~ 35°C). In this temperature range, the etching rates for the ECR SiO₂ are almost the same as those for the thermally grown silicon dioxide film which was etched simultaneously. The refractive index measured by ellipsometry is almost constant at values from 1.45 to 1.47 in wide range of microwave power. In the infrared absorption spectrum for the SiO₂ film deposited at 100W microwave power, the Si-O bond peak is clearly observed at 1065 cm⁻¹ wave number, but no Si-H bond peak is observed. From these results, it is clear that the SiO₂ film deposited on the flat surface has a dense structure. This is because the substrate is bombarded by the ions having an energy (~20 eV) suitable for the deposition reaction. In addition, hydrogen or other impurities are difficult to contain in the film during its growth because of the low gas pressure (13).

Figure 3 is an SEM micrograph of a cross-sectional view, before etching and after etching. During etching with HF, the film on the sidewall is removed, while the film on the flat surface is shallowly etched. As a result, the structure (Step C) shown in Fig. 1 is obtained. Figure 4 shows the change in the cross-sectional view with etching time. The sidewall-deposited film is already removed after 0.2 min. Since the etching rate of the sidewall-

Fig. 3. SEM micrograph showing the cross-sectional view change in step coverage by slight etching

deposited film is markedly large in the wet etchant containing HF, the exact value of the etching rate in the etchant cannot be obtained. However, from the experimental results shown in Fig. 4, the value is roughly estimated to be more than a hundred times that of the flat-surface-deposited film. The differential etch rates for the ECR SiO₂ on the flat surface and the sidewall are explained as follows. Since there is no bombardment of ions on the sidewall, the deposition reaction at the sidewall is not enough; it allows hydrogen and poor molecule bonds to remain in the film. As a result, a loose structure film is deposited on the sidewall. In spite of that, a dense structure film is deposited on the flat surface because of the ion bombardment (13). Space *d*, shown in the cross-sectional view, increases gradually with increasing etching time. The space *d* increasing rate is almost the same as the etching rate for the flat-surface-deposited film. The tapered angle does not change, even if the etching time increases. The tapered angle is determined by the ratio of the thickness between the sidewall-deposited film and the flat-surface-deposited film. From the tapered angle shown in Fig. 4 (~71°), the ratio is about 1:3.

Effect of flatband voltage and mobile ions.—Figure 5 shows the flatband voltage dependence on the SiO₂ thickness. With regard to MOS diode fabrication using ECR plasma deposition, the sample has three layers, namely, from the silicon surface, the thermal oxide, the ECR SiO₂, and Al gate electrode. For comparison, the thermal oxide flatband voltage is also shown. After oxidation or ECR plasma deposition, no heat-treatment is made. The Al electrode is deposited at room temperature by the heat-resistance method in order to prevent other effects on the MOS diode. In this result, the fixed charge density for MOS diode using ECR SiO₂ is less than that using wet SiO₂ (15). It is considered that this difference is due to the fact that the dry SiO₂ is formed between the

Fig. 4. Change in cross section with etching time.

Fig. 5. Flatband voltage shift as a function of oxide thickness

ECR SiO₂ and the silicon surface for the MOS diode using the ECR SiO₂. Because both flatband voltages are almost the same level, no damage is introduced to the fixed charge density by the ECR plasma deposition method.

Furthermore, the mobile ion density for the ECR SiO₂ is evaluated by using the above-mentioned MOS diode in the TVS method (16). The mobile ion density is less than the detectable minimum value (about $5 \times 10^9 \text{ cm}^{-2}$). Thus, it is suggested that no mobile ion contamination is introduced by the ECR plasma deposition method. In this way, with regard to fixed charge density and mobile ions, the ECR plasma deposition has no problems in MOS LSI fabrication.

Lift-off Yield and Surface Flatness

In our lift-off technique, lift-off yield and surface flatness depend on many factors, such as stencil shape, the slight etching amount before lift-off, ECR SiO₂ thickness, etc. Here, among these factors, the Al layer and ECR SiO₂ thicknesses are both fixed at 0.6 μm. Figure 6 shows the dependence of the lift-off yield or the surface flatness on the slight etching amount before lift-off. The interlevel insulator thickness is 0.8 μm. The yield is evaluated by inspection of the wafer surface using an optical microscope. A good evaluation corresponds to the wafer having no lift-off remainder. For the case where the slight etching amount is small, lift-off yield for the line patterns (2 μm wide) is completed easily, but the lift-off for the square patterns (9 μm²) is not completed. The incompleteness of the latter is caused by the photoresist edge shape, which

Fig. 6. Step height and bottom width dependence on slight etching amount.

tapered angle is small in the four edges of the square pattern. In this way, the optimum condition for the slight etching amount depends on the photoresist shape in details. Thus, when the tapered angle of the photoresist is small, as mentioned above, by increasing the slight etching amount, the good yield of the lift-off is obtained in good reproducibility, as shown in Fig. 6. However, the greater the slight etching amount is, the worse surface flatness the process offers. With increasing the slight etching amount, bottom width B and step height D, which are shown in the cross-sectional view in Fig. 6, increase gradually. Then, both B and D increase rapidly, as shown in Fig. 6. Thus, taking the lift-off yield and the surface flatness into account, in the present case mentioned above, the slight etching amount is appropriate in the 0.05-0.10 μm range.

Figure 7 shows surface flatness dependence on interlevel insulator thickness. A cross-sectional view of the sample structure is shown in the figure. The slight etching amount before lift-off is about 0.05 μm. After the lift-off process, B defined for the remaining groove shown in Fig. 6 is nearly zero. Width W decreases gradually with increasing interlevel insulator thickness. Step height D diminishes rapidly and becomes less than 0.15 μm when interlevel insulator thickness increases. The remaining groove is filled easily, and the planarized surface is obtained by depositing the interlevel insulator used in the conventional process. An SEM micrograph of a cross-sectional view of this planarized structure is shown in Fig. 8. The buried first Al line is 2 μm wide. The CVD SiO₂ used as the interlevel insulator is 0.8 μm thick. On this planarized structure, a second Al layer is formed.

LSI Fabrication

Test element group fabrication.—Before this technology was applied to LSI fabrication, it was evaluated by applying to a test element group (TEG), which is designed for evaluating the 2 μm rule MOS technology (17). This TEG contains a number of patterns for LSI elements, such as enhancement MOS FET, depletion MOS FET, p-n diode, and multilevel metallization. In most of these characteristics, there is no specific characteristic difference between the element applied by the present technology and a conventional technology. However, for the two-level Al interconnection, resistance and deviations in the second Al wiring are different from those in conventional interconnection. Figure 9 shows the experimental values for the second Al wiring, under which the first Al wiring level is planarized by using the present technology. For comparison, the experimental values for a conventional structure are also shown. These sample structures are drawn in the figure. There are 2006 cross points between the first Al line and the second Al line. Yield for the second Al line is 97-100%. The experimental values for the second Al wiring resistance for the planarized structure can be combined to form a straight line. This line can be

Fig. 7. Surface flatness dependence on interlevel insulator deposited thickness.

Fig. 8. SEM micrograph of buried Al line. Cross-sectional view

Fig. 9. Second Al wiring resistance comparison. Second Al line width is $4 \mu\text{m}$.

extrapolated to the origin. The straight line, which combines the experimental values for the conventional structure, cannot be extrapolated to the origin. These two straight lines are parallel, and difference ΔR in the figure is the resistance caused by the surface steps of the first Al layer. Thus, the second Al line resistance for the planarized structure is less than that for the conventional structure. As can be seen in the same figure, resistance deviations are also caused by the underlying layer surface flatness.

MOS LSI fabrication.—Evaluation procedure.—Logic LSI's require complicated connections and large areas for the metal interconnections. Thus, the problem of the interconnections has a great effect on the logic LSI's yield. The importance of the problem becomes larger as the LSI's change into VLSI's. In this study, a 1 kbyte associative memory (18) which has a two-level Al interconnection is regarded as TEG for the evaluation of the LSI interconnection. Since the importance of the interconnection fabrication is great in this memory, it is suitable for evaluation of the present technology. As an evaluation procedure for the effectiveness of the present technology, the comparison between the conventional technology and the present technology was carried out in the LSI fabrication process and function testing. The wafers applied to the above technologies were fabricated in the same lot except the planarization of the first Al interconnection. The memory contains about 34,000 MOS transistors. Chip size is $4.1 \text{ mm} \times 4.95 \text{ mm}$. The $2 \mu\text{m}$ n-channel E/D MOS process is used. Table III shows the interconnection scale, such as layout rules, dimensions, numbers, and length for the interconnection in the region where cell areas are arranged.

Evaluation results.—First, observation results about LSI's first Al interconnection fabrication are explained. In the

Table III. Layout rules, dimensions, numbers, and length for the Al two-level interconnections

	First Al layer	Second Al layer
Minimum width	$3.0 \mu\text{m}$	$5.0 \mu\text{m}$
Minimum space	$2.0 \mu\text{m}$	$3.0 \mu\text{m}$
Thickness	$0.6 \mu\text{m}$	$1.0 \mu\text{m}$
Number of interconnections	7550	162
Total wiring length	777 mm	456 mm
Number of through holes	41,500	15,000
Through hole size	$2 \mu\text{m}^2$	$3 \mu\text{m}^2$

present technology, a planarization process is added to the conventional process after etching the first Al. In this case, in spite of the various surface steps in the actual LSI surface, the reason that the present technology is successfully completed is as follows. The factors causing the surface steps, when the first Al layer is etched away and the photoresist on it is not removed yet, are local oxidation of silicon (LOCOS), poly-Si, first through hole, and the first Al line. In this structure, the LOCOS surface step is smooth. The poly-Si surface step becomes smooth, because the glass flow process is carried out for the PSG film covering the poly-Si. Furthermore, steep steps at the first through hole for the contact between the first Al and the diffused layer of Si substrate or between the first Al and the poly-Si gate electrodes are filled by the photoresist coated on the first Al layer. Thus, there are steep steps only at the edges of the first Al interconnection pattern and the photoresist on it. Consequently, the present technology can be applied to the first Al pattern without changing the conventional process, by only adding a few new processes. In the slight etching before the lift-off, the wet etchant mentioned in Table I scarcely attacks the Al layer and has an appropriate etching rate for the slight etching of SiO_2 . Figure 10 shows the LSI surface after the slight etching mentioned above. Only the sidewall of the first Al line and photoresist appear. Surface steps, except for the first Al line, are the ones caused by LOCOS and poly-Si gate electrode. It is suggested that this structure is very suitable for the lift-off.

Next, the observation results regarding LSI's second Al interconnection fabrication is explained. The present technology is different from the conventional technology in the condition of exposure and etching, but the process steps of both technologies are the same. In the conventional technology, since there are surface steps on the wafer surface, photolithography requires a slight overexposure time in order to prevent short-circuiting of the Al lines. Thus, the breakage in the Al lines is apt to occur on the upper part at the surface step. In addition, in the case that the interlevel insulator sidewall on the first Al line is almost vertical, short circuiting is apt to occur. In the present technology, breakage or short-circuiting rarely occurs, because the substrate surface is flat. In this case, since the small surface depression ($< 0.15 \mu\text{m}$) after the interlevel insulator deposition (see above) is completely filled by the second Al film, an appropriate exposure condition, which is almost the same as one for the flat surface, can be applied in order to offer correct lines and spaces. In addition, it is easy to observe the photoresist pattern of the Al lines by the optical microscope, because the underlying layer surface is flat. Figure 10 shows an SEM micrograph of this LSI surface after fabricating the second Al interconnection. This is the same place as that shown in Fig. 10. Since, the first Al line is fully planarized, the steps caused by the first Al line are not shown in the picture. The steps by field isolation and gate electrode are shown.

In this LSI, in order to connect directly the second Al interconnection to the poly-Si gate electrodes or Si-diffused layer, a buffered metallization, formed by the first Al layer ($5 \mu\text{m}^2$) has been used under the second Al layer (17). By using this buffered metallization, it is easy to connect an interconnection with another one lying in a different layer without a specific fabrication process. An SEM micrograph of the through hole where buffered metallization is used is shown in Fig. 11. The conventional through hole is shown in Fig. 11. For the first Al layer's planarization, no surface step caused by the buffered met-

Fig. 10. SEM micrograph of application to LSI fabrication

Fig. 11. SEM micrograph of through hole contact between second Al layer, and the diffused silicon layer using a buffered metallization of first Al layer.

alization is observed under the second Al line at the through hole, while a large surface step is observed in the conventional through hole. In the usual LSI fabrication process this structure is not used because it decreases the LSI yield. In the present technology, since the buffered metallization is planarized, the good yield is obtained.

The wafers applied to the present technology and the wafers applied to the conventional technology, which were fabricated in the same lot, were compared by testing 16 function patterns. In the good chip numbers passing the etch test pattern or all test patterns, the wafers applied to the present technology have a better yield than the conventional one. As a result, it was shown that the present planar technology offers a great advantage for LSI fabrication.

Conclusion

Planar interconnection technology, utilizing a lift-off process, which makes use of the ECR plasma deposition method, is presented. The deposition method features high directionality, high quality, and low temperature deposition. These features are suitable for the lift-off process. By using these features, the lift-off is easily completed after etching the sidewall-deposited film on the Al line and the resist film. The remaining groove, which is formed after the lift-off, is completely filled with the interlevel insulator deposition on the substrate. The surface step after planarization is less than $0.15 \mu\text{m}$. The SiO_2 etching amount for the sidewall-deposited film is appropriate in the $0.05\text{--}0.10 \mu\text{m}$ range, taking the surface flatness and the lift-off yield into account.

The present technology has no specific effect on the characteristics of LSI elements, such as a MOS FET. However, the resistance and the deviations in the upper metal interconnections decrease, because of the underly-

ing layer surface's flatness. The technology is applied to the first metallization of the 1 kbyte associative memory, in order to verify its potential for use in MOS LSI fabrication. Since the steep steps are only at the edge of the first Al interconnections, the present technology can be applied to a conventional LSI fabrication process without introducing any serious changes in the process condition. However, several additional processes, such as ECR plasma deposition, slight etching, and lift-off, are introduced to the two-level interconnection fabrication. Finally, it has been shown that this technology offers a great advantage for LSI fabrication, because it leads to a good yield and fine Al interconnections are easily obtained.

ABSTRACT

We describe a numerical model of the coupled gas-phase hydrodynamics and chemical kinetics in a silicon chemical vapor deposition (CVD) reactor. The model, which includes a 20-step elementary reaction mechanism for the thermal decomposition of silane, predicts gas-phase temperature, velocity, and chemical species concentration profiles. It also predicts silicon deposition rates at the heated reactor wall as a function of susceptor temperature, carrier gas, pressure, and flow velocity. We find excellent agreement with experimental deposition rates, with no adjustment of parameters. The model indicates that gas-phase chemical kinetic processes are important in describing silicon CVD.

The chemical vapor deposition (CVD) of solid materials is an important method for producing solid films with high purity and uniformity. Some important applications of CVD include the manufacture of microelectronic devices and silicon solar cells. Even though CVD has widespread use, a fundamental understanding of the interplay among its constituent elements is missing. A unified theoretical picture of CVD requires input from the fields of gas-phase chemical kinetics, fluid mechanics, surface chemistry, and materials science.

In this paper we describe a two-dimensional mathematical model of the coupled gas-phase kinetics and hydrodynamics in a laminar-flow chemical vapor deposition reactor. Specifically, we have studied a reactor in which silicon is deposited as the result of the thermal decomposition of silane. This system was chosen for its relative simplicity and its importance to the microelectronics industry. Nevertheless, our model is quite general, and thus can be applied to other CVD systems if the appropriate gas-phase reaction mechanisms are known.

Our model couples the chemical rate equations with the boundary layer equations describing the hydrodynamics, producing a system of parabolic partial differential equations which are solved numerically. We employ a relatively simple reaction mechanism to describe the inhomogeneous gas-surface chemistry. Ultimately we should include a more detailed model of the surface chemistry, but presently we are primarily interested in a quantitative description of the gas phase. Moreover, as we discuss later, this gas-phase model alone is very successful in describing CVD experimental observables. Our treatment of the gas phase is greatly aided by our earlier work on modeling combustion chemistry (1, 2). Also, our modeling is performed in conjunction with experimental measurements of chemical species concentrations in the gas phase (3).

Our principal purpose in this paper is to present a complete description of the mathematical and numerical formalism of the model. There have been many other theoretical approaches to modeling CVD, however, most of these models have not considered the possibility of gas-phase chemistry. The present model is the most detailed model of the gas phase in CVD to date.

Below we present details of the model, including the set of governing partial differential equations, the reaction mechanism describing SiH_4 pyrolysis, and the numerical solution method. We also present computed temperature, velocity, and chemical species concentration profiles. We compare predicted deposition rates with experimental results.

Key words: CVD, growth, kinetics, transport.

Model Formulation

Transport equations.—We assume in this work that the boundary layer approximations are valid. That is, the Navier-Stokes equations can be reduced to a system of parabolic partial differential equations describing the conservation of mass, momentum, energy, and species composition. The approximation relies on the existence of a principal flow direction in which convective transport is dominant and diffusive effects are negligible. In this approach the pressure is impressed on the flow by the boundary conditions and is uniform in the cross-stream direction. The imposition of pressure replaces the cross-flow momentum equation entirely.

After making the boundary layer approximations, we use the Von Mises transformation (4) to cast the equations in a form in which the stream function replaces the radial coordinate as an independent variable. This transformation eliminates the mass conservation equation, replacing it with an integral. Additionally, it eliminates any explicit reference to the cross-stream convective terms in the resulting system of equations.

The system of equations which form our model are described as follows

Momentum

$$\rho u \frac{\partial u}{\partial x} + \frac{\partial p}{\partial x} = \rho u \frac{\partial}{\partial \psi} (\rho u \mu y^{2\alpha} \frac{\partial u}{\partial \psi}) + \rho g \quad [1]$$

Species

$$\rho u \frac{\partial Y_k}{\partial x} = \dot{\omega}_k W_k - \rho u \frac{\partial}{\partial \psi} (y^\alpha \rho Y_k V_{ky}) \quad (k = 1, K) \quad [2]$$

Energy

$$\rho u c_p \frac{\partial T}{\partial x} = \rho u \frac{\partial}{\partial \psi} (\rho u \lambda y^{2\alpha} \frac{\partial T}{\partial \psi}) - \sum_{k=1}^K \dot{\omega}_k W_k h_k - \rho^2 u y^\alpha \sum_{k=1}^K Y_k V_{ky} c_{pk} \frac{\partial T}{\partial \psi} \quad [3]$$

State

$$p = \rho \frac{R}{\bar{W}} T \quad [4]$$

The diffusion velocity V_{ky} is given in the new coordinates by

$$V_{ky} = - \frac{D_k}{X_k} \rho u y^\alpha \frac{\partial X_k}{\partial \psi} \quad [5]$$

In these equations, the independent variables x and ψ represent the axial coordinate and stream function, re-

spectively. For an axisymmetric flow, the parameter α is 1, and y represents the radius measured from the flow centerline. For $\alpha = 0$ the equations are in planar coordinates. In both cases, the cross-stream coordinate y is a dependent variable and is given in terms of stream function by the following integral

$$\frac{y^{\alpha+1}}{\alpha+1} = \int_0^\psi \frac{d\psi'}{\rho u} \quad [6]$$

or, in the differential equation form that we actually use, by

$$\frac{\partial y^{\alpha+1}}{\partial \psi} = \frac{\alpha+1}{\rho u} \quad [7]$$

Other variables are given by: u , the axial fluid velocity; ρ , the mass density; p , the thermodynamic pressure; T , the temperature; Y_k , the mass fraction of the k th species; X_k , the mol fraction of the k th species; W_k , the molecular weight of the k th species; R , the universal gas constant; g , the acceleration of gravity; D_k , the binary diffusion coefficient of the k th species into the mixture; μ , the mixture viscosity; λ , the mixture conductivity; c_p , the specific heat at constant pressure; h_k , the specific enthalpy of the k th species; ω_k , the rate of production of the k th species by chemical reaction; \bar{W} , the mixture's mean molecular weight.

The transport properties (viscosity, thermal conductivity, and diffusion coefficients) are temperature dependent and are obtained from Lennard-Jones parameters for each of the chemical species using standard techniques (5-8). The specific formulas employed are discussed in detail by Kee and Miller (9).

We compute thermodynamic properties (heat capacities, entropies, and enthalpies) for each of the chemical species from temperature-dependent fits of data [JANAF when available (10)] in the form used by the NASA chemical equilibrium code (11). Thermochemical data were not available for SiH_2 , SiH_3 , Si_2H_2 , Si_2H_3 , Si_2H_4 , Si_2H_5 , and Si_2H_6 . For these species we used the results of an extensive set of electronic structure calculations by Binkley (12) to estimate entropies, energies, and harmonic vibrational frequencies. Standard statistical mechanical techniques (13) were used to convert the frequencies and energies to $c_p(T)$, $h(T)$, and $s(T)$, which were then fit to the polynomial form of Gordon and McBride (11). In the code all chemical production rate terms, thermodynamic properties, and equation of state variables are evaluated by appropriate subroutine calls to CHEMKIN (14), a general-purpose package of chemical kinetics Fortran subroutines.

Boundary conditions.—The two different channel types treated here, axisymmetric and planar, each require slightly different boundary condition formulations. In both cases the equations are parabolic, so boundary conditions are specified for u , T , Y_k , y , and p at the boundary $x = 0$. However, since the x coordinate is time-like for purposes of numerical solution algorithms, the boundary conditions at $x = 0$ may be regarded as initial conditions. In equations of this type (differential/algebraic equations), all of the initial conditions are not independent. Once u , T , Y_k , and p are specified at $x = 0$, the cross-stream velocity v follows as an integral of the mass conservation equation. In stream function coordinates, where v has been eliminated as a variable, it follows that the physical coordinate y must be consistent with the other initial conditions.

The channel walls (or an axis of symmetry and a wall) define the flow boundaries. In stream function coordinates, the walls correspond to streamlines, or lines of constant stream function. By definition, flow is tangent to streamlines; thus, no flow crosses a wall (or axis of symmetry). The boundary condition, corresponding to either the lower wall or the axis of symmetry, is applied at $\psi = 0$. The other boundary condition is applied at ψ_0 , where ψ_0 is determined from Eq. [6] when ψ and u are evaluated at the initial conditions, and an initial mesh in y is specified.

For axisymmetric problems, an axis of symmetry is specified at $\psi = 0$ by

$$\frac{\partial u}{\partial \psi} = \frac{\partial T}{\partial \psi} = \frac{\partial Y_k}{\partial \psi} = 0 \quad [8]$$

In addition, we specify that $y = 0$ at $\psi = 0$.

On solid walls we specify the no-slip boundary, $u = 0$. In some cases we specify T itself, while in others we specify a heat flux, *i.e.*, a temperature gradient. Zero gradients are imposed for the mass fractions of species that do not react at walls (implying no mass flux to the wall). For species that react at the wall, the boundary conditions are more complex, and are discussed below.

Chemical reactions at solid surfaces.—The boundary conditions on chemical species concentrations at a heated surface depend on the extent to which each species undergoes surface reactions. Some species react at the heated surface, depositing silicon. In this model we consider two types of deposition reactions, depending on whether the species is a saturated or unsaturated compound.

Because of the reactive nature of unsaturated chemical species, we assume that they react with the solid surface with unit probability and release molecular hydrogen; in this model these species are SiH , SiH_2 , SiH_3 , Si_2H_2 , Si_2H_3 , Si_2H_4 , and Si_2H_5 . Species that react with unit probability on the surface cannot exist there (because they react instantaneously), and thus the boundary condition for those species is given by

$$Y_{\text{SiH}} = Y_{\text{SiH}_2} = Y_{\text{SiH}_3} = Y_{\text{Si}_2\text{H}_2} = Y_{\text{Si}_2\text{H}_3} = Y_{\text{Si}_2\text{H}_4} = Y_{\text{Si}_2\text{H}_5} = 0 \quad [9]$$

Results of our model are relatively insensitive to this boundary condition. For example, changing the assumed surface-reaction probability from 1 to 0.8 changes the predicted deposition rate by 5% or less.

We assume that the species H , Si_2H_6 , and inert carrier gases do not react at the surface. These species have zero flux to the surface, and thus we enforce the following boundary conditions

$$V_{\text{yH}} = V_{\text{ySi}_2\text{H}_6} = 0 \quad [10]$$

We use the empirical silane surface reaction coefficient of Farrow (15) to describe the deposition due to SiH_4 reacting at the surface. The fraction of silane molecules that decompose upon collision with a heated surface is given by

$$\gamma = 5.45 \exp(-8556/T) \quad [11]$$

However, only a fraction of the silane that decomposes at the surface leads to the formation of solid silicon. According to Farrow's data, this fraction is given by

$$\sigma = 7.6 \times 10^{-3} \exp(3535/T) \quad [12]$$

We assume, as did Farrow, that the rest of the silicon formed by the surface decomposition diffuses away from the surface as gas-phase silicon atoms.

The surface-decomposition fraction (γ) is incorporated into the model as a boundary condition on the SiH_4 concentration. This reaction coefficient is defined as the fraction of the silane flux into the boundary which is decomposed. At steady state, the net flux (incoming minus outgoing flux) at the boundary is equal to the surface reaction rate. The ratio of the flux that would be present for a fractional reaction probability to the flux for a unit reaction probability equals the fraction of the flux which is decomposed. In other words, this ratio is equal to γ of Eq. [11], and the boundary condition derived from this relationship is

$$(V_{\text{ySiH}_4})_{\psi=1} = \gamma (J_{\text{ySiH}_4})_{\psi=1} \quad [13]$$

The notation $(J_{\text{ySiH}_4})_{\psi=1}$ refers to flux which would exist if the concentration of SiH_4 were zero on the boundary, *i.e.*, unit reaction probability.

From Eq. [12] we can calculate the amount of gas-phase Si atoms formed as a fraction $(1 - \sigma)$ of the silane decomposed at the surface. Equation [14] determines the flux of $\text{Si}(g)$ away from the surface

$$-\frac{V_{\text{ySi}} Y_{\text{Si}}}{W_{\text{Si}}} = (1 - \sigma) \frac{V_{\text{ySiH}_4} Y_{\text{SiH}_4}}{W_{\text{SiH}_4}} \quad [14]$$

We now need a relationship between the flux of reactive species into the surface and the flux of hydrogen away from the surface. The hydrogen that was initially tied up in silicon containing species is released when the silicon is deposited. In our model the hydrogen atom flux to the surface is balanced by a flux of molecular hydrogen from the surface. (These incoming hydrogen atoms are contained in the surface reacting species.) This relationship is stated in the following boundary condition

$$-\frac{V_{yH_2}Y_{H_2}}{W_{H_2}} = \frac{V_{ySiH}Y_{SiH}}{2W_{SiH}} + \frac{V_{ySiH_2}Y_{SiH_2}}{W_{SiH_2}} + \frac{3V_{ySiH_3}Y_{SiH_3}}{2W_{SiH_3}} + \frac{2V_{ySiH_4}Y_{SiH_4}}{W_{SiH_4}} + \frac{V_{ySi_2H_2}Y_{Si_2H_2}}{W_{Si_2H_2}} + \frac{3V_{ySi_2H_3}Y_{Si_2H_3}}{2W_{Si_2H_3}} + \frac{2V_{ySi_2H_4}Y_{Si_2H_4}}{W_{Si_2H_4}} + \frac{5V_{ySi_2H_5}Y_{Si_2H_5}}{2W_{Si_2H_5}} \quad [15]$$

The cross-flow velocity must vanish at both the upper and lower boundaries of a channel, *i.e.*, $v = 0$. In stream function coordinates this is accomplished by requiring that the physical coordinate y is zero at the lower surface (or axis of symmetry), and that y equals the channel width (or radius) at the upper streamline ψ_0 . However, since the equation for y [7] is first order, we normally could not require two boundary conditions. We overcome this restriction by retaining the pressure as dependent variable. The extra boundary condition thus allows us to obtain the unique pressure function $p(x)$ (subject to the given value of p at $x = 0$), which is consistent with having two walls (or one wall and an axis of symmetry) in the problem. During the course of the solution we must determine the $p(x)$ which allows the two boundary conditions on $y(\psi)$ to be satisfied simultaneously. In other words, the pressure drop is computed to balance the shear forces exerted by the walls on the fluid.

Chemical reaction mechanism.—The kinetics of SiH_4 thermal decomposition has been the subject of a number of studies (16-20). The reaction mechanism for silane decomposition employed in this work is given in Table I. A further discussion of the reaction mechanism is presented elsewhere (21). Its development was in essentially two stages. First, a large system of 120 elementary reactions was constructed. Using that mechanism, we performed extensive sensitivity analysis (without any transport effects). From this analysis we determined that silane pyrolysis under conditions of interest could be described as a constrained equilibrium process (22). That is, the time evolution of all the species concentrations is determined strictly by the initial silane dissociation step, whose rate coefficient has been experimentally determined (16). Subsequent radical-molecule and radical-radical reac-

tions simply act to shuffle the intermediate species concentrations to their constrained equilibrium values. Therefore, in the interests of simplicity in the boundary layer computations, we reduced the reaction mechanism to the current 20-step mechanism. Over the range of interest this reduced reaction set reproduces the essential features of the full mechanism, *i.e.*, the initiation step is correct and the constrained equilibrium character is preserved.

As part of the analysis of the reaction mechanism we did a formal sensitivity analysis (23), and determined small sensitivities for all rate constants except the initiation step. In addition, in the boundary layer calculations, we did a series of tests in which each of the rate constants of the secondary reactions (R2-R20) were arbitrarily increased and decreased by a factor of 10, and we found that the predicted deposition rates were unaffected. On the other hand, similar tests show a measurable sensitivity to the initiation step. This sensitivity, of course, depends on the particular temperature and flow conditions.

Numerical method.—Method-of-lines formulation.—Our general approach is that of the method-of-lines. After discretization of the spatial derivatives, numerical solution of the resulting system of differential/algebraic equations (DAE's) is accomplished with a code developed by Petzold (24) called DASSL. DASSL solves the equations in a marching fashion, starting from the inflow boundary ($x = 0$) and going toward the outflow boundary. The code implements a variable-order, variable-step algorithm based on the backward differentiation formula (BDF) methods (25). These are stable methods that are particularly well suited for solution of the stiff equations that occur in chemical kinetic models. The DASSL code chooses a sequence of time steps (actually x -coordinate steps) such that the local truncation error in the marching direction is controlled to within a prespecified error tolerance. The general approach in using DASSL is to write a residual function $g(t, y, y')$ at each mesh point, which is zero when the equations are satisfied. DASSL iterates on the solution at each time step until the approximate solution y and y' are sufficiently accurate and so g is zero.

We make the distinction here between standard form ordinary differential equations (ODE's) which are written as $y' = f(t, y)$, and DAE's, which are written in the more general form $g(t, y, y') = 0$. For our purpose, systems of DAE's are distinguished from ordinary systems of parabolic equations by (i) an inability to isolate one time-like derivative per equation (the x derivatives in the boundary layer problem), and/or (ii) coupled equations which have no time-like derivatives. The former situation occurs in our equations when both $\partial u/\partial x$ and $\partial p/\partial x$ appear in the momentum equation. The latter situation occurs in the equations defining the spatial coordinate y in terms of the stream function via Eq. [7], and in specifying a uniform pressure across the channel. The boundary conditions in the y -coordinate are also regarded as algebraic equations.

Approximation of the spatial derivatives is accomplished by finite difference representations on a fixed grid in the stream function. In the momentum, species, and energy equations, we approximate the second derivatives with conventional central difference formulas as

$$\frac{\partial}{\partial \psi} \left(a \frac{\partial f}{\partial \psi} \right) \approx \left(\frac{2}{\psi_{j+1} - \psi_{j-1}} \right) \left[a_{j+1/2} \left(\frac{f_{j+1} - f_j}{\psi_{j+1} - \psi_j} \right) - a_{j-1/2} \left(\frac{f_j - f_{j-1}}{\psi_j - \psi_{j-1}} \right) \right] \quad [16]$$

where the subscript j denotes the j th grid point. We approximate the first derivatives, as needed in Eq. [3], by central differences as

$$\frac{\partial T}{\partial \psi} \approx \frac{T_{j+1} - T_{j-1}}{\psi_{j+1} - \psi_{j-1}} \quad [17]$$

We evaluate terms with no derivatives, such as the chemical production rate in Eq. [2], using the conditions existing at ψ_j . Likewise, the coefficients of derivatives, such as ρu in Eq. [1], are also evaluated at ψ_j .

Table I. Reaction mechanism

Reaction number	Reaction	A^a	E_a^a	Reference
R1	$SiH_4 \rightarrow SiH_3 + H_2$	5.00E12	52.2	(16)
R2	$SiH_4 \rightarrow SiH_3 + H$	3.69E15	93.	(17, 21)

^a Arrhenius parameters for the rate constants in the form $k_i = A_i \exp(-E_i/RT)$. The units of A_i depend on the reaction order, but are given in terms of mols, cubic centimeters, and seconds. E_a is in kcal/mol.

Integral conditions such as Eq. [6] (or, equivalently, first-order ODE's) are differenced according to the trapezoidal rule as

$$\frac{y_j^{\alpha+1} - y_{j-1}^{\alpha+1}}{\psi_j - \psi_{j-1}} = (\alpha + 1) \frac{2}{\rho_j u_j + \rho_{j-1} u_{j-1}} \quad [18]$$

It is important to represent the integral equations as first-order differential equations and include the variables such as $y^{\alpha+1}$ in the dependent variable vector. The reason for this choice is associated with the structure of the Jacobian matrix which is needed ultimately to solve the problem. When Eq. [18] is used, the number of dependent variables increases, but the Jacobian remains banded (a very desirable feature). On the other hand, if $y^{\alpha+1}$ is considered as a coefficient in the transport equations as defined by the integral Eq. [6], then the Jacobian loses its banded property and the required computer storage increases enormously.

Boundary conditions.—We treat the boundary mesh points the same way logically as we do the interior points. That is, we consider each dependent variable as an unknown on the boundaries and solve a system of equations to determine its value. Since the boundary equations usually do not involve marching derivatives, using such a formalism requires that the full system be solved as a system of DAE's. The procedure may appear inefficient when the boundary values are known exactly and therefore need not be considered as variables. However, its advantage is that all boundary conditions, regardless of complications (e.g., surface reactions involving many species), are treated in the same manner logically. Thus the boundary conditions of a problem can change without changing the logical structure of the dependent variable vector and the Jacobian. Changing from one set of boundary conditions to a completely different set requires very little programming effort. Moreover, with this formalism, boundary conditions on one equation may be functions of variables which would nominally be associated with another equation. For example, a surface reaction boundary condition typically involves several species concentrations and temperature.

As a final note on the numerical method, we discuss application of the uniform pressure condition. Since it is uniform, we could consider the pressure as a single component in the dependent variable vector. However, since the pressure appears in each equation at each mesh point (either directly as $\partial p/\partial x$ or indirectly in transport property

evaluations), using only one variable is undesirable because so doing destroys the block tridiagonal Jacobian structure. We therefore consider the pressure to be an unknown at each mesh point, and solve an equation that forces the pressure at adjacent mesh points to be equal, i.e., $dp/d\psi = 0$. Although we increase the number of dependent variables, we retain the desired Jacobian structure. The finite difference equation at the mesh points states simply that pressure at adjacent nodes is equal

$$p_j - p_{j+1} = 0 \quad [19]$$

The boundary condition applied to Eq. [19] is that y at the outer channel wall is equal to the physical coordinate at the wall. In other words, there is no explicit boundary condition on pressure per se, but the needed boundary condition on y is used implicitly. Note that unlike Eq. [18], which involves nodes j and $j - 1$, Eq. [19] involves nodes j and $j + 1$. This indexing is needed to maintain the block tridiagonal Jacobian structure. We evaluate Eq. [18] at the inner boundary and Eq. [19] at the outer boundary; therefore they are both part of the boundary condition specification at their respective boundaries.

Predictions of Model

The computer model predicts a large number of experimentally observable quantities in the CVD cell; these are discussed individually below. These predictions fall into three broad categories: gas-flow properties, chemical species concentration fields, and deposition rates. Calculated fluid flow quantities include temperature fields, flow streamlines, and velocity fields; these are plotted in Fig. 1.

Two dimensional temperature contours predicted by the model are given in Fig. 1a for a typical run. The incoming gas temperature, at the left of Fig. 1a, is taken as 300 K. The gas is heated from contact with the hot lower surface, causing temperature gradients above the susceptor. Temperature profiles predicted depend on susceptor temperature, flow rate, and carrier gas. As an example, in Fig. 2 we compare temperature profiles under different flow conditions at a fixed susceptor temperature and distance along the susceptor.

Temperature profiles in Fig. 2 for He and H₂ are almost identical because their transport properties are very similar. However, gas-phase chemistry rates and deposition rates are dramatically different in these two carrier gases. The effect of flow velocity on temperature profiles is illustrated in Fig. 2. Increasing the He flow rate by a factor

Fig. 1. Fluid flow properties predicted by the numerical model for a typical CVD calculation. Input conditions: susceptor temperature = 1018 K, inlet gas temperature = 300 K, average gas velocity = 15.3 cm/s, 0.6 torr SiH₄ in 640 torr He. A, upper left: temperature contours, labeled in Kelvin. B, upper right: flow streamlines. C, left: gas velocity contours, labeled in cm/s.

Fig. 2. Temperature profiles as a function of height above the susceptor, calculated for different carrier gases and initial velocities. Input conditions: susceptor temperature = 1018 K, 0.6 torr SiH_4 in 640 torr carrier gas. Profiles are calculated at 4.5 cm from the leading edge of the susceptor. Carrier gases and average velocities are as follows, N_2 : 15.3 cm/s (dashed curve). H_2 : 15.3 cm/s (dotted curve). He: 15.3 cm/s (solid curve). He: 30.6 cm/s (alternating dash-dot curve).

of two creates a sharper temperature gradient; the gas has shorter residence time in the heated region, and therefore higher temperatures cannot extend as far into the gas. Temperature profiles in N_2 carrier are much steeper than in He because nitrogen has a much smaller thermal conductivity. Although N_2 and He are both inert CVD carrier gases, they are not completely interchangeable. The dissimilar temperature profiles will make the extent of gas-phase reactions much different.

Flow streamlines predicted by the model are plotted in Fig. 1b. The streamlines are forced away from the susceptor at its leading edge. The physical explanation for this phenomena is simple. When the gas enters the heated region it expands. Because, by definition, the volume flow rate between two streamlines is constant, the y position of the lower streamline must increase. Most of the expan-

sion of the gas takes place at the leading edge of the susceptor, so the streamlines remain relatively horizontal downstream. Figure 1c shows velocity contours for a typical calculation. We assume the velocity profile at the inlet to be fully developed, *i.e.*, parabolic. The velocity profile remains roughly parabolic further downstream, but the maximum velocity increases due to expansion of the gas.

Chemical species concentrations result from gas-phase chemical reactions in the fluid-flow field. Because the reactions are very temperature sensitive, they exhibit a 2-D spatial variation with the gas-phase temperature. The resulting concentration profiles are thus a sensitive function of susceptor temperature, flow velocity, and carrier gas. Thermal decomposition of silane is rapid in the gas phase close to the hot susceptor. The model predicts the SiH_4 concentration profiles as a function of distance along the susceptor, as illustrated in Fig. 3. At the inlet there is a uniform concentration of room temperature SiH_4 above the susceptor. Downstream, chemical reactions, primarily reaction R1, deplete silane in the gas phase. The depletion is greater and the concentration profile is broader as distance downstream increases.

Figure 4 depicts the sensitivity of predicted silane partial pressure profiles to carrier gas and flow rate. The silane profile in the nitrogen carrier is steeper than in helium, due to the different temperature profile, as discussed above, which results in different decomposition rates. Because the gas-phase temperature is higher in He than in N_2 at a given height above the susceptor, more silane decomposition occurs in He and the silane partial pressure is reduced.

Hydrogen is a product of the SiH_4 decomposition reaction. Thus, an excess of H_2 used as a carrier gas tends to equilibrate the decomposition, resulting in less SiH_4 decomposition. This suppression is reflected in the silane profile in H_2 carrier gas plotted in Fig. 4. At a given temperature, there is much less decomposition of SiH_4 in H_2 than in He. As a result, there is less silane depletion in H_2 , and the deposition rate (discussed in the next section) is much less than in He.

Gas velocity has an important effect on the gas-phase concentration profiles. As gas velocity is increased, the residence time of silane in the heated region is reduced. Therefore, when gas-phase kinetics are slow (at low temperatures), the SiH_4 does not react as extensively, and there is less depletion in the silane partial pressure profile. Figure 4 shows this result when the gas velocity is doubled in He carrier gas.

Because H_2 is a product of the silane decomposition, the H_2 concentration profiles are closely related to those of SiH_4 . Figure 5 is a plot of hydrogen concentration profiles for a calculation in He carrier. The H_2 concentration increases with distance along the susceptor and is at

Fig. 3. Silane mass fraction profiles as a function of height above the susceptor and distance along the susceptor for a typical calculation. Input conditions: susceptor temperature = 1000 K, average gas velocity = 12 cm/s, 1.74 torr SiH_4 in 620 torr He.

Fig. 4. Silane partial pressure profiles as a function of height above the susceptor, calculated for different carrier gases and initial velocity. Input conditions and identification of curves are the same as in Fig. 2.

maximum near the surface, where silane decomposition is most rapid.

We computed concentration profiles for all chemical species in the reaction scheme (Table I). As an example of

the behavior of a typical intermediate species, we plotted profiles of Si_2H_2 in Fig. 6. The Si_2H_2 profile increases with distance along the susceptor as more chemical reactions take place. However, the Si_2H_2 concentration drops to zero at the surface, due to the boundary condition describing deposition (Eq. [9]). Since it has a large gradient at the surface, Si_2H_2 makes a large contribution to the deposition rate in He carrier gas, as we discuss in the next section.

We observed that a reaction zone begins at the leading edge of the susceptor, and it moves outward and downstream as the silane is depleted and heat diffuses out. In this zone chemical production and depletion takes place; outside the zone only transport processes are active. We also observe that the secondary reactions are all equilibrated in the reaction zone. In high temperature cases, even the initiation step equilibrates in the reaction zone. The position of the reaction zone is determined both by heat transfer away from the heated susceptor and mass transfer processes in the gas phase. The process is quite analogous to what occurs in a diffusion flame [see for example, Miller and Kee (26)].

We picture the process as one in which a reaction zone moves away from the susceptor, eating into the unreacted silane. There is a diffusive flux of silane into the reaction zone from the cold region, and there is little diffusive

Fig. 5. Hydrogen mass fraction profiles as a function of height above the susceptor and distance along the susceptor. Input conditions are the same as in Fig. 3.

Fig. 6. Si_2H_2 mass fraction profiles as a function of height above the susceptor and distance along the susceptor. Input conditions are the same as in Fig. 3.

flux of silane out of the reaction zone to the susceptor. In high temperature cases, nearly all the silane is depleted in the reaction zone, while in low temperature cases, the silane is not all depleted in the reaction zone because the initiation step is slower. The intermediate species that are chemically produced in the reaction zone diffuse in both directions. The species that diffuse to the susceptor ultimately react on the surface and deposit silicon. The species that diffuse into the cold region remain essentially frozen or unreacted (far from equilibrium) until the reaction zone ultimately reaches them, and reaction occurs.

Within the reaction zone we find a state of "constrained equilibrium" (22). That is, all reactions, except the initiation step, are sufficiently fast that they are essentially in chemical equilibrium. The species production and depletion rates are controlled by diffusive transport and thermodynamic considerations, rather than individual reaction rates. Therefore, we find that the deposition rates and the species profiles are insensitive to the specific rate constants used (except the initiation step). This is fortunate, since there are few measurements of elementary rate constants for the reaction of the silicon intermediate species. However, in many cases the thermodynamic properties that are needed to compute equilibrium constants have been measured, and the others can be estimated from *ab initio* electronic structure computations (12).

Deposition Rate Predictions

A common feature of many CVD systems is that the apparent activation energy for deposition rates at high temperatures is much smaller than at low temperatures. At high temperatures the CVD reactions are very fast. In this case, the deposition rate is limited by the rate at which reactive species can diffuse to the surface, and is not sensitive to temperature. There have been many models for silicon CVD in the high temperature regime (27-46). Usually these models assume that silane does not react in the gas phase, but instead reacts instantaneously at the hot surface. Thus, the SiH_4 concentration at the surface is set to zero as a boundary condition. In many high temperature models, parameters, such as boundary-layer thickness and diffusion constants, are adjusted so that predicted deposition rates match experimental data.

At low temperatures, the apparent activation energy for deposition is much larger than at high temperatures. Because reactions at low temperature are relatively slow, these lower deposition rates have previously been attributed to the kinetics of surface reactions (47-55).

Figure 7 presents a comparison between experimental and theoretical deposition rates as a function of distance along a 1323 K susceptor in H_2 carrier gas. The log of the deposition rate *vs.* distance, from Eversteyn *et al.* (29), was found to be linear, and is represented in Fig. 7 as the solid line. Results of our numerical model are plotted as the square symbols. The agreement between theory and experiment is excellent without adjusting parameters.

At 1323 K, gas-phase decomposition of silane is very fast, and the deposition rate is limited by the rate of diffusion of silicon containing species to the surface. The calculation in Fig. 7 indicates that for these experimental conditions, the radical SiH_2 is primarily responsible for the deposition.

It is useful to compare our model with ones that make the assumptions typically employed in modeling high temperature silicon CVD. These assumptions are that gas-phase decomposition of the SiH_4 does not occur and that SiH_4 reacts instantaneously at the surface, *i.e.*, its concentration is zero there. The results plotted in Fig. 7 as triangles are obtained when our numerical model is used to solve the fluid flow equations with gas-phase chemistry suppressed and the concentration of silane set to zero at the surface, to mimic the previous models. Agreement is very close between the two models, although the mechanisms are dramatically different. This apparent inconsistency is readily explained. The SiH_4 reacts very rapidly in the gas phase close to the susceptor, creating a steep concentration gradient. This silane concentration gradient is nearly equal to that in the second calculation, in which the SiH_4 concentration was set to zero at the surface. In addition, the SiH_2 formed near the surface via re-

Fig. 7. Comparison of theoretical and experimental deposition rates as a function of distance along the susceptor. Experimental data from Eversteyn *et al.* (29) is well described by the solid line. Points are from model calculations with the following input conditions: susceptor temperature = 1323 K, average gas velocity = 17.5 cm/s, 0.76 torr SiH_4 in 1 atm of H_2 , cell height = 2 cm. Squares are results of the full model. Triangles are results when gas-phase chemistry is omitted and the SiH_4 concentration on the surface is set to zero. Diamonds are results when gas-phase chemistry is omitted and the SiH_4 surface concentration is obtained from Eq. [11].

action R1 diffuses rapidly toward the surface with a diffusion constant close to that of silane. Thus, the rate of diffusion of silicon containing species toward the surface is almost identical in the two calculations.

The assumption that silane reacts with unit probability upon collision with the surface is in variance with experimental results (15, 56-61). Deposition rates calculated when gas-phase chemistry is again suppressed and the surface-reaction probability from Eq. [11] is used as the silane boundary condition are plotted in Fig. 7 as diamonds. This calculation indicates that the measured silane reaction efficiency at the surface is not sufficient to explain the deposition rates of Eversteyn *et al.* (29), and that gas-phase reactions must be included.

Deposition rates predicted by our model as a function of temperature, carrier gas, and total pressure are plotted in Fig. 8. The range of conditions covered in Fig. 8 represents a rigorous test of the model. Experimental deposition rates for a simple cell geometry that can be described well by our two-dimensional model were available only for the case of H_2 carrier gas. The data of van den Brekel (62) are plotted in Fig. 8 as solid triangles. Agreement between experimental and theoretical deposition rates is excellent over the temperature range 700°-1000°C. The model quantitatively predicts the deposition rates, as well as the transition between the high temperature behavior (weak temperature dependence) and low temperature behavior (much higher apparent activation energy). The correct prediction of the low temperature rate is significant because our model includes only the simple surface reaction mechanism described by the boundary conditions, Eq. [9] through [14]. In our model, at low temperatures the apparent activation energy for deposition is principally due to the temperature dependence of the gas-phase reactions in Table I.

The remaining theoretical predictions in Fig. 8 are in qualitative agreement with experimental deposition rate behavior (49, 63, 64). The model predicts two distinct temperature regions, where the apparent activation energies are significantly different. At 1 atm total pressure (APCVD) the low temperature deposition rate in He carrier gas is much higher than in H_2 , while at high temperatures they are almost equal. The activation energy is nearly equal in He and H_2 for low temperature APCVD. The knee in the APCVD plot occurs at a temperature 200 degrees higher in H_2 than in He carrier. For the case of 6 torr total pressure (LPCVD) the deposition rate is much greater than for APCVD, and there is very little dependence of deposition rate on carrier gas. The knee in the He curve is shifted to higher temperature as the total pres-

Fig. 8. Deposition rates predicted by the model (open symbols) as a function of temperature, total pressure, and carrier gas. Input conditions for all calculations: average gas velocity = 60 cm/s, 0.76 torr SiH_4 in either 760 torr of carrier gas (APCVD) or 7.6 torr of carrier gas (LPCVD), cell height = 1.25 cm. Deposition rates for APCVD and LPCVD are calculated 15 cm and 1 cm from the leading edge of the susceptor, respectively. Experimental data of van den Brekel (62) is given by the solid triangles. The solid curves have been drawn to distinguish between sets of calculated results.

sure is reduced with the silane partial pressure held fixed.

Many of the reaction rate constants in Table I were estimated. However, all of the calculations represented by

Fig. 1-8 were performed with the same set of rate constants, diffusion coefficients, etc. There has been no adjustment of parameters in the model to obtain agreement with experimental CVD data.

The chemical species that contributes most to the deposition process changes with experimental conditions. Figure 9a gives the percent contribution to the deposition rate of the various silicon containing chemical species in H_2 carrier gas, over the temperature range 600°-1200°C. At low temperatures, the silane surface decomposition reaction described by the boundary conditions in Eq. [11] through [13] contributes most to deposition. Below about 700°C, gas-phase reactions are very slow in H_2 carrier gas. Presence of the excess of H_2 inhibits the rate of decomposition by shifting the equilibrium toward the reactants. At higher temperatures, SiH_2 becomes the most important species contributing to deposition. SiH_2 is the product of the first step in the decomposition mechanism of silane. It is assumed to react at the surface with unit probability to form solid silicon and liberate H_2 gas.

Figure 9b is a similar plot for He carrier gas. Gas-phase chemistry is much faster in He than in H_2 and so, even at 600°C, the surface decomposition of SiH_4 is not nearly as important as in H_2 carrier. At temperatures below about 1000°C, Si_2H_2 is the species that contributes most to the deposition rate. Si_2H_2 is formed primarily because of the series of reactions R1,-R4,-R14. Each of these reactions is suppressed in an excess of H_2 , which is why Si_2H_2 is unimportant in Fig. 9a. At higher temperatures, Si_2 and Si_3 make the largest contribution to the deposition rate. These chemical species are formed in the reaction sequence R1,-R4,-R14,-R17,-R20, and -R13. This reaction sequence is also suppressed in H_2 .

Large concentrations of Si_2 and Si_3 are predicted in the gas phase, close to the susceptor. The model predicts 0.01 torr partial pressure of Si_2 above the susceptor at 1000°C in He carrier gas for the conditions described in Fig. 8. On the basis of these model predictions, Ho and Breiland (65) recently have used laser-excited fluorescence to detect Si_2 above the susceptor in a CVD reactor. This observation of Si_2 is a dramatic confirmation that the gas phase is far from thermodynamic equilibrium [in which Si_2 concentration would be roughly 2×10^{-18} torr, for the conditions of their experiment (65)]. The presence of Si_2 is predicted to turn on very rapidly with temperature, and to be sup-

Fig. 9. Percent contributions made to the deposition rate by various chemical species as a function of temperatures in (a, left) H_2 carrier gas, and (b, right) He carrier gas. The chemical species and symbol in each plot are: SiH_4 (open circle), SiH_2 (open triangle), Si_2H_2 (open square), Si_2 (open diamond) and Si_3 (closed square).

pressed by about 5 orders of magnitude in an atmosphere of H₂ carrier. The behavior of the Si₂ and Si₃ concentrations closely mimic experimental observations of gas-phase nucleation of particulates in a CVD reactor. Particulates are observed to form very rapidly above a threshold temperature and are suppressed in H₂ carrier. It is possible that the reaction pathway leading to Si₂ and Si₃ is the precursor to the formation of these nucleation particles.

Summary

We have presented results of a detailed mathematical model of the coupled hydrodynamics and gas-phase chemical kinetics in the CVD of silicon from silane. The model has been used to predict gas-phase temperature, velocity, and chemical species concentration fields. The model also predicts deposition rates as a function of experimental variables, such as susceptor temperature, carrier gas, pressure, and flow velocity. Predicted deposition rates were in excellent agreement with experimental data in Fig. 7 and 8, without use of adjustable parameters.

The model indicates that at high temperatures silane decomposes very rapidly in the gas phase. Radicals formed from this decomposition diffuse to the surface and are primarily responsible for the deposition. The low temperature deposition rate was also described well by our gas-phase kinetics model. The success of the model at low temperature is significant, because the temperature dependence of the deposition rate there has previously been attributed to the rate of reactions on the surface.

These results indicate that the gas phase is very important in silicon CVD. The role of the gas phase merits much more attention than it has previously been given.

Acknowledgments

We would like to thank W. G. Breiland for many helpful discussions about the research presented here. The assistance of L. R. Petzold and J. S. Binkley is also gratefully acknowledged. This work was performed at Sandia National Laboratories and was supported by the U.S. Department of Energy under contract no. DE-AC04-76DP00789 for the Office of Basic Energy Sciences.

Controlled Reactive Sputter Synthesis of Refractory Oxides

SiO_x, The Silicon-Oxygen System

Troy W. Barbee, Jr., Douglas L. Keith, Lynn Nagel, and William A. Tiller

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

Reactive sputter deposition of refractory oxides, under conditions in which the reaction between the sputtered species and the oxygen is isolated to the deposition surface, has been experimentally investigated, and results have been obtained for the formation of SiO_x (0 < x < 2). It is shown that the dependence of the deposited film stoichiometry on oxygen pressure and the incidence rate of silicon can be correlated with reported results of oxygen adsorption onto single-crystal silicon surfaces and amorphous silicon surfaces. This correlation is made in terms of oxygen exposure and, in our work, a dynamic exposure (L_D) is defined for steady-state synthesis conditions by placing the origin of a moving reference frame at the deposition surface. This correlation shows that the sticking coefficient of oxygen onto room temperature substrates is independent of oxygen coverage (*i.e.*, surface stoichiometry) for coverages less than 0.8. This requires that a mobile precursor adsorption process be operative for oxygen in our experiments. The deduced pressure-independent oxygen sticking coefficient is 1.5 to 4.1 × 10⁻³.

Sputter deposition of refractory compound films of high quality from compound targets is difficult because of the low mechanical integrity of such targets, their low thermal conductivities, inherently low deposition rates, poor stoichiometry control, and the often substantial contamination incurred during the sputter target preparation (1-5). These difficulties may be diminished by reactive sputtering in which the target, consisting of the metal component, is sputtered using a gas mixture consisting of an inert gas (typically argon) and a reactive component, one element of which is active in the formation of the desired compound (1, 2, 6-11). Despite present drawbacks, associated with the difficulty of closely controlling film stoichiometry, reactive sputtering often yields much higher quality films at deposition rates somewhat higher than those attained using compound targets.

The purpose of the work presented in this paper was to develop the reactive sputtering synthesis process so that continuous layers of controllable structure and composition could be formed in a reproducible and routine manner. In this paper we report the results of our studies on the reactive deposition of the oxides of silicon (SiO_x). Films of SiO_x (0 ≤ x ≤ 2) were synthesized at high rates onto substrates held at room temperature. A systematic investigation of the structure-composition-synthesis process variables was conducted for this system, and it was clearly demonstrated that films of controllable stoichiometry, varying over the range SiO_{0.1} to SiO₂, can be reproducibly synthesized at rates (>5 Å/s) equal to or greater than those typically encountered in industry. In addition, the substrate temperature during synthesis was held close to the ambient condition (T_s ≤ 65°C). The low temperature nature of this process is a unique feature of high industrial potential, as it provides a method for forming SiO_x passivating films that does not include time-temperature cycling which could degrade existing device structures.

Experimental Approach and Procedures

The experimental approach was to design experiments so that reaction between the sputtered species (Si in this case) and the reactive gas (O₂) was forced to occur at the deposition surface. It was believed that under such conditions, high deposition rates plus control of structure and stoichiometry would be attainable through control of the relative rates of incidence of the two reactive components

Key words: sputtering, refractories, deposition.

onto this surface. Additionally, if such control were possible, it would facilitate both modeling of the reactive sputtering process and experimental reproducibility in both a given laboratory and between laboratories.

The experimental arrangement (type II) used was designed to isolate the sputter-source plate from the oxygen gas, maintaining it in an inert argon gas atmosphere while introducing an oxygen pressure at the substrate. Two approaches were taken here. In the first (type IIA), argon and oxygen were brought into the chamber separately, with the oxygen inlet surrounding the substrate and the argon introduced as under normal sputtering conditions. In these experiments, the oxygen, though localized at the substrate, was nonuniformly distributed. Also, although higher oxygen concentrations were attainable, source contamination by oxygen still limited the experimental range. A series of experiments was performed using this apparatus, in which the rate of incidence of silicon was held constant and the oxygen pressure at the substrate varied. In this work, the source to substrate distance was 11.5 cm and (100) single-crystal silicon wafers were used as substrates. The silicon incidence rate was 2.9 Å/s (1.45 × 10¹⁵ Si atoms/cm²s). Oxygen incidence rates were varied from 0 to 8 × 10¹⁷ O₂/cm²s (0 ≤ P_{O₂} ≤ 1.6 mtorr).

A second-generation apparatus (type IIB) was designed so that the range of oxygen pressures could be extended and the distribution of oxygen at the deposition surface would be uniform. Two gas ring sources, one for argon and the other for oxygen, were fabricated with the gas inlets in each ring consisting of slits 0.002 in. wide on the inner diameter of two-piece annular structures. For oxygen, the sample was mounted in the ring with the oxygen directed down onto the substrate. For argon, the ring was mounted near the sputter source with the argon stream directed at the sputter-source target. This arrangement is schematically shown in Fig. 1. Improved film uniformity both in thickness and composition was attained with this apparatus. Additionally, oxygen pressures approximately twice those accessible without the argon isolation ring were usable without oxidation of the silicon source plate in the magnetron sputter head. For these experiments, silicon incidence rates were 3.4, 5.9, and 8.2 Å/s or 1.72 × 10¹⁵ Si/cm²s, 2.9 × 10¹⁵ Si/cm²s and 4.1 × 10¹⁵ Si/cm²s, respectively. The general oxygen pressure varied from 0 to 0.6 mtorr (0.08 Pa) in the system. This is considerably lower than the oxygen pressure at the substrate, which was not locally measured in these experiments.

Fig. 1. Experimental apparatus used in type IIA experiments. The center of the sputter source, argon ring, oxygen ring, and substrate were vertically aligned. Deposition was initiated by shutter motion after the flow of argon and oxygen was established.

In summary, experimental apparatus allowing reactive sputter deposition, in which the chemical reaction occurs at the deposition surface, has been developed. In the following, experimental results for SiO_x films synthesized in this manner will be presented. Specific emphasis will be placed on the stoichiometry control and uniformity.

Experimental Results

Type IIA experiments were performed with substrates 11.5 cm away from a 5 cm diam planar magnetron sputter-deposition source. Oxygen was introduced at the substrate; argon was generally introduced into the vacuum chamber. Argon pressure was held constant at 2.1 mtorr, and the total system oxygen pressure varied from 0 to 1.5 mtorr by flow rate control. The silicon source was RF excited with a resulting deposition of 2.9 \AA/s at the substrate onto single-crystal (100)-orientation silicon substrates. Analysis of the film thickness and refractive index by ellipsometry indicated that the oxygen distribution at the substrate was nonuniform. Additionally, oxygen contamination of the sputter source was observed at oxygen pressures greater than 1.5 mtorr.

A second experimental arrangement, type IIB (Fig. 1), was constructed, and experiments similar to those performed above were carried out. A 7.5 cm diam planar magnetron source, a 12 cm source-to-substrate spacing, oxygen pressures from 0 to 0.6 mtorr total system pressure, and silicon deposition rates of 3.4, 5.8, and 8.2 \AA/s were used. The lower range of oxygen pressures necessary here indicates that the partial pressure of oxygen at the deposition surface was at least a factor of 4 to 5 larger than the increase in total system pressure resulting from the introduction of oxygen.

In the following, a systematic presentation of the results obtained with configuration type IIA will be made and then compared to those obtained using configuration type IIB on the basis of the relative rates of incidence of oxygen and silicon. The uniformity of the deposit attained using configuration type IIB will also be demonstrated.

Steady-state synthesis was established by use of a constant flow rate of O_2 into the deposition chamber at the substrate surface and a constant rate of incidence of silicon atoms onto the deposition surface. SiO_x formation was initiated by opening a shutter which isolated the substrate from the silicon sputter source so that both Si and O_2 (at the constant) flux were incident on the substrate and the film was of uniform stoichiometry throughout its thickness. A series of synthesis experiments was performed with constant Si deposition rate, deposition time, source-to-substrate distance, and argon pressure, while the oxygen pressure was varied from 0 to 1.5 mtorr. Film thickness and relative index were determined using ellipsometric techniques ($\lambda = 6328 \text{ \AA}$; angle of incidence = 70°). Film thickness was also measured using mechanical stylus techniques at steps introduced by masking.

The composition of these films was deduced from the refractive index data correlation with results reported for SIPOS material (12) and by electron microprobe analysis of four of our samples. The refractive index has been cor-

related with oxygen concentration in both SIPOS films and our films, as shown in Fig. 2. Oxygen contents were measured using electron microprobe analysis techniques in both cases.

The thickness of our type IIA-deposited SiO_x films, as determined using mechanical stylus techniques and ellipsometry, are presented in Fig. 3 as a function of oxygen pressure during synthesis. The data points represent the average thickness observed at different step positions; the vertical bar provides the range of thickness observed for a given sample. This wide variation results from drift in the oxygen pressure during a given experiment as well as a nonuniform oxygen distribution at the substrate. Since the oxygen incidence rates on the substrate increase linearly with pressure, a linear dependence of t_f with P_{O_2} is expected if a constant fraction of incident oxygen atoms results in the formation of SiO_2 clusters with the specific volume of SiO_2 . Departures from the expected linearity could be related to two primary sources; (i) oxygen contamination of the target which reduces the Si incidence rate, and (ii) the incorporated oxygen does not all form SiO_2 clusters with the expected equilibrium specific volume, but rather takes forms with different specific volumes. At the highest oxygen pressures, the measured thicknesses are smaller than predicted, a result we interpret as being caused by sputter-source contamination with oxygen.

The optical transmission of the films deposited on the masks was indicative of the oxidation state of the films. It is expected that the transmission will increase as the oxygen content increases. Even with the increasing film thickness observed with increasing oxygen pressure, the transparency increases in a nearly monotonic fashion with increased oxygen pressure during synthesis. At the highest oxygen pressures the deposits are transparent, as expected for SiO_2 .

The refractive index for these films was also observed to systematically vary with oxygen pressure from that expected for silicon ($n_f \approx 3.6$ [amorphous] to 3.8 [crystalline]) to that observed for amorphous SiO_2 ($n_f \sim 1.45$). The n_f values were measured on films deposited onto (100) Si substrates using standard ellipsometric techniques ($\lambda = 6238 \text{ \AA}$; angle of incidence = 70°). These results are plotted as a function of oxygen pressure during synthesis in Fig. 4. The extent of the blocks surrounding each data point represents the effect of the variation of P_{O_2} during synthesis as well as the nonuniform distribution of oxygen at the substrate. Oxygen concentration in our films determined using the refractive index-composition relation (Fig. 2) are plotted vs. P_{O_2} during synthesis in Fig. 5. Examination of the samples indicated that nonuniform flow of the oxygen, and therefore, nonuniform oxygen pressure, at the substrate was the primary cause of the variations in composition and film thickness.

Fig. 2. Refractive index, as determined by ellipsometry, correlated with oxygen concentration as determined by electron microprobe analysis for four SiO_x films formed by reactive sputtering and CVD-synthesized SIPOS films reported in the literature.

Fig. 3. SiO_x film thicknesses for type IIA experiments as determined by ellipsometry and mechanical stylus techniques ($R_{\text{Si}} = 29 \text{ \AA/s}$) as a function of oxygen pressure.

Fig. 4. Refractive index (n_f) as determined by ellipsometry for the films of Fig. 3 (type IIA) as a function of oxygen pressure.

Fig. 5. Oxygen concentration in the films of Fig. 3 (type IIA) as a function of oxygen pressure.

The system was modified (type IIB) as already described (Fig. 1), and a series of depositions made using silicon deposition rates of 3.4, 5.4, and 8.2 \AA/s with total system oxygen pressures of 0 to 0.6 mtorr. Note that these oxygen pressures are approximately a factor of 4 to 5 smaller than those used in the type IIA experiments. This difference is believed to be due to an increased oxygen partial pressure at the deposition surface resulting from the more effective arrangement for introduction of oxygen at the substrate fixture.

The increased homogeneity of the films formed using the type IIB system is shown in Fig. 6, where refractive index and film thickness are plotted as a function of radial distance from the substrate edge to the wafer center. The substrates used were 7.5 cm diam (100) silicon wafers, centered beneath the deposition-source center in the oxygen ring. The decrease in refractive index from the center of the substrate to the edge is very slight, indicating nearly constant stoichiometry. Near the edge, the refractive index drops rapidly because of a slight overpressure of oxygen in that region and shadowing of the incident silicon by masking. The film thickness varies by approximately 16% over a distance of 3.0 cm. This is slightly larger than the expected variation of approximately 12%. The variation is a result of the deposition profile of the sputter source. It is indicative of a composition variation over 3.0 cm of approximately 1 atom percent (a/o). The compositional uniformity of this sample is so demonstrated.

It is useful to compare the results of these type IIB synthesis runs with the type IIA results. This is done in Fig. 7, where oxygen concentration in the films, as determined by the refractive index correlation, is plotted as a function of the relative rates of incidence of O_2 and silicon ($\nu_{\text{O}_2}/\nu_{\text{Si}}$). The silicon rate of incidence was estimated by normalizing the deposition rate to a unit area so that a volume rate was defined, and dividing this by the atomic volume of silicon ($\sim 20 \text{ \AA}^3$) (i.e., $1 \text{ \AA/s} \approx 5 \times 10^{14} \text{ atoms/cm}^2\text{s}$). The incidence rate of oxygen was calculated from the partial pressure of oxygen assuming a temperature of 300 K. Also plotted on this figure for comparison is the data of Ritter (13), where reactive synthesis of SiO_x was carried out using electron-beam evaporation techniques. The general behavior observed is similar for all three sets of data. The lower incidence rate ratios of type IIB as compared to type IIA experiments is believed to be the result of a higher oxygen concentration at the substrate due to a more effective means of oxygen introduction being used. The low oxygen pressures for oxide formation in the work of Ritter (13) will be discussed more fully below.

Mechanism of Reaction

The experimental results presented demonstrate that the synthesis of silicon-oxygen films under controlled conditions, designed so that reaction between silicon and

Fig. 6. Film thickness and refractive index plotted as a function of radial distance on a 7.5 cm diam silicon wafer demonstrating both compositional and thickness uniformity in type IIB apparatus synthesized films.

Fig. 7. Oxygen concentration for reactively synthesized films as a function of the ratio of the oxygen (O_2) and silicon incidence rates for types IIA and IIB experiments and for the thermal source results of Ritter (13).

oxygen occurs at the deposition surface, allows formation of films of reproducible stoichiometry and high uniformity onto room temperature substrates. So far we have been discussing our results in terms of the relative rates of incidence of the two reacting species onto the deposition surface. It is important at this point to consider experimental results reported by other investigators concerning the adsorption of oxygen onto surfaces of bulk single crystals and of amorphous silicon. Such surfaces are static in that the number of Si atoms is fixed by the character of the initial surface. In our experiments, a dynamic moving surface, in which both silicon and oxygen are supplied to a moving surface (*i.e.*, where a film is being grown) is studied.

More sophisticated experiments, in which ultrahigh vacuum studies of oxygen absorption on high index silicon planes (14, 15, 16) and amorphous silicon (17), have been reported. In these studies, the oxygen was observed to be absorbed with the coverage being a linear function of oxygen exposure in Langmuirs (torr/s). Sticking probabilities are small (2×10^{-4} to 3×10^{-3}) and strongly affected by the presence of excited oxygen. Additionally, the oxygen is absorbed in an unreacted state. This reaction ($Si + O_2 \rightarrow SiO_2$) is apparently strongly catalyzed by the presence of small amounts of carbon (16). Adsorption on amorphous silicon does not appear to be substantially different from absorption on (111) or (110) silicon surfaces. The sticking coefficient of oxygen on silicon (111) and (110) surfaces were reported to be 2×10^{-4} and 6×10^{-3} , respectively. The higher value on (110) surfaces can be explained by its higher index and the possibility of surface step effects.

In other works (14, 15, 16), the sticking coefficient (S) was determined by analysis of experimental data obtained using Auger electron spectroscopy (AES) (14, 15, 16), High resolution electron spectroscopy (HRES) (14, 15), and ellipsometry (E) (14, 15). It was assumed in all these experiments that the coverage (θ) was directly proportional to the intensity of the signal monitored which was determined as a function of oxygen exposure (L), and that unit coverage was attained when the experimental signal saturated. Under these assumptions, the coverage dependence of the sticking coefficient $S(\theta)$ could be derived as

$$\frac{d}{dt}(\theta) = S(\theta) \frac{\nu P}{N_0} \quad [1]$$

where θ is the fractional coverage, p the pressure, $\nu = 3.48 \times 10^{20}$ molecules/cm²s torr, and N_0 the number of surface sites available for absorption.

The relationship between coverage and exposure is similar to the relationship between composition and relative rates of incidence shown in Fig. 7. A more direct comparison can be made if our data are displayed in terms of the oxygen concentration given as x in SiO_x with $0 \leq x \leq 2$ and a dynamic exposure L_D . The correspondence between coverage and x in SiO_x is clear if we assume that the absorbed species is O_2 and that unit coverage is attained when there is one oxygen molecule absorbed for each silicon surface atom.

Dynamic exposure (L_D) is defined by the time necessary to deposit a monolayer of silicon atoms used in the calculation of oxygen exposure at pressure P_{O_2} . The number of atoms on an exposed (111) silicon surface is calculated to be $\sim 3.96 \times 10^{14}$ /cm². The rate of incidence of silicon atoms (ν_{Si}) has been already given as $\nu_{Si} = R_{Si}/V_{Si}$, where R_{Si} is the deposition rate in $\text{\AA}^3/\text{s}$ and V_{Si} is atomic volume of silicon. The time (τ) to deposit one monolayer (*i.e.*, 3.96×10^{14} atoms/cm²) is then

$$\tau = \frac{3.96 \times 10^{14}}{\nu_{Si}} = \frac{3.96 \times 10^{14} V_{Si}}{R_{Si}} \quad [2]$$

Thus, a dynamic exposure L_D for oxygen can be defined as

$$L_D = P_{O_2} \tau \quad [3]$$

where P_{O_2} is given in torr and τ in seconds. During a steady-state synthesis experiment, static exposure and dynamic exposure are analytically equivalent at small time steps.

Our experimental results are plotted as x in SiO_x vs. dynamic exposure calculated, as outlined above, in Fig. 8. The results of Ritter (13) are also plotted for comparison. The differences are striking. First, the dynamic exposure range, in Langmuirs, over which our data extend is approximately 10^{-4} to 10^{-3} L. In order to gain the same results, Ritter's exposure range was approximately 10^{-8} L to 10^{-2} L. No clear explanation for this appears in the data of either investigation. It is likely, though, that in Ritter's work a substantial amount of excited oxygen was present. The absorption and reaction probability of excited O_2 is orders of magnitude higher than those of unexcited O_2 . Therefore, the reactivity of the oxygen in the evaporation experiment was undoubtedly strongly increased by the experimental arrangement used. In our work, the oxygen was introduced at the substrate in an unexcited state. The substrate-to-sputter-source spacing was large enough to make the coupling between the plasma and the deposition surface minimal (a characteristic of planar magnetron systems). Additionally, substrate heating consistent with the deposition parameters ($T_s < 65^\circ\text{C}$) was observed for extended synthesis experiments (>2h), even with nonwater-cooled substrates, showing that the source-substrate coupling was minimal.

It is useful to compare coverage (14, 15) as determined by E, HRES, and AES with our data for x in SiO_x vs. ex-

Fig. 8. Oxygen concentration (x in SiO_x) as a function of L_D for films deposited using the type IIA and IIB experimental arrangements and the thermal source data of Ritter (13).

posure (L_D), as shown in Fig. 9. The qualitative behaviors are similar, and quantitative agreement occurs with respect to the exposure range involved (i.e., 10^{-4} to 10^{-3} torr/s). This implies that the rate-controlling step in the synthesis process is identical to that in the absorption process of O_2 on silicon. Hence, our rate-controlling step is the absorption of O_2 with reaction to form SiO_x occurring once the absorption step has taken place.

The slopes of the film stoichiometry curves (x in SiO_x) are steeper than the absorption curves, implying a somewhat larger sticking coefficient. When plotted in a linear manner (Fig. 10), the relationship between it and x in SiO_x is observed to be a linear function of exposure within our experimental scatter. This shows that the sticking coefficient of oxygen is independent of coverage, a condition which can be explained (18, 19, 20) by the presence of a mobile precursor to the chemisorption event. Therefore, it is quite likely that, in our work, a mobile precursor of O_2 adsorbed onto the surface exists and facilitates the chemisorption process.

A sticking coefficient (S) for O_2 onto our moving deposition surface can also be estimated for these data. If we assume unit coverage, when $x = 2$ for x in SiO_x , the coverage can be linearly related to x by $\theta = x/2$. At constant pressure (p) the time rate of change of the coverage (θ) can

Fig. 9. Experimental results for type IIA (□) and type IIB (●, ■, ▲) compared to the reported results of oxygen coverage on Si(111) surfaces as determined by HRES (□), ellipsometry (○), and Auger analysis (△), assuming that dynamic exposure (L_D) and exposure (L) are equivalent.

Fig. 10. x in SiO_x as a linear function of L_D (torr/s) allowing estimation of S for oxygen in the type IIA and type IIB experiments (see Eq. [1]).

be related (Eq. [1]) to the sticking coefficient, $S(\theta)$. The sticking coefficients derived on this basis are in the range 1.56×10^{-3} to 4.17×10^{-3} . These numbers are a factor of 5 to 20 larger than the value reported by Ibach (14) ($S = 2.2 \times 10^{-4}$) for an atomically flat (111) surface. This increase in S may be due either to the presence in our work of activated oxygen or to an enhanced reactivity of our amorphous SiO_x surface relative to ideal crystalline surfaces. The latter explanation is consistent with the effects of surface steps on the sticking probability. It would require 6-8% of the surface atoms to be associated with surface steps to achieve sticking probabilities, as we have inferred. Computer simulation studies of amorphous surfaces by Garofolini *et al.* (21) tend to support this interpretation.

The observed independence of the sticking coefficient on θ for O_2 on the silicon surface can be explained by a mechanism in which a physisorbed mobile precursor state for oxygen exists on the sample surface prior to chemisorption. This allows O_2 molecules to move on the surface so that, at substantial coverages ($\theta = 0.5$), the remaining unoccupied chemisorption sites are accessible. A simple model (21) of the combined physisorption-chemisorption process gives the sticking coefficient $S(\theta)$ for the chemisorbed state as

$$S(\theta) = \frac{\alpha(1-\theta)}{(1+r_d/r_c) - \theta(1+r_d/r_m)^{-1}} \quad [4]$$

where θ is the coverage, α the fraction of incident gas molecules entering the precursor state, r_d the rate of desorption, r_m the rate of migration, and r_c the rate of transition from the precursor to the chemisorbed state. In the limit of $\theta \rightarrow 0$, the sticking coefficient S_0 is given by

$$S_0 = \frac{\alpha}{(1+r_d/r_c)} \quad [5]$$

The relationship between r_d and r_c is easily explained in terms of a potential energy diagram, as seen in Fig. 11. There, the potential energy of an adsorbed oxygen molecule is plotted as a function of the molecule's distance from the solid surface. In Fig. 11, q_p represents the heat of physisorption and E_p the activation energy for transition from the physisorbed to the chemisorbed states. If we assume the ratio of the pre-exponential factors of r_d and r_c is K_1 , then

$$r_d/r_c = K_1 \exp[-(q_p - E_p)/RT] \quad [6]$$

where R is the gas constant and T the absolute temperature. Equation [5] then becomes

$$S_0 = \frac{\alpha}{1 + K_1 \exp[-(q_p - E_p)/RT]} \quad [7]$$

In all likelihood $\alpha \approx 1$ at low substrate temperatures, so that the quantity $1 + K_1 \exp[-(q_p - E_p)/RT]$ is equal to

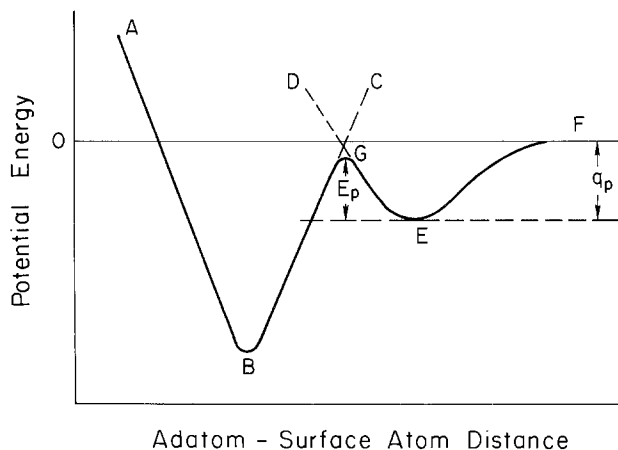

Fig. 11. The intramolecular potential (V_p) vs. distance illustrating the potential wells for both chemisorption and physisorption. The physisorbed state (DEF) represents the mobile precursor with an adsorption energy q_p . If the activation energy E_p for transition from the precursor to the chemisorbed state (ABC) is less than q_p , the activation energy for chemisorption is zero.

approximately 500, since $S = 2 \times 10^{-3}$. Therefore, to a good approximation

$$S_0 = \frac{\alpha}{K_1} \exp [q_p - E_p/RT] \quad [8]$$

indicating that chemisorption occurs with an activation energy close to zero (*i.e.*, $q_p > E_p$), a phenomenon found (22, 23, 24) in the oxidation of many metals.

The result of this interpretation is that the residence time of a physisorbed oxygen molecule on the surface and its migration rate determine the number of chemisorption sites accessible per physisorbed molecule and, therefore, the chemisorption rate. Hence, as the substrate temperature is increased at fixed oxygen pressure and silicon incidence rate, the oxygen concentration in the SiO_x deposit will decrease. This is observed in the reactive deposition of many oxides. The increase is due to the decrease in residence time of physisorbed molecules on the deposition surface relative to the increase in physisorbed oxygen mobility with increasing temperature. Therefore, the reactivity of oxygen and the depositing silicon is decreased by increasing substrate temperature.

Conclusions

A series of experiments, in which the reaction between oxygen and silicon during reactive sputtering is forced to occur at the deposition surface, has been performed and analyzed. A suitable technique was developed for isolating the magnetron sputter source from the ambient oxygen and SiO_x films over the complete range of stoichiometry, $0 < x < 2$, prepared. These films were of excellent uniformity in both thickness and index of refraction. An incidence frequency ratio of O_2 to Si ~ 500 was required for the formation of SiO_2 films.

The present data have been found to correlate well with ultrahigh vacuum oxygen adsorption experiments on clean single-crystal Si surfaces. A sticking coefficient for oxygen of 1.5 to 4×10^{-3} was inferred. The sticking coefficient was found to be independent of coverage (*i.e.*, surface stoichiometry). An appropriate model was deduced to be physisorbed oxygen in a mobile precursor state prior to chemisorption. Such a model yields a consistent explanation of the temperature dependence of the stoichiometry of reactively sputtered oxides in general and SiO_x in particular. These results demonstrate that fundamental information concerning the interaction of oxygen and various elements is accessible through systematic reactive deposition experiments in which the reaction is localized to the deposition surface.

ABSTRACT

CdS films were grown by spray pyrolysis in a nitrogen atmosphere in an attempt to reduce the oxygen contamination and therefore the resistivity. This would reduce the loss due to series resistance in solar cells fabricated from them. It was determined that the oxygen contamination could not be reduced in this way due to the fact that a major source of oxygen is the solvent, water. Further, the films were found to contain more chlorine, carbon, and, in some instances, tin than was previously thought. It is suggested that these impurities are responsible for the resistivity of SP films being more strongly affected by oxygen adsorption than are vapor deposited or sintered films, and the resistivity of SP films being extremely sensitive to the deposition temperature of the film.

The spray pyrolysis (SP) (1-3) method for preparing CdS films is an economically attractive method for producing CdS based solar cells (4-8) because it can easily be scaled up for mass production, and the deposition temperature of 320°-450°C is relatively low. However, because the starting materials contain many different elements, the chemicals are in aqueous solution, and the films are grown in air, the potential for film contamination is great.

One of the primary contaminants is thought to be oxygen adsorbed on the surface and at the grain boundaries (2, 3). The oxygen increases the resistivity by decreasing both the carrier concentration and the mobility with the latter effect being more pronounced (2, 3, 9). Further, the effect can be enhanced by heating in air (2, 3), or an oxygen atmosphere (9), and it can be reduced by heating for 5 min at 400°C in H₂ or by heating in a vacuum or a nitrogen ambient. That the SP films do contain a substantial amount of oxygen has been shown by Auger studies (10). Also, the authors concluded that the oxygen contamination was a direct result of growing the films in air.

The larger resistivity of the as-grown films reduces the solar efficiency through a higher series resistance and, therefore, a smaller fill factor. The efficiency can be increased by the hydrogen anneal, but this is a somewhat expensive and dangerous procedure. In this work we investigated the possibility of eliminating this step altogether by growing the films in a nitrogen ambient and thereby removing the source of the oxygen contamination. We did this by comparing the light and dark resistivities, the film composition as determined by XPS measurements, and x-ray diffractometer 2 θ scans of air grown and nitrogen grown films.

Our efforts to eliminate the oxygen contamination were not successful, and we show that this is due to water from the aqueous solution being the primary contamination source. Further, we show that the films contain more chlorine and carbon than was previously thought, and speculate that other compounds form from these elements, and they enhance the sensitivity of the film's resistivity to oxygen adsorption and temperature changes.

Experimental Procedure

The apparatus consisted of a liquid tin bath heated by a hot plate inside a bell jar, a spray system, and a cradle that could be used to raise or lower the substrate. The hot plate was set such that the surface of the glass substrate resting on top of the tin bath was 340°C when there was no spray present. This temperature was chosen because Ma and Bube (3) determined that the conductivity at this substrate temperature is at a local maximum, and other investigators have used a similar deposition temperature (4, 10).

Key words: solar cells, oxygen adsorption, impurities, XPS, x-ray diffraction.

The spray solution, which is identical to that used by Ma and Bube, was equimolar 0.1M cadmium chloride (CdCl₂) and thiourea [CS(NH₂)₂]. It was difficult to dissolve the CdCl₂ in the distilled water so it was necessary to heat the solution.

The solution was pumped at 0.5 ml/min by a syringe pump, and it was atomized into a fine spray by air or dry nitrogen flowing through a stainless steel nozzle located 7 in. above the substrate. At this height the spray coated the substrate uniformly. A spray catch was used to protect the substrate until the spray system reached its steady state (~2 min). The polygard plastic tubing carrying the solution was water cooled by a copper coil wrapped around it, and it was further protected from the heat by aluminum foil.

The substrates were squares 1 cm on a side cut from microscope slides. They were thoroughly washed in a glass cleaning solution and then repeatedly rinsed in distilled water.

In a typical run the substrate was loaded into the cradle, the bell jar was lowered, the system was in some instances purged with dry nitrogen (<1 ppm O₂), the power was turned on, the spray was turned on when the substrate reached its steady-state temperature (~20 min), the spray catch was removed after the air bubbles had been purged from the solution line, the film was deposited for 10 min (to a thickness of ~7 μ), the spray catch was set in place, the spray and power were turned off, and the substrate was allowed to cool off either above (fast cool) the tin bath or on (slow cool) it. Some of the films were then annealed in air at 400°C for 30 min or in dry nitrogen for 5 min at 400°C.

Ohmic contacts were made to some films by depositing indium spots 0.7 mm in diameter (*d*) and 1.6 mm apart (*l*), and then annealing the film in a N₂ atmosphere at 225°C for 5 min. It was found that it was easier to make contacts to the air-grown films than it was to the N₂-grown films. The contacts were assessed to be ohmic when the *I-V* curves were linear. The sheet resistance, *R*, in the dark and under room illumination was then determined, and the resistivity, ρ , was calculated using the relationship

$$\rho = Rdt/l$$

where *t* is the film thickness. The thickness was measured using an SEM. The SEM was also used to examine the film morphology. An attempt was also made to measure the carrier concentration and the mobility using a Hall effect apparatus and the van der Pauw technique.

Three XPS profiles of four separate films were taken. One profile was taken at the surface, another after 100Å of material had been sputtered off, and a third after 500Å had been removed. The elements present were identified, and their concentrations were computed from their peak heights using known cross sections. Of the four films examined one was air grown, slow cooled (AS); another was air grown, fast cooled (AF); the third was air

Fig. 1. SEM micrograph of the film morphology (1250 \times)

grown, fast cooled, nitrogen annealed (AFN); and the last was nitrogen grown, slow cooled (NS).

X-ray diffractometer 2θ scans were made to determine if the cubic and the hexagonal phases of CdS were present, and to see if other crystalline materials were present. $\text{CuK}\alpha$ radiation was used in this study. A film was prepared under one of the four conditions (ANF, NS, AF, or AS) examined, annealed in air, and then re-examined. In addition, the AS film was examined after a 2 min wash in distilled water and after a 5 min wash.

Experimental Results

The morphology of the films grown under different conditions was quite similar. A representative example is shown in Fig. 1. This morphology is similar to that seen by Alaei and Rouhani (10).

The resistivities of films grown under similar conditions could vary up to an order of magnitude. However, there were trends, and these are illustrated in Table I where the dark and light resistivities of a sequence of films (NS, AF, AS, and AFN) are listed. There it is seen that the NS resistivity is less than the AF resistivity which, in turn, is less than the AS resistivity. Also, the AFN resistivity is similar to that of the NS sample. The results for the Hall effect measurement on an AS film were that $\mu = 66 \text{ cm}^2/\text{V}\cdot\text{sec}$ and $n = 2.1 \times 10^{14} \text{ cm}^{-3}$. This measurement yields a resistivity of $453 \text{ }\Omega\cdot\text{cm}$ which is larger than the resistivity measurements made on similar films using the other resistivity measurement technique.

The XPS data in Table II, like the Auger data of Alaei and Rouhani (10), show that the films contain large amounts of oxygen, chlorine, and surface carbon. Perhaps the most striking feature is that the nitrogen-grown film contains more, not less, oxygen than the other films. In addition, it contains tin throughout whereas none of the other films do. Another important feature is that all of the films contain surface carbon, but only the annealed film contains carbon at the 500 Å depth.

The diffractometer 2θ scans for $23^\circ < 2\theta < 33^\circ$ are shown in Fig. 2-5. There it is seen that both the cubic phase, represented by the (200) ($2\theta = 31^\circ$) peak, and the hexagonal phase, represented by the (10 $\bar{1}$ 0) ($2\theta = 25^\circ$) and (10 $\bar{1}$ 1) ($2\theta = 28.5^\circ$) peaks, are present. However there are two additional peaks at 24.5° and 30.5° (indicated by the arrows) in

all of the as-grown films except the NF film, and these peaks are eliminated by the anneal in the NSA and AFA films and are reduced in the ASA. They are further reduced in the latter film by the 2 min wash in distilled water and are eliminated by the 10 min wash. It can also be seen that the anneal increases the peak heights of most of the CdS peaks.

Discussion

Our resistivity data support the suggestion that the resistivity is increased by adsorbed oxygen (9, 11-13). There should be the most adsorbed oxygen in AS films, less in AF films, and the least in NS films. Also, the similarity of the NS and ASN resistivities indicate that at least some of the adsorbed oxygen can be removed by an anneal in nitrogen (9).

Fig. 2. 2θ diffractometer scans for a nitrogen grown, fast cooled film (a) in the as-grown condition and (b) after a 30 min air anneal.

Fig. 3. 2θ diffractometer scans for a nitrogen grown, slow cooled film (a) in the as-grown condition and (b) after a 30 min air anneal.

The mobility calculated from the Hall effect data is comparable, but the carrier concentration is a couple of orders of magnitude less than those of Ma and Bube (3). One possible explanation for our small carrier concentration is that the films are not homogeneous as they must be in order for the van der Pauw method to be applicable.

Fig. 4. 2θ diffractometer scans for an air grown, fast cooled film (a) in the as-grown condition and (b) after a 30 min air anneal.

Fig. 5. 2θ diffractometer scans for an air grown, slow cooled film (a) in the as-grown state, (b) after a 30 min anneal in air, (c) after a 30 min air anneal and a 2 min wash in distilled water, and (d) after the film was washed for 10 min.

This could also be why the resistivity measurements made using the van der Pauw technique were larger. This explanation is plausible because the films contain excessive amounts of oxygen and chlorine, and in some instances a second phase is detected.

According to the XPS measurements, there is a substantial amount of oxygen present even when the films are grown in nitrogen. The likely explanation is that a major source of oxygen contamination is the solvent, water. Moreover, the nitrogen-grown film contains more oxygen because it has more tin which is better able to getter the oxygen. It contains more tin since the tin bath is not coated by a protective oxide film. That having a metal present which can getter oxygen increases the oxygen content, was also observed by Alae and Rouhani (10), who found that films containing much indium also contained more oxygen. The tin and the extra oxygen present in the nitrogen grown films could also be responsible for the greater difficulty in making ohmic contacts to them.

Even though the nitrogen-grown films have more oxygen incorporated into them, they have lower resistivities. We speculate that this is due to oxygen being gettered from the CdS film by the extra tin, and also due to less oxygen being adsorbed during the cool down. Most of the resistivity changes caused by oxygen have been attributed to adsorbed oxygen, not oxygen incorporated into the lattice.

Others have also determined that the films contain an excessive amount of chlorine (6, 10). We were unable to determine in what form the chlorine was present. We did look for CdCl₂ diffraction peaks but detected them only when a white film formed when the spray was not a fine mist.

The surface carbon contamination was also observed by others (6, 10). Carbon was found at the 500Å depth only in the annealed sample so it must be removed by the formation of gaseous species. The anneal does drive some of the carbon in, and this could be a factor in the resistivity changes.

The extra x-ray peaks at 24.5° and 30.5° indicate that a phase other than the CdS phases is present. We use the word indicate because the (200) and (10 $\bar{1}$ 0) peaks appear to split. However, the unknown peaks indicated by the arrows do not always appear, and can be reduced or eliminated by an anneal or by rinsing the film in water. We thus attribute these variable peaks to a second phase. This phase is eliminated or its concentration is greatly reduced by the air anneal possibly because it goes into solution at the higher temperature, and it is removed by washing because it is water soluble. An extra x-ray peak was observed by Ma and Bube (3) who attributed it to a (220) reflection of the rock salt CdS phase, and Alae and Rouhani (10) found some extra peaks which they attributed to hydrated CdCl₂. We are not able to compare these results with ours because in neither case did they list the 2θ values.

There are a number of experimental observations that can be explained by these "impurity phases." First, the dark resistivity in the SP films (2, 3, 9) is much more sensitive to oxygen adsorption than either evaporated (3, 14) or sintered CdS (15) films because the impurities greatly enhance the effect. Also, the extreme sensitivity of the dark resistivity to the deposition temperature (3) can be

attributed to the precipitation and dissolution of the "impurity phases." The dependence the resistivity has on the state the impurities are in can also be used to explain the effects the deposition rate has on the resistivity that were observed by Ma and Bube (3).

Other observations made from the x-ray data are, in general, similar to those of others. These include that there is a substantial amount of the cubic phase present in films deposited at 340°C as is evidenced by the existence of the (200) peak (1, 3, 16, 17), there is not a strong preferred orientation in the hexagonal phase as is indicated by the simultaneous appearance of the (10 $\bar{1}$ 0) and (10 $\bar{1}$ 1) peaks (1), and the peak heights are enhanced by an air anneal possibly due to an increase in the film crystallinity (1). There is, however, some preferred orientation as is indicated by the relative peak heights. If the orientation were completely random the 10 $\bar{1}$ 1/10 $\bar{1}$ 0 ratio would be 4/3 and the 111/200 ratio would be 5/2. This, clearly, is not the case as the (10 $\bar{1}$ 0) peak heights are larger than the (10 $\bar{1}$ 1), and the (200) peak heights are larger than the (111).

Acknowledgments

Naval Research Laboratory, Washington, DC 20375

ABSTRACT

A number of iron and iron arsenide films have been grown using pentacarbonyl iron and arsine by conventional organo-metal chemical vapor deposition (OM-CVD) on single-crystal GaAs. Auger sputter profile on a 1240Å-thick iron arsenide sample gave a composition consistent with the intended compound, FeAs₂, a narrow-gap semiconductor. Infra-red transmission data on the same film yielded an optical gap of 0.16 ± 0.01 eV, which compares with the known electrical gap of 0.22 eV for bulk FeAs₂. An apparent catalytic action of pentacarbonyl with arsine allows the iron arsenide to form from arsine at low temperatures near 300°C. The low temperature of growth suggests the possibility of forming heterostructures between a narrow-gap semiconductor and a ferromagnetic film. Such a structure was successfully grown on GaAs.

Recent work by Prinz and Krebs (1) has shown that high quality epitaxial Fe can be grown on GaAs surfaces for film thicknesses less than 1 μm. These thin epitaxial films were deposited by the molecular beam epitaxy (MBE) technique using high purity elemental Fe as the source. In those experiments, the optimum growth conditions, as determined by reflection high energy electron diffraction and ferromagnetic resonance occur for substrate temperatures between 175°-225°C.

More recently, Kaplan and Bottka (2) have shown that high quality epitaxial Fe on GaAs surfaces can also be grown using chemical vapor deposition (CVD) by decomposing the organo-metal (CO)₅Fe thermally on the substrate at 200°C in an ultrahigh vacuum chamber. In that UHV-OM-CVD process, *in-situ* Auger electron spectroscopy (AES) and low energy electron diffraction (LEED) analysis was used to characterize the growth process of the Fe film. Those studies showed that Fe growth on GaAs proceeds by layer rather than island formation. The LEED data elucidated the nature of the atomic arrangement of Fe on GaAs for various surface orientations for the first few monolayer coverage.

In the present work, we investigated the growth of films of iron and one of its compounds, the narrow-gap semiconductor FeAs₂, on GaAs by the more conventional technique of OM-CVD, which uses H₂ as a carrier gas to transport the OM species to the substrate. The conventional technique is simple, efficient, and amenable to large scale application.

We have found that with care normal OM-CVD technique does allow the production of Fe and FeAs₂ films on GaAs. Indeed, to our knowledge, this study has produced the first synthesis of FeAs₂ in thin film form. This synthesis is apparently aided by a catalytic enhancement of the decomposition of the arsenic source (AsH₃) in the presence of the iron source, pentacarbonyl iron (CO)₅Fe, which allows FeAs₂ to be formed at a relatively low substrate temperature.

Experimental

The vertical OM-CVD reactor used in these experiments (Fig. 1) is a conventional setup used to grow high quality GaAs and AlGaAs/GaAs on GaAs substrates but with the addition of the (CO)₅Fe source added to the manifold. The reactor gas manifold and mixing system were constructed from passivated stainless steel tubing. Parts were either welded or joined with vacuum-compatible VCR fittings. The system utilizes mass flow controllers for control of the various gaseous flow rates and pneumatically controlled bellow valves for switching all gaseous flows.

The carrier gas used was ultrahigh purity, palladium-purified hydrogen. The arsenic source was ultrahigh pu-

rity arsine contained in a commercially supplied high pressure cylinder. The 99.5%-grade (CO)₅Fe from Alfa Ventron was twice vacuum distilled and transferred into a stainless steel cylinder/bubbler which was held at 24°C during growth. All saturated vapors and gases were mixed and diluted with H₂ in a manifold prior to introduction into the reactor.

The GaAs substrates were undoped liquid-encapsulated Czochralski (100) oriented wafers which were bromine-methanol polished, cleaned, and etched in 1:1 NH₄OH:H₂O prior to loading into the reactor.

The cold-walled growth vessel was a quartz cylinder coupled to the manifold with ultratorr fittings. The sample rested on a silicon carbide-coated graphite susceptor and was RF inductively heated.

Growth of Fe Films

Typical growth conditions for Fe on GaAs are shown in Table I. Iron films grow easily in the temperature range 150°-300°C, and the optimum temperature is at 200°C. This is similar to that found in MBE and in UHV-OM-CVD experiments. The growth rate depends upon the partial pressure of (CO)₅Fe in the reactor. For typical flows of 15 cm³/min of hydrogen through the (CO)₅Fe bubbler and 1 l/min of H₂ dilution, the growth rate was about 200 Å/min, as determined from Dektak measurements.

The sample temperature and its surface IR emissivity was monitored during growth with an Iacon pyrometer¹ operating in the 2-2.6μ spectral range. At 200°C, and just prior to growth, the value of the GaAs substrate emissivity was 0.7. Upon initiation of growth, this value dropped to 0.29, indicating the formation of a metallic, infrared reflecting film. The grown Fe films are highly reflective (Fig. 2), show no indication of tarnishing with time, and are very strongly bonded to the GaAs substrate. A total of 15 Fe/GaAs samples were grown.

Growth of FeAs₂ Films

There are a number of compounds which can be formed between iron and arsenic, including Fe₂As, FeAs, and FeAs₂. The last compound, iron di-arsenide, appears naturally as the mineral loellingite (3), and its growth is favored by an arsenic-rich environment during formation. It is a narrow-gap semiconductor whose properties have been partially studied.

Bulk FeAs₂ has been grown (6) by the vapor transport method in the temperature range 600°-800°C, but, to our knowledge, thin film FeAs₂ had never been previously synthesized. FeAs₂ has the cell dimension (4-7) of $a = 5.300\text{Å}$, $b = 5.983\text{Å}$, and $c = 2.882\text{Å}$, an enthalpy of formation of 10.4 kcal/mol (8, 9), specific gravity of 7.4 (10), and is diamagnetic (11, 12).

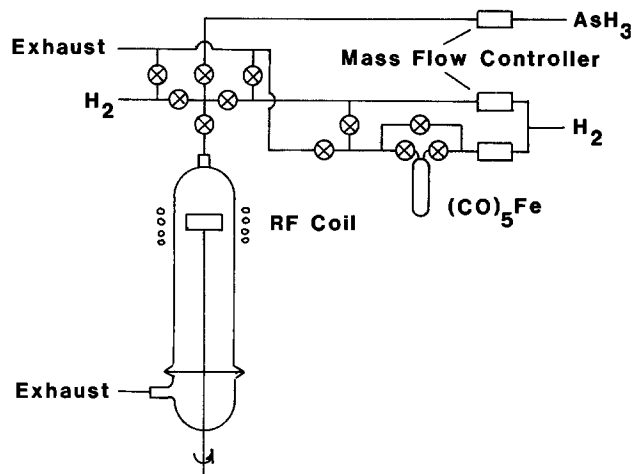

Fig. 1. OM-CVD system used in the growth of Fe and FeAs₂ on GaAs. Arsine and hydrogen enter from tanks located to the right and are exhausted through a bubbler and a burner (neither shown) to the left. The substrate is rotated at approximately 30 rpm.

Table I summarizes the growth conditions of FeAs₂ on GaAs. These films grow in the temperature range 200°-400°C, and the optimum growth temperature seems to be near 300°C, considerably below the vapor transport temperature used for bulk growth (6). We believe that the low temperature growth of FeAs₂ in our OM-CVD system may result from a catalytic action of Fe or (CO)₅Fe on the decomposition rate of AsH₃. Schlyer and Ring (13) have observed pyrolytic decomposition of (CH₃)₃Ga and PH₃ over product-crusted walls at 240° and 270°C. On the basis of their analysis, the authors propose that AsH₃ and (CH₃)₃Ga can catalytically decompose at low temperatures on GaAs surfaces after surface adsorption and formation of complexes. A similar surface catalysis may be operable in our case.

The grown films are highly reflective, and their emissivity during growth is about 0.7, similar to GaAs and distinctly different from the surface emissivity of the growing iron films. The high emissivity is consistent with the low diffuse reflectivity of loellingite (14). The iron di-arsenide films have low surface conductivity, are soft, and show no signs of degradation after nine-month exposure to the atmosphere.

X-ray diffraction measurements at grazing incidence was attempted to obtain crystallographic information about the thin FeAs₂ film. However, results were inconclusive due to the strong background signal of the GaAs substrate.

Figure 3 shows the sputter Auger profile of one of the six FeAs₂-grown films. Atomic concentration estimates from this data indicate that the preferred stoichiometry is nearer FeAs₂ rather than FeAs or Fe₂As, two other possible formations. The interface between the film and the substrate is about 80Å wide. The Ga and carbon peak was monitored but not found in the film. The observed 20% drop in the As atomic concentration in going from FeAs₂ into GaAs is near the 23% atomic concentration difference expected between the two compounds. Interferometric

Table I. Growth condition for Fe and FeAs₂ on GaAs

	Fe	FeAs ₂
Reactor pressure (torr)	760	760
Growth temperature (°C)	150-300	200-400
Optimum growth temperature (°C)	200	300
Total gas flow (l/min)	1.0	1.1
(CO) ₅ Fe source temperature (°C)	24	24
H ₂ /(CO) ₅ Fe bubbler flow (cm ³ /min)	15	10
Arsine flow (cm ³ /min)	—	90
Growth rate (Å/min)	200	80

Fig. 2. Typical Fe film grown on single-crystal GaAs

measurements on the sputtered crater gave estimate of the film thickness and its growth rate. Matrix effects were taken into consideration in presenting the data in Fig. 3. The effect of preferential sputtering in stoichiometric ratio is not known.

Infrared transmission measurements were conducted on the grown 1240Å film sample profiled in Fig. 3 and on a companion GaAs single-crystal substrate. Figure 4 presents the results in terms of the normalized ratio of sample transmittance to that of the substrate over the region from 3.5 to 20 μm. The electrical gap of FeAs₂ determined from the temperature dependence of a bulk sample is 0.22 eV (11) and that energy lies almost exactly at the energy where the normalized transmission has risen half way. If we define the optical gap conventionally as the energy at which the absorption coefficient is 10⁴ cm⁻¹, and neglect interference effects in the optically thin sample, the optical gap of the deposited film is 0.16 ± 0.01 eV. The observed gap energy difference of 0.06 eV between the bulk and our film stems from the different methods of determining gap energies. The bulk conductivity *vs.* temperature measurement gives the extrapolated gap energy at 0 K, whereas our optical data were

Fig. 4. Normalized ratio of sample transmittance (FeAs_2) to that of the GaAs substrate in the infrared. Arrow indicates the electrical gap energy (11) of FeAs_2 . Uncertainty in the measurement is shown by the bar at the right lower corner.

taken at 300 K. The 2×10^{-4} eV/K gap variation is close to the value observed in most semiconductors. The sample transmission data reveal repeatable optical structures within the measured range which are absent in the GaAs substrate and which appear to be real properties of the film.

Summary

Conventional OM-CVD has been used to grow high quality films of the metal Fe and one of its compounds, FeAs_2 , upon single-crystal GaAs. The successful growth of the narrow-gap semiconductor FeAs_2 raises the possibility that less well-known narrow-gap semiconductors of the type (Fe, Ni, Co)-(P, As, Sb) may be possible. In addition, the growth of compatible Fe and FeAs_2 films within the same OM-CVD system offers promise that heterostructures involving metal and narrow-gap semiconductors may be fabricated in a simple manner by OM-CVD. This possibility is accentuated by the low temperature required at which FeAs_2 grows from arsine in the presence

of pentacarbonyl iron. Because of this relatively low growth temperature, attempts were made to deposit alternate thin layers of FeAs_2/Fe on GaAs. We were successful in a preliminary growth of a $\text{FeAs}_2/\text{Fe}/\text{FeAs}_2/\text{Fe}$ heterostructure, whose overall thickness was approximately 150Å, on single-crystal GaAs. The resulting heterostructure has a brilliant luster, and is strongly bonded and lasting. Further work is needed to characterize its properties.

Oxygen-Doped Molybdenum Films for MOS Gate Application

Shin-ichi Ohfuji, Chisato Hashimoto, Takao Amazawa, and Junichi Murota

Nippon Telegraph and Telephone Public Corporation, Atsugi Electrical Communications Laboratory, 1839, Ono, Atsugi-shi, Kanagawa Pref., 243-01 Japan

ABSTRACT

Intentionally oxygen-doped Mo films (MoO_x) for MOS gate electrodes are investigated to eliminate the penetration of implanted As ions into the silicon substrate through the gate electrodes and gate oxides. The MoO_x films are prepared by reactive sputtering of Mo in a mixture of Ar and O_2 gases. Depth profiles of As ions and MOS C-V curves are measured to estimate stopping properties. For as-deposited MoO_x films, whose oxygen concentrations are higher than 20 atom percent (a/o), As ion penetration depth is within 0.15 μm under 100 keV As ion implantation. This depth is about one third of that in normal Mo films. This excellent stopping property can be attributed to the nearly amorphous structure, which suppresses As ion channeling in the films resulting from oxygen doping. The resistivity of MoO_x films with 39 a/o oxygen after annealing at 1000°C for 30 min is 25 $\mu\Omega\text{-cm}$, which is only three times as large as that for normal Mo films. In MoO_x gate MOS structures, MOS characteristics are independent of oxygen concentrations in the films, and are almost the same as the characteristics for normal Mo gate electrodes.

Thin molybdenum (Mo) films have been attracting much attention as self-aligned gate electrodes and interconnections for highly packed MOSFET integrated circuits (1, 2). The reason for this is their low resistivity, high temperature resistance, and high density (10.3 g cm^{-3}), which is beneficial for ion implantation masking materi-

Key words: metals, integrated circuits, ion implantation, sputtering.

als. Nozaki, however, has reported that unwanted depletion modes have been observed in Mo gate MOSFET characteristics when arsenic (As) ion implantation is carried out using Mo gates as masks (3). Fujinaga has pointed out that the main cause of this phenomenon is the anomalous penetration of As ions into the silicon substrate caused by As ion channeling in some columnar Mo grains (4). To improve stopping properties, silicon nitride (5) and molybdenum nitride (6) coatings on Mo films, as

well as a direct nitridation technique for Mo gate electrodes (4, 7), have been proposed.

The authors propose the adoption of oxygen-doped Mo (MoO_x) gate electrodes having a simple formation process for a powerful masking material against ion implantation. Degradation in conductivity and MOS characteristics is shown to be low compared with normal Mo gate electrodes. MoO_x films were prepared by the reactive sputtering of Mo in an Ar and O₂ gas mixture. The electrical and structural properties of these films were investigated, and the effect of oxygen doping into Mo films on MOS characteristics was examined using MoO_x-gate MOS capacitors.

Experimental Procedures

MoO_x films (0.2-0.6 μm thick) were deposited on oxidized silicon wafers at room temperature in a mixture of Ar and O₂ gases using an RF planar magnetron sputtering apparatus. A pure Mo target, with nominal purity of 99.95%, was used. Prior to deposition, the deposition chamber was evacuated to 3×10^{-7} torr by a turbo molecular pump. The oxygen concentration (C_o) in the MoO_x films was controlled within the range of 3-39 atom percent (a/o), by varying the partial pressure of the O₂ gas introduced into the chamber between 0 (undoped) and 2.5×10^{-4} torr. A 3 a/o concentration was observed as a background value when no O₂ gas was introduced, at which the partial pressure of residual O₂ gas in the Ar-introduced chamber was less than 5×10^{-8} torr, as measured by a quadrupole mass analyzer. The partial pressure of Ar gas and RF deposition power were 7.5×10^{-3} torr and 1.5 kW, respectively. After deposition, several of the samples were annealed in the temperature range of 600°-1000°C for 30 min in an N₂ ambient.

The C_o was measured by Auger electron spectroscopy (AES) for the as-deposited state using sensitivity corrections for the constitutional elements (8). The measurement error in this method was at most several atom percent; the measurement accuracy of the relative concentration among samples was better. The depth distribution of oxygen in the films was uniform and changed very little even after annealing at 1000°C for 30 min.

Arsenic ions were implanted at room temperature into the MoO_x films and gate electrodes of MOS capacitors at 100 keV energy to a dose of 1×10^{16} ions-cm⁻². The implantation angle was 6° from the normal to the sample surface. The arsenic depth profiles were measured by SIMS (Cameca, IMS-3F).

The film structure was investigated using an x-ray diffractometer. The average grain size for Mo and molybdenum oxide (in this experiment, only MoO₂) was determined from the broadening of the diffraction peaks of Mo(211) and MoO₂(110)(111), respectively, using Scherrer's equation (9). The morphology of the surfaces and cleaved sections of the films were observed by a scanning electron microscope (SEM).

The electrical resistivity of the films was determined by a four-point probe method in conjunction with thickness measurements using a Talystep (Rank Taylor Hobson).

To clarify the effects of oxygen doping into Mo gate electrodes on MOS characteristics, basic MOS capacitor structures were fabricated on p-type (5 Ωcm) (100) silicon wafers. The gate oxide was grown in dry O₂ at 950°C to 40 and 140 nm thick. Step etching was carried out on the 140 nm thick oxide to have four oxide steps. After the deposition 0.2 μm-thick MoO_x films onto the oxide, gate electrode areas 500 μm square were defined by photolithography and wet chemical etching in a mixed solution of H₃PO₄, HNO₃, and CH₃COOH. Several wafers were implanted with As ions, and both the implanted and unimplanted samples were annealed in N₂ at 1000°C for 30 min. Next, low temperature annealing in a mixture of H₂ and N₂ at 450°C was carried out for 30 min to reduce both interface trap density and fixed oxide charge density in the MOS structures. Under these annealing conditions, the molybdenum oxide in the films was not reduced.

The work function of MoO_x gate electrodes was obtained by measuring 1 MHz C-V flatband voltages as a function of gate oxide thickness. In addition, interface trap densities were estimated by quasistatic C-V measurement.

Fig. 1. Depth distribution profiles of implanted As ions in 0.6 μm thick MoO_x films. Smooth curves represent LSS theoretical distributions for C_o = 0 and 35 a/o.

Results and Discussion

Arsenic ion stopping properties.—Figure 1 shows depth distribution profiles for the As ions implanted into 0.6 μm thick MoO_x films. For comparison, two calculated profiles are shown as smooth curves. These profiles represent LSS theoretical distributions in samples with C_o = 0 and 35 a/o. Here, it is assumed that (i) film structures are amorphous, (ii) ion distribution profiles in the films are Gaussian, and (iii) the density for MoO_x films, d_{MoO_x} (g cm⁻³), is calculated from the bulk densities of Mo ($d_{\text{Mo}} = 10.3$ g cm⁻³) and MoO₂ ($d_{\text{MoO}_2} = 6.44$ g cm⁻³) in accordance with C_o (a/o), and is expressed as

$$d_{\text{MoO}_x} = \frac{(100 - \frac{3}{2} C_o) A_{\text{Mo}} + \frac{C_o}{2} A_{\text{MoO}_2}}{(100 - \frac{3}{2} C_o) \frac{A_{\text{Mo}}}{d_{\text{Mo}}} + \frac{C_o}{2} \cdot \frac{A_{\text{MoO}_2}}{d_{\text{MoO}_2}}} \quad [1]$$

where A_{Mo} is the atomic weight of Mo (95.9), and A_{MoO_2} is the molecular weight of MoO₂ (127.9). For MoO_x films with C_o = 3 a/o, the deep penetration of As ions is observed. At the depth of 0.3 μm, which is a typical gate electrode thickness in refractory metal gate MOS devices (10), As ions are still detected and an exponentially distributed tail is shown. This tail is probably caused by As ion channeling in columnar Mo grains in the films (4). With an increase in C_o from 3 to 35 a/o, the As concentration near the film surface increases, and the penetration depth becomes shallower. Here, the As concentration below 2×10^{18} cm⁻³ is due to background noises in the SIMS measurements. For films with C_o = 35 a/o, the experimentally determined distribution comes closer to the LSS theoretical distribution for a density of 8.6 g cm⁻³, calculated from Eq. [1].

The excellent stopping properties of MoO_x films were also confirmed by the MOS C-V measurement of MOS capacitors, as shown in Fig. 2. For examples with C_o = 5 a/o, the C-V curve for implanted capacitors shifts remarkably to the negative direction of gate bias from that for unimplanted capacitors. For comparison, the C-V curve for implanted capacitors with C_o = 22 a/o is also shown in Fig. 2. The C-V curve roughly agrees with that for unimplanted capacitors with C_o = 5 a/o. When C_o was higher

Fig. 2. 1 MHz C-V curves for $\text{MoO}_x(0.2 \mu\text{m})/\text{SiO}_2(40 \text{ nm})/\text{Si}$ capacitors surrounded by a $0.85 \mu\text{m}$ -thick oxide guard band. Several samples were implanted with As ions at 100 keV energy to a dose of $1 \times 10^{16} \text{ ions-cm}^{-2}$.

than 20 a/o and the MoO_x films were thicker than $0.2 \mu\text{m}$, no large shift in the C-V curves was observed after As ion implantation. The C-V shift in the samples with $C_o = 5 \text{ a/o}$ is probably caused by interface traps at the SiO_2/Si interface, as well as changes in carrier concentration at the silicon substrate surface resulting from the penetration of As ions into the substrate (11). Therefore, it is suggested that oxygen doping ($C_o = 20\text{-}35 \text{ a/o}$) into Mo films in the film preparation process is very effective for preventing the penetration of implanted As ions into the silicon substrate.

Film structure.—The remarkable improvement in the stopping properties of MoO_x films is presumed to be due to the structural change caused by the doped oxygen. Figure 3 shows x-ray diffractometer traces for as-deposited MoO_x films with $C_o = 3, 22,$ and 35 a/o . It is found that the film with $C_o = 3 \text{ a/o}$ (Fig. 3a) consists of preferentially oriented $\langle 110 \rangle$ Mo grains perpendicular to the film surface. The intensities of the (110) peak and other diffraction peaks from Mo become lower with an increase in C_o (Fig.

3b) and almost disappear at $C_o = 35 \text{ a/o}$ (Fig. 3). This suggests that the doped oxygen suppresses Mo grain growth during deposition, and makes the films nearly amorphous. Therefore, the high stopping properties of MoO_x gate electrodes can be attributed to the amorphous structure which suppresses the ion channeling effect in Mo grains.

Next, annealing effects on film structures were investigated for normal process temperatures. Figure 4 shows x-ray diffractometer traces for films with $C_o = 22 \text{ a/o}$ annealed at 1000°C . Both MoO_2 and Mo are found to be structural components, and the Mo(110) reflection intensity is higher than that for as-deposited films (Fig. 3b). The diffraction peaks for MoO_2 were also observed when C_o was above 7 a/o . Figure 5 shows the reflection intensities for Mo and MoO_2 as a function of annealing temperature for films with $C_o = 3$ and 39 a/o . For films with $C_o = 39 \text{ a/o}$, abrupt increases in both $\text{MoO}_2(110)(111)$ and Mo(110) peak intensities are observed in the temperature range of $600^\circ\text{-}800^\circ\text{C}$. This result indicates that the doped oxygen in the films, which may exist as a Mo-O solid solution at the boundaries of fine Mo grains before annealing, crystallizes into a MoO_2 accompanied with Mo grain growth in the range between 600° and 800°C . Above 800°C , the $\text{MoO}_2(110)(111)$ peak intensity almost reaches saturation. The Mo(110) peak intensity increases slightly in the same manner as for films with $C_o = 3 \text{ a/o}$. These results show that MoO_2 crystallization is almost completed in annealing below 800°C , whereas Mo grain growth continues at temperatures of over 800°C . Figure 6 shows directly observed SEM images of MoO_x films. The as-deposited films have flat surfaces and very fine grains (Fig. 6a and 6b), whereas an increase in grain sizes is observed after annealing at 1000°C (Fig. 6c and 6d). In these images, no difference can be seen between the samples with $C_o = 3 \text{ a/o}$ and those with $C_o = 39 \text{ a/o}$. Grain size for both Mo and MoO_2 after annealing at 1000°C , measured by x-ray diffraction, was about $0.15 \mu\text{m}$ diam for all samples. This is responsible for the lack of difference observed between the samples with $C_o = 3 \text{ a/o}$ and those with $C_o = 39 \text{ a/o}$.

From these results, it is concluded that by annealing at 1000°C , nearly amorphous MoO_x films become polycrystalline films composed of Mo and MoO_2 grains having almost the same diameters.

Electrical resistivity.—Figure 7 shows electrical resistivity for $0.33 \mu\text{m}$ thick MoO_x films as a function of annealing temperature. The resistivity, which increases as a result of oxygen doping for as-deposited films, decreases slightly after annealing up to 600°C . However, it decreases abruptly in the temperature range between 600° and 800°C , and saturates above 800°C . After annealing at 1000°C , a resistivity of $25 \mu\Omega \text{ cm}$ can be obtained for films

Fig. 3. X-ray diffractometer traces for as-deposited MoO_x films with (a) $C_o = 3 \text{ a/o}$, (b) $C_o = 22 \text{ a/o}$, and (c) $C_o = 35 \text{ a/o}$.

Fig. 4. X-ray diffractometer traces for C_o = 22 a/o films annealed in N₂ ambient at 1000°C for 30 min.

with C_o = 39 a/o, which is only 3 times as large as that for normal Mo films (C_o = 3 a/o, 9-10 μΩ cm). The resistivity of the MoO_x films can further be decreased close to that for pure Mo film by a high temperature annealing in either H₂ or a mixture of H₂ and N₂ (12). Indeed, a resistivity of 10 μΩ cm was obtained for C_o = 39 a/o by annealing at 1000°C in a mixture of H₂ (10%) and N₂ for 5 min.

The abrupt decreases in resistivity in the temperature range between 600° and 800°C (Fig. 7) agree well with the MoO₂ and Mo grain growth characteristics as shown in Fig. 5. On the other hand, the bulk resistivity for MoO₂ (90 μΩ cm) (13) is much higher than that for pure Mo (5.3 μΩ cm). Thus it is thought that the abrupt decreases in resistivity are attributed to the occurrence of electron conduction through the highly conductive Mo grains which grow in accordance with the conversion of doped oxygen into crystallized MoO₂.

For the resistivity of MoO_x films (C_o = 3-39 a/o) annealed above 800°C, it was found that it was nearly a linear function of the number of Mo grain boundaries per

unit length (reciprocal of average Mo grain size <D> in MoO_x films), when electron conduction through the highly resistive MoO₂ grains was eliminated. This elimination procedure was performed by subtracting an equivalent MoO₂ layer thickness, calculated from the C_o and bulk densities for Mo and MoO₂, from the total MoO_x film thickness. Furthermore, the extrapolated resistivity at 1/<D> = 0, which approximately represented the intrinsic resistivity of Mo grains in the films (14), was less than 8 μΩ cm for C_o = 3-39 a/o. This value is only 1.5 times as large as the bulk resistivity for pure Mo. From these results, it is suggested that, in addition to the highly resistive MoO₂ grains, the contribution of electron scattering at the Mo grain boundaries to film resistivity is relatively large compared with that due to lattice defects or impurity scattering in Mo grains. This is similar to the conduction mechanism in undoped Mo films (15).

Characteristics of MoO_x gate MOS structures.—An important parameter for MOS characteristics in new gate materials is the work function, which is obtained from the

Fig. 5. Variations in x-ray reflection intensities for Mo(110) peaks (C_o = 3 and 39 a/o) and MoO₂(110)(11T) peaks (C_o = 39 a/o) as a function of annealing temperature in N₂ ambient for 30 min.

Fig. 6. SEM images showing surfaces and cleaved sections of (a) and (b) as-deposited, and (c) and (d) 1000°C annealed MoO_x films with C_o = 3 and 39 a/o.

Fig. 7. Variations in the electrical resistivity of MoO_x films with C_o , = 3, 11, 22, and 39 a/o as a function of annealing temperature in N_2 for 30 min.

metal-semiconductor work function difference, ϕ_{MS} , given as an intercept of flatband voltage vs. oxide thickness, shown in Fig. 8. Prior to flatband voltage measurements, samples were annealed at 1000°C in N_2 for 30 min followed by low temperature annealing in a mixture of H_2 and N_2 at 450°C for 30 min. The difference in ϕ_{MS} values for MoO_x films with $C_o = 5$ -30 a/o is only 0.03V, which is within the experimental error. Therefore, the work function ($4.8 \pm 0.03\text{V}$) obtained from the ϕ_{MS} is almost independent of C_o . This result is comparable with the Mo and Mo nitride work function of $4.69 \pm 0.03\text{V}$, which is independent of the nitrogen concentration (16). Furthermore, this result suggests that $\text{MoO}_x/\text{SiO}_2$ interfaces in the MOS structures continue to be dominated by the contact between Mo grains and SiO_2 in spite of the existence of large MoO_2 grains in the gate electrodes. In addition, fixed oxide charge density (N_f) calculated from the slope of flatband voltage vs. oxide thickness relation, is as low as $2.3 \times 10^{10} \text{ cm}^{-2}$, and interface trap density (D_{it}) is less

Fig. 8. Variations in flatband voltages as a function of oxide thickness for MoO_x gate MOS capacitors with $C_o = 5, 22,$ and 30 a/o.

than $5 \times 10^{10} \text{ cm}^{-2} \text{ eV}^{-1}$. These results are also independent of C_o .

From these results, it is concluded that the effect of oxygen doping into the Mo films on MOS characteristics is negligible and that the good MOS characteristics of MoO_x gate MOS structures are confirmed.

Conclusion

The effects of oxygen doping on Mo films has been investigated from the viewpoints of As ion stopping properties, film structure, electrical resistivity, and MOS characteristics.

The penetration depth of implanted 100 keV As ions in MoO_x films decreases from $0.4 \mu\text{m}$ (in normal Mo films) to $0.15 \mu\text{m}$, with an increase in oxygen concentration (C_o) to higher than 20 a/o. This remarkable improvement can be attributed to the amorphous film structure, which suppresses the ion channeling effect in Mo grains.

The resistivity, which increased as a result of oxygen doping in as-deposited films, decreases abruptly after annealing above 600°C . After annealing at 1000°C , a value of $25 \mu\Omega \text{ cm}$ is obtained for $C_o = 39$ a/o, which is sufficiently low for MOS gate electrodes. The abrupt decrease in resistivity in the 600°C - 800°C range can be explained by the electron conduction through highly conductive Mo grains, which grow in size because of the conversion of doped oxygen into crystallized MoO_2 .

The work function of MoO_x gate electrodes in MOS structures is independent of C_o . The fixed oxide charge density and interface trap density are also sufficiently low. Therefore, it is concluded that MoO_x film is a possible metal gate material for overcoming As ion penetration observed in normal Mo gate structures. Moreover, this material is compatible with the polysilicon gate process.

Photoresist Adhesion Promoters for Gold Metallization Processing

J. N. Helbert

Motorola, Incorporated, Semiconductor Products Sector, Process Technology Laboratory, Phoenix, Arizona 85008

The final step in the fabrication of integrated circuits requiring lithographic pattern delineation is usually metallization. In this step, a metal film is deposited, lithographically patterned using a polymeric resist, then selectively etched, either wet chemically or dry, using the resist pattern mask (1). The result is an intricate metal line network connecting the appropriate transistors, resistors, and other devices of the integrated circuit (IC).

Two metals are widely used in IC metallization processes—aluminum and gold. While aluminum is attractive from a cost point of view, gold is very resistant to chemical corrosion and is also much less prone to the electromigration effect which becomes very important when metallization lines become very small, as is the case for very large-scaled IC's (1).

When using gold as the metallization layer, where metal patterns $2-3\ \mu\text{m}$ wide are concerned, it becomes imperative that the polymeric resist has excellent adhesion to that surface. Various (and sometimes intermittent) degrees of resist pattern adhesion failure to gold have been observed at Motorola in the fabrication of advanced bipolar circuits and RF modules. As a result, an extensive amount of work has been expended to find silane adhesion promoting agents for gold, and the results of this search are reported in this note.

Silane coupling agents for mineral surfaces are well known (2), but silane promoters for gold are virtually unknown for IC resist metallization processes. These agents promote polymer adhesion to mineral surfaces through the chemical interaction with surface silanol moieties encountered at the surfaces of these systems (2-4). Gold has a surface drastically different in that it does not possess these surface adhesion promoting sites because it is a noble metal and is essentially corrosion resistant (5). As an example for comparison, the surface of aluminum metal is known to be easily chemically oxidized, while gold does not oxidize even under O_2 plasma conditions (6). Therefore, coupling agents for which a different adhesion promoting mechanism is operative are needed more for gold than for oxidizing metals, minerals, and the synthetic dielectric layers encountered in electronic device fabrication.

A practical experimental approach for testing polymeric resist (*i.e.*, positive photoresist) adhesion during pattern development has been adopted. The test pattern (or metal etch mask) is one that yields a series of unexposed resist islands of varying dimensions from 0.5 to 5 μm wide and 4 to 20 μm long, surrounded by larger exposed and developed areas. Prior to resist spinning by conventional spinning techniques, the gold substrates were water rinsed and dried 30 min to 1 h at 200°C. Gold wafers, utilized for simulated wafer rework testing, were cleaned with acetone, followed by 10-30 min of O_2 plasma cleaning at 300W. The commercially available promoters (Petrarch Systems, Incorporated) were applied as dilute solutions 0.3-7% by weight in acetone. The promoter coated substrates were not thermally cured prior to photoresist (PC-129-SF or Allied P-2025) application. The photoresist, however, was cured 30 min at 90°C in air. Control substrates were not treated with promoters and usually exhibited 50-90% island image "lifting" when adhesion failure occurred (see Fig. 1). In some control tests no "lifting" occurred, but inferior adhesion was observed at pattern edges. Adhesion failure in control samples

occurred most frequently when the lithographic exposure was E-beam (Cambridge EBMF-II), but adhesion failure was also observed on optically (Cobilt 2020H) exposed control substrates.

When the gold testing substrates were primed with promoter solutions of silanes containing phosphorus (DPETS), carbonyl (TMSA), or sulfur (BTPTS) or (MPTS), no adhesion failure was ever observed (*i.e.*, 0% resist island loss) as is depicted in Fig. 2. Test wafers for all four systems were capable of withstanding 30-40% overdevelopment without incurring any test pattern island "lifting," and adhesion promotion on both new and reworked gold test wafers was achieved. Control samples, on the other hand, often failed even when the control substrates were underdeveloped, as is the case for the substrate pictured on the left-hand side of Fig. 1. Underdevelopment is indicated by resist nonclearing around the edges of the written outer squares.

Similarly dramatic adhesion enhancement has been demonstrated and reported for silane promoted silicon dioxide substrates (2-4, 7, 8). These results were achieved due to the chemical interaction of organosilane promoters with the surface silanols of that particular substrate system. Analogous surface moieties, aluminols ($-\text{Al}-\text{OH}$), are also present on oxidized aluminum samples, and good adhesion has been observed for this substrate due to chemical interactions between adhering polymeric films and these surface groups (6, 9). In contrast, gold surfaces are free of surface adhesion promoting groups like silanols as pointed out earlier; therefore, any photoresist adhesion enhancement observed for it must be attributed to a different and unique promotion enhancement mechanism. In fact, tests carried out with the halogenated, alkoxy or amino silanes successfully tested for improving resist adhesion to SiO_2 surfaces of Ref. (2-4, 8) failed to demonstrate improved

Fig. 1. Optical micrographs of "lifted" photoresist test images. The pointers mark areas where island images or parts of them are missing due to adhesion failure following exposure and development.

Fig. 2. Optical micrographs of gold test island images where photoresist adhesion has been promoted with TMSA. The areas around the gold island images have been ion-milled to the substrate and the photoresist has been removed by O_2 plasma etching.

adhesion to gold test wafers. Definitive improved resist image adhesion to gold was observed only with the four silane adhesion promoters listed above.

The improved lithographic resist adhesion to gold, observed for test wafers primed with the four silanes of this work, is attributed to a complexation or chemisorption mechanism. The $-C=O$ of TMSA, $-S-$ of BTPTS and MPTS, and $=P-$ of DPTS are moieties capable of acting as chelating or chemisorption sites for the molecular silanes; thus, creating layer to layer bonding with greater strength than that observed where just van der Waals interactions occur to the gold surface atoms. Polymeric adhesion of oxygen containing poly-

mers (e.g., $+CH_2-C(CH_3)-\overset{O}{\parallel}C-OCH_3$) to metal surfaces

has been recently attributed to metal-oxygen-polymer complexation, as evidenced by observed x-ray photo-

emission and infrared spectroscopic results which were consistent with a chelation-like interlayer bonding mechanism (9, 10). Although these studies do not deal with adhesion promoters per se, they do illustrate the principle of a weak chemical bonding mechanism at the interface between metal and organic and/or polymeric layers. There is no inherent reason why a silane containing oxygen would not interact similarly to yield a more organic-like and resist adhering gold metal substrate from one of less adhering. As for the silanes containing phosphorus and sulfur, it is well-known that stable gold complexes involving ligands containing these elements have been synthesized (5). Thus, gold has an affinity for chemical interaction with these elements and most probably with silanes containing them.

In conclusion, it is felt that the improved resist adhesion of this work is due to the chemical interaction of the chelating silanes to the gold surface-atoms, which creates an improved and adhering substrate to resist from one previously more chemically inert or non-adhering.

A 3.8 μm Period Sawtooth Grating in InP by Anisotropic Etching

C. J. Keavney¹ and Henry I. Smith

Massachusetts Institute of Technology, Research Laboratory of Electronics, Cambridge, Massachusetts 02139

Anisotropic etching has often been used to create unusual structures in crystals. The technology is highly developed in the case of silicon, and many useful devices and applications have been realized (1-5). While many reagents are known which will etch the (100) planes of InP faster than the (111)A planes (6-8), there is no known etchant which is as highly selective for InP as KOH is for Si. Accordingly, the production of sawtooth and square-wave profile structures on a fine scale in InP is problematical. We describe here a procedure which has been used to

make 3.8 μm period gratings with sawtooth profiles on the (100) surfaces of InP wafers.

Hydrobromic acid (HBr) was selected as the etchant in this experiment, because it was shown by Adachi and Kawaguchi (6) to reveal (111)A planes in InP, and because it is compatible with photoresist masking. The ratio between (100) and (111)A etch rates was not high enough at room temperature to achieve useful sawtooth profiles, but it was found that this ratio increased at lower temperatures. This increase is expected from the assumption that the etch rate is activation limited and follows a simple Arrhenius rate equation, and that the anisotropy results from a higher activation energy for the (111)A plane

¹ Present address: Spire Corporation, Patriots Park, Bedford, Massachusetts 01730.

Fig. 1. Scanning electron micrograph of a sawtooth profile grating etched in InP with HBr. The grating period is $3.8 \mu\text{m}$.

than for the (100) plane. A temperature of -15°C was found to give a sufficiently high anisotropy.

The samples used in this work were cleaved from commercially available (100) Sn-doped InP wafers. After polishing, a corner of each wafer was etched with 1:1 HCl (12N) and H_2O_2 (30%) solution for 30s at room temperature. This etch produced elongated pits on the (100) surface. Because it also etches the (111)B planes faster than the (111)A planes, the long directions of these pits indicate the line of intersection of the (111)A planes with the surface. These pits are useful for aligning the grating mask.

The wafers were then cleaned by ultrasonic agitation in a sequence of solvents: trichloroethylene, acetone, and methanol. They were immersed in 60% KOH in water at 50°C for 20 min, then washed in detergent (with ultrasonic agitation) and rinsed in deionized water. An adhesion promoter, octadecyl dimethyl [3-(trimethoxysilyl) propyl] ammonium chloride, known as DMOAP, was applied (other adhesion promoters are expected to work as well), and then $0.5 \mu\text{m}$ of Shipley² AZ1350B positive resist was spin-coated onto the wafers and prebaked according to the manufacturer's recommendations.

A photomask with a $3.8 \mu\text{m}$ period grating was placed in contact with the wafer. The lines on the grating were aligned manually with a cleaved edge of the wafer, in the same direction as the long axes of the pits which were

²Shipley Corporation, Newton, MA 02158.

etched into the wafer corner beforehand. This ensured that the (111)A planes would form a sawtooth grating. The resist was exposed, developed, and postbaked according to the manufacturer's recommendations. After development, the grating lines were about $1.4 \mu\text{m}$ wide.

The etching was carried out in a glass beaker at -15°C with agitation. The etchant was 9N (48% by weight) HBr. The etch was stopped when undercutting of the resist lines caused them to begin to lift off of the wafer; this took about 10 min. The resist was stripped, and the sample was examined in an optical microscope and a scanning electron microscope (Fig. 1). As can be seen in the electron micrograph, the remaining (100) portion of the top of each sawtooth is about $0.4 \mu\text{m}$ wide. The bottoms of the grooves, where two (111)A planes meet, appear sharp at the resolution of the micrograph. The origin of the ripple on the (111)A facets is not known.

Assuming that the resist mask will lift off when the flat tops of the sawtooth structure reach $0.4 \mu\text{m}$ in width, a ratio of (100) etch rate to (111)A etch rate of at least 8.3 is needed in order for the grooves to be completely etched before the resist mask fails. Our result shows that HBr at -15°C meets this requirement. We have made other measurements which indicate that HBr at 4°C has a ratio of about 7.7.

In summary, HBr at -15°C has been used to etch a $3.8 \mu\text{m}$ period sawtooth grating in (100) InP through a photoresist mask. The observation that reducing the temperature of the etch increases the anisotropy indicates that the activation energy (as described by an Arrhenius rate law) for the (111)A surface is greater than that for the (100) surface.

Deep Donor Levels in He Implanted n-Type Silicon

Masahiro Yoshizawa, Masayasu Miyake, and Hiroyuki Harada

Nippon Telegraph and Telephone Public Corporation, Atsugi Electrical Communication Laboratory, 1839, Ono, Atsugi-shi, Kanagawa, 243-01 Japan

In VLSI fabrication, ion beam technology using light ions (H, He) has many applications, such as ion beam lithography (1, 2) and FIPOS technology (3). In these technologies, it is important to investigate the energy level, concentration profile, and annealing behavior of damage produced by ion implantation. There have been many works on damage produced by proton implantation (4-6). However, there have been only a few studies on damage produced by He implantation (7). Energy levels and concentration profiles of deep levels in He-implanted Si have been studied for a $5 \times 10^8 \text{ cm}^{-2}$ implantation dose without annealing by using the DLTS method (7). For applying He implantation to the preceding technologies,

Key words: Schottky C-V method, implantation damage, energy level, annealing behavior.

however, it is necessary to study the properties of the damage in a higher dose range.

In the present study, energy levels and the concentration profiles of deep levels in n-type Si produced by He implantation with doses of $10^{14} \sim 10^{15} \text{ cm}^{-2}$ are investigated by the Schottky contact C-V measurement method. The implantation energy dependence of the peak depth and the annealing behavior in an N_2 atmosphere between 500° and 700°C are also reported.

CZ n-type $\langle 100 \rangle$ silicon wafers with $0.83 \sim 0.92 \Omega\text{-cm}$ resistivity were used. Arsenic was implanted into the back side of the wafers at 100 keV with a 10^{15} cm^{-2} dose, and the wafers were annealed at 900°C for 30 min to obtain an ohmic contact. Helium ions were implanted into the wafers at $40 \sim 150 \text{ keV}$ with a $10^{14} \sim 10^{15} \text{ cm}^{-2}$ dose.

After annealing in an N_2 atmosphere at $500^\circ \sim 700^\circ\text{C}$ for 30 min, Au electrodes (0.155 mm diam) were evaporated on the wafers in order to obtain Schottky contacts, and Al back contacts were evaporated.

In the C-V measurement (8), the concentration profile is given by the width of the space charge layer (x_m) and the concentration of the level (N_m). For the deep level, the observed profile obtained by using $x_m - N_m$ is an apparent profile, and is not equal to the actual profile of the deep level. For the deep level produced by implantation, donor and acceptor levels can be identified from the shape of the observed peaks. The number of peaks equals the number of levels. The C-V measurements having temperature variations separate the deep and shallow levels.

Figure 1 shows the apparent concentration profile measured by the Schottky C-V method at different measurement temperatures. Helium implantation was performed at 60 keV with a dose of 10^{15} cm^{-2} . The annealing temperature was 600°C . A flat concentration profile deeper than $0.9 \mu\text{m}$ shows the substrate impurity concentration, which is $6 \times 10^{15} \text{ cm}^{-3}$. Two donor peaks are observed. We call the smaller x_m peak level 1, and the other level 2. Figure 2 shows the temperature dependence of the apparent peak depths of the two levels. Level 2 is a deep level, since the apparent peak depth decreases with an increase in temperature. The apparent peak depth of level 1 decreases with an increase in temperature below 30°C , and does not shift above 30°C . This indicates that the energy of level 1 (E_1) is nearly equal to the Fermi level at 30°C , which is $E_c - E_1 = 0.21 \text{ eV}$, and level 1 is a deep level below 30°C . The energy of level 2 (E_2) is deeper than E_1 , because the apparent peak depth of level 2 changes in the higher temperature range; that of level 1 does not change. The measured profile above 30°C equals the actual profile of level 1. The peak depth of level 1 at 60 keV is determined to be $0.48 \mu\text{m}$.

Since level 2 is a deep level and level 1 is shallower than the Fermi level above 30°C , E_2 and the concentration of level 2 (N_2) are expressed as the following equations (8)

$$\frac{\epsilon(E_F - E_2)}{q^2} = \frac{N_0(x_m - x_2)^2}{2} + \int_{x_m}^{x_2} \int_{x_m}^{x'} N_1(x) dx dx' \quad [1]$$

$$N_2(x_2) = (N_m - N_0 - N_1[x_m]) \frac{x_m}{x_2} \frac{\partial x_m}{\partial x_2} \quad [2]$$

$$\frac{\partial x_m}{\partial x_2} = \frac{N_0(x_m - x_2) + \int_{x_2}^{x_m} N_1(x) dx}{N_0(x_m - x_2) + N_1(x_m)(x_m - x_2)} \quad [3]$$

Fig. 1. Apparent concentration profiles measured by the Schottky C-V method at different measurement temperatures.

Fig. 2. Temperature dependence of the apparent peak depth of levels.

where N_0 is the substrate impurity concentration, $N_1(x)$ is the concentration of level 1 at depth x , and x_m and x_2 are the depths at which the levels 1 and 2 cross the Fermi level, respectively.

It is thought that level 1 and level 2 are related to the damage produced by He implantation. Thus it is relevant to assume that the actual peak depth of level 2 is equal to that of level 1. Under this assumption, energy level E_2 is calculated to be $E_c - E_2 = 0.52 \text{ eV}$ from Eq. [1] in the temperature range of above 30°C . The peak concentration of level 2 is determined to be $1.5 \times 10^{16} \text{ cm}^{-3}$, using Eq. [2] and [3] and the concentration profile of level 1. The obtained peak concentration of level 2 is equal to that of level 1.

Figure 3 shows the implantation energy dependence of the actual peak depth of the levels. The points represent experimental data in the present study. The solid line is the calculated curve of the peak depth of the energy transfer rate into atomic displacements from the extended LSS theory (9). This corresponds to the peak depth of the vacancy concentration. Both are in good agreement. The concentration profile obtained in the present study is nearly Gaussian. It was confirmed that these two levels have the same annealing behavior in the $500^\circ \sim 700^\circ\text{C}$ range, and have the same peak concentration in the dose range of $10^{14} \sim 10^{15} \text{ cm}^{-2}$. The peak concentration decreases as the annealing temperature increases. Both peaks disappear after a 30 min annealing at 700°C when the dose is 10^{15} cm^{-2} , and disappear after a 30 min annealing at 600°C when the dose is 10^{14} cm^{-2} .

Three levels have been observed in He implanted n-type Si at $E_c - 0.18$, $E_c - 0.23$, and $E_c - 0.41 \text{ eV}$ using the DLTS method (7) for a dose of $5 \times 10^8 \text{ cm}^{-2}$ when annealing is not performed. The $E_c - 0.18$, $E_c - 0.23$, and $E_c - 0.41 \text{ eV}$ energy levels have been identified as the A center (O-V), the divacancy center, and the phosphorus vacancy center (P-V), respectively. The P-V center cannot be observed in the present study, because the concentration of the center is less than the substrate concentration. The A center and the divacancy center have been also observed in a proton-implanted Si (6) or an electron-irradiated Si (7). The $E_c - 0.21 \text{ eV}$ energy level obtained in the present study is tentatively identified as a divacancy from its annealing threshold (6). In the previous studies, the $E_c - 0.52 \text{ eV}$ energy level has not been observed, because the range of the measuring temperature is not high enough. For the electron-irradiated Si, the $E_c - 0.54 \text{ eV}$ energy

Fig. 3. Implantation energy dependence of the peak depth of the levels. The solid line is the peak depth of the vacancy concentration profile calculated from the extended LSS theory.

level, which is identified as a divacancy center, has been observed in the photoconductivity measurement (10). The $E_c - 0.52$ eV energy level in the present study is close to this level, and is identified as a divacancy. Both levels observed in the present study are considered to be divacancy centers. This is consistent with the results that both levels have the same peak depth, concentration, and annealing behavior.

In summary, the deep levels produced by He implantation were studied in a dose range of $10^{14} \sim 10^{15} \text{ cm}^{-2}$ by the Schottky contact C-V measurement method. Two deep donor levels having the same peak depth and concentration were observed. Energy levels are located at $E_c - E_1 = 0.21$ eV, and $E_c - E_2 = 0.52$ eV. Implantation energy dependence of the peak depth of the levels is in good agreement with the calculated peak depth of vacancy concentration profile from the extended LSS theory. These two levels have the same annealing behavior between 500° and 700°C . It is thought that the levels can be identified because of divacancies.

Equilibrium Calculations for the Si-H-Cl System from 300 to 3000 K

Carlyle S. Herrick* and Rony A. Sanchez-Martinez

General Electric Company, Corporate Research and Development, Schenectady, New York 12345

The Si-H-Cl system is an important concern to semiconductor technology since at least four different compounds belonging to that system have been used as starting materials in the manufacture of merchant silicon for the semiconductor trade, or for the deposit of solid epitaxial layers in silicon device fabrication. These activities are supported by a considerable amount of available information on equilibrium compositions at temperatures below 1700 K, approximately the melting point of solid silicon (1-10). Exploratory experiments or surveys at those higher temperatures comprising the liquid range of silicon find no comparable support in the literature. Only fragmentary and sometimes conflicting equilibrium data are available (1, 2). To fill that need, this note describes the results of equilibrium calculations covering the temperature range from room temperature to 3000 K. The term silane homolog as used here may refer to any compound in the series SiH_4 , SiH_3Cl , SiH_2Cl_2 , SiHCl_3 , and SiCl_4 .

A number of authors have employed a variety of computer codes to solve the equilibrium calculation problem (1, 2, 8, 10). We used a modified version of the system free energy minimizing code prepared by Gordon and McBride (11). It routinely performed a second equilibrium calcu-

lation using the output of the first calculation as input for the second. Checking the code in this way proved to be necessary for reliable results. Twenty chemical species were considered in each calculation, more than in prior studies. Heat capacity, enthalpy, and entropy data

Key words: silanes, chlorosilanes, conversion, yield.

Fig. 1. Calculated equilibrium conversions, gas phase compositions, and yields for the condensation of solid or liquid silicon from individual silane compounds or from mixtures. $Cl/H=1.0, 0.1, 0.01$. $P=1.0 \text{ atm}$.

were obtained from JANAF tables (12) in combination with the most recently reported values of heat of formation (8, 13).

Calculations included the entire range of temperatures at which elemental silicon might be condensed from equilibrium gas from room temperature up to the boiling point of silicon at about 3500 K. In no case did silicon vapor saturate equilibrium gas at a temperature above 3000 K. Since thermally ionized species occur only to a very minor extent below the boiling point of silicon, they were not considered in this work. Also omitted was consideration of possible unfavorable kinetics at temperatures near ambient.

Equilibrium vapor phase composition values calculated at four widely separated temperatures are listed in Table I. The data for the two lower temperatures, and others, have been compared with published data from four separate sources (3, 5-7). All major constituents and most minor ones agree well. $SiCl_3$ values are an exception, being two orders of magnitude greater than previously reported (6, 7). This small difference is thought to be due to more recent thermodynamic data and the larger number of chemical species considered.

The results of many equilibrium calculations are correlated in Fig. 1 and 2. In both figures, the three graphs comprising each vertical column all relate to the pressure and composition conditions listed at the top of the

column. In each case, the topmost graph shows equilibrium conversion data, the middle graph shows equilibrium composition data, and the bottom graph has equilibrium yield data. Conversion refers to the degree of completion of the reaction to form condensed phase elemental silicon, while yield refers to the amount of such silicon formed in unit volume of equilibrium gas.

Figure 2 illustrates one novel way in which equilibrium data can be arranged to give a broad view of condensed phase elemental silicon availability. Comparisons made in a horizontal direction show the effects of changing relative compositions, (Fig. 1) and of changing system total pressure (Fig. 2). Comparisons made in a vertical direction show the effects of choosing various silane homologs or intermediate mixtures thereof. Note that vertical lines are isotherms and due to system invariance a single gas phase composition describes the equilibrium behavior of all of the different starting compounds.

Along any isotherm, both conversions and yields of mixtures of neighboring silane homologs may be found by a linear interpolation between the two curves on Fig. 1 and 2 based on relative proportions of the constituents. Of course the input relative proportions of silane homolog and hydrogen must change for different silane compounds or mixtures in order to maintain Cl/H constant.

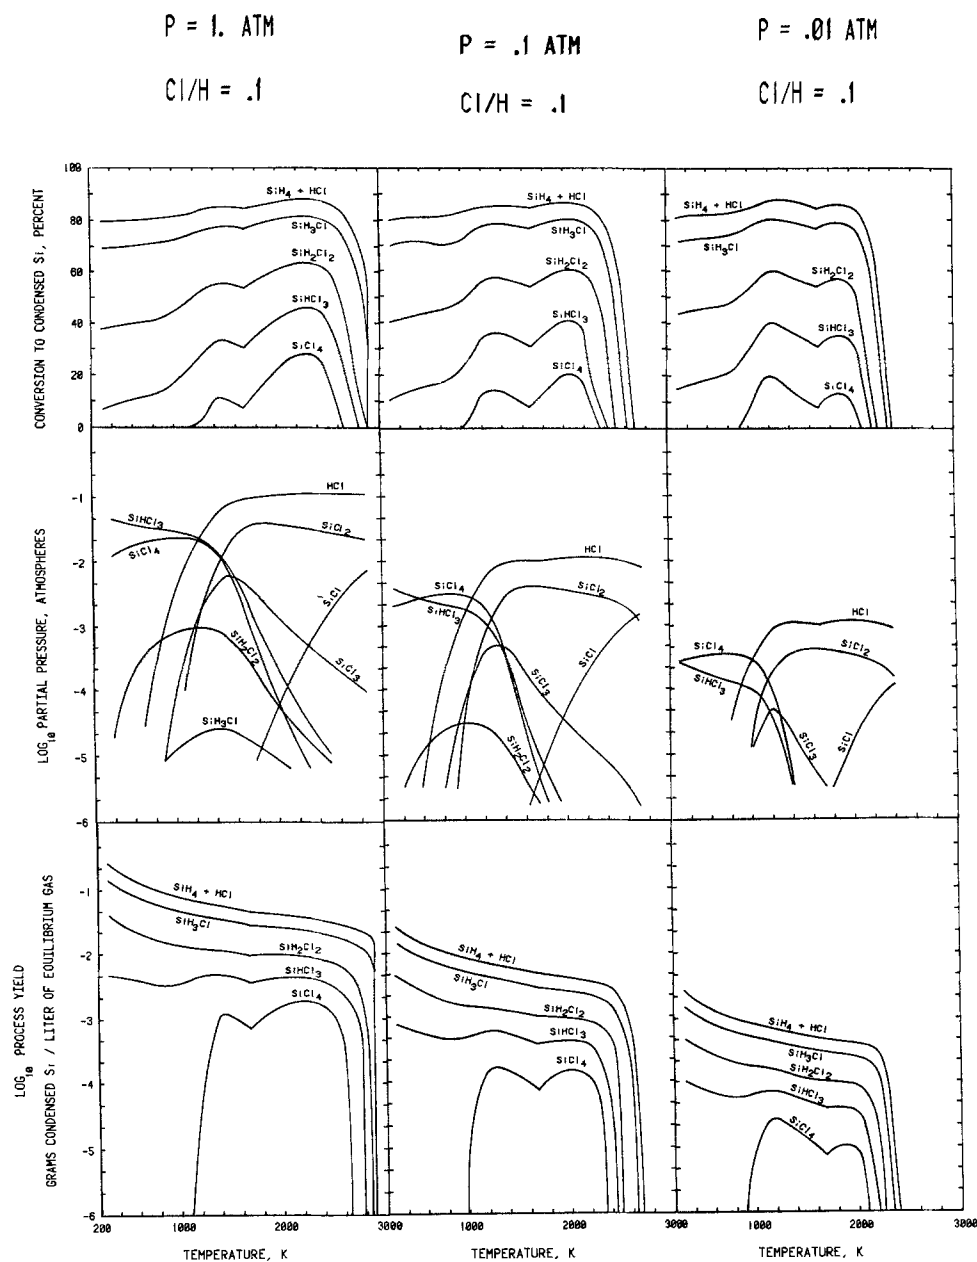

Fig. 2. Calculated equilibrium conversions, gas phase compositions, and yields for the condensation of solid or liquid silicon from individual silane compounds or from mixtures. $P=1.0, 0.1, 0.01$ atm. $\text{Cl/H} = 0.1$.

There are a number of special cases for mixtures. For example, 1-1 molar mixtures of silanes which differ in constitution by two hydrogen atoms will normally have the same atomic composition (add HCl to SiH_4) as the pure silane compound of intermediate constitution and will therefore give identical results at equilibrium. Similarly, 2-1 or 1-2 mixtures of silanes which differ by three hydrogen atoms will have the same atomic composition and give identical equilibrium results as one of the two intermediate silanes. Additional special cases exist for mixtures of silane differing by four hydrogen atoms.

Additions of HCl or Cl_2 produce equilibrium changes which are proportional to the changes they create in the atomic composition of the feed in exactly the same manner as for mixtures. Special cases also occur in the same way. See the left-hand column of Fig. 1 for an example.

Figure 2 can provide preliminary answers to a number of questions related to increasing silicon production. For example, in some instances the conversion and yield curves are bimodal, with a minimum occurring at the melting temperature of silicon and maxima at both lower and higher temperatures. In column 2 of Fig. 1, it is apparent that silicon processes operating near the left-hand peak (solid silicon region) for the conversion of SiCl_4 , SiHCl_3 , or SiH_2Cl_2 would enjoy substantially higher conversions and the same yield if operated near the right-hand peak (liquid silicon region).

A second example in column 2 of Fig. 1 originates from the near equality of conversion of SiCl_4 at the right-hand peak maximum (liquid silicon) and the conversion of SiHCl_3 at the silicon melting temperature. Any process using SiHCl_3 near the melting temperature could maintain the same conversion but change to SiCl_4 as the feed material by raising the operating temperature to attain the right-hand peak. The bottom graph in column 2 of Fig. 1 suggests a yield decrease of about one-half for that exchange. The overall result is that an operator who could double reactor space velocity or reactor volume or an equivalent combination, could also enjoy whatever price differential existed between the two feed materials.

Many other factors enter into silicon processing decisions, particularly those relating to silicon purity. It is possible, therefore, that advantages suggested by equilibrium data such as the examples above may not be compatible with some other process requirement in a particular situation.

Patterning of Tantalum Polycide Films

R. W. Light* and H. B. Bell*

Sandia National Laboratories, Albuquerque, New Mexico 87185

Gate level interconnect composed of a layer of doped polysilicon covered by a refractory metal silicide (polycide structure) is becoming an important feature of some integrated circuit technologies (1). These composite structures retain the relatively well characterized polysilicon/SiO₂ interface while permitting a lower resistivity than possible with polysilicon alone. Dry etching chemistries used for patterning polysilicon are not generally compatible with these composite materials, often producing an undesirable etched line profile or other complications. For example, a fluorine based plasma will typically etch the polysilicon out from under the silicide resulting in an overhang that will reduce step coverage by subsequent depositions. It has been recently shown that by adding Cl₂ to an SF₆ plasma, a continuous profile can be formed on Ta polycide lines (2). In this paper we discuss the etching behavior of TaSi₂/polysilicon films in a BCl₃/Cl₂ based reactive ion etching process. Control of the etched line profile by variation of the process parameters will be emphasized.

EXPERIMENTAL

TaSi₂/polysilicon (polycide) samples are prepared by depositing 3000 Å of LPCVD polysilicon on thermally oxidized 100mm diameter silicon wafers, phosphorus doping the polysilicon to 30 Ω/□, cleaning the polysilicon surface in 50:1 HF, and sputtering 3000 Å of TaSi₂ onto the polysilicon from a composite target.

Key words: semiconductor, plasmas, etching.

The wafers are coated with 1.8 μm of KTI 820 photoresist and patterned with 2, 3, 4, and 5 μm lines and spaces. Single film samples of TaSi₂ and polysilicon films are prepared in a similar fashion on oxidized silicon wafers. SiO₂ etch rates are determined from oxidized wafers patterned with a photoresist grid pattern.

A Plasma Therm, Inc., Hexetch 640 reactive ion etching system with a 3000 W, 13.56 MHz rf power supply is used for this study. This reactor holds 24, 100 mm diameter wafers on a central, vertically configured, hexagonal cathode enclosed in a bell jar. RF power is applied to the cathode and is regulated to maintain a preset dc self bias voltage on the cathode. The wafer holding cathode and the bell jar are temperature regulated at 30°C. SiO₂ coated wafers are placed in wafer locations not containing sample wafers. The system pressure is fixed at 10 mT and the total gas flow at 40 sccm. Endpoint is determined by monitoring the intensity of the 451 nm Cl₂ emission signal. Profile data are obtained by SEM.

RESULTS AND DISCUSSION

The etched line profile of the polycide structure is a function of the dc self bias voltage, the BCl₃/Cl₂ ratio and the number of wafers in the reactor (loading). A slightly sloped, continuous profile is desired to give adequate step coverage by later deposition processes. The effect of the dc self bias voltage and the percentage of Cl₂ in BCl₃ on the character of the etched profile is illustrated in Fig. 1 for polycide wafers (one wafer load) etched to endpoint. As the dc self bias volt-

age increases (more negative) and/or the Cl_2 percentage in BCl_3 decreases, the lateral etch rate of the TaSi_2 layer decreases relative to the vertical etch rate. While a fluorine based process often produces lateral etching of the polysilicon layer, lateral etching of the TaSi_2 layer dominates with this application of BCl_3/Cl_2 chemistry. Loading also affects the line profile with the relative lateral etch rate of TaSi_2 decreasing with an increase in the number of wafers. For example, in Fig. 1, the profile obtained at 60% Cl_2 , -300 V, and one wafer in the reactor displays a lateral etching of the TaSi_2 layer. If the number of wafers is increased to 6 or more, the profile no longer appears undercut. At voltages less than -300 V (more positive), TaSi_2 undercut can be reduced with increased reactor loading but cannot be totally eliminated. These profile dependencies are similar to those found for reactive ion etching of Al/Si with BCl_3/Cl_2 mixtures (3).

The profile dependence on BCl_3/Cl_2 composition and load is consistent with a sidewall passivation model in which the boron species limit the lateral etching reaction by recombining with the Cl etching species in the absence of ion bombardment (4). In this description of etch directionality decreasing the percentage of Cl_2 in BCl_3 or consuming Cl_2 by using larger wafer loads at constant dc bias voltage increases the relative concentration of boron type recombinants. The dependence of line profile on dc self bias voltage is consistent with positive ion assisted chemistry occurring on the bombarded surfaces. Lateral etching of the polysilicon layer was not detected under any of the experimental conditions.

A significant loading effect is observed for both the polycide and photoresist films with the etch rates decreasing as the number of wafers in the reactor is increased. Both the TaSi_2 and the polysilicon components of the polycide composite contribute to the observed loading effect as shown in Fig. 2 for 20% Cl_2 in BCl_3 and -300 V dc bias. A slightly

sloped continuous polycide profile is obtained when the etch rates of polysilicon, TaSi_2 , and photoresist are similar. A 3.0 μm wide polycide line etched with 20% Cl_2 in BCl_3 , -300 V, and a 12 wafer load is shown in Fig. 3. The original photoresist line profile must have a slope to obtain this degree of taper on the etched line. Sloped photoresist profiles may be formed by a judicious choice of photolithographic parameters and/or postdevelopment bake temperatures. Linewidth variation of 3.0 μm lines wafer to wafer and within a wafer etched under these conditions is typically +5% ($+\sigma$). The combined loading effect observed for polycide films is shown in Fig. 4 for 20% and 60% Cl_2 in BCl_3 and -300 V dc bias. SiO_2 etch rates range between 40 and 70 $\text{\AA}/\text{min}$ with a dc self bias voltage of -300 V, 20% to 60% Cl_2 in BCl_3 , and 1 to 18 wafers in the reactor.

CONCLUSION

Fine line patterning of Ta polycide interconnect can be achieved with a BCl_3/Cl_2 reactive ion etching process. The etched line profile is a function of the BCl_3/Cl_2 composition, the dc bias voltage, and the wafer load. A continuous, tapered line profile can be obtained by using wafer loading conditions in which the TaSi_2 , polysilicon, and photoresist etch rates are similar. This type of profile is often necessary to insure adequate step coverage by later deposition steps.

Conformal Step Coverage of Electron Beam-Assisted CVD of SiO₂ and Si₃N₄ Films

L. R. Thompson,* L. Gobis,** D. Bishop, J. J. Rocca, K. Emery, and G. J. Collins

Department of Electrical Engineering, Colorado State University, Fort Collins, Colorado 80523

We have recently reported electron beam assisted chemical vapor deposition (CVD) of silicon dioxide (SiO₂) and silicon nitride (Si₃N₄) films at low (200°C) substrate temperatures (1,2,3). Herein, we examine the ability of the electron beam deposition technique to conformally cover patterned aluminum and polysilicon steps.

Conformal coverage of such uneven features by deposited dielectric layers without thinning and cusping is important in multilayer metal devices. Thinning of dielectric sidewalls lowers interlayer breakdown voltages and cusping causes step coverage problems in subsequent metallization steps.

Details of the experimental arrangement and the electrical, physical and chemical properties of both SiO₂ and Si₃N₄ films deposited using the electron beam assisted CVD technique have been presented elsewhere (1, 2, 3). Reactant gases used for the deposition of SiO₂ and Si₃N₄ films include nitrous oxide and ammonia as respective oxygen and nitrogen donors. The silicon donor was 5% silane in nitrogen.

The deposition technique uses an electron beam to generate a spatially confined plasma reaction volume. To a first approximation the plasma region is a planar sheet with cross sectional area 1 x 25 mm. Deposition occurs at rates up to 500 Å/min on a heated substrate (150-500°C) located directly beneath the planar region defined by the electron beam generated plasma.

To study the step coverage properties of the electron beam deposition technique aluminum was sputter deposited (8000Å thick) upon a thermal SiO₂ (1000Å thick) covered silicon wafer. The wafer was masked using conventional photolithography and wet chemically etched to achieve aluminum lines 10 to 20 μm wide. Separately a polysilicon layer (4000Å thick) was deposited over another thermal SiO₂ (1000Å thick) covered silicon wafer. The polysilicon

was also masked and standard dry processing techniques were used to achieve polysilicon lines 10 to 20 μm wide.

SiO₂ layers were then electron beam deposited on both aluminum and polysilicon patterned silicon wafers. The SiO₂ films were deposited at a substrate temperature of 350°C, with a N₂O/SiH₄ mass flow ratio of 20 and a chamber pressure of 0.3 Torr. The electron beam discharge current and voltage were 50 mA and 4 kV, respectively.

Separately Si₃N₄ films were electron beam deposited at substrate temperatures of 350°C, with a NH₃/SiH₄ mass flow ratio of 60 and a total chamber pressure of 0.35 Torr. The electron beam current and voltage were 25 mA and 4.2 kV, respectively.

After electron beam SiO₂ and Si₃N₄ deposition the silicon wafers were cleaved revealing the coverage over aluminum and polysilicon steps using a SEM. For the case of polysilicon steps the wafer was etched in a 1 M KOH solution in order to distinguish the polysilicon and SiO₂ or Si₃N₄ interface while aluminum covered wafers were cleaved at 77 K to obtain sharp metal lines.

Figure 1 (a,b,c,d,) shows electron beam deposited SiO₂ and Si₃N₄ films conformally covering both aluminum and polysilicon patterns. A slight cusping of the 0.5 μm SiO₂ film in figure 1b at the base of the polysilicon step is evident. Optimization of the deposition conditions to reduce cusping has not been undertaken. Figure 1d depicts smooth Si₃N₄ coverage to the right of the polysilicon step while coverage on the surface of the step is rough due to the uneven polysilicon. Likewise the electron beam deposited SiO₂ and Si₃N₄ films conformally cover the surface of aluminum steps as in figure 1a and 1c. Film thinning over step sidewalls is less than 10 percent as measured by inspection of the SEM micrographs. Also, no film cracking was visible for all of the SiO₂ and Si₃N₄ layers investigated (0.4 μm to 5 μm thick).

In Situ Preparation of Undoped p-Type CdTe by Cathodic Electrochemical Deposition

Juan Llabres†

Solar Energy Research Institute, Solid State Research Branch, Golden, Colorado 80401

Recently, photovoltaic materials researchers have been investigating the use of several II-VI semiconductor compounds (e.g., CdS, CdTe, CdSe) in a new technique—electrochemical deposition (1). Low-cost preparation of polycrystalline CdTe as an absorber material has also been investigated for p-CdTe/n-CdS heterojunction solar cells (2). This paper presents details about the in-situ preparation of p-type CdTe deposited on polished stainless steel and low-sheet-resistance indium-tin oxide (ITO). The deposition process was carried out in an aqueous solution (18 MΩ-cm deionized water) containing CdSO₄ (1M) and saturated TeO₂. The solution pH, a parameter that mainly regulates the deposition rate in the potentiostatic mode, was adjusted by adding more H₂SO₄ to a previously chosen value. The pH range that produces uniform thin films is 2.0–3.5 (3). Several material combinations have been tested for the counter-electrode. The best, most reproducible results were obtained by using a platinum foil with an area similar to that of the cathode in combination with a short rod of tellurium (99.9999) acting as an auxiliary anode. The reduction reactions at the electrode,

lead to the compound formation at the cathode, under stoichiometric conditions that are controlled by the cathodic potential (4). Therefore, at potentials more positive than a certain value [−660 mV vs. standard calomel electrode (SCE)] reaction [2] is more favorable than reaction [1], resulting in an undoped semiconductor material with a p-type majority carriers intrinsic conduction caused by excess Te atoms placed interstitially (5).

Manuscript submitted Oct. 4, 1983; revised manuscript received Nov. 11, 1983.

†Permanent address: Solid State Physics Institute C.S.I.C. Spain.

Key Words: semiconductor, film, deposition.

Special emphasis has been given to preventing electrolyte poisoning by undesired neutral or ionized impurities. Small amounts of chlorine atoms, which may come from the reference calomel, have been observed by Auger electron spectroscopy in a few samples deposited from aged electrolytes. A mechanism of impurification could be the Cl₂ molecule formation at the anode, its diffusion through the liquid, and a subsequent reduction to Cl[−] at the cathode and immediate incorporation in the film. In any case, the chloride ions lead to a compensation of acceptor centers, resulting either in an increase in resistivity or in a change in majority carriers type (6). The electrolytic cell was operated potentiostatically by means of a PAR Potentiostat-Galvanostat Model 173. A PAR Digital Coulometer Model 179 was used to determine film thickness during deposition. Cell temperature was kept at 82° ± 3° C, and a low-speed magnetic stirrer aided in solution convection. The CdTe zincblende structure appears clearly in the X-ray diffraction diagrams of samples grown at potentials ranging from −620 to −660 mV (vs. SCE). A second phase of tellurium is observed with materials grown at more positive potentials. The preferred orientation found in single-phase samples grown on stainless steel, the only kind analyzed by the X-ray diffraction, is [111]. Scanning electron microscopy has revealed an average grain size of about 5 μm. For samples grown on ITO substrates, the grain size appears to be significantly smaller (<1 μm).

As we already pointed out about reactions [1] and [2], one can conclude that the electrical resistivity depends upon material stoichiometry. In order to find out the Cd/Te ratio, compositional measurements by electron probe for microanalysis measurements were performed. Results showed that the Te and Cd atomic percentages decrease and increase, respectively, as the cathodic potential is made more negative, and that both atomic percentages equal unity for a

potential of about -660 mV (vs. SCE). These results are in agreement with those obtained from X-ray diffraction diagrams.

Electric properties of thin films (with a thickness of 0.7-1.3 μm) prepared by in-situ electrochemical deposition have been examined in devices consisting of a conductive substrate, a CdTe thin film, and metallic dots. Since the CdTe/Au contact behaves differently whether the semiconductor is p- or n-type (7), and p-CdTe/In is a Schottky barrier (8), the behavior of these two contacts becomes a criterion for determining the material majority carrier type. Therefore, several gold and indium dot contacts $1.1 \times 10^{-2} \text{cm}^2$ in area were evaporated (pressure $\approx 10^{-6}$ torr) on each sample through a metallic mask. Before any evaporation occurred, samples were etched in a hot KOH solution to remove any remaining superficial Te that would either shunt the evaporated contacts or distort the results, due to a TeO_x isolant thin layer in series with the device. A method has been described (9) that enables us to measure the bulk resistivity as well as the specific contact resistivity.

Fig. 1 shows the dependence of the bulk resistivity on cathodic potential in devices formed by a stainless steel substrate, an undoped p-CdTe junction, and an ohmic gold contact. The base stainless steel/p-CdTe contact is made ohmic by depositing a few atomic monolayers of Te before CdTe deposition begins. In Figure 1, the vertical bars represent the resistivity variation found at different dots located along the two dimensions of the sample surface (with an area of $\approx 2 \text{cm}^2$). The CdTe/Au contact behaves ohmically in a wide range of applied voltages; in contrast, the CdTe/In presents a Schottky barrier characteristic. These results demonstrate the p-type property of the reported material. Figure 1 also shows that bulk resistivity is notably decreased by the incorporation of excess Te into the materials crystal lattice. Note that the range for single-phase CdTe preparation is quite short (40 mV, approximately). In fact, high infrared transmission values demonstrate that there is not a Te second phase in films grown in this range. Specific p-CdTe/Au contact resistivity values depending on bulk resistivity range from 2 to $2 \times 10^{-2} \Omega\text{-cm}^2$.

Anodic Dissolution of Iron Phthalocyanine Film Electrodes

Carlos A. Melendres*

Argonne National Laboratory, Materials Science and Technology Division, Argonne, Illinois 60439

Shu Qian-Xu

Department of Chemistry, University of Science and Technology of China, Hefei, Anhwei, China

In a recent presentation (1), we showed the existence of an anodic wave at about 0.6V vs. Hg/Hg₂SO₄ in the cyclic voltammogram of iron phthalocyanine (FePc) film electrodes in 0.05 M H₂SO₄ solution. We now present results of investigations by rotating ring-disc electrode and Raman spectroscopic techniques which indicate that this wave is associated with the anodic dissolution of the FePc film. This observation is relevant to the problem of stability of phthalocyanine electrodes for O₂ reduction.

Experimental.--FePc films supported on gold electrodes were prepared by (1) evaporation of 0.2-0.25 wt.% FePc/pyridine solutions on the Au surface and (2) by vapor deposition under high vacuum. Further experimental details and instrumentation are the same as described in previous publications (2,3). All potentials were measured against a Hg/Hg₂SO₄ reference.

Results and Discussion.--The anodic behavior of FePc films in 0.05 M H₂SO₄ solution is exemplified in the cyclic voltammogram at a rotating disc (with ring) electrode as shown in Fig. 1a. Both peak current and peak potential appear to vary with film thickness but are independent of the presence of oxygen in the solution. Integration of the area under the wave indicates that the charge passed corresponds to multiple layers of material being involved in the oxidation process. At low scan rates, (<5mv/sec) the integrated charge is directly proportional to the weight of FePc film taken for evaporation, and hence also to the film thickness. Complete quantitative oxidation of the film can be accomplished coulometrically by holding the potential at about 0.75V. Fig. 2 shows the relation between the weight of the FePc film (W) and the charge (Q) passed during controlled potential oxidation. From the slope of the line in Fig. 2, we calculate the number of electrons involved in the oxidation process to be 1.2±0.2.

Measurements of current at the Au ring were also made as a function of ring potential

while simultaneously scanning the disc potential. A typical result is shown in Fig. 1b. Significant ring current is measured with the ring potential set at about -0.2V and at more negative values. Thus the anodic oxidation process results in the production of a soluble species which is reducible on a Au electrode. Cyclic voltammetry shows that the reduced species is not re-oxidizable at a Au electrode. Following excursion of the potential to +0.75V and beyond, we find by microscopic examination that the electrode surface is as smooth and clear as before the FePc film was laid on it.

To determine whether the film is indeed dissolving anodically or whether the iron center is coming off the macrocycle as is commonly believed, laser Raman spectroscopic examination of the film "in-situ" was undertaken. If the FePc were dissolving, we expect the Raman bands due to the whole molecule to disappear following the anodic oxidation. If only the iron center were removed, the phthalocyanine framework should remain and give a spectrum somewhat different from that of the original FePc (3,4). Results showed that on scanning the potential very slowly to +0.8V, the whole FePc spectrum disappeared completely. We also followed the intensity of a prominent band, e.g. at 1520 cm⁻¹, in the Raman spectrum of FePc as a function of potential. Our normal coordinate analysis (5) shows this band to be a mixture of normal modes due to C-N and C-C stretches as well as C-N-C angle deformation. A typical result is shown in Fig. 3. Disappearance of this band and the whole spectrum at 0.8V indicates removal of the FePc from the electrode surface. Since we find no greenish blue particles in solution that would indicate a spalling-off of the FePc film, we are lead to conclude that the film is irreversibly anodically oxidized and passes into solution either as a solvated cation or other soluble entity.

While the results described above were obtained with films prepared by solution evaporation, we observed the same anodic dissolution behavior with films prepared by vapor

deposition on Au substrates under high vacuum. This is in contrast with observations made by Green and Faulkner (6) who claim to have found that FePc undergoes an irreversible electrochromic change on oxidation. They, however, used a different electrolyte and electrode substrate.

Reports on the Energy Research Summer Fellowship Awards

Jesús A. del Alamo

Jean-Noël Gorce

D. B. Graves

Leslie C. Hardy

James A. Osborn

During the summer of 1983, the following students were awarded Energy Research Summer Fellowships. Each award carried with it a grant of \$2000.

- Mr. Jesús A. del Alamo, of Stanford University, Stanford, California.
- Mr. Jean-Noël Gorce, of the Georgia Institute of Technology, Atlanta, Georgia.
- Mr. D. B. Graves, of the University of Minnesota, Minneapolis, Minnesota.
- Mr. Leslie C. Hardy, of Northwestern University, Evanston, Illinois.
- Mr. James A. Osborn, of Rutgers University, Piscataway, New Jersey.

The Energy Research Summer Fellowship Awards are made "without regard to sex, citizenship, race, or financial need. They are made to graduate students pursuing work between the degrees of B.S. and Ph.D., in a college or university in the United States or Canada." The recipients' projects are in fields relating to energy research or of interest to The Electrochemical Society. The Awards were sponsored by the Department of Energy and made by the Summer Fellowship Committee of the Electrochemical Society.

Jesús A. del Alamo was born in Soria, Spain. He received his Ingeniero de Telecomunicación degree from the Universidad Politécnica de Madrid, Spain, in 1980, and his M. S. degree from Stanford University, Stanford, California, in 1983. He is working on his Ph. D. degree at Stanford.

Mr. del Alamo has received numerous awards, and has been a visiting student at Katholieke Universiteit Leuven in Belgium, and the University of Edinburgh in Scotland.

Mr. del Alamo's report is given below.

Epitaxial Growth of Heavily Phosphorus-Doped Silicon

Material problems have so far precluded a systematic characterization of heavily doped Si. The intrinsic and technological limitations of as-grown crystal, diffused or implanted layers have permitted only partial knowledge of the band structure and minority carrier properties of heavily doped Si. An understanding of the physics of heavily doped Si is of enormous importance for VLSI bipolar transistors, high concentration solar cells, and low temperature CMOS.

Epitaxially grown heavily doped Si is a good candidate for carrying out this fundamental study because of its ability to fabricate flat and very abrupt impurity profiles, lack of limitations in layer thickness, and technological simplicity. The problems to solve are the incorporation of dopant species in the growing Si layer to obtain the high doping levels of interest and the control of the density of defects to allow the fabrication of test devices.

Epitaxial heavily doped Si by itself may be of interest as a material for VLSI bipolar base regions if grown under low pressure, low temperature conditions, because of the tight control of impurity profiles it allows and the lack of compensation of impurities. Its use has already been reported in the fabrication of hyperabrupt IMPATT Si diodes (1).

Experimental

In this work epitaxial heavily phosphorus doped Si has been grown on <100> B-doped 0.1-0.2 Ω -cm substrates. All the ex-

periments were carried out in a horizontal, RF-heated epitaxial reactor (Hugle Model HIER II) operating at atmospheric pressure. The quartz reactor tube had an effective cross section of 27 cm² above the susceptor. The silicon carbide-coated graphite susceptor was tilted at an angle of 2°. Hydrogen was used as the carrier gas at a flux of 79 l/min. Silane was the source of silicon at a partial pressure of 10⁻³ atm in all cases. Phosphine was delivered as the dopant source through a double-dilution system. With PH₃ tanks of 1 and 5% (in H₂), partial pressures ranging from 1.2 × 10⁻⁶ to 3.3 × 10⁻³ atm were reached in the reaction chamber. All depositions herein reported were done during 10 min at 1050°C. Prior to growth, all wafers were vapor etched in 5 × 10⁻³ atm HCl for 4 min at 1200°C.

One quarter of a 3 in. wafer was processed at a time. After epitaxy, it was sawn into 7 × 7 mm² chips. On these chips the characterization of the layers was carried out by a combination of techniques: spreading resistance, groove and stain, van der Pauw measurements, and Secco etch for defect count.

Characterization and Discussion

Figure 1 shows a typical spreading resistance profile. The carrier distribution throughout the layer is very flat, and an abrupt transition occurs at the interface. The small bump near the junction and the slightly lower surface concentration are artifacts of the spreading resistance numerical algorithm.

Figure 2 collects the resulting electron concentration in the epitaxial layer vs. the partial pressure of PH₃ in the reaction tube. Electron concentrations as high as 1.5 × 10²⁰ cm⁻³ were obtained. In the lower concentration range, from 1.7 × 10¹⁹ to approximately 6 × 10¹⁹ cm⁻³, the electron concentration is proportional to a power of the PH₃ partial pressure with an exponent of \approx 0.3, in good agreement with theoretical predictions of Bloem *et al.* (2) of 0.25. At higher concentrations, the electron concentration rolls off.

The physical origin of this power-law dependence of the P concentration in the epitaxial layer is based on the following reactions (2)

Fig. 1. Spreading resistance profile of a typical heavily doped epitaxial region.

Fig. 2. Epitaxial layer electron concentration vs. initial partial pressure of PH_3 in the reactor (temp = 1050°C , $p_{\text{SiH}_4} = 10^{-3}$ atm).

We have in this case the following equilibrium constants as defined by Bloem *et al.* (2)

$$K_1 = \frac{(\rho_{\text{P}_2})^{1/2} (\rho_{\text{H}_2})^{3/2}}{\rho_{\text{PH}_3}} \approx \frac{(\rho_{\text{P}_2})^{1/2}}{\rho_{\text{PH}_3}} \quad [1]$$

$$K_a = \frac{[\text{P}]}{(\rho_{\text{P}_2})^{1/2}} \quad [2]$$

$$K_b = \frac{[\text{P}^+] \cdot n}{[\text{P}]} \quad [3]$$

which gives

$$[\text{P}^+] = K_a K_b \frac{(\rho_{\text{P}_2})^{1/2}}{n} = K_1 K_a K_b \frac{(\rho_{\text{PH}_3})}{n} \quad [4]$$

Bloem *et al.* computed the equilibrium concentration in H_2 of P , P_2 , P_4 , PH , PH_2 , and PH_3 as a function of the input concentration of PH_3 at several temperatures. A thermodynamical approach was used by assuming that equilibrium in the gas phase is attained near the silicon surface. The result of their calculation showed that at high partial pressures of PH_3

$$\rho_{\text{PH}_3} \approx K (\rho_{\text{PH}_3}^0)^{1/2} \quad [5]$$

where $\rho_{\text{PH}_3}^0$ represents the initial partial pressure of PH_3 .

In Eq. [4] we therefore have

$$[\text{P}^+] = K K_1 K_a K_b \frac{(\rho_{\text{PH}_3}^0)^{1/2}}{n} \quad [6]$$

If the semiconductor is intrinsic, $n = n_i(T)$, and

$$[\text{P}^+] \sim (\rho_{\text{PH}_3}^0)^{1/2} \quad [7]$$

If it is extrinsic

$$n = [\text{P}^+] \quad [8]$$

and

$$[\text{P}^+] \sim (\rho_{\text{PH}_3}^0)^{1/4} \quad [9]$$

The intrinsic carrier concentration in Si at 1050°C is between 10^{18} and 10^{19} cm^{-3} ; its value is not well known (3, 4). In any case, at the levels of doping obtained in the present experimental work, the growing Si layer is definitely extrinsic, and Eq. [9] applies.

Our exponent of 0.3 rather than 0.25 as indicated by Eq. [9] may be due to small divergences in the computer result (5).

The deviation from this power law at higher partial pressures of PH_3 may lie in the failure of Eq. [8] because of incorporation of inactive P in the growing layer, or the failure of the Henry's law ($k = \rho_{\text{P}}/[\text{P}]_{\text{Si}}$) as solid solubility is approached. Total P activation in epitaxial Si layers have been demonstrated up to a concentration of $3 \times 10^{19} \text{ cm}^{-3}$ (5). SIMS analysis of our samples will reveal the reason for the lower electron concentration at the higher PH_3 levels.

Figure 3 shows the growth rate vs. partial pressure of PH_3 . The growth rate is fairly constant up to a level of $\approx 4 \cdot 10^{-4}$ atm, above which it decreases abruptly. Similar results have been found by Gupta (6) in the $\text{AsH}_3/\text{SiH}_4$ and $\text{B}_2\text{H}_6/\text{SiH}_4$ systems. It is interesting to note that the deviation of the power-law dependence of the electron concentration vs. the PH_3 partial pressure occurs at approximately the same point as the decay in the growth rate. This coincidence suggests that both effects may be related to the reaction kinetics, rather than the dopant incorporation in the Si.

Figure 4 shows electron mobility vs. electron concentration in the layer. Both measurements were obtained by measuring resistivity and Hall mobility in a van der Pauw setup, with a magnetic field of 1.12 kG at 23°C . The Hall coefficient was assumed to be equal to unity, as the work of Nakanuma (5) suggests. Each data point represents an average of five measurements carried out at five different current levels. The data here reported closely follow the NBS data (7) and extend the range beyond their maximum concentration. Their analytical fitting significantly diverges at the high doping range. The fitting to the experiments of Massetti *et al.* (8) is lower at the very high concentration regime, probably due to the large scattering of their experimental data.

Figure 5 collects the density of etch pits defined by Secco etch in 5 min. The defects seem to be perfect or misfit dislocations. There appears to be a strong correlation between doping level and defect density. The values here reported are compatible with the fabrication of test devices for the characterization of minority carrier behavior.

Summary

Heavily doped epitaxial silicon has been grown in a PH_3/SiH_4 system. Electron concentrations as high as $1.5 \times 10^{20} \text{ cm}^{-3}$ have been obtained. At the highest doping range the electron concentration diverges from theoretical expectations. The origin of

Fig. 3. Epitaxial layer growth rate vs. initial partial pressure of PH_3 . (1050°C , $p_{\text{SiH}_4} = 10^{-3}$ atm).

Fig. 4. Electron mobility vs. electron concentration at 23°C. The continuous lines represent fittings to experimental data of the indicated authors.

Fig. 5. Density of etch pits defined by Secco etch vs. electron concentration.

this discrepancy is not clear. Electron mobilities have been measured. The obtained values agree very well with previous measurements on bulk and thermally diffused silicon. The defect density in the epitaxial layers allow the fabrication of test devices for the characterization of heavily doped silicon.

Mr. Gorce's report is given below.

Voltammetric Investigation of a Selenocarbonyl-Iron Porphyrin

The discovery of cytochrome P450 possessing a biochemically active iron-carbene bond (1) prompted us to investigate related model compounds. The iron-carbene bond in the cytochrome P450 hemoprotein was generated during the metabolic reduction of polyhalogenated compounds. Knowledge of carbene-iron porphyrin redox stabilities is essential for comprehending the role played by this moiety in cytochrome P450. A series of synthetic, isoelectronic carbene-iron porphyrin compounds are presently under investigation in this laboratory. These include the carbonyl, thiocarbonyl, and selenocarbonyl complexes of 5,10,15,20-tetraphenylporphyrinatoiron(II). Of present interest is the selenocarbonyl iron porphyrin, TPPFeCSe. This complex is one of just a few complexes containing a Fe-C=Se bonding arrangement. The paucity of metalloselenocarbonyl complexes is a result of the lack of stable precursors such as CSeCl₂ or CSe₂.

The preparation of TPPFeCSe was accomplished via a modification of the procedure presented by Battioni *et al.* (2). The synthesis requires three consecutive reactions.

The reductive electrochemistry of carbene-iron porphyrins has been investigated (3, 4). The initial injection of one electron occurs reversibly while the injection of a second electron is succeeded by chemical complications. The electro-oxidation of TPPFeCSe has been extensively investigated (5). This complex underwent two discrete one-electron quasireversible oxidations. This is unlike the C=O complex of Fe-porphyrins, in which the oxidation resulted in the dissociation of the Fe-C bond (6, 7).

The purpose of this report is to provide a detailed description of the synthesis and the oxidative electrochemistry of the only known selenocarbonyl iron porphyrin.

Experimental

The chemicals used were or were presumed to be highly toxic. Selenium containing compounds gave off a noxious odor. All reactions were carried out under a well-ventilated hood. Selenium containing waste products were disposed of by treatment with sodium hypochlorite solution.

The purpose of this report is to provide a detailed description of the synthesis and the oxidative electrochemistry of the only known selenocarbonyl iron porphyrin.

Experimental

The chemicals used were or were presumed to be highly toxic. Selenium containing compounds gave off a noxious odor. All reactions were carried out under a well-ventilated hood. Selenium containing waste products were disposed of by treatment with sodium hypochlorite solution.

Material.—Benzylselenocyanate ($C_6H_5CH_2SeCN$) was obtained via modification of the procedure used by Jackson (8). To 100 ml of acetone, 10.0g of potassium selenocyanate was added. This mixture was stirred for 15 min until all of the potassium salt dissolved. To this solution was added a slight excess, (10.0g) of benzylchloride. The solution was vigorously stirred for 1h at room temperature, at which time a white precipitate developed. The KCl precipitate was removed by filtration. The filtrate was cooled to $10^\circ \pm 2^\circ C$ and left to stand for 30 min. A second crop of solid KCl was removed by filtration. The remaining solution was reduced to approximately 30 ml and set aside to permit crystallization of the desired product. Over a 2h period, white crystals grew. They were filtered and twice recrystallized from acetone. A melting point of $72^\circ-73^\circ C$ was obtained (literature value (8) was $71.5^\circ C$). This product was obtained in a 74% yield based on potassium selenocyanate.

Benzyl trichloromethyl selenoether ($C_6H_5CH_2SeCCl_3$) was obtained using the procedure used by Makosza and Fedorynski (9) for their synthesis of the analogous sulfur compound. 4.40g of benzyl selenocyanate and 70 mg of the phase-transfer agent triethylbenzylammonium chloride (TEBA) were dissolved in 8.00g of chloroform. This mixture was stirred at room temperature for 30 min. To this solution, 4.5 ml of 50% NaOH was added dropwise over a period of 10 min. The reaction was maintained at a temperature of $40^\circ \pm 2^\circ C$ for a period of 4h and allowed to cool to room temperature. 20 ml of water was added to the mixture, and then the organic and aqueous layers were separated. The aqueous layer was extracted with three 15 ml portions of $CHCl_3$. These extracts were combined with the initial organic phase. This solution was washed thrice with water, dried, and the solution volume was reduced by evaporation *in vacuo* at $50^\circ C$. The remaining liquid was vacuum distilled. A transparent, light-yellow liquid was collected at $67^\circ \pm 2^\circ C$ and 5 ± 5 mm Hg. An NMR spectrum obtained on the distillate was comparable to that reported by Battioni *et al.* (1). Based on the benzyl selenocyanate, the yield of benzyl trichloromethyl selenoether was 69%.

150 mg of $TPPFcCl$ was obtained by twice extracting a dichloromethane solution of $(TPPFc)_2O$ with 20 ml portions of 2M aqueous HCl, drying the organic layer over anhydrous Na_2SO_4 , and reducing to dryness on a rotary evaporator. The u-oxo iron porphyrin dimer had been prepared previously by the method of Adler *et al.* (10). The porphyrin monomer was dissolved in 45 ml of freshly distilled benzene and placed in the central compartment of a three-compartment Schlenk pot. In the two remaining compartments were placed 80 mg of benzyl trichloromethyl selenoether and 2 ml of a 1.5% Na/Hg amalgam, respectively. The entire system was taken through five freeze-pump-thaw cycles to remove all oxygen and then maintained under an atmosphere of N_2 . At this point, the reducing agent was introduced to the porphyrin solution, and this mixture was stirred for 15 min. Benzyl trichloromethyl selenoether was then added, and the mixture was vigorously stirred for 1h. Consequently, the porphyrin solution changed from a dark brown to a blood red. The mixture was filtered and evaporated to dryness. The remaining purple solid was dissolved in dichloromethane and applied to a column of neutral alumina. With dichloromethane as the eluting solvent, a fast moving red band separated from a slower moving dark brown-green band and a stationary black one. The first band gave a visible spectrum characteristic of $TPPFcSe$ (2). Based on $TPPFcCl$, the yield was calculated at 38%.

The supporting electrolyte, tetrabutylammonium perchlorate (TBAP) was obtained from the Eastman Chemical Company. Prior to use, TBAP was recrystallized three times from absolute ethanol and vacuum dried for 24h. 1,2-dichloroethane was extracted successively from concentrated sulfuric acid and distilled water. The resultant organic phase was dried over anhydrous $MgSO_4$, filtered, fractionally distilled over phosphorous pentoxide in a nitrogen atmosphere, and stored in the dark over 4Å molecular sieves.

Instrumentation.—Cyclic voltammetric experiments were carried out on an EG&G Princeton Applied Research Model 174A Polarographic Analyzer. A conventional three-electrode setup was used with a Pt button working electrode, a Pt wire counterelectrode and a saturated calomel electrode (SCE) as reference. Aqueous contamination of the electrochemical solution was minimized by isolating the reference electrode via a fritte. Voltammograms were recorded on a Houston Omni-graphic 2000 X-Y recorder. To compensate for solution resist-

ance, positive feedback was employed using the accessory 174-50 Polarographic Analyzer Interface.

Differential pulse voltammetry was performed using the instrument mentioned above except that the mainframe polarographic analyzer was modified to allow user selection of the pulse direction independent of the potential sweep direction. For the differential pulse experiments, a potential scan rate of 10 mV/s was employed. The pulse interval was maintained at 0.5s while the pulse amplitude varied between 5 and 100 mV.

Coulometric and chronocoulometric experiments were carried out using an EG&G Princeton Applied Research Model 173 Potentiostat/Galvanostat. Coulometry was executed in a specially designed microvolume sealed cell. Large surface working and counter Pt electrodes were substituted for those used in the voltammetric experiments. Visible spectral measurements were taken using a Tracor Northern Optical Multichannel Analysis System.

All solutions were deoxygenated by passing a stream of solvent-saturated prepurified N_2 into the solution for at least 10 min prior to acquiring voltammetric data. To maintain an O_2 -free environment, the solution was blanketed with N_2 during all experiments. All potentials reported herein were referenced to the SCE and were uncorrected for liquid-junction potentials.

Results and Discussion

A solution of $TPPFcSe$ in 0.10M TBAP/1,2-dichloroethane gave a visible spectrum with a predominant Soret band at 408 nm and a corresponding extinction coefficient of 2.24×10^5 . Alpha and beta bands were located at 551 ($\epsilon = 9 \times 10^3$) and 524 nm ($\epsilon = 17 \times 10^3$), respectively. These values are similar to those reported by Battioni *et al.* (2) for the pentacoordinated $TPPFcSe$ complex in benzene. A comparable visible spectrum was reported for the analogous $TPPFcS$ complex (5); however, it had a less intense Soret band.

In the 1,2-dichloroethane solution, $TPPFcSe$ underwent two consecutive electro-oxidations. Typical cyclic voltammograms depict these events in Fig. 1. Cyclic voltammograms studies from 20 to 500 mV/s were carried out on the first oxidative process. In this range of potential-sweep rates, the ratio of anodic to cathodic peak currents were all near unity. Calculated $E_{1/2}$ values remained constantly at 0.83V. The ratio of the anodic peak current to the square root of the scan rate was found to be

Fig. 1. Cyclic voltammograms obtained for the electro-oxidation of $TPPFcSe$ in 0.1M TBAP/1,2-dichloroethane. The upper trace depicts the first oxidation of $TPPFcSe$, and the lower trace depicts both the first and the second oxidations of $TPPFcSe$. Both cyclic voltammograms were obtained at a potential-scan rate of 200 mV/s.

² $W_{1/2}$ = peak width at half height.

independent of scan rate. The separation between anodic and cathodic peak currents decreased from 96 mV at 500 mV/s to 62 mV at 20 mV/s. A separation of 59 mV would be expected for a totally reversible one-electron transfer. Furthermore, at a scan rate of 20 mV/s, $E_{p,a} - E_{p/2,a}$ and $E_{p,a} - E_{1/2}$ values were calculated to be 62 and 31 mV, respectively. Theoretical values for a totally reversible one-electron transfer are 56.5 and 28 mV, respectively. A summary of the cyclic voltammetry studies of TPPFeCSe is given in Table I.

Typical differential pulse voltammograms of TPPFeCSe in solution are shown in Fig. 2. A series of differential pulse voltammograms with pulse amplitudes ranging from 5 to 100 mV were carried out on the first oxidation. At a pulse amplitude of 5 mV, the peak width at half height gave a value of 104 ± 2 mV

Fig. 2. Differential pulse voltammograms of the electro-oxidations of TPPFeCSe in 0.1M TBAP/1,2-dichloroethane. The upper trace was obtained by superimposing negative potential pulses on a linear-potential ramp. The lower trace was obtained by superimposing positive potential pulses on a linear-potential ramp. The pulse amplitude was set of 25 mV.

and increased to 157 ± 2 mV at a pulse amplitude of 100 mV. For a reversible one-electron transfer the peak width at half height is expected to approach 90.4 mV as the pulse amplitude approaches zero. Differential pulse voltammograms were obtained by imposing first positive and then negative potential pulses on linear-potential ramp. This permitted analysis of data with the Birke's method (11). Separation between potential peaks [$E_{p(-)} - E_{p(+)}$] were within 1 mV of the pulse amplitude. Current ratios were about unity. The $E_{1/2}$ value of 0.84V was independent of the pulse amplitude but slightly more positive than the value obtained via cyclic voltammetry. A summary of the differential pulse voltammetric data of TPPFeCSe is given in Table II.

Cyclic and differential pulse voltammograms were also obtained in the characterization of the second charge-transfer event. Cyclic voltammetry yields a $E_{1/2}$ value of 1.11V regardless of scan rate. At a scan rate of 20 mV/s, the separation between anodic and cathodic peak was measured at 64 mV while $E_{p,a} - E_{1/2}$ gave a value of 32 mV. Both these values increased with increasing scan rate. Via inspection of the differential pulse voltammograms, $E_{1/2}$ was calculated at 1.12V with no apparent dependency on pulse amplitudes. Peak current values for this second electro-oxidation resembled that of the first. The peak width at half height was measured at 102 ± 2 mV. In considering Birke's criteria, the ratio of the current peaks resulting from the positive and negative application of potential pulses on a linear ramp were again essentially unity. The potential separation between these current peaks were all within 2 mV of the applied potential pulses.

Taken collectively, the voltammetric results indicate that the electro-oxidation of TPPFeCSe in 1,2-dichloroethane is best described as taking place in two discrete one-electron quasireversible charge transfers. Exhaustive electrolysis at 0.97V resulted in a charge transfer of 1.02 electron per equivalent. Subsequent electrolysis at 1.35V resulted in a charge transfer of 1.08 electrons per equivalent. Reversal of the potential to the initial potential of zero charge (0.12V) gave a charge transfer of 2.21 electrons per equivalent.

Chronocoulometric experiments were employed to deduce the diffusion coefficient of TPPFeCSe in solution. A value of $9.7 \pm 0.3 \times 10^{-6}$ cm²/s was obtained. From this value and cyclic voltammetry results, the heterogeneous rate of electron transfer was computed (12) as $4.6 \pm 0.4 \times 10^{-2}$ cm/s. This value resides just within the boundary zone suggested by Matsuda and Ayabe (13) for a quasireversible electron transfer.

By analogy to TPPFeCS (5), the following reaction pathway is proposed for the electro-oxidation of TPPFeCSe.

The first oxidation process involves a metal-centered reaction. The abstraction of the first electron occurs from a metal orbital. The second oxidation process involves the production of a porphyrin cation radical. The second electron is removed from a porphyrin π orbital.

Future research will consider the electroreduction of TPPFeCSe and investigate the redox mechanism of TPPFeCSe in the presence of the nucleophiles.

Plasma Enhanced Chemical Vapor Deposition

My work is aimed towards a more quantitative treatment of plasma-enhanced chemical vapor deposition (PCVD) primarily as used in microelectronics manufacturing processes. The specific objective of the research is to predict the behavior of PCVD reactors given operating conditions or changes in operating conditions. This will be possible only if the roles of physical transport and chemical kinetics in the overall deposition process, including in particular the role of the highly nonequilibrium gas discharge plasma, are understood.

The strategy for achieving this goal is to combine measurements from a carefully designed experimental reactor with results from a mathematical model of the reactor. The experiment and model are complementary tools: the model results, validated by comparison to experimental measurements, can be used to extend and generalize experimental results.

The reactor is designed with parallel-plate electrodes (RF at 13.56 MHz). The lower electrode is powered. It is porous, so that the reactant gas may pass through and impinge on the heated, grounded upper electrode upon which film deposition takes place. The flow is always laminar, since PCVD reactors are operated at pressures around 1 torr, which keeps the Reynolds number, typically, at less than 10. The stagnation-point flow configuration is one of the easiest flows to model, since a transformation of the equations of motion results in a single nonlinear ordinary-differential equation describing axial and radial velocities. This configuration will give a radially uniform rate of deposition over a significant portion of the deposition

plate. Besides the equation of motion, additional model equations include chemical species balances, an energy balance, and equations describing the behavior of the discharge. The fluid mechanics, heat, and mass transfer equations have been solved for this configuration.

Another key feature of the experimental reactor is the use of the quartz crystal microbalance to measure, *in situ* and in real time, the rate of film deposition. This deposition-rate measurement is based on the change in resonant frequency of a thin slice of piezoelectric quartz crystal as a thin, solid, adherent film is deposited on the surface of the crystal. This technique is well recognized and several commercial devices are available for room temperature processes. We are extending the technique to higher temperatures (200°-300°C) by using dual crystals, one exposed to film deposition, the other shielded, both experiencing the same temperature. The temperature problem arises because crystal resonant frequency is a very sensitive function of temperature as well as film thickness.

The stagnation-point flow parallel-electrode reactor is simple and relatively easy to model. The well-defined flow field and *in situ* film deposition measurement could make this configuration as popular in the study of CVD as the rotating disk electrode is in the study of liquid phase electrochemical systems. Naturally, any CVD system of interest can be studied using this configuration: we concentrate on deposition of transition metals and silicides, because these films are currently of considerable practical interest.

Leslie C. Hardy received his B. A. degree from Oberlin College, Oberlin, Ohio, in 1979. He is working for his Ph. D. at Northwestern University, Evanston, Illinois.

Mr. Hardy has studied at the University of Akron. He has worked as an Associate Research Chemist for the A. E. Staley Manufacturing Company.

Solid Polymer Electrolytes

Solid electrolytes are currently the subject of intensive research, and solid-state rechargeable batteries are one of their principal potential uses. Most solid electrolytes are ceramic or glassy inorganic materials in which one charged species is mobile and the countercharge is held in a fixed lattice position. Thus the electrical properties displayed by these conductors may be attributed to a known charge carrier. Unlike solvent-swollen ion exchange resins, solid-polymer electrolytes are solvent free. In poly(ethylene oxide) complexed with sodium iodide, for example, the salt is dissociated so that either ion may be mobile. Knowledge of relative mobilities of the oppositely charged ions is important for fundamental studies as well as various applications. To date, determination of the transport numbers for ions in solid-polymer electrolytes has been difficult and experimentally inconsistent from one laboratory to another. Here we report the study of chloride conduction in anhydrous films of poly(diallyldimethylammonium chloride) plasticized with poly(ethylene glycol) (average MW = 300). In this polymer electrolyte, the positive countercharge is anchored in the polymer backbone where its mobility is limited to backbone fluctuations and not diffusion of the polymer chain, since the time scale of experimental measurements is short (alternating current measurements from 10 Hz - 500 kHz).

Variable temperature conductivity of the chloride ion in the amorphous polymer matrix yields curved plots of $\ln(\sigma T)$ vs. $1/T$. This behavior, which is similar to that of diffusion of small molecules through polymers, has been seen previously for other amorphous polymer electrolytes. Transport of ions in these materials may be described by equations similar to the WLF equation rather than the Arrhenius law.

An important reason for the use of poly(diallyldimethylammonium chloride) is that the positive charge on the nitrogen is surrounded by four aliphatic groups, thus separating opposite charges somewhat to allow for possible mobility. Tight ion pairing has been shown to significantly reduce the mobility of charge carriers in solid-polymer electrolytes.

Use of plasticizers is known to increase polymer chain flexibility and free volume, and decrease the glass-transition temperature. These changes are also known to increase ionic conductivity in solid-polymer electrolytes. The conductivity of brittle pure polymer at 25°C was not measurable on our instruments, while the flexible plasticized polymer has conductivities on the order of 10^{-8} ($\Omega^{-1} \text{ cm}^{-1}$) at 25°C to 10^{-5} at 100°C. Prelimi-

nary results indicate that increasing the plasticizer level from 0.32 to 0.65 weight fraction (mole ratios of chloride to hydroxyl of 2 and 0.67, respectively) increases conductivity by about 100 times at room temperature.

AC complex impedance data collected over the frequency range of 10 Hz – 500 kHz with platinum ion blocking electrodes were used to calculate bulk conductivity of samples. Complex impedance plots are typical of those seen for ionic conductors with blocking electrodes. Although calomel electrodes are normally used with liquid electrolytes, their use with the solid chloride conductor was found to be successful. Complex impedance data collected using the ion-reversible electrodes indicate that chloride ions are mobile and may be transferred across the electrode-electrolyte interface. The spur due to double-layer capacitance seen for ion blocking electrodes is converted to an arc for charge-transfer resistance, as predicted by impedance/frequency response theory, and as has been seen for other solid-polymer electrolyte systems.

In addition to the conductivity data discussed above, these polymer electrolytes have been characterized by IR spectroscopy, differential scanning calorimetry, hot-staged polarized microscopy, and x-ray diffraction.

Further work will include dc polarization studies with ion blocking and ion-reversible electrodes. Conductivity of different anions of varying size and geometry along with different quaternary ammonium polymers may also yield useful information on the nature of charge transport in solid-polymer electrolytes. In addition, extending variable frequency measurements down to 10^{-1} Hz should facilitate interpretation of complex impedance plots since the relative mobilities of the charged species are known. This situation is different from other cases, where techniques have been used in which either charged species may be mobile.

James A. Osborn was born in Salem, New Jersey. He received his B. A. degree in chemistry from Rutgers College, New Brunswick, New Jersey, in 1981. He is working on his Ph. D. degree at Rutgers University Graduate School in Piscataway, New Jersey.

Mr. Osborn's current interest in immobilized enzyme chemically modified electrodes.

Mr. Osborn's report is given below.

Mr. Osborn's research has centered around the use of chemically modified carbonaceous supports for the immobilization of enzymes and coenzymes, their use as analytical sensors, and the characterization of the modified surfaces.

The area of immobilized enzymes in analytical chemistry has received widespread attention over the past ten years. The immobilization of enzymes onto various electrode materials has been motivated by several factors, including the provision of convenient and straightforward measurement of species of biological and clinical interest. As the use of immobilized enzymes in analysis continues to be developed, research dealing with effects of immobilization on biological molecules has also kept pace.

His interest in immobilized enzymes was motivated through his work on a project involving the use of activated carbon as a support for the immobilization of enzymes. Activated carbon was ground and sifted to a uniform size with subsequent modification involving the well-known linking agent, cyanuric chloride. Steps were also taken to increase the surface hydroxyl functionality concentration with which the cyanuric chloride presumably reacts specifically. The cyanuric chloride activated surface was then used to react with the enzyme chymotrypsino-

gen through its lysine residues. It was shown that samples prepared this way retained a higher specific activity than on samples that were prepared by physical adsorption of the enzyme. Activated carbon was chosen due to its high surface area and electrical conductivity among other things.

Characterization of the cyanuric chloride modified activated carbon was accomplished by the potentiometric titration of the hydrolysis product: chloride ion. This helped to evaluate the effects of various surface pretreatments on the eventual loading of cyanuric chloride. These results were also correlated with the results of thermal analysis of the samples.

The enzymes, alcohol dehydrogenase and glycerol dehydrogenase, were both investigated by attachment to spectroscopic grade graphite rods through a procedure similar to the above in an attempt to sense for ethanol and glycerol amperometrically. The inability to oxidize the NADH reaction product cleanly and reproducibly led to further investigation of the electrochemistry of both free and immobilized NADH.

The electrocatalytic and electrochemical properties of thin films of the coenzymes FMN and FAD irreversibly adsorbed on highly ordered pyrolytic graphite were examined in buffer solutions which contained ferricyanide, NADH, and dissolved oxygen. The latter gave the most pronounced effect on voltammograms of the thin films with the other two giving irreproducible or no effects indicating an interaction.

Currently, his work centers around attaching the enzymes chymotrypsin and trypsin to spectroscopic grade graphite electrodes and attempting to observe a change in activity with change in surface potential. Since it has been shown that an immobilized enzyme is greatly affected by its microenvironment, the change in potential might then conceivably have an effect.

Attempts to observe the above effects were at first hampered by preparations of low overall activity, making observation of small changes difficult. In an attempt to increase the binding sites for covalent attachment of the enzymes, a poly(acrylic acid) film was first adsorbed from aqueous solution by the electrode. The next step involved the activation of the carboxylic acid groups with a water soluble carbodiimide. The electrodes were then reacted with the appropriate enzyme. Such preparations have demonstrated both increased activity and stability. The properties of the preparations have been investigated with regard to the effect on activity of pH, ionic strength, metal ions in solution, temperature dependence, and certain other comparisons between the free and immobilized preparation, including the effects of several inhibitors.

The activity of the preparations was determined by a spectroscopic technique. A closed flowing system which allowed for continuous mixing and monitoring of the absorbance of the substrate solution was used in conjunction with a three electrode system in order to observe the effects of surface potential change on the activity. The reference electrode was a miniature SCE, the auxiliary electrode a coiled Pt wire, and the working electrode made up of the enzyme immobilized graphite rod. The coiled Pt wire was placed concentrically around the working electrode in a system designed to minimize the volume of substrate solution. At this point, applied potentials have been observed to have a pronounced effect on the apparent activity of the rods.

The need for a uniform surface for subsequent modification was also motivated by a project involved in observing the potentiometric response of peptidase electrodes to various substrates and inhibitors. Thus far, chymotrypsin and trypsin have been immobilized via the previous procedure. These electrodes have responded to substrates and an inhibitor thus far. The dependence of response on concentration has also been observed. The effects of inhibitors on further response to substrates is also being investigated.

Ionic Conductivity and Phase Transition of the Spinel System $\text{Li}_{2-2x}\text{M}_{1+x}\text{Cl}_4$ ($\text{M} = \text{Mg, Mn, Cd}$)

Ryoji Kanno, Yasuo Takeda, Kazuaki Takada,* and Osamu Yamamoto*

Department of Chemistry, Faculty of Engineering, Mie University, Tsu 514, Japan

ABSTRACT

The spinel systems $\text{Li}_{2-2x}\text{M}_{1+x}\text{Cl}_4$ ($\text{M} = \text{Mg, Mn, Cd}$) with $0 \leq x \leq 0.33$ has been studied by means of impedance measurement, differential thermal analysis, and x-ray diffraction analysis. The ionic conductivity increases and the activation energy for conduction decreases with increasing x within the solid solution range, $0 \leq x \leq 0.20$ in $\text{Li}_{2-2x}\text{Mg}_{1+x}\text{Cl}_4$, $0 \leq x \leq 0.24$ in $\text{Li}_{2-2x}\text{Mn}_{1+x}\text{Cl}_4$, and $0 \leq x \leq 0.05$ in $\text{Li}_{2-2x}\text{Cd}_{1+x}\text{Cl}_4$. The highest conductivity is found to be $1.5 \times 10^{-5} \text{Scm}^{-1}$ in $\text{Li}_{1.52}\text{Mn}_{1.24}\text{Cl}_4$ at room temperature and 0.35Scm^{-1} in $\text{Li}_{1.9}\text{Cd}_{1.05}\text{Cl}_4$ at 400°C . The three chloride spinels exhibit a first-order phase transition and a diffuse transition. The diffuse transition temperatures decrease with increasing x .

Solid lithium ion conductors having high ionic conductivity are of particular interest for the Li-based high energy density batteries. Many systems have been studied to search high lithium ion conductivity solids (1-10). Recently, a new class of lithium ion conductors, Li_2MCl_4 ($\text{M} = \text{Mg, Mn, Fe, Cd}$), has been reported by Kanno *et al.* (11) and Lutz *et al.* (12), which has a high ionic conductivity at elevated temperatures. The compound Li_2MCl_4 has been determined by the neutron diffraction method to have the inverse spinel structure (13); half of the lithium ions are tetrahedrally surrounded by chloride ions, and the other half of them, together with the M ions, are distributed statistically over the octahedral sites. Lutz *et al.* (14) found the reversible phase transition from the spinel structure to a cubic defect structure at a high temperature with the help of differential thermal analysis and high temperature x-ray diffraction analysis. Of these compounds, Li_2CdCl_4 has the highest conductivity of 0.35Scm^{-1} at 400°C , the value of which is comparable or more than that of the high lithium ion conductors reported previously.

A solid solution $\text{Li}_{2-2x}\text{M}_{1+x}\text{Cl}_4$ may be expected to have higher ionic conductivity than the stoichiometric compound because the substitution of M^{2+} ion for Li^+ ion could produce the lithium ion vacancy which leads to high Li^+ ion conductivity. The solid solution $\text{Li}_{2-2x}\text{Cd}_{1+x}\text{Cl}_4$ has been examined briefly by Kanno *et al.* (11). $\text{Li}_{1.9}\text{Cd}_{1.05}\text{Cl}_4$ was found to have higher conductivity than Li_2CdCl_4 .

In this study, the electrical properties of the solid solution systems $\text{Li}_{2-2x}\text{M}_{1+x}\text{Cl}_4$ ($\text{M} = \text{Mg, Mn, Cd}$) are examined. Further, the phase transition in these systems is discussed on the basis of the results of electrical conductivity measurement, differential thermal analysis, and high temperature x-ray diffraction technique.

Experimental

Reagent grade LiCl , CdCl_2 , and MnCl_2 dried under vacuum at elevated temperatures were used as starting materials. Dehydrated MgCl_2 was prepared by heating $\text{MgCl}_2 \cdot \text{NH}_4\text{Cl} \cdot 6\text{H}_2\text{O}$ under vacuum at 400°C .

* Electrochemical Society Active Member.

Key words: solid electrolyte, lithium ion conductor, lithium chloride, spinel structure.

The melting points of these chlorides were in good agreement with the reported values. The appropriate quantities of LiCl and MCl_2 ($\text{M} = \text{Mg, Mn, Cd}$) were ground together and were pressed into pellets under 90 MPa in an argon-filled glove box. Then the pellets were heated in an evacuated Pyrex tube for one week at a temperature just below the corresponding melting points. X-ray powder photographs were taken by a Debye-Scherrer camera using nickel-filtered $\text{CuK}\alpha$ radiation. The powder samples were encapsulated in glass capillaries. Silicon powder was used as an internal standard. Differential thermal analysis (DTA) was carried out for the sample sealed in a Vycor tube under vacuum; $\alpha\text{-Al}_2\text{O}_3$ powder sealed in a Vycor tube of the same size was used as a standard. The electrical conductivities were measured in the temperature range between room temperature and 500°C in a dry argon gas flow. A sample of about 0.7g was pressed under a pressure of 60 MPa into a pellet of 10 mm diam. The densities of the pellets were about 80% of the theoretical densities calculated from the lattice parameters. Ionically blocking electrodes were obtained by evaporating gold on both sides of the pellets. The conductivity was measured at frequencies between 5 Hz and 500 kHz using an HP 4800A vector impedance meter. The resistances were derived by interpretation of complex impedance plane diagrams of the data. The EMF of the cell, $\text{LiTiS}_2/\text{Li}_2\text{MCl}_4/\text{TiS}_2$, was measured to determine the ionic transport number. Commercial grade titanium disulfide was used without further purification. The lithium intercalation compound LiTiS_2 was prepared by the reaction of n-butyl lithium with TiS_2 (15).

Results and Discussion

X-ray measurement.—X-ray powder diffraction patterns of the samples obtained at room temperature showed the cubic spinel structure reported previously (11-14). The observed lattice parameter of the stoichiometric compound Li_2CdCl_4 at room temperature (10.635Å) is in good agreement with the value reported by Lutz *et al.* (10.635Å) (14) and by van Loon and de Jong (10.637Å) (13), while those of Li_2MgCl_4 (10.426Å) and Li_2MnCl_4 (10.491Å) are slightly different from the reported values. The lattice parameters for the systems $\text{Li}_{2-2x}\text{Mg}_{1+x}\text{Cl}_4$, $\text{Li}_{2-2x}\text{Mn}_{1+x}\text{Cl}_4$, and

$\text{Li}_{2-2x}\text{Cd}_{1+x}\text{Cl}_4$ are shown in Fig. 1 as a function of x . The lattice parameters decrease linearly with increasing x for $0 \leq x \leq 0.20$ in $\text{Li}_{2-2x}\text{Mg}_{1+x}\text{Cl}_4$, for $0 \leq x \leq 0.24$ in $\text{Li}_{2-2x}\text{Mn}_{1+x}\text{Cl}_4$ and for $0 \leq x \leq 0.05$ in $\text{Li}_{2-2x}\text{Cd}_{1+x}\text{Cl}_4$. The solid solution range in $\text{Li}_{2-2x}\text{Cd}_{1+x}\text{Cl}_4$ is rather small compared with the other systems because the ionic radius of cadmium is rather larger than that of lithium. The x-ray powder diffraction patterns of the samples with $x < 0$ showed the lines due to LiCl and those of the samples with a higher x value than the solubility limit showed the lines due to MCl_2 . The decrease in the lattice parameters by substitution of Li^+ for M^{2+} ion in $\text{Li}_{2-2x}\text{M}_{1+x}\text{Cl}_4$ could be explained by assuming that one lithium ion vacancy is produced by each divalent cation substituted into lithium ion sites to keep the charge neutral. Hanebali *et al.* (16) reported that $\text{Li}_{2-2x}\text{V}_{1+x}\text{Cl}_4$ with spinel structure showed the decrease in the lattice parameter with increasing x . They also suggested the formation of lithium ion vacancies by substitution of lithium ions by divalent metal ions. $\text{Li}_{1.60}\text{Mg}_{1.20}\text{Cl}_4$, $\text{Li}_{1.52}\text{Mn}_{1.24}\text{Cl}_4$, and $\text{Li}_{1.90}\text{Cd}_{1.05}\text{Cl}_4$ should have 10%, 12.5%, and 2.5% lithium ion vacancies, respectively. The radius of magnesium ion for tetrahedral coordination (CN4), 0.58 Å, and for octahedral coordination (CN6), 0.67 Å (17), is very close to lithium ion for the corresponding coordination, 0.59 and 0.67 Å. In view of the ionic radius, excess magnesium ion in $\text{Li}_{2-2x}\text{Mg}_{1+x}\text{Cl}_4$ could occupy both the octahedral and tetrahedral sites. On the other hand, the radii of manganese ion (0.83 Å for CN6) and cadmium ion (0.95 Å for CN6) are larger than that of lithium ion. Therefore, it could be considered that the excess divalent ions occupy only the octahedral sites, which are more open compared to the tetrahedral sites. Hanebali *et al.* (16) suggested that vacancies were pro-

duced on the octahedral sites in $\text{Li}_{2-2x}\text{V}_{1+x}\text{Cl}_4$ from analogy to oxide spinel such as $\text{A}^{2+}\text{M}^{2+}\text{O}_3$ (A = Mn, Co, Zn and M = Ti, Mo). However, a more detailed structure determination will be necessary to discuss the sites of vacancy.

Magnetic susceptibilities χ were measured to determine the spin state of Mn^{2+} ion in Li_2MnCl_4 with the help of a Faraday balance from 78 K to room temperature. The sample was contained in evacuated silica tube. The susceptibilities are well described by the Curie-Weiss law. The magnetic moment 5.42 BM obtained from the paramagnetic susceptibility is close to the calculated value, 5.92 BM, which corresponds to the value of high spin Mn^{2+} ions in the octahedral environment.

Electrical conductivity.—The electrical conductivities were measured in the temperature range between room temperature and 500°C. The conductivities of the samples with ionically blocking electrodes showed a frequency dependence over the temperatures examined. In order to estimate the bulk resistance, the data were plotted in the complex impedance planes, X (imaginary component) vs. R (real component). The typical results of Li_2MnCl_4 at 27° and 304°C are shown in Fig. 2. The high frequency semicircle in the impedance diagram at room temperature is due to a parallel combination of the bulk electrolyte resistance with the bulk capacity. The bulk resistance was obtained by the extrapolated real-axis intercepts of the semicircle at a lower frequency. The impedance diagram at 304°C appears to consist of a straight line, and no semicircle due to bulk capacity is observed. The electrolyte resistances are obtained by extrapolation to the real axis. The temperature dependence and the composition de-

pendence of the conductivity, σ , of $\text{Li}_{2-2x}\text{M}_{1+x}\text{Cl}_4$ ($\text{M} = \text{Mn, Mg, Cd}$) are shown in Fig. 3, 4, and 5, where dotted lines indicate two-phase structures as described later. The Arrhenius plots showed a change in slope at a high temperature. The temperatures of the conductivity knee decrease with increasing x in $\text{Li}_{2-2x}\text{M}_{1+x}\text{Cl}_4$. The conductivity knee will be discussed in the later section. At room temperature, the conductivity vs. composition curves show a maximum conductivity of $1.5 \times 10^{-5} \text{ Scm}^{-1}$ at $x = 0.24$ for $\text{Li}_{2-2x}\text{Mn}_{1+x}\text{Cl}_4$, $3.4 \times 10^{-5} \text{ Scm}^{-1}$ at $x = 0.20$ for $\text{Li}_{2-2x}\text{Mg}_{1+x}\text{Cl}_4$, and $2.9 \times 10^{-6} \text{ Scm}^{-1}$ at $x = 0.05$ for $\text{Li}_{2-2x}\text{Cd}_{1+x}\text{Cl}_4$. The compositions that exhibit the maximum conductivity correspond to the phase boundary of the solid solution $\text{Li}_{2-2x}\text{M}_{1+x}\text{Cl}_4$. At a higher temperature, such as 400°C , no significant composition dependence of the conductivity is found. The composition dependence of the activation energy for conduction calculated from the logarithm of the conductivity vs. reciprocal of the absolute temperature curve is observed in $\text{Li}_{2-2x}\text{M}_{1+x}\text{Cl}_4$ both above and below the conductivity knee. At lower temperatures, the samples that show the maximum conductivity have the lowest activation energy: 48 kJmol^{-1} for $\text{Li}_{1.52}\text{Mn}_{1.24}\text{Cl}_4$ and $\text{Li}_{1.6}\text{Mg}_{1.2}\text{Cl}_4$, and 54 kJmol^{-1} for $\text{Li}_{1.9}\text{Cd}_{1.05}\text{Cl}_4$. The maximum conductivity and lowest activation energy of the samples of the phase boundary in the solid solution $\text{Li}_{2-2x}\text{M}_{1+x}\text{Cl}_4$, which may have the highest mol fraction of lithium ion vacancy, suggest that the conduction of the lithium ion seems to be affected by the number of lithium ion vacancies produced by substitution of Li^+ ion for M^{2+} ion. Li_2MCl_4 transforms to a cubic defect structure at high temperatures, which has a structural lithium ion vacancy. No composition dependence of the conductivity at high temperatures may indicate that trans-

port via lithium ion vacancies is not the proper way to understand the phenomenon.

The EMF of the cell $\text{LiTiS}_2/\text{Li}_2\text{MnCl}_4/\text{TiS}_2$ was measured to determine the ionic transport number, where LiTiS_2 was prepared chemically by using *n*-butyllithium, and the EMF of the cell Li/LiClO_4 in propylen carbonate/ LiTiS_2 , 1.8V, agreed very closely with that reported previously (18). The open-circuit voltage of 0.58V at room temperature was in good agreement with 0.59V calculated from free enthalpy change of the reaction $\text{TiS}_2 + \text{Li} = \text{LiTiS}_2$ (18). This result suggests that the ionic transport number is nearly unity at room temperature.

Decomposition potential.—The decomposition potential was measured with the help of the cell $\text{Pt}/\text{Li}_2\text{MCl}_4/\text{Pt}$ under vacuum at 400°C for Li_2MnCl_4 and Li_2CdCl_4 , and at 480°C for Li_2MgCl_4 . A dc current was applied across the cell. The current vs. applied voltage curves are shown in Fig. 6. The decomposition potentials were estimated to be 1.2, 1.1, and 1.3V for Li_2MgCl_4 , Li_2MnCl_4 , and Li_2CdCl_4 , respectively. The decomposition potentials are not well-defined, since the chemical potentials at neither electrode were defined. They do, however, give an indication of the stability of these phases.

Phase transition of the systems $\text{Li}_{2-2x}\text{M}_{1+x}\text{Cl}_4$.—Figures 7, 8, and 9 show the temperatures of the conductivity knees and the phase transition temperatures obtained by DTA together with the results of high temperature x-ray diffraction photographs of $\text{Li}_{2-2x}\text{Mn}_{1+x}\text{Cl}_4$, $\text{Li}_{2-2x}\text{Mg}_{1+x}\text{Cl}_4$, and $\text{Li}_{2-2x}\text{Cd}_{1+x}\text{Cl}_4$, respectively.

In $\text{Li}_{2-2x}\text{Mn}_{1+x}\text{Cl}_4$, solid-state transition temperatures, T_1 , obtained by DTA increase with x from 417°C at the stoichiometric composition to 537°C at $x = 0.33$. The temperatures of the conductivity knees, T_{cond} , obtained by the electrical conductivity measurement, decrease with x . No peak in DTA curves corresponding

Fig. 5. Temperature dependence and composition dependence of the conductivity, σ , of $\text{Li}_{2-2x}\text{Mg}_{1+x}\text{Cl}_4$.

to the conductivity knees was observed. The high temperature x-ray photographs of the samples with $x = 0.24$ and 0.33 above T_1 showed the patterns with NaCl type cubic structure, which was reported by Lutz *et al.* (14) in the stoichiometric compound. Therefore, the transition temperatures in the solid solution system obtained by DTA correspond to a transition from the spinel structure to NaCl type cubic phase. No significant difference between x-ray photographs was found below and above T_{cond} .

In $\text{Li}_{2-2x}\text{Mg}_{1+x}\text{Cl}_4$, the solid-state transition temperatures obtained by DTA also increase with x from 518°C at $x = 0.0$ to 541°C at $x = 0.1$. For the samples with $x > 0.1$, no solid-state transition was observed in

Fig. 6. The current, A , vs. voltage, V , curves for the cell $\text{Pt}/\text{Li}_2\text{MCl}_4/\text{Pt}$.

Fig. 7. Phase relation in the $\text{Li}_{2-2x}\text{Mn}_{1+x}\text{Cl}_4$ system. (○) Spinel phase; (□) defect NaCl structure phase; (△) spinel phase + MnCl_2 .

Fig. 8. Phase relation in the $\text{Li}_{2-2x}\text{Mg}_{1+x}\text{Cl}_4$ system. (○) Spinel phase; (□) defect NaCl structure phase; (△) spinel phase + MgCl_2 .

the DTA curves. The x-ray diffraction photograph of the sample with $x = 0$ at 540°C showed the pattern with cubic defect NaCl structure. The solid-state transition is related to the transition from the spinel structure to the cubic defect NaCl structure. The temperatures of the conductivity knees decrease with increasing x as in $\text{Li}_{2-2x}\text{Mn}_{1+x}\text{Cl}_4$. There is no peak in DTA curves corresponding to the temperature of the conductivity knees. The x-ray photograph of the sample with $x = 0.33$ at 200°C showed mixed spinel phase and MgCl_2 . The photograph at 300°C , however, showed no extra lines due to MgCl_2 . The composition of the phase boundary of the solid solution $\text{Li}_{2-2x}\text{Mg}_{1+x}\text{Cl}_4$ at 300°C is $x = 0.33$ or more.

In $\text{Li}_{2-2x}\text{Cd}_{1+x}\text{Cl}_4$, phase transitions obtained by DTA are rather complicated compared with those in $\text{Li}_{2-2x}\text{Mn}_{1+x}\text{Cl}_4$ and $\text{Li}_{2-2x}\text{Mg}_{1+x}\text{Cl}_4$. Three solid-state phase transitions were observed; T_1 was observed only in the stoichiometric compound at 305°C , T_2 was observed for the samples with $x > 0.1$, and T_3 observed for all the samples with $x > 0$. Lutz *et al.* (14) reported the transition T_1 and T_3 for the stoichiometric compound. X-ray diffraction photographs below the transition temperature T_3 showed the pattern with the spinel structure and those above T_3 the pattern with a cubic NaCl structure. These results suggest that the transition temperature T_3 is related to the phase transition from the spinel phase to a cubic defect NaCl structure. No clear difference was observed in x-ray diffraction photographs below and above the transition temperatures T_1 and T_2 . The temperatures of the conductivity knees decrease with increasing x . There is no peak in DTA curves corresponding to the temperatures of the conductivity knees. Further, x-ray diffraction photographs showed that the solid solution range of the system $\text{Li}_{2-2x}\text{Cd}_{1+x}\text{Cl}_4$ broadens with increasing temperature.

In all the systems $\text{Li}_{2-2x}\text{M}_1+x\text{Cl}_4$, the conductivity knees were observed between 300° and 200°C . Lutz *et al.* (12) suggested that the lithium lattice deformation occurred gradually below the phase transition temperature from a spinel structure to a defect cubic structure, and that the conductivity knee was related to an order-disorder type phase transition.

O'Keefe (19) empirically classified ionic solids into three categories with respect to fast ionic conduction. Class I solids do not undergo "nonconducting-conducting transformation" in the solid state but become highly conducting only upon melting. Class II solids, such as notably Ag^+ and Cu^+ salts, exhibit a first-order phase transition to the high conducting state. There are also a number of salts in which the nonconducting-conducting transformation is not a first-order transition as in class II solids but is spread out over a substantial temperature range. Such salts are classified as class III. The transition was named the Faraday (diffuse) transformation. The diffuse phase transitions were found in CaF_2 (20) and PyAg_5I_7 (Py: pyridinium ion) (21). CaF_2 shows a conductivity knee at about 1160°C . The diffuse phase transition is associated with disorder of the anion sublattice. The cation lattice retains the fcc structure through the phase transition. The activation energy changes from 200 to 140 kJmol^{-1} below and above the conductivity knee. PyAg_5I_7 also has diffuse phase transition associated with disorder of the cation sublattice, and a conductivity knee was found at around 52°C . In the lower temperature phase, not all the Ag^+ ions are completely mobile, while in the higher temperature phase, all are mobile. The transition in the system $\text{Li}_{2-2x}\text{M}_1+x\text{Cl}_4$ obtained by the electrical conductivity measurement also seems to be classified as a diffuse type transition. The decrease of transition temperatures with x in $\text{Li}_{2-2x}\text{M}_1+x\text{Cl}_4$ suggests that the order-disorder transition temperature is decreased with the incorporation of lithium ion vacancies. In $\text{Li}_{2-2x}\text{Mn}_{1+x}\text{Cl}_4$, the transition temperature at the composition $x = 0.33$ obtained by conductivity measurements was higher than the transition temperature at $x = 0.24$. X-ray diffraction photographs at 20° and 200°C of $\text{Li}_{1.34}\text{Mn}_{1.33}\text{Cl}_4$ showed the diffraction lines due to a mixture of the spinel phase and MnCl_2 , while those at 300°C showed only lines due to a spinel phase. Therefore, the change in slope at 280°C does not correspond to an order-disorder transition. Further comment on an order-disorder transition must await studies based on heat capacity measurement and more detailed high temperature x-ray experiments.

Conclusion

The solid solution with spinel structure, $\text{Li}_{2-2x}\text{M}_1+x\text{Cl}_4$, has been examined and found to have high ionic conductivity. $\text{Li}_{1.9}\text{Cd}_{1.05}\text{Cl}_4$ shows the highest conductivity of $3.5 \times 10^{-1}\text{ Scm}^{-1}$ at 400°C , which is higher than that of $\text{Li}_{14}\text{Zn}(\text{GeO}_4)_4$, reported previously with the highest conductivity in the temperature range $300^\circ\text{--}400^\circ\text{C}$. At room temperature, $\text{Li}_{1.52}\text{Mn}_{1.24}\text{Cl}_4$ exhibits the highest conductivity of $1.5 \times 10^{-5}\text{ Scm}^{-1}$. In spite of the high conductivity, the solid solutions show the low decomposition potential of about 1.1–1.3V. Because of this value, the utilization of this electrolyte in batteries will be limited.

Quantitative Phase Analysis of Crystalline and Amorphous Components of Positive Plates in Lead-Acid Batteries Operated under Simulated Electric-Vehicle Service

K. Harris, R. J. Hill, and D. A. J. Rand

Institute of Energy and Earth Resources, CSIRO Division of Mineral Chemistry, Port Melbourne, Victoria 3207, Australia

ABSTRACT

The crystalline and amorphous component phases of positive plates taken from lead-acid batteries in simulated electric-vehicle service were examined by quantitative XRD analysis. They were compared with independent determinations from electrical measurements and wet chemical analysis. Changes in temperature, discharge current, the ratio of α -PbO₂: β -PbO₂, and the amount of amorphous material are correlated with the capacity and cycle life of the batteries.

The ability of a lead-acid battery to supply and store energy depends on the initial electrochemical activity of the material in the positive plate and the rate at which this activity is lost during cycling. Utilization of the active mass at the beginning of service is a function of the discharge current density, the rate of electrolyte diffusion into the plate, the total surface area of the active material, the degree of electrical contact between the particles of material in the plate and between the particles and the current collector (grid), and the intrinsic electrochemical activity of the particles themselves. These factors are found to change both during a given discharge cycle and between subsequent discharge cycles, so that the battery is eventually unable to supply a useful discharge rate and/or amount of energy.

The relationship between the composition of the formed positive-plate material and some of its performance characteristics has been a subject of continuing interest for almost fifty years (1-21). In the charged condition, the positive plate consists of a lead-alloy grid supporting variable amounts of the polymorphs α -PbO₂ and β -PbO₂, both of which are converted to PbSO₄ during discharge (22). The relative proportions of the two forms of PbO₂ have been found to influence the discharge capacity (4-6, 8, 9), mechanical strength (6, 7), oxygen overvoltage characteristics (9), particle- and pore-size distribution (8, 9, 12), and surface area (8, 12) of the active material. In addition, measurements of the amount of PbSO₄ produced on discharge and/or left unconverted at the end of charging can provide information about the

efficiency of the charge/discharge process and the nature and whereabouts of any material which is not participating in the cell reaction. Changes in the relative proportions of the PbO₂ and PbSO₄ phases, and quantitative measurements of the utilization of the active material are, therefore, of particular importance in attempts to understand and improve the performance characteristics and cycle life of lead-acid batteries.

In addition to these crystalline phases, numerous studies have documented the presence of poorly crystalline, or "amorphous," material¹ in battery plates, and changes in its abundance according to the method of plate preparation and cycling history have been reported (11, 12, 16, 17, 19, 20, 23-26). Indeed, Caulder and Simon (23) have suggested that there is an inverse relationship between the degree of structural order of PbO₂ and its electrochemical activity, and that the amount of the inactive (ordered) variety increases during charge/discharge cycling (23, 24, 27, 28). However, since these observations have been disputed (29), the need for more quantitative estimates of the active and inactive components is apparent (22, 29).

The application of an XRD method to the analysis of positive plates of lead-acid batteries has already been reported (21). However, that study involved analysis of only the crystalline component phases. In the present work, we have further developed this technique for determining both the crystalline and the amorphous components of large numbers of samples taken from the positive plates of lead-acid batteries operated under simulated electric-vehicle service. In

Key words: amorphous, cell, energy conversion, phase transformation.

¹The term "amorphous," as used in this paper, refers to material which does not give rise to normal x-ray diffraction peaks, either because it is truly structureless, or because the particle size is very small (*i.e.*, < 100Å).

order to assess the performance of such plates, the XRD phase analysis results have been compared with independent measurements obtained from electrical parameters and wet chemical analysis, with particular emphasis being placed on the role of the amorphous component in the cell reaction.

X-Ray Diffraction Method for Positive-Plate Phase Analysis

The method that we have selected for the analysis of the positive-plate material is a version of the internal standard technique (30-37) specifically designed to (i) minimize the diffraction problems associated with the particular phases under study, and (ii) address questions relating to battery performance. The amount of amorphous material present in battery plate samples is determined accurately by the use of CaF_2 as the reference phase.

As discussed by Chung (32, 33) and others (34-37), the fundamental equation relating phase concentration (W) and diffracted peak intensity (I) in the internal standard method is

$$W_i = (I_i/I_s) (W_s/RI_i) \quad [1]$$

where RI_i , the so-called reference intensity ratio, is a constant for a given phase i in the presence of an internal standard s (in the present case, CaF_2) added in the weight proportion W_s . The weight fraction of the phase i (W_i) is obtained simply by measuring the intensity ratio I_i/I_s , given that W_s is known and RI_i has been determined previously for a mixture containing the same weight fraction of s .

For reasons outlined previously (21), we have chosen not to obtain values of RI_i from measurements of I_i/I_s in synthetic samples of known W_i/W_s , that is, from calibration curves corresponding to the rearrangement of Eq. [1]: $RI_i = (I_i/I_s) (W_s/W_i)$. Instead, we have decided to calculate RI_i from first principles using the known structural and x-ray scattering properties of the individual phases, that is, from the expression

$$RI_i = (Q_i/Q_s) (D_s/D_i) \quad [2]$$

where Q is the calculated powder diffraction intensity, and D is the product of the unit-cell volume and mass of the unit-cell contents (in atomic mass units) for each phase (21, 38).

The weight percentages (w/o) of the different phases are determined using Eq. [1]. Any difference between the sum of the determined weight percentages and 100% is assigned to the amount of amorphous material present in the sample. A complete description of the method, including details of the preparation of samples, the regions of diffraction record scanned, the treatment of backgrounds, and the calculation logic, has been presented elsewhere (21, 39).

Test Batteries and Operational Procedure

The XRD phase analysis method was applied to samples taken from the positive plates of test lead-acid batteries subjected to charge/discharge cycles that simulated electric-vehicle service in an urban environment. Details of test station design and charging procedure have been reported previously (21, 39-46). The batteries themselves consisted of six 2V cells joined in series, with each cell containing four positive and five negative flat plates and having a nominal capacity of 60 Ah (20h rate). Positive plates were wrapped in fiberglass cloth. The cell containers had detachable lids and the intercell connectors were specially designed to allow the batteries to be disassembled easily for collecting plate specimens at various stages of cycle life.

All of the batteries were operated under the Australian Electric Vehicle Association (AEVA) standard driving schedule (47) shown in Fig. 1. The current profiles of two vehicles operating over the AEVA driving schedule were obtained. The vehicles involved were a

Fig. 1. AEVA driving schedule (---) and battery current approximation (—) for (a) IMP electric van, and (b) Batronic electric van.

Batronic electric van on loan from the Australian Lead Development Association, and an Induction Motor Propulsion (IMP) van developed by Gosden (48) under the sponsorship of the Australian National Energy Research, Development and Demonstration Council. The Batronic van has a ten-year-old design, whereas the IMP van is representative of present-day electric vehicle design, having ac motor drive and microprocessor-controlled operation with a regenerative braking facility.

The current profiles of the two vans were scaled down from those experienced by the vehicle battery packs to equivalent rates for the test batteries used in the laboratory simulated studies (Fig. 1). The scaling factor was equal to the ratio of the test-battery capacity to the vehicle-battery capacity. After scaling down, test batteries operating under the simulated Batronic van profile experienced an average discharge current of 30.5A, whereas those under the IMP van profile drew only 12.4A (Table I). As a result, test batteries with the same nominal capacity at the 20h rate have different capacities in the simulated service of the IMP and Batronic vehicles, and have markedly different initial ranges over the AEVA schedule (Table I). A comparison of the performance of batteries under simulated driving of the two vans therefore enables an assessment to be made of the advantages gained by the introduction of advanced vehicle design. For all batteries tested, smooth-current discharge was used and terminated at 9.6V. The end of useful battery life was taken as the point at which the discharge capacity, converted to the 20h rate, had fallen to 75% of the nominal value at 25°C.

Table I. Characteristics and performance summary of test batteries

Parameter	Battery				
	T1	T2	T3	T4	T5

³ All batteries have a nominal capacity of 60 Ah at the 20h rate at 25°C and a positive-plate active-material density of 4.58 kg liter⁻¹.

⁴ Defined as the point at which the battery capacity has fallen to 75% of its nominal value at the AEVA rate at 25°C.

More than 60 batteries of various types have now been cycled under simulated electric-vehicle service in our laboratories. We report herein the detailed quantitative XRD phase analysis results obtained from five of these batteries, spanning a range of operating temperatures (25°-60°C), two different initial α -PbO₂: β -PbO₂ ratios (~0.4 and ~0.9), and two different discharge currents (for Batronic and IMP vans). These and other characteristics of the five test batteries are summarized in Table I.

The five batteries were operated at 25° (two batteries), 40°, 50°, and 60°C in thermostatically controlled water baths. At various stages of cycle life, the batteries were disassembled and specimens (1 cm²) of charged and discharged grid/active material were collected from the plates with a specially designed set of cutters. Sampling was rotated between plates and cells so that all plates were treated equally. During the sampling procedure, care was taken to preserve the fiberglass wrapping around the plates, and to minimize plate separation and disturbance. Earlier studies (42-44) have shown that periodic sampling of this kind has no deleterious effect on battery capacity or cycle life. However, heavier sampling (*e.g.*, samples from all 24 positive plates at one time) can severely diminish battery performance.

Results and Discussion

XRD analyses of "single-phase" samples.—Before applying the XRD method of phase analysis to samples taken from batteries, studies were made on several commercially available samples of chemically prepared CaF₂, β -PbO₂, and PbSO₄, together with α -PbO₂ prepared by oxidation of β -PbO at 340°C (11), and α -PbO₂ and β -PbO₂ prepared by electroformation of positive battery plates in 1M NaOH and 4M H₂SO₄ (49), respectively. The results are given in Table II.

For all samples analyzed, the integrated observed peak intensities for each scan region agreed closely with the calculated values. Compared to the diffraction patterns from chemically prepared α -PbO₂, the patterns from α -PbO₂ prepared by electroformation in 1M NaOH had much higher backgrounds and broad tails on

the peaks. Both of these factors indicate that a significant proportion of the crystallites have sizes less than about 0.2 μ m, and give rise to the possibility that many of these particles are too small to diffract at all and may therefore contribute to an amorphous component. This was confirmed by analysis; *e.g.*, in Table II the electroformed α -PbO₂ sample is seen to contain about 48% of its mass as amorphous material.

Chemically prepared α -PbO₂ is also poorly crystalline (Table II) with a variable amorphous content between about 20 and 35 w/o, but both electroformed and chemically prepared β -PbO₂ usually contain less than 15 w/o of noncrystalline material. In addition, both α -PbO₂ and β -PbO₂ usually contain small amounts of the other polymorph. In contrast, PbSO₄ was found (Table II) to be essentially 100% crystalline and very pure.

Kordes (12) used a combination of x-ray and neutron diffraction methods to determine the proportions of amorphous and crystalline material in various samples of PbO₂. It was found that the amorphous content of α -PbO₂ was in the range 40-70 w/o and that of β -PbO₂ in the range 18-50 w/o. As found in our studies (Table II), the amount of amorphous material was dependent on the method of preparation of the lead dioxide.

The ranges of values shown in Table II for each sample were obtained from repeated analyses of samples prepared by different operators, using different sample thicknesses, grinding times, and weights. Values suggest that the results are conservatively reproducible to within about 5% by weight for all four components. As discussed below, XRD analyses were also performed on various synthetic mixtures of PbSO₄ and β -PbO₂ (and α -PbO₂ in other studies not reported here) in order to check the accuracy and precision of the method. In all cases, the XRD results were well within 5 w/o of the known compositions of the mixtures.

XRD analyses of positive plate material.—Figure 2 shows the progressive changes in the α -PbO₂, β -PbO₂, PbSO₄, and amorphous material contents for both the charged [plots (a)] and the discharged [plots (b)] state

of battery T4 as a function of the number of cycles of simulated electric-vehicle operation. These plots for battery T4 are typical of those found for the other four batteries tested. In order to discuss trends in plate composition with cycle life, groups of analyses typical of the early, middle, and late stages of operation have been averaged and presented in numerical form in Table III. Also included in Table III are the amounts of active material (crystalline plus amorphous) discharged to PbSO₄ at each of these three stages of cycle life.

Inspection of the phase analysis results summarized in Table III shows that:

(i) Utilization of the positive-plate active material during the early and middle stages of battery operation was about 50% higher with the IMP than with the Batronic van driving profile (cf. batteries T1 and T2 operated at 25°C). This difference is due to the lower average discharge current required by the IMP profile and leads to a much greater initial driving range for this vehicle (Table I).

(ii) For a given vehicle current-profile, utilization of active material during the early stages of battery operation increased more or less uniformly with temperature from a value of ~18 w/o for battery T2 at 25°C to ~36 w/o for T5 at 60°C. A similar observation has been reported by Asai *et al.* (50). Active material utilization remained fairly constant during the early and middle stages of battery life, and declined sharply during the final stage of operation. These utilization rates are typical for batteries operated under the high rates of discharge experienced in electric vehicles.

(iii) The five test batteries began service with α -PbO₂: β -PbO₂ ratios between 0.37 and 0.98, and subsequent charge/discharge cycling reduced this ratio to 0.11-0.18 at failure (Table I). This decline in the oxide ratio was found to be more rapid with increase in temperature and decrease in discharge rate. This can be explained by the fact that both of these operating conditions promote penetration of the electrolyte into the active material and hence decrease the pH in the interior of the plates. This leads to an environment more favorable to the formation of β -PbO₂ from α -PbO₂ (through PbSO₄) on recharging.

(iv) At all stages of battery operation, the conversion of α -PbO₂ to PbSO₄ was less than that of β -PbO₂ to PbSO₄, e.g., for battery T2, the maximum conversion rates of α -PbO₂ and β -PbO₂ were 5 and 30%, respectively. Both rates increased with temperatures, e.g., for battery T5, the maximum conversion rates of α -PbO₂ and β -PbO₂ were 20 and 45%, respectively. However, whereas the conversion of α -PbO₂ remained approximately the same throughout the life of each battery,

the conversion of β -PbO₂ dropped significantly (to values around 20%) as battery failure was approached. Since analysis showed that the α -PbO₂ resided predominantly in the interior of the plates during the middle and late stages of battery operation, it is concluded that the loss of PbO₂ activity is primarily associated with the lead dioxide present in the external portions of the plates, i.e., those areas most affected by loss of interparticle contact through active material "softening."

(v) Throughout battery life, the PbSO₄ content of the charged plates remained fairly constant, especially at high temperature. The amount of PbSO₄ produced during battery discharge was significantly reduced in the final stages of operation. These results, and those of others (51), suggest that the decline in battery capacity is due not to sulfation of the positives in the charged state, but to an inability of the PbO₂ to be reduced during discharge. Electrical isolation of the active material by grid corrosion, therefore, does not appear to be a major cause of failure, since decreased reactivity would then be observable during both the charge and discharge processes. A more likely explanation for the decline in battery performance is the electrical isolation of unconverted PbO₂ particles by the growth of PbSO₄ particles or films during discharge (8, 52-55).

(vi) The amount of amorphous material in the positive plates varied between 10 and 29 w/o for the batteries studied and may be compared to a value of 34 w/o determined by Kordes (12). Within a given battery, there is a tendency for the amount of amorphous material to increase as cycling proceeds (Fig. 2), and for the material in inner portions of the plate to be less crystalline than in the outer parts.

(vii) The variability of phase composition between adjacent plates in any one battery was higher in the discharged than in the charged state. This again suggests that it is the reduction of PbO₂ to PbSO₄ which is the life limiting factor in battery performance, rather than the oxidation of PbSO₄ to PbO₂. In other studies reported both below, and previously (21, 39, 43, 44), we have observed that individual plates within a battery do indeed develop their own unique phase compositions as cycling proceeds and that this nonuniformity can lead to severe loss of capacity and cycle life. It was found that plate uniformity was maintained for longer periods of time at higher temperatures of operation.

*Comparison of XRD analyses with alternative measurements of battery performance.—Electrical measurements.—*From a knowledge of the weight of the

³ Amount = Σ(net positive changes (D-C) in PbSO₄ and amorphous material).

active material in the positive plates (~590g per cell), it is possible to calculate the weight percentage of PbSO₄ produced by the passage of a given amount of electricity during discharge. The weight percentages of PbSO₄ so calculated (assuming no shedding of material) for each of the cycles at which the battery was sampled for XRD analysis are plotted for batteries T2 and T4 in Fig. 3. Also shown are the corresponding values of the weight percentages of PbSO₄ (and amorphous material) produced during discharge of the batteries (as determined by XRD analysis), together with the values of PbSO₄ content obtained from chemical analysis (LECO method) of the total sulfur content of the same samples (Table III).

Despite the fact that the PbSO₄ contents calculated from capacity measurements are averages over all six cells in the battery, whereas the XRD and chemical analysis values are single-sample estimates from a quantity of material approximately equal to 0.6% of the mass of only one of the four positive plates in one of the cells, there is good agreement between the three PbSO₄ curves for each battery in Fig. 3. Why the XRD-derived values should, on average, be slightly lower than the electrical and chemical values is unclear, but it could be related to the fact that the discharge of amorphous PbO₂ to amorphous PbSO₄ cannot be de-

tected by XRD phase analysis alone; the parallelism of the XRD and chemically determined values suggests that this is indeed the case.

Chemical measurements.—Attempts to determine the overall composition of the bulk active material by chemical analysis for lead are limited by the uncertainty associated with the assumption of a valence state for lead, the level of nonstoichiometry, and/or the presence of intermediate oxides, water molecules, hydroxyl groups, etc. (11, 22, 56). However, the sulfur present in cycled plates is unambiguously present as PbSO₄ (no basic lead sulfates were visible in the diffraction patterns), and this material is not affected by any of the problems associated with the oxide phases. Any excess in the sulfur content of the charged or discharged bulk material (determined by chemical means) over that measured in the crystalline fraction (by XRD phase analysis) must therefore represent the sulfur contained within the amorphous material.

Samples of positive-plate active material from battery T4 in both the charged and discharged states, and also samples from two other test batteries after slow discharge at the 20h rate, were subjected to total sulfur analysis. The results are plotted in Fig. 4 against the corresponding XRD estimates of the crystalline PbSO₄

Fig. 3. Comparison of XRD-determined utilization of positive material in test batteries T2 and T4 with the corresponding amount determined either coulometrically or chemically. (▲) Ah converted to equivalent PbSO_4 (w/o). (■) XRD determination of active material discharged (w/o). (●) Total S content converted to equivalent PbSO_4 (w/o).

content of other portions of the same samples. The least squares linear regression line through all the data points for T4 is indicated by the dashed line (correlation coefficient = 0.991), and the 1:1 relationship between total S and PbSO_4 content is drawn as a solid line (labeled as 100% crystalline). The error in each total S measurement is estimated to be about 1% (relative to the amount determined); the error bars for total S have been omitted from the low-value data points (<2 w/o) since they are within the width of the data point itself. A uniform error of about ± 2 w/o (absolute) is estimated to apply to all the values obtained from XRD analysis.

The most obvious feature of the data plotted in Fig. 4 is that the amount of crystalline sulfate in battery

plates, when obtained from XRD measurements, is always significantly less than the amount calculated from determination of the total S content. Assuming that the total S values are not in doubt, this feature could be due to: (i) the presence of a systematic error in the XRD method of analysis whereby the amount of PbSO_4 is consistently underestimated, or (ii) the presence of noncrystalline PbSO_4 , which is measured by the total S analysis, but is not detected by XRD analysis.

As a check on the accuracy and precision of the XRD method in the context of this experiment, five synthetic samples were prepared containing a 1:1 by weight mixture of CaF_2 (internal standard) with Unilab PbSO_4 and Univar $\beta\text{-PbO}_2$; the latter compounds were in the ratios 0:100, 10:90, 20:80, 40:60, and 60:40, respectively. Unilab PbSO_4 and Univar $\beta\text{-PbO}_2$ are known to consist of 100 and 95 w/o crystalline material, respectively (Table II). The five mixtures were then subjected to XRD phase analysis, and the resultant crystalline PbSO_4 contents were plotted against the total S weight percentage (Fig. 4). For all five synthetic samples, the theoretical 1:1 line lies well within the estimated error of the XRD determination, adding further credence both to the accuracy and to the estimated precision of the XRD phase analysis method. The deviation of the T4 test battery analyses from the theoretical 1:1 (i.e., 100% crystalline) relationship in Fig. 4 is therefore considered to be real and to be due to the presence of amorphous PbSO_4 in the plates.

Chemical and XRD analyses of samples taken from battery T2 operated at 25°C exhibited the same relationship between the crystalline PbSO_4 and the total S content as that observed in Fig. 4 for battery T4 at 50°C. This suggests that the temperature of operation has little, if any, effect on the partitioning of the PbSO_4 between the crystalline and amorphous components.

Role of the amorphous component in positive-plate material.—Of particular interest is the fact that not only is there PbSO_4 in the amorphous fraction, but that the amount of this noncrystalline sulfate increases with the amount of crystalline PbSO_4 . For example, for a T4 battery sample ostensibly containing no crystalline sulfate, the intersect of the regression line in Fig. 4 suggests that there is actually 0.4 w/o total S present, corresponding to 4.1 w/o amorphous PbSO_4 , whereas

Fig. 4. Comparison of PbSO_4 content (XRD analysis, w/o) in synthetic samples and in charged/discharged positive plates of test battery T4 operated at 50°C under the AEVA driving schedule, with total S content determined by chemical analysis. (---) Least squares regression line through battery data. (—) Theoretical 1:1 relationship between plotted parameters. Also included are corresponding results obtained for two other test batteries subjected to a slow discharge at the 20h rate. The estimated precision of the determinations are indicated by error bars.

for a sample containing 30.0 w/o crystalline PbSO_4 there is an additional 12.1 w/o of amorphous PbSO_4 .

Taking battery T4 as a case in point, the amount of amorphous material increased from 20 to 29 w/o during cycle life (Table III). However, there was no significant change in the amorphous content between the charged and discharged states at any stage of cycle life. The increase in the deviation of the experimental PbSO_4 line from the 100% crystalline line in Fig. 4 as the sulfate content increased cannot, therefore, be related to a corresponding increase in the total amount of amorphous material in the plates as they were discharged. Instead, the proportion of PbSO_4 in the amorphous fraction must be increasing, i.e., amorphous dioxide (either $\alpha\text{-PbO}_2$ or $\beta\text{-PbO}_2$) must be discharging to amorphous PbSO_4 . Behavior of this kind was typical of all five test batteries. In only three cases in Table III (T1, middle life; T3, early life; T5, early life) was a significant change in the amount of amorphous material observed during discharge. This suggests that the processes of charge and discharge generally take place between particles of broadly equivalent size during the operation of the batteries, i.e., crystalline material converts to crystalline material, and amorphous to amorphous.

Table IV presents calculations of the relative utilization of the amorphous and crystalline fractions of the positive-plate active material of batteries T2 and T4, together with corresponding results for another test battery subjected to a slow discharge at the 20h rate (top right-hand corner of Fig. 4). For a given battery, the results show that, within the accuracy of the determinations, there is little difference in the degree of utilization of the two forms (i.e., crystalline and amorphous) of lead dioxide in batteries operated under either simulated-electric-vehicle or slow-discharge conditions. Thus, it appears that particle size (as delineated in the present study) has little, if any, effect on the activity of the positive-plate material. As discussed above, the utilization of both forms of lead dioxide increases both with increase in temperature and with decrease in discharge rate.

The indication that amorphous lead dioxide has the same electrochemical activity as crystalline lead dioxide is somewhat surprising when it is noted that neutron diffraction studies (25, 39) have shown that part of the amorphous component is a lead-rich intermediate oxide with $\sim 40\%$ lead atoms in the Pb(II) valency state. It can only be concluded at this stage, therefore, that this intermediate oxide has a similar electrochemical activity to near-stoichiometric PbO_2 .

Battery cycle life and equivalent distance traveled.—Of the three parameters tested in the present study, namely, operating temperature, discharge current, and initial $\alpha\text{-PbO}_2\text{:}\beta\text{-PbO}_2$ ratio, the former two exert by

Fig. 5. Number of charge/discharge cycles (○ IMP, ● Batronic) and equivalent kilometers traveled (□ IMP, ■ Batronic) plotted as a function of operating temperature for batteries T1-T5.

far the greatest influence on overall battery performance (Table I).

In Fig. 5, the number of charge/discharge cycles and equivalent kilometers traveled for each of the five test batteries have been plotted against the operating temperature. For the four batteries, T2-T5, subjected to the Batronic van discharge profile, the improvement in battery performance with temperature, as given by both cycle life and equivalent kilometers traveled, is dramatic (see also Table I); both measures of performance are improved by more than a factor of three on raising the temperature from 25° to 60°C.

Although the increase in battery performance with temperature appears to be relatively uniform, it is interesting to note that the two batteries (T2 and T4) with initial $\alpha\text{-PbO}_2\text{:}\beta\text{-PbO}_2$ ratios around 0.9 (Table I) lie above the smooth curves in Fig. 5, whereas the two batteries (T3 and T5) with a low initial oxide ratio (i.e., around 0.4) lie below the curves. A high value for the initial $\alpha\text{-PbO}_2$ content of the formed plates therefore appears to be advantageous to battery performance, albeit to an extent less than that effected by increasing the operating temperature. The fact that even a modest correlation obtains between the $\alpha\text{-PbO}_2\text{:}\beta\text{-PbO}_2$ ratio and cycle life is somewhat surprising, since for most of the batteries (especially T4 and T5 operated at higher temperatures) the lead-

Table IV. Calculation of relative utilization rate of amorphous and crystalline lead dioxide in test batteries T2 (25°C) and T4 (50°C) in the early (E), middle (M), and late (L) stages of battery life, and in another test battery subjected to a slow discharge at the 20h rate at 25°C†

† Data for T2 and T4 obtained from Table III; data for slow discharge battery not given in detail.

* Ratio factor = (molecular weight PbO_2) / (molecular weight PbSO_4).

dioxide ratio was lowered to a value around 0.15 early in the service life. This suggests that the ratio itself is not important, but that it is the conditions of curing and/or formation of the plates (giving rise to an initially high ratio) that determine the final performance level.

A comparison of the performance of battery T1, operated at the same temperature (25°C) as T2 but under the IMP driving profile, shows that the lower average discharge current (12.4 compared to 30.5A, Table I) results in a 35% improvement in cycle life and a five-fold increase in equivalent kilometers traveled. It can be seen from Fig. 5 that a similar improvement in vehicle range under the Batronic profile would only be achieved by operating the same battery above 60°C. The advantages of advanced vehicle design are obvious.

Mode of battery failure.—Detailed examination of the XRD phase analysis results presented in Fig. 2 and Tables III and IV reveals that the onset of battery failure is associated with several factors.

(i) An accelerating decline in the conversion rate of β -PbO₂ to PbSO₄, both in the crystalline and amorphous components, despite the fact that the overall PbO₂ content of the charged plate remains relatively constant (especially at low temperatures). Neutron diffraction, structural, and electrochemical activity studies discussed elsewhere (25, 39) suggest that β -PbO₂ particles in battery plates remain intrinsically electrochemically active and that the inability of bulk β -PbO₂ to discharge is probably a consequence of the individual particles becoming electrically isolated from each other in the active mass and from the current collecting grid itself. Similar conclusions have been drawn by other workers (8, 53-55), although the possibility of a loss in electrochemical activity of the PbO₂ itself has received support (23, 24, 27, 28, 52, 57, 58). Since the majority of the PbSO₄ produced on discharge continues to be converted back to PbO₂ on charge, progressive encapsulation of the PbO₂ by insulating particles or films of PbSO₄ would appear to be the more likely mechanism for this electrical isolation (as opposed to passivation of the grid by PbSO₄ films). The former mechanism is eminently feasible, since PbSO₄ particles grow at the expense of PbO₂ particles and are able to convert back to PbO₂ since they remain in contact with the electrolyte.

(ii) An increase in the amount of amorphous material. The amorphous material displays a somewhat more rapid decline in utilization with battery cycling than the crystalline component (Table IV). A rise in temperature may be expected to increase the amount of fine-grained material with cycling, and we note (Table III) that batteries T3, T4, and T5 do indeed display the greatest relative increases in the amorphous component over their service life.

(iii) An increase in the variability of positive-plate phase composition and active material utilization (see particularly batteries T1-T3 operated at lower temperatures). The occurrence of an occasional sulfated plate has been accepted in the past as a consequence of variability in plate manufacture, but this has not been considered to be a major cause of failure (44). However, measurements of the potentials of positive- and negative-plate groups in individual cells of batteries monitored during charge/discharge cycling have shown that catastrophic declines in battery capacity can be related to the failure (*i.e.*, sharp drop in discharge voltage) of a positive-plate group in only one of the cells (39). Subsequent XRD phase analysis of the positive plates in the failed cells has often revealed that one or more of the plates are heavily sulfated in the charged state. The heavy sulfation has therefore contributed to a sharp decrease in the electrical conductivity of the active material and thus to a rapid decline in its discharged voltage (8, 54, 55). Why only

certain plates are sulfated when the majority of the others in the battery, and indeed in the same cell, are not, remains to be determined. Whatever the cause of sulfation, it is clear from Fig. 2 that the operation of a battery at high temperature promotes the maintenance of a more uniform distribution of phases between the plates and prevents the early formation of "hard" sulfate.

(iv) An increased rate of shedding in the cell observed (by potential measurements) to fail first. Nonetheless, the amount of material shed was not sufficient by itself to cause cell failure. No marked increase in the rate of material shedding from the plates was observed on raising the operating temperature from 25° to 60°C (Table I).

(v) Negative plate degradation at high temperatures. For example, autopsies conducted on T5 operated at 60°C revealed that swelling and mossiering of the negative plates took place. This led to internal shorting of the battery. In addition, the grids of the positive plates were found to be in a badly corroded state and extremely fragile. Since this battery was observed to maintain a relatively uniform plate composition during its considerable period of service, it is likely that batteries operated at high temperature fail by a different mechanism (namely, positive-plate grid corrosion and/or negative-plate mossiering) from those operated at lower temperatures (namely, plate inhomogeneity/sulfation of the charged plates).

Summary and Conclusions

Application of the XRD phase analysis procedure to single-phase samples of various chemically and electrochemically prepared varieties of PbO₂ and PbSO₄, and to synthetic mixtures of these compounds, has demonstrated the viability of the method for phase analysis of positive plates of lead-acid batteries. This conclusion has been confirmed by comparisons of XRD results for real battery plates with those for independent estimates of composition obtained from electrical measurements and wet chemical analysis.

Studies of batteries operated under simulated electric-vehicle service at four temperatures, two ratios of the PbO₂ dimorphs, and two mean discharge currents have indicated that the overall utilization of active material increases substantially with increasing temperature and decreasing current. The utilization of β -PbO₂ is observed to be higher than that of α -PbO₂ under all conditions. The amount of α -PbO₂ declines rapidly during the early stages of battery operation due to an irreversible conversion to β -PbO₂, but the utilization of this oxide remains fairly constant, whereas that of β -PbO₂ declines. This observation may explain why batteries with higher initial values of the α -PbO₂: β -PbO₂ ratio appear to have longer cycle lives.

Decline in battery capacity at all temperatures is brought about by the failure of the β -PbO₂ particles to be reduced to PbSO₄ on discharge, rather than a failure of the PbSO₄ to be oxidized on charge. This suggests that electrical isolation of the β -PbO₂ particles is the cause of capacity loss rather than the development of extensive grid corrosion. However, at low temperatures of operation, variability in phase composition between individual positive plates can be quite large, and the occasional development of a few heavily sulfated charged plates can lead to the failure of the entire battery, even though the majority of the plates are not sulfated.

At higher temperatures of operation, the positive plates are more uniform in composition and failure of the battery does not result from heavy sulfation of a few individual plates. Instead, the battery fails due to negative-plate swelling and mossiering, and/or the presence of substantial positive-plate grid corrosion. Nevertheless, as at lower temperatures, the capacity of the battery slowly declines throughout the middle and

later stages of operation as the conversion efficiency of β -PbO₂ to PbSO₄ decreases.

Comparison of XRD results with wet chemical analysis results shows that the amorphous PbO₂ component of the positive plates discharges at a similar rate to that of the crystalline component, but that the amorphous material utilization declines somewhat more rapidly with cycling. Since the amorphous content of plates varies from only 10 to 29 w/o, and increases slightly during cycling, the presence of amorphous material has only a small adverse effect on overall battery performance. Nevertheless, the results suggest that the amorphous content should be kept to a minimum during plate manufacture.

ABSTRACT

A process to manufacture the positive plate of the lead-acid battery that eliminates conventional curing and formation steps via the direct incorporation of PbO_2 active material into the grid is described. "Precharged" plates made from a mixture of tetrabasic lead sulfate, PbO_2 , and water were found to be strong and capable of delivering first cycle (*i.e.*, with no formation) cranking rate capacity which was 35% of conventionally produced plates tested in the same format. Full capacity is obtainable within three to five charge-discharge cycles. At this point, the precharged plates were found to be structurally indistinguishable from conventionally processed plates. To ensure in these initial studies that the PbO_2 was electrochemically active, the material was obtained from electrochemically formed conventional positive plates. The successful use of chemically prepared PbO_2 is demonstrated in the following paper. This new process is simple and will allow the manufacture of ready-to-use plates on modern automated expanded metal platemaking equipment.

The work described in this paper addresses a radical approach to lead-acid battery manufacture which would result in a simpler processing technology more amenable to modern automated expanded metal plate making equipment and would offer the marketing advantage of a truly dry charged battery with an "infinite" shelf life. To aid in the understanding of the significance of this work, a brief description of current lead-acid battery processing technology is required (1, 2).

Conventional battery plates are made from a starting material consisting of an incompletely oxidized Pb powder (Pb, PbO orthogonal and tetragonal forms), sometimes mixed with Pb_3O_4 in various ratios. This powder is mixed with H_2SO_4 and water to form a paste which is then applied to a lead alloy grid. Subtle differences exist between the positive and negative pastes, but the reactive paste chemistry is not different. Numerous complex chemical reactions occur during the mixing of this reactive paste leading to PbSO_4 , $\text{PbO} \cdot \text{PbSO}_4$, $3\text{PbO} \cdot \text{PbSO}_4 \cdot \text{H}_2\text{O}$, $4\text{PbO} \cdot \text{PbSO}_4$, and Pb_3O_4 in various relative concentrations depending on: (i) starting material composition; (ii) relative amount of acid and water added; and (iii) mixing rate and mixing temperature. The pasted plates are allowed to cure, usually for several days. During curing, the water is removed from the plates in a manner such that dissolved compounds are deposited at paste particle contact points in a manner analogous to cement setting (1). Additional chemical reactions occur during curing which can change the relative concentrations of the species in the pasted plate. Additionally, shrinkage of the paste from the grid members may occur during curing. This shrinkage can deleteriously affect the resulting battery plate, particularly when nonantimonial alloys are used in the battery grids. The variables influencing the curing process are time, temperature, and humidity. After curing, the plates are immersed in acid and a formation current which anodically forms lead dioxide at the positive and cathodically forms sponge lead at the negative is applied to the plates for an extended period up to about 24h. This formation current generates a conductive network of positive and negative active materials and an integral grid/active mass interface. Both phenomena

aid in the subsequent discharge of the battery plates by forming a conductive network between the grid and the active mass. Additionally, much speculation regarding the production of a lead dioxide (in the positive plate) of intrinsic electrochemical activity exists in the literature and is discussed in the following paper (3). The variables to be considered during formation are: (i) current density; (ii) acid concentration; (iii) time; and (iv) the composition of the cured plate. The above-mentioned process variables are considered critical to the formation of a good positive plate and this topic has been the subject of numerous technical papers (4-6). The numerous variables involved in conventional lead-acid battery manufacture and their concomitant effect on battery performance make a simpler more controllable manufacturing scheme highly desirable.

Consequently, the goal of this work was the direct incorporation of the active masses (*i.e.*, lead dioxide and sponge lead) into a grid, thus eliminating the process steps of curing and formation. In eventual application, it would be desirable for these "precharged" electrodes when incorporated in an automotive starting, lighting, and ignition (SLI) battery to be capable of delivering sufficient cranking rate capacity to start an automobile with subsequent charging by the automobile's electrical system generating the additional reserve capacity. In addition to providing a simpler, more controllable automated process, this envisioned manufacturing scheme would offer a type of dry-charged product with an extended shelf life. Since these battery plates need not come in contact with sulfuric acid prior to their use, the sulfation of the active masses which limits conventionally manufactured battery shelf life would not occur.

Work on the precharged positive electrode process has been divided into two areas: (i) development of a technique to incorporate PbO_2 into a grid in a dischargeable form, and (ii) identifying a chemically produced but electrochemically active form of PbO_2 which may be incorporated into the above process. The first topic is covered in this paper. The second is the subject of a subsequent paper (3). The method of preparation, performance, and characteristics of positive electrodes produced via this novel process have been described in two patent applications (7, 8). A

* Electrochemical Society Active Member.

process for manufacturing a precharged negative electrode will be reported at a later date.

Experimental

Experimental evaluation of the precharged active mass formulations was conducted on $40 \times 68 \times 2$ mm grids cast in a Pb-0.065% Ca-0.50% Sn alloy as shown in Fig. 1. The test cell consisted of one test positive between two conventionally manufactured negative plates from the Exide 10 A-h small rechargeable battery separated by microporous rubber separators. Positive polarization was recorded vs. a Hg/Hg₂SO₄ reference electrode in the same solution. The electrochemical evaluation was conducted in 100 ml of 1.280 sp gr sulfuric acid electrolyte. Cells were discharged (without any prior "boost" charging) at a 10A (200 mA/cm²) cranking rate at room temperature. Capacity was measured as the time in seconds to reach 500 mV positive polarization. Capacity is also expressed in this work as utilization efficiency; i.e., the percentage of the theoretical ampere-hour capacity based on the weight of active material delivered by the experimental plate. The cells were then recharged to a potential limit of 2.5V with initial current density limited to 60-80 mA, and the process was repeated until five cranking rate discharge capacities were recorded.

The general processing scheme involved applying a water paste of the precharged active mass to the grid followed by hot-pressing the pasted grids between two stainless steel platens at 130°C for 30-60s at about 36 MPa (5200 psi). The precharged electrode performance was compared to that of conventionally produced positive electrodes tested in the same format.

Results

To separate the intrinsic activity consideration of electrochemically produced lead dioxide from precharged formulations, initial experiments were conducted with lead dioxide obtained by crushing pellets from well formed positive plates. The initial approach to binding the lead dioxide into the grid was to thoroughly mix lead dioxide and 0.5 w/o (weight percent) Teflon¹ (du Pont K-10) powder in a mechanical mixer with substantial shearing action. The mass was

¹ Registered trademark of the E. I. du Pont de Nemours and Company.

Fig. 1. The small Pb-0.065% Ca-0.50% Sn cast grid used in this study. Dimensions are $40 \times 68 \times 2$ mm.

then wet with water, pasted, and pressed into grids as described above. One batch of plates made in this manner was overpasted by 0.8 mm (0.030 in) to determine if any benefit was incurred from the additional compacting action. Teflon-bonded plates and the laboratory standard plates made by conventional paste technology are described in Table I, and the discharge characteristics are presented in Table II. No capacity at the cranking rate was observed with Teflon-bonded electrodes, and during charge, the active mass was observed to mechanically disintegrate from the grids. Some electrodes from these two batches were then tested at a 10 mA/cm² rate. The flush-pasted electrodes exhibited poor first cycle capacity and could not mechanically tolerate the subsequent charging. The overpasted electrodes could withstand subsequent charging but still were far inferior to the standard plates even after a third cycle low rate conditioning discharge.

At this point it was concluded that material which could add mechanical support to the precharged active mass and could additionally be converted to lead dioxide on charging would be beneficial. Tetrabasic lead sulfate (TTB) was identified as a possible material which could serve this purpose. TTB has a fibrillar, needle-like morphology as shown in Fig. 2. TTB is used in place of a conventional paste by Western Electric to manufacture the round cell for stationary float service applications (9). The advantages of a TTB paste are: (i) it may be prepared from water, (ii) shrinkage during curing is eliminated, and (iii) increased cycle life performance has been reported (9, 10). The improved cycle life performance of plates formed from a TTB paste appears due to its metasomatic conversion to PbO₂ (9, 10) in which the initial TTB morphology is maintained. Metasomes are generally characterized as hard, dense materials due to their diffusional growth mechanism, analogous to zone refining (9). Apparently the resultant interlocking prismatic needles of PbO₂ act to delay the active mass shedding. The presence of needles of PbO₂ in conventional pastes (presumably resulting from the TTB in the cured mass) has additionally been correlated to improved cycle life behavior (11). One drawback of positive plates produced from a TTB paste is the longer formation time required and the necessity to form in low gravity acid (1.001-1.005) to prevent sulfation of the TTB (12). TTB is oxidized to PbO₂ via the following reaction (5)

Table I. Active mass weight, porosity, and theoretical capacity of Teflon-bonded precharged electrodes and lab standard positive electrodes

	Active mass weight (g)	Porosity, %	Theoretical capacity (A · h)
Flush-pasted	31.3 ± 0.57	40	7.01 ± 0.128
0.8 mm (30 mil) overpasted	40.9 ± 1.9	38	9.16 ± 0.426
Lab standard	25.9 ± 1.1	41	5.80 ± 0.246

Table II. Discharge times of Teflon-bonded and lab standard positives at a 10 mA/cm² rate to a 1.75V cutoff

Cycle	Average data from four electrodes		Lab standard positives
	Discharge time (s) Teflon-bonded positives		
	Flush-pasted	Overpasted

* 2 mA/cm² conditioning discharge.

Fig. 2. Scanning electron micrograph of tetrabasic lead sulfate (TTB) as received from the Eagle-Picher Company.

1g of TTB converts to 1g of PbO_2 , and a 15% volume reduction accompanies the conversion.

A mix of 30 w/o TTB and 70 w/o PbO_2 obtained from battery plates was thoroughly blended in a wire mill, and 29 ml of water was added per 100g of mix. Grids were then hand-pasted and hot-pressed. A scanning electron micrograph of a pellet of this active mass after hot-pressing is shown in Fig. 3. In this particular micrograph, the PbO_2 is a chemically prepared material from Eagle-Picher. The characteristics of these plates along with their first and second cycle performance are shown in Table III. Note that included in the 25.9g of precharged active mass is 30% of material (TTB) which is incapable of delivering capacity. These plates were able to deliver first discharge capacity at the cranking rate (200 mA/cm^2), and exhibited improved discharge capacity after their first charge. Note the initial polarization (IP) characteristic in Table III. This is the voltage drop just after the discharge current is applied to the plate and is attributed to IR losses in the grid/active mass and at the grid/active mass interface. In the first cycle, the IP for the precharged plates is somewhat larger than for standard plates and may be rationalized by insufficient interparticle and grid/active mass contact resulting in larger "IR" losses relative to the standard plates. The decrease in IP with subsequent cycling indicates the development of a more integral active mass and grid/active mass interface. The bulk porosity of these plates is somewhat lower than one would encounter in automotive plates (~45%) but porosity could perhaps be increased later by judicious choice of PbO_2 particle

Table III. Performance of TTB-bound precharged positives using battery plate PbO_2 at two degrees of overpasting at 200 mA/cm^2 cranking rate

	Average of six electrodes		
	TTB-bound precharged positives		Lab standard positives*
	0.8 mm (30 mil) Over-pasted	0.25 mm (10 mil) Over-pasted	
Active mass weight (g)	29.6 ± 0.71	25.9 ± 0.87	25.9 ± 1.1
Porosity (%)	39	40	41
IP (mV)			
1st discharge	346 ± 4	332 ± 18	264 ± 9
2nd discharge	273 ± 9	273 ± 6	
Discharge time (s)			
1st discharge	59.9 ± 5.4	57.6 ± 6.5	160 ± 15
2nd discharge	114 ± 15	123 ± 3	
Utilization efficiency (%)			
1st discharge	2.51 ± 0.23	2.76 ± 0.31	7.61 ± 0.75
2nd discharge	4.78 ± 0.63	5.89 ± 0.14	

* Conventional well-formed plates after 10 charge-discharge cycles.

size and size distribution or even with the use of pore formers if necessary.

Some overpasting of the grid to enhance the effectiveness of the pressing operation was found to be beneficial. The data of Table III shows, however, that an overpaste as large as 0.8 mm (30 mil) is not necessary and that somewhat higher utilization efficiencies are obtained with the 0.25 mm (10 mil) overpaste.

The active mass after three discharge and two charge regimes is shown in Fig. 4. No evidence of TTB is observed, indicating its nearly total conversion to PbO_2 . This active mass appears more integral and it is apparent that the conversion of TTB to PbO_2 has acted to cement the structure together. The cranking rate performance of these precharged plates expressed as utilization efficiency during the first five cycles is shown in Fig. 5. By the third cycle, the cranking rate performance of the precharged plates is within the error range of the conventional positives.

Discussion

A limited amount of work was done to better understand the role of tetrabasic lead sulfate as a binder in the active material. Study of a number of scanning electron micrographs of the active material after hot-pressing but before immersion in acid (similar to Fig. 3) seemed to indicate little if any mechanical interaction of the PbO_2 particles with the needle-shaped TTB fibers. To determine if the morphology of the TTB had any effect on the initial performance of the plate, a mix of PbO_2 and 30 w/o TTB was prepared from TTB that had been ground in a mortar and pestle. The TTB before and after grinding is shown in the SEM's of

Fig. 4. Scanning electron micrograph of "precharged" positive material in the charged state after three discharge-recharge cycles.

Fig. 5. Utilization efficiency at cranking rate (200 mA/cm^2) vs. cycle number for TTB-bound positives compared to standard positives. PbO_2 obtained from formed SRB positives. 0.25 mm (10 mil) overpasting of a 30% TTB-70% PbO_2 mix.

Fig. 6. After assembling these plates into cells, the capacity on the initial discharge was very similar to plates made with "as-received" TTB. It was noted, however, that the plates with ground TTB seemed to charge more rapidly and by the third discharge-recharge cycle, the capacity was in the range of conventional plates having similar density and pore size distribution characteristics. Plates were also made using no binder of any kind. After hot-pressing, these plates are reasonably strong and on initial discharge, they exhibit capacity and utilization efficiency greater than precharged plates made with TTB. But on subsequent cycles these plates deteriorated rapidly due to severe shedding of the PbO_2 .

From these experiments, it is concluded that the TTB makes no contribution to the mechanical properties of the plate in the hot-pressed condition and that a hot-press operation in itself results in a plate able to withstand handling. The TTB does, however, provide effective binding action on charge and through subsequent discharge-recharge cycles. Further, the morphology of the TTB is not important. In fact, binding of the plate is accelerated if the characteristic needle shape of the TTB is destroyed by grinding to effectively decrease the particle size of the TTB in the mix. Apparently, binding or cementing action on cycling results from local dissolution and reprecipitation and is markedly promoted by the presence of the tetrabasic lead sulfate.

Conclusion

These initial studies have shown that using TTB and battery plate PbO_2 , a "precharged" positive plate may be manufactured by a scheme which eliminates the conventional process steps of curing and formation. In the initial discharge with no prior formation, these "precharged" electrodes deliver ~35% of the cranking rate capacity at room temperature relative to conventionally prepared positives. Additional capacity is then generated from the "cycle up" capability of these

Fig. 6. Scanning electron micrographs of tetrabasic lead sulfate before (A, top) and after (B, bottom) grinding.

plates during subsequent charge or discharge-recharge cycles.

Clearly, a manufacturing process of this type offers the advantages of a process more amenable to automated continuous battery plate manufacture. Additionally, as with all dry-charged batteries, these batteries could be shipped at 1/3 less weight since they need not come in contact with acid until ready for sale, and the limited shelf-life problems resulting from a reactive paste would not be encountered.

This work addressed the problem of incorporating battery PbO_2 into a dischargeable structure. Clearly, an economical way of preparing an electrochemically active form of PbO_2 to be incorporated into this process is required. The following paper addresses the effect of various PbO_2 samples on precharged performance and plate morphology, and presents cycle life data results.

It is recognized that much work remains to be done to prove and to optimize the proposed new process. The critical effects of low temperatures on discharge performance, among many factors, had not been evaluated at the time work on the concept was discontinued.

ABSTRACT

A positive lead-acid battery electrode made by the direct incorporation of PbO₂ and a binder into the grid was described in the previous paper (1). The performance of "precharged" PbO₂ electrodes formulated with PbO₂ from various sources is reported in this paper. The PbO₂ samples were first characterized by x-ray diffraction, wet chemical analysis, differential scanning calorimetry, thermogravimetric analysis, BET surface area, and particle size distribution. Positive plates made from these PbO₂ samples were constructed using tetrabasic lead sulfate and other materials as binders according to the "precharged" plate concept previously described (1). Performance of these plates correlates with active material morphology and PbO₂ particle size rather than any intrinsic PbO₂ activity. Tetrabasic lead sulfate (TTB) and lead sulfate were shown to be the preferred binding materials for the "precharged" positive plate. Plates made with about 30% TTB and strengthened for early cycle performance with dynel fiber and Teflon¹ for green strength exhibited superior cycle life performance on a simulated automotive cycle life test relative to conventionally prepared positive electrodes.

A previous paper (1) described a novel lead-acid battery manufacturing process using tetrabasic lead sulfate (TTB) and lead dioxide to form a "precharged" positive plate which could be discharged at the automotive cranking rate. The lead dioxide used in that work was obtained from well formed conventionally processed battery plates to eliminate the effect of any intrinsic activity differences between battery and chemically produced lead dioxides. Clearly, for such a plate-making process to be economical, a relatively inexpensive chemically prepared PbO₂ would have to be suitable.

Numerous studies have been reported in the literature concentrating on the differences between chemically and electrochemically prepared lead dioxide. Chemical analysis indicated that, in general, electrochemically prepared lead dioxide was nonstoichiometric, whereas chemically prepared lead dioxide was nearly stoichiometric (2, 3). Using differential thermal analysis (DTA) and x-ray diffraction (XRD), it was shown that battery plate lead dioxide exhibited a considerable defect structure compared to chemically produced lead dioxide (4). Using nuclear magnetic resonance, other workers detected the presence of two types of combined hydrogen in battery plate lead dioxide compared to one form of combined hydrogen in chemically prepared samples (5). In addition, more combined hydrogen was observed in battery lead dioxide than in the chemical lead dioxide. The battery

positive capacity loss was attributed solely to the gradual conversion of the active form of lead dioxide to the inactive form during cycling. This inactive form of lead dioxide was indistinguishable from the reagent grade chemically prepared material. Using DTA, these workers identified an exothermic peak near 200°C in battery lead dioxide which was not present in chemically prepared samples (6). This peak was associated with the presence of combined hydrogen and attributed to the reordering of the lead dioxide lattice with the evolution of oxygen and combined water. During cycling, this peak area decreased (along with the battery plate capacity) and eventually disappeared with the thermogram becoming indistinguishable from that obtained from reagent grade lead dioxide. Other researchers, using neutron powder diffraction were able to show that battery lead dioxide contained hydrogen in the lattice along with an associated lead deficiency (7). Finally, other workers studying chemically and electrochemically prepared lead dioxide found amorphous material in the electrochemically prepared sample (8). The decrease in positive plate performance was attributed to the conversion of the "intrinsically" active amorphous lead dioxide to the nonactive crystalline form during cycling. Inelastic neutron scattering has also been used to attempt to distinguish between chemical and electrochemical forms of PbO₂. Moseley *et al.* found that both forms contained hydrogen probably in the form of water (9). Varma and co-workers found PbO₂ from battery plates to be associated with water molecules (10). Much evidence and speculation in the literature suggest that the intrinsic electro-

chemical inactivity of chemical lead dioxides would be a major barrier to its use in a positive electrode.

Consequently, this work focuses on the effect of various lead dioxide samples on "precharged" positive performance. In addition, the influence of active material particle size, porosity, and pore size distribution, as well as alternate binding materials in place of TTB, and cycle life performance of the "precharged" positives are reported. The binding material must convert to lead dioxide during the first few cycles of plate life.

Experimental

The processing and evaluation of "precharged" positive electrodes is as described in the preceding paper (1). Various lead dioxide samples were obtained from commercial sources for evaluation in the precharged positive format. These samples along with lead dioxide from battery plates were characterized by thermal gravimetric analysis (TGA), differential scanning calorimetry (DSC), XRD, wet chemical analysis, BET surface area, and particle size distribution. Bulk porosity and pore size distribution of the precharged electrodes and three conventionally cured and formed lab standard batches of varying bulk porosity were characterized by mercury porosimetry.

Tribasic lead sulfate and simple lead sulfate were substituted for TTB in the precharged format and evaluated. Finally, one precharged electrode batch was cycle life tested using an accelerated test regime having relatively high discharge rate and considerable overcharge. The test consisted of discharge at 3A for 4 min, followed by a 5A-2.5V per cell charge for 10 min, followed by 1 min at open circuit. Discharge and charge currents were adjusted to account for slight weight differences in the various electrode groups tested. The test is characterized by a shallow discharge at a reasonably high rate (20 min rate for the standard electrodes) followed by substantial overcharge. This is the type of regime encountered in automotive applications. The test was terminated when the cell polarization was greater than 625 mV prior to completing 4 min of discharge. This test is nonstandard but would be expected to yield a valid comparison between the experimental electrodes and conventionally prepared plates of the same size.

Results

PbO₂ characterization.—A number of lead dioxide samples were incorporated into the "precharged" positive format and evaluated. The oxides used, their BET surface area, and wet chemical analysis are shown in Table I. The reagent grade samples (Baker, Mallinckrodt, and Eagle-Picher ASC) were all characterized by a high PbO₂ content and a BET surface area in the range of 0.7-1.0 m²/g. Eagle-Picher also produces lead dioxide samples of increasing surface area for use as curing agents to promote polymer cross-linking. The Eagle-Picher high surface area samples were all pro-

duced in the same basic manner as the reagent grade samples; i.e., chemical oxidation of a divalent lead compound. The chemical analysis of these materials was ~90% PbO₂ with XRD indicating the presence of Pb₃O₄. The β-PbO₂ polymorph was the only form indicated by XRD in all the above samples. The battery plate lead dioxide obtained from a conventionally cured and formed positive plate contained 93% PbO₂ and exhibited a BET surface area of 9 m²/g. XRD indicated the presence of a small amount of the α-PbO₂ polymorph in addition to the β-PbO₂ polymorph.

The particle size distributions of the various lead dioxide samples are given in Fig. 1. The battery PbO₂ Sample A consisted of particles in the 1-3.0μ range. The Eagle-Picher ASC Sample B was typical of the reagent grade samples with a relatively broad particle size distribution. The Eagle-Picher high surface area samples all exhibited relatively sharp particle size distributions which become shifted to the submicron range as the BET surface area increased. The higher surface area of the chemical lead dioxides results from particles of smaller and smaller diameter, whereas the relatively high surface area of the battery sample results from its roughened irregular structure.

Thermogravimetric analysis (TGA) was obtained for the various PbO₂ samples after oven drying them overnight at 130°C to remove surface water. The TGA weight loss of the battery PbO₂ was 2% up to 300°C under argon at 10 psig and 10°C/min heating. The weight loss of all the other samples under the same conditions was less than 0.05%. DSC for these lead dioxide samples are shown in Fig. 2. The region of specific interest is the vicinity of 200°C, where various workers have attributed an exothermic peak observed in battery PbO₂ to the reaction (6)

This exothermic peak was observed in the battery lead dioxide Sample A and no evidence of the peak was seen in the chemically prepared samples, consistent with the reports in the literature and noted above.

Active material characterization.—The active material porosity characteristics as determined by mercury intrusion, and performance on a room temperature cranking rate (200 mA/cm²) discharge test of three

Fig. 2. Differential scanning calorimetry for various lead dioxide samples. As identified in Fig. 1.

conventionally prepared positive electrodes of different bulk porosity are shown in Table II. Note that while the active mass weights remain roughly the same, the bulk porosity range is $\sim 10\%$. A measure of pore size distribution is the pore radii at which 50, 80, 90, and 95% of the pore volume is intruded. In all three batches, 95% intrusion occurs by the time the pore radii have decreased to $0.03\text{--}0.06\mu$. In going from a bulk porosity of 35 to 45%, the pore radii at which 50% intrusion occurs increases from 0.562 to 1.52μ . In other words, bigger pores become apparent as the bulk porosity increases. The high rate discharge time increases with increasing porosity.

In Table III, the characteristics of "precharged" positive electrodes made with 30% TTB and 70% of the various PbO_2 samples and processed as described previously (1) are given. Water was added to these mixes so as to obtain pastes of similar plasticity. Larger amounts of water were required for the higher surface area lead dioxide samples. The mercury intrusion data may be classified into three groups for comparison with the standard electrodes. Precharged plates made with Sample A battery PbO_2 exhibit similar intrusion data

to the lab standards. Plates made with high surface area PbO_2 exhibit 50% intrusion at $\sim 0.1\mu$ and 95% intrusion at $\sim 0.03\mu$. Conversely, plates made with low surface area reagent grade PbO_2 exhibit 50% intrusion at $>1.0\mu$ and 95% intrusion at $>0.4\mu$. The significance of these data is exemplified by considering the pore volume distribution *vs.* pore radii shown in Fig. 3. The lab standard and precharged plates made with battery PbO_2 have a relatively large range of pore sizes. The precharged electrodes made with large particle reagent grade PbO_2 (Sample B), consists of large pores. Those made with high surface area PbO_2 (12 and $27\text{ m}^2/\text{g}$) (not shown in Fig. 3) consist of pores less than 0.1μ radii. A reasonable compromise is found in the medium cure PbO_2 Sample D.

Performance

The performance of the precharged plates to five high rate discharges ($200\text{ mA}/\text{cm}^2$) with no charge prior to the first discharges is shown in Fig. 4. Capacity is expressed here as utilization efficiency; *i.e.*, the percentage of the theoretical ampere hour capacity based on the weight of the active material delivered by the

experimental plate. No first cycle capacity was obtained at this rate from precharged electrodes made with reagent grade lead dioxide (Sample B), although these electrodes did "cycle up" after subsequent charge. The first cycle performance of the precharged electrodes made with the 27 m²/g PbO₂ (Sample F) was remarkable, especially when one considers the presence of 30% inactive material in the active mass weight. These electrodes were not able to withstand subsequent charging, and it is suspected that this deterioration is related to the active material pore size distribution. The Eagle-Picher (Sample E-fast cure) precharged plate exhibited reasonable first discharge performance with subsequent "cycle up" capability. However, the Eagle-Picher (Sample D-medium cure) precharged plate seemed to offer the best compromise between first cycle performance and "cycle up" capability which approached that of the Batch 11 lab standard positive electrodes (Table II).

The physical plate characteristics of a batch of precharged positives made from Eagle-Picher Sample E

Fig. 4. High rate discharge (200 mA/cm²) utilization efficiency vs. cycle number of various precharged positive plates made with 30% TTB-70% PbO: ASC-Eagle-Picher reagent grade PbO₂; E.P.-M Eagle-Picher (medium cure) PbO₂; E.P.-F Eagle-Picher (fast cure) PbO₂; E.P.-FF Eagle-Picher (faster cure) PbO₂.

PbO₂ were characterized at three times; (i) after pressing, (ii) after soaking in acid for 1h but not discharged, and (iii) after discharge followed by the first charge. The data are presented in Table IV. The plates show a decrease in PbO₂ and an increase in SO₄ after soaking in acid for 1h. The data correlate with the fact that the acid specific gravity was also observed to drop during this soak along with the porosity decrease. A 15% volume increase is associated with PbO₂ → PbSO₄. The 3.9% drop in PbO₂ would account for a 1.58% SO₄ increase, whereas we observe a 5.1% increase in SO₄. Presumably, the TTB or an impurity therein is sulfating. A certain amount of sulfation may be beneficial by acting to hold the PbO₂ particles in contact. After charging, the pore size distribution remains the same, but the BET surface area and the PbO₂ content increase. This data would seem to indicate that the bulk porosity and pore size distribution of these precharged plates do not change significantly on putting them in acid and on charging, whereas the BET surface increases to that of a standard plate, apparently by nucleation of an array of extremely small particles on the surfaces of the structure present.

Tribasic lead sulfate as a binder.—A batch of precharged plates was made with 30 w/o (weight percent) tribasic lead sulfate-70% Eagle-Picher medium cure PbO₂ (Sample D). Tribase also has a needle-like morphology and should convert to PbO₂ via

These plates exhibited extensive sulfation after submersion in acid and no first discharge capacity was derived from them. They did, however, exhibit good capacity after four or five 200 mA/cm² discharges and recharge cycles. The extensive sulfation of the tribase precharged plates apparently severely decreased the plate porosity and limited its initial discharge capability. Therefore tribasic lead sulfate is not a suitable "binder" for these plates.

PbSO₄ as a binder with dynel and Teflon.—Neutral lead sulfate, PbSO₄, was also tried as a binder for the PbO₂. Because prior work had shown that in the hot-pressed condition, the sulfates do not contribute to

the mechanical strength of the plate, additions of 1 w/o dynel fiber and 0.5 w/o Teflon were also made to the mix to improve the "green" strength. Dynel fiber is commonly used in positive plates to strengthen the active material. The Teflon was added to the dry powder mix as an emulsion, and dried over night. Sufficient water was then added to provide the desired consistency for pasting. In these experiments, 75 w/o Eagle-Picher medium cure PbO_2 (Sample D-Table I) was mixed with 25 w/o of either TTB or $PbSO_4$. The performance of these plates in the 200 mA/cm² discharge test at room temperature is shown in Fig. 5. The initial performance was very good for both batches with capacity increasing markedly in the first few cycles. The better initial discharge performance of the plates made with $PbSO_4$ may be attributed to the absence of sulfation. The initial performance of the batch of plates made with TTB is somewhat lower than those made with $PbSO_4$, however these plates also "cycled up." These plates were cycle life tested with the rather severe test described above. After 3000 cycles these electrodes showed 20% failure (2 out of 10) compared to 40% failure after 1500 cycles (4 out of 10) for lab standard electrodes (Batch 11 of Table II).

Conclusion

A process for making positive battery plates not requiring curing or formation and using high surface area chemically prepared lead dioxide mixed with TTB or lead sulfate has been described. During their first discharge, these plates deliver roughly 40% of the cranking rate capacity of conventionally prepared positive electrodes. In the first few discharge-recharge cells, the TTB or lead sulfate is converted to lead dioxide and acts to cement the structure together and increase the capacity to that of standard conventionally produced plates.

The precharged plate bulk porosity and pore size distribution is controlled by the particle size distribu-

tion and morphology of the lead dioxide used to make the plates. The plate porosity characteristics and lead dioxide morphology and size, rather than intrinsic lead dioxide activity, are apparently the critical parameters dictating the precharged positive performance. Tetrabasic lead sulfate and neutral lead sulfate appear to be suitable "binder" additives at about the 25 w/o level. Although a material such as tribasic lead sulfate which sulfates heavily and blocks the plate porosity is not acceptable, a certain amount of sulfation may be beneficial to precharged electrode performance.

Plates made from TTB with 1 w/o addition of dynel fiber and 0.5 w/o Teflon significantly out-performed standard positive electrodes on a cycle life test which simulated but was more severe than the SAE J-240 test used to characterize automotive starting, lighting, and ignition (SLI) batteries.

This envisioned process for manufacturing positive battery plates (a process for making negative battery plates will be reported later) would appear simpler and more amenable to continuous automated manufacture than the conventional process. Additionally, the marketing advantage of a truly dry-charged SLI battery with extended shelf life enhances the attractiveness of this scheme.

Acknowledgments

This work was conducted under the auspices of Inco Research and Development Center at Sterling Forest, NY. The authors would like to acknowledge the work of J. T. Arms in the formulation studies using Teflon and dynel fiber. The Lithium/Sulfuryl Chloride Electrochemical Cell

K. A. Klinedinst*

GTE Laboratories, Incorporated, Waltham, Massachusetts 02254

ABSTRACT

The development of a practical sulfuryl chloride-based lithium/oxyhalide cell technology has been delayed by anode corrosion and cathode polarization problems encountered when the standard oxyhalide cell electrolyte and cathode formulations are used. The anode stability problem can be significantly alleviated by the use of a reverse polarity cell design, the substitution of $\text{Li}_2\text{B}_{10}\text{Cl}_{10}$ for LiAlCl_4 as the electrolyte salt, and the addition of a suitable cosolvent (SO_2 or SOCl_2). Further, at least under ambient temperature storage and discharge conditions, anode passivation is completely absent with hermetically sealed $\text{Li}/\text{SO}_2\text{Cl}_2$ cells of this type. Cathode polarization can be reduced most effectively by the use of a supported platinum cathode material. This cathode material also results in substantially increased discharge capacities, although the overall reaction stoichiometry is unaffected by the catalyst. Finally, SO_2Cl_2 thermal decomposition measurements indicate that, as the temperature of the SO_2Cl_2 electrolyte in a hermetic cell is increased from 25° to 80°C, the pressure differential across the cell case will rise to about 3.5 atm. Then, as the temperature is decreased to a lower value, the pressure differential will also decrease to the equilibrium value characteristic of that lower temperature, indicating a thermally stable, reversible system.

Soon after the discovery of the lithium/thionyl chloride electrochemical cell, optimization studies led to the development of storable, high performance cells suitable for a variety of applications (1, 2). It was realized, however, that cells with sulfuryl chloride (SO_2Cl_2) rather than thionyl chloride (SOCl_2) as the oxyhalide might offer some advantages. In particular, the higher OCV of the $\text{Li}/\text{SO}_2\text{Cl}_2$ system (3.90V for $\text{Li}/\text{SO}_2\text{Cl}_2$ vs. 3.65V for Li/SOCl_2) should translate into higher load voltages. Further, the absence of elemental sulfur as a discharge product with SO_2Cl_2 might lead to improved capacities and to improved safety characteristics (3). However, even though the expected load voltage and capacity advantage was observed at low current densities with cells containing PTFE-bonded carbon cathodes, it was lost at higher rates (this was apparently a cathode performance problem) (4). Further, $\text{Li}/\text{SO}_2\text{Cl}_2$ cells were found to undergo self-discharge at a rate at least twice that experienced with Li/SOCl_2 cells (5). Another source of concern has been the tendency of SO_2Cl_2 to undergo thermal decomposition to SO_2 and Cl_2 , leading to higher internal cell pressures and to possible effects upon cell chemistry (3, 6).

Several techniques have been suggested for the alleviation of the cathode polarization and anode corrosion problems. Among the techniques proposed for the reduction of cathodic polarization are the use of a very high surface area carbon black in place of the standard Shawinigan black cathode material (3), the addition of halogens to the SO_2Cl_2 electrolyte (7, 8, 9), and the use of supported platinum to catalyze the electroreduction of the oxyhalide (5, 10, 11, 20). The only suggested technique for reducing the severity of the anode corrosion problem has been the traditional one of employing a cell design which minimizes the amount of metallic cell hardware that is both in contact with the anode and exposed to the oxyhalide electrolyte (12).

Reported here are the results of an investigation designed to find optimal solutions to the anode corrosion and cathode polarization problems. Additionally, the thermal decomposition of the oxyhalide has been investigated.

Experimental

Electrolytes.—The SOCl_2 and SO_2Cl_2 were obtained from Hooker Chemical Company and Aldrich Chemical Company, respectively. They were distilled over lithium before use. Fluka aluminum chloride was used without further purification. Lithium chloride (Baker Chemical) was ground in a mortar and dried *in vacuo*

* Electrochemical Society Active Member.

Key words: sulfuryl chloride, lithium battery, oxyhalide cathodes.

at 160°C for 30h prior to use. Solutions of LiAlCl_4 were prepared by dissolving the required amount of AlCl_3 in the oxyhalide followed by the addition of excess LiCl . These electrolytes were purified by refluxing over lithium for 15-20h. The preparation and purification of the $\text{Li}_2\text{B}_{10}\text{Cl}_{10}$ has been described previously (13). A 0.25M $\text{Li}_2\text{B}_{10}\text{Cl}_{10}$ in SO_2Cl_2 electrolyte was prepared by directly dissolving the required amount of $\text{Li}_2\text{B}_{10}\text{Cl}_{10}$ in purified SO_2Cl_2 . In some cases, a quantity of purified SOCl_2 or SO_2 was also added to the $\text{Li}_2\text{B}_{10}\text{Cl}_{10}/\text{SO}_2\text{Cl}_2$ electrolyte.

Lithium/oxyhalide cells.—AA-size Li/SOCl_2 and $\text{Li}/\text{SO}_2\text{Cl}_2$ cells were used in much of the experimental work. Standard bobbin-design cells with lithium anodes and PTFE-bonded Shawinigan black cathodes were used for much of the work (1, 4). Additionally, a reverse polarity AA cell design was employed (5). In cells of this type, the 8.3 cm² PTFE-bonded Shawinigan black cathode is pressed against the inside wall of the 304 stainless steel can, and the central cylindrical lithium anode is connected to the insulated terminal. The standard and reverse polarity cells contained glass-fiber separator paper and were filled with about 4 cm³ of the oxyhalide electrolyte. They all contained pre-weighed 0.65g lithium anodes and were hermetically sealed via TIG welding. Finally, some experiments were performed using planar geometry cells in Pyrex containers with ground-glass joints and glass-to-metal feed throughs for the lead wires (14). The cathodes employed in these cells were formed from PTFE-bonded Shawinigan black with or without the addition of 10% supported platinum.

Cell discharge, self-discharge, and voltage delay.—Sets of twelve identically constructed hermetically sealed AA cells were stored for one month at ambient temperature before being examined. During the one-month storage period, microcalorimetric measurements were performed using a Tronac Model 350 calorimeter. The stored cells were discharged briefly through 50Ω loads to determine the degree of anode passivation (voltage delay) resulting from the open-circuit stand. Then, two-thirds of the stored cells were discharged to termination through 200Ω loads. The resulting discharge curves were analyzed to yield the average plateau voltages and capacities (to a 2.0V cutoff). Next, the self-discharge characteristics of the discharged and undischarged stored cells were determined in the following way. The cells were cut open in an inert atmosphere, and the remaining metallic lithium was removed, washed with purified THF, and allowed to dry. The amount of remaining lithium was then determined by an acid-base titration procedure to obtain the amount of lithium consumed by self-discharge dur-

ing storage or during the combined periods of storage and discharge.

Sets of identically constructed hermetic and non-hermetic cells were also discharged to termination across a series of constant loads to yield average current densities ranging between 2 and 200 mA/cm². The load voltages were recorded as a function of time, and the discharge characteristics were obtained from analyses of the resulting discharge curves.

Product analysis.—A number of cathode-limited Li/SO₂Cl₂ cells in Pyrex containers and with Shawinigan black and 10% platinum on Shawinigan black as cathode materials were discharged to termination at a 2 mA/cm² rate. The fully discharged cathodes were removed from the cells and leached with pure SO₂Cl₂ to remove most of the residual LiAlCl₄ electrolyte salt. (The amount of LiAlCl₄ remaining after the SO₂Cl₂ leach was determined by atomic absorption analysis.) After vacuum drying, the cathode materials were weighed and leached with distilled water to remove the LiCl discharge product. Then, potentiometric chloride ion titrations were performed using a 0.1M AgNO₃ solution with a Ag/AgCl ion-sensitive electrode. The titration results, adjusted for the amount of residual LiAlCl₄ not removed by the SO₂Cl₂ leach, were compared with the amount of Cl⁻ that would be contained within each cathode assuming the overall discharge reaction to be

Microscopic analysis.—Lithium foil samples were prepared for scanning electron microscopic (SEM) analysis by the following procedure. Strips of freshly exposed lithium (Foote Mineral Company) were sealed in glass ampuls filled with purified SO₂Cl₂, 1.8M LiAlCl₄ in SO₂Cl₂, and 0.25M Li₂B₁₀Cl₁₀ in SO₂Cl₂. The samples were stored at ambient temperature for one or two month intervals. The ampuls were then opened in an argon-filled dry box and the lithium samples were removed, washed with purified THF, and mounted for analysis. The mounted samples were transferred to a JEOL Model JSM-U3 SEM without exposure to air.

Gas pressure measurements.—Five milliliter quantities of purified SO₂Cl₂ containing 1.8M LiAlCl₄, 0.1M AlCl₃, or 0.01M AlCl₃ were sealed within a Monel tube fitted with a Monel pressure gauge. In some cases, the tube also contained 20 mg of Shawinigan black with or without the presence of 10% supported platinum. These samples were stored in a thermostatically controlled oven. With each sample, the equilibrium pressure within the sealed tube was recorded as a function of increasing and decreasing temperature for temperatures between 50° and 80°C.

Results and Discussion

Li/oxyhalide cells with SOCl₂ and SO₂Cl₂ electrolytes.—Standard configuration (case negative) hermetically sealed AA-size Li/SOCl₂ and Li/SO₂Cl₂ cells were discharged to termination at ambient temperature through constant loads ranging between 2 and 100Ω. These cells contained as electrolytes 1.8M solutions of LiAlCl₄ in the two oxyhalides. Typical discharge curves obtained with SOCl₂ cells discharged through 20Ω loads are compared in Fig. 1. The average load voltages and the discharge capacities obtained from such discharge curves are plotted vs. the log of the average discharge rate in Fig. 2 and 3, respectively. (Each plotted point in Fig. 2 was obtained by averaging over the plateau portion of the complete constant load discharge curve of a separate Li/SOCl₂ or Li/SO₂Cl₂ cell. The discharge capacities were obtained by integrating the discharge curves to a 2.0V cutoff.)

At discharge rates no higher than a few milliamperes per square centimeter of geometric surface area, the average load voltages obtained with the two oxyhalides

Fig. 1. AA size Li/oxyhalide cell discharge curves

Fig. 2. AA size Li/oxyhalide cell polarization data

are similar. However, the higher the discharge rate, the lower the load voltage obtained with the SO₂Cl₂ electrolyte relative to that obtained with the SOCl₂ electrolyte. In contrast, as shown in Fig. 3, the Li/SO₂Cl₂ cells yielded capacities far greater than those obtained with the SOCl₂ electrolyte. In fact, for discharge rates above 15 mA/cm², the use of the SO₂Cl₂ electrolyte produced capacities between 2 and 3 times those obtained with the standard SOCl₂ electrolyte.

Typical lithium corrosion, voltage delay, and performance results obtained with standard configuration SOCl₂ and SO₂Cl₂ AA cells stored for one month at ambient temperature are compared in Table I.

Listed first in Table I are the average amounts of lithium consumed by self-discharge during storage (expressed as ampere-hour equivalents). As indicated, about twice as much lithium was lost through self-discharge with SO₂Cl₂ as with SOCl₂.

Listed next are the average voltage delay characteristics obtained with the two electrolytes. The initial load voltage and the plateau voltage measured when the stored cells were briefly discharged through 50Ω

Fig. 3. AA size Li/oxyhalide cell capacity data

loads are both indicated, as is the time required for the load voltage to reach 90% of the plateau value. Clearly, the anode passivation incurred with the SO_2Cl_2 electrolyte is much less severe than is that with SOCl_2 .

Listed next are the average plateau voltages, the average discharge rates, and the capacities (to a 2.0V cutoff) characteristic of the two groups of stored cells when discharged through 200 Ω loads. In keeping with the fresh cell polarization data, there was no significant difference between the average load voltages obtained with the two oxyhalides. Moreover, the SO_2Cl_2 cells yielded discharge capacities that were, on average, about 15% below those obtained with SOCl_2 .

The final entry in the table is the amount of lithium anode material lost through self-discharge during the combined periods of storage and discharge. With the SOCl_2 electrolyte, no significant lithium corrosion occurred while the cells were being discharged. In contrast, with SO_2Cl_2 nearly as much lithium was lost during discharge as was lost on storage.

With the exception of the improved voltage delay characteristics, the AA cells containing the SO_2Cl_2 electrolyte apparently offer no advantages over those containing SOCl_2 . On the contrary, the severe cathodic polarization and anode corrosion problems encountered with SO_2Cl_2 would seem to make its use highly impractical.

Table I. Standard configuration Li/oxyhalide AA cells stored one month at ambient temperature—1.8M LiAlCl_4 electrolytes

	SOCl_2	SO_2Cl_2
Li lost during storage	0.12 Ah	0.23 Ah
50 Ω discharge Init E \rightarrow load E t to 0.9 load E	1.45 \rightarrow 3.00V 6.0s	2.45 \rightarrow 3.20V 1.0s
200 Ω discharge E avg I avg C (to 2.0V) Li lost during storage and discharge	3.34V 16.7 mA 2.15 Ah 0.13 Ah	3.35V 16.8 mA 1.84 Ah 0.42 Ah

Anode passivation and corrosion.—In the standard configuration (case negative) cylindrical cell, a substantial amount of metallic cell hardware is both in electrical contact with the anode and exposed to the electrolyte. On the assumption that the high self-discharge rates observed with SO_2Cl_2 -based electrolytes are at least partly due to the reduction of SO_2Cl_2 upon this exposed hardware (with the simultaneous oxidation of the lithium anode material), a so-called reverse polarity (case positive) cell design was developed. With cells of this type, the lithium anode is connected to the insulated terminal so that there is much less exposed metal hardware in electrical contact with the anode. The averaged anode corrosion, voltage delay, and performance results obtained with standard and reverse polarity Li/ SO_2Cl_2 cells stored for one month at ambient temperature are compared in Table II. As indicated, the polarity reversal technique resulted in an approximate 50% reduction in the self-discharge rate during both storage and discharge. However, polarity reversal had no effect upon the voltage delay characteristics of the stored cells. Finally, the case positive cells exhibited slightly higher load voltages. So, except for a small loss of capacity, polarity reversal has an overall beneficial effect upon the characteristics of the stored cells. Nevertheless, the corrosion rates experienced with the reverse polarity cells are still much higher than could be tolerated in most applications.

It is known that, with Li/ SOCl_2 cells, the substitution of lithium closoboranes, e.g., $\text{Li}_2\text{B}_{10}\text{Cl}_{10}$, for LiAlCl_4 in the electrolyte significantly alters the nature of the passivating LiCl film (13, 15, 16). Further, SOCl_2 cells with the $\text{Li}_2\text{B}_{10}\text{Cl}_{10}$ electrolyte salt often exhibit improved voltage delay and self-discharge characteristics. So, experiments were performed in order to determine whether similar performance improvements might also result from the use of the $\text{Li}_2\text{B}_{10}\text{Cl}_{10}$ salt in SO_2Cl_2 electrolytes.

That the electrolyte salt may play a decisive role in determining the Li/ SO_2Cl_2 self-discharge rate is certainly suggested by the microcalorimetric data listed in Table III. The table compares the heat outputs measured on the twentieth day of ambient temperature storage with reverse polarity SO_2Cl_2 cells as a function of the molar concentration of LiAlCl_4 . (The tabulated values are the averages of data obtained with several identical cells.) As indicated, the higher the salt concentration, the greater the rate of heat evolution.

Table II. Standard and reverse polarity Li/ SO_2Cl_2 AA cells stored one month at ambient temperature—1.8M LiAlCl_4 electrolytes

	Standard configuration	Reverse polarity
Li lost during storage	0.23 Ah	0.10 Ah

200 Ω discharge E avg I avg C (to 2.0V) Li lost during storage and discharge	3.35V 16.8 mA 1.84 Ah 0.42 Ah	3.40V 17.0 mA 1.74 Ah 0.26 Ah

Table III. Heat output measured on the twentieth day of ambient temperature storage with reverse polarity Li/ SO_2Cl_2 AA cells as a function of LiAlCl_4 concentration

LiAlCl_4	Heat output (μW)
0.00	210
0.25	328
1.80	1003

The performance results obtained with reverse polarity AA cells containing 1.8M LiAlCl₄ and 0.25M Li₂B₁₀Cl₁₀ in SO₂Cl₂ as electrolytes after being stored for one month at ambient temperature are compared in Table IV. As indicated, the salt substitution reduced the rate of lithium corrosion to a value within the standard error limit for this experiment, both during storage and discharge through a 200Ω load. Further, the use of the alternate electrolyte salt resulted in a 150 mV rise in average load voltage, and in the virtual elimination of anode passivation. (In fact, the voltage delay incurred when the stored cells were discharged through a 50Ω load was so slight as to be undetectable on a sensitive high speed recorder.) The only negative result of the salt substitution was a further loss of capacity.

The use of the Li₂B₁₀Cl₁₀ salt to form the SO₂Cl₂ electrolyte is at least as effective in the elimination of anode passivation and corrosion as the corresponding salt substitution with SOCl₂. To investigate this phenomenon SEM analyses were performed upon lithium samples stored at ambient temperature for one and two month intervals in pure SO₂Cl₂, in SO₂Cl₂ containing 1.8M LiAlCl₄, and in SO₂Cl₂ containing 0.25M Li₂B₁₀Cl₁₀. The surfaces of the lithium samples stored in the pure oxyhalide, after one month storage, give no indication of the formation of surface films (see Fig. 4a). However, the surfaces of the samples stored in the two electrolyte solutions were all found to be covered by films of LiCl. With the LiAlCl₄ electrolyte, the LiCl films were composed of closely packed, well-formed crystallites ranging in size between 2.5 and 25 μm (see Fig. 4b). In contrast, with the Li₂B₁₀Cl₁₀ electrolyte, the LiCl films were generally amorphous in appearance, with the largest recognizable crystallites being about 2 μm in size (see Fig. 4c). (In general, the surfaces of the samples stored in the electrolytes for two months were very similar in appearance to the surfaces of the samples stored for only one month.)

The performance improvements achieved by the use of a reverse polarity cell configuration and by salt substitution are listed in Tables II and IV. As indicated, the combination of these two techniques resulted in a reduction in the rate of anode corrosion to a value almost below the level of detectability, the virtual elimination of voltage delay, and in a 200 mV increase in load voltage at a 1.6 mA/cm² current density. Unfortunately, these performance improvements were accompanied by a 10% reduction in average discharge capacity.

This capacity limitation can be overcome by the addition of a cosolvent (SO₂ or SOCl₂) to the SO₂Cl₂ electrolyte. Typical results achieved by the addition of 25% SOCl₂ to the 0.25M Li₂B₁₀Cl₁₀ in SO₂Cl₂ electrolyte are presented in Table V. (Comparable results have been obtained by the addition of 7.5% SO₂ to the electrolyte.) As indicated, the use of the cosolvent increased the average discharge capacity from 1.66 to 1.94 Ah. Furthermore, this was accomplished without a reduction in average load voltage, without initiating

Table IV. Reverse polarity Li/SO₂Cl₂ AA cells stored one month at ambient temperature—1.8M LiAlCl₄ and 0.25M Li₂B₁₀Cl₁₀ electrolytes

Table VI. Heat output measured on the twentieth day of ambient temperature storage with reverse polarity Li/SO₂Cl₂ AA cells as a function of electrolyte composition (all cells contained 0.25M Li₂B₁₀Cl₁₀)

Cosolvent	Heat output (μW)
none	666
7.5% SO ₂	160
25% SOCl ₂	172

anode corrosion, and without causing any detectable voltage delay. (The cosolvent apparently improves the cathode utilization efficiency, perhaps by modifying the nature of the crystalline LiCl deposited within the porous cathode.)

In Table VI are listed the microcalorimetry results obtained with reverse polarity SO₂Cl₂ cells on the twentieth day of ambient temperature storage. These cells contained as electrolytes 0.25M solutions of Li₂B₁₀Cl₁₀ in SO₂Cl₂ without a cosolvent, with the addition of 7.5% SO₂, and with the addition of 25% SOCl₂. As indicated, the use of a cosolvent also reduces the rate of heat evolution by a factor of four, suggesting that, in addition to improving the cathode utilization efficiency, the cosolvent may also further reduce self-discharge.

In Fig. 5 is shown a typical discharge curve for a reverse polarity AA cell with 0.25M Li₂B₁₀Cl₁₀ in SO₂Cl₂ containing 25% SOCl₂ as electrolyte and stored for one month at ambient temperature before being discharged through a 200Ω load. A 3.57 average plateau voltage was achieved at a 2 mA/cm² discharge rate. The capacity was approximately 2.1 Ah. In Fig. 6 is a typical initial load voltage vs. time (voltage delay) curve achieved with a reverse polarity AA cell with the electrolyte stored for one month at ambient temperature before being discharged through a 50Ω load. This curve demonstrates that, even with the use of a sensitive high speed recorder, no anode passivation was detected with any of the stored cells containing the closoborane electrolyte salt.

Cathode performance.—It is apparent from the Li/SOCl₂ and Li/SO₂Cl₂ AA cell polarization data (see Fig. 2) that the standard acetylene black Li/oxyhalide cell cathode material is not a particularly good catalyst for the electroreduction of SO₂Cl₂. This fact becomes more and more apparent the higher the discharge rate. As indicated above, several techniques have been suggested for the alleviation of the cathode polarization problem, including the use of an alternate high surface area carbon black as the cathode material (3), the addition of halogens to the SO₂Cl₂ electrolyte (7, 8, 9), and the doping of the acetylene black cathode material with substances that catalyze the electroreduction of the SO₂Cl₂ (5, 10, 11, 17). Of the known catalytic cathode additives, supported platinum is the most efficient, particularly at high discharge rates. (It has been suggested that the platinum facilitates the decomposition of SO₂Cl₂ at the electrode surface so that

Fig. 4. Micrographs of lithium surfaces stored in SO_2Cl_2 for one month at 25°C . A, upper left: pure SO_2Cl_2 . B, upper right: 1.8M LiAlCl_4 in SO_2Cl_2 . C, left: 0.25M $\text{Li}_2\text{B}_{10}\text{Cl}_{10}$ in SO_2Cl_2 .

the reduction of SO_2Cl_2 proceeds through chlorine, even with a SO_2 -saturated electrolyte (19).

Cathode limited $\text{Li}/\text{SO}_2\text{Cl}_2$ cells with planar electrode geometry and with 1.8M LiAlCl_4 in SO_2Cl_2 as electrolyte were discharged at ambient temperature across a series of constant loads so as to produce average discharge rates ranging between 10 and $200\text{ mA}/\text{cm}^2$. Duplicate tests were run with cells containing $1\text{ cm}^2 \times 1\text{ mm}$ PTFE-bonded Shawinigan acetylene black cathodes with and without the presence of 10% supported platinum. The resulting discharge curves were analyzed to yield the polarization and discharge

capacity data shown in Fig. 7 and 8, respectively. (Figure 7 is a semilogarithmic plot of the average current density vs. the average plateau load voltage. Figure 8 is a semilogarithmic plot of the average current density vs. the discharge capacity to a 2.0V cutoff.)

As shown in Fig. 7, the higher the discharge rate, the greater the decrease in polarization that results from the use of the supported platinum electrocatalyst. For instance, at a $200\text{ mA}/\text{cm}^2$ current density, an average load voltage of about 3.0V is obtained with the supported platinum cathode material vs. 2.15V in the absence of the supported platinum. As shown in Fig. 8,

Fig. 5. 200Ω discharge curve for reverse polarity $\text{Li}/\text{SO}_2\text{Cl}_2$ AA cell stored for one month at ambient temperature.

Fig. 6. 50Ω discharge curve for reverse polarity $\text{Li}/\text{SO}_2\text{Cl}_2$ AA cell stored for one month at ambient temperature.

Fig. 7. Li/SO₂Cl₂ cell polarization dataFig. 8. Li/SO₂Cl₂ cell capacity data

the use of the supported platinum cathode material also results in much-improved cathode utilization efficiency over the entire range of discharge rates. For instance, at 20 mA/cm² a four-fold increase in cathode utilization efficiency is accomplished by the addition of 10% metallic platinum to the cathode. Typical 20Ω constant load Li/SO₂Cl₂ discharge curves obtained with and without the catalyst are compared in Fig. 9.

In Fig. 10 are compared polarization curves characteristic of Li/SOCl₂ and Li/SO₂Cl₂ cells with 10% Pt on Shawinigan black cathode and with 1.8M LiAlCl₄ electrolytes. It is apparent that, with this cathode ma-

terial, the approximately 300 mV difference in OCV experienced with the two oxyhalides is maintained even at current densities in the 100-200 mA/cm² range. The corresponding Li/SOCl₂ and Li/SO₂Cl₂ cell discharge capacities (to a 2.0V cutoff) are compared as a function of log *I* in Fig. 11. As shown, the capacities obtained with the SO₂Cl₂ electrolyte are far superior to those obtained with SOCl₂ for current densities ranging over two orders of magnitude.

The overall Li/SO₂Cl₂ cell reaction has been demonstrated to be

According to this reaction, one mol of LiCl is produced per mol of discharged lithium. Experiments (described above) were performed to determine if a change in the overall reaction stoichiometry might

Fig. 11. Li/oxyhalide cell capacity data with 10% Pt on Shawinigan black cathodes.

result from the addition of supported platinum to the acetylene black cathode material. With the cathodes not containing any supported platinum, the titration results predicted discharge capacities 1.3% greater than the measured capacities [in agreement with the earlier results of Gilman and Wade (3)]. With the cathodes containing 10% supported platinum, the titration results predicted discharge capacities 6.0% greater than were actually measured. Thus, it was concluded that, for both cathode materials, the discharge of a Li/SO₂Cl₂ cell at a moderate rate results in the formation of one mol of LiCl for every mol of oxidized lithium anode material. To further substantiate this conclusion, the discharged cathode materials were subjected to a battery of qualitative analytical tests designed to indicate the presence of any other discharge product that might be insoluble in the SO₂Cl₂ electrolyte (18). No indication of the presence of any other product was found, save for a trace of SO₄⁼ possibly produced by the hydrolysis of a small amount of residual SO₂Cl₂ that might not have been removed during the vacuum drying step.

SO₂Cl₂ decomposition.—The relative thermal instability of SO₂Cl₂ (compared to SOCl₂) is well recognized (3, 5, 10, 19). It is well established that, in the presence of a suitable catalyst, SO₂Cl₂ decomposes to SO₂ and Cl₂

The extent of decomposition increases with increasing temperature. From a practical point of view, therefore, the usefulness of SO₂Cl₂-based electrolytes will be partly determined by the thermal stability of the SO₂Cl₂ and by the reversibility of the decomposition reaction. As described above, the equilibrium decomposition pressure has been measured as a function of temperature (for temperatures between 50° and 80°C). Five milliliter quantities of purified SO₂Cl₂ containing 1.8M LiAlCl₄, 0.1M AlCl₃, or 0.01M AlCl₃ were used. In some cases, the SO₂Cl₂ solutions were in contact with 20 mg portions of Shawinigan black with or without the presence of 10% supported platinum. The experi-

mental results are compared in the log pressure vs. reciprocal temperature plot shown in Fig. 12.

As indicated, the equilibrium pressures are independent of the identity and concentration of the dissolved compound and of the presence and identity of the high surface area material. Moreover, no evidence of any hysteresis was observed with increasing and decreasing temperatures. However, the equilibrium pressures were attained much more slowly with the 0.01M AlCl₃ solution than with 0.1M AlCl₃ and 1.8M LiAlCl₄ solutions. Finally, the absence of any dissolved AlCl₃ or LiAlCl₄, much lower final pressures were obtained (even after more than 24h at temperature). This suggests that the dissolved material functions as a catalyst for the decomposition, presumably by a chloride exchange mechanism. Thus, as the temperature of the SO₂Cl₂ electrolyte in a hermetically sealed cell is increased from 25° to 80°C, the pressure differential across the metal case will rise to about 3.5 atm. Then, as the temperature is decreased to a lower value, the pressure differential will also decrease to the equilibrium value characteristic of that lower temperature, indicating a reversible dissociation for SO₂Cl₂.

Summary and Conclusions

Traditional Li/SOCl₂ cell technology is based upon the use of an acetylene black cathode material coupled with LiAlCl₄ dissolved in the oxyhalide as an electrolyte. However, when this approach is taken with SO₂Cl₂ rather than SOCl₂ as the oxyhalide, anode corrosion and cathode polarization problems are encountered, which have discouraged the development of a practical Li/SO₂Cl₂ cell technology.

It has been found that, by the use of a reverse polarity cell design, the substitution of Li₂B₁₀Cl₁₀ for LiAlCl₄ as the electrolyte salt, and the addition of a suitable cosolvent (SO₂ or SOCl₂), a hermetic Li/SO₂Cl₂ cell is achieved by which can be realized the recognized potential advantages of SO₂Cl₂-based electrolytes (high load voltages and capacities with the absence of elemental sulfur as a discharge product), coupled with a low self-discharge rate and (at least under ambient temperature storage and discharge conditions) the complete absence of voltage delay.

Fig. 12. SO₂Cl₂ decomposition pressure vs. reciprocal temperature.

Cathode polarization can be reduced most effectively by the use of a supported platinum cathode material. For instance, at a 200 mA/cm² discharge rate, polarization is reduced by 0.85V through the addition of 10% metallic platinum to the acetylene black cathode material. Further, with this cathode material, the approximately 300 mV difference in OCV experienced with SOCl₂ and SO₂Cl₂ electrolytes is maintained on load, even at current densities in the 100 to 200 mA/cm² range. Increased cathode utilization efficiencies also result from the use of this catalytic additive. However, the increased capacities do not result from a change in the overall reaction stoichiometry. The use of supported platinum cathode materials in hermetic cells with electrolytes selected primarily for their effects upon anode stability and passivation will be the subject of a later report.

Finally, the thermal decomposition of SO₂Cl₂ has been studied for temperatures between 50° and 80°C as a function of the presence and concentration of dissolved AlCl₃ or LiAlCl₄. The dissolved material apparently functions as a catalyst for the decomposition reaction. However, the equilibrium decomposition pressures are independent of the presence or absence of acetylene black cathode materials. With SO₂Cl₂ electrolyte solutions, no hysteresis is observed with increasing and decreasing temperatures, indicating a reversible thermal dissociation.

Electrochemical and Ellipsometric Investigations of Passive Films on Iron in Borate Solutions

II. Cathodic Reduction of Passive Films on Iron

Z. Szklarska-Smialowska* and W. Kozlowski

Institute of Physical Chemistry, Polish Academy of Sciences, Warsaw, Poland

ABSTRACT

Passive films formed under strictly controlled conditions during anodic polarization of iron in borate buffer solution were reduced in the same solution with a constant cathodic current. The cathodic charge consumed for the reduction of passive film was greater than the theoretical value calculated under the assumption that Fe₂O₃ was reduced to Fe²⁺. The higher the oxidation potential was and the longer oxidation time was employed, the greater was the consumed charge found experimentally. At certain characteristic thicknesses of the passive film associated with changes in film growth during its formation, inflections of the E_{red} vs. time and E_{red} vs. film thickness were observed.

Investigations of passive films on iron have usually been performed by measuring either the film growth during the anodic oxidation of metal or the cathodic reduction of the oxide film. No detailed studies aimed at elucidating mechanisms of both these processes on the same specimen and in the same electrolyte have been carried out so far. The purpose of the present work was to undertake such studies in continuation of our previous investigation of passive film formation

(1). This approach was thought to be useful in providing a better understanding of the nature of several consecutive passivation stages found by Kruger and Calvert (2) and in our work (1). The set of Armco iron specimens and the two borate buffer solutions of pH 8.45 differing in H₃BO₃ and Na₂B₄O₇ content were the same as those used in the first part of this work (1).

If a low constant cathodic current density is applied, two plateaus appear in the graph of consumed charge as a function of potential. The first plateau is commonly attributed to the reduction of the external film layer,

* Present address: Department of Metallurgical Engineering, The Ohio State University, Columbus, Ohio 43201.

and the second plateau to the reduction of the internal layer of Fe_3O_4 (3-7). According to others (8-10), the anodic film contains a single layer of $\gamma\text{-Fe}_2\text{O}_3$ which is reduced to Fe^{2+} and Fe^0 . It has also been assumed that the reductive dissolution of the film is accompanied by other reduction processes occurring in the solid phase. For example, such mechanisms have been proposed by Sato *et al.* (11), and Chen and Cahen (12) for galvanostatic and potentiostatic reduction, respectively. The following expression is used to calculate film thickness (d)

$$d = \frac{QMw}{zF\rho r}$$

where Q is the cathodic charge consumed, Mw = molecular weight of the compound undergoing reduction, z = number of electrons used, F = Faraday constant, ρ = density of the compound, r = roughness coefficient. Because neither the exact chemical composition of the reduced compound nor the roughness coefficient is known, arbitrary values are commonly assumed for Mw , z , ρ , and r . Therefore, the results obtained are uncertain and must be treated with caution. Even if the chemical composition is well defined, the density of a very thin film may well differ from that attributed to the bulk phase. Moreover, water molecules and anions present in the electrolyte can be incorporated into the film. Roughness coefficients, particularly in the case of passive films, are unknown.

Experimental

The measurements were carried out with the same Armco iron which was used to study the anodic oxidation process (1). In fact, the cathodic reduction was commenced in the same electrolyte solution immediately after the passivation experiment was completed. A constant current of $17 \mu\text{A} \cdot \text{cm}^{-2}$ was used. During reduction, the potential, cathodic charge, and changes in optical constants were recorded. This procedure was chosen because during the time required to change the electrolyte, taking into consideration that the cell had a volume of 0.5 liter, the exposure of the electrode to the argon atmosphere could result in modification of the surface film. However, the procedure employed had also some potential disadvantage, namely, that if ferric ions passed into solution during oxidation, they could be reduced to ferrous, which would lead to an excessive consumption of cathodic charge. Calculations showed, however, that this factor would give rise to a negligible error in the cathodic charge consumed during film dissolution.

Another process which can occur during the cathodic reduction of anodic films should be taken into consideration. Ferrucous ions formed in the reduction process would precipitate as $\text{Fe}(\text{OH})_2$ on the film surface if the solubility product of this compound in the electrolyte were exceeded.

The time dependence of Fe^{2+} concentration during cathodic reduction of the passive film at different current densities is shown in Fig. 1. These values were calculated from the formula

$$C_{(0,t)} = \frac{2i}{nF\pi D} \sqrt{t}$$

Fick's second law and the Laplace transform method were used, with initial and final boundary taken as $t = 0$, $x \cong 0$, $C = 0$, and $t \cong 0$, $x \rightarrow \infty$, $C \rightarrow 0$. The following equation was also used

$$i = nFD \left[\frac{\partial c}{\partial x} \right]_{x=0}$$

for $x = 0$ and $t > 0$, and following values were taken for calculations: $i = 0.17$, 0.1 , and $0.05 \text{ A} \cdot \text{m}^{-2}$; $n = 1$, and $D = 10^{-5} \text{ cm}^2 \cdot \text{s}^{-1}$. The concentration of $\text{Fe}(\text{OH})_2$, $1.26 \times 10^{-7} \text{ mol} \cdot \text{cm}^{-3}$, at which the solubility product

Fig. 1. Concentration of Fe^{2+} at the electrode as a function of reduction time. Reduction currents 0.17, 0.1, and 0.05 A/m^2 .

is exceeded at pH 8.45, is marked in Fig. 1. This value was calculated from the solubility product ($K_{so} = [\text{FeOH}^+][\text{OH}^-] = 10^{-9.4}$) established by Misawa (13). It is seen that at $i = 0.17 \text{ A} \cdot \text{cm}^{-2}$, the solubility product is exceeded already after 4s of the cathodic reduction. At $i = 0.05 \text{ A} \cdot \text{cm}^{-2}$, this time period is 46s.

Some evidence that $\text{Fe}(\text{OH})_2$ precipitates during reduction on the film surface and hampers exit of Fe^{2+} can be gathered from the difference observed in the $\delta\psi$ vs. $\delta\Delta$ curves obtained in solution 1 in the course of the oxidation and reduction processes (Fig. 2). At the beginning of the reduction process, ψ increases for an almost constant value of Δ , while the $\delta\psi$ vs. $\delta\Delta$ curve obtained during reduction was higher than that obtained during oxidation. So, values of n and k are slightly decreased during reduction. This seems to indicate that the presence of hydroxide affects the average optical properties of the film. These effects were evident only in solution 1 for films formed at high anodic potentials and for oxidation times longer than 10 min.

Results

Variations in potential and film thickness with time during the cathodic reduction process have been measured for films grown in solution 1 for 1.5, 10, 30, 600, and 3600s, and for those grown in solution 2 for 1.5,

Fig. 2. $\delta\psi$ vs. $\psi\Delta$ measured during oxidation of iron and reduction of iron oxide in solution 1.

10, 30, 1200, and 3600s. Only some of the results obtained will be presented here, because the character of relationships recorded for times longer than 1.5s were similar. Typical examples of potential *vs.* cathodic charge curves obtained for films formed at various anodic potentials and for different time periods are

Fig. 3. Dependence between potential and cathodic charge during the reduction of films formed in 1.5s at different anodic potentials in solution 1.

Fig. 4. Dependence between potential and cathodic charge during the reduction of films formed in 30s at different anodic potentials in solution 1.

Fig. 5. Dependence between potential and cathodic charge during the reduction of films formed in 1h in solution 1.

Fig. 6. Dependence between potential and cathodic charge during the reduction of films formed in 1h in solution 2.

given in Fig. 3-6. In these graphs, characteristic points based on ellipsometric measurements of film thickness *vs.* reduction potential at constant current density are marked by the letters "A," "B," "C," and "D;" their meaning will be discussed later.

During reduction of times formed in short oxidation times, i.e., 1.5s, a rapid drop of potential to about -0.76 and -0.95 V occurred in solutions 1 and 2, respectively. After these potentials were attained, further changes were insignificant. Specimens oxidized for $t \geq 10$ s in both solutions showed potential plateaus (or bends) which were more pronounced for films grown for a longer time at higher anodic potentials, especially in solution 2.

Comparison of the curves obtained leads to the conclusion that the cathodic charge necessary to reach the potential plateau (about -0.8 and -0.95 V in solutions 1 and 2, respectively) increases with both anodization time and oxidation potential.

Figures 7, 8 (solution 1), and 9 (solution 2) compare changes in film thickness with cathodic charge density. Thicknesses were determined ellipsometrically for films formed at different oxidation potentials as marked on the respective curves.

During reduction of films grown for 1.5s in both solutions, a linear dependence initially exists between film thickness and charge density. Later, the reduction rate and film thickness diminish, and the d vs. Q relationship becomes nonlinear. During reduction of films grown for $t \cong 10$ s, the linear segment of the d vs. Q curve is preceded and followed by nonlinear segments.

Hence, for passivation times longer than 10s, and passivation potentials higher than about -0.1 V in solution 1 and -0.3 V in solution 2, the relationship between film thickness and cathodic charge density indicates that reduction occurs in three stages characterized by different reduction rates of the film.

The following conclusions can be reached on the basis of the results obtained for both solutions:

1. The longer the passivation time of iron at the given potential, and the higher the anodic potential for the given passivation time, the higher the charge consumed in film reduction is.

Fig. 7. Dependence between film thickness determined ellipsometrically and cathodic charge for specimens passivated for 1.5s in solution 1 at different potentials.

Fig. 8. Dependence between film thickness determined ellipsometrically and cathodic charge for specimens passivated for 30s in solution 1.

Fig. 9. Dependence between film thickness determined ellipsometrically and cathodic charge for specimens passivated 1h in solution 2.

2. The higher the passivation potential and the longer the passivation time, the greater the thickness of the film reduced in the final stage of reduction is.

3. The charges consumed for the reduction of films formed at the same potential and time are higher for films grown in the dilute solution 1 than in the more concentrated solution 2.

The last observation appears to suggest that less dense films are formed in solution 2 relative to solution 1.

Figures 10-14 show typical examples of changes in potential vs. film thickness during galvanostatic reduction of films formed at different passivation potentials and times. Results obtained in solution 1 are plotted in Fig. 10-12, and those in solution 2 are given in Fig. 13.

Fig. 10. Dependence between reduction potential and film thickness determined ellipsometrically for specimens passivated for 1.5s in solution 1 at different potentials.

Fig. 11. Dependence between reduction potential and film thickness determined ellipsometrically for specimens passivated for 30s in solution 1.

Fig. 12. Dependence between reduction potential and film thickness determined ellipsometrically for specimens passivated for 1h in solution 1.

Fig. 13. Dependence between reduction potential and film thickness determined ellipsometrically for specimens passivated for 1h in solution 2.

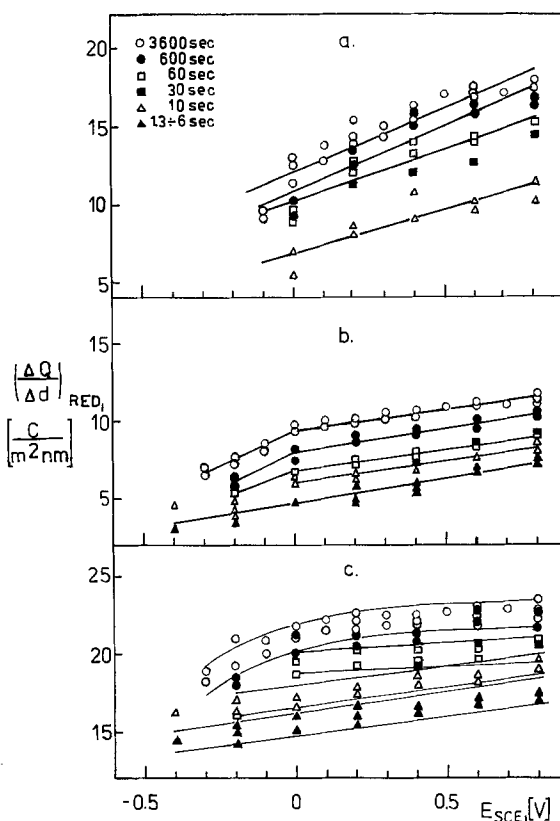

Fig. 14. Cathodic charge consumed for the reduction of film formed in Stages A-B (a), B-D (b), and D-Me (c) in different periods of time and at different anodic potentials; solution 1.

For films formed over about 1.5s, the relationship between cathodic potential and film thickness shows two linear segments at higher anodic potentials. The initial decrease of potential with thickness is faster than the final decrease. However, during reduction of films formed over 10s, and at $E \approx -0.1V$ in solution 1, and at $E \approx -0.2V$ in solution 2, the potential vs. d curves exhibit four linear segments, which are more pronounced for films oxidized for a longer time at higher anodic potentials.

In Fig. 10-13, points at which changes in slope of the E vs. d curves occur are marked "B," "C," and "D," while "A" indicates a film formed over 60 min. The same letters are marked in certain plots of d vs. Q and E vs. Q . It is seen that points B and D in the E vs. d plot also appear in E vs. Q and d vs. Q plots, while point C is clearly noticeable in the E vs. d relationship but is absent in the d vs. Q plot.

The individual reduction steps that appear in the E vs. d and E vs. Q relationships correspond to the four oxidation stages discussed in the first part of our work (1). Specifically, the A-B step showing reduction of the outermost film layer corresponds to the oxidation Stage IV; B-C corresponds to Stage III, C-D to Stage II, and D-Me (reduction of the metal-adhering layer) to the oxidation Stage I. However, film thicknesses at potentials corresponding to the point D are higher during reduction than during oxidation.

It follows from the experimental results that:

1. The potential values corresponding to point B range from -0.50 to $-0.53V$ in solution 1 and from -0.51 to $-0.53V$ in solution 2. These potentials are independent of both passivation potential and time.
2. Potential values corresponding to point C range from -0.57 to $-0.60V$ in both solutions and are independent of passivation potential and time.
3. Potential values corresponding to point D range from -0.7 to $-0.77V$ in solution 1 and from -0.8 to $-0.86V$ in solution 2. These values become lower for greater thicknesses of films to be reduced during the

D-Me step. Reduction of the film ended at potentials ranging from -0.76 to -0.86 V in solution 1 and from -0.85 to -0.95 V in solution 2.

Calculated values of the cathodic charge (Q) consumed for the reduction of the anodic film of $d = 1$ nm and an area of 1 m^2 in three consecutive steps A-B, B-D, and D-Me are collected in Fig. 15 and 16 for solution 1 and 2, respectively. These graphs correlate values of $(\Delta Q/\Delta d)_{\text{red}}$ with passivation potentials and time.

The $(\Delta Q/\Delta d)_{\text{red}}$ values for the B-D step apply to all potentials studied because a linear dependence exists between film thickness and charge. For the A-B and D-Me steps, average values were considered for each individual step, in accordance with the fact that no linear dependence exists between d and Q .

It follows from Fig. 14 that:

1. The $\Delta Q/\Delta d$ ratios during the D-Me step are greater in solution 1 compared with those in solution 2, but the opposite is true for the B-D step. For the A-B step, both solutions give rise to similar values of $\Delta Q/\Delta d$.

2. For all the reduction steps, the $\Delta Q/\Delta d$ ratios increase with increasing oxidation potential and passivation time. The influence of potential is most prominent in step A-B. At constant oxidation time, $\Delta Q/\Delta d$, for both steps A-B and B-D, is a linear function of potential starting from about 0.0 V in solution 1 and about -0.2 V in solution 2. The difference in $\Delta Q/\Delta d$ obtained for specimens oxidized in solution 2 for 30 and 60 min are insignificant.

Discussion

In Table I, calculated values are given for the cathodic charge necessary to reduce a unit volume of film containing a definite compound of iron. Charges consumed for reduction from Fe^{3+} to Fe^{2+} and from Fe^{3+} to Fe^0 are listed in the upper and lower part of the table, respectively.

Since it is possible that at potentials more negative than those corresponding to point D, Fe^{3+} could be reduced to Fe^0 and the fraction of the cathodic charge could be consumed in the reduction of hydrogen ions, only steps A-B and B-D, during which the above two reactions could not occur, will be discussed here.

Comparison of the theoretical charges given in the upper part of Table I with those found experimentally (Fig. 14) indicates that in most cases the latter are much greater than the former. Only for low oxidation potentials and short oxidation times are the experimental results close to the theoretical data. There are two likely reasons for this difference in charges: (i) during film growth and reduction, roughening of the surface takes place, and (ii) reduction to Fe^{2+} proceeds from an oxidation degree higher than Fe^{3+} .

Considerations based on the results of ellipsometric measurements and on tentative calculations of the most probable variations in the roughness coefficient have led to the conclusion that surface roughening alone could not be responsible for the observed excess

of cathodic charge consumed. For example, increased passivation potential has been found to increase the refraction index slightly, while surface roughening produces an opposite effect. Although surface roughening can probably occur during both anodic and cathodic reduction (3), this fact is expected to have an insignificant effect on the cathodic charge consumed.

Much more important effects might be expected if reduction from an oxidation degree higher than Fe^{3+} occurs.

The occurrence of highly oxidized iron compound in passive films was presumed by several authors (3, 14, 15). According to Nagayama and Cohen (3), the internal (i.e., iron-adherent) layer of the film is composed of Fe_3O_4 , while the external layer is composed of Fe_2O_3 , but contains iron oxidized to Fe^{6+} on the surface. Konno and Nagayama (13) claim that in the outermost film layer the average oxidation degree significantly exceeds that of Fe^{3+} . Using XPS method, they found an average valence of iron in the film equal to 3.59. Higher oxidation degrees have also been assumed by Chen *et al.* (15), and others.

Taking into consideration the occurrence of higher oxidized iron (above Fe^{3+}) in the external part of film, average oxidation degrees (v) were calculated assuming different values of the roughness coefficient (r). For $r = 1$, high, unrealistic values were obtained. If $r = 1.5$ was assumed, the computed v value was slightly higher than $3+$ for the reduction step and slightly lower than $3+$ for the B-D step. At longer oxidation times, and higher anodic potentials, higher v values were obtained. The v values obtained for $r = 1.5$ seem probable and are lower than those found by Konno and Nagayama (14).

As mentioned before, four distinct stages are observed during both the anodic oxidation and the cathodic reduction of oxide film. In addition, at film thicknesses corresponding to the characteristic points B and C, the reduction potentials are independent of both oxidation potential and time. Since, at the characteristic points B and C, the film thicknesses obtained from measurements of the change in d vs. t during anodic oxidation, and from the changes in d vs. E during cathodic reduction, are the same, it can be deduced that during oxidation Stages II, III, and IV at a given anodic potential, no substantial change in film composition occurs, irrespective of time of oxidation and reduction.

There is no agreement in the pertinent literature regarding electrochemical reactions responsible for two waves on the E vs. t curve during cathodic reduction of passive films at constant current density.

It seems reasonable to assume that a bend appears in the E vs. t plot when a characteristic potential is reached at which the film adopts certain specific properties (composition, conductivity, density) leading to a substantial change in the mechanism and rate of the further process of oxidation or reduction. It would be premature to speculate on the actual composition and

Table I. Calculated cathodic charge necessary to reduce a unit volume of film containing a definite compound of iron

Compound	$\left(\frac{\Delta Q}{\Delta d}\right)_{\text{red}} \left[\frac{C}{\text{m}^2\text{nm}}\right]$	$d \left[\frac{\text{g}}{\text{cm}^3}\right]$	Mw	Type of reaction

structure of the film having these characteristic properties.

Conclusions

1. In borate solution of pH 8.45, the cathodic charge consumed for the reduction of passive film is greater than the theoretical, calculated charge.

2. The charge consumed for reduction of passive film is greater for higher oxidation potentials and longer oxidation times.

3. The charge consumed for reduction of passive film in borate buffer solution of pH 8.45 depends on the concentration of H_3BO_3 and $Na_2B_4O_7$ and is less in the more concentrated solution 2 than in the dilute solution 1.

4. At certain characteristic thicknesses of the passive film, which correspond to changes in the growth of the film during its formation, inflections of the E_{red} vs. t and E_{red} vs. d curves are observed. These characteristic film thicknesses occur at constant potentials independent of either the oxidation potential or time.

Atmospheric Sulfidation of Copper Alloys

I. Brasses and Bronzes

G. W. Kammlott, J. P. Franey, and T. E. Graedel

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Although it is widely recognized that copper alloys are subject to sulfidation upon exposure to the atmosphere, the information available on the sulfidation rates of these alloys has come largely from field exposures under uncontrolled conditions. To gain more definitive information on the rates and processes involved in atmospheric sulfidation of copper alloys, we exposed nine copper alloys (brasses, nickel-substituted brasses, and other common compositions) to low concentrations of hydrogen sulfide in humidified air. Among the specific results are the following. (i) The resistance to sulfidation of the brasses was 50-100 times better than that of pure copper. (ii) The substitution of nickel for part or all of the zinc produces alloys even more resistant to sulfidation for low to moderate exposures; at longer exposures their behavior is mixed. (iii) Beryllium copper and phosphor bronze are somewhat more resistant to sulfidation than copper except for long exposures, when all three behave similarly. (iv) A silicon bronze sulfidized more rapidly than copper for most exposure periods. (v) Alloying copper with 10% aluminum yields an alloy with a sulfidation resistance nearly as good as the brasses. These results are discussed in conjunction with the information available on oxide growth on these alloys, and it is demonstrated that the sulfidation resistance of the alloys is quite similar to their resistance to oxidation, once an initial oxide film has formed. The degree to which the surface oxide film inhibits copper diffusion is thus reflected in the oxidation and sulfidation behavior of a given alloy. The results indicate that the performance in sulfidizing environments of equipment containing copper alloy components or parts can thus be markedly influenced by the particular alloys selected by the physical designer.

Unalloyed copper is valued highly as a metal because of its high electrical conductivity and ease of fabrication. Among the disadvantages for certain applications are its relative softness and its susceptibility to certain forms of atmospheric corrosion. These disadvantages can be minimized, however, by alloying the copper with other metals to form harder, more corrosion-resistant alloys while retaining much of copper's good workability properties.

Among the trace gases present in the atmosphere, those containing sulfur in a reduced chemical state are often the most detrimental to copper. The cuprous sulfide that forms under atmospheric conditions degrades its electrical and mechanical surface properties, as well as its appearance. Although the rates of sulfidation of the copper alloys are generally considered less rapid than that of pure copper (1, 2), few quantitative data are available. In a related paper (3), we report on studies of the sulfidation of copper-nickel-tin alloys by hydrogen sulfide (H_2S), one of the most reactive of atmospheric corrodants. In this paper, we describe similar studies dealing with several brasses and related nickel alloys, together with common alloys of copper containing the elements aluminum, beryllium, phos-

phorus, and silicon. Taken together, the studies provide quantitative information on the sulfidation characteristics of virtually all the copper alloy families, including most of the common materials in industrial use.

Experimental Technique

Sample characteristics.—Nine different alloys were selected for this study; their characteristics are presented in Table I. Five of the alloys form a group composed of brasses (copper-zinc alloys), alloyed brasses (alloys of copper, zinc, and <4% additional elements), and alloys in which nickel has been substituted for part or all of the zinc (nickel silver, copper nickel). The remaining four alloys were chosen to explore the sulfidation behavior of copper alloyed with other metals. In addition to the elements shown in Table I, small (<1%) amounts of other metals (Pb, Fe, etc.) are typical constituents of some of these alloys.

The alloys were procured in a variety of commercially available forms. Alloys 17200, 46400, 51000, 63000, and 65500 were received as 2.5 cm diam rods. Alloys 44300 and 71500 were received as 2.4 cm diam tubes with wall thicknesses of ~0.2 cm. Alloys 26000 and 75200 were received in sheet form. Wafers were cut

Table I. Characteristics of samples

Designation		Composition (w/o)					Properties

* From Smith (4): F = fair, G = good, E = excellent. In the discussion section, the differences and similarities between these ratings and our results are described. \dagger Designation system administered by the Copper Development Association. \ddagger Typical values are from Ref. (31). Values of samples used in this work were determined following the complete surface preparation and polishing sequence.

from the rods and sectioned, producing wedge-shaped samples of radius 1.2 cm. The tubes were opened by a single cut along their axes, rolled flat, and cut to produce samples of dimension 1.0 cm \times 1.0 cm. The sheet samples were cut to sizes similar to those of the tube samples.

The sample hardness was measured with a Wilson Hardness Tester, Model no. 3JR-PL, using a 100K Rockwell B scale. Alloy 75200, which had the lowest hardness value, was further examined with a Wilson Superficial Hardness Tester, Model no. 3JS, using a 15T scale. The resulting values are given in Table I.

Although little quantitative information on the sulfidation rates of any of these alloys is available, qualitative assessments of their corrosion resistance have been presented by Smith (4). These assessments, reproduced in the last column of Table I, suggest that the corrosion resistance of most of the materials is satisfactory, although alloys 46400 (naval brass) and 26000 (cartridge brass) rank below the other materials. Smith's ratings apply, of course, to general field service rather than to exposure to a single corrosive species (as we study). We compare his assessments with our own results later in this paper.

Sample preparation.—The reproducibility of atmospheric corrosion is influenced markedly by the surface preparation of the samples (5, 6). Careful and consistent sample preparation is thus vital if corrosion experiments are to be of maximum usefulness. Our approach to sample preparation was to cut the samples to the desired size, anneal them if desired, and then prepare the surfaces by mechanical polishing techniques. The first step in the polishing process was wet smoothing on 600 grit Al_2O_3 paper. This was followed by sequential wet polishing with Al_2O_3 powders (7). This polishing sequence yielded a surface with mean roughness $<0.3 \mu\text{m}$. Replicate samples produced by this technique showed variations in sulfidation rate of $<2\%$, much less than that of replicate samples prepared by etching techniques (8).

Sample exposure.—Nine samples of each of the nine alloys were exposed to hydrogen sulfide in wet air for periods ranging from 1-170h. The thicknesses of the sulfide films which formed were then determined. In several cases, sulfidation behavior that was particularly interesting led us to expose additional samples to study that behavior in more detail. As a result, this analysis is based on results from a total of 100 samples.

The corrosive environment to which the samples were exposed consisted of 3.0 ± 0.2 parts per million (ppm) of hydrogen sulfide gas in humidified air (RH = $93 \pm 3\%$) at room temperatures ($20^\circ \pm 1^\circ\text{C}$). H_2S concentrations higher than a small fraction of a ppm are rare in field environments (9). It has been reported, however, that the sulfidation of pure copper is a linear

function of total H_2S exposure (10). If we assume this dependence to hold also for copper alloys, we can use H_2S concentrations higher than ambient levels to accelerate the rate of sulfidation (i.e., to shorten the exposure time) of the alloys.

The details of the multiport corrosion exposure chamber and its accessories are described elsewhere (11); we summarize them briefly here for convenience. Each of the samples was attached to a flexible insert sized to fit one of the ports of the exposure chamber; this permitted samples to be inserted and withdrawn rapidly and without noticeably altering the corrosive environment. Control of the H_2S concentration in the chamber was achieved by using polymer permeation techniques. The water content of the air was varied by adjusting the portion of the air supply that passes through the humidifier. A dew point hygrometer and hot wire anemometer monitored the dew point and flow rate continuously. Each sensor was sampled periodically throughout the exposure period by a dedicated desktop computer system; the resulting values for the exposure conditions were derived from statistical analyses of these data.

Sample examination and analysis.—The morphology of the copper sulfide films was studied with a Kent-Cambridge 2A scanning electron microscope equipped with a solid-state x-ray detector and a multichannel analyzer. The thicknesses of the corrosion films were determined by energy-dispersive x-ray analysis (EDXA). The preparation of thickness standards necessary for this method is discussed elsewhere (12). The calibration curve that resulted related the ratio of intensities of sulfur and copper x-rays to the thickness of the Cu_2S sulfidation film. The thickness values were accurate to $\pm 20\%$ or $\pm 8 \text{ nm}$, whichever was smaller.

Results

The sulfidation of the three brasses is shown in Fig. 1, together with data previously acquired (8) on the sulfidation of "oxygen-free, high conductivity" copper (99.99% pure). It is apparent that the sulfidation rates of the brasses are all lower than that of copper, and that the rates of the brasses are rather closely grouped. The highest of the three, cartridge brass (alloy 26000), has a sulfidation rate about 1/50 that of copper. This performance is significantly better than that of cartridge brass on a long-term field-exposure test (13). Since both sulfidation and chloridation of samples are common in field exposures, this result may suggest that the resistance of alloy 26000 to sulfidation is better than its resistance to chloridation. Admiralty brass (alloy 44300), which differs from cartridge brass chiefly in the substitution of $\sim 1\%$ tin and $\sim 1\%$ arsenic for $\sim 2\%$ zinc, shows essentially the same sulfidation rate. The best resistance to sulfidation is displayed by naval brass (alloy 46400), in which the copper is alloyed with zinc to a higher percentage than

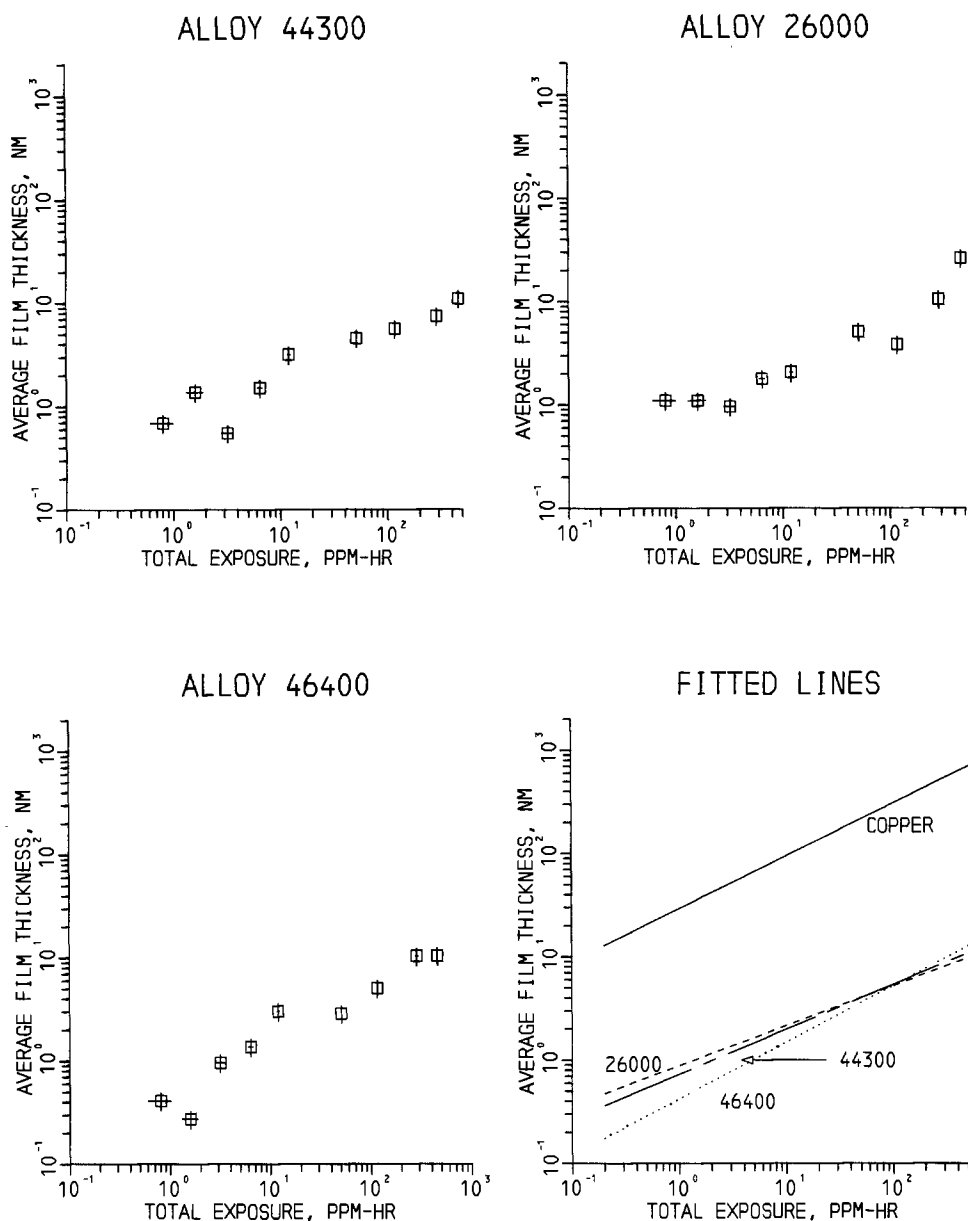

Fig. 1. Cu_2S film thickness as a function of total exposure (the product of exposure time and H_2S concentration) for pure copper and for three common brasses: cartridge brass (alloy 26000), admiralty brass (alloy 44300), and naval brass (alloy 46400). The estimated error bars are shown for each data point. The linear and quadratic lines on this and the following graphs are least squares fits to the data points, except that the final alloy 26000 point is eliminated from the fit (see text). Alloy samples receive a total H_2S exposure of $10 \text{ ppm} \cdot \text{h}$ in about a year's time at the average urban location (8).

in any other alloy in these experiments.

The sulfidation of copper is known to be markedly reduced by alloying the copper with nickel (13). In Fig. 2, we explore the sulfidation of alloys similar to naval brass in degree of alloying, but with nickel substituted for half (nickel silver, alloy 75200) or nearly all (copper nickel, alloy 71500) of the zinc. At the shorter exposures, the addition of nickel reduces the sulfidation rate below even that of naval brass. The low hardness of alloy 75200 (Table I) is consistent with its measured average grain size of 0.09 mm , a size that is characteristic of a fully annealed material. Thus, the sulfidation resistance may be somewhat enhanced by annealing. At longer times, the sulfidation rate of alloy 75200 becomes equal to that of naval brass. For the longest exposure, the rate of alloy 75200 sulfidation exceeds that of naval brass. Similar poor performance at long exposure times has been seen in a similar alloy exposed to field environments (14). Alloy 71500 shows superior sulfidation resistance at low and moderate exposures, but the sulfide film thickness increases rapidly near $E = 70 \text{ ppm} \cdot \text{h}$ to nearly that of copper. Our data provide quantitative support for LaQue and Copson's statement (13) that "the high-zinc brasses and the nickel silvers are more resistant to tarnishing than copper," at least for low and moderate exposures.

The samples with smaller fractions of alloying com-

ponents showed considerable variation in their sulfidation behavior. In Fig. 3, the sulfidation of copper is compared with those of two alloys containing about 95% copper: phosphor bronze (alloy 51000) and silicon bronze (alloy 65500). The sulfidation rates of all three materials are rather high. That of silicon bronze is very similar to that of copper, both showing a steady increase in sulfidation followed by transition to a limiting sulfide thickness of $\sim 250 \text{ nm Cu}_2\text{S}$ under our exposure conditions. These results are consistent with field exposure results for this alloy (13). The sulfidation behavior of phosphor bronze is quite different. At low to moderate exposures it is significantly more resistant to sulfidation than are the other two materials. At $E \sim 20 \text{ ppm} \cdot \text{h}$, its sulfidation rate increases suddenly to that of copper, which it follows thereafter.

Figure 4 compares copper sulfidation with that of beryllium copper (alloy 17200) and aluminum bronze (alloy 63000). The resistance to sulfidation of the aluminum bronze is much better than that of copper, rather close to that of the brasses, and monotonic throughout, as has been seen for similar alloys in field tests (13). The beryllium copper sulfidizes at a rate about a factor of five below that of copper for low and moderate exposures, but at $E = \sim 10 \text{ ppm} \cdot \text{h}$, the rate suddenly increases to that of copper, which it follows thereafter. Although alloys 51000 and 71500, and possibly 26000 and 75200, exhibit somewhat the

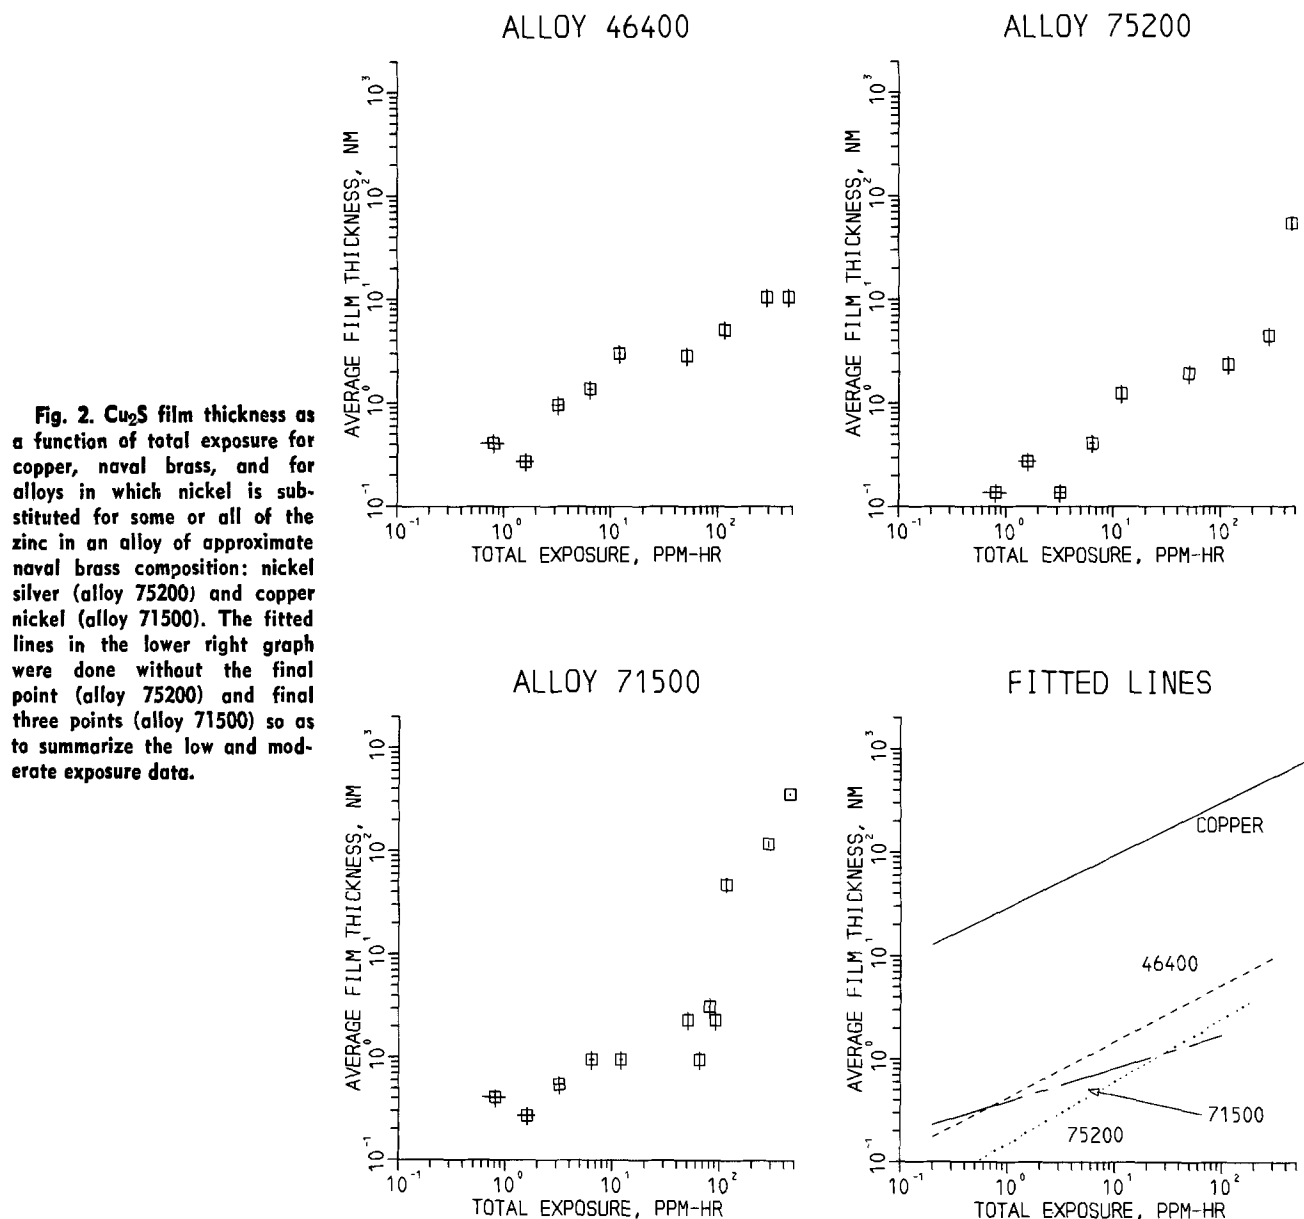

Fig. 2. Cu_2S film thickness as a function of total exposure for copper, naval brass, and for alloys in which nickel is substituted for some or all of the zinc in an alloy of approximate naval brass composition: nickel silver (alloy 75200) and copper nickel (alloy 71500). The fitted lines in the lower right graph were done without the final point (alloy 75200) and final three points (alloy 71500) so as to summarize the low and moderate exposure data.

same characteristics in their sulfidation rates, the rate behavior of alloy 17200 is the most clearly defined sigmoid in our data.

To summarize the data, of the nine alloy samples tested, five (26000, 44300, 46400, 63000, and 75200) are markedly superior to copper in resistance to sulfidation, one (65500) is similar to copper in that respect, and three (17200, 51000, and 71500) exhibit behavior superior to copper at low and moderate exposures and essentially equal to that of copper for higher exposures.

Discussion

The results of this work demonstrate that the common brasses are one to two orders of magnitude more resistant to H_2S sulfidation than is pure copper. The substitution of nickel for a portion of the zinc produces an alloy at least as resistant to sulfidation as are the brasses. Aluminum also forms sulfidation resistant alloys with copper. The relative merits of copper nickel (alloy 71500), phosphor bronze (alloy 51000), and beryllium copper (alloy 17200) from the standpoint of resistance to sulfidation depend largely on the use to which they are put. This is a consequence of the sigmoidal behavior of their sulfidation curves. Generally satisfactory performance at low exposures gives way to performance similar to that of copper at higher exposures. These sigmoidal curves, apparently the first to be observed for sulfidation, are perhaps the

most intriguing feature of our data. They indicate the existence of at least three different regimes of sulfidation behavior. The first, at low exposures, is characterized by moderate increases in sulfidation with exposure. The second, at intermediate exposures, shows a rapid increase in the sulfidation rate with exposure, perhaps reflecting a breakdown in the protective oxide layer. The third, at long exposures, shows a transition to a regime in which a limiting film thickness is approached. Sigmoidal corrosion curves have occasionally been seen in oxidation studies (15-18). The explanation given is that the initial stage of oxide adsorption on the metal surface is followed by the growth of oxide nuclei (16, 19-20). This growth is rapid, since the initial resistance to nucleation has been overcome. Once the nuclei have grown enough to coalesce, new oxide must form atop an oxide layer, and the diffusion rate through that layer becomes the rate-limiting step (16, 20).

The situation in the present case differs in that the sulfide layer must be grown atop the existing oxide layer. [Auger analysis (21) shows that there is very little growth of sulfide within the oxide layer or of additional oxide growth during sulfidation.] Diffusion of metal ions through the oxide layer will thus provide a relatively uniform damping of the sulfidation rate in all regimes. We envision the sequential picture as follows. In the first stage, individual H_2S molecules are adsorbed randomly onto the oxide layer. When Cu_2S

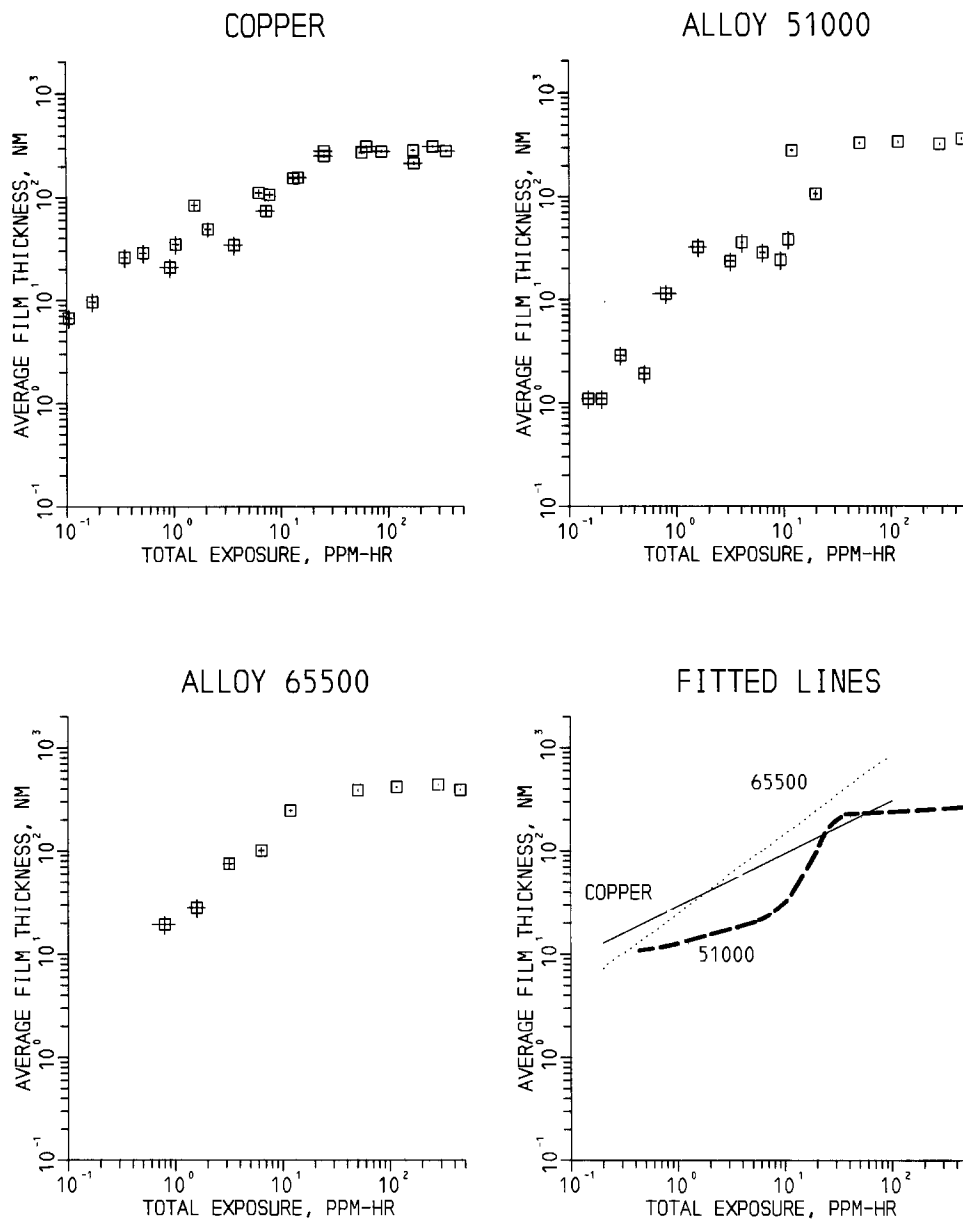

Fig. 3. Cu_2S film thickness as a function of total exposure for copper, phosphor bronze (alloy 51000), and silicon bronze (alloy 65500), two alloys that contain approximately the same percentage ($\sim 95\%$) of copper. For ease in comparison, the two groups of data for alloy 51000 close to the transition region are given separate linear fits and joined by eye.

nuclei become sufficiently well formed [probably at defect sites in the oxide lattice or at surface imperfections (8)], more rapid lateral growth occurs. This stage ends when a coalesced sulfide layer is formed by the intersecting, growing Cu_2S islands. The requirement for Cu^+ diffusion through both the oxide and sulfide layers then produces an exponential approach to the surface film thickness produced after long exposures.

A remaining item of discussion is the relationship between the sulfidation rate behavior of the different alloys and their composition. Little sulfidation research on these alloys is available, but their oxidation has been investigated fairly extensively. The success of an alloying constituent in minimizing oxidation is strongly related to the strength and permeability of the initial oxide film that forms on the alloy (22). In the case of a brass, a zinc-rich oxide layer is formed (23, 24); this layer is relatively impervious to diffusing copper ions and thus inhibits both oxidation and sulfidation (24, 25). Nickel forms a mixed oxide when alloyed with copper (26-28) and is a good oxidation inhibitor only at relatively high ($>10\%$) concentrations (27, 29). Copper rich alloys with aluminum form films of $\gamma\text{-Al}_2\text{O}_3$ which allow moderate Cu^+ diffusion (30). The effect of beryllium is to form a thin protective film of BeO which partially inhibits oxidation (23). When silicon is alloyed with copper, the surface film

is largely SiO_2 (18), but it is both permeable to copper ions and subject to rupture (18) and thus provides little oxidation protection (30).

The data we have presented indicate that the sulfidation resistance of the copper alloys is quite similar to their resistance to oxidation following the formation of the initial surface oxide film. Since each process involves the diffusion of copper ions from the bulk material through the oxide layer, it is clear that this diffusion is rate limiting for most of the sulfidation exposures in our work. Some of the influences of alloy composition on corrosion may reflect their individual reaction and diffusion characteristics. For example, brasses are known to lose zinc from surface layers as part of the corrosion process (2, 25, 32), a process which changes both the morphology and composition of the surface layers. In a subsequent study, we will examine the relationships of sulfide layer growth to localized forms of corrosion and dealloying of samples exposed to controlled corrosive atmospheres in the laboratory.

A final topic of interest is the comparison of our results with the "corrosion resistance" assessments of Smith which appear in Table I. His qualitative ratings suggest that the nickel alloys 71500 and 75200 have the highest resistance, that cartridge brass (alloy 26000) and naval brass (alloy 46400) are sometimes only fair, and that the others are roughly equivalent and of high

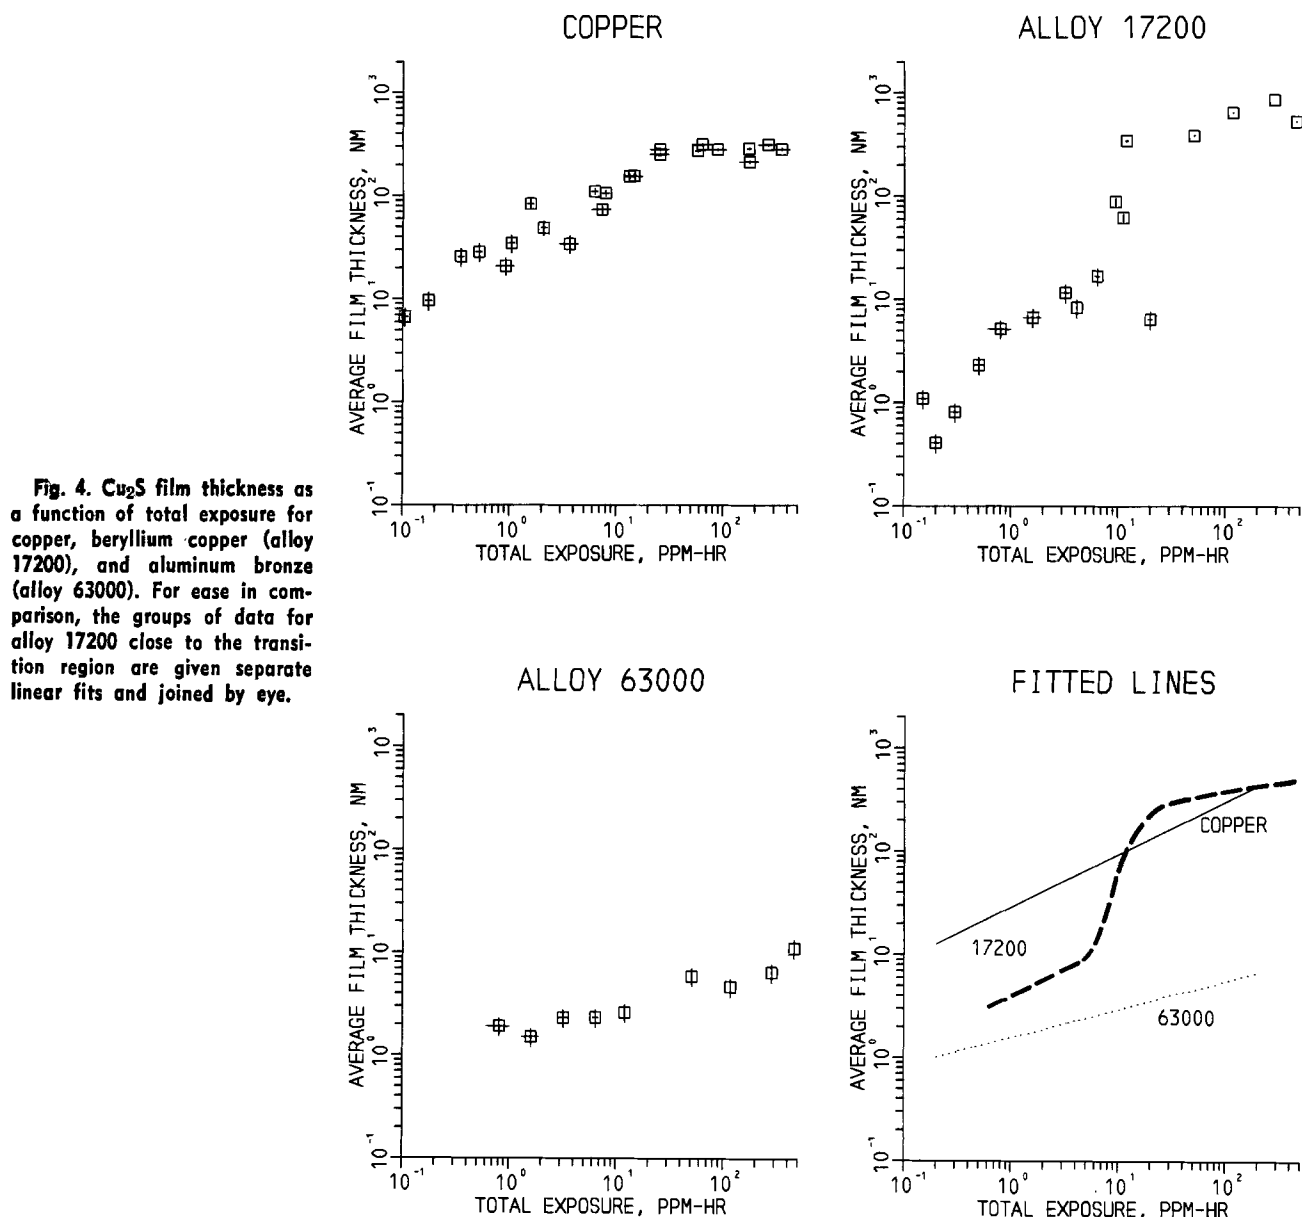

Fig. 4. Cu_2S film thickness as a function of total exposure for copper, beryllium copper (alloy 17200), and aluminum bronze (alloy 63000). For ease in comparison, the groups of data for alloy 17200 close to the transition region are given separate linear fits and joined by eye.

corrosion resistance. For sulfidation, at least, our quantitative results (for sulfidation only, rather than for the more general field corrosion to which Smith's assessment applies) differ with some of Smith's ratings and permit more precise comparisons in all cases. At high exposures, the brasses are superior. Alloying with nickel in place of zinc produces mixed behavior. Aluminum bronze is quite resistant to sulfidation, as is beryllium copper at low and moderate exposures. Phosphor bronze is relatively poor except for low exposures. Alloying with silicon appears to be of no advantage from a sulfidation resistance standpoint.

It is apparent that there are wide differences in sulfidation susceptibility among the common industrial alloys of copper, and that physical designers concerned with such susceptibility can greatly improve the sulfidation resistance of their designs by careful selection of the appropriate copper alloy.

Atmospheric Sulfidation of Copper Alloys

II. Alloys with Nickel and Tin

G. W. Kammlott, J. P. Franey, and T. E. Graedel

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

In order to assess quantitatively the sulfidation characteristics of industrially used alloys of copper, we have exposed a variety of copper-nickel-tin alloys as well as the pure metals to hydrogen sulfide in humidified air. The thicknesses of the resulting sulfide films were then determined. Nickel and tin were very resistant to sulfidation and copper alloys containing at least a combined total of 8% of these metals were resistant as well. The rate of sulfidation for the 92 Cu/4 Ni/4 Sn alloy is decreased with respect to copper by a factor of about four for moderate exposures. The rate continues to decrease as more alloying metal is added to the copper, reaching an equivalent rate of $<0.2 \text{ nm Cu}_2\text{S yr}^{-1}$ for an alloy of 78 Cu/15 Ni/8 Sn in a typical field environment. The content of nickel in the alloy appears to be more important to the inhibition of sulfidation than the tin content. A spinodal alloy after heat-treatment is less resistant to sulfidation than the same alloy as cold-worked. Annealed 725 alloy (89 Cu/9 Ni/2 Sn) is more prone to initial sulfidation than is the same alloy when work hardened. The results of this and earlier work demonstrate that alloys of copper containing at least 10% of any of the common alloying metals are some thirty times more resistant to sulfidation than pure copper.

Pure copper is subject to progressive sulfidation upon exposure to atmospheric environments containing reactive sulfur compounds. Some of its alloys are much more corrosion resistant. Experience has demonstrated that alloys containing more than a few percent of nickel are relatively tarnish-free under normal use conditions. This qualitative knowledge is often insufficient, however, as when a materials scientist attempts to predict an alloy's behavior in a severe corrosive environment or when new alloys are prepared for which no field experience exists.

The object of the present work is to provide quantitative information on the atmospheric sulfidation of several ternary alloys of copper, together with the base metals. Because of their industrial utility, especially for electrical and electronic applications, we have performed corrosion experiments on copper, nickel, and tin, and on copper/nickel/tin ternary alloys of varying composition, spinodal structure, and hardness. The results of those experiments are described here. In a companion paper (1), we describe the results of similar experiments on alloys of copper with zinc, silicon, beryllium, and aluminum.

Experimental Technique

The metals and alloys selected for these experiments are representative of a variety of spinodal and non-spinodal materials in common industrial use. Their properties are summarized in Table I. Our experiments included simultaneous exposure of copper metal to provide a base line against which the sulfidation of the samples could be compared. The copper was of the "oxygen-free, high conductivity" type of 99.99% purity. Nickel and tin metals were also exposed in-

dividually so that their sulfidation sensitivities could be assessed; both were 99.99% pure. The alloys were taken from manufactured stock. Their compositions are accurate to ½%.

The samples used in the experiments had surface dimensions of about $1 \times 2 \text{ cm}$ and were about 2 mm thick. Surface preparation of the samples, exposure to corrosive environments, and post-exposure examination and analysis followed techniques previously described (1).

Table I. Properties of samples

CDA code†	Common name	Nominal composition (w/o)				Percent cold-work‡	Hardness*

Results

Sulfidation of nickel and tin metals.—The susceptibilities of unalloyed nickel and tin to sulfidation were examined by exposing samples of the metals to the corrosive environment for periods of as long as 3 weeks, i.e., to a total exposure of ≈ 1500 ppm · h. Such an exposure is equivalent to approximately a century of reduced sulfur exposure in a typical environment or to approximately 10 yr in an extremely corrosive environment (2). The surfaces of these samples did not undergo degradation visible to the naked eye during that period, nor was any sulfur detectable by SEM/EDXA techniques. These results set upper limits of ≈ 0.2 nm to the amount of sulfide film present on the samples. Since less than 5 min in such an environment is sufficient to grow 1 nm of sulfide film on copper, the sulfidation rates of nickel and tin under our conditions are less than 10^{-4} that of copper and may be disregarded in our subsequent analyses. Such low sulfidation rates for nickel and tin are qualitatively consistent with the results of other investigators (3-6).

Sulfidation of Cu/Ni/Sn alloys of different composition.—Ternary alloys of copper, nickel, and tin customarily consist of ≈ 75 weight percent (w/o) copper. The nickel to tin ratio is generally between one and two. For our tests, we selected four alloys in commercial use, as shown in Table I. The nickel content of the alloys ranged from 4 to 15 w/o, and the total alloying metals content from 8 to 23 w/o. The sulfidation of these alloys upon exposure to the H_2S atmosphere is shown in Fig. 1. It is evident that the resistance to sulfidation increases with decreasing copper content. The vertical line labeled E_1 is the total exposure received in a 10 yr period at a typical field H_2S concentration of 1 ppb (2). Although clearly a crude approximation of a lifetime exposure, the intercepts of the fitted curves with this exposure line suggest that for alloys containing at least 15% of the alloying metals, < 10 nm of sulfide film can be expected during a 10 yr exposure to a field environment with typical concentration of reduced sulfur gases. (In general, of course, other

Fig. 1. Film thickness as a function of total exposure for Cu/Ni/Sn ternary alloys. The lines on this and most of the following graphs are least squares fits to the logarithms of the data points. That for the 72600 alloy is fit only to the first five data points (see discussion of Fig. 3 in text).

corrosive agents are present as well, so our results are probably lower limits to the corrosion anticipated in field service.)

To show the dependence of sulfidation on alloy composition in more detail, and for comparison of the results with those for pure copper, Fig. 1 also includes a vertical line at a total exposure of 2.5 ppm · h. (At this exposure, the ternary alloy sulfidation has proceeded far enough for the differences to be distinguished, while that for copper has not yet reached the exponential fall-off region). Using the intercepts of the fitted curves with the $E_{2.5}$ line, we then proceed to plot in Fig. 2 the film thickness (ψ) as a function of nickel content. The data have the form

$$\log(\psi_{2.5}) = 1.70 - 0.15f \quad [1]$$

where (f) is the nickel content in weight percent. The sulfidation rate is decreased by about a factor of four from that of pure copper for the 72600 alloy; this factor becomes approximately two hundred as the content of alloying metals is increased to 15 Ni/8 Sn.

Effect of individual alloy constituents on sulfidation.—To examine in more detail the effects on sulfidation of the nickel content of the alloy, exposures were conducted with samples of phosphor bronze, an alloy containing ≈ 5 w/o tin, a very small amount of phosphorus, and no nickel. In Fig. 3, the results of these exposures are compared with those of the 72600 alloy, which has nearly the same tin content as phosphor bronze, in addition to ≈ 4 w/o nickel. We have noted previously (1) that phosphor bronze shows sigmoidal behavior, as seen also in Fig. 3. Figure 3 shows that sigmoidal behavior appears to be a property of the 72600 alloy as well, but the rapid increase in the sulfidation rate occurs at about twice the exposure required to produce the same effect in phosphor bronze. Thus it appears that the presence of the nickel reduces sulfidation sig-

Fig. 2. Film thickness (ψ) as a function of weight percent nickel for $E = 2.5$ ppm/h.

nificantly at the longer exposure times, a result in qualitative agreement with experiments on high-temperature corrosion of copper-nickel alloys by sulfur vapor (5).

A similar approach was used to examine the effects of tin content on sulfidation. The comparison was made between the 72800 alloy (85 Cu/9 Ni/6 Sn) and the 72500 alloy (89 Cu/9 Ni/2 Sn). The elimination of 4 w/o of alloying tin has little effect on the sulfidation rate (Fig. 4).

We conclude from Fig. 3 and Fig. 4 that the presence of nickel in these ternary alloys is more important for

Fig. 4. Film thickness as a function of total exposure for the 72700 alloy (solid line) and for the 72500 alloy (dashed line).

their corrosion resistance than is the presence of tin. Additional evidence is provided by studies of a high-tin bronze (70-75 Cu/20-25 Sn/1-5 Pb) described in more detail elsewhere (7). Its sulfidation rate proved to be between that of pure copper and of phosphor bronze, i.e., relatively susceptible to sulfidation.

Effect of spinodal structure on sulfidation.—Ternary alloys of copper, nickel, and tin may be heat-treated to develop an extremely fine modulated structure which provides a substantial increase in mechanical yield strength (8, 9). The structure so developed is characterized by a wavelength of approximately 10 nm and a compositional amplitude of ≈ 1 w/o Sn. The data discussed above would suggest that a variation of this magnitude should not noticeably influence sulfidation kinetics. To investigate this prediction, we performed parallel exposure tests on samples of the 9/6 alloy prior to and following a heat-treatment to develop the spinodal structure (10). The results are presented in Fig. 5. Although both alloys are relatively resistant to sulfidation, the segregation produced by the spinodal heat-treatment is seen to have increased the tendency of the alloy to sulfidize. The effect is approximately equivalent to reducing the quantity of alloying nickel from 9 to 4% (see Fig. 1). The apparent anomaly in these data may be explained by the fact that coincident with spinodal decomposition in the matrix, equilibrium precipitation occurs at the grain boundaries. Corrosion reactions are favored at such boundaries (11).

Effect of work hardening on sulfidation.—Corrosion of various types is often influenced by cold-working (12). To examine this phenomenon for copper alloys, we annealed samples of the 72500 alloy in air at 100°C. Metallographs of the annealed and work-hardened (i.e., as-received) samples are shown in Fig. 6. Matched samples of the annealed and work-hardened samples were then exposed to the corrosive atmosphere. The results are plotted in Fig. 7. It is apparent that the work-hardened material was more resistant to initial sulfidation (by a factor of two to three). The result appears contradictory to that for the spinodal alloy, in which grain boundaries seem to play a central role in

Fig. 5. Film thickness as a function of total exposure for the 72700 alloy prior to and following heat-treatment to produce spinodal structure.

Fig. 6. Metallographs of the 72500 alloy in the work-hardened condition: as-received (a, top); after annealing (b, bottom).

sulfidation. We note, however, that heavily cold-rolled copper develops a preferred texture different from that of the fully annealed form (13), and that the oxidation rate of copper differs with the crystal face that is exposed (4). We suggest that sample texture may have been an important cause of these results. The results

are consistent with those obtained by other workers on binary alloys of copper and nickel at temperatures of 320°-500°C (14). We will report subsequently on experiments to determine whether the effect is restricted to copper-nickel alloys or is somewhat more general.

Discussion and Summary

Sulfidation rate testing of pure metals has quantified previous observations that nickel and tin are quite sulfidation resistant, while copper sulfidizes readily. The addition of nickel and tin to pure copper decreases sulfidation at a rate exponentially dependent on the amount of alloying nickel. Thus, 92 Cu/4 Ni/4 Sn sulfides much less rapidly than pure copper, and increasing the nickel content to 9 w/o lowers the rate such that little formation of sulfide film may be expected in a typical field environment.

To investigate the relative merits of nickel and tin as sulfidizing inhibitors in alloys, commercial alloys having similar concentrations of one metal and dissimilar concentrations of the other were exposed to corrosive environments. At 9 w/o Ni, the removal of 4 w/o Sn (from 6 to 2) had little effect on sulfidation. At 4-5 w/o Sn, the removal of 4 w/o Ni (from 4 to 0) resulted in formation of thick sulfidation films at lower exposure. Such a result is consistent with an interpretation that sulfidation is inversely related to nickel content, a result supported by corrosion studies of bronzes (copper-tin alloys not containing nickel).

Comparative sulfidation tests of an 85 Cu/9 Ni/6 Sn alloy prior to and subsequent to spinodal heat-treatment demonstrated that the spinodal structure tends to sulfidize more rapidly, although the rate is still moderate. This result must be related to the structure of the spinodal alloy, perhaps involving modification of the composition at grain boundaries.

Comparative sulfidation tests of 72500 alloy (89 Cu/9 Ni/2 Sn) in annealed and work-hardened states demonstrated that the latter was the more resistant to sulfidation. This result may reflect the influence of texture on sulfidation and is consistent with work by others on copper-nickel binary alloys, but is in contrast with the conventional picture that the cold-working of materials increases their tendency to corrode (12). We are now engaged in detailed metallographic analyses in conjunction with corrosion experiments to explore in detail the relationship between corrosion and cold-working of copper alloys. The results will be reported separately.

When the sulfidation results of this work and of our work on brasses and bronzes (1) are compared with the alloy compositions, it can be seen that the sulfidation rate reflects the percentage of alloying constituents. In Fig. 8, this relationship is displayed. To construct the figure, the sulfide film thickness at a moderate total exposure of 10 ppm-h is plotted as a function of alloying percentage. It can be seen that the percentage of alloying metal is a reasonably successful ordering parameter. Obviously, the behavior of the individual alloying metals is responsible for deviations from the general pattern. Several of these deviations deserve comment. Beryllium-copper (alloy 17200) is significantly more resistant to sulfidation at this moderate exposure than would be suggested by its alloying percentage. Silicon-bronze (alloy 65500) is less resistant to sulfidation than might be anticipated. In general, it appears that alloys of copper containing at least ten percent of any of the common high-percentage alloying metals (Zn, Ni, Sn, Al) are some thirty times as resistant to sulfidation as is pure copper, and that no major improvement in sulfidation resistance results from alloying copper to a degree higher than about 10 percent.

Acknowledgments

We thank P. R. White for providing most of the samples, J. T. Plewes for numerous discussions, and R. C.

Inhibition of Low Temperature Hot Corrosion by Zn, Na Mixed Sulfates

Relation Between Sulfation and Corrosion Reactions

James G. Foggo, III, Douglas B. Nordman, and R. L. Jones*

Naval Research Laboratory, Chemistry Division, Washington, DC 20375

ABSTRACT

Zinc effects in low temperature hot corrosion (LTHC) were investigated by examining the sulfation of Co_3O_4 and NiO by SO_3 in 50 mol percent (m/o) $\text{ZnSO}_4\text{-Na}_2\text{SO}_4$ melts at 700°C. Sulfation was substantially reduced as compared to sulfation in pure Na_2SO_4 , especially for Co_3O_4 . Corrosion tests with $\text{ZnSO}_4\text{-Na}_2\text{SO}_4$ deposited on BC-21 composition CoCrAlY, showed LTHC to be inhibited under SO_3 concentrations up to 500 ppm. The results demonstrate that the corrosive properties of Na_2SO_4 melts are significantly affected by ZnSO_4 . LTHC inhibition is postulated to result from reduced solubility of CoSO_4 in the $\text{ZnSO}_4\text{-Na}_2\text{SO}_4$ melt, and/or formation of "barrier" films on the oxide and metal surfaces.

Zinc anodes, and occasionally Zn-containing coatings, are used to protect sea water ballasted fuel tanks on ships. With gas turbine powered ships, the possibility of zinc contamination of the fuel causes concern, since zinc has been reported to produce intergranular corrosion in nickel-based superalloy turbine blades (1). However, Canadian Navy ship gas turbines have burned zinc-contaminated fuel, with ZnSO_4 being formed on the hot section blades, with apparently little harm (2). Canadian studies indicate, in fact, that 2.5-5.0 weight percent (w/o) additions of ZnSO_4 inhibit hot corrosion in aggressive 90 w/o $\text{Na}_2\text{SO}_4\text{-10 w/o NaCl}$ melts at 900°C (2). Only cobalt-based superalloys were tested, but nickel-based blades withstood

corrosion in the ship engines apparently as well as cobalt-based vanes, indicating that ZnSO_4 may protect both metals under some circumstances.

Other tests also suggest Zn may have inhibitive effects. In 900°C burner rig trials, Zn was more effective as an inhibitor additive than Cr for Mar M-509, IN-792, and IN-738, but not for corrosion susceptible IN-100 (3). In addition, early NRL low temperature hot corrosion (LTHC) experiments showed that 50 mol percent (m/o) deposits of $\text{ZnSO}_4\text{-Na}_2\text{SO}_4$ (eutectic mp 470°C) gave essentially no corrosion of BC-21 CoCrAlY (a Co-based gas turbine blade coating used in Navy shipboard engines) at 700°C, whereas severe corrosion was produced by molten Co-, Ni-, Fe-, or Cu-Na mixed sulfate deposits (4).

These instances of apparent hot corrosion inhibition

by zinc have not been explained. For 700°C hot corrosion, the sulfation of cobalt and nickel oxides in the presence of Na₂SO₄ to form low-melting mixed Co,Na- or Ni,Na-sulfates on the blade surface is known to be crucial (5-7). Conceivably therefore, ZnSO₄ could inhibit LTHC by interfering with the sulfation of Co or Ni oxides, or by affecting other reactions in the mixed sulfate formation.

Accordingly, experiments were undertaken (i) to investigate mixed sulfate formation and decomposition reactions in the presence of ZnO/ZnSO₄, and (ii) to determine whether ZnSO₄ can inhibit 700°C hot corrosion of BC-21 CoCrAlY blade coating under SO₃ concentrations relevant to Navy marine gas turbine operation.

Experimental

The general procedures and apparatus have been described previously (6, 8). The experiments were conducted at 700 ± 5°C in multizone constant temperature tube furnaces fitted with a catalytically inert (quartz) combined furnace tube and analytic trap system which allowed determination of the SO₂ and SO₃ concentrations in the exhaust gas. Filtered laboratory air at 200 ml/min was used as the furnace gas, with electronic controllers providing input of controlled concentrations of SO₂ or equilibrated SO₂-SO₃ (obtained by placing a platinum catalyst upstream in the 700°C temperature zone). The concentrations ranged from approximately 100-3000 ppm (1 × 10⁻⁴-3 × 10⁻³ atm) SO_x, where SO_x = SO₂ + SO₃, and were controlled to ±10% as verified by gas analysis. Since SO₃ appears to be the critical species, our discussions will refer principally to SO₃ concentrations, although the SO₃, in fact, is present in an SO₂-SO₃ mixture.

The metal oxides studied were fine powders of 99.998% purity (Puritronic grade, Johnson Matthey Chemicals). The sodium sulfate was ACS certified reagent grade (Fisher) and the anhydrous SO₂ of 99.98% purity (Matheson). For the mixed metal oxide-sodium sulfate experiments, a stock of each mixture was prepared, with thorough mixing and grinding, and then samples (usually 250 mg) were taken from this stock for each individual experiment. The powder specimens were spread evenly (without compaction) over the bottom of glazed porcelain boats (Coors 6A, 97 × 16 × 10 mm od) in a layer 1-2 mm thick. The sample size and arrangement were chosen to facilitate equilibration with the furnace gas, and to simulate (to some degree) the thin sulfate films occurring on turbine blades.

Two different CoCrAlY specimens were employed in the corrosion experiments. One was a 5 mil PVD coating of CoCrAlY [20.9Cr, 12.9Al, 0.32Y, bal Co (w/o)] on Rene 80, and the other a bulk casting of CoCrAlY alloy [22Cr, 11Al, 0.5Y, bal Co (w/o)]. The compositions, listed here as provided by the suppliers, are within BC-21 specifications. No difference in corrosion behavior between the two specimens was noted. No analysis was made of the Rene 80, which was assumed to be within alloy specifications. The corrosion specimens were mounted in epoxy and metallurgically cross-sectioned (with dry polishing) and then examined by scanning electron microscopy/energy dispersive x-ray analysis (SEM/EDXA) using a 20° specimen tilt angle and palladium anticharging coating.

Results and Discussion

ZnO catalysis.—The sulfation of Co₃O₄ and NiO appears to involve SO₃ specifically (6, 8). However, this fact has been obscured because these oxides catalyze the reaction, SO₂ + ½ O₂ = SO₃, and sulfation can be obtained even when the furnace gas contains only SO₂. To understand the sulfation of ZnO, it is important to know, therefore, whether ZnO is catalytic for the SO₂-SO₃ equilibrium reaction. Accordingly, tests

were made where air containing 500 ppm SO₂ was passed at 200 ml/min over 100 mg samples of ZnO or Co₃O₄ powders maintained at 700°C in porcelain boats. Zinc oxide produced SO₃/SO₂ ratios of 0.03-0.05 (very near the "blank" obtained without any oxide present) whereas Co₃O₄ consistently produced SO₃/SO₂ ratios of about 0.4.

Zinc oxide thus evidently has low catalytic activity for the SO₂-SO₃ reaction. There was no weight gain for either ZnO or Co₃O₄, indicating that neither oxide is directly sulfated under these conditions.

Evolved SO₃/SO₂ ratios from mixed sulfate decomposition.—Zinc sulfate has been reported to evolve SO₂ upon decomposition, while nickel sulfate and cobalt sulfate were found to yield SO₃ (9). Since SO₃ is more corrosive than SO₂ in mixed sulfate corrosion (10), sulfate mixtures containing ZnSO₄ might, if they produce SO₂ rather than SO₃, be less corrosive than pure NiSO₄-Na₂SO₄ or CoSO₄-Na₂SO₄ deposits. The thermal decomposition of 50 m/o mixes of CoSO₄-Na₂SO₄ and ZnSO₄-Na₂SO₄ under air alone (200 ml/min) at 700°C was therefore compared. The decompositions were carried out under two conditions: in porcelain boats where no substrate effect would be expected, and on CoCrAlY surfaces where corrosion reactions can enter. Both sulfate mixtures melted and flowed initially, giving sulfate layers of less than 1 mm thickness. As found in previous research (4), there was extensive corrosion of the CoCrAlY under the CoSO₄-Na₂SO₄ deposits, but very little apparent corrosion under the ZnSO₄-Na₂SO₄ deposits.

The data from the decomposition experiments are presented in Table I. Although the SO₃/SO₂ ratios showed considerable variation between individual experiments, clear trends in behavior are nonetheless evident.

In particular, we note that, except for Co,Na sulfate on CoCrAlY, the ratios obtained were generally well above the equilibrium ratio of 1.1 for SO₃/SO₂ for the SO₂-SO₃-air system at 700°C (11). Both Zn,Na- and Co,Na-mixed sulfates must therefore evolve SO₃ as the major decomposition gas, and differences in corrosivity of the two mixed sulfates cannot be explained on the basis that one emits SO₂ and the other SO₃.

The origin of the SO₂ in the decomposition gas has not been established, but presumably some SO₃ could be converted to SO₂ by catalysis by the oxide produced during decomposition. Mass spectrometric studies of the thermal decomposition of pure sulfates have shown that catalysis by oxides within the sulfate powder affects the SO₃/SO₂ ratio, tending to move it toward equilibrium (12). This possibility would be consistent also with Co,Na sulfate (Co₃O₄ being a better catalyst than ZnO) showing lower SO₃/SO₂ ratios than Zn,Na sulfate for decomposition on porcelain. The very low SO₃/SO₂ ratios (0.6-0.3) measured for decomposition of Co,Na sulfate on CoCrAlY suggest, on the other hand, that SO₃ is being consumed, or reduced to SO₂, by corrosion reactions with the CoCrAlY.

Single sulfate formation.—As a basis for study of mixed sulfate formation, the equilibrium SO₃ partial pressures required for formation of the pure sulfate (or oxysulfate) from ZnO, Co₃O₄, and NiO were determined. In these determinations, the SO₃ concentra-

Table I. Evolved SO₃/SO₂ ratios in 700°C decomposition of mixed sulfates in air flowing at 200 ml/min

Mixed sulfate	Substrate	Range of observed SO ₃ /SO ₂ ratios
50 m/o ZnSO ₄ -Na ₂ SO ₄	Porcelain	8.7-2.0
50 m/o ZnSO ₄ -Na ₂ SO ₄	CoCrAlY	3.6-0.9
50 m/o CoSO ₄ -Na ₂ SO ₄	Porcelain	4.0-0.8
50 m/o CoSO ₄ -Na ₂ SO ₄	CoCrAlY	0.8-0.3

tion in the air flowing over 100 mg samples of the respective oxides in porcelain boats at 700°C was increased at 24h intervals until a weight gain was obtained which indicated formation of the sulfate or oxysulfate. The SO₃ concentration was subsequently increased for two or more tests (using fresh oxide samples each time) and the 24h weight gains then extrapolated to zero (as indicated in Fig. 1) to define the SO₃ equilibrium pressure. The species formed were identified by x-ray diffraction and confirmed to be CoSO₄ and NiSO₄ for the cobalt and nickel oxides, but ZnO · 2ZnSO₄ for ZnO. From Fig. 1, the equilibrium SO₃ concentrations at 700°C are indicated to be 250 ppm (2.5 × 10⁻⁴ atm) for ZnO-ZnO · 2ZnSO₄, 600 ppm (6.0 × 10⁻⁴ atm) for Co₃O₄-CoSO₄, and 1250 ppm (1.25 × 10⁻³ atm) for NiO-NiSO₄.

For the treatment in Fig. 1 to be valid, it is necessary that the oxides react only with SO₃. This was shown previously for Co₃O₄ (8) and NiO (6). Two observations from the present work indicate that ZnO also reacts specifically with SO₃. This was shown first in experiments in the sulfation of ZnO where the platinum catalyst was removed at two concentrations which had given sulfation. No sulfation then occurred in either case (Fig. 1), even though the total SO_x concentration (SO_x = SO₂ + SO₃) remained unchanged. The second observation was in the sulfation of 50 m/o ZnO-Na₂SO₄ (see below). In this case, in the early time periods when the rate of ZnSO₄ formation was high, the exhaust gas was found to be depleted in SO₃ (but not SO₂), giving SO₃/SO₂ ratios of the order of 0.5-0.7. As the ZnSO₄ formation became completed, the SO₃ levels increased, and the exhaust SO₃/SO₂ ratios returned to the equilibrium value of 1.1. Thus sulfation of ZnO appears clearly to occur via reaction with SO₃, and not SO₂.

The validity of the sulfation experiments was verified by calculating the standard free energies for the sulfation reactions as written below, using the relationship $\Delta G^\circ = -RT \ln K$ and the equilibrium SO₃ partial pressures determined in Fig. 1, and then comparing these energies with the standard free energies from the literature

Fig. 1. Equilibrium SO₃ concentrations for sulfation of metal oxides at 700°C. (Note: the "ZnO, no Pt catalyst" results are plotted for comparison at the SO₃ concentrations achieved with equilibrated SO_x; the actual SO₃ levels in the absence of Pt were below 50 ppm in both cases.)

Table II. Free energy of formation (kcal/mol) at 700°C

CoSO ₄	-13.8 ± 0.6	-16 ± 5	-11.9
NiSO ₄	-12.9 ± 0.6	-12.9 ± 0.6	-18.1

These energies, along with their expected uncertainties which were calculated assuming the SO₃ concentrations to be within ±20% and the temperature within ±5°, are compared in Table II with data from the literature. There is good agreement except perhaps for the CoSO₄ value which, according to Turkdogan, has a high uncertainty. The equilibrium SO₃ partial pressures determined here can therefore be taken as being of good accuracy.

The kinetics of sulfation for the different oxides were also studied to a limited extent. Representative data are shown in Fig. 2 where the SO₃ concentrations used were 500 ppm (2× equilibrium) with ZnO, 800 ppm (1.3× equilibrium) with Co₃O₄, and 1600 ppm (1.3× equilibrium) with NiO. The difference in yield is most likely inherent with the oxides, and not caused by the slight differences in relative SO₃ sulfation pressures. Notice also that the high yield for ZnO is to the oxysulfate, and not the sulfate which comes at a higher P_{SO₃}. Studies of NiO vs. CoO sulfation have shown CoO to sulfate significantly more rapidly and to a greater extent than NiO as the result of the formation of a Co₃O₄ layer on the CoO surface (15).

Most to be noted in Fig. 2 are the low yields of both CoSO₄ (~50%) and NiSO₄ (~40%), even though thermodynamics predicts that there should be complete conversion to the sulfate. The failure to obtain 100% yields is not unusual, however, since the problem of achieving complete sulfation even under highly favorable thermodynamic conditions is well known. Generally it is thought that sulfate films form on the oxide particles and act as "barrier" layers which reduce access of SO₃ to the remaining oxide in the particle interior (16).

Mixed sulfate formation.—As pointed out in the introduction, the sulfation of Co and Ni oxides to form low melting mixed Co,Na and Ni,Na sulfates is a criti-

Fig. 2. Sulfation kinetics of metal oxides at 700°C

cal step in low temperature hot corrosion (5-7), and we are interested therefore in determining what effect ZnO/ZnSO₄ might have in these processes. Pure zinc sulfate is highly hydrophilic and difficult to keep dry. Consequently, our experimental procedure was to generate ZnSO₄ *in situ* by bringing 250 mg specimens of 50 m/o ZnO-Na₂SO₄ to equilibrium under different SO₃ partial pressures at 700°C. Weighed quantities of Co₃O₄ (90 mg) or NiO (84 mg) were then added to the ZnSO₄-Na₂SO₄ melt, with the subsequent sulfation of the Co₃O₄ or NiO (at the same temperature and SO₃ level) being followed by monitoring of the weight gain. The quantities of reagents were selected so that, if all the oxides were completely sulfated, the final solution would be 33 m/o each in ZnSO₄, NaSO₄, and Co or Ni sulfate. Complete sulfation would correspond to 90 mg weight gain with ZnO, and to 84 or 90 mg gain with Co₃O₄ or NiO, respectively.

A liquid phase occurs in the ZnSO₄-Na₂SO₄ system at 700°C once the ZnSO₄ concentration exceeds ~20 m/o (17), and there was a question as to whether this liquid phase would interfere with sulfation of the remaining ZnO. However, nearly complete conversion (i.e., 50 m/o ZnSO₄ formation) was achieved within 48-72h in each experiment (cf. Fig. 3 and 4), which indicates that access of SO₃ to the ZnO was not significantly hindered by the presence of the intervening liquid ZnSO₄-Na₂SO₄ film. Similarly, it is assumed that sulfation of the added oxides, which were wetted by and incorporated into the ZnSO₄-Na₂SO₄ melt at temperature, was not significantly affected by reduced transport of SO₃ through the liquid ZnSO₄-Na₂SO₄ phase.

A second set of experiments was run for comparison using Co₃O₄ (90 mg)-Na₂SO₄ (320 mg) and NiO (84 mg)-Na₂SO₄ (320 mg) mixtures which would lead to 33 m/o Co (or Ni)SO₄-67 m/o Na₂SO₄ if completely sulfated. Thus, the same amount of "solvent" sulfate was available in each set of experiments, with the only difference being that the cations are Na⁺ only in the one case, but mixtures of Zn²⁺ and Na⁺ in the other. This direct comparison allows the influence of Zn to be the most clearly seen.

The weight gain data for representative ZnO-Na₂SO₄-Co₃O₄ experiments are given in Fig. 3. Notice that 95% conversion to ZnSO₄ is achieved even at 175 ppm SO₃, which is below the 250 ppm SO₃ concentration shown earlier to be required for Zn oxysulfate formation. Evidently ZnSO₄ formation is promoted by solution in

Fig. 3. Effect of ZnO on sulfation of Co₃O₄-Na₂SO₄ at 700°C

Fig. 4. Effect of ZnO on sulfation of NiO-Na₂SO₄ at 700°C

Na₂SO₄; the same effect has been seen earlier where the formation of CuSO₄-MnSO₄ solid solution caused CuSO₄ to be generated at SO₃ concentrations normally producing the oxysulfate (18). Conversely, the weight gains indicate that conversion is not totally complete even at 1600 ppm SO₃ (Fig. 4), and traces of ZnO could in fact be found by analysis (see below). The ZnSO₄ was very near 50 m/o, however, and the sulfate was fully molten as predicted by the phase diagram.

When the Co₃O₄ was added, surprisingly little further sulfation occurred, with the apparent weight gains deriving from the sulfation of Co₃O₄ ranging from only ~5 mg at 175 ppm SO₃ to ~10 mg at 800 ppm SO₃. This contrasts to the behavior for Co₃O₄ in Na₂SO₄ (also shown in Fig. 3) where, for the same total amount of "solvent" sulfate and SO₃ concentration, weight gains corresponding to nearly ten times greater sulfation of Co₃O₄ were obtained. Thus, the presence of the Zn cation appears to very strongly inhibit the sulfation of Co₃O₄.

Note that substantial sulfation of Co₃O₄ occurs in the presence of Na₂SO₄ at SO₃ levels, e.g., 175 ppm, well below the 600 ppm SO₃ equilibrium concentration found here for the sulfation of pure solid Co₃O₄ at 700°C. This is possible because the CoSO₄ activity is lowered by dissolution in Na₂SO₄. Lowering of the CoSO₄ activity occurs also in Zn,Na sulfate, but evidently to a lesser extent. Advantage of this solution behavior has been taken in industry where, e.g., the use of Na₂SO₄ has been proposed to improve yields in the sulfate roasting of Co, Cu, Ni, and Zn ferrites (19). On the other hand, complete sulfation of the Co₃O₄ did not occur, with the Zn,Na sulfate melts, even at 800 ppm SO₃ which exceeds the 600 ppm SO₃ level required for direct sulfation of Co₃O₄. This point will be discussed in a later section.

Essentially the same sulfation behavior was seen at the 175 and 500 ppm SO₃ concentration levels for ZnO-

Na_2SO_4 -NiO (Fig. 4), with only very limited sulfation of NiO appearing to occur in contrast to the NiO- Na_2SO_4 system (also Fig. 4). At 1600 ppm SO_3 , however, (i.e., above the 1250 ppm equilibrium concentration level for direct sulfation of NiO), there was substantial sulfation of NiO in the Zn,Na sulfate melt, with sulfation proceeding at a finite rate even after 100h at temperature.

Mixed sulfate analysis.—At the end of the sulfation runs, selected specimens of the residual mixed sulfate/oxide masses were analyzed by dc argon plasma atomic emission spectrometry to verify the amounts of sulfate formed. The specimens were taken up in dilute acid (0.01N H_2SO_4) to prevent possible precipitation of $\text{Zn}(\text{OH})_2$ or $\text{Co}(\text{OH})_2$, with the solutions filtered through 0.47 μ Millipore filters to remove the insoluble oxide residue. Care was taken to ensure that the sulfates were completely dissolved and that the filtered oxides were well rinsed. Control tests were also made which indicated that there should be little (<10%) dissolution of the residual oxide by the dilute acid wash solution with the techniques used. The filtered oxides were not quantitatively analyzed, but they were examined by EDXA in the SEM which confirmed that a trace of ZnO remained unsulfated even at 1600 ppm SO_3 .

The results in Table III show good agreement between the expected and found quantities of ZnSO_4 and NiSO_4 in the sulfation of ZnO- Na_2SO_4 -NiO (Sample 2). However, the values for CoSO_4 in sulfated ZnO- Na_2SO_4 - Co_3O_4 (Samples 1 and 3) were more than twice as high as expected, while the ZnSO_4 results were low. A check of the analytical procedure using a solution containing a known amount of CoSO_4 (Sample 4) gave moderately high results, but analytical inaccuracy is not likely the cause of the Samples 1 and 3 discrepancies. Rather, it appears that ZnSO_4 may be partially displaced as ZnO from the ZnSO_4 - Na_2SO_4 melt as the added Co_3O_4 is sulfated and goes into solution. The observed weight gain for " Co_3O_4 sulfation" then would be the net difference between the weight loss resulting from ZnSO_4 going to ZnO, and the weight gain for Co_3O_4 going to CoSO_4 . Recalculating the data in Table III on this basis gives expected weights for CoSO_4 of 20 mg for Sample 1 and 28 mg for Sample 3. The substantially better agreement of these values with the analytical results suggests that ZnSO_4 is in fact displaced from the melt as Co_3O_4 is sulfated.

Solution behavior.—It is well known, e.g., from metallurgy, that the solubility of a species in a melt can be strongly affected by the introduction of a second species into the melt. The effect, which is often characterized through "interaction" parameters (20), may be either to increase or reduce solubility. In the study at hand, the presence of ZnSO_4 in the Na_2SO_4 melt clearly appears to reduce the solubility of CoSO_4 .

Table III. Mixed sulfate analysis by dc argon plasma atomic emission spectrometry

Sample	Expected sulfates from weight gain	Analytic results ($\pm 5\%$)		
		Co	Ni	Zn
1 (500 ppm SO_3 , Fig. 3)	11 mg CoSO_4 , 175 mg ZnSO_4	28 mg CoSO_4	—	166 mg ZnSO_4
2 (500 ppm SO_3 , Fig. 4)	25 mg NiSO_4 , 175 mg ZnSO_4	—	27 mg NiSO_4	175 mg ZnSO_4
3 (175 ppm SO_3 , Fig. 3)	12 mg CoSO_4 , 173 mg ZnSO_4	27 mg CoSO_4	—	157 mg ZnSO_4
4 (Test standard)	27 mg CoSO_4 (from 50 mg $\text{CoSO}_4 \cdot 7\text{H}_2\text{O}$)	33 mg CoSO_4	—	—

Beyond this, however, there may also be barrier film formation, as suggested by the following line of reasoning. Several experiments were run using SO_3 levels which exceeded the equilibrium SO_3 concentration determined here for 700°C sulfation of solid Co_3O_4 (600 ppm) and NiO (1250 ppm) in air. When the mixtures were only the metal oxide and Na_2SO_4 , the result was essentially complete sulfation of the metal oxide (e.g., 14 m/o Co_3O_4 - Na_2SO_4 in Fig. 3). However, when the mixture contained ZnO/ ZnSO_4 , only limited sulfation of the metal oxide occurred, particularly for Co_3O_4 (cf. Fig. 3). From a thermodynamic basis, complete sulfation would be expected even in this case. Given free access of SO_3 , the Co_3O_4 should sulfate and dissolve in the melt until its solubility is exceeded, and then solid CoSO_4 should be produced until the remainder of Co_3O_4 is consumed. This is the behavior seen with the SO_3 - Co_3O_4 - Na_2SO_4 system (7). The lack of complete sulfation under higher than equilibrium SO_3 partial pressures is therefore indirect evidence that a compound or barrier layer is forming on the Co_3O_4 surface which interferes with further sulfation of the oxide.

The reaction kinetics indicated in Fig. 3 are also consistent with this theory; i.e., there is a quick weight gain after Co_3O_4 addition (corresponding to barrier film formation) and then little further reaction (because of barrier film stifling of the sulfation reaction). The barrier film could be precipitated CoSO_4 itself, displaced ZnO, or a combination of both. The slow, continued sulfation of NiO at 1600 ppm SO_3 (Fig. 4) suggests that the barrier film formed in this case is not as protective as that formed with ZnSO_4 - Na_2SO_4 - Co_3O_4 , perhaps because ZnO is not being displaced from the melt (cf. Table III).

Corrosion tests with ZnSO_4 - Na_2SO_4 .—The 700°C corrosion of BC-21 CoCrAlY was studied using (i) deposits of 50 m/o ZnSO_4 - Na_2SO_4 under air, or (ii) deposits of 50 m/o ZnSO_4 - Na_2SO_4 or ZnO- Na_2SO_4 under 175 and 500 ppm concentrations of SO_3 in air. In the latter case, the ZnO- Na_2SO_4 was found to be quickly converted to ZnSO_4 - Na_2SO_4 , with no discernible difference then seen in the corrosion behavior. The majority of work therefore was simply with ZnSO_4 - Na_2SO_4 deposits. The deposits melted and flowed at temperature, giving final sulfate layers of generally less than 0.5 mm thickness.

The residual salts on the corroded specimens were not analyzed because very small quantities were involved. However, analyses of the sulfate salts on low temperature corroded turbine blades routinely show water soluble Ni and Co, but not (presumably because the SO_3 partial pressure is not high enough) Cr or Al. Mixed sulfate formation involving Co and Ni, but not Cr or Al, would therefore be expected in the present experiments (see below).

As in our earlier observations (4), little corrosion was found with 50 m/o ZnSO_4 - Na_2SO_4 under air; i.e., where simply the thermal decomposition of ZnSO_4 - Na_2SO_4 is involved. This contrasts to thermal decomposition of 50 m/o CoSO_4 - Na_2SO_4 on CoCrAlY which produces severe corrosion (4). Typical results are shown in Fig. 5 which is for rather thick deposits of ZnSO_4 - Na_2SO_4 on a section of bulk CoCrAlY. No corrosion is visible under the heavy ZnSO_3 - Na_2SO_4 layer, but there are small pits on the bottom of the section which probably result from a thin film of sulfate creeping to the underneath of the section. These pits display the morphology which is characteristic of low temperature hot corrosion (7). Figure 5 shows also that as the sulfate decomposes, ZnO is deposited out both at the air-sulfate and sulfate-metal interfaces. Presumably therefore, the SO_3 partial pressure within the sulfate layer is less than 1.75×10^{-4} atm, since this pressure was shown sufficient to maintain >45 m/o ZnSO_4 in Na_2SO_4 in our sulfation studies (Fig. 3 and

Fig. 5. $\text{ZnSO}_4\text{-Na}_2\text{SO}_4$ (50 m/o) on bulk BC-21 composition CoCrAlY after 24h in air at 700°C . The characteristic two-phase structure of the alloy is visible in the metal.

4). Thus, one explanation for $\text{ZnSO}_4\text{-Na}_2\text{SO}_4$ deposits not corroding CoCrAlY may be that the SO_3 partial pressure within the deposit is too low for significant cobalt sulfation to occur.

Corrosion of CoCrAlY by mixtures of $\text{ZnSO}_4\text{-CoSO}_4\text{-Na}_2\text{SO}_4$ was also studied, and it was found that as long as the ZnSO_4 concentration exceeded the CoSO_4 concentration, corrosion was inhibited, but when the CoSO_4 concentration was larger by, e.g., two to one or more, the CoCrAlY was corroded.

When tests were made under SO_3 , little corrosion was generally seen for specimens exposed up to 150h under 175 ppm SO_3 . A representative test specimen cross section is shown in Fig. 6 where x-ray mapping identifies the $\text{ZnSO}_4\text{-Na}_2\text{SO}_4$ surface layer and shows that the sulfate film contains essentially no cobalt. Some typical LTHC pitting corrosion did occur in the

175 ppm SO_3 tests, especially in thin areas of the sulfate deposits. However, the total corrosion was always much less than occurred with equivalent Na_2SO_4 or $\text{CoSO}_4\text{-Na}_2\text{SO}_4$ deposits for the same P_{SO_3} and time of exposure, so ZnSO_4 clearly inhibits LTHC in this sense.

Corrosion experiments were also conducted using 500 ppm SO_3 . More attack was noted than with 175 ppm SO_3 , but corrosion was still substantially less with $\text{ZnSO}_4\text{-Na}_2\text{SO}_4$ than for equivalent times of exposure with Na_2SO_4 alone.

The corrosion pits formed under 175 and 500 ppm SO_3 were found almost invariably at the thin edge rather than under the thicker portion of the $\text{ZnSO}_4\text{-Na}_2\text{SO}_4$ deposit. The $\text{ZnSO}_4\text{-Na}_2\text{SO}_4$ mixture was molten at 700°C , but not totally fluid. Thus the sulfate at the deposit edge may not be 50 m/o $\text{ZnSO}_4\text{-Na}_2\text{SO}_4$, but may contain less ZnSO_4 which would make the edge sites

Fig. 6. $\text{ZnSO}_4\text{-Na}_2\text{SO}_4$ interface with BC-21 composition CoCrAlY coating after 146h under 175 ppm SO_3 in air at 700°C .

more corrosion susceptible. When the sulfate deposits on corroded specimens were examined by low power light microscopy, color micrographs were obtained which clearly showed localized reddish (rich in CoSO_4) regions in the greenish-white ZnSO_4 - Na_2SO_4 surface film. This shows that the sulfate deposits are only sluggishly miscible at 700°C , and gives reason to expect that the wetting and mixing properties of the sulfates, as well as the specific sulfate concentration, will be critical in determining the effectiveness (and reproducibility) of ZnSO_4 inhibition of 700°C hot corrosion of CoCrAlY .

The corrosion of the Rene 80 blade metal was not studied explicitly, since the CoCrAlY coating is meant to provide the principal protection of the blade against hot corrosion. However, several instances were observed where the specimen was corroded severely at its cut edge (*i.e.*, where both the coating and blade metal are exposed to sulfate and SO_3) even though the CoCrAlY coating over the body of the specimen was essentially unattacked. A representative example is shown in Fig. 7.

The x-ray maps in Fig. 7 indicate (i) that there is a sulfur concentration near the corrosion front, and (ii) that Ni and Co are intermingled throughout the corrosion phase which is evidence of substantial intertransport of cobalt and nickel in the corrosion process. This corrosion may be similar to "cut-edge" attack of CoCrAlY -coated Rene 80 by pure Na_2SO_4 (no SO_3 overpressure) at 885°C , which appears to involve an internal liquid nickel sulfide (21). In the present case, examination at high magnification did not reveal the large sulfide phases found with 885°C corrosion. At 700°C under 175 ppm SO_3 , it may well be (although it cannot be proved here) that the morphology in Fig. 7 results from formation of mixed Co,Ni,Na sulfates, with sulfides not being principally involved.

In either event, it is possible that accelerated corrosion could occur if the CoCrAlY coating on a Ni-based blade were penetrated, even in the presence of "inhibitive" Zn,Na sulfate. Also, Ni-based alloys may be more susceptible to Zn,Na sulfate corrosion than cobalt alloys, especially at higher SO_3 concentrations, as indicated by the substantial NiO sulfation shown in Fig. 4. The degree of corrosion may differ depending on the inherent corrosion resistance of the Ni alloy, as seems to be the case in the 900°C burner rig testings cited (3).

Conclusions

The sulfation of Co_3O_4 and NiO in molten eutectic 50 m/o ZnSO_4 - Na_2SO_4 is substantially reduced as compared to their sulfation in the presence of an equivalent amount of Na_2SO_4 . The reduced sulfation appears to be caused by decreased solubility of CoSO_4 and NiSO_4 in ZnSO_4 - Na_2SO_4 as a result of solute-solute interactions with ZnSO_4 , and/or formation of a barrier film (perhaps displaced ZnO or precipitated CoSO_4 or NiSO_4) on the metal oxide surface which inhibits further sulfation of the remaining oxide.

Although corrosion is not totally halted, the low temperature hot corrosion of CoCrAlY is inhibited by deposits of ZnSO_4 - Na_2SO_4 for SO_3 concentrations up to 500 ppm. The post-test morphologies are consistent with inhibition being caused by reduced CoSO_4 solubility in the sulfate surface film.

In particular, the present investigation demonstrates that the chemical and corrosive properties of sulfate melts can be significantly affected by addition of secondary sulfates. The methodology should be applicable for the study of other potential hot corrosion inhibitor additives.

ABSTRACT

The attack of fluoride on passive nickel has been studied in strongly acidic solutions (1M HClO₄) and weakly acidic and alkaline buffers. Two main potential ranges with different kinetics of metal dissolution were found. In the whole passive range, the corrosion current density is increased. Up to 1.1V, the transfer of the Ni²⁺ ions from the oxide into the electrolyte is catalyzed by HF with an electrochemical reaction order of 1.63. This leads to a thinning of the oxide film to a higher electrical field strength and consequently to the increased stationary corrosion current density. At potentials $\epsilon \geq 1.2V$, an NiF₂ overlayer is formed on the rest of the passivating oxide. This leads to an electrochemical reaction order of -0.79 for HF. The kinetics of the two potential ranges are explained with appropriate mechanisms involving the formation of a Ni²⁺F⁻ surface complex or the presence of a passivating fluoride film. Fluoride may be seen as a simpler model system for the other halides which cause a localized breakdown of passivity.

The action of aggressive anions on passive metals like iron and nickel leads to a locally or generally increased dissolution rate. Among the halides, fluoride is of special interest. Its presence yields only a general increase of the corrosion rate in strongly acidic solutions, which facilitates the interpretation of the results (1). Consequently, it can aid in deeper insight into the processes occurring during the breakdown of passivity. Passive nickel and iron in fluoride containing electrolytes may thus be seen as model systems for localized corrosion in the presence of other aggressive anions, especially chloride. In this work, we examine the influence of fluoride on the passivity of nickel in acidic solutions. In a second part, we study the thickness and composition of the films formed before and after the fluoride attack by surface analysis like x-ray photoelectron spectroscopy (XPS) and low energy ion scattering spectroscopy (ISS). These results helped to interpret the electrochemical findings.

Key words: passivity, breakdown of passivity, corrosion of nickel in HF solutions.

Experimental

For the nickel electrodes a 99.95% material of Vakuumschmelze Hanau was used. Small flag-shaped electrodes of 1.7 cm² surface area were electropolished in an H₂SO₄-H₂O mixture (2), soldered to a copper wire, and fixed to a glass tube. The contact area was covered with epoxy resin. For surface analysis, the pretreated specimens were rinsed with triply distilled water and cut close to the epoxy covered part. Rotating disk electrodes were prepared from a 5 mm diam cylindrical material embedded in epoxy resin. Details about the specimen preparation and the experimental setup were briefly described previously (3). All solutions were prepared from chemically pure substances (*pro analysi*) and triply distilled water. Most experiments were performed in 1M HClO₄ and some in phthalate buffer pH 4.9 (0.05M KH phthalate plus 0.023M KOH) and borate buffer pH 8.0 (0.05M H₃BO₃ plus 0.039M KOH). After prepassivation of the specimen at appropriate electrode potentials for typically 1 and 2h, fluoride was added by 1 cm³ of a concentrated HF solution

or by solid KF. All experiments were performed at $25^\circ \pm 0.2^\circ\text{C}$. $\text{Hg}/\text{Hg}_2\text{SO}_4/0.5\text{M H}_2\text{SO}_4$ served as a reference electrode. All potential values are given in reference to the standard hydrogen electrode and are corrected for liquid junction potentials.

Results

The current density potential curve in fluoride containing electrolytes has been described previously (1, 4) and is given again in Fig. 1. In 1M HClO_4 , nickel has a large passive range of $>1\text{V}$, with a transpassive increase at $\epsilon > 1.5\text{V}$. A step at $\text{ca. } \epsilon = 1.8\text{V}$ is due to the overlap of the decrease of the dissolution current by the formation of a nickel III oxide layer and an increase of the current of oxygen evolution. This behavior is similar to $1\text{M H}_2\text{SO}_4$ (5). The addition of fluoride causes a generally increased current density (Fig. 1). The maximum current of active dissolution, however, is decreased by one order of magnitude. The step in the transpassive region is still observed; however, all features of the polarization curve are shifted by about 0.1V in the anodic direction. A broad current peak with its maximum at $\epsilon = 1.15\text{V}$ is obtained in the passive range. The HF concentration does not influence the peak position, and the maximum current increases only slightly with HF concentration (Fig. 2). The two current minima (I and II), however, are markedly affected. Minimum I increases and minimum II decreases with HF concentration. During the action of HF, a general attack of the surface is obtained. In addition many small pits are formed on the grains, particularly at the grain boundaries (1). However, the diameter of these hemispheric pits does not grow larger than $2\ \mu\text{m}$ in more than 1h. Therefore, they cannot be related to the increase of the current density to several mAcm^{-2} .¹ The metal surface appears unchanged and bright or roughened, depending on the achieved current density and time of exposure. No current density at the minima depends on the stirring of the electrolyte or the rotation of the disk electrode up to $\leq 2000\ \text{rpm}$. Therefore, these processes are not controlled by diffusion processes. At the current maximum at 1.1V , a visible dark blue film is formed. It has a good adhesion to the metallic substrate and cannot be washed off in a jet of water. A sufficiently vigorous stirring of the electrolyte, e.g., $\geq 400\ \text{rpm}$ for the rotating disk, leads to a removal of the visible film at the current maximum and an increase of the current to a new nontransport-controlled level. At the falling edge of the maximum at $\epsilon = 1.2\text{--}1.3\text{V}$, current oscillations are observed for rotated and nonrotated electrodes, and only a temporary partly covering visible film is formed. These oscillations are also found in fluoride containing sulfuric acid (4).

¹ No covered pits were found after careful *in situ* and *ex situ* inspection with an optical and scanning electron microscope of high resolution. Therefore, localized corrosion can be excluded.

Fig. 1. Potentiodynamic polarization curve of nickel in 1M HClO_4 (solid line), and in 1M HClO_4 plus 0.1M HF (dashed line). $d\epsilon/dt = 10\ \text{mVs}^{-1}$.

Fig. 2. Potentiodynamic polarization curves of nickel in 1M HClO_4 with different concentrations of HF.

For a prepassivated specimen, the corrosion current density in 1M HClO_4 shows a pronounced change with time after the fluoride addition. The results for the two characteristic potentials at the minima of Fig. 1 are shown in Fig. 3a and 3b for different HF concentrations. For minimum I, the current increases faster with higher HF content and achieves a plateau in every case. This final stationary value increases with the HF concentration. At minimum II, a peak is obtained, especially for high HF contents, with a final approach to a stationary plateau value. The current peak gets smaller with decreasing HF and vanishes for $[\text{HF}] = 0.001\text{M}$, whereas the plateau value increases. This completely different behavior suggests that the corrosion mechanisms are different for the two parts of the passive range. Figure 4 compares the stationary values of the polarization curve in 0.1M HF containing 1M HClO_4 with potentiodynamic results. The change of the current density from the active dissolution to the minimum I is less pronounced when stationary conditions have been achieved.

A double logarithmic plot of the stationary current densities and the HF concentration for the two representative potentials (minima I and II) shows a linear relationship (Fig. 5)

$$\epsilon = 0.5\text{V}: \quad \log i = 1.75 + 1.63 \log [\text{HF}] \quad [1]$$

$$\epsilon = 1.4\text{V}: \quad \log i = -1.4 - 0.79 \log [\text{HF}] \quad [2]$$

Fig. 3. Increase of the current density with time on nickel specimen prepassivated for 2h in 1M HClO_4 , after the addition of different concentrations of HF. a, left: $\epsilon = 0.5\text{V}$, minimum I, above: $\epsilon = 1.4\text{V}$, minimum II.

Galvanostatic transients of specimen after reaching potentiostatic stationary conditions reflect the characteristics of the potentiodynamic polarization curve. If the galvanostatic current is higher than the stationary potentiostatic value at $\epsilon = 0.5\text{V}$, slightly more positive electrode potentials are achieved after an intermediate maximum. If smaller values are chosen, the potential falls in the region of active dissolution after a plateau near 0.5V (Fig. 6a). Its length decreases with the given current density. The time is used apparently for the removal of the remaining passive film.

For a specimen pretreated at $\epsilon = 1.4\text{V}$, the potential falls in two steps (Fig. 6b). The length of the first step at $\epsilon \approx 1.4\text{V}$ decreases linearly with the current density. Apparently, the deviation of the stationary current corresponds to the removal rate of a surface layer. The second step is of equal length for all applied current densities, indicating that the surface of the electrode is

in the same situation when the first step is finished. Apparently, the same surface layer has to be moved. If higher current densities than $i_{c,s} = 0.06\text{mAcm}^{-2}$ are chosen, potential oscillations within the range of the second minimum are found. For sufficiently high current densities, the amplitude of these oscillations may cause the potential to drop to $\epsilon \approx 0.5\text{V}$ and finally into the active potential range (curve 5 in Fig. 6b). These galvanostatic transients suggest that passivating films are removed.

In F^- -free $1\text{M H}_2\text{SO}_4$, a change from potentiostatic to galvanostatic conditions causes damped potential oscillation with a final constant value in the transpassive range or negatively damped oscillation with a final constant amplitude (4). When this amplitude is high enough, a change to the higher values of oxygen evolution is observed rather than a drop to the potential range of active dissolution, which might be a conse-

Fig. 4. quence of the smaller current densities within the passive range of F⁻-free solutions. No potential oscillations are reported for pure perchlorate solutions but they are found in F⁻ containing electrolytes (4).

The nature and composition of these films cannot be deduced only from electrochemical experiments. For this purpose, surface analytical methods, such as XPS and ISS, have been applied (6). They show a pronounced difference of the surfaces for the two characteristic ranges of the polarization curve. At minimum I up to the maximum at $\epsilon = 1.1V$, a passivating oxide film is found with a reduced thickness compared to the HF-free solution. About 6Å of the remaining oxide (NiO) are covered by 8Å of nickel hydroxide [Ni(OH)₂]. At $\epsilon > 1.2V$ (minimum II), thick films of NiF₂ cover the thinned oxide layer (4A). The thickness of these fluoride films decreases with increasing electrode potential from several thousand angstroms at the current maximum (visible layer) to a few nanometers at minimum II. They apparently reduce the corrosion process to the small values at minimum II.

For higher pH values (phthalic acid pH 4.0, phthalate buffer pH 4.9) similar features are found for the polarization curves (Fig. 7a). The current densities are smaller, and the peak of the maximum is shifted by -60 mV/pH. In borate buffer pH 8.0, no peak is found in the passive range, and the current density is increased only slightly by the fluoride addition (Fig. 7b).

Discussion

The different electrochemical behavior of nickel in the two characteristic potential regions of minimum I and II is interpreted as a consequence of two different passivity mechanisms. Figure 8 shows a phase diagram of a passive film on nickel with the related processes. A high electrical field strength within the passive layer causes the migration of Ni²⁺ ions for compensation of the dissolution reaction and a possible layer formation at the oxide electrolyte interface. The potential drop $e_{2,3}$ determines the charge transfer reaction of Ni²⁺ or its complexes with F⁻, i.e., the corrosion reaction [4] (see below). For stationary conditions, when the layer

is neither growing nor getting thinner, this potential drop is determined by the equilibrium [3] of the formation of anions at the layer surface, i.e., O²⁻ for an oxide and F⁻ for a fluoride. In the case of passive iron, this leads to a characteristic pH dependence of the logarithm of the stationary corrosion current density (7). For unstationary conditions, $e_{2,3}$ may contain an overpotential because reaction [3] will occur in either direction and the equilibrium might be distorted. For nickel, the stationary dissolution current density is potential dependent (5). Therefore, one has to assume that $e_{2,3,s}$ is changing with the electrode potential ϵ . This, in turn, requires a change of the composition of the oxide surface or, in other words, of its oxidation state (8). In this regard, the situation of passive nickel is more complicated than that of iron. The small potential dependence of the current density depicted in Fig. 1 in HF-free HClO₄ should be seen as a consequence of the applied potentiodynamic condition when compared to the stationary values in 1M H₂SO₄ of Ref. (5).

The transfer of Ni²⁺ ions from the oxide into the electrolyte is catalyzed by fluoride. This process is similar to the catalysis of the corrosion of passive iron in sulfate (7), chloride (9), or fluoride (10) containing electrolytes. We assume that the Ni²⁺ ions at the oxide surface are first complexed after reaction [4]. This surface complex is transferred into the electrolyte by the ion transfer reaction [5] and finally transformed to a higher complexed anion by reaction [6].

Assuming equilibrium for reaction [4] and taking reaction [5] as the rate-determining step, one gets for the stationary corrosion current density $i_{c,s}$

$$i_{c,s} = 2kF[NiF_{ad}^+] \exp\left(\frac{\alpha F}{RT} e_{2,3,s}\right) \quad [7]$$

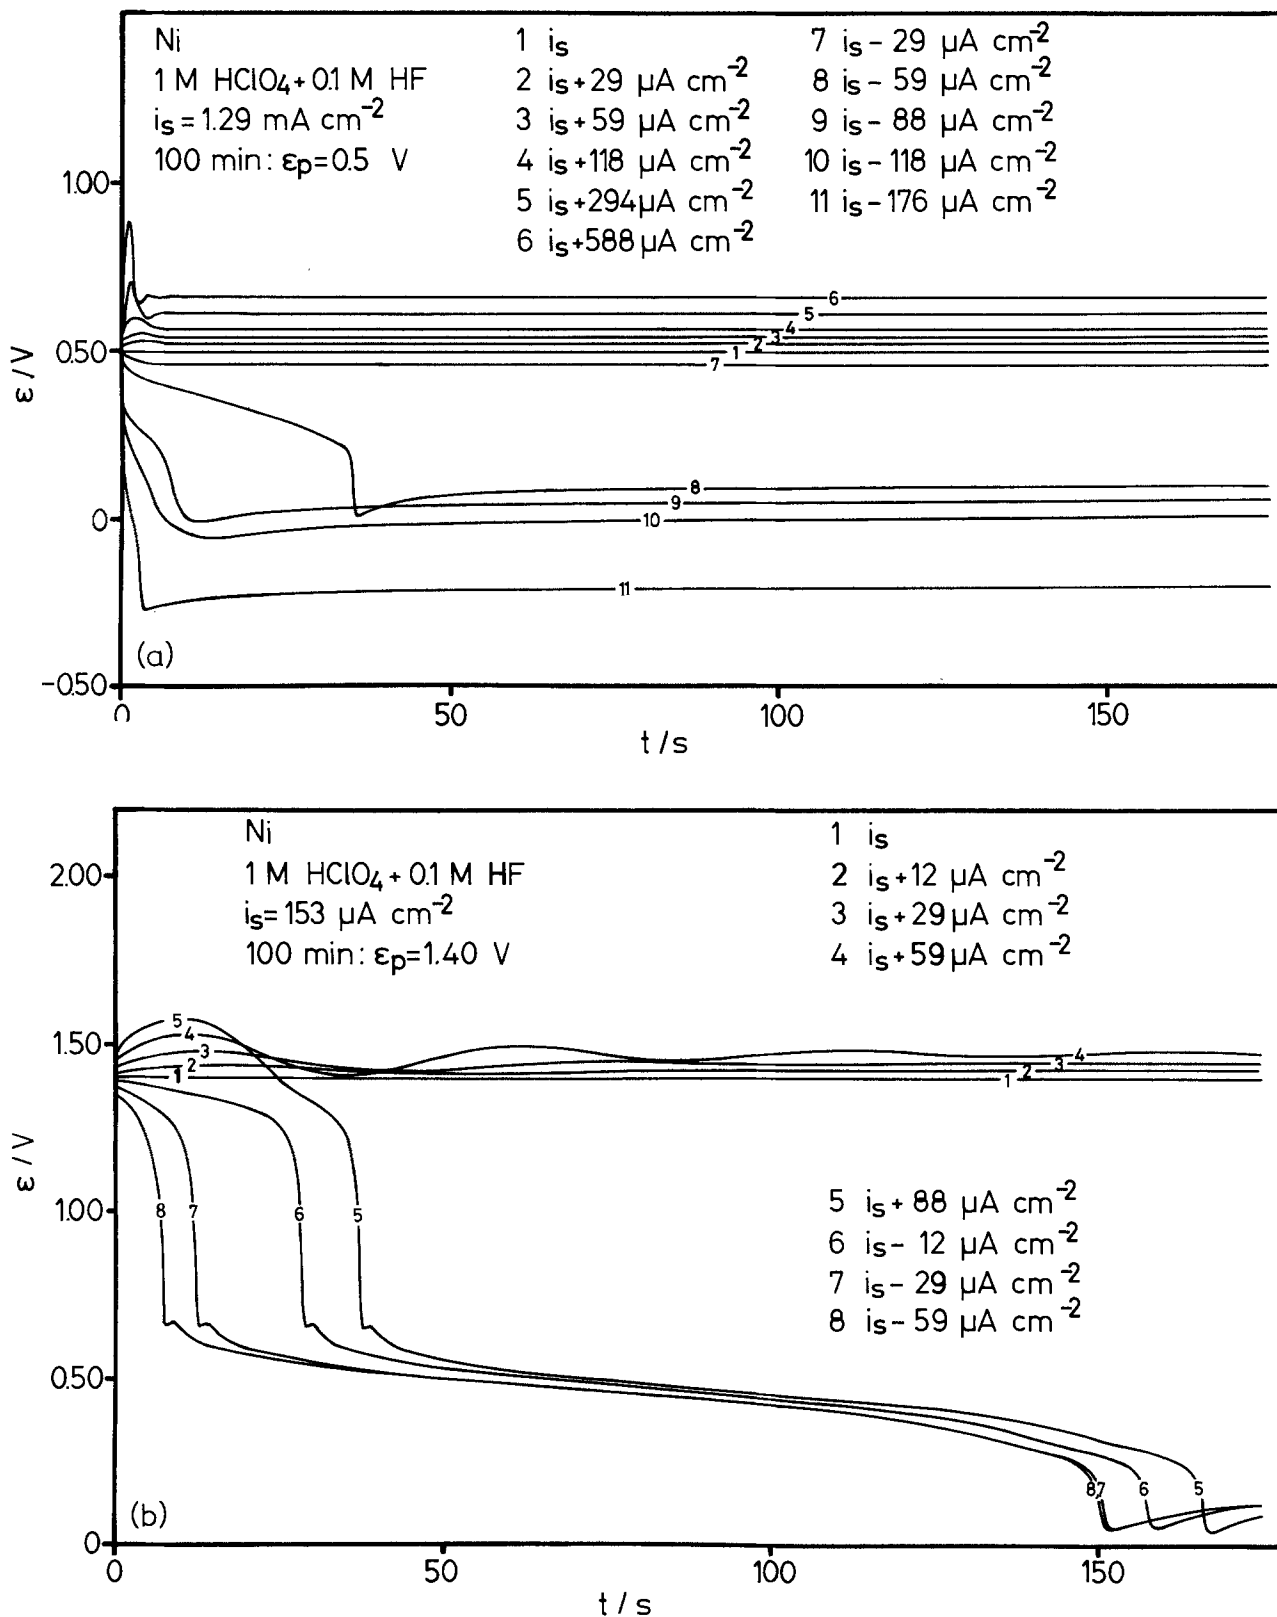

Fig. 6. Galvanostatic transients of nickel electrodes, prepassivated for 2h at ϵ in 1M HClO₄, in 1M HClO₄ plus 0.1M HF with currents higher or smaller than the stationary potentiostatic values. a, top: $\epsilon = 0.5\text{V}$, minimum I. b, bottom: $\epsilon = 1.4\text{V}$, minimum II.

with $[\text{NiF}_{\text{ad}}^+]$ being the surface concentration of the intermediate complex.

From the equilibrium for the electroadsorption [4] follows

$$[\text{NiF}_{\text{ad}}^+] = \frac{[\text{Ni}_{\text{ox}}^{2+}][\text{HF}_{\text{aq}}]}{[\text{H}_{\text{aq}}^+]} \exp\left(-\frac{\Delta G^\circ}{RT}\right) \exp\left(\frac{\gamma F}{RT} \epsilon_{2,3,s}\right) \quad [8]$$

The electroadsorption valency (γ) takes into account that only part of the total potential drop $\epsilon_{2,3,s}$ is effective because of the own dimensions of the anion. γ may also include a possible partial electron exchange between adsorbens and adsorbate (11).

Equation [8] is a Langmuir isotherm for the electroadsorption equilibrium [4], as is shown more clearly by introducing the surface coverage (θ) of the fluoride

Fig. 7. Potentiodynamic polarization curve of nickel, $d\epsilon/dt = 1 \text{ mVs}^{-1}$. a, left: phthalate buffer plus 0.1M KF, $\text{pH} = 4.9$. b, right: borate buffer plus 0.1M KF, $\text{pH} = 8.0$.

complex

$$\frac{[\text{NiF}_{\text{ad}}^+]}{[\text{Ni}_{\text{ox}}^{2+}]} = \frac{\theta}{1 - \theta} = \frac{[\text{HF}_{\text{aq}}]}{[\text{H}_{\text{aq}}^+]} \exp\left(-\frac{\Delta G^\circ}{RT}\right)$$

$$\exp\left(\frac{\gamma F}{RT} \epsilon_{2,3,s}\right) = a[\text{HF}_{\text{aq}}] \quad [9]$$

$[\text{Ni}_{\text{ox}}^{2+}]$ is the surface concentration of those nickel ions not transformed into a surface complex, or, in other words, it is the concentration of the free adsorption places. The adsorption constant a depends on the pH and the potential drop $\epsilon_{2,3,s}$ at the oxide elec-

trolyte interface. θ is the concentration ratio of the surface complex and the sum of the free and occupied adsorption places $[\text{Ni}_{\text{ox}}^{2+}]_t = [\text{NiF}_{\text{ad}}^+] + [\text{Ni}_{\text{ox}}^{2+}]$

$$\theta = \frac{[\text{NiF}_{\text{ad}}^+]}{[\text{Ni}_{\text{ox}}^{2+}]_t} = \frac{a[\text{HF}_{\text{aq}}]}{1 + a[\text{HF}_{\text{aq}}]} \quad [10]$$

Introducing θ in Eq. [7] yields

$$i_{c,s} = 2kF\theta [\text{Ni}_{\text{ox}}^{2+}]_t \exp\left(\frac{\alpha F}{RT} \epsilon_{2,3,s}\right) \quad [11]$$

From the equilibrium of reaction [3], one gets the pH dependence of $\epsilon_{2,3,s}$

$$\epsilon_{2,3,s} = \epsilon_{2,3,s}^\circ - 0.059 \text{ pH} \quad [12]$$

Introducing Eq. [10] and [12] in [11] and assuming a small surface coverage $\theta \ll 1$ with $a[\text{HF}_{\text{aq}}] \ll 1$ so that Henry's adsorption isotherm is valid with $\theta = a[\text{HF}_{\text{aq}}]$, one gets

$$i_{c,s} = i_{c,s}^\circ [\text{HF}_{\text{aq}}] \exp\{-2.303 \text{ pH} (\alpha + \gamma - 1)\} \quad [13]$$

$$i_{c,s}^\circ = 2kF \exp\left(-\frac{\Delta G^\circ}{RT}\right) \exp\left\{\frac{(\alpha + \gamma)F}{RT} \epsilon_{2,3,s}^\circ\right\} \quad [14]$$

This mechanism yields the following electrochemical reaction orders for HF and H^+

$$\frac{d \log i_{c,s}}{d \log [\text{HF}_{\text{aq}}]} = 1; \quad \frac{d \log i_{c,s}}{d \text{ pH}} = 1 - \alpha - \gamma \quad [15]$$

Assuming a higher Ni^{2+} - F^- complex for the corrosion mechanism, a higher reaction order is obtained for HF as follows

Fig. 8. Phase diagram for a passivated nickel electrode in HF containing electrolyte with the related electrode reactions. a: Surface catalytic mechanism of the minimum I. b: Mechanism in presence of a fluoride layer, minimum II.

The electroadsorption equilibrium of Eq. [16] leads to a Langmuir isotherm similar to the case of the association of two adsorbed species. This equilibrium yields

the following equation

$$\frac{\theta}{1-\theta} = \frac{[\text{NiF}_{2,\text{ad}}]}{[\text{Ni}_{\text{ox}}^{2+}]} = \frac{[\text{HF}_{\text{aq}}]}{[\text{H}_{\text{aq}}^+]^2} \exp\left(-\frac{\Delta G^{\circ}}{RT}\right) \exp\left(\frac{2\gamma F}{RT} \epsilon_{2,3,s}\right) \quad [19]$$

Applying Eq. [12] for the equilibrium of O^{2-} formation yields

$$\frac{\theta}{1-\theta} = a' [\text{HF}_{\text{aq}}] = [\text{HF}_{\text{aq}}] \exp\left(-\frac{\Delta G^{\circ}}{RT}\right) \exp\left(\frac{2\gamma F}{RT} \epsilon_{2,3,s}\right) \exp\{4.606(1-\gamma)\text{pH}\} \quad [20]$$

$$\theta = \frac{[\text{NiF}_{2,\text{ad}}]}{[\text{Ni}_{\text{ox}}^{2+}]_t} = \frac{a'[\text{HF}_{\text{aq}}]^2}{1+a'[\text{HF}_{\text{aq}}]^2} \quad [21]$$

For the rate-determining step [17], one obtains

$$i_{c,s} = 2k'F[\text{NiF}_{2,\text{ad}}] = 2k'F\theta[\text{Ni}_{\text{ox}}^{2+}]_t \quad [22]$$

Introducing Eq. [20] and [21] in [22] and applying Henry's law with $a'[\text{HF}_{\text{aq}}] \ll 1$ for Eq. [21], one gets

$$i_{c,s} = i_{c,s}^{\circ} [\text{HF}_{\text{aq}}]^2 \exp\{4.606(1-\gamma)\text{pH}\} \quad [23]$$

$$i_{c,s}^{\circ} = 2k'F[\text{Ni}_{\text{ox}}^{2+}]_t \exp\left(-\frac{\Delta G^{\circ}}{RT}\right) \exp\left(-\frac{2\gamma F}{RT} \epsilon_{2,3,s}\right) \quad [24]$$

$$\frac{d \log i_{c,s}}{d \log [\text{HF}]} = 2; \quad \frac{d \log i_{c,s}}{d \text{pH}} = 2 - 2\gamma \quad [25]$$

The experimental value for the reaction order of HF (1.63) is between those of the two discussed mechanisms. If the simplification of Henry's law is no longer valid, reaction orders < 2 will result for HF also for the second mechanism (Eq. [16]-[18]). After Eq. [21] and [22], θ will vary with [HF], causing a change from a second-order law to no dependence for high surface coverages when saturation is achieved. With the experimental result of 1.63 for the HF reaction order, we favor the second mechanism (Eq. [16]-[18]). After the first mechanism (Eq. [4]-[6]), only a reaction order ≤ 1.0 is expected (Eq. [10], [11], [15]).

$i_{c,s}$ decreases with increasing pH after the experiments. After Eq. [25], this cannot be understood for $\gamma \leq 1$ with the second mechanism (Eq. [16]-[18]), but it would not contradict Eq. [15] of the first one. However, one has to take into account that hydrogen fluoride ($\text{pK} = 3.45$) is fully dissociated at pH 5 and that the fluoride anion might be involved in the dissolution process instead of HF. Thus the H^+ ion no longer participates in the electroadsorption reactions [4] and [16], which in turn changes the pH dependence of the stationary current to $d \log i_{c,s}/d \text{pH} = -(\alpha + \gamma)$ for the first mechanism (Eq. [4]-[6]), and to $d \log i_{c,s}/d \text{pH} = -2\gamma$ for the second one (Eq. [16]-[18]). These circumstances explain the high decrease of $i_{c,s}$ with increasing pH and complicate the interpretation, especially in alkaline solutions where small $i_{c,s}$ values are found.

The fluoride-induced dissolution mechanism leads to a thinning of the oxide film in the potential range of minimum I, as has been found by XPS analysis (6). About 2 min after the addition of HF, the thinning of the passive layer is finished, and a new stationary state for $i_{c,s}$ is achieved (Fig. 3a). The thinner oxide layer results in a higher electrical field strength, providing a sufficient ion transport to compensate the increased stationary dissolution current density at the oxide-electrolyte interface. No fluoride was found by

XPS at the surface of the specimen after HF exposure at minimum I after carefully rinsing with triply distilled water (6). These findings support further the surface catalytic mechanism and make impossible explanation by a chemical change of the passive layer.

With increasing electrode potential (ϵ), the current density rises to its maximum. Apparently, the potential drop $\epsilon_{2,3}$ increases, which leads to a higher concentration of fluoride complexes or surface coverage of F^- via the electroadsorption equilibrium of reaction [16]. These effects are in favor of the anodic dissolution process. a' increases exponentially with the potential drop $\epsilon_{2,3,s}$ (Eq. [19], [20]), which causes a decrease of the reaction order of HF after Eq. [21] and [22]. When a monolayer of NiF_2 is obtained, $i_{c,s}$ should no longer increase with $[\text{HF}_{\text{aq}}]$. This is apparently the situation when a continuous NiF_2 layer is formed at the current maximum ($\epsilon = 1.1\text{V}$). The current values of the potentiodynamic polarization curve show a very reduced dependence of the HF concentration at these potentials (Fig. 2).

The high current densities at the maximum lead to the formation of a visible NiF_2 layer, presumably by precipitation. The composition of this layer has been determined by XPS analysis and by comparison with standards (6). This passivating NiF_2 layer reduces the corrosion current density. The change from an oxide to a fluoride layer has pronounced consequences for the mechanism at minimum II. The potential drop $\epsilon_{2,3,s}$ for stationary conditions is now determined by the equilibrium of F^- formation [26] on a fluoride layer

With the ion transfer of Eq. [27] as the rate-determining step, one obtains

$$i_{c,s} = 2k''F[\text{Ni}_1^{2+}] \exp\left(\frac{2\alpha''F}{RT} \epsilon''_{2,3}\right) \quad [29]$$

The electrochemical equilibrium [26] leads to the following dependence of the potential difference $\epsilon''_{2,3}$ at the fluoride-electrolyte interface

$$\mu_{\text{F}^-} + \mu_{\text{H}^+} - \mu_{\text{HF}} - F\epsilon''_2 + F\epsilon''_3 = 0$$

Inserting the concentration dependence of the chemical potentials $\mu_i = \mu_i^{\circ} + RT \ln a_i$ and introducing $\epsilon''_{2,3} =$

$$\epsilon''_2 - \epsilon''_3 \text{ and } \epsilon''_{2,3} = \frac{1}{F} \sum \mu_i^{\circ} \text{ for the sum of the stan-}$$

dard potentials μ_i° , one gets

$$\epsilon''_{2,3} = \epsilon''_{2,3}^{\circ} - 0.059 \text{pH} - 0.059 \log [\text{HF}_{\text{aq}}] \quad [30]$$

Inserting Eq. [30] in [29] yields

$$i_{c,s} = i_{c,s}^{\circ} [\text{HF}]^{-2\alpha''} \exp(-4.606\alpha'' \text{pH}) \quad [31]$$

$$i_{c,s}^{\circ} = 2k''F[\text{Ni}_1^{2+}] \exp\left(\frac{2\alpha''F}{RT} \epsilon''_{2,3}\right) \quad [32]$$

This results in the following electrochemical reaction order for HF and pH

$$\frac{d \log i_{c,s}}{d \log [\text{HF}]} = -2\alpha''; \quad \frac{d \log i_{c,s}}{d \text{pH}} = -2\alpha'' \quad [33]$$

With the measured value of -0.79 for the HF reaction order at minimum II, one obtains $\alpha'' \approx 0.4$ for the charge transfer coefficient. This is a reasonable value for the ion transfer step.

The approach to the new stationary condition for $i_{c,s}$ at minimum II with time after the HF addition (Fig. 3b) is caused by the thinning of the passivating oxide and the formation of the NiF_2 overlayer. The current-

time behavior corresponds closely to the results of the surface analysis. The thinning of the oxide layer is completed after 1 min (6) when the current achieves its intermediate maximum (Fig. 3b). The following current decrease occurs in close relation to the formation of the NiF₂ overlayer. Stationary conditions are achieved after ca. 10 min.

The removal of the visible nickel fluoride film at the current maximum of Fig. 1 by vigorous stirring with >400 rpm goes along with a complete removal of any fluoride at the surface as has been found by XPS analysis (6). This shows that the surface catalytical mechanism of minimum I is still effective at the current maximum.

The potential oscillations of Fig. 6b should be seen as a consequence of the form of the current-density potential curve and of changes within the surface layers with time. These processes are not fully understood, although they have been already reported for similar conditions for this system (4). Apparently, damped oscillation occurs in both directions of minimum II if $i > i_s$. However, if the potential drops below the value of the current maximum, it does not recover and moves to minimum I with the related changes of the surface layer. As i is too small to maintain the potential at minimum I (cf. Fig. 1), ϵ has to drop to the active region with a complete removal of the passive film. If $i < i_s$, a final stable situation is achieved only with an active electrode potential in any case.

Conclusions

The presence of aggressive anions affects decisively the passive corrosion current density. In a lower potential range the passive layer of nickel is thinned by the action of HF (minimum I). This causes a higher electrical field strength and an increased corrosion current density. The transfer of the nickel ions from the oxide to the electrolyte is catalyzed by the formation of a fluoride complex at the surface. The electrochemical reaction order for HF is 1.63. In the second minimum, the corrosion current is decreased by the formation of an NiF₂ overlayer with a thinned oxide still present underneath. According to the changed chemistry of the surface, a different mechanism is effective. The reaction order of HF is -0.79. This is a consequence of the equilibrium of F⁻ formation on the surface, which determines the potential difference $\epsilon_{2,3}$ at the fluoride layer-electrolyte interface.

The effect of anions on the dissolution kinetics of passive metals is rather common. In many cases, a localized attack is observed, i.e., as for iron and nickel in solutions of the other halides. In these cases, the increased current density leads to a local accumulation of the corrosion products and hence of the halides. This, in turn, increases the catalytic activity with a severe thinning of the passive film and its complete removal. The high halide concentration thus prevents a repassivation of the growing pits autocatalytically. Simi-

larly, a high bulk concentration of chlorides ($\cong 1M$) may prevent the formation of a passive film completely (12, 13).

The general attack of the passive oxide by acidic HF solutions in comparison to the local effects of the other halides may be a consequence of the stronger complexing ability of fluoride. Therefore, it might not be necessary to accumulate corrosion products and thereby fluoride by an intense local or general metal dissolution. HF adsorbs most readily at the total passive surface, so that the formation of two-dimensional salt nuclei does not dominate the breakdown, as in the case of iron in chloride solutions (9). The more general attack of fluoride on passive nickel or iron (10) simplifies the complicated process of localized corrosion. In this regard, fluoride is a model system for the breakdown of passivity. The complexing and catalytical capability of the halides should be seen as the main source of breakdown of passivity and localized corrosion. A further support by ohmic drops in large pits, especially when they are occluded, and acidification by hydrolysis which, however, is not effective in already strongly acidic solutions, may help to stabilize the pit growth.

ABSTRACT

Amorphous iron-zirconium alloys, ranging in composition from $\text{Fe}_{90}\text{Zr}_{10}$ to $\text{Fe}_{33}\text{Zr}_{67}$, have been studied by anodic polarization and passivation decay in 1N sulfuric acid. The results showed a compositional enhancement of corrosion resistance with increasing zirconium concentration. Auger electron spectroscopy indicated that exposure to the sulfuric acid solution enhances the surface zirconium concentration with respect to the bulk of the exposed alloy and also with respect to the as-deposited surface composition. X-ray photoemission spectroscopy shows that the passive film is a mixture of zirconium oxides and hydroxides and iron oxides and hydroxides.

As part of its mission to conserve resources, the Bureau of Mines is studying the factors leading to the corrosive degradation of materials from exposure to reactive species, especially in mining and metallurgical processing environments. Metallic glasses, because of their amorphous character, which eliminates crystalline defects, and because they can be formed over wide ranges of compositions, have significant potential for materials applications in environments susceptible to corrosion. This potential was demonstrated initially by Hashimoto *et al.* (1), who discovered that several iron-based amorphous alloys have corrosion properties superior to those of crystalline alloys of stainless steel. Subsequently, several amorphous alloys have been studied to determine their corrosion properties. For a recent review, see Waseda and Aust (2).

There are two major groups of alloy systems which form amorphous structures: metal-metal and metal-metalloid. Results of Hashimoto *et al.* indicate that the incorporation of a metalloid, *e.g.*, phosphorus, carbon, or boron, into a metal to form an amorphous alloy results in a chemically unstable alloy and does not anodically passivate in acidic solutions (3). However, the inclusion of a second metal to form a ternary system often results in anodic passivation and greatly improves corrosion resistance.

Metal-metal amorphous alloys have not been as extensively studied. Naka *et al.* (4) examined the corrosion behavior of amorphous $\text{Cu}_{50}\text{Zr}_{50}$ and $\text{Cu}_{50}\text{Ti}_{50}$ and compared their results with Cu, Zr, and Ti polycrystalline metals and with Cu-Zr and Cu-Ti polycrystalline alloys. Their data indicate that these metal-metal amorphous alloys have superior corrosion resistance compared to crystalline alloys of similar composition. However, based upon available data, Waseda and Aust (2) and Hashimoto (5) conclude that the enhancement in corrosion behavior due to amorphicity is much greater in metal-metalloid systems than in metal-metal systems. Waseda and Aust (2) and Hashimoto (5) concluded that in metal-metal systems the corrosion properties of the alloy are principally determined by the most corrosion resistant metal. If such is the case, an amorphous metal-metal alloy can be produced for a specific corrosion environment based on the corrosion behavior of the individual components.

Subsequent work by Walmsley (6) indicated that perhaps metal-metal amorphous systems are not superior to crystalline materials if crystalline defects can be eliminated. Walmsley studied the Cu-Zr amorphous system ranging from $\text{Cu}_{85}\text{Zr}_{15}$ to $\text{Cu}_{20}\text{Zr}_{80}$. The corrosion resistance of amorphous Cu-Zr is better than

that of crystalline systems at low concentrations of Zr. This is because of the presence of alpha-Cu, which does not passivate in the crystalline system. However, at high Zr compositions, all phases contain Zr, and the amorphous and crystalline materials display comparable corrosion properties. Therefore, the author concludes that any enhancement in corrosion resistance is due to lack of crystalline defects instead of the amorphicity of the films.

Based upon these limited studies of metal-metal amorphous alloys, the effect of crystallinity *vs.* composition is not clear. This study is concerned with the compositional effect on the electrochemistry of iron-zirconium amorphous alloys formed by ion sputtering onto a vitreous carbon substrate. Anodic polarization and passivation decay tests were conducted in 1N H_2SO_4 to study corrosion properties. After electrochemical testing, the surface films were characterized by Auger electron spectroscopy (AES) and x-ray photoemission spectroscopy (XPS).

Experimental

Zirconium samples were cut from Alpha¹ high purity (99.9%) 0.25 mm foil into 1.9 cm squares, chemically polished with a solution of nitric and hydrofluoric acids in high-purity (HP) water (resistivity of 18 $\text{M}\Omega\text{-cm}$), rinsed in HP water, and dried in a stream of dry nitrogen.

High purity (99.5%) 0.25 mm Materials Research Corporation iron foil was cut into 1.9 \times 1.3 cm samples, degreased sequentially in acetone and methanol, and rinsed with HP water. Polycrystalline Fe12Cr and Fe18Cr were cut into 1.9 cm squares from sheet stock, ground with 180 through 600 grit silicon carbide paper, annealed for 2h at 600°C under an argon atmosphere, pickled in a 20% nitric acid solution with a few drops of HF added, and rinsed with HP water. The iron, Fe12Cr, and Fe18Cr samples were then electropolished in a 9:1 volume ratio of glacial acetic acid and 70% perchloric acid solution, rinsed with HP water, and dried in a stream of dry nitrogen.

Vitreous carbon was used as a substrate for the amorphous Fe-Zr films because it is not expected to form a good galvanic couple with the Fe-Zr film nor react with 1N H_2SO_4 . Vitreous carbon sheet stock, 2 mm thick, was cut into 1.9 cm squares, ground with 320 through 600 grit silicon carbide paper, and polished with 5 and 0.05 μm gamma alumina powders. After polishing, a few small pits could be seen in an otherwise highly polished surface. Polished samples were sequentially degreased with acetone and methanol,

rinsed with HP water, and dried in a stream of dry nitrogen.

Amorphous Fe₉₀Zr₁₀, Fe₈₀Zr₂₀, Fe₆₀Zr₄₀, Fe₅₀Zr₅₀, and Fe₃₃Zr₆₇ samples were produced by argon ion sputtering from a pellet of desired composition onto a vitreous carbon substrate. The substrate was cooled by either liquid nitrogen or water during sputtering. Prior to sputtering, the chamber vacuum was in the 10⁻⁶ Pa range. Deposition rates were between 50 and 100 nm/min utilizing argon ions. In order to verify that the deposited films were amorphous, we utilized Mossbauer spectroscopy with a 57 Co in Rh source. The magnetic and hyperfine interactions of thick amorphous and polycrystalline Fe-Zr films have been previously studied by Mossbauer spectroscopy and correlated with x-ray diffraction studies (7, 8). Films which were amorphous based upon x-ray diffraction demonstrated significantly different Mossbauer spectra compared to polycrystalline films. Therefore, we were able to verify amorphicity of films which were too thin for x-ray analysis and were deposited on vitreous carbon substrates. Composition of selected alloys was verified by proton-induced x-ray emission.

All electrochemical tests were run in a 1 liter modified Greene cell (9) equipped with a nitrogen gas bubbler, a platinum sheet counterelectrode, and a glass Luggin probe connected by a solution bridge to a saturated calomel electrode (SCE). All potential measurements were with respect to the SCE and converted to the normal hydrogen electrode (NHE). The samples were held in a polycarbonate sample holder with a FETFE Teflon O-ring sealing the exposed region from the remainder of the sample. Depending on the O-ring size, 1/3 to 1/2 cm² of the sample surface was exposed. The test solution was 1N H₂SO₄ which had been deaerated by bubbling nitrogen gas through the solution 12h prior to the test. The nitrogen purity was 99.998% with <10 ppm oxygen, <2 ppm hydrogen, and <1 ppm methane.

After electrochemical testing, Fe-Zr amorphous samples were analyzed with Auger electron spectroscopy (AES). One analysis was performed on an untested portion of the film and another on the region which had been exposed to 1N H₂SO₄. Base pressure of the AES system prior to use was 1 × 10⁻⁶ Pa. A primary beam of 4 μA, 5 keV electrons was used to excite Auger electrons, which were then detected by a cylindrical mirror analyzer. The analyzer was modulated at 1300 Hz with 2V peak to peak. To obtain depth profiles, inert gas sputtering was used. An argon ion beam was obtained at 2.5 keV utilizing a pressure of 5 × 10⁻³ Pa. The ion beam was rastered over an area of approximately 2 × 3 mm. The electron beam had a diameter (full width at half maximum) of approximately 150 μm and was aligned in the center of the rastered area. The ion sputter rate was calibrated against a 100 nm thick Ta₂O₅ film. No correction was made for variation in sputtering due to different matrices.

X-ray photoemission spectroscopy (XPS) was used to determine the chemical nature of the as-sputtered amorphous films and the passive films formed in 1N H₂SO₄. Passive films were formed by placing samples into solution at a selected potential (the "hold-release potential" shown in Table I) and holding them at this potential until the current reached steady state. Then the samples were withdrawn from the solution, rinsed in HP water, and dried in dry nitrogen. XPS analyses were performed by Perkin-Elmer, Edison, New Jersey, utilizing a Mg K_α source and a Physical Electronics Model 560 system. All spectra were charge corrected to the 284.6 eV peak of carbon. Each sample was analyzed in two areas: inside and outside the exposed region. Initially a survey scan was done in each region to determine film composition. This was followed by high resolution scans of each peak to determine chemical structure.

Table I. Passivation decay times and potentials and corrosion potentials for Fe-Zr amorphous alloys and for polycrystalline Fe-Cr alloys, Fe, and Zr

Metal or alloy	t _d (mean, min)	No. samples	E _{hold-release} (V _{NHE})	E _{corr} (V _{NHE})
Fe	0.23 ± 0.04	2	1.492	-0.29
Fe ₉₀ Zr ₁₀	2.8 ± 0.8	2	0.592	-0.19
Fe ₆₀ Zr ₄₀	•	2	0.592	-0.20
Fe ₅₀ Zr ₅₀	•	1	0.592	-0.23
Fe ₃₃ Zr ₆₇	•	1	0.592	-0.26
Zr	•	1	0.592	-0.24
Fe12Cr	20 ± 17	6	0.742	-0.25
Fe18Cr	2130	1	0.842	-0.26

* Samples were still passive at the end of the 2.5 day test.

Two electrochemical tests were used for evaluating the corrosion properties of the amorphous alloys, polycrystalline Fe, Zr, Fe12Cr, and Fe18Cr in deaerated 1N H₂SO₄. Anodic polarization was used to indicate whether a particular metal would passivate in the test environment and to compare its passivation ability with those of other metals tested. Prior to anodic polarization, the Fe12Cr and Fe18Cr alloys were cathodically reduced at -17 μA/cm² until the potential dropped discontinuously, indicating that the air-formed oxide had been reduced. Cathodic reduction was not done on the amorphous Fe-Zr alloys, polycrystalline iron, or polycrystalline zirconium. The oxide film on iron dissolved readily upon being placed in solution. Zirconium was not reduced to eliminate the possibility of introducing hydrogen into the matrix. Instead of cathodic reduction, zirconium samples were placed in solution at open circuit and allowed to reach a steady potential before testing was begun. Amorphous Fe-Zr alloys were not cathodically reduced, since AES showed that the air-formed oxides were only tens of nanometers thick. Polarization scans were run potentiodynamically in the anodic direction at 60 V/h, beginning at potentials negative to the corrosion potential (E_{corr}). [See Ref. (10) for a definition of the corrosion potential.] However, for zirconium scans, the current in the region of the corrosion potential was so low that it could not be recorded potentiodynamically. Instead, the region between ±100 mV of E_{corr} was obtained galvanostatically and incorporated with the potentiodynamic results into Fig. 1. Passivation decay tests were conducted by placing the sample in the test cell at or near the passive potential having the lowest current density as determined from the anodic polarization curve, holding the selected potential until a quasi-steady-state current was achieved, and then releasing potential control and monitoring open-circuit potential (E_{oc}) vs. time. A sample was determined to have lost passivity when E_{oc} reached the corrosion potential, the latter having been determined from anodic polarization (see Fig. 1). If the sample had not reached the corrosion potential after 2.5 days, the test was terminated in order to avoid leakage of solution into the sample holder. An active-passive metal will remain passive as long as its potential is anodic to the primary passive potential (E_{pp}) defined in Ref. (10). However, few active-passive metals remain passive at open circuit; most drift back to the corrosion potential. The passivation decay time (t_d) defined in Fig. 2, is a measure of the metal's ability to remain passive and allows comparisons to be made between samples in a given test environment.

Results and Discussion

Polarization curves for Fe-Zr alloys are shown in Fig. 3. The cathodic portion of the scan is shown only for Fe₃₃Zr₆₇ since it is similar for all the amorphous Fe-Zr alloys tested. Increasing the zirconium concentration decreases the critical anodic current density until the active-passive current peak is not found in

Fig. 1. Polarization curves in deaerated 1N H₂SO₄ at 60 V/h. A: Zr. B: Fe₃₃Zr₆₇ amorphous alloy. C: Fe18Cr. D: Fe.

Fig. 2. Passivation decay test

the Fe₆₀Zr₄₀ or Fe₃₃Zr₆₇ curves. The polarization curve for Fe₅₀Zr₅₀ (not shown) fits between those of Fe₆₀Zr₄₀ and Fe₃₃Zr₆₇ and also lacks the active-passive current peak. The absence of an active-passive peak seems to indicate that the hydrogen reduction curve intersects the metal oxidation curve only in the passive region (11).

A comparison of the polarization scans for polycrystalline Fe, Zr, Fe18Cr, and amorphous Fe₃₃Zr₆₇ in Fig. 1 shows that Fe₃₃Zr₆₇ has a significantly lower current density than Fe18Cr or iron. In addition, amorphous Fe₃₃Zr₆₇ compares favorably to zirconium above 0.4V NHE, but zirconium exhibits significantly lower current densities between the corrosion potential and approximately 0.4V NHE. The corrosion potentials listed in Table I are the crossover potentials for the potentiodynamic polarization scans. Table I shows that the corrosion potential of the amorphous iron-zirconium alloys becomes more negative as the zirconium concentration is increased. This trend suggests that increasing the zirconium concentration may decrease the hydrogen exchange current density (i_0) as defined in Ref. (10). Extrapolation of the cathodic branches of the curves shown in Fig. 3 indicates that the amorphous Fe-Zr alloys trend toward lower i_0 values as the Zr concentration increases. However, this could also be due to alterations in the anodic partial

Fig. 3. Polarization curves of Fe-Zr amorphous alloys in deaerated 1N H₂SO₄ at 60 V/h. A: Fe₃₃Zr₆₇. B: Fe₆₀Zr₄₀. C: Fe₈₀Zr₂₀. D: Fe₉₀Zr₁₀.

process or a combination of alterations in both anodic and cathodic processes. It should be noted that polycrystalline iron does not fit this trend, since E_{corr} of iron is more negative than for any of the amorphous alloys.

The corrosion current density as defined in Ref. (10) was also determined. Owing to the relatively fast polarization scan rate used, these values are not reported. However, the trend observed was that increasing the zirconium concentration lowered the corrosion current density for the amorphous iron-zirconium alloys.

The potentials used to passivate each sample prior to passivation decay are given in Table I. The potential of 0.592V NHE, which is the potential where the mini-

imum passive current density of $\text{Fe}_{90}\text{Zr}_{10}$ occurs, was selected as the hold-release potential for the passivation decay test on zirconium and iron-zirconium alloys. As Fig. 3 shows, this is in the passive region for each of the samples which has an identifiable active-passive region. Polycrystalline Fe and Fe12Cr samples were held at the potential determined from their polarization curves to yield the minimum passive current.

The results from Table I show that a significant increase in passivation decay time can be gained by increasing the zirconium concentration of an iron-based amorphous alloy. It should be noted that $\text{Fe}_{80}\text{Zr}_{20}$, $\text{Fe}_{50}\text{Zr}_{50}$, and $\text{Fe}_{33}\text{Zr}_{67}$, which are above the critical composition for loss of active-passive peaks, maintained passivity for the maximum duration of the test.

These data compare favorably with the results of Walmsley (6) on amorphous Cu-Zr alloys in 0.1N H_2SO_4 . His data also show a continuous decrease in the active-passive peak with increasing zirconium concentration until at $\text{Cu}_{32}\text{Zr}_{68}$ it disappears completely. Direct comparisons are not possible due to different solution concentrations and different scan rates.

Linear polarization was performed on an $\text{Fe}_{50}\text{Zr}_{50}$ amorphous alloy after a 2.5 day passivation test in which the potential had remained at 0.274V NHE for the previous 1.5 days. The corrosion rate was determined from linear polarization to be $0.8 \mu\text{m}$ per year, indicating the alloy is probably passive at this potential. As a test of the stability of this passive potential, the sample was potentiostated to the corrosion potential of $\text{Fe}_{50}\text{Zr}_{50}$ (-0.23V NHE) and released. The potential drifted back to 0.274V. This implies that the passive film is not easily reduced. For this film reduction to occur, the potential may have to be held to -0.23V for some time or at an even more negative potential.

Even though Hashimoto (5) concluded that metal-metal systems generally do not possess extremely high corrosion resistance compared to metal-metalloid systems, the effect of alloying with a metal can yield a much more corrosion resistant material than a metal-metalloid system if the alloying metal is chosen to have good corrosion properties. This is demonstrated by comparing the data for $\text{Fe}_{80}\text{Zr}_{20}$ with those of Hashimoto *et al.* (3) for amorphous alloys with 20% metalloid. The critical current density (10) for $\text{Fe}_{80}\text{Zr}_{20}$ is more than two orders of magnitude lower than that for Fe-1Zr-13P-7C.

The results of four AES analyses are shown in Fig. 4-7 for $\text{Fe}_{80}\text{Zr}_{20}$ and $\text{Fe}_{60}\text{Zr}_{40}$ amorphous alloys. From these the effects of both composition and exposure to the test solution can be seen. The deposited low zirconium alloy ($\text{Fe}_{80}\text{Zr}_{20}$) shows zirconium depletion and high oxygen levels in the surface region ($<5 \text{ nm}$ deep). A comparison of Fig. 4 and 5 demonstrates the effect of exposure to 1N H_2SO_4 on the surface film. As can be seen, the near surface region ($<2 \text{ nm}$) of the sample exposed to 1N H_2SO_4 is significantly enhanced in zirconium and depleted in iron with respect to their relative concentrations in the bulk. The higher

Fig. 7. AES depth profile of $\text{Fe}_{60}\text{Zr}_{40}$ amorphous alloy after passivation in 1N H_2SO_4 . Δ : oxygen. \circ : iron. \square : zirconium.

zirconium alloy ($\text{Fe}_{60}\text{Zr}_{40}$) shows the same effect, but because of higher initial zirconium concentration, the zirconium enhancement in the passive film is not as pronounced (Fig. 6 and 7). Other compositions tested demonstrate the same phenomenon with increasing zirconium composition of the as-deposited alloy, until $\text{Fe}_{33}\text{Zr}_{67}$, at which the enhancement of surface zirconium is not detected.

XPS data agreed well with previously determined AES data. Surface films on as-deposited amorphous alloys consisted of iron, zirconium, oxygen, and carbon. After exposure, sulfur was present, and the iron to zirconium ratio had changed to indicate significant surface enhancement of zirconium. High resolution scans revealed that surface carbon was present as graphitic carbon. Oxygen scans indicated a mixture of metal oxide and hydroxide with a larger hydroxide contribution in the exposed region. High resolution scans of iron and zirconium peaks verified the presence of both oxides and hydroxides and that hydroxides were enriched after exposure to the test solution. Iron oxides were determined to be a mixture of Fe_2O_3 and Fe_3O_4 . High resolution scans of sulfur showed that all sulfur was present as sulfate.

These AES and XPS results indicate that the improvement in corrosion properties of amorphous Fe-Zr alloys in 1N H_2SO_4 is partially due to a compositional effect in the surface region, probably caused by the loss of iron into solution. Therefore, this system's corrosion properties would be determined more by the effect of zirconium than by that of iron. This agrees with the idea expressed by Hashimoto (5) that the corrosion properties of amorphous metal-metal alloys are mainly determined by the content of the element having the higher corrosion resistance. This raises the possibility that amorphous metal-metal alloys can be selected based upon the high corrosion resistance of one member but having mechanical, physical, or other properties of the base metal.

Conclusions

The alloying of zirconium to form amorphous iron-base alloys results in significant enhancement of corrosion properties in 1N H_2SO_4 , compared to polycrystalline iron and iron-chromium alloys, as demonstrated by both anodic polarization and passivation decay. AES and XPS results show that the passivation of the amorphous alloys is due to surface enrichment of zirconium. XPS data demonstrate that the passive film is a mixture of iron and zirconium oxides and hydroxides.

The corrosion data agree with previous studies showing that the corrosion properties of metal-metal amorphous alloys are determined by the metal with the highest corrosion resistance. This is in contrast to metal-metalloid amorphous alloys, which can display significantly better corrosion resistance than any of the component elements. However, it is important to note that this does not imply that metal-metalloid amorphous alloys have superior corrosion properties compared to metal-metal amorphous alloys. The data obtained in this study showed that the amorphous Fe-Zr system has better corrosion resistance than many metal-metalloid amorphous alloys.

Multivalent Ions in the Electrical Double Layer: The Extended Mean Spherical Approximation

C. J. McClanahan and D. A. McQuarrie

Department of Chemistry, University of California, Davis, California 95616

ABSTRACT

An extension of the mean spherical approximation, MSA, is used to study the restricted primitive model of the electrical double layer involving multivalent ions. Comparisons are made between this approximation, the MSA, and the Poisson-Boltzmann approximation.

The electrical double layer is prevalent in a large variety of systems of interest in chemistry and biology. It also plays an important role in many technological processes. In many instances, the ionic solutions contain multivalent ions which very significantly effect the behavior of these systems. Of these multivalent ion solutions, those containing a mixture of divalent and monovalent ions are the most commonly found in double layer systems.

Recently, the statistical mechanical integral equations used to describe bulk ionic fluids have been applied to the planar electrical double layer. This has been done in an effort to consistently account for ion size which is not done in the simpler Poisson-Boltzmann approxi-

mation, PBA (1-3). Many of these integral equation approaches have not yet been used to study the effects of multivalent ions on the structure and thermodynamics of the double layer. There is, however, a limited amount of Monte Carlo data available (4). Here we use an extension of the mean spherical approximation, MSA, to investigate multivalent systems and compare the results with the MSA and the PBA.

Development

The wall is considered to be hard, of uniform charge density, $eE/4\pi$, and of dielectric constant ϵ . The ionic solution is modeled as a neutral mixture of charged hard spheres in a uniform medium of dielectric constant

ϵ . Note that no image or specific solvent effects are accounted for. Ions of type i are of diameter σ_i , have a valence z_i , and are of number density, ρ_i , in the bulk fluid. The wall-particle Ornstein-Zernike equation for this system is (5)

$$h_{w1}(x) = c_{w1}(x) + 2\pi \sum_j \rho_j \int_0^\infty dt c_{ij}(t) \int_{x-t}^{x+t} ds h_{wj}(s) \quad [1]$$

where $h_{w1}(x)$ is the wall-particle indirect correlation function, in which x is the distance from the wall to the particle. $h_{w1}(x)$ is related to the wall particle correlation function, $g_{w1}(x)$, by

$$h_{w1}(x) = g_{w1}(x) - 1 \quad [2]$$

The function $c_{ij}(t)$ is the bulk direct correlation function for ion pairs i, j . A closure relation and specification of $c_{ij}(t)$ is required before Eq. [1] can be solved for $h_{w1}(x)$. In the approximations considered here, the bulk MSA direct correlation function is used for $c_{ij}(t)$. The MSA for the wall particle correlation functions involves setting

$$h_{wj}(x) = -1 \quad x < \sigma_j/2 \quad [3]$$

$$c_{wj}(x) = -z_j \beta e E x \quad x > \sigma_j/2 \quad [4]$$

where e is the magnitude of elementary charge and $\beta = 1/kT$ with k being the Boltzmann constant and T the temperature. Blum has solved Eq. [1] in this approximation using the Wiener-Hopf technique as applied by Baxter (5, 6). The solution is in terms of the factor-correlation functions for the corresponding bulk problem. It leads to analytic expressions for both the correlation functions and the potential drop across the interface. The MSA is a linearized theory and is only applicable at small electric fields. It is very desirable to develop a theory which would describe the interface at higher electric fields yet would not have to be solved numerically. One possibility is to try to improve the wall-particle direct correlation function by adding to it a sum of parameterized exponentials, i.e., setting

$$c_{wj}(x) = -z_j \beta e E x + \sum_n A_{nj} \exp(-\mu_{nj} x) \quad [5]$$

where the A_{nj} and μ_{nj} are parameters to be determined by some means. We now turn to solving Eq. [1] using Eq. [3] and [5] as closure relations and return to the problem of determining the A_{nj} and μ_{nj} .

The method of solving the extended mean spherical approximation, EMSA, has been briefly given by Blum and Henderson (7). It is quite similar to Blum's solution of the MSA. For completeness and to aid in understanding the application of the MSA to multivalent ionic solutions, we present a condensed derivation of the solution.

To aid in the analysis, we introduce the short range functions $c_{ij}^o(r)$ and $c_{w1}^o(x)$ defined by

$$c_{ij}(r) = c_{ij}^o(r) - \beta \frac{z_i z_j e^2}{\epsilon r} \quad [6]$$

and

$$c_{w1}(x) = c_{w1}^o(x) - \phi_{w1}(x) \quad [7]$$

where in the EMSA

$$\phi_{w1}(x) = -z_1 \beta e E x + \sum_n A_{n1} \exp(-\mu_{n1} x) \quad [8]$$

Multiplying Eq. [1] by $\sqrt{\rho_1}$, taking the Fourier transform, and using Eq. [6] and [7] gives

$$\tilde{h}_w(k) [I - \tilde{c}(k)] = \tilde{c}_w^o(k) - \tilde{\phi}(k) \quad [9]$$

where the matrices are defined by the components

$$\tilde{h}_{w1}(k) = \sqrt{\rho_1} \int_{-\infty}^{\infty} dx e^{ikx} h_{w1}(x) \quad [10]$$

$$\tilde{c}_{w1}^o(k) = \sqrt{\rho_1} \int_{-\infty}^{\sigma_1/2} dx e^{ikx} c_{w1}^o(x) \quad [11]$$

$$\phi_{w1}(k) = \sqrt{\rho_1} \int_{\sigma_1/2}^{\infty} dx e^{ikx} \phi_{w1}(x) \quad [12]$$

$$\tilde{c}_{ij}(k) = \lim_{\mu \rightarrow 0} \frac{4\pi\sqrt{\rho_i\rho_j}}{k} \int_{-\infty}^{\infty} dr r (\sin kr) c_{ij}^o(r) - D_{ij}/(k^2 + \mu^2) \quad [13]$$

where

$$D_{ij} = z_i z_j \alpha^2 \quad [14]$$

and

$$\alpha^2 = 4\pi\beta e^2/\epsilon \quad [15]$$

Blum has argued that via the Weiner-Hopf technique the bracketed term in Eq. [9] can be factored, i.e.

$$[I - \tilde{c}(k)] = Q(k) Q^T(-k) \quad [16]$$

where the superscript T denotes transpose. The factor correlation functions are defined by

$$Q_{ij}(k) = \delta_{ij} - \sqrt{\rho_i\rho_j} \int_{\lambda_{ij}}^{\infty} dr e^{ikr} Q_{ij}(r) \quad [17]$$

where

$$\lambda_{ij} = (\sigma_i - \sigma_j)/2 \quad [19]$$

By combining Eq. [9] and [16], we obtain

$$\tilde{h}_w(k) \tilde{Q}(k) = [\tilde{c}_w^o(k) - \tilde{\phi}_w(k)] \{\tilde{Q}^T(-k)\}^{-1} \quad [20]$$

Fourier inverting Eq. [20] for $x > \sigma_1/2$ yields

$$\begin{aligned} \sqrt{\rho_1} h_{w1}(x) - \sum_k \sqrt{\rho_k\rho_1} \int_{\lambda_{k1}}^{\infty} dr h_{wk}(x-r) Q_{k1}(r) \\ = - \sum_k \sqrt{\rho_1} \int_{\sigma_k/2}^{\infty} dr \phi_{wh} P_{kj}(r-x) \end{aligned} \quad [21]$$

where

$$P_{kj}(z) = \frac{1}{2\pi} \sqrt{\frac{\rho_k}{\rho_1}} \int_{-\infty}^{\infty} dk e^{-ikz} \{\tilde{Q}^T(-k)\}_{kj}^{-1} \quad [22]$$

The $c_{wk}^o(k)$ term gives no contribution to this inverse since it is a bounded function without singularities in

the complex half-plane, $Imk < \delta$, where $\tilde{Q}^T(-k)$ is also nonsingular. A contour around the lower complex plane may be used to show that the term vanishes. Dividing Eq. [21] by $\sqrt{\rho_1}$ and using Eq. [2] and [3] it may be rewritten as

$$\begin{aligned} g_{w1}(x) - \sum_k \rho_k \int_{\lambda_{k1}}^{x-\sigma_k/2} dr g_{wk}(x-r) Q_{k1}(r) = 1 \\ - \sum_k \rho_k \int_{\lambda_{k1}}^{\infty} Q_{k1}(r) dr \\ - \sum \sqrt{\frac{\rho_k}{\rho_1}} \int_{\sigma_1/2}^{\infty} dr \phi_{wk} P_{k1}(r-x) \end{aligned} \quad [23]$$

The Laplace transform of Eq. [23] is

$$\begin{aligned} \tilde{g}_{w1}(s) = \sum_{jk} e^{-s\sigma_j/2} \tilde{Q}_{kj}(0) \tilde{Q}_{j1}(s)/s \\ - \sum_j e^{-s\sigma_j/2} F_j(s) \tilde{Q}_{j1}^{-1}(s) \end{aligned} \quad [24]$$

where

$$\tilde{F}_j(s) = \int_0^{\infty} dx e^{-sx} \int_{\sigma_1/2}^{\infty} dr \phi_{wh}(r) P_{kj}(r-x) \quad [25]$$

and

$$\tilde{Q}(s)_{ij} = \delta_{ij} - \rho_i \int dx e^{-sx} Q_{ij}(r) \quad [26]$$

In his careful analysis of the solution of the MSA for the bulk system (8, 9), Blum has derived explicit expressions for $\tilde{Q}(s)_{ij}$ and its inverse. For the case of similar size ions

$$\tilde{Q}_{ij}^{-1}(s) = \delta_{ij} + \frac{\rho_i}{\rho} \tilde{P}^o(s) + \frac{z_i \rho_i z_j}{\xi} \tilde{P}^\pm(s) \quad [27]$$

where $\rho = \sum \rho_i$ and $\xi = \sum z_i^2 \rho_i$. $\tilde{P}^o(s)$ is the hard core portion given by

$$1 + \tilde{P}^o(s) = \frac{(1 - \eta)^2 s^3 e^{s\sigma}}{12\eta L(s) + S(s) e^{s\sigma}} \quad [28]$$

with

$$L(s) = \left(1 + \frac{1}{2}\eta\right)s + 1 + 2\eta \quad [29]$$

$$S(s) = (1 - \eta)^2 s^3 + 6\eta(1 - \eta)s^2 + 18\eta^2 s - 12\eta(1 + 2\eta) \quad [30]$$

and $\eta = \rho\sigma^3/6$. The charge portion is defined by

$$1 + \tilde{P}^\pm(s) = \frac{s^2}{s^2 + 2\Gamma s + 2\Gamma^2(1 - e^{-s\sigma})} \quad [31]$$

where

$$2\sigma\Gamma = \sqrt{1 + 2\sigma\kappa} - 1 \quad [32]$$

and

$$\kappa^2 = \alpha^2 \xi \quad [33]$$

Before we can invert Eq. [24] to obtain $g_{wi}(x)$, a suitable expression for $\tilde{F}_j(s)$ (Eq. [25]) is needed. This in turn requires an expression for $\tilde{P}_{ij}(k) = \sqrt{\rho_i/\rho_j} \{\tilde{Q}^T(-k)\}_{ij}^{-1}$ where $\tilde{Q}_{ij}(k)$ is given in Eq. [17]. Noting that

$$\tilde{Q}_{ij}(-is) = \sqrt{\frac{1}{\rho_i}} \tilde{Q}_{ij}(s) \sqrt{\rho_j} \quad [34]$$

where $\tilde{Q}(s)$ is given in Eq. [27], we have

$$\begin{aligned} \tilde{P}(-is)_{ij} &= \sqrt{\frac{\rho_i}{\rho_j}} \{\tilde{Q}^T(-is)\}_{ij}^{-1} \\ &= \sqrt{\frac{\rho_i}{\rho_j}} \left\{ \sqrt{\frac{1}{\rho_i}} \tilde{Q}_{ij}^{-1}(s) \sqrt{\rho_j} \right\}^T \\ &= \delta_{ij} + \frac{\rho_i}{\rho} \tilde{P}^o(s) + \frac{z_i \rho_i z_j}{\xi} \tilde{P}^\pm(s) \quad [35] \end{aligned}$$

Now since $P_{ij}(x) = 0$ for $x < \sigma/2$, inverting Eq. [25] and changing variables gives

$$F_j(x) = \sqrt{\frac{\rho_k}{\rho_j}} \int_0^\infty dr' \phi_{wk}(x+r') P_{kj}(r') \quad [36]$$

Using Eq. [8] in [36] yields

$$\begin{aligned} F_j(x) &= \sum_k \sqrt{\frac{\rho_k}{\rho_j}} z_k \beta e E \int_0^\infty dr' (x+r') P_{kj}(r') \\ &+ \sum_{k,n} \sqrt{\frac{\rho_k}{\rho_j}} A_{nk} \int_0^\infty dr' e^{-\mu_{nk}(x+r')} P_{kj}(r') \\ &= -\lim_{s \rightarrow 0} \beta e E \sum_k \sqrt{\frac{\rho_k}{\rho_j}} z_k \left(x - \frac{\partial}{\partial s} \right) \tilde{P}_{kj}(s) \\ &+ \sum_{k,n} \sqrt{\frac{\rho_k}{\rho_j}} A_{nk} e^{-\mu_{nk}x} P_{kj}(\mu_{nk}) \quad [37] \end{aligned}$$

where

$$\tilde{P}_{kj}(s) = \int_0^\infty dr e^{-sr} P_{kj}(r) \quad [38]$$

With the use of Eq. [35] and [28]-[33], it can be shown that

$$\lim_{s \rightarrow 0} \sum_k z_k \tilde{P}_{kj}(s) = 0 \quad [39]$$

and

$$\lim_{s \rightarrow 0} -\frac{\partial}{\partial s} \sum_k z_k \tilde{P}_{kj}(s) = -z_j/\kappa \quad [40]$$

Thus

$$\begin{aligned} F_j(x) &= -z_j \beta e E x / \kappa \\ &+ \sum_{k,n} \sqrt{\frac{\rho_k}{\rho_j}} A_{nk} \tilde{P}_{kj}(\mu_{nk}) e^{-\sigma/2/(s + \mu_{nk})} \quad [41] \end{aligned}$$

or

$$\begin{aligned} \tilde{F}_j(s) &= -z_j \beta e E e^{-s\sigma/2} / \kappa s \\ &+ \sqrt{\frac{\rho_k}{\rho_j}} A_{nk} \tilde{P}_{kj}(\mu_{nk}) e^{-\sigma/2(s + \mu_{nk})} / (s + \mu_{nk}) \quad [42] \end{aligned}$$

Equation [42] combined with Eq. [24] is essentially the solution to the problem. All that is required is the Laplace inverse of this expression. Analytic expressions have been derived for the inverses of $\tilde{P}^o(s)$ and $\tilde{P}^\pm(s)$ (10). The EMSA solution simply involves these expressions and their convolutions with an exponential function.

Fig. 1. Diffuse layer potential as a function of charge density on the wall for ± 1 and $+2 \pm 1$ electrolyte solutions of the same ionic strength with $\sigma = 0.425$ nm, $T = 298$ K, $\epsilon = 78.5$, and $\sigma\kappa = 0.9877$. The concentration of the ± 1 solution is 0.5M. The solid curves mark the PBA results and the broken curves mark the MSA and EMSA results as labeled.

By choosing the parameters in Eq. [8] such that

$$\sum_i z_i \rho_i \phi_{wi}(x) = -\xi \beta e E x + \xi \sum_n B_n e^{-\nu_n x} \quad [43]$$

and

$$\sum_i \rho_i \phi_{wi}(x) = \rho \sum_n A_n e^{-\mu_n x} \quad [44]$$

where A_n, B_n, μ_n, ν_n are the EMSA parameters, the solution is greatly simplified. In this instance, the local net charge density is given by

$$\sum_i z_i \rho_i g_{wi}(x) = \xi \left[b + \sum_n B'_n \right] F(x) - \sum_n \nu_n B'_n \int_0^x \exp[-\nu_n(x-t)] F(t) dt \quad [45]$$

where $F(x)$ is the Laplace inverse of $[1 + \tilde{P}(s)]/s$, $B'_n = B_n[1 + \tilde{P}^\pm(\nu_n)]$, and $b = \beta e E/k$. The total local number density is

$$\sum_i \rho_i g_{wi}(x) = \rho \left[1 + \frac{(1-\eta)^2}{1+2\eta} A'_n \right] g_o(x) - \frac{(1-\eta)^2}{1+2\eta} \sum_n \mu_n A'_n \int_0^x \exp[-\mu_n(x-t)] g_o(t) dt \quad [46]$$

where $g_o(t)$ is the inverse of $(1+2\eta)[1 + \tilde{P}^o(s)]/s(1-\eta)^2$; that is, the distribution function for hard

spheres near a hard wall and $A'_n = A_n[1 + \tilde{P}^o(\mu_n)]$. For Eq. [45] and [46] the values at contact are

$$\sum_i z_i \rho_i g_{wi}(\sigma/2) = \xi \left[b + \sum_n B_n \right] \quad [47]$$

$$\sum_i \rho_i g_{wi}(\sigma/2) = \rho \left[\frac{1+2\eta}{(1-\eta)^2} + \sum_n A_n \right] \quad [48]$$

The diffuse layer potential is

$$\phi = \frac{4\pi e}{\epsilon} \sum_i z_i \rho_i \int_0^\infty g_{wi}(x) dx \quad [49]$$

$$= \frac{b(1-\sigma^2\Gamma^2)}{\kappa^2} - \frac{4\pi\xi}{\epsilon\kappa} \sum_n \frac{B_n}{\nu_n} \quad [50]$$

Note that the first term in each of these expressions corresponds to the MSA solution of this problem.

Now we can return to the question of how to determine the parameters used in the EMSA. Several different approaches have been used for the symmetric electrolyte case. These can roughly be grouped into two categories; one in which the parameters are used to cause the results to agree with theoretical constraints or with specific results from other approximations and the other in which Eq. [8] is fitted to a reasonable approximation for the direct correlation function. In the case of a mixture of divalent and monovalent ions, there are usually too many parameters for the first type approach to be used. The second approach is actually an adaptation of the EMSA used in describing bulk ionic systems. An approximate $\phi_{wi}(x)$ is obtained by using a hypernetted chain, HNC, type closure relation

$$\phi_{wi}(x) = -\beta e E x + g_{wi}(x) - 1 - \ln [g_{wi}(x)] \quad [51]$$

Fig. 2. Diffuse layer potential as a function of charge density for a positively charged wall. The results for the ± 1 (dotted line), $+2-1$ (solid line), and $+2\pm 1$ (dashed line) cases are given. The PBA and EMSA results are the upper and lower set of curves as labeled. The model parameters are listed in Fig. 1.

Fig. 3. Diffuse layer potential as a function of charge density on the wall demonstrating how it varies with the amount of divalent cations present. These results are for the EMSA. The solutions have the same ionic strength. The curves for $+2\pm 1$ cases are labeled by the ratio of $+2$ to $+1$ ions, $k = 0.005$, $k = 0.05$, and $k = 0.25$. ± 1 case (solid line), $\pm 2-1$ case (dotted line). The model parameters are listed in Fig. 1.

Fig. 4. Reduced net charge density as a function of distance demonstrating how it varies with the amount of divalent cations present. In all cases, $\sigma\kappa = 0.9877$, and the other model parameters are listed in Fig. 1. The wall has a charge density of -0.15 C/m^2 . $G_{wd}(x')$ and x' are defined in Fig. 5 and $\xi = \sum z_i^2 \rho_i$. The solid curves give the results for the ± 1 and $+2-1$ cases as labeled. The results for the $+2\pm 1$ case with divalent to monovalent cation density ratios of $k = 0.25$ (dotted line) and $k = 0.05$ (dashed line) are given.

with an approximate $g_{wi}(x)$. The analogy to the method of Medina-Noyola *et al.* (11) would be to use

$$g_{wi}(x) = \exp(-z_i b e^{-\kappa x}) \quad [52]$$

Another possibility, in hopes of obtaining better results at higher electric fields, would be to use the appropriate $g_{wi}(x)$ from the PBA using a Stern type layer to account for ion size (12). With the $g_{wi}(x)$ chosen, the parameters of the EMSA can easily be determined by a curve fitting procedure.

Results

One of the most important quantities associated with the electrical double layer is the potential drop across the interface. It was found that use of Eq. [52] in Eq. [51] leads to unrealistic results for the diffuse layer potential except at low surface charge densities. Therefore, the appropriate PBA $g_{wi}(x)$ was used in Eq. [51] and much more reasonable results were obtained. Figures 1-3 show these results. In most instances, only two exponential terms or four parameters were used in Eq. [8]. The general trend is for the EMSA to predict a diffuse layer potential of lower

Fig. 5. Plot of the reduced net charge density vs. distance for the $+2\pm 1$ case. Here $x' = x/\sigma - 0.5$ where x is the distance measured from the wall. $G_{wd}(x')/\rho_2 = \sum g_{wi}(x')/\rho_2$ where ρ_2 is the bulk density of the $+1$ ion. The ratio of $+2$ to $+1$ ions is 0.05 and $\sigma\kappa = 0.9877$. The model parameters are listed in Fig. 1. The wall has a charge density of -0.15 C/m^2 . PBA (solid line), EMSA (dashed line), and MSA (dotted line).

magnitude than the PBA, the difference increasing with the absolute value of the charge density. This trend is consistent with the Monte Carlo and HNC results for the ± 1 ion case (12, 13). The relative positioning of the curves in the EMSA for the different cases such as ± 1 , $+2-1$, and $+2\pm 1$ is the same as in the PBA. Note that the EMSA diffuse layer potential is much more realistic than the linear MSA result. Figure 3 shows that the magnitude of the diffuse layer potential decreases with an increase in the relative amount of divalent cations at constant ionic strength. This is due to the ability of the divalent ions to screen the charged wall more effectively than the monovalent ions.

The structure of the interface appears to be similar to that predicted by the PBA. Figures 4 and 5 show typical distributions of reduced net charge densities. The EMSA can be seen to be a great improvement over the MSA in this regard.

Although not shown in Fig. 1-5 the agreement of EMSA and PB with Monte Carlo data is quite good (13). There are no MC data for 2-1-1 systems, but Fig. 6 shows the reduced electrostatic potential $e\phi/kT$ as a function of distance from the wall for a 2-1 electrolyte for a negatively charged wall. This system has been shown to have a great discrepancy between PB and Monte Carlo data (14). Most unusual is the dip in the potential near the wall as predicted by the Monte Carlo data; the potential actually becomes negative. The EMSA demonstrates this same behavior even though the Poisson-Boltzmann wall particle correlation functions are used for input in the direct

Fig. 6. Reduced electrostatic potential as a function of distance from the wall for a +2-1 electrolyte. The divalent ion has a concentration of 0.5M and the surface charge density is -0.1512 C/m^2 .

correlation function. In an effort to try to improve the EMSA results, the $g_{wi}(x)$ obtained from the EMSA were used in Eq. [51] in place of the Poisson-Boltzmann distribution functions. This new direct correlation function was then used to obtain new $g_{wi}(x)$. The procedure was carried out twice and the results are labeled EMSAI in Fig. 6. This demonstrates a possible way of improving the EMSA.

The explanation for the dip in the $\phi(x)$ curves is pictured in Fig. 7. Here the EMSAI ion distributions are seen to oscillate about their bulk value of 1, causing the potential to change signs. This prediction of a counterion concentration less than the bulk value is very unusual. Such oscillations cannot be predicted by the PBA. The EMSAI ion distributions are nearly identical to the Monte Carlo data for this case.

Summary

The EMSA is a convenient analytic approximation which describes the electrical double layer much more accurately than the MSA. Also, it can easily be applied to multivalent ionic solutions. These results demonstrate the versatility of the EMSA. However, it is difficult at the moment to assess their accuracy. The EMSA is an improvement of the MSA and appears to be quite useful in studying the electrical double layer. The procedure used here, while easy to implement, is restrictive since no size dependence is accounted for

Fig. 7. The ion distributions as a function of distance from the wall a +2-1 electrolyte. The electrolyte concentration and the surface charge density are the same as in Fig. 6.

in the direct correlation function. It is very desirable to adapt approaches similar to those used for the ± 1 case (7) to these multivalent electrolyte cases or to develop new procedures which could account more consistently for size effects.

Film Thickness Determination of PMMA on InP by Ellipsometry

Richard Scheps¹

Department of Electrical Engineering, Colorado State University, Fort Collins, Colorado 80523

ABSTRACT

The thickness of polymethylmethacrylate (PMMA) films deposited in solution on InP is measured by ellipsometry to determine its dependence on terminal spin speed. The PMMA solution behaves as a steady-state Newtonian fluid. Film thickness in excess of the periodic thickness is measured by combining data taken at three angles of incidence; a procedure for applying this technique is discussed. The main feature consists of assigning the film index from data taken at the incident angle where the ellipsometer readings are most sensitive to film index, and using this index in determining the film thickness at the other two angles. The basis supporting this procedure is presented, and the dependence of the ellipsometric model on uncertainties in the assignment of film and substrate optical constants is discussed specifically in terms of its effect on the three-angle technique.

It was recently shown (1) that the thickness of polymethylmethacrylate (PMMA) films on GaAs can be measured ellipsometrically for films as thick as 2.7μ . The sensitivity of the ellipsometric data to film index and film thickness is angle dependent, and in the course of performing film measurements on GaAs it was found that certain measurements were highly imprecise and led to large uncertainties in the film thickness. In the present work, the three sets of data are treated somewhat differently. The data set from the incident angle most sensitive to film index is used to assign the film index. This index is then used in the analysis of the other data points to obtain the film thickness. This procedure considerably simplifies the data generation and analysis tasks and results in more precise film thickness determinations.

The work that follows presents the basis for treating the data in this manner. The angle dependence of the ellipsometric sensitivity is presented for a range of dielectric films on InP, and the method for selecting the data set that determines the film index is described. The influence of uncertainties in the substrate optical constants on the accuracy of the film index and thickness is addressed, and results of film thickness ellipsometry of PMMA on InP are presented.

Theory

The model used for the representation of elliptically polarized light and the interpretation of the ellipsometric data was described in detail by McCrackin *et al.* (2). The Fortran program used in the data analysis is that described by them (2) (referred to below as MPSS) and was provided by McCrackin (3). The MPSS equations show that the ellipsometer readings are periodic in film thickness. The ellipsometer used in this work allows incident angles (ϕ) of 30° , 50° , or 70° . Using a film index of 1.49 [the index of PMMA at 632.8 nm (4)] the periodic film thicknesses (T_ϕ) are

$$\begin{aligned} T_{30} &= 225.42 \text{ nm} \\ T_{50} &= 247.58 \text{ nm} \\ T_{70} &= 273.63 \text{ nm} \end{aligned} \quad [1]$$

The film thickness d can be written as

$$d = t_\phi + n_\phi T_\phi \quad [2]$$

where t_ϕ is the "residual" thickness, that is, the film thickness less an integral multiple of T_ϕ , and n_ϕ is an integer ≥ 0 .

It has been shown for the film measurements on GaAs (1) that ellipsometric data taken at three angles of incidence uniquely determine the n_ϕ and d for thickness as great as 2.7μ . The method relies on the fact that the T_ϕ are different at each angle, and the relative magnitudes of the residual thicknesses t_ϕ are used to select the appropriate quantitative expression

to calculate the n_ϕ . A table relating the magnitudes of the residual film thickness to the expressions for n_ϕ was presented by the author (1) for films of index 1.49.

To obtain accurate film thickness values, one needs to measure the PMMA film index after deposition. However, the ellipsometer is not equally sensitive to the index at all three angles of incidence. For example, at a given angle the residual film thickness may be close to T_ϕ . In such a case the coordinates are determined by the substrate optical constants, and one could not expect to obtain film index data near T_ϕ with reasonable accuracy without an ellipsometer having high angular resolution capabilities. This suggests that a more appropriate method would be to assign the film index from data taken at the angle of incidence where the ellipsometer is most sensitive to film index. This index is then inserted into the Fortran program, and the other two data points are analyzed to determine the film thickness only. The film thickness determination is then made from the residual thicknesses using the method of the author (1) with the assigned film index. The method for determining which data set is most sensitive to film index is straightforward; it requires mapping the data points on grids where the ellipsometer readings and film optical constants are parameters. This method is illustrated below.

Experiment and Results

The ellipsometer used in the present work is a Gaertner Model L117 with a compensator fixed at $+45^\circ$. Two sets of polarizer and analyzer readings are taken at each angle of incidence, and the computer program uses the average of these two readings. The relationship between the two sets of data is

$$\begin{aligned} P1 &= P2 + 90^\circ \\ A1 &= 180^\circ - A2 \end{aligned} \quad [3]$$

where $A1$, $P1$ and $A2$, $P2$ are the first and second set of analyzer and polarizer readings, respectively. These readings are related to Δ and ψ by

$$\begin{aligned} \Delta &= 270^\circ - 2P1 \\ \psi &= A1 \end{aligned} \quad [4]$$

The ellipsometer angular resolution is 0.1° , and the re-settability was found to range from 0.1° for the 30° angle of incidence measurements to 0.5° for the 70° angle of incidence.

Prior to performing the film thickness measurements, a number of InP substrates were examined ellipsometrically to assign the optical constants. Substrates were iron doped, cut in the (100) plane, and chemomechanically polished. The surface treatment consisted of a light scrub, a 3 min etch in 10 weight percent (w/o) HIO_3 , followed by a rinse in deionized distilled water and blowing dry with dry nitrogen. Substrates treated in this manner gave reproducible optical constants.

¹ Present address: Naval Ocean Systems Center, Code 8113, San Diego, California 92152.

Key words: PMMA, InP, ellipsometry, E-beam writing.

Data on the bare substrates were taken at three angles of incidence, but the 70° data were considered the most accurate. Determination of the substrate optical constants resulted from the average of many measurements on a number of substrates taken at 70°. Figure 1 illustrates the sensitivity of Δ and ψ to changes in the optical constants at the different angles of incidence. The complex refractive index can be written as

$$n = N - ik = N(1 - iK) \quad [5]$$

where $K = k/N$. The instrumental resolution is shown in the figure, as well as the literature value (5) and experimentally determined value for the optical constants. These values are $N = 3.42$, $K = 0.0813$, and $N = 3.47 \pm 0.02$, $K = 0.13 \pm 0.01$ for the literature and experimentally determined optical constants, respectively. The figure illustrates the reason for preferring the 70° data, and also indicates that resolution or re-settability limits cannot account for the discrepancy between measured and literature values. (Note that while these limits are the same for both the polarizer and analyzer readings, the factor of 2 in Eq. [4] makes Δ twice as uncertain as ψ .)

A similar discrepancy was observed for GaAs (1), and its source remains unknown. One possible source is instrumental misalignment, which MPSS indicates is critical for accurate substrate optical constant determination (but not critical for accurate film thickness measurements). No special alignment procedures were followed in this work. A native film on the substrate is another likely possibility. InP is known (6) to develop oxide films, and no exceptional precautions

were taken to inhibit film growth. For reasons mentioned in the Theory section, the ellipsometer could not be expected to provide accurate thickness and index data for a thin native film. However, analyzing the "bare substrate" experimental data as if it were a film-covered substrate, using the literature values for the substrate optical constants, and assigning the film index arbitrarily to 1.5 results in a film thickness determination of 2.8 nm. For the subsequent film analysis, the experimentally determined optical constants were used.

Substrates prepared as above had films deposited by spinning a solution of 9 w/o 496 K PMMA in chlorobenzene for 60s. Films were then baked for 75 min at 160°C. Film thickness was generally uniform within 5% up to 0.5 nm from the sample edge.

The central issue in this work is the minimization of film thickness errors when simultaneously using data taken at different incident angles and, hence, different sensitivities. Figures 2 and 3 illustrate the variation of Δ and ψ with film thickness for the three incident angles and for a series of film indexes. The curves are shown for a complete cycle of film thickness: the Δ and ψ values repeat for films in excess of the periodic film thickness T_ϕ . The origin of each curve is given by the Δ and ψ for the bare substrate ($N = 3.47$, $K = 0.13$) and for films of thickness $n_\phi T_\phi$, as in Eq. [2].

When the film index is unknown, the steep slopes near the origin for the curves translate the uncertainty in the analyzer reading to uncertainty in the film index, and hence uncertainty in the film thickness. This thickness uncertainty is particularly large for Δ , ψ points just above the origin, where adjacent index curves have film thicknesses close to the appropriate T_ϕ . Figure 4 presents the origin region for the 50° curves in greater detail. The method used in this work to determine the film index and thickness was to map the Δ , ψ points for a given sample on curves such as those shown in Fig. 2 and 3. The film index was then assigned using the data at that incident angle where the adjacent film index curves showed the greatest separation. The other two data points were analyzed with the assigned film index, and the resulting t_ϕ give

Fig. 1. Bare substrate ellipsometry coordinates for incident angles of 30°, 50°, and 70°. For each angle of incidence, a grid of substrate N and K values is used to generate corresponding Δ and ψ coordinates. The locus of Δ , ψ points for fixed N or fixed K is drawn in the figure as a vertical or horizontal line, respectively. The instrumental resolution in Δ and ψ units is shown, and the literature (x) and present work (o) values for N and K are indicated. Note breaks in horizontal scale. Grid lines at 50° and 30° are unlabeled but correspond to the 70° grid lines.

Fig. 2. Locus of Δ , ψ points for films of index N and thickness d as shown, for incident angles of 50° and 30°. Film thickness is shown directly on curves in nm. Note scale expansions for 30° curve relative to 50° (factor of 2 for both horizontal and vertical axes).

Fig. 3. Locus of Δ, ψ coordinates for films of index N and thickness d as shown, for a 70° angle of incidence. Film thickness in nm written directly on curve.

the total film thickness using the three-angle technique as described by the author (1).

The results of the film thickness vs. spin rate measurements are shown in Fig. 5. Points were taken at spin rates ranging from 2800 to 8000 rpm. The characteristic spin curve is very similar to that found for GaAs. An earlier study of the dependence of photoresist film thickness on final spin velocity (7) attempted to fit the data to an equation of the form

$$d = b\omega^n \quad [6]$$

where d is the film thickness in nm and ω is the angular velocity in 1000 rpm. The photoresists examined by O'Hagen and Daughton (7) gave angular velocity exponents in the range of -0.4 to -0.7 . The exponent for a steady-state Newtonian fluid is predicted (8) to be $-2/3$. The data for PMMA was fitted to Eq. [6] using a linear regression least squares fit and resulted in the curve

$$d = 2549.7 \omega^{-0.663} \quad [7]$$

The close agreement between the angular velocity dependent exponent in Eq. [7] and the steady-state Newtonian exponent indicate that transient effects due to solvent volatility are unimportant. Substrate type and topography also appear to have little effect on the "Newtonian-mess" of the 9% PMMA solution.

The variation in calculated film thickness as a function of substrate optical constants was measured for a range of N and K chosen to be symmetric about the value used in this work and include the literature

Fig. 4. Detail of 50° curves in Fig. 2; d in nm and N as labeled. Near $\Delta = 180^\circ$ film thickness points are labeled with the corresponding film index in parentheses. Note scale difference between ordinate and abscissa.

Fig. 5. Film thickness as a function of terminal spin speed for a solution of 9% PMMA in chlorobenzene. Dots are data points, line is least squares fit to data.

value at the limit. Calculations at all three angles of incidence showed the range of film thickness to lie between 1 and 3 nm of the value obtained with $N = 3.47, K = 0.13$ when the film index was fixed at 1.49. In cases where the film index is unknown, the film thickness uncertainty for the same range of substrate optical constants is generally larger. A variational computation was performed in which the Fortran program was required to find both the film thickness and index as the substrate parameters were varied. For Δ, ψ coordinates near $t_\phi = 100$ nm, the range of substrate parameters produced film indexes of 1.49 ± 0.1 . Film thickness variations were similar in magnitude to those found when the film index was fixed. Over the thick-

ness range $50 \text{ nm} \leq t_{\phi} \leq (T_{\phi} - 50 \text{ nm})$ and the same range of substrate optical constants, the film index variation is larger and ranged from between 1.45 and 1.53 at 30° to between 1.44 and 1.55 at 70° . The corresponding film thickness variations were within $\pm 5 \text{ nm}$ in all cases, except for the 70° point at 200 nm , which showed a variation of 15 nm . In evaluating the effects of substrate optical constants on film thickness accuracy, it should be recognized that the range of substrate parameters used for the variational calculations is much greater than the experimental uncertainty of the bare substrate ellipsometry, and for the results presented for PMMA on InP there is little impact of the substrate parameter uncertainty on film index and thickness.

Conclusion

The technique of assigning the film index from ellipsometric data taken at one angle of incidence reduces the inaccuracies involved in using the three-angle technique for measuring film thickness. The ellipsometric sensitivity to film thickness at three angles of incidence is discussed for the case where the film index is known, as well as for the case where the film index must be determined. This leads to a graphical evaluative technique to assess the most favorable data with which to assign the film index, and allows one to assess the expected accuracy of the results. Uncertainties in assigning the substrate optical constants are seen to have only a small effect on the film thickness accuracy when the film index is known, but may be larger when the substrate parameter uncertainty is large and the film index is unknown. Results of the

film thickness dependence on spin rate are given for PMMA on InP, and it is concluded that the film thickness varies inversely as the $2/3$ power of the terminal spin speed.

Relationships among Electrochemical, Thermodynamic, and Oxygen Potential Quantities in Lithium-Transition Metal-Oxygen Molten Salt Cells

N. A. Godshall,^{*,1} I. D. Raistrick,* and R. A. Huggins*

Department of Materials Science and Engineering, Stanford University, Stanford, California 94305

ABSTRACT

The interdependence of thermodynamic parameters, phase equilibria, and electrochemical measurements can be used as a powerful tool in the development of high specific energy cells. These principles were used in the analysis of electrochemical experiments performed on ternary lithium-transition metal-oxide ($M = \text{Mn, Fe, and Co}$) positive electrodes. The free energies of formation of LiMnO_2 , Li_2FeO_4 , LiFeO_2 , and LiCoO_2 were found to be -178.21 , -399.88 , -154.18 , and -131.62 kcal/mol at 400°C . The electrochemical displacement reactions were found to be reversible in LiCl/KCl molten salt cells over a range of 0.0 - 3.0 Li equivalents per mol at current densities of 5 - 15 mA/cm^2 . The equilibrium potential vs. Li was found to be a logarithmic function of the calculated oxygen partial pressure for any tie triangle in which Li_2O is present, or for any tie triangle containing ternary oxide phases Li_xMO_y , which are only marginally stable with respect to Li_2O and the relevant binary oxides MO_y . Compounds with oxygen partial pressures above 10^{-25} atm were found to be unstable in LiCl/KCl electrolyte at 400°C .

The reversible work ΔG_r of a secondary electrochemical cell is directly related to its equilibrium potential-composition (E - x) curve

$$\Delta G_r = -zF \int_0^x E dx \quad [1]$$

The total free energy change in the electrochemical reaction therefore represents the integral of the equilibrium potential curve (1, 2). That is, the computed ΔG_r of a given reaction represents the area under the curve, but by itself, says nothing of the shape of the curve.

The free energy change of the electrochemical reaction can be written as

$$\Delta G_r = \Delta G^{\circ}_f(\text{Products}) - \Delta G^{\circ}_f(\text{Reactants}) \quad [2]$$

That is, the available energy stored in a cell is limited by the difference between the free energy of formation ΔG°_f of reactants and products. Therefore a high energy cell is the result of formation of very stable products from very unstable reactants. Furthermore since the ultimate choice of stable products is limited (e.g., Li_2O in the case of lithium-based systems, and elements such as Fe), the search for high energy cells must focus primarily on the search for relatively unstable reactant materials.

Key words: ternary, lithium, oxides, phases, equilibria.

Phase equilibria within a multicomponent system are determined by the thermodynamic state of lowest free energy. This thermodynamic state can be monitored by reversible (open-circuit) electrochemical measurements, which thereby yield phase equilibria information. Conversely, a knowledge of the phase equilibria in a system affords a direct means of calculation of electrode capacity (number of equivalents per mol of reactant) in an electrochemical system, while thermodynamic data can be used to predict the reversible voltage.

The overall composition of a ternary positive electrode material Li_xMO_y will, in general, pass through one-, two-, and three-phase regions of a ternary phase diagram as lithium is added to it in an electrochemical cell. One-phase and two-phase equilibrium in a ternary system at constant temperature and pressure have nonzero degrees of freedom ($F = 2$ and $F = 1$, respectively), so that both the composition of one or more phases, and the reversible potential of the cell vary with Li composition (x). Solid-solution electrodes such as TiS_2 and NbSe_2 are examples of single-phase electrodes (3).

Not until three phases coexist in equilibrium at constant temperature and pressure, is a ternary system truly invariant ($F = 0$). The resulting region of phase equilibrium in a ternary phase diagram must have the shape of a triangle. The Gibbs phase rule for an isothermal isobaric ternary system dictates that an area bounded by four or more sides violates thermodynamic equilibrium. The reversible potential vs. Li will be the same for any composition lying within a three-phase tie triangle. An electrochemical titration resulting in a change in the overall composition within the same tie triangle involves only changes in the amounts of the three phases present, not in their compositions, and is known as a displacement reaction. In general, displacement-reaction electrodes contain as many phases (P) as they contain components (C), so that electrochemical cells containing them yield constant voltage plateaus. This is different from solid-solution electrodes, where the potential varies with composition, even under conditions of zero current flow.

Equilibrium Oxygen Partial Pressure Calculations

Free energy calculations based on Eq. [1] and [2] predict that many binary and ternary transition metal oxides should yield quite high cell voltages vs. lithium. In particular, the higher oxides should yield the highest cell potentials because of their larger free energy of reaction ΔG_r upon reduction by lithium. Unfortunately, this principle is somewhat offset by the fact that many of these higher oxides have been found to reduce to lower oxides when in contact with some electrolytes, such as the common LiCl/KCl molten salt. For this reason, it was determined that an analysis of the equilibrium oxygen partial pressures of these transition metal oxides was necessary.

An Ellingham diagram (4) is a common means of graphically representing ΔG°_f vs. temperature data, as illustrated in Fig. 1 for the case of several manganese oxides. Each (solid) line represents the Gibbs free energy of formation of an oxide phase from its elements M and O_2

Each formation reaction is usually written on a "per mol O_2 " basis so that lines in an Ellingham diagram are generally parallel, since the gaseous O_2 accounts for most of the entropy change of the reaction ΔS_r , which is manifested in the slope of the $\Delta G^\circ_f - T$ lines.

An equilibrium oxygen partial pressure scale was later added to the standard Ellingham diagram to permit a graphical means of determining the p_{O_2} above these oxides (5). It is important to note, however, that

Fig. 1. Ellingham diagram illustrating "integral" (solid line) and "difference" (dashed line) formation reaction lines for manganese oxides.

this is valid only for reactions where reactants and products are at equilibrium, and is not generally true for reactions describing the formation of a compound from its elements. Only the lowest line in Fig. 1 (MnO) represents both a "formation" and "equilibrium" reaction. Higher oxide lines (solid lines Mn_3O_4 , Mn_2O_3 , and MnO_2) represent "formation" reactions of these products, but are not true "equilibrium" lines since elemental Mn would not be stable in contact with these higher oxides.

The equilibrium oxygen partial pressure p_{O_2} above two oxides in equilibrium at a given temperature and total pressure depends, therefore, not on the free energies of formation ΔG°_f of these oxides from their elements; but rather on the free energy of reaction ΔG_r of the higher oxide MO_y from its next lower oxide MO_p

This free energy of reaction is given by

$$\Delta G_r = 2/(y-p) [\Delta G^\circ_f(\text{MO}_y) - \Delta G^\circ_f(\text{MO}_p)] \quad [5]$$

The free energies of reaction between neighboring manganese oxides (again on a "per mol O_2 " basis) are illustrated by the dashed lines of Fig. 1. They represent the differences between the formation reaction (solid) lines after adjustment for the stoichiometric numbers. They also lie higher in the diagram since the ΔG values of these "difference" reactions are smaller in magnitude than those for the formation, or "integral" reactions. Furthermore, the "difference" lines represent the true stability regions of each oxide, as illustrated in Fig. 1. They also yield proper oxygen partial pressure information when used in conjunction with the p_{O_2} scale of Fig. 1.

The oxygen partial pressure when the two oxides are in equilibrium may be found analytically through the use of

$$\Delta G_r = -RT \ln K \quad [6]$$

Fig. 2. Equilibrium oxygen partial pressures exhibited by manganese oxides as a function of composition at 400°C.

since the equilibrium constant K for reaction [4] is given by $1/p_{O_2}$ if both oxides remain pure and in their standard states. That is

$$\Delta G_r = +RT \ln p_{O_2} \quad [7]$$

so that this specific value of oxygen partial pressure is given by

$$p_{O_2} = \exp(\Delta G_r/RT) \quad [8]$$

It is useful to define a logarithmic parameter p_0 analogous to the hydrogen ion concentration parameter pH

$$p_0 = -\log p_{O_2} \quad [9]$$

This oxygen potential parameter may therefore be calculated directly from the free energy of reaction [4] and the absolute temperature

$$p_0 = -\Delta G_r/(2.303 RT) \quad [10]$$

The variation of oxygen partial pressure with overall composition in the manganese-oxygen system is illustrated in Fig. 2. This system is used as an example because it contains several binary oxide phases. In this case, the composition parameter was chosen as the oxygen/manganese ratio, or "y" in MO_y . The variable stoichiometry of single-phase regions is illustrated on the abscissa through the use of heavy dark lines. The oxygen potential p_0 is plotted on the ordinate, but may also be given by the free energy of reaction ΔG_r at fixed temperature (Eq. [10]). As discussed above, the range of p_{O_2} over which a phase is stable is determined by the equilibrium with its two neighboring phases; one stable at lower oxygen pressures, and the other stable at higher oxygen pressures.

The oxygen partial pressure is seen to remain constant in two-phase regions ($F = 0$), but may vary over many orders of magnitude in single-phase regions ($F = 1$). This is a direct result of the Gibbs phase rule at constant temperature and total pressure. The dashed lines shown within single-phase regions are schematic only; they are not typically linear functions of composition. The equilibrium oxygen partial pressures at 400°C of all first-row transition metal binary oxides were calculated from Eq. [4]-[10] and are illustrated in Fig. 3.

The expected high voltages of some lithium cells with transition metal oxides as positive electrodes cannot be realized with LiCl-KCl molten salt electrolytes because it has been found that the highest oxides reduce to lower oxides in this electrolyte at 400°C. This is because their equilibrium oxygen partial pressures are higher than the p_{O_2} present in the LiCl-KCl salt. For instance, MnO_2 and $LiMn_2O_4$ yield very high theo-

retical voltages vs. lithium, but were found to reduce when placed in this molten salt.

In order to determine the limit of p_{O_2} for which no reduction will occur in this electrolyte, many binary and ternary transition metal oxides were individually mixed with solid LiCl/KCl powder and placed in molybdenum tubes. They were then immersed in molten LiCl/KCl at 400°C for approximately 18h. This was followed by ambient temperature x-ray analysis under Kapton film. It was found that all oxides with calculated oxygen partial pressures above 10^{-25} atm either reduced to well-defined lower oxides (e.g., Fe_2O_3 reduced to Fe_3O_4) or yielded amorphous x-ray patterns (e.g., MnO_2). Below 10^{-25} atm (solid line in Fig. 3), all binary oxides were found to be stable in the LiCl/KCl molten salt. The stability ranges of the binary oxides were then used to project the approxi-

Fig. 3. Equilibrium oxygen partial pressures of binary first-row transition metal oxides at 400°C. Also illustrated are isobaric O_2 lines (1 atm total pressure): air, $p_{O_2} = 0.21$ atm (dash-dot line); helium glove box, $p_{O_2} = 10^{-6}$ atm (dashed line); LiCl/KCl electrolyte, $p_{O_2} = 10^{-25}$ atm (solid line).

mate positions of isobaric O_2 lines within a ternary phase diagram, since the constant partial pressures above two neighboring binary oxides provide an estimation of where ternary O_2 isobars intersect the legs of a Gibbs composition triangle.

Equilibrium Potential-Composition Curves

The electrochemical reduction of Li_xMO_y cathodes by reaction with lithium was studied in cells of the type

The cathode material (positive electrode) was a ternary compound composed of lithium, oxygen, and the first-row transition metals Mn, Fe, or Co (1, 2). The electrochemical reactions were found to be reversible at 400°C. Electrochemical reduction and oxidation was performed at current densities of 5-15 mA/cm². The current was repeatedly interrupted so that the equilibrium, or open-circuit, cell potential was obtained as a function of Li composition (6). The changes in composition were calculated from the integrated current and Faraday's law. Two equilibrium potential-composition curves are illustrated in Fig. 4 and 5 for the initial electrode compositions of Fe_3O_4 and $LiFe_5O_8$, respectively.

The tie triangles in each ternary system were thus determined by plotting the extent of the various constant voltage plateaus, determined by reacting lithium with several different initial compositions, on each respective Gibbs composition triangle, Fig. 6. Tie lines exist where steps occur between plateau voltages, Fig. 7. The three phases present in each tie triangle were confirmed by x-ray diffraction analyses of samples taken from the positive electrodes.

This technique also permits a determination of the thermodynamic properties of these intermediate ternary compounds where little or no literature data existed thus far (7). The integral free energy of formation (ΔG_f°) of each initial compound was calculated by integration of its respective equilibrium potential curve according to the equation

$$\Delta G_f^\circ (Li_xMO_y) = zF \int_x^{2y} E dx + y\Delta G_f^\circ (Li_2O) \quad [11]$$

The free energies of formation at 400°C of $LiMnO_2$, Li_3FeO_4 , $LiFeO_2$, and $LiCoO_2$ were calculated this way and found to be -178.21, -399.88, -154.18, and -131.62 kcal/mol, respectively.

The activities of all species are constant in any three-phase region of a ternary system at constant temperature and pressure. Furthermore, the activities of all species, not just the electroactive one (Li), may be calculated within each tie triangle, so long as the free energy of formation of each of the three equilibrium phases is known. Oxygen partial pressures may be calculated for each tie triangle by writing an equilibrium reaction between O_2 gas and the three phases of which the tie triangle is composed. For example, in the case of the MnO , Li_2O , $LiMnO_2$ tie triangle

for which, at 400°C

$$\Delta G_r = -146.68 \text{ kcal/mol } O_2 \quad p_{O_2} = 2.37 \times 10^{-48} \text{ atm} \quad [13]$$

Analytical Relation Between Tie Triangle Voltages and Oxygen Partial Pressures

Any relationship between the voltage vs. lithium E and the oxygen partial pressure p_{O_2} would be of fundamental importance, for it would allow oxygen partial pressure calculations to be used to predict equilibrium voltages of lithium electrochemical cells. It is also possible to extend such a relation to other alkali metal (Na, K, etc.) cells, and other cathode materials (e.g., sulfides). However, such a relation would be expected to carry a constraint, since a ternary system ($C = 3$) would not, in general, have the activity of one component vary directly as a function of only a second component.

It was therefore desired to analytically derive the relation between E and p_{O_2} in a ternary system to better understand any voltage limitation imposed by the p_{O_2} limitation (10^{-25} atm) of the $LiCl/KCl$ electrolyte. The general equilibrium equation for a ternary tie triangle composed of two binary transition metal oxides (MO_y and MO_{y-x}) and lithium oxide (Li_2O) may be written as

where the free energy of this reaction is given by

Fig. 4. Equilibrium potential-composition curve for the initial composition Fe_3O_4 .

Fig. 5. Equilibrium potential-composition curve for the initial composition LiFe_5O_8 .

$$\Delta G_r = \Delta G_r^1 + \Delta G_r^2 \quad [15]$$

when the ternary reaction [14] is written as the summation of two binary reactions according to Hess's law

Reaction [16] specifies the equilibrium oxygen partial pressure above two adjacent binary transition metal oxides, and reaction [17] represents the formation of Li_2O . Substitution into Eq. [15] yields

$$E = -\Delta G_r/zF = -\Delta G_r^1/zF - \Delta G_r^2/zF \quad [18]$$

The charge number z of reaction [14] is given by $[2x]$. So long as both binary transition metal oxides of reaction [16] remain pure and in their standard states, their activities may be taken as unity, resulting in

$$E = RT/(2xF) \ln(p_{\text{O}_2})^{x/2} - \Delta G_f^\circ(\text{Li}_2\text{O})/(2F) \quad [19]$$

Simplification results in a linear relation between E and $\ln p_{\text{O}_2}$ with a slope of $RT/(4F)$ and a Y-intercept of 2.654V.

$$E = RT/(4F) \ln(p_{\text{O}_2}) - \Delta G_f^\circ(\text{Li}_2\text{O})/(2F) \quad [20]$$

This, of course, may alternately be expressed in terms of $\log p_{\text{O}_2}$ and p_0

$$E = -2.303 RT/(4F) \log(p_{\text{O}_2}) - \Delta G_f^\circ(\text{Li}_2\text{O})/(2F) \quad [21]$$

and

$$E = -2.303 RT/(4F) p_0 - \Delta G_f^\circ(\text{Li}_2\text{O})/(2F) \quad [22]$$

Experimental Relation Between Tie Triangle Voltages and Oxygen Partial Pressures

The electrochemical titrations of lithium into Li_xMO_y cathodes were used to experimentally determine the equilibrium potentials E of tie triangles in the ternary systems containing manganese, iron, and cobalt. In addition, the free energies of formation ΔG_f° of intermediate ternary compounds were then calculated by integration of the equilibrium potential-composition curves. This, in turn, permitted the calculation of equilibrium oxygen partial pressures p_{O_2} of the same tie triangles for which E values were determined experimentally. Both values are listed in the tie triangles of Fig. 7. An uncertainty remains in the Li-Fe-O ter-

nary system regarding the relative stability of the $\text{LiFeO}_2/\text{Fe}_3\text{O}_4$ tie line vs. the $\text{LiFe}_5\text{O}_8/\text{Fe}$ tie line, illustrated by the dash-dot lines in Fig. 7(b).

The equilibrium voltage vs. Li of each three-phase region is plotted as a function of the equilibrium oxygen partial pressure of that region in Fig. 8. The result is a linear relationship between E and the logarithm of p_{O_2} of the form

$$E = m \log p_{\text{O}_2} + b \quad [23]$$

The equation for the experimental line of Fig. 8 was found to be

$$E = 1.45 \times 10^{-2} \ln p_{\text{O}_2} + 2.65V \quad [24]$$

Extrapolation of this line results in X- and Y-intercepts of

$$E = 0.0V \quad p_0 = 80$$

$$p_0 = 0 \quad E = 2.65V$$

Like the analytical derivation leading to Eq. [20], these experimental data indicate that Li_2O is a primary factor in this relation, since the X-intercept is the same as the equilibrium oxygen partial pressure above a mixture of Li and Li_2O at 400°C, and the Y-intercept is the theoretical voltage of a lithium/oxygen cell at 400°C. Furthermore, the slope of this line was found to be $(RT/4F)$, where the factor of 4 is the number of Li equivalents required to react with 1 mol of O_2 to form Li_2O .

Equation [20] was derived for tie triangles containing Li_2O , such as the $\text{Mn}, \text{Li}_2\text{O}, \text{MnO}$ tie triangle included in Fig. 8. In addition, it was found that the potentials of binary first-row transition metal monoxides, when compared with their equilibrium oxygen partial pressures, also follow the relation of Fig. 8. This relation is therefore generally valid for any tie triangle containing Li_2O and two binary oxides as constituents.

Although most tie triangles in these ternary Li-M-O systems are not composed of Li_2O and binary transition metal oxides, they were experimentally found to also follow the linear relation between E and $\ln p_{\text{O}_2}$ of Fig. 8 and Eq. [20]. Specifically, all tie triangles studied in the lithium-manganese-oxygen ternary system have Li_2O present as one phase, but the two higher voltage triangles have ternary oxide phases present—not just binary oxides as used in the analytical derivation shown

Fig. 6. Constant voltage plateaus found in the (a, top) Li-Mn-O, (b, middle) Li-Fe-O, and (c, bottom) Li-Co-O ternary systems at 400°C.

Fig. 7. Phase equilibria in the (a, top) Li-Mn-O, (b, middle) Li-Fe-O, and (c, bottom) Li-Co-O ternary systems at 400°C.

above. However, their lithium and oxygen activities were still found to obey Eq. [20]. Conversely, two tie triangles studied in the lithium-iron-oxygen system have binary oxides, yet contain no Li₂O. They, too, were found to follow this relation.

This correlation may be extended to tie triangles not containing Li₂O, so long as the ternary oxide phases of

which the tie triangles are composed are only marginally stable with respect to Li₂O and their neighboring binary oxides. The marginal stabilities of most ternary oxides studied in this work explain why the tie triangles cited above in the manganese and iron systems correspond closely to this relation, although it is strictly valid only for tie triangles containing Li₂O and binary transition metal oxides. That is, a ternary oxide

Fig. 8. Relation between tie triangle voltages and equilibrium oxygen partial pressures in Li-M-O systems at 400°C.

which is only marginally stable with respect to other oxides behaves as though it were composed of the proper amounts of Li₂O and binary oxide MO_y, for which the E vs. p_{O_2} derivation is exact.

Furthermore, tie triangles with phases much more thermodynamically stable than their "weighted averages" will deviate from this relation in a predictable manner. Tie triangles with reactant phases significantly more stable than their "weighted averages" will have voltages lower than those predicted by this relation. Conversely, triangles with product phases significantly more stable than their "weighted averages" will have voltages higher than those predicted by this relation.

An example of the latter is given by the LiCoO₂, CoO, Co tie triangle, which has an equilibrium oxygen partial pressure of 10⁻³⁰ atm (the same as that between CoO and Co). The voltage vs. Li predicted by Fig. 8 is 1.684V, but was found experimentally to be 1.807V. The voltage of 1.684V would have been observed had the ternary compound LiCoO₂ not existed. The fact that it is considerably more stable (14.9%) than the "weighted average" increases the voltage to 1.807V, since in this triangle, LiCoO₂ is a product phase.

Conclusions

The free energies of formation of four intermediate ternary oxides (LiMnO₂, Li₅FeO₄, LiFeO₂, and LiCoO₂) were determined from electrochemical experiments,

and found to be -178.21, -399.88, -154.18, and -131.62 kcal/mol, respectively, at 400°C. Lithium could be reversibly reacted with these oxides at current densities of 5-15 mA/cm² over a range of 0.0-3.0 eq/mol at voltages of 1.0-1.8V vs. Li. Compounds lying closer to the oxygen corner of these ternary lithium-metal-oxygen systems yield higher cell voltages, because these higher oxides represent less stable compounds. They therefore yield greater energy when reduced to more stable compounds during the electrochemical reactions which occur within the cell. This effect, unfortunately, is somewhat limited by the fact that the highest oxides of each system have been found to reduce to lower oxides when placed in the molten salt electrolyte. That is, their equilibrium oxygen partial pressure is too high when in contact with the LiCl-KCl salt. For instance, MnO₂, LiMn₂O₄, V₂O₅, CuO, and Cu₂O yield very high theoretical voltages vs. lithium, but were found to reduce when placed in molten LiCl/KCl salt. The linear relationship between cell voltage (E) and oxygen potential ($\ln p_{O_2}$) imposes a maximum cell voltage of 1.820V vs. Li on cells utilizing oxide cathode materials in contact with LiCl/KCl molten salt electrolyte at 400°C. For a limit of 10⁻²⁵ atm, the $[RT/(4F) \ln p_{O_2}]$ term of Eq. [20] represents a loss of 0.835V from an idealized lithium/oxygen (1 atm) cell, which would have an equilibrium voltage of 2.654V.

The oxygen partial pressure limit of 10⁻²⁵ atm ($E = 1.820V$) imposed by the LiCl/KCl electrolyte or its surroundings represents, perhaps, the largest impediment to the development of even more desirable oxide cells. So long as an alloy of lithium (e.g., Li-Al or Li-Si) is required in the anode compartment, the specific energy of a cell cannot be increased significantly by simply finding longer plateau materials. This is because the additional energy of reaction obtained from longer plateau materials is offset by the weight of the additional allowing element required. Therefore, the specific energy of these cells can be significantly increased only by increasing their operating voltages, which requires that the oxygen partial pressure limit be increased.

ABSTRACT

The influence of lattice defects produced by mechanical polishing of the surface upon the photoelectrochemical properties of polycrystalline SrTiO₃ anodes was investigated. The lattice defects were correlated to various subbandgap energy levels. Part of them were attributed to local Ti-O bond weakening; they should lie close to the bandedges thus causing a tailing of the bandgap absorption and a shift of the flatband potential towards more positive values. Deeper subbandgap states resulting from Ti-O bond breaking should render the semiconductor strongly sensitive to visible light. However, these lattice defects should also act as recombination centers causing a decrease of the hole diffusion length and therefore a decrease of the photocurrent efficiency.

Suitable semiconducting anodes for photoelectrolysis of water must satisfy the following main conditions: (i) chemical stability against photocorrosion; (ii) a bandgap small enough (~ 2.3 eV) for maximum efficiency; (iii) ability to spontaneously drive the photodecomposition of water. This last condition requires that the conduction bandedge is well above the H⁺/H₂ redox potential in the aqueous electrolyte.

n-type SrTiO₃ has attracted widespread attention because of its chemical stability. Besides, it requires no biasing to generate H₂ and O₂: its low electron affinity fixes the bottom of its empty Ti⁴⁺:3d conduction bandedge above the H⁺/H₂ redox level (1). Unfortunately, the very large bandgap energy, $E_g = 3.2$ eV for the intrinsic material (2), precludes its use for solar energy conversion. A strategy to partially eliminate this above inconvenience consists of doping the semiconductor with Cr³⁺, either homogeneously (1, 3) or by diffusion from the surface at high temperature (4). Thus, a new cathodic Cr³⁺:3d³ valence band is formed inside the bandgap, giving rise to an impressive photosensitization at high anodic bias due to Cr³⁺ to Ti⁴⁺ charge transfer. However, under the normal working conditions required for a photocell, i.e., no bias and steady illumination, the quantum efficiency both for visible and UV light is too low because the chromium levels also act as recombination centers which lower the photoresponse (3).

Some of us have also reported that SrTiO₃ electrodes become strongly sensitive to visible light by appropriate surface pretreatments such as mechanical polishing (5, 6). As shown in Fig. 1, the visible response was related to the existence of [O:2p]_{bb} and [Ti:3d(t_{2g})]_{bb} subbandgap states [bb is the bond-breaking associated with broken Ti-O bonds produced by the abrasion of the surface (6)]. On the other hand, it is well known that lattice defects produced by mechanical polishing of ZnO (7), GaAs (8), or TiO₂ electrodes (9, 10) act as traps for electrons and holes, leading to an increased recombination and so to a significant diminution of the photocurrent.

In the present work, the photoelectrochemical behavior of polished SrTiO₃ polycrystalline anodes, designated as [pol-SrTiO₃], is compared with that of unpolished samples symbolized by [o-SrTiO₃]. This comparative study is based upon the determination, from

voltage and wavelength dependences of the quantum efficiency, of the physical parameters determining the behavior of the electrodes.

Experimental

Details concerning the anode fabrication and the surface treatment have already been reported (5). The

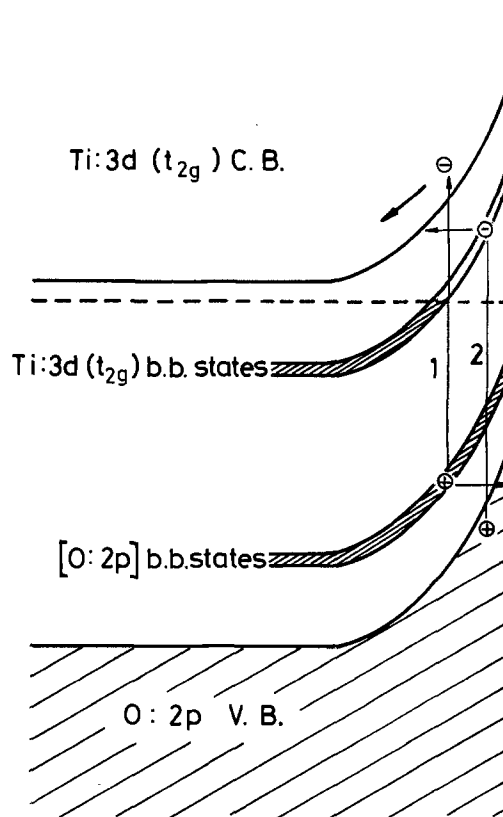

Fig. 1. Schematic illustration of the visible photoconduction mechanisms giving rise to a visible photocurrent: electrons can be photoexcited from the occupied [O:2p]_{bb} states to the conduction band (process 1) or from the valence band to empty [Ti:3d(t_{2g})]_{bb} states (process 2).

Key words: junctions, semiconductor, energy conversion.

experimental apparatus used for the electrochemical measurements has also been described previously (11). The electrolyte was a 1M Na₂SO₄ solution; the pH = 3 was adjusted by addition of H₂SO₄. The electrode potentials are quoted relative to the saturated calomel electrode (SCE). The photoelectrode was illuminated with a 150W Xe lamp followed by a Bausch & Lomb grating monochromator. Photocurrent efficiencies were measured with a high impedance HP 3478 A programmable multimeter coupled to a 4032 Commodore computer. The photon flux reaching the electrode surface was determined by means of a calibrated EG&G 4000 B silicon photovoltaic detector.

The real part of the relative permittivity (ϵ_r) of the sample was deduced from capacitance measurements using a 1680 General Radio capacitance bridge.

A Keithley high impedance multimeter allowed accurate determination of the sample conductivity.

Results

Emphasis was given to the photocurrent efficiency η calculated from

$$\eta = \frac{i_{(\text{light})} - i_{(\text{dark})}}{qI_0} \quad [1]$$

where $i_{(\text{light})}$ and $i_{(\text{dark})}$ are current densities under illumination and at dark, respectively, I_0 represents the photon flux absorbed by the photoelectrode, and q is the electronic charge.

Reflectivity of the samples was measured with a Cary 17 spectrophotometer. Polishing produced no noticeable change in reflectivity in the UV region ($\lambda < 370$ nm), while it decreased the reflectivity in the visible region (Fig. 2).

Photocurrent efficiency-voltage (η -V) and photocurrent efficiency-wavelength (η - λ) characteristics.—Figures 3a and 3b show typical η -V curves at 370 nm (bandgap illumination) and at 470 nm (subbandgap illumination). The η - λ dependences are given in Fig. 4 at 1V vs. SCE.

A substantial increase of the pol-SrTiO₃ photoreponse to visible light can be observed. However, a substantial decrease of the efficiency in the UV region is also observed. These effects were observed in all of the samples studied.

Fig. 2. Influence of polishing on the diffuse reflectance spectrum of sintered polycrystalline SrTiO₃.

Fig. 3. Photocurrent efficiency vs. potential: (a, top) $\lambda = 370$ nm; (b, bottom) $\lambda = 470$ nm.

Flatband potential V_{FB} and ionized donor density concentration, N_D .—These parameters can be reasonably estimated from the theory of depletion layer photoeffects developed by Gärtner (12) and discussed by several authors (13-16). Using this model, Kennedy and Frese (13) calculated that

$$\ln(1 - \eta) = -\alpha W - \ln(1 + L_p) \quad [2]$$

where α is the semiconductor absorption coefficient, L_p is the hole diffusion length in the bulk (outside the

Fig. 4. Photocurrent efficiency-wavelength dependence at 1V (vs. SCE).

depletion layer), and W is the depletion layer width given by

$$W = \left(\frac{2\epsilon_r\epsilon_0}{qN_D} \right)^{1/2} (V - V_{FB})^{1/2} \quad [3]$$

where ϵ_r and ϵ_0 have the usual meaning and $(V - V_{FB})$ is the band bending with V_{FB} being the flatband potential.

Implicit in Eq. [2] is also the absence of carrier recombination at the semiconductor-electrolyte interface, i.e., that the transfer of holes from the semiconductor to the electrolyte is not the limiting step (17). This has been proved to be valid at sufficiently large voltages [$(V - V_{FB}) > 1V$] for several sintered semiconducting electrodes including undoped TiO_2 (11), Al- and Nb-doped TiO_2 (18, 19), and $BaTiO_3$ (13). We have recently shown (20) that a source of surface electron-hole recombination at low band bending is the reduction by conduction band electrons of species photogenerated during water photoelectrolysis, such as O_2 and H_2O_2 . This recombination process, with rates depending on $(V - V_{FB})$, is independent of the physical bulk properties of the semiconductor and represents a general limitation of Eq. [2] for most oxide photoanodes.

Provided that $\alpha L_p \ll 1$, i.e., $1 + \alpha L_p \approx \alpha L_p$, Eq. [2] can be written

$$\ln(1 - \eta) = -\alpha(W + L_p) \quad [4]$$

Besides, if $W \gg L_p$ one gets

$$\ln(1 - \eta) = -\alpha W \quad [5]$$

These two assumptions are generally valid for penetrating radiations ($\alpha > 10^4 \text{ cm}^{-1}$) and for not heavily doped semiconducting oxides ($N_D \leq 10^{18} \text{ cm}^{-3}$) (21).

Combination of Eq. [3] with Eq. [5] leads after squaring to

$$[\ln(1 - \eta)]^2 = \frac{2\alpha^2\epsilon_r\epsilon_0}{qN_D} (V - V_{FB}) \quad [6]$$

According to Eq. [6], the plot of $[\ln(1 - \eta)]^2$ vs. potential should be linear, the intersection with the abscissa giving V_{FB} .

Figure 5, deduced from Fig. 3a, shows $[\ln(1 - \eta)]^2$ vs. potential curves at 370 nm. They present a good linearity above 0.5V (SCE), i.e., for $V - V_{FB} \geq 1.1V$. Gärtner's model does not apply at lower band bendings because of electron-hole recombination at the electrode surface (20) and also at the depletion layer for the polished sample (see Discussion).

The flatband potentials obtained by extrapolation are given in Table I. These values are in good agreement with those obtained from the UV photocurrent onset potential (Fig. 3a). Besides, the donor density concentration, N_D , can be calculated from the slope of the plots, provided the real part of the relative permittivity, ϵ_r , and the absorption coefficient at 370 nm are known. A frequency-independent value of 200 was obtained for ϵ_r in the range from 0.1 to 100 kHz, and α (370 nm) is $2.6 \times 10^3 \text{ cm}^{-1}$ (22). The calculated N_D values are included in Table I. It is to be remarked that the difference in N_D between the polished and the unpolished samples is a real effect and not an apparent one due to changes in reflectivity, as polishing has nearly no effect on the diffuse reflectivity in the UV range (see Fig. 2).

Bandgap energy, E_g .—This parameter is contained, together with the incident photon flux $h\nu$, in the following expression valid for indirect bandgap semiconductors, as is the case for $SrTiO_3$ (23)

$$\alpha = A \frac{(h\nu - E_g)^2}{h\nu} \quad [7]$$

where A is a constant.

Algebraic manipulation of Eq. [4] and [7] leads to

$$[-h\nu \ln(1 - \eta)]^{1/2} = A^{1/2} (W + L_p)^{1/2} (h\nu - E_g) \quad [8]$$

Fig. 5. Determination of V_{FB} and N_D from $[\ln(1 - \eta)]^2$ vs. potential plots at $\lambda = 370 \text{ nm}$.

Table I. Experimental physical parameters at room temperature for the samples studied

	$\sigma/0^{-1} \cdot \text{cm}^{-1}$	V_{FB} (V)	N_{D} (10^{17}cm^{-3})	E_{g} (eV)	L_{p} (cm)	W (10^{-5}cm) at 1V vs. SCE
o-SrTiO ₃	10 ⁻³	-0.70	1.7	3.15	3.1×10^{-6} (370 nm)	4.7
pol-SrTiO ₃	10 ⁻³	-0.60	3.1	2.95	9.6×10^{-7} (370 nm) 6×10^{-7} (470 nm)	3.4

Therefore, a plot of $[-h\nu \ln(1-\eta)]^{1/2}$ against $h\nu$ allows the determination of E_{g} .

Figure 6, obtained from Fig. 4, shows a linear variation of $[-h\nu \ln(1-\eta)]^{1/2}$ vs. $h\nu$ (for $h\nu > 3.3$ eV). The intercept with the $h\nu$ axis gives the E_{g} value (Table I).

Hole diffusion length, L_{p} .—Equation [2] allows L_{p} to be estimated. By introducing the value of W in Eq. [2] it can be written

$$-\ln(1-\eta) = \alpha W_0 (V - V_{\text{FB}})^{1/2} + \ln(1 + \alpha L_{\text{p}}) \quad [9]$$

where, for the sake of clarity, the ratio $(2\epsilon_r \epsilon_0 / q N_{\text{D}})^{1/2}$, whose parameters are now known, is designated as W_0 .

According to Eq. [8], the plot of $-\ln(1-\eta)$ vs. $(V - V_{\text{FB}})^{1/2}$ should be linear with a slope $S = \alpha W_0$ and an intercept

$$\ln(1 + \alpha L_{\text{p}}) = \ln \left(1 + \frac{S}{W_0} L_{\text{p}} \right)$$

from which L_{p} is obtained without needing to know the value of α .

Figures 7a and 7b are the corresponding plots at 370 nm for both samples and at 470 nm for [pol. SrTiO₃]. They are deduced from Fig. 3a and 3b and from the previously determined V_{FB} . Straight lines are obtained at high anodic bias where recombination does not exist and Gärtner's model applies. From extrapolation of the straight line obtained by minimum least squares fitting, reliable L_{p} values can be obtained. They are included in Table I. As can be seen, the assumption $W \gg L_{\text{p}}$, which allowed V_{FB} and N_{D} to be determined through Eq. [5], is now justified. The error in V_{FB} which is incurred by neglecting L_{p} in Eq. [9] is 0.09V which is not significant because the accuracy in η is not better than $\pm 10\%$, at the most.

Discussion

The two main effects of polishing on the photoelectrochemical properties of sintered n-SrTiO₃ electrodes are sensitization to visible light and decrease of the photoresponse to UV radiation. This qualitative behavior has been found to be general for the different samples studied, and has been discussed elsewhere (6). On the other hand, in an attempt to correlate this behavior with the physical properties of the electrodes, we have shown that Gärtner's model holds for the sc-electrolyte junction in the band bending region ($V - V_{\text{FB}} > 1.1\text{V}$) of negligible electron-hole recombination, both in the sc surface and in the depletion region. The experimental data shown in Table I should not be considered as reproducible to the last significant figure for different n-SrTiO₃ samples, but as typical of the effect of polishing on the physical parameters of n-SrTiO₃. A more precise study should compare measurements on several samples and probably should take into account additional information about the polishing effects; however, this exceeds the aim of the present work.

The main features observed in Table I, that polishing brings about, are a shift of V_{FB} towards positive values, an apparent increase of N_{D} , and a noticeable decrease of both E_{g} and L_{p} . The increase of N_{D} upon polishing has also been reported to occur with TiO₂ (24) and ZnO (25). This result is not surprising since lattice defects can behave as hole traps at the illuminated electrode, giving rise to an accumulation of positive charge in the depletion layer and to an apparent increase of the donor concentration. The decrease of E_{g} , as well as the positive shift of V_{FB} , could reasonably be related to a tailing of the band gap absorption due to energy states near the bandedges. These states are very likely associated with Ti—O bonds whose co-

Fig. 6. Determination of E_{g} from the variation of $[-h\nu \ln(1-\eta)]^{1/2}$ as a function of $h\nu$ at 1V (vs. SCE).

Fig. 7. Determination of L_p from $\ln(1-\eta)$ vs. $(V - V_{FB})^{1/2}$ plots. The straight lines were obtained by minimum least squares fitting of the experimental points with the following correlation factors: (a, top) 0.999 for $[o\text{-SrTiO}_3]$ and 0.997 for $[\text{pol-SrTiO}_3]$ ($\lambda = 370$ nm); (b, bottom) 0.998 for $[\text{pol-SrTiO}_3]$ ($\lambda = 470$ nm).

valency is weakened in the disordered lattice. A Ti—O bond weakening means that locally the splitting between the oxygen: 2p orbitals and the titanium: 3d (t_{2g}) orbitals is reduced. This originates $[O:2p]_{bw}$ and $[Ti:3d(t_{2g})]_{bw}$ subbandgap states (bw meaning bond weakening) close to the valence and conduction bands, respectively. As the flatband potential of the polished sample is 0.1V less negative than that of the unpolished electrode, the $[Ti:3d(t_{2g})]_{bw}$ centers should approximately lie within 0–0.1 eV below the conduction band of the unpolished sample. Besides, $E_g[o\text{-SrTiO}_3] - E_g[\text{pol-SrTiO}_3] \approx 0.2$ eV; thus, the $[O:2p]_{bw}$ levels lie within 0.1 eV above the unperturbed valence band. The shoulder in the η - λ action spectrum observed at 410 nm (3.0 eV) can be attributed to these levels (dashed line of Fig. 4). As illustrated in Fig. 8, the Ti—O bond weakening must not be misunderstood with the Ti—O bond breaking that introduces the above mentioned $[O:2p]_{bb}$ and $[Ti:3d]_{bb}$ centers.

Finally, we must remark that the charging of the tailing surface-state band generated by polishing, which is accompanied by a decrease of the net negative surface charge, could also contribute to the observed shift of V_{FB} in the anodic direction.

Figure 4 clearly shows that bandgap states generated during polishing have a deleterious effect on the

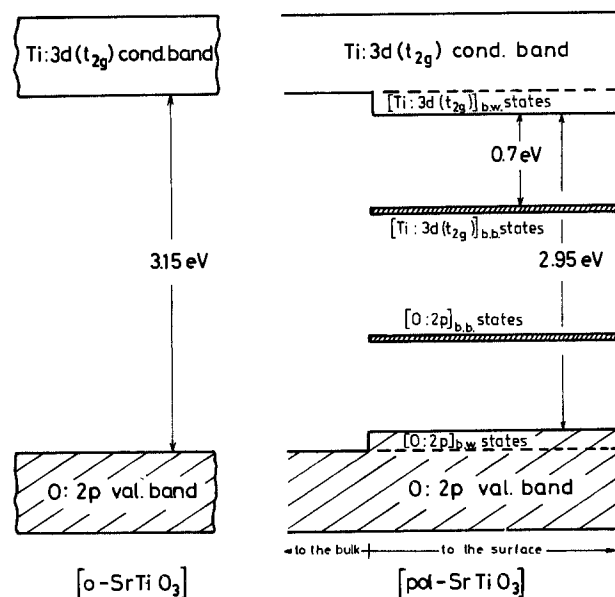

Fig. 8. Schematic of the modification of the band structure near the surface of $[\text{pol-SrTiO}_3]$.

UV photocurrent efficiency. Their influence can be described as follows.

In Eq. [2], absence of recombination at the depletion layer was assumed. However, this assumption cannot apply in the presence of a high density of recombination centers, as has been recently treated by Jarrett (26). In fact, for a hole to reach the interface with the electrolyte, its lifetime τ_r must be equal to or greater than its transit time τ_t across the electric field. Introducing the concept of "gain" used in photoconductivity experiments, it must be $Q \equiv \tau_r/\tau_t \approx 1$.

Q can be written (27)

$$Q = \frac{L_p^2 q^2 N_D}{2\epsilon_r \epsilon_0 kT} \quad [10]$$

where we distinguish the hole diffusion length in the depletion layer, L'_p , from L_p in the bulk. Then the condition for efficient electron-hole separation in the electric field region becomes (27)

$$L_p'^2 \cdot N_D \geq \frac{2\epsilon_r \epsilon_0 kT}{q^2} \quad [11]$$

For $Q < 1$, Eq. [5] (which applies to electron hole pairs generated within the depletion layer) must be written

$$\eta = Q[1 - e^{-\alpha W}] \quad [12]$$

According to Eq. [2], all the electron-hole pairs photo-generated within a $(L_p + W)$ distance from the surface must participate efficiently in the photocurrent, provided that $Q \geq 1$. A simple calculation making use of the data of Table I shows this to be the case for the unpolished sample. So, applying Eq. [11], it can be shown that $L'_p \geq 7.5 \times 10^{-6}$ cm and therefore $L'_p \geq 2.4 L_p$.

On the other hand, the net decrease in the quantum efficiency in the UV region for the polished electrode (Fig. 4) cannot be explained by a simple decrease of W and L_p (Table I). In fact, let us compare for instance η_{max} in Fig. 3 at 340 nm for the two samples. Since $Q \geq 1$ for the unpolished electrode, we can write according to Eq. [4]

$$\begin{aligned} \ln(1 - 0.41) &= -\alpha_{340 \text{ nm}}(W + L_p) \\ &= -\alpha_{340 \text{ nm}} \times 5.01 \times 10^{-5} \quad [13] \end{aligned}$$

Hence, $\alpha_{340 \text{ nm}} = 1.05 \times 10^4 \text{ cm}^{-1}$. Using the same reasoning for the polished sample, and assuming the

same $\alpha_{340 \text{ nm}}$, it should be for $Q \leq 1$ and $(L_p + W) = 3.5 \times 10^{-5}$ (Table I)

$$\eta = 1 - e^{-(L_p + W)} = 0.31 \quad [14]$$

This value is higher than the experimental one of 0.24. Obviously this discrepancy in η must result from partial recombination inside the depletion layer.

The actual value of Q can be given by the relation between both values of η , i.e., $Q = 0.24/0.31 = 0.78$, which upon insertion in Eq. [10] gives us: $L'_p = 3.7 \times 10^{-6}$ cm.

The influence of polishing on the recombination process could therefore be summarized in the following way: $[0:2p]_{bb}$ and $[\text{Ti}:3d(t_{2g})]_{bb}$ levels generated in the bandgap act as hole and electron traps, respectively, producing a measurable decrease of the carrier lifetime. In the perturbed layer, but outside the depletion layer, L_p decreases by a factor of ~ 3 ; this decrease does not affect η , as $W \gg L_p$. This factor cannot be calculated in the depletion layer (i.e., for L'_p), but it is expected to be considerably greater than that obtained for L_p , since for the unpolished sample it has been shown that $L'_p > 2.4 L_p$ (probably $L'_p \gg L_p$), while for the polished one it is only $L'_p \sim 5 L_p$. Consequently, the decrease of the quantum efficiency in the UV region after polishing is mainly due to increasing electron-hole recombination inside the electric field region. These results are in agreement with the model proposed recently by Lam and Franceschetti (28) for undoped and transition metal-doped sintered semiconducting oxide photoanodes, which took into account recombination of carriers within the depletion layer.

Recently, Praet *et al.* (10), working with TiO₂ single-crystal electrodes, arrived at the conclusion that polishing reduces L_p by a factor ranging from 3 to 183. Only the lowest value is comparable to that found in this work for polycrystalline SrTiO₃.

It becomes apparent that the optimum photoresponse is not necessarily achieved by enhancing the polishing effect in order to create a larger density of subbandgap states, but by balancing the losses due to recombination against the increase of the photoresponse in the visible region. It must also be pointed out that the holes photogenerated in the polished sample by visible ($\lambda = 470$ nm) and UV ($\lambda = 370$ nm) light have quite similar L_p values (Table I). If the visible response observed for $[\text{pol-SrTiO}_3]$ electrode was mainly due to carrier excitation from the $[0:2p]_{bb}$ states to the conduction band (Fig. 1, mechanism 1), much lower values of L_p would then have been obtained for $\lambda = 470$ nm than for $\lambda = 370$ nm, due to a partial localization of the photogenerated holes into the $[0:2p]_{bb}$ centers (small

polarons). As this does not occur, most of the holes are photogenerated in the valence band of $[\text{pol-SrTiO}_3]$ electrode. Consequently, the visible photocurrent should be mainly due to electron excitation from the valence band to the empty $[\text{Ti}:3d]_{bb}$ subbandgap states, followed by tunneling to the conduction band (Fig. 1, mechanism 2).

Vacuum Evaporated CdSe_{1-x}Te_x Thin Films for Electrochemical Photovoltaic Cells

Michael A. Russak and Charles Creter

Grumman Aerospace Corporation, Research and Development Center, Bethpage, New York 11714

ABSTRACT

CdSe_{1-x}Te_x thin films have been produced over a wide range of x values by concurrent vacuum evaporation of the constituent elements. The most consistent results in terms of producing single-phase material were obtained when substrate temperatures were in the range of 350°-450°C. Photoelectrochemical evaluation of the resultant thin films indicated postdeposition heat-treatment and surface etching were necessary to maximize photovoltaic outputs. A dependence of photoelectrochemical behavior, bandgap, and efficiency on x value was also found. The maximum efficiency recorded was 7.4% for a CdSe_{0.8}Te_{0.2} composition under simulated AM2 conditions.

The thin film CdSe/aqueous sulfide-polysulfide photoelectrochemical system has received a great deal of attention in recent years as a potentially practical, low-cost system for photovoltaic applications (1-6). However, even though CdSe electrodes with sunlight conversion efficiencies (η) of over 6% have already been reported (7), the bandgap of CdSe (1.72 eV) is not ideally matched to the solar spectrum. This may be ultimately a limitation on obtaining conversion efficiencies in excess of 10% when counterelectrode polarization losses are encountered in actual cell structures. Ideally, a semiconductor with a bandgap of 1.45 eV, such as CdTe, would provide the maximum photovoltaic efficiency for terrestrial applications (*i.e.*, AM1 to AM2 conditions) (8, 9). However, CdTe has been reported to be stable in selenide and telluride containing electrolytes, but only partially stable in sulfide containing electrolytes. The highly colored nature of the former electrolytes diminishes the advantage of the more favorable bandgap by increasing the short wavelength photocurrent losses. As a result, no significant improvement in efficiency of the CdTe/Se_n⁻² system compared to the CdSe/S_n⁻² system has been reported (10). Also, the extreme air sensitivity of the selenide and telluride containing electrolytes presents a problem for practical devices.

Fortunately, a promising compromise has been identified where polycrystalline electrodes have been produced from mixtures of CdSe and CdTe that have a bandgap of ~1.45 eV and the photovoltaic output stability of CdSe alone in sulfide-polysulfide electrolyte (11, 12). In particular, an electrode of CdSe_{0.65}Te_{0.35} composition prepared by sintering a mixture of CdSe and CdTe has been produced with η ~8% (11).

We have found that CdSe_{1-x}Te_x alloy films for photoelectrochemical solar cells can also be produced by a concurrent elemental vacuum evaporation technique. This paper presents our findings on the evaluation of these thin film electrodes in aqueous sulfide-polysulfide electrolyte.

Experimental

CdSe_{1-x}Te_x thin films were deposited by the concurrent vacuum evaporation of the constituent elements from three independently controlled resistive heated sources arranged in a parallel geometry. Each source was controlled by a microprocessor-driven feedback controller activated by an oscillating quartz crystal monitor. The actual vacuum system used is shown in Fig. 1, with the three automatic deposition controllers (Sloan Technology Corporation, Santa Barbara, California) in the background. The key feature of this system is the tubular shielding arrangement of the crystal monitors by which no interference between deposition

sources is registered. The vertical baffles between sources minimize extraneous heating of one source by the adjacent one, which could otherwise be a problem due to the low power level required to evaporate the elements used. High purity (5N⁺ or 6N) elements in 1-5 mm shot form were used as the source materials (Alpha Division, Ventron Corporation, Danvers, Massachusetts, or Atomergic, Incorporated, Plainview, New York).

Individual depositions of each element indicated that there was approximately a 10% thickness gradient for Se in going from left to right across the 12 cm substrate holder. The Te gradient is also about 10% in the opposite direction. The thickness of Cd was found to vary by less than 5% in going from the center to the edges of the substrate holder. To minimize the effect of these gradients, the substrates were placed in a 5 × 5 cm area in the center of the substrate holder for the ternary evaporations. The source to substrate distance was 45 cm. The substrates were titanium sheet (0.25 mm) that had been carefully cleaned and then etched in a dilute HCl:HF etchant to provide a slight surface roughness, which promoted good film adherence. The substrates were clamped to the copper-block substrate holder, into which cartridge-type heaters and a thermocouple were inserted to provide substrate temperature control during the deposition. Tantalum

Fig. 1. Triple source vacuum deposition system used to produce CdSe_{1-x}Te_x thin film.

Key words: semiconductor, thin films, electrolyte, energy conversion.

buffed evaporation boats, the type commonly used for silicon monoxide evaporation, were used for the Cd and Se, but the Te reacted with the tantalum boats and an Al₂O₃ crucible was used.

Qualitative chemical analysis of the thin films was done by energy dispersive analysis of x-rays (EDAX) at Grumman, and quantitative compositional data were generated using a wavelength dispersive electron microprobe (EPMA) at the Solar Energy Research Institute (SERI, Golden, Colorado). X-ray diffraction analysis was done using a diffractometer with CuK α radiation.

The thin film electrode mounting procedures and photoelectrochemical test fixturing employed have been described previously (3). I-V characteristics were measured in aqueous 2.5M Na₂S-1M S-1M KOH electrolyte using a platinum counterelectrode and a saturated calomel reference electrode in a standard potentiostatic arrangement. White light measurements were done using a simulated AM2 spectrum provided by a W-I ELH lamp mounted in a dichroic parabolic reflector (13). A 0.25m grating monochromator with a 1000W Xe light source was used to generate monochromatic I-V curves and spectral response data. All light intensities were measured with a calibrated thermopile detector.

Results and Discussion

Thin film deposition.—Several deposition parameter-variation studies were conducted in order to establish the relationships among deposition conditions, resultant film composition and structure, optical and electronic properties, and current-voltage behavior. Three critical deposition parameters for producing single-phase, crystalline ternary thin films of a specific composition were found: substrate temperature (T_s), the Se to Cd atomic vapor stream ratio, and the total Se + Te to Cd atomic vapor stream ratio. The most critical steps in optimizing the photovoltaic output of the ternary thin film electrodes were postdeposition heat-treatment and chemical surface treatment (etching) of the heat-treated electrodes.

Based on previous experience with producing CdSe thin film electrodes by vacuum evaporation, two deposition regimes were investigated in the most detail (3, 5, 14). Initially, a series of ternary depositions was done, during which T_s was held at 100°C, the total Se + Te to Cd atomic ratio was set at three, and the ratio of Se to Te was varied. This general approach was analogous to that taken in producing the CdSe films deposited with excess Se, which have produced the highest efficiencies reported to date (3, 6). The composition and associated EDAX spectra (after firing at 500°C for 15 min) for this series of depositions are shown in Fig. 2. The variation of I-V performance for these films, which were only partially crystalline as deposited, was found to depend on postdeposition heat-treatment temperature, time, and atmosphere. Heat-treatment in the range of 400°-500°C in air produced the electrodes with the best photovoltaic output ($\eta \sim 5\%$, AM2), which is similar to the results obtained in the CdSe system. However, measurement of the action spectra of these electrodes showed very little extension of response into the near IR, as would be expected with the addition of increasing amounts of Te into this alloy system. X-ray diffraction analysis revealed the films were a mixture of CdSe and TeO₂ rather than a CdSe expanded lattice as would be expected with the addition of up to 0.22 mol fraction Te (15, 16). So, even though the presence of Te was maintained in these films throughout their processing, as indicated by EDAX, it was incorporated in a nonphotoactive manner in the final processed electrode. Post-deposition processing in vacuum or inert gas atmosphere was not successful in producing good photovoltaic quality CdSe_{1-x}Te_x material from films deposited under these conditions.

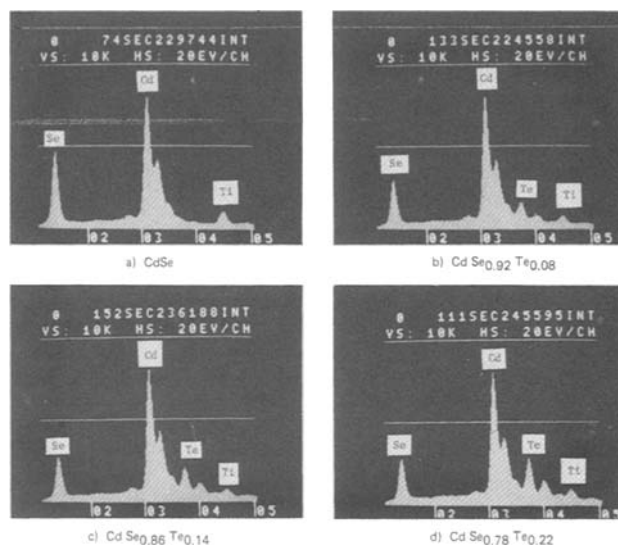

Fig. 2. EDAX spectra showing variation in relative amounts of Se and Te in alloy films deposited at 100°C and heat-treated at 500°C in air.

As a result of these findings, it was concluded that a better approach to producing single-phase CdSe_{1-x}Te_x films would be to insure the selected compound formation by deposition at high T_s followed by subsequent heat-treatment to optimize I-V output. It was found that a full range of single-phase crystalline CdSe_{1-x}Te_x films ($0 \leq x \leq 0.53$) could be produced by the direct reaction of the elements on substrates held at 300°-450°C. At temperatures below 300°C, the films were generally only partially crystallized, whereas at $T_s > 450^\circ\text{C}$, even though the films were crystalline, film adherence was poor and Te could not always be put in the film. The actual x value in the as-deposited ternary film was found to depend on the Se to Cd ratio during deposition and T_s . This is shown in Table I, where the dependence of alloy composition on this ratio is presented for $T_s = 400^\circ\text{C}$. X-ray diffraction analysis indicated that all these films were single-phase material with a strong texture. Films A through E had hexagonal wurtzite structures, with lattice parameters increasing with increased Te content, whereas film F had a cubic sphalerite structure. These findings are in agreement with those already reported for this alloy system (15, 16). The columnar microstructure of these films was quite evident, as shown in Fig. 3, which is a scanning electron micrograph of film C. Another trend in the ternary films was that at a constant Se to Cd ratio and fixed Te rate, less Te was incorporated into the film as T_s was increased. This behavior is shown in Table II for atomic vapor stream ratios of 0.63 to 1 to 0.9 for Se, Cd, and Te, respectively. The data trends summarized in Tables I and II indicate that thermodynamically it is easier to form CdSe than to

Table I. Dependence of thin film composition* on Se to Cd atomic vapor stream ratio at $T_s = 400^\circ\text{C}$

Sample	Atomic ratio (calculated) Se: Cd**	Composition (a/o)			Atomic ratio (measured) Se: Cd
		Cd	Se	Te	
A	0.90	51.06 ± 1.42	48.38 ± 1.35	0.56 ± 0.07	0.95
B	0.80	51.10 ± 1.93	46.22 ± 1.74	2.67 ± 0.88	0.90
C	0.63	51.53 ± 2.57	39.76 ± 1.98	8.72 ± 0.43	0.77

form the $\text{CdSe}_{1-x}\text{Te}_x$ ternary when sufficient Se is present. This is consistent with the difference in heats of formation for CdSe and CdTe (17).

The compositional uniformity of the thin films produced by the elemental evaporation method was checked using the electron microprobe. Figures 4-6 show the composition variation found in a CdSe, a CdTe, and a $\text{CdSe}_{0.8}\text{Te}_{0.2}$ (film C, Table I) film all deposited at $T_s = 400^\circ\text{C}$. As can be seen from these results, there is very little compositional variation.

Photoelectrochemical evaluation.—As found with CdSe thin films produced by elemental evaporation, the as-deposited $\text{CdSe}_{1-x}\text{Te}_x$ films exhibited very poor photovoltaic response. It was therefore necessary to heat-treat them to optimize their I-V performances (5). Postdeposition heat-treatment in air in the range of 400°C – 450°C provided the best photovoltaic performance. The relationship between optical bandgap and ternary composition was determined by noting the longest wavelength of light for which a photocurrent was observed for each electrode. In these experiments, a polysulfide electrolyte was used for junction formation. The electrodes were photoetched before testing (18, 19), then held in reverse bias to insure prompt photogenerated carrier separation. Lock in detection was used to measure the photoresponse. The results

Table II. Variation in Se and Te content of $\text{CdSe}_{1-x}\text{Te}_x$ thin films with T_s for Se: Cd: Te ratio of 0.63:1:0.9

T_s ($^\circ\text{C}$)	Composition (a/o)		
	Cd	Se	Te
350	51.22 ± 0.60	35.62 ± 0.42	13.16 ± 0.04

400	51.53 ± 2.57	39.76 ± 1.98	8.72 ± 0.43
425	51.10 ± 1.52	47.22 ± 1.30	2.30 ± 0.21
450	50.58 ± 1.01	49.42 ± 0.98	< 1

are summarized in Fig. 7. The E_g values used for CdSe and CdTe in this figure were determined for thin film electrodes deposited by coevaporation of Cd + Se and Cd + Te, respectively, at $T_s = 400^\circ\text{C}$. There is a decrease in bandgap with increasing Te content to a minimum at an x value of ~ 0.5 , after which it increased up to the value of 1.45 eV for CdTe. It should be noted that the minimum of 1.36 eV occurs for a film that is of the cubic structure, which is in agreement with previously reported results (15, 16). The cubic phase is, however, photoelectrochemically less stable than the hexagonal phase in sulfide-polysulfide electrolyte and therefore of less interest for actual photovoltaic cell applications (16).

Photoelectrochemical performance of thin film electrodes in this alloy system was also investigated. The significant findings were that as x was increased up to 0.53, the resultant spectral response extended further into the near IR, as shown in Fig. 7. However, only for $x < 0.25$ did J_{sc} increase with the addition of Te. The flatband potential (V_{FB}), measured by determining the high intensity photocurrent onset potential, became more positive. There was less band bending in the electrode, and the open-circuit voltage (V_{oc}) decreased. Also, as the Te content increased, the light I-V curve developed a "foot" characteristic near the V_{oc} , which is indicative of a recombination-dominated behavior rather than one dictated by dark current (20). In addition, for $x > 0.25$, the photoetching treatment was less effective in improving the I-V performance. Table III summarizes the variation of V_{FB} , V_{oc} , λ_{to} (maximum wavelength of photoresponse), and maximum AM2 conversion efficiency (η_{max}) as a function of Te content. Figures 8-10 show the effect of photoetching treatment on the I-V performance of CdSe, $\text{CdSe}_{0.8}\text{Te}_{0.2}$ (film C), and $\text{CdSe}_{0.47}\text{Te}_{0.53}$ (film F) electrodes.

Fig. 4. Compositional uniformity of a CdSe film deposited by coevaporation of Cd and Se at $T_s = 400^\circ\text{C}$.

Fig. 5. Compositional uniformity of a CdTe film deposited by coevaporation of Cd and Te at $T_s = 400^\circ\text{C}$.

Fig. 6. Compositional uniformity of a CdSe_{0.8}Te_{0.2} (film C) deposited by simultaneous evaporation of Cd, Se, and Te at $T_s = 400^\circ\text{C}$.

The data in Table III indicate there is a minimum in the V_{FB} vs. composition relationship, which correlates with the minimum in the bandgap of the alloy films. The minimum also corresponds to the maximum in spectral response. This trend is contrary to that reported in the CdSe_{1-x}S_x thin film system, where a maximum in V_{FB} was found with alloy composition (21). These results are also unexpected, based on reported values of electron affinity for CdSe (4.95 eV) and CdTe (4.28 eV) (22). Since the electron affinity of the ternary should be between these two values, a more negative V_{FB} should result for the alloy film compared with CdSe. Yet, the V_{FB} of n-CdTe (single crystal) has been measured to be somewhat positive of CdSe (single crystal) (23). Although, in some cases, the conduction-band energy level of CdTe has been placed below that of CdSe on a composite redox

couple-semiconductor energy diagram, implying a more positive V_{FB} (24). There is obviously some disagreement here, and the observed variation of V_{FB} (and V_{oc}) with Te content cannot be explained solely by consideration of the electron affinities of CdSe and CdTe. It is possible that the surface condition of these electrodes changes with increasing Te content in such a manner that a change in the Helmholtz layer potential drop occurs. This drop could then shift the V_{FB} to more positive values (20). This would be consistent with the persistence of the "foot" characteristic in the I-V curves shown in Fig. 8-10 with increasing x value, even after photoetching.

Further investigation of the CdSe_{1-x}Te_x thin film characteristics was carried out by applying a Gartner model analysis, in which, if the junction is assumed to be a Schottky barrier and recombinations can be ne-

Fig. 7. Dependence of bandgap on composition in $\text{CdSe}_{1-x}\text{Te}_x$ alloy system.

glected in the space charge layer, with sufficient reverse bias the monochromatic quantum yield (ψ_m) is given by (25)

$$\psi_m = 1 - e^{-\alpha W_0} / (1 + \alpha L_p) \quad [1]$$

where α is the absorption coefficient at a particular wavelength, L_p is the minority carrier diffusion length, and W_0 is the depletion width given by

$$W_0 = (\epsilon_0 \epsilon \Delta V / 2qN)^{1/2} \quad [2]$$

where ϵ_0 is the permittivity of free space, ϵ is the semiconductor dielectric constant, ΔV is the barrier height, which has a maximum value of $[V_{\text{FB}} - V_{\text{redox}}]$, q is the elementary charge, and N the majority carrier density. If Eq. [2] is substituted into Eq. [1], then the relationship between ψ_m and the applied reverse bias voltage (V_a) can be written as

$$\ln(1 - \psi_m) = \alpha (\epsilon_0 \epsilon / 2qN)^{1/2} (V_{\text{FB}} - V_a)^{1/2} - \ln(1 + \alpha L_p) \quad [3]$$

Then a plot of $\ln(1 - \psi_m)$ vs. $(V_{\text{FB}} - V_a)^{1/2}$ should yield a straight line (at high enough reverse bias) with a slope of $-\alpha (\epsilon_0 \epsilon / 2qN)^{1/2}$ and intercept of $-\ln(1 + \alpha L_p)$, from which N and L_p can be obtained, provided α is known.

The analysis was carried out using 700 nm radiation, a wavelength where absorption occurs in the bulk of the material, thereby eliminating surface effects, and α values determined in our laboratory for the CdSe and $\text{CdSe}_{1-x}\text{Te}_x$ films in Table III. The results of this analysis indicated that the N levels were fairly constant. However, the L_p and quantum yield (ψ_m) values decreased significantly as x increased beyond 0.2. These results are summarized in Table IV. They support the explanation that, for this type of film, recombination dominates the I-V performance as x increases.

The maximum photovoltaic performance for these films was recorded for the $\text{CdSe}_{0.8}\text{Te}_{0.2}$ composition (Fig. 9); $\eta = 7.4\%$ was obtained. In this case, the photoetching treatment had a significant effect on the light

Table IV. Variation of N , L_p , and Φ_m with x for CdSe_{1-x}Te_x thin film electrodes

Sample	x value	N (cm ⁻³)	L_p (μ m)	Φ_m (at 700 nm)
A	0.00	8×10^{16}	0.38	0.62

F	0.53	7×10^{16}	0.08	0.40

and dark I-V curves. SEM micrographs of the film before and after etching (Fig. 11) reveal a selective etch pattern that increases the electrode surface area and thereby improves light collection and electrode kinetics. But the etching also improves the long wavelength photoresponse of the electrode. This is evidenced by the change in the action spectrum of this electrode shown in Fig. 12. Photoetching significantly flattens out the action spectrum at longer wavelengths where absorption is occurring outside the space charge layer. This indicates that the bulk properties of the film have improved. However, the absorption edge itself is still rather broad, indicating that there are transitions occurring with less than full bandgap light due to energy levels within the bandgap. Any changes at shorter wavelengths are obscured by the electrolyte absorption below about 520 nm. The reasons for the decrease in effectiveness of the photoetching treatment at $x > 0.20$ are not known at present. However, based on the results shown in Table IV, the decreasing L_p found at $x > 0.20$ indicates that the electronic transport properties of the films are poor in this composition range and

Fig. 11. SEM pictures showing surface of film C before and after photoetching treatment.

may be the most dominant factor controlling the I-V behavior, regardless of the condition of the near surface region.

Fig. 12. Effect of photoetching on spectral response characteristics of CdSe_{0.8}Te_{0.2} electrode with 7.4% conversion efficiency after photoetching.

The output stability of these electrodes was found to follow a trend similar to that already reported for slurry painted CdSe_{1-x}Te_x material (16, 26). Films A to C have been run for several weeks at the maximum power point under constant illumination (~ 100 mW/cm², IR-filtered Xe arc) with less than 5% decrease in efficiency. Films D, E, and F showed decreases in power output of 15%, 40%, and 75%, respectively, after two weeks of constant illumination.

Summary

The concurrent elemental evaporation technique has been shown to be a suitable method for the deposition of alloy films in the CdSe_{1-x}Te_x system. The critical deposition parameters were found to be the substrate temperature and the Cd to Se vapor stream ratio. The compositional uniformity of the films was excellent, and the photovoltaic output improved with increasing x value up to $x = 0.20$, above which it decreased. In general, as the Te content in the films increased (over the range of $0 \leq x \leq 0.53$) the spectral response of the film was shifted to longer wavelengths, but the quantum efficiency and the minority carrier diffusion length decreased. As a result, the I-V curves took on a recombination dominated shape, rather than one dictated by dark current. However, an optimum combination of spectral response, electrode band bending, and transport properties occurred for the CdSe_{0.81}Te_{0.19} composition, resulting in a power conversion efficiency of 7.4% under simulated AM2 conditions.

Electrochemical Removal and Concentration of Hydrogen Sulfide from Coal Gas

Hyun S. Lim*† and Jack Winnick*

Georgia Institute of Technology, Atlanta, Georgia 30332

ABSTRACT

An electrochemical membrane concentration cell was demonstrated as an effective means of removing and concentrating H₂S from a hot gas stream. The device consists of a high temperature molten sulfide electrolyte with porous carbon electrodes. The process-gas is passed through the cathode chamber, where H₂S is selectively removed. With passage of current, the anion migrates to the anode, where elemental sulfur is evolved. Removal rates and cell overpotentials are reported as functions of current densities, gas flow rates and composition, and temperature.

The product gas from advanced coal gasifiers will likely be utilized in combined-cycle or molten carbonate-based energy conversion systems. Whether used in this or similar manner for electric power generation or converted to SNG for direct use, nearly all the sulfur must be removed. Hydrodesulfurization converts the complex sulfur species primarily to H₂S.

Current processes for H₂S removal are based on aqueous scrubbing (e.g., Selexol, Rectisol). Regeneration of the scrubbing liquor can provide a concentrated stream of H₂S, which can then be converted to elemental sulfur in the Claus process. Alternative processes produce SO₂, which must then be reduced to yield sulfur. There is a need for a simpler process which would operate at or near gasifier temperatures (700°-1000°C).

Electrochemical membrane concentrators have been used to remove dilute levels of contaminant gases and to concentrate them into by-product streams. Electrochemical concentration involves an electrochemical reaction at one electrode and the reverse reaction at the other electrode. Thus, there is no net cell reaction, but there is a net transfer of mass from a region of low concentration to a region of high concentration.

We here examine the application of an electrochemical concentrator to remove H₂S from coal gas and concentrate it into usable form. In concept, the contaminated coal gas is fed to the cathodes of a multi-cell stack of electrochemical concentrators operating at the gasifier temperature and pressure. Elemental

sulfur is emitted from the anodes. The clean-up process, as envisioned, would not involve scrubbing and concomitant loss of sensible heat and pressure head. Transfer of the H₂S is effected by diffusion through porous electrodes, migration of sulfide ions through the membrane, and evolution of sulfur at the other electrode.

Theory

Electrochemical membrane cells have been used to purify gaseous components. For example, oxygen has been extracted from air or other gaseous mixtures (1). The O₂ is selectively removed from the gas mixture at one electrode, transported ionically, and emitted at the other electrode. Oxygen is reduced at the cathode to form hydroxide ions

Four hydroxide ions are transported through the membrane to the anode where oxygen is liberated

Oxygen purities greater than 97% are obtained.

In principle, the gas from a coal gasifier containing H₂S could be similarly fed to the cathode of an electrochemical cell where the H₂S is reduced to form sulfide ion

With passage of current, the sulfide ion would migrate to the anode through the membrane. At the anode, elemental sulfur vapor would be generated

The driving force is supplied by an external dc power source. The minimum potential required to drive the concentration cell can be calculated from the Nernst equation

$$E = E_0 - \frac{RT}{nF} \ln \left[\frac{(a_{\text{H}_2})_{\text{ca}} (a_{\text{S}_2})_{\text{an}}^{1/2}}{(a_{\text{H}_2\text{S}})_{\text{ca}}} \right] \quad [5]$$

where

$$-nFE_0 = \Delta G^\circ_{\text{H}_2\text{S}} \quad [5a]$$

$$(a_{\text{H}_2})_{\text{ca}} = P \cdot (C_{\text{H}_2})_{\text{ca}} \quad [5b]$$

$$(a_{\text{H}_2\text{S}})_{\text{ca}} = P \cdot (C_{\text{H}_2\text{S}})_{\text{ca}} \quad [5c]$$

$$(a_{\text{S}_2})_{\text{an}} = P \cdot (C_{\text{S}_2})_{\text{an}} \quad [5d]$$

a , P , C are activity of gaseous species, pressure, and concentration, respectively.

At 927°C, E_0 is about -162.2 mV based on two-electron transfer and 7.48 kcal for the Gibbs free energy of formation of H_2S (2). The equilibrium voltage for 90% removal and concentration to 90% S_2 from 0.65% H_2S is about 437 mV at 1 atm. For operation of the entire process at 10 atm, the equilibrium voltage is about 497 mV.

The success of electrochemical concentration depends first on the selection of proper electrode materials and the stability of the electrolyte at the operating conditions. The criteria for electrode selection are primarily stability and conductivity in the hot sulfide environment. Thermodynamic analysis has indicated that gold, platinum, and carbon are the most stable materials. However, gold and platinum are so expensive that their use in a full-scale cell is not feasible. Carbon electrodes were therefore evaluated as both anode and cathode.

It is necessary to identify an electrolyte which is stable and whose melting point is compatible with coal gasification processes (700°-1000°C). No data exist for alkali sulfides, but the eutectic temperature of a binary alkali sulfide (xz - yz) can be predicted from the model proposed by Lumsden (3). The eutectic temperature is given as

$$T = \frac{KN_y^2 + \Delta H_{f,x}}{(\Delta S_{f,x} - R \ln N_x)} \quad [6]$$

where N_x , N_y , $\Delta H_{f,x}$, and $\Delta S_{f,x}$ are mol fractions of xz and yz in the mixture, and enthalpy, and entropy of pure xz , respectively. K , the interaction parameter, includes the London and polarization forces. The eutectic temperatures of $\text{Na}_2\text{S}/\text{K}_2\text{S}$ and $\text{Na}_2\text{S}/\text{Li}_2\text{S}$ were estimated with $K = 0$. Sharma (4) estimated the heat of fusion based on Temkin's model of the phase equilibrium between lithium sulfide and iron sulfide. Eutectics are predicted at 920 and 1125 K with 40 mol percent (m/o) Na_2S , 60% K_2S and 63% Na_2S , and 37% Li_2S , respectively. These mixtures appeared to be reasonable choices for preliminary experiments.

Other reactions are possible besides those desired

Reactions [7] and [8] indicate the amount of COS formed at equilibrium. At 927°C, [7] and [8] both show a maximum of 10^{-4} mol fraction COS in equilibrium with the inlet H_2S in the gas from an advanced gasifier (see Table I). Several species in the process gas may also react with the electrolyte

Table I. Typical gas composition from advanced air-blown gasifier (6)

Component	m/o
H_2	14.0
N_2	48.0
CO	29.0
CO_2	3.0
CH_4	3.3
H_2S	0.7
COS	Trace
H_2O	2.0

The reactions show the tendency of the electrolyte anion to be converted from sulfide to some other species. Thermodynamic tables (5) were used to estimate the equilibrium for each reaction based on lithium as the cation. At 927°C, reactions [9], [10], and [11] are negligible; their equilibrium constants are 2.966×10^{-4} , 3.96×10^{-4} , and 7.11×10^{-7} , respectively. Reaction [12] is the only one of consequence. Therefore, for this reaction, the thermodynamic analysis is made based on each of lithium, sodium, and potassium as the cation in the electrolyte. Their equilibrium constants are 0.058, 0.053, and 0.008, respectively, at 927°C. The equilibrium is driven to the left with increasing temperature. The electrolyte containing potassium as the cation is the most resistant to conversion from sulfide to carbonate. The equilibrium constant of 0.008 would limit the outlet H_2S to about $5 \times 10^{-4}\%$. This is equivalent to 99.9% removal of H_2S using the gas composition from advanced gasifiers (6).

Experimental

To test the concept, a small cell similar to a molten carbonate fuel cell was constructed. A schematic of the cell housing is shown as Fig. 1, and the assembled cell is shown in Fig. 2. The cell housings are made of dense graphite; the process gas was introduced and removed through 0.635 cm Al_2O_3 tubes. A thermocouple was inserted close to the gas flow channel with a 316 stainless steel tube, which also acted to transmit current from the potentiostat/galvanostat.

Fig. 1. Schematic diagram for cell housing

Fig. 2. Schematic diagram for assembled cell with Al_2O_3 ring

The process gas is prevented from leaking out by wet sealing, which is produced by contact with the electrolyte-filled membrane. Direct contact between the molten electrolyte and graphite housing produces degradation, which was prevented by thin, dense alumina shims. The face seal between shim and housing was sufficiently leak free.

Carbon electrodes having a porosity of 52%, thickness of 4.5 mm, and 3.175 cm diam were purchased from Ultra Carbon Company. They are used as both anode and cathode.

The electrolyte mixture was retained in a membrane composed of a porous inert matrix material (MgO), so that the electrolyte mass remained in a semisolid state at the operating condition. Hot pressing and impregnation were the two techniques employed to manufacture the membrane. The hot pressing involved electrolyte and matrix material compression at 6000 psi at temperatures just below the electrolyte melting point. Impregnation involved melting of electrolyte into the partially sintered matrix material in a vacuum furnace.

The process gas is a simulated syn-gas purchased from Matheson Gas Products. Condensing water vapor caused severe problems with the gas chromatograph; absorption of the water upstream altered the H_2S content. For this reason, most tests were run with a gas composed of 50% H_2 , 0.65% H_2S , and the balance N_2 . A few tests were run with CO_2 present (CO formed *in situ* due to the water-gas shift reaction) to test the effect of reaction [12].

The gases were analyzed with a Hewlett-Packard 5840 Gas Chromatograph with a thermal conductivity detector. Most of these tests were conducted with hydrogen in the anode. This allowed simple analysis of the anode effluent as H_2S rather than S_2 .

Electrochemical measurements were made using a PAR-371 Potentiostat/Galvanostat. Most data were taken in the galvanostatic mode. The ohmic resistance of the cell was estimated using the current interruption technique. Figure 3 shows the apparatus and flow system.

Results and Discussion

Electrochemical measurement made in a cell such as this, that is, with porous electrodes and an immobilized electrolyte, are subject to experimental uncertainties larger than those typical of measurements with planar electrodes in free electrolyte. This is due, for the most part, to the uncertain and variable active area and the possibility for voids within the tile. Furthermore, the electrolyte is subject to varying polysulfide content.

Although anhydrous Na_2S and Li_2S were purchased, the initial large amounts of polysulfide lowered the melting point. A slow lowering of cell impedance was observed as the temperature climbed to 785°C . Simultaneously, large quantities of H_2S were seen in both anode (H_2) and cathode (fuel-gas) exit gas streams due to reaction between H_2 and sulfur species which emitted from the polysulfides. At about 840°C , a sharp further decrease in impedance occurred, indicating melting of the stable electrolyte. The temperature corresponded closely to the temperature (852°C) predicted by the Lumsden equation.

The open-circuit potentials were measured as functions of temperature and H_2S and H_2 concentrations in cathode and anode streams. The open-circuit potential predicted by the Nernst equation was calculated using the outlet concentration of gas species. Table II shows measured and calculated open-circuit potentials, H_2S outlet concentration from cathode and anode streams, and temperature. The discrepancies between calculated and measured open-circuit potentials are probably due to concentration differences between the electrode interfaces and bulk streams.

The polarizations were lowered with the hot-pressed membrane; current densities above 30 mA/cm^2 were attained at cell overpotentials below 540 mV. A large ohmic drop prevented the cell with the impregnated membranes from operating at current densities above 15 mA/cm^2 . This can be attributed to discontinuities within the matrix material and poor wetting between the electrode and membrane. However, the impreg-

nation method produced a high residual strength so that extended cell operation was possible.

The dependence of the overpotential on the flow rate, H₂S inlet concentrations, and temperature was investigated with the impregnated membrane. The effect on overpotential of cathode flow rate is shown in Fig. 4. The overpotential at constant current density decreases with increased flow rate. Increasing the gas flow rate in the cathode cavity increases the mass transfer coefficient of the reactants from the bulk of the gas phase to the electrode reaction area. As the mass transfer coefficient increases the gas-phase limiting current increases and the concentration overpotential drops. The overpotential at constant current density decreases with increasing temperature. This is due to lowered electrolyte resistance and increased solubility of H₂S gas, as well as enhanced kinetics. At low temperature (710°C), the overpotential increased steeply as the current density increased, indicating a limiting current density. Lowering of overpotential with increasing H₂S inlet concentration is shown in Fig. 5. As the inlet H₂S concentration increases the limiting current increases pro-

Fig. 4. Overpotential vs. current density at 840°C, 0.65% H₂S concentration.

Fig. 5. Overpotential vs. current density at 918°C.

portionally, consequently lowering the concentration overpotential.

It should be emphasized that the quantitative results are highly dependent on the physical construction of the electrodes and membrane (for reasons stated earlier). Performance must improve with materials optimization. The trends found, however, are considered significant.

The results for removal efficiency as a function of current density with an inlet gas containing 0.43% H₂S, 50% H₂, and the balance N₂ are shown in Fig. 6. The removal efficiency is increased by increasing the current density. Removal efficiencies of 98.8% were achieved at flow rates as high as 260 cm³/min. The H₂S concentration was reduced to as low as 50 ppm at the cathode, and 3.2% of H₂S was achieved at the anode. This anodic value is not viewed as a real limit for the process but merely as a result of the minimum flow needed to transmit samples to the analyzer.

H₂S removals at open circuit were observed during these runs. Removal at open circuit may be due to diffusion of H₂S from the cathode chamber through the electrolyte tile to the anode. An effective diffusion coefficient of 9×10^{-4} cm²/s was obtained based on the H₂S molar flux through the membrane from the cathode to anode at open circuit. This high diffusional flux is not seen in well-manufactured membranes; it is probably due to gas channels in our crude ones. Back diffusion of H₂S from anode to cathode became significant when the H₂S concentration at the anode was high. The removal efficiencies, as adjusted for the diffusion of H₂S through the membrane, are shown in Fig. 6.

The current efficiency as a function of current density is shown in Fig. 7. The current efficiency is the ratio of the mols of H₂S removed to the theoretical mols that could be removed by 2F of electricity. High current efficiencies were achieved at low current density. Observed current efficiencies greater than 100% were due to diffusion of H₂S from cathode to anode at very low currents (and hence very low removals). A steady hydrogen flow was necessary for the anode to deliver its effluent to the chromatograph. At these conditions, the exiting anode H₂S concentrations were lower than those exiting the cathode. This would never be the case in a commercial device. A gradual decrease in the current efficiency with increasing current density was observed. The low current efficiency at high current density is apparently due in part to back diffusion of H₂S from anode to cathode. The adjusted current efficiencies are also shown in Fig. 7.

A preliminary attempt was made to assess the relative importance of activation and concentration over-

Fig. 6. Removal efficiency as a function of current density.

Fig. 7. Current efficiency as a function of current density at 840°C and 65% H₂S cathode inlet.

potential. This attempt was hindered, perhaps crucially, by the absence of a reference electrode. However, a large flow of pure hydrogen was maintained at the anode to depolarize it as much as possible. A transient galvanostatic pulse technique was used. The ohmic polarization is presumed to appear in less than 1 μ s. On planar electrodes, activation polarization is expected to occur in 10^{-6} to 10^{-4} s (7). Concentration polarization decays in the range of 10^{-4} to 10^{-3} s (7). The porous carbon electrodes in use here have slower decay response because the gas concentration in the pores changes more slowly than that at a planar electrode.

There was a distinct difference in the shape of the decay curves for runs at different temperatures (8). The response at 805°C was considerably slower than those at 840° and 896°C. If one assumes that the activation polarization decays primarily from 10^{-3} to 10^{-2} s and concentration polarization from 10^{-2} s on, some relative measure can be made. A rough Allen-Hickling plot was made, based on galvanostatic pulses made at five currents. The exchange current densities (presumed at the cathode) were found to be 4.6 and 3.3 mA/cm² at the higher temperatures. Yet, at the lower temperature, an exchange current density of 9.0 mA/cm² was calculated. Lowering of the true interfacial area with increased temperature may be the cause of this, possibly through increased electrode flooding. The concentration polarization, however, was much more severe at the lower temperature, showing typically six times that for the higher temperature runs. This effect

may be due to the solubility of the H₂S, which increases in the melt with increasing temperature. With the low concentrations of H₂S in the cathode gas, the dissolved H₂S or one of its products is likely the limiting reactant.

The effect of electrode thickness was also explored. Increasing thickness of porous graphite had no deleterious effect on cell performance. The usual thickness used was 0.762 mm. However, electrodes up to 4.5 mm were tested. These results indicate gas-phase pore diffusion is not controlling.

Most tests were performed with the anode depolarized with hydrogen. No effect on H₂S removal efficiency at the cathode was observed when the H₂ was replaced with N₂. In nondepolarized tests, an increase of 50 mV at 15 mA/cm² was needed over the depolarized voltage to maintain galvanostatic conditions. However, plugging of the anode outlet tube with condensed sulfur was observed. The tube was unplugged by purging with hydrogen, which converts the condensed sulfur to hydrogen sulfide.

When simulated syn-gas (SSG) containing 0.3% H₂S, 30% H₂, 20% CO₂, and balance N₂ was fed into the cathode, a gas composition of 12.8% CO, 7.2% CO₂, 12.8% H₂O, 17.2% H₂, 0.3% H₂S, and balance N₂ is predicted from the water-gas shift reaction equilibrium calculation at 927°C.

The water-gas shift reaction was studied by passing SSG through a stainless-steel loop inside the furnace. The CO₂ concentration at inlet and outlet were com-

pared. Conversion of 44.4% and 54% CO₂ was observed at 927° and 1027°C, respectively. Thermodynamic analysis indicated that 45% and 64% of the CO₂ should be converted to CO at 927° and 1027°C, respectively, with SSG containing 30% H₂ and 20% CO₂. Thus, the water-gas shift reaction has a fast rate of reaction and is close to equilibrium.

With CO₂ and H₂O from the water-gas shift reactions, the electrolyte anion may be converted from sulfide to carbonate by reaction [12]. The CO₂ concentrations at the exit from the loop and cathode were compared at 936 K and found to be similar. This indicated that there is little or no CO₂ removal by the molten Na₂S-Li₂S mixture. X-ray powder diffraction analysis indicated that there was no displacement of sulfide ions by carbonate ions in the electrolyte. The effect of potassium sulfide in the electrolyte was not explored experimentally due to problems with K₂S purification. However, K₂S is most favored thermodynamically. There was no effect seen on H₂S removal efficiency of the CO₂, and no CO₂ was evident in the anode exhaust.

The cell potential responded sharply to cathode gas composition. When mixtures similar to the SSG, but without H₂S, were introduced, the cell potential increased steadily at about 100 mV/min. Adding CO₂ to the gas had no effect. Reinserting the H₂S brought the potential back to its original level.

Current was held constant for several hours at a time. It was changed in steps of 5 or 10 mA/cm². The outlet gas concentrations responded immediately¹ and remained within 10% of their new values over the steady state. Gas samples were taken every 30 min or every hour. Some steps in current were positive and some negative, so that replication occurred. There was no noticeable hysteresis.

Most of the results reported here came from an experiment which ran continuously for 100h. Some other experiments ran over 500h each. Upon disassembly, the carbon electrodes were partially wetted by electrolyte. The electrodes were conductive, and no structural damage was observed even under scanning electron microscopy.

Economic Analysis

The concept of electrochemical concentration must be shown to be an economically viable method for removing H₂S from the process stream of a coal gasifier. A preliminary economic feasibility study was based on a capacity of 10,000 TPD of Illinois no. 6 coal using a Texaco air-blown gasifier.

The power needed to drive the electrochemical cell can be estimated from voltage and current demand. The theoretical potential is calculated to be about 0.5V. However, various overpotentials associated with the real process will probably bring the total required voltage to near 1V. The current needed to remove 100% of the H₂S is directly calculated from Faraday's law to be 21.5 × 10⁶A based on two-electron transfer. On this basis, the power demand is 21.5 MW, or about 1.5% of the output of the plant. This value compares favorably with the utility demand by the Selexol process, which is about 4.7% of the plant output (9). Capital costs are estimated based on the design of a battery similar to NASA's "Energy Conversion Alternatives Study for Molten Carbonate Fuel Cells" (ECAS) (10). The total area requirement to remove H₂S completely was based on a limiting current density of 50 mA/cm², which is a conservative estimate at high temperature. Current densities of 160 mA/cm² are regularly achieved in molten carbonate fuel cells (MCFC) with total overpotential of about 300 mV. A major difference between the MCFC and our device is the composition of the oxidant. The MCFC operates with up to 30% CO₂, while

our H₂S cell will have exit H₂S concentrations of a few hundred parts per million.

A closer experimental analog is the molten carbonate CO₂ concentrator, under development for NASA applications (11). Here, the oxidant typically contains 0.4% CO₂ (in air) and can be purified to about 200 ppm. The cathodic overpotential at 50 mA/cm² is typically a few hundred millivolts (11). This cell uses optimized hardware; the electrolyte tiles and porous electrodes have been developed for the MCFC over the past twenty years.

The limiting current density due to gaseous diffusion of the H₂S from the bulk gas has been calculated from standard mass transfer correlations (8). With a gas flow of 350 cm/s, this limit is about 150 mA/cm², assuming that the bulk H₂S concentration is 10% of the inlet (90% removal). Pore diffusion in a properly designed electrode has been found to be unimportant (11). Further, since we have already achieved 35 mA/cm², we feel 50 mA/cm² is realizable.

A total superficial area is then calculated at 4.3 × 10⁴ m² with a capital investment of \$24 million. The cost is estimated based on the ECAS value for a MCFC plant of about \$140/m² (1976 dollars), which was then arbitrarily scaled up by a factor of four to \$560/m². There is clearly a great deal of uncertainty in this figure. However, a Selexol plant of the same H₂S capacity is estimated to cost over \$200 million, an order higher than the concentrator estimate.

Conclusions

The feasibility of electrochemical concentration for removal of H₂S from coal gas at high temperatures was demonstrated. The concept was tested with a binary mixture of Na₂S and Li₂S as the electrolyte, and porous carbon as electrodes. The graphite electrode housings were assembled with Al₂O₃ gas tubes and found to be inert at the operating conditions. The molten sulfide is very stable in the reducing environment, and carbon electrodes were stable even at a total cell potential of 1.8V.

A 98.8% removal efficiency of H₂S has been achieved with the SSG containing no CO₂ with reasonable levels of polarization. Current densities above 35 mA/cm² were attained during tests using a cell of 7.92 cm² superficial area.

A preliminary experiment with gas containing CO₂ indicated that the removal efficiency of H₂S does not depend on CO₂. X-ray powder diffraction analysis indicated that there was no measurable displacement of sulfide by carbonate ions in the electrolyte.

Preliminary economic analysis indicates that the capital and operational costs for the electrochemical concentrator are favorable at this early stage of development.

A Quantitative Examination of the Mixed Potential Mechanism in Mineral Flotation

K. C. Pillai and J. O'M. Bockris*

Department of Chemistry, Texas A&M University, College Station, Texas 77843

ABSTRACT

The origin of the present work lies in a suggestion by Salamy and Nixon, which was implemented by Tolun and Kitchener, and has become the principal theory of some types of flotation. However, it has never been subject to quantitative verification. The electrochemical kinetics of oxygen reduction and those of the anodic oxidation of potassium ethyl xanthate were examined first individually and then together. The mineral substrates used were iron pyrites and galena. The cathodic Tafel slope on pyrites was 110 mV, and the order of reaction 1.2. On galena, the slope was 120 mV. In anodic reactions, the Tafel slope on pyrites was 95 mV, and the order 0.7. On galena, the slope was 240 mV. Results obtained with O₂ alone and xanthate alone verified the theory. Results obtained when the components were mixed gave agreement only if the excess of the adsorbed xanthate on the oxygen kinetics was taken into account.

In mechanisms suggested for flotation of sulfide minerals in the presence of xanthate collectors, one may distinguish early views, e.g., chemical (xanthate \rightleftharpoons xanthic acid \rightleftharpoons adsorbed acid) (1), and ion exchange theories (replacement of sulfide ions of the mineral by xanthate) (2, 3). However, these were not consistent with Plaksin's discovery of the dependence of the flotation process on an oxygen content in the solution (4).

This discovery was consistent with a suggestion of Salamy and Nixon (5) (which they, however, had applied experimentally only to a mercury surface): that the donation of electrons by the oxidation of xanthate was coupled to the supply of electrons to reduce oxygen. Plaksin (4) himself, however, suggested that the part played by the O₂ was to cause galena (PbS) to change from a surface of n-type to p-type, and thus facilitate anion (i.e., xanthate) adsorption [cf. Plaksin and Shafeev (6), Guarnaschelli (7), Dixon *et al.* (8), and Richardson (9)].

Tolun and Kitchener (10) are generally credited with having originated the mixed potential theory, though they themselves attribute it to Salamy and Nixon (5). By making polarographic measurements on PbS in the presence of xanthate, Tolun and Kitchener found that the potential of flotation (i.e., the open-circuit potential of PbS in the presence of both xanthate and O₂) was between the initial anodic current for xanthate oxidation and the corresponding cathodic current for oxygen reduction. This was qualitatively consistent with their model. Woods (11, 12), showed that, by using a bed of sulfide mineral particles, flotation could be achieved without oxygen by changing the potential to the more positive region, which would arise were a mixed potential mechanism with O₂ allowed to occur on the same electrode. However, later studies by Biegler *et al.* (13) of O₂ reduction on different samples of pyrite (FeS₂) failed to show any correlation between the characteristics of O₂ reduction and the semiconducting properties of the sulfide used.

Several parallel works of importance have appeared. Fuerstenau *et al.* have reported the electrochemical oxidation of xanthate on FeS₂ (14); and the oxidation

of potassium diethylthiophosphate on Cu₂S has been studied by Chander and Fuerstenau (15). In particular, *ex situ* IR studies have been made by the former (14) of the surface species (by mixing the xanthate-treated FeS₂ with a mineral oil as a mull for the IR), which they found to be dixanthogen. Quite similar studies were carried out independently by Majima and Takeda (16). However, Granville *et al.* (17) have shown evidence from IR studies that on PbS the dominating species is lead xanthate.

An interesting contribution was made by Ahmed (18), who set up connected electrochemical cells consisting, e.g., of two electrodes of PbS, one in deaerated xanthate solution and the other in deaerated solution of the same kind but lacking in xanthate. When O₂ was bubbled over the latter electrode, a current was observed between the two electrodes in qualitative agreement with a mixed potential concept.

Somasundaran [cf. Healy (19, 20), Fuerstenau (20), and Goddard (21)] made electrochemical contributions of a different kind. They are well summarized in a recent review of Somasundaran and Goddard (21). However, the systems treated here were largely oxide minerals, and the models used for the interpretation of the data do not involve electrode kinetics, since there is no evidence that O₂ reduction is a vital part of the mechanism of flotation. Here, the crux of the discussion is the degree to which it is possible to regard the interfaces concerned as being subject to potential determining absorbing ions (Nernstian) or polarizable and hence subject to double layer theory (Sternian). Charge generations (22), electrostatic adsorption (23), and some evidence for the role of ion-molecular complexes (24) have been studied.

In summary, for the sulfide minerals, there is qualitative evidence for a mixed potential view of the mechanism by which the collector comes onto the surface prior to flotation. However, many of the facts are subject to the Plaksin-originated type of interpretation, in which changes in the semiconducting properties of the interface dominate electrode kinetic features. There has been no quantitative proof of the mixed potential theory. Further, if the mixed potential theory is valid, the implication for the structure of the collector is that it must not only have a struc-

* Electrochemical Society Active Member.

Key words: mixed potential, mineral flotation, pyrite, galena, xanthate.

ture which adsorbs on the mineral and oxidizes as well in the appropriate potential range, but it should also have suitable catalytic property for the O_2 reduction reaction. The present work is aimed at the elucidation of these matters.

Experimental Details

Materials

Specimens of the minerals pyrite and galena (6.5 cm^3) were obtained from Wards Natural Science Establishment, Incorporated. The pyrite was of Spanish origin and galena was from Sweetwater Mines, Missouri.

Kodak potassium ethyl xanthate (KEX) was purified by dissolving in acetone and recrystallizing three times by addition of ether. The crystals were then stored in a dry nitrogen atmosphere. Prior to the experiment, a fresh KEX solution in the electrolyte was prepared.

Measurements of Semiconductor Properties

The resistivities and Hall mobilities for the surface of mineral disks were obtained by the method of Van der Pauw (25), developed for samples of arbitrary shape. The experimental details are similar to those reported elsewhere (26).

Electrode Preparation

About 2-3 mm thick and $0.5\text{-}1 \text{ cm}^2$ surface area specimens were cut from the massive materials using a diamond saw. Contact to the electrode was made by attaching a copper lead to one surface of the electrode with a conducting silver epoxy cement. The exposed copper lead and the back side of the electrode were then coated with a nonconducting epoxy and the hardened-capsule tight-fitted into a Teflon holder. This arrangement proofed the electrode against the effects of possible leaks. The ohmic nature of the electrical contact was checked by measuring the current-voltage characteristics of the electrode.

The electrode surface was prepared before each electrochemical run by hand polishing for about 5 min each with a succession of finer grades of silicon carbide paper, down to 600 grade. The electrode was then degreased with spectropure trichloroethylene, and washed thoroughly with deoxygenated triple-distilled water prior to immersion into the experimental solution.

Electrochemical Measurements

A conventional three-compartment glass cell with a three-electrode system was used. A saturated calomel electrode was the reference electrode; however, the potentials are expressed on the normal hydrogen scale.

To obtain $E\text{-log } i$ data, the steady-state potentiostatic polarization technique was used. The steady-state current was read at each applied potential. It was found that this was established after 3-4 min. The potential was controlled by a PAR potentiostat (Model 173), and the current-time curves were recorded with a $y\text{-t}$ (Industrial Scientific, Incorporated) recorder.

Cyclic voltammograms were recorded as preliminary measurements, using the above setup coupled with a programmer PAR Model 175.

The experiments were carried out in borate buffer of pH 9.1 (a pH near to that of the flotation process). The electrolyte was pre-electrolyzed at a current density of 1 mA/cm^2 for 15h. Experimental solutions of KEX were prepared by adding small volumes ($0.2\text{-}0.3 \text{ cm}^3$) of a concentrated solution of KEX, prepared freshly each day, to a pre-electrolyzed base electrolyte. All operations were carried out in an all-glass assembly under an N_2 atmosphere.

Measurements with different partial pressures of O_2 were achieved by mixing O_2 and N_2 under controlled-flow conditions using flowmeters (Flowrater, Fischer and Porter Company).

XPS measurements of the electrode surface before and after contact with the collector were carried out and will be reported elsewhere (27).

Methodology

Three methods of surface treatment of the mineral electrodes were tried to find out which method would give the most reproducible results. The first method involved the procedure as described in the Electrode preparation section. The second method consisted of the same procedure followed by etching in $HCl:H_2O$ (1:3) solution for 15 min, and then by thorough washing in deoxygenated conductivity water prior to introduction into the experimental solution. In the final set of experiments, the electrode surface was prepared as given in the Electrode preparation section, followed by electropolishing for 3 min at 0.375 A cm^{-2} in a mixture of conc H_3PO_4 and $HCl:H_2O$ (1:4) solution saturated with CrO_3 (28). The last method resulted in the formation of a thick oxide film on the electrode surface, giving high Tafel slopes, e.g., of $250 \text{ mV decade}^{-1}$, for O_2 reduction at $p_{O_2} = 1$ in pH 9.1.

Although the first and second methods gave similar results, the most reproducible results and those with the most linear Tafel plots for O_2 reduction were obtained by following the first method of surface preparation (see Electrode preparation), followed by a cycling of the electrode potential at a scan rate of 1 mV s^{-1} , starting from the open-circuit potential (E_{open}) and going towards more negative potentials until the cathodic reduction of FeS_2 started (in the absence of O_2 and xanthate). Then, the reverse scan was carried out in more positive regions until the anodic oxidation of FeS_2 began in the absence of xanthate. Such a scan (with return to E_{open}) was carried out only once. This approach was followed because it was the most reproducible of those examined. After scanning between about 0.0 and $-0.4V \cdot NHE$, the electrodes was disconnected from the potentiostat. The potential was then observed to change over about 30 mV until reaching, after about 30 min, a rate of variation of around 1 mV in 5 min. Potentiostatic transients were then commenced.

While the above sequence of potential cycling was adopted for O_2 reduction studies, for xanthate oxidation under an N_2 atmosphere, the electrode was scanned first in the more positive, rather than the more negative, direction. This ensured that the oxidized product of xanthate formed on the electrode in the anodic cycling step was reduced and did not exert any influence on the subsequent $i\text{-t}$ measurements.

Results

Pyrite

Semiconductor parameters.—The FeS_2 was found to be an n-type material; the charge carrier density was $3.9 \times 10^{18} \text{ cm}^{-3}$, and the resistivity was $4 \times 10^{-2} \Omega \text{ cm}$. The Hall mobility was around $4.5 \times 10^1 \text{ cm}^2 V^{-1} s^{-1}$.

Current-voltage curves.— O_2 reduction on FeS_2 .—The Tafel plots for O_2 reduction obtained on an FeS_2 electrode in pH 9.1 borate buffer at $p_{O_2} = 1$ and 0.33 are shown in Fig. 1. The number of experiments at each pressure was 5-10.

The cathodic Tafel slope ($-b_c$) for O_2 reduction is $110 \pm 5 \text{ mV decade}^{-1}$ for both $p_{O_2} = 1$ and 0.33. The exchange current density ($i_{o,c}$) was calculated by extrapolating the linear portion of the Tafel line to the theoretical equilibrium potential ($E_{e,c}$). The $E_{e,c}$ values for O_2 reduction in pH 9.1 are $+0.690V$ (NHE) for $p_{O_2} = 1$ and $+0.683V$ (NHE) for $p_{O_2} = 0.33$. The respective extrapolated $i_{o,c}$ values are $4.6 \pm 0.3 \times 10^{-12} \text{ A cm}^{-2}$ and $1.0 \pm 0.3 \times 10^{-12} \text{ A cm}^{-2}$ of apparent electrode area.

The cathodic reaction order with respect to O_2 partial pressure is

Fig. 1. E -log i plots for O_2 reduction at FeS_2 electrode in borate buffer pH 9.1. $-\Delta-\Delta-$: $p_{O_2} = 1$. $-\square-\square-$: $p_{O_2} = 0.33$.

$$\left[\frac{\partial \ln i_c}{\partial \ln p_{O_2}} \right]_{E,pH} = 1.2$$

KEX oxidation of FeS_2 .—The E -log data for the anodic oxidation of KEX studied at $10^{-2}M$ and $10^{-3}M$ concentrations under a N_2 atmosphere are given in Fig. 2. The anodic Tafel slope (b_a) for xanthate oxidation is 95 ± 5 mV decade $^{-1}$ at both concentrations of KEX studied.

In xanthate oxidation, one has to calculate a reversible redox potential necessary for the computation of the exchange current density, but one has to meet the difficulty that the components of the redox couple

where x^- is the ethyl xanthate anion and x_2 is the diethyldixanthogen, are not sufficiently soluble to be used at ratios corresponding to unit molarity or activity for each component. To calculate, therefore, a reversible redox potential, it is necessary to choose some arbitrary concentration of the KEX, and assume that an equilibrium is set up with diethyldixanthogen, the solubility of which is small. According to Fuerstenau *et al.* (14), the solubility of x_2 at 25°C.

Fig. 2. E -log i plots for KEX oxidation at FeS_2 electrode in borate buffer pH 9.1. $-\Delta-\Delta-$: $C_{KEX} = 10^{-2}M$. $-\square-\square-$: $C_{KEX} = 10^{-3}M$.

pH 9.4, and KEX concentration of $2 \times 10^{-5}M$ is $5.0 \times 10^{-6}M$. The experimental work of Majima and Takeda (16) gives the redox potentials, determined on Pt electrodes, for several homologues of xanthate in solution in equilibrium with the corresponding dixanthogens at saturation. For KEX at $10^{-3}M$, the determined redox potential is 0.13V (NHE), and at $10^{-2}M$ is 0.07V (NHE). The values of Majima and Takeda (16) are reasonably in agreement with the data of Fuerstenau *et al.* (14), *e.g.*, at KEX $10^{-2}M$ and the corresponding x_2 at $5 \times 10^{-6}M$ for pH 9.4 (the Majima and Takeda values were at pH = 9), the Fuerstenau *et al.* value is 0.087V (NHE), and the Majima and Takeda value is 0.07V (NHE) (activity coefficients neglected). Correspondingly, on an FeS_2 electrode, the resting potential attained in the presence of $10^{-2}M$ of KEX was 0.062V (NHE). It was thought appropriate, therefore, to calculate the exchange current density ($i_{o,a}$) for the xanthate oxidation at the determined reversible potential 0.07V (NHE).

The $i_{o,a}$ value at this condition is $1.0 \times 10^{-6} A cm^{-2}$ (*i.e.*, at $10^{-2}M$ concentration of KEX). At $10^{-3}M$ KEX [$E_{e,a} = +0.13V$ (NHE)], the $i_{o,a}$ value is $9.0 \times 10^{-7} A cm^{-2}$.

The anodic reaction order with respect to KEX is

$$\left[\frac{\partial \ln i_a}{\partial \ln [x^-]} \right]_E = 0.71$$

Mixture of O_2 and KEX.—The Tafel plots recorded for the O_2 reduction and xanthate oxidation when both O_2 and KEX are present together are given in Fig. 3. This corresponds to the system in which $p_{O_2} = 1$ and $C_{KEX} = 10^{-2}M$, and we designate this system A. The Tafel lines for the corresponding concentration of O_2 reduction and xanthate oxidation, taken in the absence of each other, are superimposed onto Fig. 3 for a comparison. It is evident that the anodic oxidation of xanthate remains unaffected within the experimental error in the presence of O_2 . The O_2 reduction is, however, catalyzed about 40 times in the presence of xanthate, without any indication in change of the reduction mechanism. The $i_{o,c}$ measured for the O_2 reduction reaction in the presence of $10^{-2}M$ KEX is $2.7 \pm 0.3 \times 10^{-11} A cm^{-2}$. The mixed potential (E_m) and the open-circuit current (i_m , the rate at which the collector is being used up) were calculated by the extrapolation of the linear portions of the Tafel lines. However, since the xanthate oxidation process does not show a linear Tafel region in the mixture, a tangent with a slope of 95 mV was drawn to the anodic polarization curve to

Fig. 3. E -log i plots at FeS_2 electrode in borate buffer pH 9.1. $-\circ-\circ-$: O_2 reduction ($p_{O_2} = 1$) in the presence of $10^{-2}M$ KEX. $-\bullet-\bullet-$: KEX oxidation ($C_{KEX} = 10^{-2}M$) in the presence of O_2 of $p_{O_2} = 1$. —: Measurements in the absence of other component.

calculate these parameters.¹ The E_m and i_m values of the mixtures are 0.167V (NHE) and 9×10^{-8} A cm⁻², respectively.

The Tafel plots for O₂ reduction and xanthate oxidation when both O₂ and xanthate were present were recorded for different combinations of p_{O_2} and xanthate concentrations, as follows. B: $p_{O_2} = 1$ and $C_{KEX} = 10^{-3}M$. C: $p_{O_2} = 0.33$ and $C_{KEX} = 10^{-2}M$. D: $p_{O_2} = 0.33$ and $C_{KEX} = 10^{-3}M$. These are shown in Fig. 4-6. These graphs are drawn in a way similar to that of Fig. 3, in which the individually measured anodic and cathodic curves are superimposed for comparison. In all these systems, the general behavior is similar to that shown in Fig. 3 for system A (i.e., $p_{O_2} = 1$ and $C_{KEX} = 10^{-2}M$), except that in systems with $p_{O_2} = 0.33$, the $-b_c$ is decreased to 70-75 mV by KEX (from 110 mV without it). The E_m and i_m values of the mixture are given in Table I.

With these experimental values of E_m and i_m obtained for the mixtures, the coefficients of the variation of E_m and i_m with reactant concentration were calculated. These are given in Table II.

tion, was found to give reproducible results. The other two methods (cf. Methodology section, above), namely, the one involving etching in HCl:H₂O (1:3) solution for 15 min prior to introduction into the experimental solution, and the one in which the electrode was chemically polished (28), gave irreproducible results for O₂ reduction. Hence, the surface preparation by polishing with different grades of emery paper, degreasing with trichloroethylene, and ending with a thorough water wash, was adopted in the further studies with PbS electrodes.

Even with this method of surface preparation, the cycling of the electrode potential was found to affect the subsequent i - t measurements. Thus, the anodic polarization of PbS was found to affect the cathodic current, probably because of electrode dissolution in the anodic region. Hence, the electrode potential was not cycled prior to the i - t measurements. The electrode was introduced into solution, the rest potential was established, and the i - t measurements were then carried out.

Semiconductor parameters.—The PbS was found to be an n-type material; the charge carrier density was 9.8×10^{16} cm⁻³, and the resistivity was 7×10^{-1} Ω cm. The Hall mobility was around 9.0×10^1 cm² V⁻¹ s⁻¹.

Current-voltage curves.—The Tafel plots for the cathodic O₂ reduction alone and the anodic xanthate oxidation alone, on PbS, are shown in Fig. 7. The $-b_c$ for $p_{O_2} = 1$ is 120 ± 10 mV decade⁻¹, and $i_{o,c}$ at $E_{e,c}$ of +0.690 (NHE) is $2.8 \pm 0.3 \times 10^{-12}$ A cm⁻².

The E -log i plot for xanthate oxidation (conc = $10^{-2}M$) is linear over a small current density region, and the b_a has a high value, i.e., 240-260 mV decade⁻¹. The $i_{o,a}$ at $E_{o,a}$ of 0.07V (NHE) is 2.4×10^{-7} A cm⁻². The E -log i plot shows a depolarization at higher current densities (slope = 45-50 mV), and this is followed by a region in which the current decreases with increasingly positive potential. This indicates an inhibition of the electrode processes. Similar behavior was not observed with FeS₂.

The measurement of O₂ reduction and xanthate oxidation, carried out in the presence of O₂ ($p_{O_2} = 1$) and

KEX (conc = $10^{-2}M$) together, are given in Fig. 8. When O_2 is added to the xanthate in solution, the b_a for xanthate oxidation has a higher value, i.e., 240-260 mV decade $^{-1}$. However, the rate of oxidation of xanthate is increased by about 2.5 times in the presence of O_2 . The O_2 reduction is inhibited by about 10 times in the presence of xanthate, although the $-b_c$ remains the same. The $i_{0,a}$ and $i_{0,c}$, correspondingly, are 5.6×10^{-7} A cm $^{-2}$ and 1.4×10^{-14} A cm $^{-2}$, respectively. The E_m and i_m values in the mixture are $-0.065V$ (NHE) and 1.6×10^{-7} A cm $^{-2}$, respectively.

Discussion

Pyrite

Oxygen reduction kinetics.—To elucidate the mechanism of reduction of O_2 and FeS_2 , some seventeen reaction schemes for O_2 reduction have been considered, and these are given in Appendix 1.

Fig. 7. E -log i plots at PbS electrode in borate buffer pH 9.1. A: O_2 reduction ($p_{O_2} = 1$) in the absence of KEX. B: KEX oxidation ($C_{KEX} = 10^{-2}M$) in the absence of O_2 .

Mechanisms C9, C12, C14, and C16 are the only ones of the mechanism in Table A-I which give a $[\partial E / \partial \ln i]$ of $2RT/F$ and $[\partial \ln i_c / \partial \ln p_{O_2}]$ of unity, with the first step rate determining (rds). These four mechanisms proceed through H_2O_2 (HO_2^- in alkaline solution) as an intermediate. H_2O_2 was identified in the O_2 reduction at the FeS_2 electrode, in $HClO_4$ acid solution (13), and in alkaline solutions (32). However, these above four mechanisms with the first step as rds also predict that

$$\left[\frac{\partial \ln i_c}{\partial (2.3pH)} \right]_{E,T} = 0$$

The available experimental data indicate that O_2 reduction at noble metals (33, 34) and at FeS_2 (13, 32) is pH dependent at $pH > 4$. These four mechanisms can be regarded as not applicable in the present studies, since they were carried out at $pH 9.1$.

The present experimental results are, however, consistent with mechanism C17, which involves H_2O_2 as an intermediate. The reaction scheme is

With step II as rds, and with the condition that the intermediates $[O_2H^+]_{ads}$ and $[O_2H]_{ads}$ are present at limitingly low coverages, it is evident that this mechanism does predict finite values for the pH dependence of i_c (cf. Table A-I).

The solvent displacement mechanism has not been considered here (see below) because, studying reactions involving H_2 and O_2 evolution or their dissolution, one is concerned either with zero water displacement [as with H_3O^+ discharge (40)], or with the displacement of one (as, probably, when direct electron transfer to O_2 occurs).

Xanthate oxidation mechanism.—Various reaction schemes for xanthate oxidation have been worked out and are compiled in Table III. The anodic mechanisms 3 and 4 are similar to 1 and 2, respectively, but they have the desorption of dioxanthogen as an additional reaction step. Table III indicates that none of the kinetic parameters for the mechanisms listed are in agreement with the values reported here for b_a and $[d \ln i_a / d \ln C_{KEX}]_E$.

In organoelectrochemical reactions, the competition between adsorbed intermediates and water molecules may be important (41). Further, in flotation mechanisms, water displacement by the collector has an effect on hydrophobicity. Accordingly, kinetic parameters have been calculated in terms of solvent displacement

² Step [IV] is often quoted in the oxygen reduction literature (29, 31, 33). However, it involves the difficulty of surface anion recombination. This may be diminished in two ways. Thus, image forces reduce the repulsion (35); and also, it seems reasonable to suppose that charge transfer adsorption occurs, i.e., the surface charge on the anion must be < 1 . For example, anion adsorption on perovskites (36) shows full coverage with respect to OH^- in alkaline solution, and this would not be possible unless partial charge transfer had occurred.

Experimental						

* m and l are the number of water molecules replaced by one molecule of x_{ads} and $x_{2_{\text{ads}}}$, respectively. $m = 1.5$ and $l = 6-7$ (see text).

mechanisms (41), and the results are given in Table IV. The mechanism 4 with step 3 as the rds, and with the intermediates following the Temkin adsorption isotherm, predicts b_a of 90-95 mV³ and $[\partial \ln i_a/\partial \ln C_{\text{KEX}}]_E = 0.67-0.64$, which are in good agreement with the experimental values of 95 \pm 5 mV and 0.71.

The reaction scheme is, therefore

with step VII as rds, and $x_{2_{\text{ads}}}$ following a Temkin adsorption isotherm. The corresponding current density is (41)

³The range arises because of uncertainty in the number of water molecules displaced by dioxanthogen. This has been taken, on the basis of space filling models, as 6-7.

$$i^+_{\text{VII}} = 2Fk^+_{\text{VII},0} \theta_{X_2} \exp \left[(1 - \gamma) \frac{l\mu FE}{e_0 \delta RT} \right] \cdot \exp[(1 - \epsilon) l r \theta] \quad \text{[14]}$$

where l = the number of water molecules replaced by one molecule of $x_{2_{\text{ads}}}$, μ and δ are the dipole moment and the diameter of water molecule, respectively; e_0 = unit electronic charge; $r\theta$ is a function of the surface coverage θ of the adsorbed intermediates. The symbols γ and ϵ are symmetry factors.

⁴In taking m and r to be the Temkin parameters for the interaction of x_{ads} with $x_{2_{\text{ads}}}$, we follow Gileadi and Stoner (41). In fact, there is no precise justification for assuming that the interaction parameters in a Temkin formulation should be proportional to the number of water molecules which an adsorbent displaces, i.e., to the adsorbent's size. Conversely, this treatment is at least better than the previous treatments which assume identity of all the Temkin r values. In fact, r will tend to increase with the size of the adsorbent.

The quantity $r\theta$ can be calculated from the equilibrium step [VI]⁵

$$r\theta = \ln \left\{ [K_{VI,0}]^{\frac{1}{l-m}} \cdot [x^-]^{l-m} \cdot \exp \left[-\frac{\mu}{e_0\delta} \frac{FE}{RT} \right] \cdot \exp \left[\frac{1}{l-m} \frac{FE}{RT} \right] \right\} \quad [2]$$

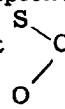

where m is the number of water molecules replaced by one molecule of x_{ads} .

Therefore

$$i^+_{VII} = K[x^-]^{0.51} \exp \left[\frac{l}{l-m} (1-\gamma) F \frac{E}{RT} \right] \quad [3]$$

Hence

$$b_a = \left[\frac{\partial E}{\partial \log i^+_{VII}} \right]_{x^-} = \frac{1}{(l/l-m)} \frac{1}{(1-\gamma)} \frac{2.303RT}{F} \left[\frac{\partial \ln i^+_{VII}}{\partial \ln [x^-]} \right]_E = \frac{0.5l}{(l-m)}$$

The parameters m and l require the area occupied by the adsorbed species x and x_2 . The projected surface areas for the discharged radical are 16.0 Å² and 62.6 Å², respectively, for the orientation in which the planar part  lies on the surface with the alkyl

group pointing into the solution. These values were calculated considering molecules as spherical and arranged in hexagonal close packing. With a value of 10.2 Å² for water,⁶ m and l are 1.5 and 6-7, respectively. The kinetic parameters are thus 90-94 mV, and 0.67-0.64.

These considerations are based on a model in which there are no multilayers. In the flotation region for FeS₂, there is evidence for their absence (42-44). The findings of recent XPS measurements (27) also indicated that the mineral surface contains less than a monolayer of the collector. Gardner and Woods (12) have interpreted sweep measurements in a more anodic region to indicate multilayer formation of dixanthogen on FeS₂. However, (i) if multilayer formation were uniform, steady-state xanthate oxidation partnered by oxygen reduction would be difficult to conceive (45), (ii) the $i-t$ transients do not increase their rate of decline with time at more anodic potentials where the suspected multilayers would be thicker, (iii) in Ahmed's results (18), hydrophobicity could be rapidly (i.e., < 100-200 ms) turned on and off by closing and opening the circuit, which would be improbable if dixanthogen were present in multilayers, and (iv) it is possible that the calculations by Gardner and Woods (12) of the coulombs in the sweep regions were increased by solute readsorption.

Mixed potential model.—The rate equations for the O₂ reduction and xanthate oxidation can be written as

$$i_c = -4F\theta_c k_c^0 p_{O_2} [H^+] \exp [-\beta FE/RT] \quad [4]$$

and

$$i_a = 2F\theta_a k_a^0 [x^-]^{0.51} \exp \left[\frac{l}{(l-m)} (1-\gamma) FE/RT \right] \quad [5]$$

⁵ It is correct to consider only step [VI] (and not [V]) when evolving $r\theta$ in the Temkin mode. Thus, applying the Temkin conditions to [V], one obtains $r\theta_{x_{ads}} = -EF + \ln|x^-| + \text{const.}$, i.e., $\theta_{x_{ads}}$ is linear with potential. In the deduction of Eq. [2], were $\theta_{x_{ads}}$ expressed in terms of [V], no change in the exponential terms of [2] would occur.

⁶ This value was calculated by assuming hexagonal close packing of H₂O on the electrode surface and no dimer formation.

where θ_c and θ_a are the areas over which the cathodic and anodic reactions, respectively, take place, and k_c^0 and k_a^0 are the respective rate constants under zero-field conditions.

Equations [4] and [5] can be expressed, in terms of the exchange current density as

$$i_c = i_{o,c} \exp [-\beta F(E - E_{e,c})/RT] \quad [4']$$

$$i_a = i_{o,a} \exp \left[\frac{l}{l-m} (1-\gamma) F(E - E_{e,a})/RT \right] \quad [5']$$

For the mixed potential theory to be applicable to a system, in which the above two are the partial reactions which determine the open-circuit mixed potential E_m and the corresponding current i_m , the following conditions should be satisfied

$$|i_c| = i_a = i_m \quad [6]$$

and

$$E = E_m \quad [7]$$

The applicability of the mixed potential model can be tested by two methods.

Method 1: Calculation of E_m and i_m .—Combining Eq. [4'] and [5'] to get E_m and i_m

$$E_m = \frac{RT}{(\alpha_a + \alpha_c)F} \ln \left[\frac{i_{o,c}}{i_{o,a}} \right] + \frac{\alpha_c}{\alpha_a + \alpha_c} E_{e,c} + \frac{\alpha_a}{\alpha_a + \alpha_c} E_{e,a} \quad [8]$$

and

$$i_m = [i_{o,a}]^{\frac{\alpha_c}{\alpha_a + \alpha_c}} [i_{o,c}]^{\frac{\alpha_a}{\alpha_a + \alpha_c}} \exp \left[\frac{\alpha_a \alpha_c}{\alpha_a + \alpha_c} \cdot \frac{F}{RT} E_{e,cell} \right] \quad [9]$$

where

$$\alpha_a = \frac{(1-\gamma)l}{l-m}$$

$$\alpha_c = \beta$$

and

$$E_{e,cell} = E_{e,c} - E_{e,a}$$

By knowing $i_{o,a}$ and $i_{o,c}$ values in the mixture (from Fig. 3-6), E_m and i_m can be calculated, since α_c and α_a are known. These calculated values of E_m and i_m can be compared with experimentally obtained values in the mixture.

The degree of agreement is high, as shown in Table V.

Method 2: Test of differentials.—Equating Eq. [4] and [5], we get

$$\left[\frac{\partial E_m}{\partial \log p_{O_2}} \right]_{x^-,pH} = \frac{b_a |b_c|}{b_a + |b_c|} \left\{ 1 + \left[\frac{\partial \log (\theta_c/\theta_a)}{\partial \log p_{O_2}} \right]_{x^-,pH} + \left[\frac{\partial \log (k_c^0/k_a^0)}{\partial \log p_{O_2}} \right]_{x^-,pH} \right\} \quad [10]$$

and

$$\left[\frac{\partial \log i_m}{\partial \log p_{O_2}} \right]_{x^-,pH} = -\frac{b_a}{b_a + |b_c|} \left\{ 1 + \left[\frac{\partial \log (\theta_c/\theta_a)}{\partial \log p_{O_2}} \right]_{x^-,pH} + \left[\frac{\partial \log (k_c^0/k_a^0)}{\partial \log p_{O_2}} \right]_{x^-,pH} \right\} + \left[\frac{\partial \log \theta_c}{\partial \log p_{O_2}} \right]_{x^-,pH} + \left[\frac{\partial \log k_c^0}{\partial \log p_{O_2}} \right]_{x^-,pH} \quad [11]$$

Table V. A comparison of experimental and calculated E_m and i_m

Systems	E_m V		$i_m \times 10^6$ A cm ⁻²	
	Experimental	Calculated	Experimental	Calculated
(A) $p_{O_2} = 1$ and $C_{KEX} = 10^{-2}$	0.17	0.16	9.00	7.20
(B) $p_{O_2} = 1$ and $C_{KEX} = 10^{-3}$	0.19	0.19	7.30	7.80
(C) $p_{O_2} = 0.33$ and $C_{KEX} = 10^{-2}$	0.10	0.08	2.20	1.40
(D) $p_{O_2} = 0.33$ and $C_{KEX} = 10^{-3}$	0.18	0.17	3.30	2.40

As a "zeroeth" approximation, let it be assumed that the pressure terms in the parentheses are zero. A comparison of the calculated values with the experimental values is then as follows (Table VI).

The results of Table VI show poor consistency between fact and model. In reconsidering Eq. [10] and [11], it seems reasonable to continue to accept a negligible variation of rate constant with pressure, but to admit that the relative occupancy of cathodic and anodic sites (θ_c/θ_a) may depend upon oxygen pressure. One can then calculate the change of θ_c/θ_a caused by a change of oxygen pressure (the assumption is that the discrepancies of Table VI are due entirely to this variation).

Considering the system (A)/(C), one finds, thus, the value of 1.3 for

$$\left[\frac{\partial \log i_m}{\partial \log p_{O_2}} \right]_{x^-, pH}$$

i.e., a change of 10 times in p_{O_2} causes a change of 19.9 times in i_m . From Eq. [4] and the values of Table VI

$$\frac{(i_c)_{p_{O_2}=1}}{(i_c)_{p_{O_2}=0.1}} = \frac{(\theta_c)_{p_{O_2}=1}}{(\theta_c)_{p_{O_2}=0.1}} \exp \left[-\frac{\beta F}{RT} (0.150) \right]$$

where 0.150 is the corresponding change of the mixed potential. Hence

$$\frac{(\theta_c)_{p_{O_2}=1}}{(\theta_c)_{p_{O_2}=0.1}} \approx 677 \quad [12]$$

Similar reasoning, applied to the anodic reaction, shows that

$$\frac{(\theta_a)_{p_{O_2}=1}}{(\theta_a)_{p_{O_2}=0.1}} = 0.53 \quad [13]$$

The sum of θ_c and θ_a at each pressure may be taken as unity for each pressure, respectively. The resulting two equations, together with Eq. [12] and [13], yield the values of Table VII. The same approach can be applied to the systems (B)/(D).

⁷ The large change is not irrational in view of the attractive interaction between xanthate and radicals from oxygen reduction (see Fig. 3 and Fig. 5).

Table VI. Experimental and calculated coefficients (with the assumption of cathodic/anodic area ratio independent of O_2 pressure)

	Systems (A)/(C) (i.e., at a constant $C_{KEX} = 10^{-2}M$)		Systems (B)/(D) (i.e., at a constant $C_{KEX} = 10^{-3}M$)	
	Experimental	Calculated	Experimental	Calculated
$\left[\frac{\partial E_m}{\partial \log p_{O_2}} \right]_{x^-, pH}$ V decade ⁻¹	0.150	0.044	0.002	0.048
$\left[\frac{\partial \log i_m}{\partial \log p_{O_2}} \right]_{x^-, pH}$	1.300	0.500	0.700	0.500

Table VII. Calculation of degree of occupancy of FeS_2 surface with cathodic and anodic sites

Systems (A)/(C)	$p_{O_2} = 0.1$		$p_{O_2} = 1$	
	θ_c	θ_a	θ_c	θ_a
Systems (A)/(C)	0.613	0.990	0.480	0.520
Systems (B)/(D)	0.890	0.110	0.460	0.540

It can be seen (Table VII) that the model used (mixed potential hypothesis; negligible pressure dependence of rate constant but pressure dependence of cathodic/anodic site ratio) gives a reasonable order of changes for the system (A)/(C), in which KEX is at $10^{-2}M$ and the oxygen pressure varies by ten times. However, for the systems (B)/(D) ($KEX = 10^{-3}M$), the results are unfavorable, θ_c decreasing anomalously with increase of oxygen pressure. It is possible that this discrepancy arises because, in the systems (B)/(D), there is a competing oxidation of the substrate. Some evidence for this can be seen by the increased deviation (from Tafel relation) of the i-V curves in Fig. 4 and 6.

Galena

The O_2 reduction on PbS will be assumed to occur through a mechanism similar to that on FeS_2 . The only evidence available is that $-b_c$ on PbS has the same slope as on FeS_2 , i.e., 120 mV decade⁻¹.

The high b_a value (>240 mV) observed for xanthate oxidation on PbS can be explained in terms of the anodic mechanism 4 (Table IV) is operative on PbS (solvent displacement mechanism) with the step II as the rds, and the intermediate following a Langmuir adsorption isotherm with $\theta \rightarrow 1$. At more positive potentials (see Fig. 7), the slope changes to one of 40 mV and this would be consistent with mechanism 4, although step III would now be the rds.

The decrease of the xanthate oxidation rate observed at higher potentials (Fig. 7) indicates that the surface compound formed on PbS in the presence of KEX is chemically different from that on FeS_2 , where the current increases continuously with potential. In the case of PbS, it is possible that step III of the mechanism 4 (Table IV) may be the rds, as long as the surface coverage of x_{2ads} is small. With increase in $\theta_{x_{2ads}}$, there is a possibility that x_{2ads} is converted to surface compounds such as lead ethyl xanthate and elemental sulfur (17), which can inhibit the further electron transfer reaction at the interface.

Coming to the mixed potential model, as applicable to PbS in the mixture of O_2 and KEX (Fig. 8), the experimental values of E_m and i_m [$-0.065V$ (NHE) and $1.6 \times 10^{-7}A$ cm⁻²] are in good agreement with the calculated values from Eq. [8] and [9] [$-0.078V$ (NHE) and $1.35 \times 10^{-7}A$ cm⁻²].

Comparison of the Behavior of FeS_2 and PbS

O_2 reduction.—The $i_{o,c}$ values for O_2 reduction at $p_{O_2} = 1$, of $4.6 \pm 0.3 \times 10^{-12}A$ cm⁻² and $2.8 \pm 0.3 \times 10^{-12}A$ cm⁻² at FeS_2 and PbS electrodes, respectively, indicate a higher catalytic activity of FeS_2 for this reaction. This is in accordance with studies (46, 47) on electrocatalytic reduction with thiospinels of the transition elements.

Both FeS_2 and PbS are semiconductors (see Experimental section). A value of 0.5 for the transfer coefficient (α) for the O_2 reduction at both FeS_2 and PbS indicates the absence of a Schottky barrier within the sulfides (48) and that the semiconductor-solution interphase properties predominate over the semiconductor properties. Surface states are evidently present.

Xanthate oxidation.— FeS_2 shows a higher $i_{o,a}$ value for xanthate oxidation ($1 \times 10^{-6}A$ cm⁻² for $C_{KEX} = 10^{-2}M$) than PbS ($2.4 \times 10^{-7}A$ cm⁻²). These values

Experimental									

* τ is the p.d. between outer Helmholtz plane and the bulk of the solution.

^a Temkin interaction parameter for all intermediates is taken as equal.

^b Value for the coefficient, when ξ is not constant. Thus, with the step

as rds

$$[\partial \ln i / \partial (2.3 \text{ pH})]_{1F} = -1 + (\beta - 1)(F/2.303RT) [\partial (\delta \text{ pH}) / \partial \text{ pH}]_{1F}$$

The ξ potential may be related approximately to Cor^- by an equilibrium equation (37-39)

$$\xi = \xi_0 - (RT/F) \ln \text{Cor}^-$$

Hence

$$[\partial \ln i / \partial (2.3 \text{ pH})]_{1F} = -0.5$$

^c Value extrapolated from experimental i-V plots of Ref. (13b) (pH range 9.1-12.1).

differ by too small a degree to justify significant theoretical interpretation.

The consistence found with a Temkin isotherm for xanthate oxidation of FeS₂ (but Langmuir for PbS) may be related to the Fe-Fe distance (3.82Å) compared with the Pb-Pb distance in PbS (4.18Å). The adsorbed organics are probably orthogonal to the electrode surface (see Xanthate oxidation section, above), and may adsorb on the metal sites (49). The lateral interaction between the same organic molecules apart at these two distances would be in a ratio of around 1.5:1 (FeS₂ to PbS).

Mixture of O₂ and KEX.—The oxidized xanthate present on the surface accelerates O₂ reduction of FeS₂; it inhibits it on PbS. This is in accordance with the literature that the hydrophobic species that forms on FeS₂ is different from that on PbS (14, 16, 17).

Conclusions

1. The mechanism of O₂ reduction on both FeS₂ and PbS involves the rds of O₂H⁺_{ads} + e → O₂H_{ads}. H₂O₂ is an intermediate.

2. The mechanism of the oxidation of xanthate occurs through a solvent displacement mechanism. The rds is the desorption of dixanthogen for FeS₂; and x_{ads} + x⁻ → x_{2ads} + e for PbS.

3. The mixed potential theory is consistent with the measured electrode kinetics with respect to the comparison of E_m and i_m values. The measured differential coefficients [∂E_m/∂ log pO₂]_{x⁻,pH} and [∂ log i_m/∂ log pO₂]_{x⁻,pH} are, however, different from the values predicted by the simple model, in which the cathodic to anodic area ratio (θ_c/θ_a) is assumed independent of O₂ partial pressure. By considering the variation of θ_c/θ_a with O₂ partial pressure,⁸ it is possible to bring a consistency between the theory and experiment, in systems containing high concentrations of KEX in solution. When KEX concentration is low, theory and experiment are not in good agreement. This may be due to partial oxidation of the substrate.

4. Within this situation, the mixed potential theory is consistent with the available data.

Acknowledgment

The authors are grateful to Dr. Ron Woods of the CSIRO, Melbourne, Australia for discussion and to the National Science Foundation, Washington, D.C. for financial support under grant No. CPE-8006977.

Manuscript submitted March 14, 1983; revised manuscript received Sept. 15, 1983.

⁸The origin of such a variation may arise from reaction of the adsorbed xanthate intermediate and a possible peroxide. Enhancement of the oxygen kinetics could come as a result of bubble adhesion.

Use of the Junction Between Two Solid Electrolytes for the Potentiometric Measurement of Gaseous Oxides

A. Bélanger,* M. Gauthier,* and D. Fauteux*

Institut de recherche d'Hydro-Québec, Varennes, Québec, J0L 2P0, Canada

ABSTRACT

The contact between two solid electrolytes such as a stabilized zirconia and potassium sulfate can be used to measure the activity of volatile oxides, SO₂ or SO₃ for instance. On this basis, a new type of sensor has been designed which produces stable voltages logarithmically dependent on the concentration of the gas to be measured. This principle was extended to the measurement of other gaseous oxides, namely carbon oxides, using K₂CO₃ as the electrolyte. The range of these sensors covers a few parts per million to several thousand parts per million and their operating temperature varies from 600° to 900°C.

The last years have witnessed many publications on the application of solid electrolytes for analytical purposes, the best known being the oxygen sensor in which a stabilized zirconia is used as the electrolyte (1, 2). More recently, the operating principle of the oxygen sensor has been applied to other types of potentiometric devices, especially for the measurement of gases containing halogen and volatile oxides (3, 4). In the latter category, a new type of solid-electrolyte sensor has been developed and patented at IREQ for measuring the activity of gaseous oxides in air or in combustion gases; it has proven particularly suitable for measuring carbon and sulfur oxides (3-5). In these applications, the solid electrolyte contains an alkaline or alkaline earth salt of the oxyanion corresponding to the oxide whose activity is to be measured. For SO₂ and SO₃, potassium sulfate is used for example, whereas for CO and CO₂ the electrolyte will consist basically of K₂CO₃. In the case of the sulfur oxide sensors, the electrode reaction may be written as follows (6)

In the sulfur oxide sensor, the metal electrodes are comprised of platinum or gold, according to whether the total sulfur content is to be measured or just the SO₃ without modifying the gas phase equilibrium (7, 8).

The development of the new sensor involved studying different types of reference electrodes, of which the most important so far as sulfur oxides are concerned are (i) gas reference electrodes based on circulation of a known mixture of SO₂ and air (6), (ii) gas reference electrodes obtained by the thermal decomposition of a sulfate (7), (iii) Ag/Ag⁺ type of reference electrode [1% Ag₂SO₄ added to the K₂SO₄ of the electrode (6)], and (iv) zirconia reference electrodes where two solid electrolytes are brought into contact, one containing the oxyanion of the oxide to be measured, e.g., K₂SO₄, the other being stabilized zirconia (7).

The stabilized zirconia reference electrode enters into the following electrochemical chain

During the development, the stabilized zirconia reference was found to be far less stable than the other three, despite its practical advantages. For example, if used discontinuously on a daily basis, the cell EMF may vary by several tens of millivolts for no apparent reason. The nature of the atmosphere surrounding the zirconia-sulfate junction had a considerable influence on the EMF stability. This was easily solved by sealing the zirconia-sulfate junction with a suitable ceramic product, whereupon the reference signal became far more stable (7).

The foregoing observations led to a study of the mechanism involved in the influence of the junction atmosphere on the signal. The first step in this study was to examine the equilibria at the triple junction between the solid sulfate, the stabilized zirconia, and the gas phase

A first treatment of these equilibria and some preliminary results were presented recently (9, 10). For these studies, an experimental device was designed which would optimize the contact between the gas phase and the electrolyte junction by means of a very small zirconia tip slightly embedded in the K₂SO₄ (or K₂CO₃) electrolyte. The device comprises three totally independent atmospheres, so that the junction atmosphere can be changed without modifying the other two (see Experimental).

The aim of this paper is to discuss the mechanism operating at these junctions and to present detailed experimental results which demonstrate the potential interest of the triple junction for analytical purposes, especially for monitoring trace gaseous constituents such as SO₂, SO₃, CO, and CO₂. Electrolytic junction sensors are the product of technologies very similar to

* Electrochemical Society Active Member.

those employed for detectors with metallic electrodes. A detailed insight into the different models and the variety of measuring instruments that exist may be gained from the literature (3-7), so that only the section of the sensor where the various electrochemical equilibria are established will be described here (see Fig. 1 and 2a).

Experimental Materials and Procedures

The techniques used for the preparation of the gas mixtures and of the electrolytes, as well as the experimental setups, were reported in previous papers (4, 5, 7). Briefly, three similar setups were used, as schematized in Fig. 2. The three-atmosphere sulfur oxide sensor (Fig. 2a) comprises an airtight alumina crucible containing a mixture of powdered MgSO_4 and MgO which determines the partial pressures of SO_3 , SO_2 , and O_2 in the crucible through thermal decomposition of MgSO_4 at the temperature of measurement. For this atmosphere (referred to as S) the electrode is made of platinum. The second atmosphere (O) is similarly generated by the equilibrium between Pd , PdO , and O_2 , which are sealed inside the zirconia-doped ($\text{ZrO}_2\text{-Y}_2\text{O}_3$) oxygen minisensor (11, 12); again, the electrode is made of platinum. Finally, the third atmosphere (J) is established by circulating gas mixtures of SO_2 and O_2 through the sensor. A platinum catalyst is placed in the inlet tube of the sensor to ensure that the equilibrium between SO_3 , SO_2 , and O_2 is reached.

The two-atmosphere sulfur oxide sensor (Fig. 2b) is similar to that of Fig. 2a, except that the oxygen sensor was unsealed and the Pd-PdO mixture withdrawn so that the atmosphere (O) is replaced by the circulating atmosphere (J), which serves at the reference gas.

Fig. 1. Photograph showing details of the tip of the sensing element of the sulfur oxide 2-compartment sensor. The components from top to bottom are: (1) dual-port quartz tube (ϕ in ≈ 3 mm); (2) oxygen minigauge ($\phi = 2$ mm; $l = 10$ mm) and platinum wire ($\phi = 0.2$ mm); (3) K_2SO_4 electrolyte pellet ($\phi = 7$ mm; $l = 3$ mm); (4) alumina spacer with platinum wire; (5) perforated platinum grid with platinum wire forming the electrode; and (6) alumina crucible containing powdered MgO and MgSO_4 .

Fig. 2. Schematic of sulfur oxide (A) 3-compartment sensor, (B) sulfur oxide 2-compartment sensor, and (c) carbon oxide 2-compartment sensor.

For the two-atmosphere carbon oxide sensor (Fig. 2c), the $\text{ZrO}_2\text{-Y}_2\text{O}_3$ oxygen minisensor was replaced by calcia-stabilized zirconia ($\text{ZrO}_2\text{-CaO}$). As in Fig. 2b, atmosphere (O) is the same as atmosphere (J). The reference atmosphere (C) is defined by circulating a gas mixture consisting of a known concentration of CO_2 in air.

Results and Discussion

General expression for the electromotive force (EMF).—The electrochemical cell of the measurement junction may be described as (3)

The EMF resulting from this electrochemical chain may be expressed as follows if the electrochemical potential of the majority carriers is assumed to be constant within each electrolyte

$$\tilde{\mu}_{\text{O}_2}^{\text{S}} = \tilde{\mu}_{\text{O}_2}^{\text{J}} \quad [2]$$

and

$$\tilde{\mu}_{\text{K}^+}^{\text{S}} = \tilde{\mu}_{\text{K}^+}^{\text{J}} \quad [3]$$

where the indexes O²⁻ and K⁺ identify the majority carriers while J, O, and S denote the interface. Assuming also that equilibrium is reached at the different interfaces, then

from which the following expressions can be derived

$$\mu^{\text{S}}_{\text{SO}_3} + \frac{1}{2} \mu^{\text{S}}_{\text{O}_2} + 2\tilde{\mu}^{\text{S}}_{\text{K}^+} + 2\tilde{\mu}^{\text{S}}_{e^-} = \mu^{\text{S}}_{\text{K}_2\text{SO}_4} \quad [7]$$

$$\mu^{\text{J}}_{\text{SO}_3} + 2\tilde{\mu}^{\text{J}}_{\text{K}^+} + \tilde{\mu}^{\text{J}}_{\text{O}^{2-}} = \mu^{\text{J}}_{\text{K}_2\text{SO}_4} \quad [8]$$

$$\mu^{\text{O}}_{\text{O}_2} + 4\mu^{\text{O}}_{e^-} = 2\mu^{\text{O}}_{\text{O}^{2-}} \quad [9]$$

The last three equations yield the difference in the electrochemical potential of the electrons

$$\tilde{\mu}^{\text{S}}_{e^-} - \tilde{\mu}^{\text{O}}_{e^-} = -\frac{1}{2} \mu^{\text{S}}_{\text{SO}_3} - \frac{1}{4} \mu^{\text{S}}_{\text{O}_2} + \frac{1}{4} \mu^{\text{O}}_{\text{O}_2} + \mu^{\text{J}}_{\text{SO}_3} \quad [10]$$

The difference in internal electrical potential is

$$\Delta\phi = -\frac{1}{2F} \mu^{\text{S}}_{\text{SO}_3} - \frac{1}{4F} \mu^{\text{S}}_{\text{O}_2} + \frac{1}{4F} \mu^{\text{O}}_{\text{O}_2} + \frac{1}{2F} \mu^{\text{J}}_{\text{SO}_3} \quad [11]$$

From which the EMF is obtained by expressing the chemical potential of the different species

$$E = -\frac{RT}{2F} \ln p^{\text{S}}_{\text{SO}_3} - \frac{RT}{4F} \ln p^{\text{S}}_{\text{O}_2} + \frac{RT}{4F} \ln p^{\text{O}}_{\text{O}_2} + \frac{RT}{2F} \ln p^{\text{J}}_{\text{SO}_3} \quad [12]$$

The general expression of the cell EMF becomes

$$E = \frac{RT}{2F} \ln \frac{p^{\text{J}}_{\text{SO}_3}}{p^{\text{S}}_{\text{SO}_3}} \cdot \frac{(p^{\text{O}}_{\text{O}_2})^{1/2}}{(p^{\text{S}}_{\text{O}_2})^{1/2}} \quad [13]$$

The sensor EMF depends only on the SO₃ partial pressure at the junction whenever the reference atmospheres (O) and (S) are fixed; the junction then acts as a specific SO₃ detector. Experimentally, there are a number of situations which can be described by Eq. [13]. On the one hand, for sulfur oxide references of the circulation or decomposition type, Fig. 2b and 2c, we can experimentally fix $p^{\text{S}}_{\text{O}_2} = 0.21$ in air. On the other hand, when the sensor includes only two independent atmospheres, $p^{\text{O}}_{\text{O}_2}$ can be replaced by $p^{\text{J}}_{\text{O}_2}$. Finally, as previously shown (4), $p^{\text{J}}_{\text{SO}_2}$ and $p^{\text{J}}_{\text{SO}_3}$ can be expressed in terms of $(p^{\text{J}}_{\text{SO}_2})_{\text{in}}$, which is the SO₂ concentration of the gas mixture prepared at room temperature in the laboratory for circulating past the electrolytic junction (4, 6)

$$p^{\text{J}}_{\text{SO}_2\text{in}} = p^{\text{J}}_{\text{SO}_2} + p^{\text{J}}_{\text{SO}_3} \quad [14]$$

If fully catalyzed, the different species are related by the equilibrium constant

$$K = \frac{p^{\text{J}}_{\text{SO}_2} \cdot (p^{\text{J}}_{\text{O}_2})^{1/2}}{p^{\text{J}}_{\text{SO}_3}} \quad [15]$$

of the reaction

On the basis of Eq. [14] and [15], Eq. [13] becomes

$$E = \frac{\left[\frac{(p^{\text{J}}_{\text{SO}_2})_{\text{in}}}{1 + \frac{K}{(p^{\text{J}}_{\text{O}_2})^{1/2}}} \right] \cdot (p^{\text{O}}_{\text{O}_2})^{1/2}}{p^{\text{S}}_{\text{SO}_3} \cdot (p^{\text{S}}_{\text{O}_2})^{1/2}} \quad [16]$$

For a two-atmosphere sensor, the index O merely has

to be replaced by (J), since the atmosphere becomes common. Then

$$E = C + \frac{RT}{2F} \ln (p^{\text{J}}_{\text{SO}_2})_{\text{in}} + \frac{RT}{2F} \ln p^{\text{J}}_{\text{O}_2} - \frac{RT}{2F} \ln [K + (p^{\text{J}}_{\text{O}_2})] \quad [16a]$$

where C is a constant that includes the sulfate reference signal. This expression is identical in all aspects to the one derived for sensors with metallic electrodes (7). Relations [16] and [16a] are valid only if the gases reaching the junction have been suitably catalyzed to respect relation [15].

Two-atmosphere sulfur oxide sensor.—The variation in the EMF for a two-atmosphere quartz device sketched in Fig. 2b as a function of $\ln p^{\text{J}}_{\text{SO}_2\text{in}}$ is given in Fig. 3. These results agree with the theoretical behavior predicted by Eq. [16] and [16a] for a two-atmosphere sensor using a reference sulfur oxide atmosphere obtained by decomposing an equimolar mixture of MgO and MgSO₄. The $p^{\text{S}}_{\text{SO}_3}$ value resulting from this decomposition reaction may be obtained from the literature. The decomposition equilibrium of sulfates has been studied using many analytical techniques. Mention may be made, among others, of the work by Marchal (14) (total pressure measurement), Dewing and Richardson (15) (differential thermal analysis), Skeaff and Espelund (16) (p_{O_2} measurements) and, finally, Kellogg (17) (review article). For the purpose of this study, Skeaff and Espelund's data (16) were used because they were obtained under experimental conditions similar to ours and are in fairly good agree-

Fig. 3. EMF of a sulfur oxide 2-compartment sensor (Fig. 2b) plotted vs. SO₂/air gas mixtures circulating at the junction. These results show the influence of the flow rate with and without a catalyst at two temperatures; 790° and 650°C. Solid lines show calculated values by Eq. [16] while the dotted lines describe the experimental results.

ment with ours. The latter authors proposed the following thermodynamic data for the decomposition of magnesium sulfate according to the reaction (valid between 940 and 1230 K)

$$\Delta H^\circ = 69.73 \text{ kcal mol}^{-1}$$

$$\Delta S^\circ = 44.27 \text{ cal K}^{-1} \text{ mol}^{-1}$$

These values can then be used to calculate ΔG° and, therefore, p_{SO_3} in Eq. [13] and [16] since

$$K_{\text{decomp.}} = \exp(-\Delta G^\circ/RT) = \frac{[\text{MgO}]p_{\text{SO}_3}^{\text{S}}}{[\text{MgSO}_4]} = p_{\text{SO}_3}^{\text{S}} \quad [18]$$

assuming that the activities of the two pure solids equal unity.

On the other hand, to calculate the equilibrium constant K [15], the expression put forward by Kellogg (17) was slightly modified to take account of the more recent results compiled by Stern and Weise (18)

$$\log_{10} K = 8.987 - \frac{5590}{T} - 1.2157 \log_{10} T \quad [19]$$

where T is in Kelvin.

Combining relations [18] and [19] with [16], the value of the EMF of a two-compartment sensor can be determined for all values of $p_{\text{SO}_2}^{\text{J}}$ in. The calculated curves are shown as continuous lines for two temperatures in Fig. 3. At 790°C, the curve runs through the experimental points for the entire range of $p_{\text{SO}_2}^{\text{J}}$ in for all flow rates shown, provided that the gas passes over a suitable catalyst maintained at the sensor operating temperature before it reaches the zirconia-sulfate junction. For lower temperatures, the calculated curve deviates from the experimental points even when the gases are circulating slowly over the catalyst, probably because of incomplete catalysis of the reaction [16]. Actually, even with catalysis, the flow rate always has a considerable influence on the signal, which was not the case at the higher temperature. Catalysis is even more noticeably incomplete at higher concentrations, so much so that above 1000 ppm, the EMF

reaches a maximum and can even drop again slightly if the concentration is further increased, which is indicative of a serious poisoning of the catalyst.

Figure 4 illustrates the performance of the sulfate-zirconia sensor (two atmosphere device, Fig. 2b) as a function of the variation in the oxygen content of the gas circulating at the junction. When Eq. [16a] was used to calculate the theoretical values, the curves obtained often differed from the experimental results. This behavior is believed to result from the difficulty in maintaining a constant temperature throughout the sensor, particularly when one or more atmospheres are circulating. For this reason, it was felt that for comparative purposes an analytical expression describing only the expected trends of the results would be preferable. In Eq. [16], $p_{\text{SO}_2}^{\text{J}}$ in and $p_{\text{SO}_3}^{\text{S}}$ can be considered constant and the relation becomes

$$E = C + \frac{RT}{2F} \ln (p_{\text{O}_2}^{\text{J}})^{1/2} - \frac{RT}{2F} \ln \left[1 + \frac{K}{(p_{\text{O}_2}^{\text{J}})^{1/2}} \right] \quad [20]$$

and eliminating the constant C

$$E' = \frac{RT}{2F} \ln p_{\text{O}_2}^{\text{J}} - \frac{RT}{2F} \ln [K + (p_{\text{O}_2}^{\text{J}})^{1/2}] \quad [21]$$

The calculated values of the two terms in Eq. [21] are given in Table I at three temperatures. Since the value of C in Eq. [20] is unknown, the values of E' have no absolute meaning; therefore it was deliberately decided to have the calculated and experimental points meet at one point, at $p_{\text{O}_2} = 20.8\%$ in air (numbers in parentheses in Table I). For instance, at $T = 583^\circ\text{C}$ and $p_{\text{O}_2} = 20.8\%$, the experimental EMF is 170 mV. Using Eq. [21], the calculated value of E' is -35 mV. Since the experimental and calculated curves are to meet at $p_{\text{O}_2} = 20.8\%$, the correction will be zero at this particular point. Thus in Fig. 4, the EMF is 170 mV in air. For $p_{\text{O}_2} = 10.18\%$, $E' = -50$ mV, the correction will be $[-50 - (-35)] = -15$ mV, as in Fig. 4, at $p_{\text{O}_2} = 10.18\%$ EMF = 170 - 15 = 155 mV, and so on.

The agreement between the calculated values of Fig. 4 (continuous line) and experimental points is

Fig. 4. EMF of a sulfur oxide 2-atmosphere sensor (Fig. 2b) plotted vs. oxygen content of the gas circulating at the junction at different temperatures. The sulfur dioxide concentration used for each curve is shown in parentheses. The continuous lines describe the theoretical profile calculated from Eq. [21]. The dotted lines show the slope of $RT/2F$ and $RT/4F$, respectively, at low and high p_{O_2} (see text).

Table I. Calculated data using Eq. [21] to obtain the dotted profiles described in Fig. 4

O ₂ (%)	E' (Eq. [21])		
	T = 583°C (mV)	T = 650°C (mV)	T = 800°C (mV)
0.58	-121	-155	-251
1.13	-103	-133	-221
4.8	-67	-87	-158
10.18	-50	-66	-126 (92)
20.8	-35 (170)	-44 (279)	-97 (-20)
48.8	-17	-25	-64 (-118)
100.0	-3	-8	-37
RT			
2F	84.9	91.6	106.5
K	0.78	0.21	1.24

generally satisfactory, except at extreme temperatures and concentrations [e.g., (p_{SO_2})_{in} = 10 ppm at 800°C and (p_{SO_2})_{in} = 1000 ppm at 600°C] when catalysis effects or detection limits can have an influence. This will be discussed later.

Furthermore, two borderline cases exist which simplify Eq. [21], as shown by the dotted lines in Fig. 4. In accordance with Eq. [21], the signal varies with a slope of $RT/4F$ at low temperatures for high p_{O_2} ($K \ll p_{\text{O}_2}$) and a slope of $RT/2F$ at high temperatures for low p_{O_2} ($K \gg p_{\text{O}_2}$). These two limiting conditions at high and low p_{O_2} are interesting because they allow elimination of the signal dependence on p_{O_2} by simple electronic subtraction of the EMF of a zirconia oxygen sensor, which is a function of $RT/4F$ [see Ref. (4)].

Three-atmosphere sulfur oxide sensor.—The results presented in Fig. 5 were obtained with a three-atmosphere quartz arrangement (Fig. 2a) using the University of Grenoble minisensor (see Experimental). The figure shows plots of the sensor EMF vs. ($p^{\text{J}}_{\text{SO}_2}$)_{in} for three operating temperatures.

As with the two-atmosphere sulfur oxide sensor, gas phase equilibrium is not achieved at low temperatures (SO₃ favored), particularly when the sulfur oxide concentration is high; this produces a clearly visible deviation in the curve. At higher temperatures, e.g., 780°C, catalysis is excellent and the curve is linear up to ($p^{\text{J}}_{\text{SO}_2}$)_{in} = 10,000 ppm (≈1%). However, the detection threshold for sulfur oxides is better at lower temperature (0.3 ppm) whereas the sensor response ceases to be linear at 800°C for ($p^{\text{J}}_{\text{SO}_2}$)_{in} ≤ 10 ppm. The theoretical slope of the curves in Fig. 5 was drawn through the mean of the experimental points (continuous line).

In order to calculate the theoretical position of the curve exactly, it is essential to refer to the general expression of the EMF, i.e., Eq. [16], in which the temperature dependence of the two reference electrodes

Table II. Data used to calculate the expected position of the experimental curve in Fig. 5 by Eq. [16]

Parameter	600°C (873 K)	648°C (921 K)	705°C (978 K)	780°C (1053 K)
RT 2F (mV)	86.6	91.4	97.0	104.5
K (atm) ^{1/2}	0.1019	0.2427	0.4324	1.0091
K _{atm} = p^S_{SO₃} (atm)}	1.65 × 10 ⁻⁸	1.34 × 10 ⁻⁷	1.24 × 10 ⁻⁶	3.12 × 10 ⁻⁵
(p ^S _{O₂}) ^{1/2} (atm) ^{1/2}	0.458	0.458	0.458	0.458
(p ^O _{O₂}) ^{1/2} Pd- PdO (10) (atm) ^{1/2}	2.47 × 10 ⁻³	5.67 × 10 ⁻³	1.35 × 10 ⁻¹	3.61 × 10 ⁻¹
E at (p ^J _{SO₂}) _{in} = 10 ⁻⁴ atm (mV)	+210	+163	+105	+20

is taken into account: $p^{\text{S}}_{\text{SO}_3} = \int (\text{MgO-MgSO}_4)$ and $p_{\text{O}_2} = \int (\text{Pd-PdO})$. When ($p^{\text{J}}_{\text{SO}_2}$)_{in} is equal to 10⁻⁴ atm (100 ppm), for example, the calculated EMF's are respectively 210 mV (at 600°C), 105 mV (at 705°C) and 20 mV (at 780°C). The corresponding curves are shown by short dotted lines in Fig. 5. The data used for the calculation are summarized in Table II.

Considering all experimental errors and, in particular, the inevitable temperature gradient inside the sensor, the agreement between calculated and experimental curves may be considered satisfactory. In fact, a temperature difference of 20°C between the measured temperature and the crucible temperature can account for a 20 mV shift in the experimental EMF ($\Delta E/\Delta t \approx 1$ mV/°C), while an equivalent temperature difference between the measured temperature and that of the platinum catalyst at the inlet can be responsible for an additional 6 mV shift in the EMF ($\Delta E/\Delta t \approx 0.3$ mV/°C).

Figure 6 shows the dependence of the signal of the three-atmosphere sensor on the oxygen content of the gas circulating at the junction. Again the experimental curves show very good agreement with the calculated values. In fact, the p_{O_2} dependence of Eq. [16] can be expressed very simply if ($p^{\text{J}}_{\text{SO}_2}$)_{in}, ($p^{\text{O}}_{\text{O}_2}$)^{1/2}, $p^{\text{S}}_{\text{SO}_3}$, and $p^{\text{S}}_{\text{O}_2}$ are constants. Thus, the following equation is obtained

$$E'' = \frac{RT}{2F} \ln \left[1 + \frac{K}{(p^{\text{J}}_{\text{O}_2})^{1/2}} \right] \quad [22]$$

or

$$E'' = \frac{RT}{2F} \ln [K + (p^{\text{J}}_{\text{O}_2})^{1/2}] - \frac{RT}{2F} \ln (p^{\text{J}}_{\text{O}_2})^{1/2} \quad [23]$$

The latter expression shows that the EMF of the sensor will be independent of p_{O_2} when the temperature is

Fig. 5. EMF of sulfur oxide 3-compartment sensor (Fig. 2a) plotted vs. SO₂ concentration in air for three temperatures. The dotted lines describe the experimental performance of the sensors compared to theoretical prediction (continuous line). Short dotted lines indicate the calculated position of the curves using Eq. [16] (see text).

Fig. 6. EMF of sulfur oxide 3-compartment sensor (Fig. 2a) plotted vs. p_{O_2} of the gas circulating at the junction. The results were obtained at three temperatures: 595°C (10 ppm), 705°C (100 ppm), and 780°C (1000 ppm). The sulfur dioxide concentration used for each curve is shown in parentheses. The continuous line describes the calculated behavior of the EMF. At low concentrations, the three dotted lines correspond to the $RT/4F$ values predicted by relation [23] at low p_{O_2} .

low at high levels of $p_{O_2}^J$; in other words, for $K \ll (p_{O_2}^J)^{1/2}$. On the other hand, at high temperatures and low $p_{O_2}^J$, the slope of the curve E vs. $\ln p_{O_2}^J$ will be $RT/4F$, i.e., when $K \gg (p_{O_2}^J)^{1/2}$. This dependence of the signal on p_{O_2} is summarized in Table III. For easier comparison of the results, the calculated curve was made to fit the experimental values for $p_{O_2}^J = 0.21$ atm (continuous line in Fig. 6). The general agreement between the two curves may be considered quite satisfactory considering the inevitable catalysis and thermal-gradient problems encountered with this type of device.

Interference study.—Finally in this study, an attempt was made to determine the sensitivity of this type of sensor to the presence of other gases normally found in stack effluents. A two-atmosphere sulfur oxide sensor was used for these tests. The results may be found in Table IV.

These results appear to confirm that sulfate-stabilized zirconia junctions are virtually insensitive to the pres-

ence of interferants, as already shown for sulfur oxide sensors with metallic electrodes (4).

Two-atmosphere carbon oxide sensors.—The following test (Fig. 7) was performed on a setup adapted for use with a reference electrode obtained by circulating a known concentration of CO_2 in air (Fig. 2c). The sensor consists of an alumina cylinder comprising two pairs of tubes that serve as gas inlets and outlets. The pointed zirconia rod is located at the outlet of one of the pairs. The first tests were performed using the ZrO_2 - Y_2O_3 minisensor, as in the case of the sulfur oxides but, it was soon realized that this material was being chemically attacked by the K_2CO_3 pellet, making the EMF very unstable. This problem was solved by replacing the yttria-doped zirconia by calcia-doped zirconia. For similar reasons, the platinum electrodes in contact with the K_2CO_3 electrolyte had to be replaced by gold.

The expression for this sensor EMF is similar to the one used for sulfur oxides except that the gaseous species detected, in this case CO_2 , is the same as the one used to prepare the gas mixture at room temperature. Furthermore, at the sensor operating temperature, the thermodynamic equilibrium between CO , CO_2 , and O_2 is totally shifted towards CO_2 ($K_{eq} \approx 10^{10}$ in air at $700^\circ C$). For these two reasons, it is unnecessary to use the notation $(p_{CO_2}^J)_in$ as in the case of SO_2 . The electrochemical cell describing the carbon oxide sensor is

The half-reaction corresponding to the carbon oxide electrode is

which yields the expression for the EMF of a two-atmosphere sensor

$$E = \frac{RT}{2F} \ln \frac{p_{CO_2}^J \cdot (p_{O_2}^O)^{1/2}}{p_{CO_2}^C \cdot (p_{O_2}^O)^{1/2}} \quad [24]$$

where (C) refers to the carbonate reference interface. In Eq. [24] the indexes (O) and (J) are the same since they correspond to a common atmosphere.

As illustrated in Fig. 7, the plot of the potential vs. the log of the concentration of the gaseous oxide circulating at the junction produces straight lines with slopes of $RT/2F$ as a function of $\ln p_{CO_2}$ and $RT/4F$ as

Table III. Calculated data from Eq. [23] to obtain the theoretical profile described in Fig. 6

p_{O_2} in nitrogen (%)	E^* (Eq. [23])		
	$T = 595^\circ C$ (mV)	$T = 705^\circ C$ (mV)	$T = 780^\circ C$ (mV)

Table IV. Sensitivity of the sulfur oxide sensor to some other gaseous species

10, 100, or 1000 ppm SO_2 -air	+ 1000 ppm NO_2	no influence
10, 100, or 1000 ppm SO_2 -air	+ 10% CO_2	no influence
100 ppm SO_2 -air	+ 100 ppm HCl	no influence (after 10 min)

Fig. 7. EMF of a carbon oxide 2-compartment sensor (Fig. 2c) plotted vs. CO_2 concentration in air (lower curve) and vs. p_{O_2} when the carbon oxide content ($p_{\text{CO}_2}^j$)_{in} is constant (upper curve).

a function of $\ln p_{\text{O}_2}^j$. The calculated slopes appear as the continuous lines in the same figure. Curve *E* vs. $\ln p_{\text{CO}_2}^j$, as expected, crosses zero when the atmosphere circulating at the junction and in the carbonate reference compartment is the same. Contrary to the sulfur oxide sensor, in which one or two reference atmospheres, namely (S) and (O), are established by thermal decomposition of solid powder mixtures, carbon oxide sensors have a single reference atmosphere (C) which is obtained by circulating a gas mixture of a known composition of CO_2 in air. As mentioned earlier, at the sensor operating temperature, the thermodynamic equilibrium shifts towards CO_2 , and the kinetics of the gas-phase reaction are sufficiently rapid, making the use of a catalyst unnecessary. Furthermore, in the design of the carbon oxide sensor, the reference atmosphere (C) and the junction atmosphere (J) are so close to each other that little thermal gradient could exist. This is not true for the sulfur oxide sensor, for which the theoretical values of the EMF calculated by Eq. [16] and the experimental values have to be corrected to take into account the effect of thermal gradients (see Fig. 5). For the carbon oxide sensor, since there are no thermal gradients, the experimental and theoretical values of the EMF are close, which eliminates the need for any correction term.

At concentrations below 500 ppm, the same curve shows a deviation corresponding to a lower detection threshold, apparently characteristic of the electrolyte, in this case K_2CO_3 (19). The lower detection level could be associated with the dissociation of CO_3^{2-} to give K_2O and CO_2 , a process which can be quite important, especially if the solubility of the K_2O in K_2CO_3 is high. The detection threshold always increases with the temperature: in the case of K_2SO_4 , for example, the deviation starts at ≈ 10 ppm at 800°C whereas at 600°C , the curve is still linear at concentrations as low as 0.3 ppm (see Fig. 5). It is also worthwhile mentioning that the lower detection level is of the same order of magnitude for gaseous oxide sensors using metallic electrodes. It may thus be concluded

that this phenomenon is not related to partial solubility of the zirconium oxides in K_2CO_3 or in K_2SO_4 .

The study of the sensor with a carbonate-zirconia junction was completed by examining the device response for mixtures of combustible gases and/or interferants in air. These results, listed in Table V, are expressed in terms of deviations from the response of the sensor to a gas mixture containing 1000 ppm of CO_2 in air. Because complete oxidation of most gases is reached in those tests, the value of +29 mV for C_2H_4 is not surprising, since two molecules of CO_2 are formed for each C_2H_4 that enters the sensor. In the case of CH_4 , the device would need to incorporate a catalyst in the inlet port to reach total oxidation of the molecule, especially at high flow rates.

Conclusion

The results obtained from various tests on a sensor with an electrolytic junction demonstrate advantages for analyzing gaseous effluents containing sulfur or carbon oxides, especially for stack monitoring. Its operating principle is the same as that of a gaseous-oxide sensor using metallic electrodes; in particular, in the case of the two-atmosphere sensor, the EMF expression is identical to that of an equivalent sensor with metallic electrodes.

Table V. The effect of some gases on the signal of the carbon oxide sensor

Gas mixture	Δ EMF's at different flow rates (reference atm: 1000 ppm CO_2 in air)		
	1 cm^3/min (mV)	10 cm^3/min (mV)	50 cm^3/min (mV)
1000 ppm CH_4 -air	-5	-15	-39
1000 ppm C_2H_4 -air	+29	+29	+25
1000 ppm CO -air	0	0	+3
1000 ppm CO_2 /air + 10% H_2O	—	—	≈ 0 (after 5 min)
1000 ppm CO_2 /air + 10 ppm HCl	—	—	≈ 0 (after 5 min)

Both types of sensor produce a stable potentiometric signal that can be measured with a modicum of electronic equipment. When the gases are not catalyzed, the sulfur oxide sensor can act as a SO₃-specific sensor; otherwise, the total sulfur content is measured. For continuous use on a long-term basis, particularly at high SO₂ values, junction-type devices will probably have a better lifespan because they do not comprise metallic electrodes, which are susceptible to aging and can consequently induce malfunctions of the probe.

The EMF of the sensor is sometimes independent of p_{O₂} at the junction (Eq. [13]), or the dependence on p_{O₂} can be eliminated through a signal compensation device. This is easily achieved by attaching a metallic electrode to the minisensor of a three-atmosphere sensor and subtracting the signal from this complementary oxygen sensor electronically from the sulfur oxide signal (4), thus obtaining an oxygen-independent signal. In this particular case though, care should be taken in the choice of the complementary metallic electrode to minimize aging problems associated with the aggressive conditions normally encountered in chimney stacks.

Acknowledgments

The authors would like to express their appreciation to Dr. M. Kleitz of the Laboratoire d'Énergétique Electrochimique (LEE) of Grenoble, France, for valuable discussions on the equilibria involved and on the operating principles of the electrolytic junctions. Many thanks are also due to Dr. G. Vitter, also from the LEE, who kindly supplied the oxygen minisensor. The assistance of R. Bellemare in the experimental work is likewise acknowledged.

Ion Transport in the Polymer Electrolytes Formed Between Poly(ethylene succinate) and Lithium Tetrafluoroborate

R. Dupon,* B. L. Papke, M. A. Ratner, and D. F. Shriver*

Department of Chemistry and Materials Research Center, Northwestern University, Evanston, Illinois 60201

ABSTRACT

Solid electrolyte complexes of poly(ethylene succinate), PESc, and LiBF₄ were prepared by heating the salt with the molten polymer. The complexes were completely amorphous over the concentration range 1:1 to 3:1 polymer repeat units:metal cation. At salt concentrations above the 1:1 composition, a salt phase was present, and at salt concentrations less than 3:1, free crystalline polymer was observed. Within the 1:1 to 3:1 concentration range, increasing salt concentration was accompanied by decreasing conductivity, and increasing glass transition temperatures. This behavior is discussed in terms of free-volume theory, with dynamical corrections.

Recent studies reveal an interesting and potentially useful class of solid polymer electrolytes formed by the interaction of polyethers with alkali metal salts (1-3). The formation of these polymer salt complexes appears to be facilitated by a high concentration of polar groups in the polymer, high polymer chain flexibility which permits polymer reorientation for the effective sol-

vation of a salt, small lattice energy for the salt, and low cohesive energy density of the polymer (4). With these ideas in mind, we have studied the interaction of poly(ethylene succinate), I, with alkali

metal salts. This host polymer has the requisite high

* Electrochemical Society Active Member.

concentration of polar groups and judging from the relatively low glass transition temperature, T_g (-1°C), the polymer chain is fairly flexible. Also the value of T_g and mechanical properties suggest that the cohesive energy density is low.

We report here the first preparation and characterization of the polymer salt complexes formed between PESc and alkali metal salts, along with information on the electrical properties of these materials. A very brief preliminary description of this system has appeared (3).

Experimental

Poly(ethylene succinate) (Aldrich) was dissolved in chloroform, filtered, precipitated with hexane, air dried, and then dried under high vacuum. Reagent grade LiBF_4 (Pfaltz and Bauer) was dried by heating under vacuum at 125°C for 12h. Infrared spectra were used to check for the presence of water in the purified salt, polymer, and polymer electrolytes. Only anhydrous materials were used for electrical measurements. Starting materials and complexes were manipulated in a nitrogen-filled glove box or air-free apparatus. Poly(ethylene succinate) $\cdot \text{LiBF}_4$ complexes were prepared by heating above the polymer melting point on intimately ground stoichiometric mixtures of anhydrous polymer and salt contained in a Teflon dish. Temperatures on the order of 125°C were typically used. The samples were then cooled slowly over a period of 2h.

Infrared spectra were recorded using a Perkin-Elmer 399 grating infrared spectrophotometer for samples in the following form: LiBF_4 as a Nujol mull and PESc as a cast film from chloroform solution. The IR spectra of pure PESc were obtained using the cast sample contained in an evacuable cell and PESc $\cdot \text{LiBF}_4$ complexes as heat-pressed films between KBr plates.

The pure polymer and the respective complexes between sealed glass plates were examined at 12.5 power magnification using a Leitz Wetzlar polarizing microscope equipped with a Mettler FP52 hot stage. The heating rate was typically $10^\circ/\text{min}$.

Differential scanning calorimetry measurements were performed on samples sealed in Perkin-Elmer aluminum volatile sample pans using a Perkin-Elmer DSC-2 instrument equipped with a liquid nitrogen cooling system. A dry helium atmosphere was maintained over the sample chamber, and transition temperatures were obtained by extrapolation of a plot of observed transition temperature *vs.* (heating rate) $^{1/2}$ to zero heating rate.

X-ray diffraction patterns were determined using $\text{CuK}\alpha$ radiation on pressed samples protected from the atmosphere. Scattering and receiving slits were adjusted to optimize sample illumination. Slit widths were changed at the same 2θ locations for all samples and the scans at different slit widths were overlapped in order to estimate relative peak intensities.

Conductivities were measured using complex admittance/impedance techniques over the frequency range 5 Hz to 500 kHz. Samples were pressed (under an inert atmosphere) at 10,000 psi into 0.5 in. diam pellets. Samples which were relatively noncompliant were

pressed at 50°C . Electrical measurements were made in a specially designed two-electrode Kel-F cell, which permitted exclusion of the atmosphere. Ion blocking platinum disks 0.5 in. diam, 0.005 in. thick, were used as electrodes. Variable temperature measurements were performed in a thermostated forced-air heating chamber which was controlled by a Bruker B-ST 100/700 temperature control unit. Temperatures were monitored to within $\pm 0.1^\circ\text{C}$ by an iron-constantan thermocouple. All connecting leads were coaxial cable. The data was collected using a Hewlett Packard 4800A vector impedance meter, which is accurate to $\pm 5\%$ under our conditions.

Results

The average molecular weight of the PESc was determined to be 1700 from the sharp melting endotherm of this polymer using the empirical melting point (T_m)-molecular weight relationship (5)

$$1/T_m = 2.59 \times 10^{-3} + 0.179/\bar{M} \quad [1]$$

The limiting stoichiometry of the poly(ethylene succinate)- LiBF_4 complex formation was determined by physical measurements on materials prepared with various polymer to metal salt ratios. The x-ray diffraction patterns of pure polymer, salt, and unreacted mixtures agreed well with the published data (6, 7). In contrast to the highly crystalline parent PESc, all of the PESc- LiBF_4 complexes were found to be amorphous. Crystalline phases which were observed in the PESc- LiBF_4 materials always matched with the pure polymer or pure salt. The maximum salt concentration in the complex was thus established as one polymer repeat unit per salt formula unit, $\pm 10\%$. As judged by x-ray diffraction and optical microscopy, the PESc $\cdot \text{LiBF}_4$ complexes remain completely amorphous as the salt concentration is progressively decreased to a value of 3:1 polymer repeat units per LiBF_4 . These amorphous materials range from a hard plastic-like material at 1:1 concentration to compliant rubbery species at 3:1 stoichiometry.

Below salt concentrations corresponding to the ratio 3:1 PESc: LiBF_4 , crystalline regions of uncomplexed PESc appeared. These were observed as spherulites when viewed through the polarizing microscope, and their identity was confirmed by the presence of x-ray diffraction peaks at $d = 3.80\text{\AA}$ and 4.39\AA . The infrared spectra of the pure polymer (Fig. 1) showed sharp, well-defined bands over the spectral range 700-4000 cm^{-1} , whereas the spectra of the complexes are broad and diffuse, especially in the 1500-1000 cm^{-1} region, which is characteristic of amorphous polyester systems (8). Comparison of the spectra before and after complex formation revealed no detectable shifts for any of the polymer band positions. Spectra obtained for amorphous samples cooled to 77 K displayed no significant improvement in resolution. Judging from the published kinetics of crystallization of poly(ethylene succinate) (7, 9-11) and various annealing experiments which we performed on the complexes, the amorphous phases do not arise from supercooled glassy PESc.

Fig. 1. Infrared spectrum of PESc $\cdot \text{LiBF}_4$, 2:1.

Table I. Comparison of glass transition temperatures and conductivities for PESc · LiBF₄ complexes at various stoichiometries

Ratio of PESc to LiBF ₄	T _g , K	Conductivity at 65°C, (Ω cm) ⁻¹
(Pure PESc)	272.1	—
3:1	288.2	3.4 × 10 ⁻⁶
2:1	288.4	1.8 × 10 ⁻⁶
1.5:1	295.8	4.9 × 10 ⁻⁷
1:1	299.7	2.0 × 10 ⁻⁷

The observed change in mechanical rigidity and in electrical conductivity (see below) over the 1:1 to 3:1 range prompted an investigation of the glass transition temperatures. The values of T_g were found to increase with increasing salt concentration, Table I. The trend in glass transition temperatures thus parallels qualitative changes in mechanical properties.

Complex admittance plots of the conductivity response in these systems, using ion-blocking electrodes, were consistent with a model equivalent circuit containing a capacitance (geometric) in parallel with both a resistance (bulk) and a second capacitance (double layer). Such a combination should result in a single arc followed by a spur when plotted in the complex plane. A representative plot is shown in Fig. 2 for a PESc · LiBF₄ sample at 70°C. Within the 1:1 to 3:1 stoichiometry range, the conductivity decreases dramatically as the salt concentration increases, Fig. 3. In addition, a gentle curve is obtained when the conductivity data are plotted in Arrhenius coordinates, Fig. 4, which agree with expectations for amorphous conductors. It should be noted that samples of pure PESc exhibited a conductivity response outside of the measuring capability of the vector impedance meter over the temperature range 25°–90°C. The uncomplexed polymer thus has a conductivity less than 10⁻⁹ (Ω cm)⁻¹ over this temperature range.

As stated above, at salt concentrations lower than the 3:1 stoichiometry, uncomplexed crystalline polymer appeared in the x-ray diffraction patterns. In the 3:1 to 4:1 stoichiometry range, a large decrease in conductivity is observed as a second phase of crystalline PESc appears. Between 4:1 and 5:1 stoichiometry, the amount of crystalline PESc continues to increase but the conductivity remains nearly constant and low, Fig. 3.

Discussion

The identity of the charge carrier in PESc · alkali metal salt complexes has not been determined unambiguously, however, several lines of evidence suggest that both cation and anion mobility are important. The absence of an obvious electronic conduction mechanism in pure PESc and the observed low conductivity of this material suggest that the conductivity of the complex is ionic in nature. The similarity in the observed magnitudes of the conductivity for a variety of Li⁺ salts (LiCF₃SO₃, LiCF₃COO, LiBF₄) implicates the Li⁺ ion as a charge carrier (3).

To further clarify the nature of the mobile species, the conductivity responses of PESc · NaCF₃SO₃ complexes were investigated using both ion-blocking Pt electrodes and sodium ion-reversible amalgam electrodes. The complex admittance spectrum of PESc · NaCF₃SO₃ using ion-blocking Pt electrodes consists of an arc followed by a spur. This behavior may be effectively modeled with an equivalent circuit containing a capacitance (apparently geometric) in parallel with both a resistance (apparently bulk electrolyte) and a

second capacitance (apparently electrical double layer). The admittance plots obtained using sodium ion-reversible Na-Hg electrodes consisted of a single vertical line, a result which may be modeled by an equivalent circuit containing a capacitance (geometric) in parallel with a resistance (bulk). Since the magnitude of the double layer capacitance was greatly reduced by the use of sodium ion-reversible electrodes, the cation is implicated as a charge carrier. However, it appears from preliminary measurements, performed with a polarization cell, that the transference number for Na⁺ is on the order of 0.1 at 60°C; therefore the bulk of the current is carried by the anion (12).

The conductivity behavior observed in the PESC · LiBF₄ stoichiometry range 1:1 to 3:1 demonstrates that effects other than that of charge carrier concentration dominate the ion mobility. The temperature dependent conductivity, whether of Arrhenius form or in a form related to amorphous behavior, contain a prefactor which predicts increasing conductivity with increasing carrier concentration. The observation of the opposite behavior indicates that changes in the physical characteristics of the PESC · LiBF₄ complexes dominate the conductivity response.

Decrease of conductivity with increasing carrier concentration is well known in framework solid electrolytes, where it is associated with strong correlation of the charge carriers (13). It has also been observed previously for polymeric solid electrolytes such as cross-linked poly(ethylene oxide) (14) and poly(propylene oxide) (15).

Large amplitude polymer segmental motion is thought to be important in the ion transport process in polymer electrolytes (3, 14-16). The variation in ionic conductivity with carrier concentration in the PESC · LiBF₄ complexes may be attributed to the relative freedom of mobility of polymer chain segments. The 3:1 PESC · LiBF₄ stoichiometry represents the lowest salt concentration for which complex formation is complete, *i.e.*, no crystalline regions of uncomplexed polymer remain. As salt concentration is increased above the 3:1 ratio, the rigidity is observed to increase, and higher glass transition temperatures and diminished conductivity result, apparently due to the progressive immobilization of polymer chains. It is, however, noteworthy that in the present case the variations in conductivity (and in apparent fluidity) are so sizable, given the very small change in glass transition temperatures. Table I shows only small changes in glass transition temperature over the same stoichiometry range for which Fig. 3 shows large conductivity variation, and over which the apparent viscosity rises sharply. The inverse viscosity, or the fluidity, is given, using simple free-volume type arguments (14, 17)

$$\eta^{-1} = C \exp \left[-\frac{E_a}{kT} - \frac{\gamma V^*}{V_{Fg} + \alpha(T - T_g)} \right] \quad [2]$$

Here C is a constant, E_a an activation energy for polymer rearrangement, and γ a geometric factor accounting for free-volume overlap; V^* and V_{Fg} are, respectively, the minimum hole size to accommodate the moving chain segment and the free volume at T_g ; and α is the derivative of free volume with temperature. Upon changing from 1:1 to 3:1 salt concentration, only α and T_g in Eq. [2] will change very much. But the very small T_g change (17° out of 300) substituted into Eq. [2] will not lead to substantial changes in η^{-1} unless α is very large.

Again using free-volume theory, the ionic conductivity can be written (14)

$$\sigma T = \sigma_0 \exp \left[-\frac{\gamma V_2^*}{V_{Fg} + \alpha(T - T_g)} - \frac{E_a + E_b + W/2e}{kT} \right] \quad [3]$$

where σ_0 is temperature-independent, V_2^* is the minimum hole size for an ionic hopper, and the second activation-energy term in the exponent characterizes the ion-pair dissociation and activated jumping. The simple point to be made is that the observed sharp peak in Fig. 3 appears to go beyond the free-volume result, Eq. [3]. The essential behavior of the σT product should, from comparison of Eq. [3] with Eq. [2], follow the sample fluidity if free-volume ideas hold. This is reasonable in a free-volume context: as T is increased above T_g , the volume available for motion, either of polymer chains or of solvent, should increase proportionally to $T - T_g$. As T_g increases, with increased salt concentration, the free volume should drop, decreasing both σT and η^{-1} . What is not expected is the very sharp drop of Fig. 3, given the small change in T_g . A possible explanation for this lies in the kinetic behavior of the free volume: if the polymer motions occur slowly (high viscosity), the ions may not be able to take advantage of the free volume for transport. This possibility was alluded to by Cohen and Grest (17), and forms the basis of a dynamic percolation theory being developed in this laboratory (18).

An X-Ray Radiography-Densitometry Technique for the Quantitative Determination of Metal Deposit Profiles

Fritz G. Will* and Charles D. Iacovangelo*

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

ABSTRACT

The application of x-ray radiography in conjunction with high resolution optical densitometry for the quantitative determination of metal deposit profiles parallel and perpendicular to the substrate surface is described. The principles of the technique and the range of its applicability are discussed. The technique is applied to the study of zinc deposition on highly porous carbon foams from circulating aqueous zinc bromide solutions. The effect of substrate pore size on the zinc distribution is explored. Zinc is found to deposit predominantly on the porous substrate/electrolyte and substrate/current collector interfaces. Smaller pore size favors smoother and more uniform deposits throughout the substrate.

Battery electrodes often contain the active material distributed within a porous conducting substrate. Examples are Zn electrodes utilizing porous carbon substrates, as employed in Zn-Cl₂ (1, 2), Zn-Br₂ (3-5), and Ni-Zn (6) batteries. Repeated charge and discharge sometimes leads to a redistribution of the active material and concomitant changes in electrode performance. Thus, techniques that allow a study of the effect of various electrode and process parameters on the metal distribution across and within the porous substrate are of interest. X-ray radiography is one such technique.

In the past, x-ray radiography has mainly been used in battery studies to determine the porosity of separators (7) and electrodes (8), or to establish the position of a liquid electrolyte or reactant in capillaries (9, 10).

In this paper, the application of x-ray radiography in conjunction with high resolution optical densitometry for the quantitative determination of the depth and surface profile of metal deposits in porous substrates (11) is discussed. The technique yields quantitative information with excellent spatial resolution in cases where the x-ray absorption coefficient of the metal deposit is considerably larger than that of the substrate. Depending on the magnitude of the absorption coefficient and the theoretical density, the metal deposit may be a few millimeters thick; in that case, sufficient x-ray intensity is transmitted to the film. These conditions are met for electrodes which employ porous carbon substrates and active materials such as Zn. Results on the deposition of Zn on a highly porous carbon substrate in Zn-Br₂ cells with electrolyte flow parallel to the electrode surface are described. The effect of substrate pore size on the Zn distribution in the substrate and on its surface is examined.

The technique is readily applicable to studying the effect of a variety of electrode and process parameters on metal deposit morphology. Furthermore, the changes in deposit morphology as a function of plating time can be investigated.

Experimental

Zn was deposited in Zn-Br₂ cells on porous reticulated vitreous carbon (RVC) foams¹ cemented to graphite current collector plate² with a conductive adhesive.³ The dimensions of the foam and the graphite plate are 10 × 10 × 0.2 cm and 13 × 12 × 0.64 cm, respectively. A Nafion 120 cation exchange membrane (E. I. du Pont de Nemours and Company) was spaced 0.2 cm from the carbon foam, separating the bromine electrode from the foam. A schematic diagram of the cell design is shown in Fig. 1.

* Electrochemical Society Active Member.

¹ Produced by Chemotronics, Incorporated, now Franklin Engineering, Ann Arbor, Michigan.

² Union Carbide, Grade CGW.

³ Dylon Industries, Incorporated, Grade GC.

A peristaltic pump was used to circulate the electrolyte at a flow rate of 160 cm³/min, equivalent to a Reynolds number of 2500. The electrolyte entered into a free electrolyte gap at the bottom of the cell and exited through another free electrolyte space at the top. This aided attaining uniform electrolyte flow across the electrode surface. A rubber gasket around the edges of the foam prevented the electrolyte from flowing through the foam. Foams of two different average pore diameters, namely, 0.22 and 0.45 mm, were employed. These foams are designated by the manufacturer as 100-pore and 45-pore foam, based upon an average number of 100 and 45 pores per inch, respectively. The open cellular structure of these foams is shown in the scanning electron micrographs (SEM's) of Fig. 2a and b, taken at a magnification of 30×. The void volume of both foams is about 97%. The values for surface area/volume ratio and resistivity are 26.2 cm²/cm³ and 0.5 Ω · cm for the 45-pore foam and 65.6 cm²/cm³ and 0.3 Ω · cm for the 100-pore foam, respectively (11). Zn deposition, corresponding to battery charging, was performed at room temperature at a constant current density of 25 mA/cm² for 4h in 30 weight percent (w/o) aqueous ZnBr₂ solution. Reagent grade chemicals and double-distilled water were used in preparing the solution. After Zn deposition and prior to obtaining x-ray radiographs, the cell electrolyte was removed, and distilled water was circulated through the cell at 160 cm³/min for 10 min.

Fig. 2. SEM's of vitreous carbon foams at 30 \times magnification. A, left: 45-pore foam. B, right: 100-pore foam.

X-ray radiographs were taken of the face and cross sections of the electrodes with a Hewlett Packard Faxitron series x-ray system. Polaroid 55 positive/negative film was employed. A quantitative measure of the zinc density profile perpendicular to the foam surface was obtained through densitometer measurements of the radiograph film negatives at a magnification of 20 \times . An automatic recording microdensitometer (Joyce-Loebel Model MKIIC) with slit dimensions 8 \times 0.04 mm was employed for this purpose. The quantitative results, obtained with the densitometer, were compared with SEM's of electrode surfaces and cross sections. In order to examine the Zn profile perpendicular to the foam, three 6 mm-wide segments were cut from the top to the bottom of the electrode. The location of these segments is shown in Fig. 3, a photomicrograph of the foam face.

Principle of Measurement Technique

The measurement principle is shown in the three schematic drawings of Fig. 4. A segment of height H (10 cm), width W (6 mm), and total thickness $L + L_p$ (foam 2 mm; plate 6.4 mm) is cut from the electrode and placed on x-ray film with x-rays penetrating the width W . The largest attenuation of the incident x-ray beam intensity occurs in regions of high metal density; the beam is essentially unattenuated in areas where only carbon foam is present. The transmitted x-ray intensity thus produces an image on the film negative, in which the lightest areas correspond to areas of highest metal density in the electrode cross section. The radiographs shown in this paper are film positives for which the opposite is true.

In the densitometer evaluation of the film negatives, visible light, confined by a slit, penetrates a 0.04 mm-wide section of the negative at a time, and the transmitted light intensity is measured with a photomultiplier tube; the highest light intensity corresponds to areas with the densest metal deposit on the electrode segment. This is indicated schematically in the lower part of Fig. 4.

Actually, the densitometer records the optical density of the film negative by comparison with the density of an optical attenuator or gray wedge. The principle of operation of the densitometer is based on a true double-beam light system, in which two beams from a single light source, one of which passes through the sample film negative, are switched alternately to a single photomultiplier. If the two beams are of different intensity, a signal is produced by the photomultiplier, which, after amplification, causes a servo motor to move the optical attenuator which reduces the intensity difference to zero. In this way, a continuously null balancing system is obtained, in which the position of the optical attenuator is made to record the optical density at any particular part of the film negative.

The quantitative relationship between the apparent metal density in the carbon foam and the recorded optical density is readily obtained. When a beam of

Fig. 3. Photomicrograph of carbon foam (10 by 10 cm) at 1 \times , showing three segments used for radiography.

x-rays penetrates a material of known width W , its intensity is attenuated according to

$$J_{XR} = {}_0J_{XR} \exp[-\mu W] \quad [1a]$$

where ${}_0J_{XR}$ is the incident beam intensity, J_{XR} the transmitted intensity, and μ the linear x-ray absorption coefficient of the material. In cases where the density of the material is different from the theoretical bulk density of the solid, it is more convenient to write Eq. [1a] in terms of the mass absorption coefficient μ/ρ and the apparent density ρ_{app}

$$J_{XR} = {}_0J_{XR} \exp[-(\mu/\rho) \rho_{app} W] \quad [1b]$$

μ/ρ is related to the x-ray wavelength λ according to

$$\mu/\rho = Kz^4\lambda^3 \quad [2]$$

where K is a constant, and z is the atomic number. Thus, the absorption coefficient increases strongly with increasing wavelength.

In the present study, the continuous x-ray spectrum or white radiation of a tungsten tube at 30 keV was employed (12). The shortest wavelength at which radiation is emitted is 0.413 \AA , and the peak intensity occurs at 0.54 \AA . Toward longer wavelengths, the intensity decreases, attaining a value of 18% of peak intensity at 1 \AA .

The x-ray mass absorption coefficients for a number of elements of interest in battery research are summarized in Table I as a function of the x-ray wavelength (13). At the K and L absorption edges of the heavier elements, the absorption coefficients show a discontinuity. This is indicated in the table by lines leading through the table.

At the peak intensity of 30 keV tungsten radiation at 0.54 \AA , C has a mass absorption coefficient of only 0.31 cm^2/g . Therefore, with the exception of Al, the x-ray

Fig. 4. Schematic diagram of radiography-densitometry procedure.

absorption of C is negligible compared to that of the elements listed in Table I. In the present case of Zn deposited on a carbon foam of 3% theoretical density, the effect of the carbon foam is not detectable.

The optical density (degree of darkening) of the developed film negative, D , is related to the logarithm of the exposure in a "characteristic curve." In the normal working range of the film, the relationship is expressed by⁴

$$D = \gamma \log E \quad [3]$$

where γ is the development factor and

⁴ Many industrial x-ray films yield a linear density-exposure relationship and, hence, result in a different form of Eq. [5].

Table I. X-ray mass absorption coefficients for selected elements, μ/ρ (cm^2/g)

λ (Å)	C	Al	Ni	Zn	Br	Ag	Cd	Pb
0.1	0.14	0.15	0.30	0.35	0.50	1.05	1.10	3.41
0.2	0.15	0.26	1.25	1.51	2.31	5.19	5.51	3.86
0.3	0.17	0.50	3.88	4.69	7.15	16.07	17.03	11.9
0.4	0.23	1.03	8.68	10.47	15.97	35.89	38.04	26.6
0.5	0.31	1.93	16.19	19.54	29.78	9.4	10.0	49.7
0.6	0.42	3.22	27.00	32.58	49.66	15.7	16.8	82.9
0.8	0.83	7.21	60.38	72.88	111.07	35.3	37.6	176.5
1.0	1.54	13.50	113.04	136.44	27.29	66.1	70.3	66.6

$$E = J_{\text{XR}} \cdot t \quad [4]$$

the exposure of the negative to the constant x-ray intensity, J_{XR} , for time t . Combining Eq. [1b] and [4] results in

$$D = \gamma \log {}_0J_{\text{XR}t} - (\gamma/2.3) (\mu/\rho) W\rho_{\text{app}} \quad [5]$$

The optical density is thus linearly related to the apparent metal density in the foam, and the radiograph is a true map of the metal density distribution parallel or perpendicular to the foam face as long as the exposure range of the film is not exceeded. Calibration of the optical density curve in terms of apparent metal density is obtained by determining the total area under the D vs. x curve, which corresponds to the total known amount of metal deposited into a given electrode volume.

The requirement to stay in the linear exposure range of the film places inherent limitations on the applicability of the technique. For x-rays, the density range from $D = 0.1$ to 4 is feasible. The incident beam exposure, ${}_0J_{\text{XR}t}$, must be chosen such that $D = 4$ is not exceeded for the minimum value of ρ_{app} present in the electrode. The largest possible value of ρ_{app} that still results in discernible film darkening is then fixed by Eq. [5] with $D = 0.1$ for specified film properties, mass absorption coefficient, and material width W . In the case of Zn with $\mu/\rho = 10.5 \text{ cm}^2/\text{g}$ for the short wavelength limit of the spectrum and $W = 6 \text{ mm}$, this leads to a maximum value of $\rho_{\text{app}} = 1.8 \text{ g/cm}^3$ or 26% of theoretical density.

Results and Discussion

Scanning electron microscopy.—SEM's of the surface and a cross section of 45-pore foam after Zn plating with 25 mA/cm^2 for 4h at $N_{\text{Re}} = 2500$ are presented in Fig. 5. The SEM's relate to the center segment of the electrode (cf. Fig. 3) and were taken at a magnification of $30\times$ from the surface and $14\times$ from the cross section. The major features of the Zn deposit evident from the SEM's are a nodular Zn growth at and near the surface of the foam, no discernible Zn deposit in most of the interior, and some Zn particles near the foam/graphite plate interface. Not evident from the SEM's, but clearly visible in the optical microscope, is a continuous Zn coating on the foam strands in the interior and on the graphite plate surface.

For comparison, Fig. 6a and b show the equivalent SEM's of the Zn deposit on the 100-pore foam, demonstrating the effect of smaller pore size. The deposit on the foam surface consists of a larger number of smaller Zn nodules, and they are more evenly distributed across the surface. A somewhat larger number of small Zn particles is also visible in the interior and at the plate interface of the foam.

The observed differences in Zn morphology between 45- and 100-pore foam are most likely due to the larger surface area and lower resistivity of the latter. This results in a larger number of nucleation sites for Zn growth and in more uniform current density.

Fig. 5. SEM's of 45-pore foam after Zn plating from 30% ZnBr_2 solution with 25 mA/cm^2 for 4h at $N_{\text{Re}} = 2500$. A, left: electrode face at $30\times$. B, right: electrode cross section at $14\times$.

Fig. 6. SEM's of 100-pore foam with Zn deposited for 4h at 25 mA/cm². A, left: electrode face at 30 \times . B, right: electrode cross section at 14 \times .

The characteristic bimodal Zn distribution, with maxima in apparent Zn density occurring at the two C foam interfaces, corresponds to long plating times. It is to be expected that the Zn distribution in the initial stages of plating is different and changes with time as the Zn deposit alters the conductance of the foam substrate.

Radiography.—Figures 7a and b show x-ray radiographs of the surface and center cross section of the 45-pore foam after Zn plating. The dark areas correspond to Zn, the light areas to voids or carbon foam. In contrast to the SEM's, Fig. 7a and b show essentially the complete objects in actual size. Therefore, the uniformity of Zn plating parallel and perpendicular to the entire foam surface can immediately be judged. The Zn deposit is relatively uniform across the surface, with a slightly denser deposit on the far side of the electrolyte inlet (left side of Fig. 7a). The radiograph of the cross section reveals a dense Zn deposit at and near the foam/electrolyte interface, only isolated Zn aggregates in the interior, and a thin dense Zn coating at the foam/plate interface.

The corresponding radiographs of 100-pore foam, shown in Fig. 8a and b, display generally similar features, except that smaller Zn particle size and smoother, more uniform Zn plating is evident.

Densitometry.—The cross-sectional radiographs of 45- and 100-pore foam, shown in Fig. 7b and 8b, were evaluated with the densitometer, and the results are shown in Fig. 9. In the graph, $x = 0$ corresponds to the

Fig. 7. X-ray radiographs of Zn deposit on 45-pore foam after 4h at 25 mA/cm². A, left: electrode face at 1 \times . B, right: cross section at 1 \times .

Fig. 8. X-ray radiographs of Zn deposit on 100-pore foam after 4h at 25 mA/cm². A, left: electrode face at 1 \times . B, right: cross section at 1 \times .

Fig. 9. Densitometer traces of Zn deposit profiles perpendicular to surface on 45- and 100-pore carbon foam, plated for 4h at 25 mA/cm² in 30% ZnBr₂ solution circulating at $N_{Re} = 2500$.

foam/electrolyte interface and $x = 2$ mm to the foam/graphite plate interface. The graph shows that significant amounts of Zn have been plated on the surface of the foam, extending approximately 1 mm into the electrolyte. Furthermore, considerable Zn plating has occurred within 0.6 mm of the foam/graphite plate interface. The apparent densities of the Zn deposits near the foam face and the plate are both between 0.5 and 0.6 g/cm³ or 7 to 9% of the theoretical density. Considerably less Zn was deposited in the interior of the 45-pore foam. This small amount of Zn corresponds to the thin continuous Zn coating of the carbon strands, clearly discernible in the optical microscope.

Use of 100-pore instead of the coarser 45-pore foam results in less Zn deposit on the surface and comparatively more Zn plating within the foam interior. Also, the Zn deposit on the 100-pore foam protrudes less into the electrolyte. The fractions of Zn deposited on the foam surface, in its interior, and near the graphite plate for both foams are summarized in Table II.

Fig. 10. Densitometer traces of Zn distribution parallel to electrode surface on 10×10 cm 100-pore carbon foam along centerlines from left to right (lower trace) and bottom to top (upper trace).

As a result of the uniform electrolyte flow across the surface, applicable to our study, the Zn distribution across the surface is also quite uniform. Such uniform electrolyte flow is produced by the use of a rectangular cavity, spanning the whole width of the electrode at the bottom and the top. This "free electrolyte space" has a very small flow resistance compared to that of the electrode/membrane gap. Densitometry of the x-ray radiograph of the electrode face of 100-pore foam (see Fig. 8) demonstrates the uniformity of the Zn deposit. Figure 10 shows densitometer traces across the electrode surface along the centerlines from left to right (lower trace) and from bottom to top. The mean apparent Zn density is seen to be fairly constant along both centerlines. The large, almost periodic fluctuations in actual Zn density demonstrate the spatial resolution of the technique: with a slit width of only 0.04 mm and an average pore diameter of 100-pore foam of 0.22 mm, the densitometer resolves the relatively higher Zn density on C strands as compared to the lower density in the voids between strands.

The uniform Zn distribution across the surface leads one to expect Zn deposit profiles which are rather invariant with location across the surface. This was actually observed on cross sections taken from various parts of the electrode surface, as shown in Fig. 3.

Conclusions

X-ray radiography in conjunction with optical microdensitometry can be used as a quantitative tool in the study of various parameters affecting metal deposit profiles on porous substrates. The technique yields apparent metal density with a spatial resolution of 0.04 mm. Applicability of the technique requires (i) that the x-ray absorption of metal and substrate be

different enough to produce sufficient contrast and (ii) working in the linear exposure range of the film. For a given material, the second criterion can often be met by suitable choice of the sample thickness and x-ray wavelength.

The technique has been applied to the case of zinc deposited on a high porosity carbon foam. A study of the effect of pore size on the zinc distribution in the foam yields the finding that smaller pore size favors more uniform zinc distribution throughout the foam. This is most likely due to the higher surface area and lower resistivity of the fine-porous foam, resulting in a larger number of nucleation sites and more uniform current distribution than in the coarse foam.

Shifts in Redox Formal Potentials Accompanying the Incorporation of Cationic Complexes in Perfluoro Polycarboxylate and Polysulfonate Coatings on Graphite Electrodes

Yu-Min Tsou and Fred C. Anson*

California Institute of Technology, Arthur Amos Noyes Laboratories, Division of Chemistry and Chemical Engineering, Pasadena, California 91125

ABSTRACT

The formal potentials of several redox couples incorporated in coatings of a perfluoropolycarboxylate on graphite electrodes were measured and compared with the formal potentials of the same couples in homogeneous solution. The differences observed agreed with those calculated from the Nernst equation with the independently measured incorporation coefficients for both halves of the redox couples. The dependences of the shifts in formal potentials on the nature of the incorporating complex ion, the ionic strength, and the temperature were determined and indicated that the incorporation equilibrium is governed by electrostatic and hydrophobic interactions that act in opposite directions. The incorporation of most cations examined was driven by large increases in entropy which overcame the usually unfavorable enthalpy changes.

Redox reactants incorporated in polyelectrolyte coatings on electrode surfaces will exhibit formal potentials that are shifted from their values in solution whenever the two oxidation states of the reactant have different equilibrium constants for incorporation by the polyelectrolyte. This situation has been recognized in earlier reports (1, 2) and in a recent study this aspect of the electrochemistry of redox polymer coatings was examined in detail (3). In continuing studies of the electrochemical responses obtained from redox reactants at electrodes coated with Nafion, I, and the related polyelectrolyte, II,

Nafion

Polyelectrolyte II

we noted unusually large shifts in the formal potentials of certain redox couples upon incorporation into these

coatings. Both the magnitude of the shift in formal potential and its sign were influenced strongly by the nature of the ligands coordinated to the metal center of the redox couples. It was the purpose of the experiments described here to document the behavioral differences observed with several redox couples in both polyelectrolytes and to attempt to understand their origins. The results indicate that both electrostatic and hydrophobic interactions of incorporated electroactive ions with the polyelectrolyte combine to determine the direction of shifts in formal potentials. The temperature dependences of the shifts in formal potential were also measured. They pointed to large entropic contributions to the differences in the equilibrium incorporation of the oxidized and reduced halves of the redox couples.

Experimental

Materials.—Nafion¹ coatings were prepared as previously described (4) by evaporation of aliquots of a solution of the polymer supplied by E. I. du Pont de Nemours and Company several years ago. Polymer II was supplied in the form of a fine suspension of the methyl ester by Asahi Glass Company, Tokyo. To prepare coatings, aliquots of the suspension were evaporated on freshly cleaved electrodes. The resulting deposit was exposed to 1M NaOH for 5 min to convert the ester to the carboxylate, and the electrode was then washed thoroughly with water. The extent and uniformity of the de-esterification were not examined in detail, but it was established that increasing the time that the coatings were exposed to the 1M NaOH produced no changes in their behavior. Electrodes were prepared from pyrolytic graphite (Union Carbide Company, Chicago) and mounted according to previously described procedures (5). Ru(NH₃)₆Cl₃ (Mathey-Bishop Company) was recrystallized before use.

[CpFeCp-CH₂-N⁺(CH₃)₃]Br⁻ (Cp = cyclopentadienide) (Research Organic/Inorganic Company) was used as received. Ru(NH₃)₅isonicotinamide(ClO₄)₂ (6) and Os(bpy)₃ClO₄ (7) were synthesized according to the cited references. Solutions were prepared with distilled water, which was further treated by passage through a purification train (Barnstead Nanopure).

¹ Nafion is a trademark of E. I. du Pont de Nemours and Company.

Procedures.—Conventional two-compartment cells and apparatus were employed to obtain cyclic voltammograms. To evaluate formal potentials for reactants incorporated in electrode coatings, the cyclic voltammograms were recorded at scan rates low enough (e.g., a few mV s^{-1}) to obtain symmetrical waves with almost equal peak potentials. The quantities of the oxidized and reduced halves of redox couples incorporated by coatings were measured chronopotentiometrically (8) to avoid possible alterations in the equilibrium ratio of oxidant to reductant by insufficiently precise potentiostatic control of the electrode potential. Potentials were measured and are quoted with respect to a calomel reference electrode saturated with sodium chloride, SSCE.

Temperature dependences of formal potentials were evaluated from cyclic voltammograms recorded in a nonisothermal cell having a thermally jacketed compartment for the working and auxiliary electrodes and a separate compartment for the reference electrode. The reference electrode was maintained at a fixed temperature. The principles and assumptions involved in the use of such cells have been examined in detail (9) and several recent experimental examples of their successful applications are available (10). Exposure of the polyelectrolyte coatings to solutions at 50°C caused the measured formal potentials of incorporated redox couples to drift slightly before new stable potentials resulted. We believe this behavior is the result of reproducible structural changes in the coatings. For this reason, the temperature dependences of formal potentials were measured with coatings that had been exposed to a solution at 50°C long enough for the cyclic voltammetric response to stabilize (ca. 30 min). Thereafter, reproducible peak potentials were obtained at all temperatures.

Results

Cyclic voltammograms for the $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ couple at a graphite electrode coated with the carboxylate polyelectrolyte, II, are shown in Fig. 1. The effects of changes in scan rate on the response are the subject of Fig. 1a, while 1b is concerned with the effects of changes in the coating thickness at a fixed scan rate. With thinner coatings or lower scan rates, the voltammograms exhibit two peaks. These are more clearly separated in the anodic half of the voltammograms.

The anodic peak at -0.15V is quite close to the corresponding peak obtained at an uncoated electrode, and it is this peak that disappears when the electrode used to record the voltammograms in Fig. 1 is transferred to a pure supporting electrolyte solution. Similar behavior was reported earlier for the voltammetry of $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ at electrodes coated with polyvinylsulfate (1). The peak that is present only in solutions containing $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ is believed to arise from the diffusive penetration of the polymer coating by the complex so that it is reduced and reoxidized directly at the electrode surface. That the peak does not arise from reaction at bare patches of the electrode exposed by imperfections in the coating was indicated by tests of coated electrodes with nonincorporating anions, such as $\text{Fe}(\text{CN})_6^{4-}$, which exhibited much smaller peak currents and much greater peak potential separations at coated than at bare electrodes. In any case, the present study was devoted to comparisons between the voltammetric responses of redox couples at bare electrodes and those taken after their incorporation into coatings on electrodes which are subsequently transferred to a pure supporting electrolyte solution. Thus, the second peak evident in Fig. 1 presented no problems.

In Fig. 2 the cyclic voltammogram for $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ at a bare graphite electrode is compared with that for the same couple incorporated in a coating of the carboxylate polyelectrolyte, II. The large difference in the average of anodic and cathodic peak potentials (i.e., the formal potentials) of the couple in the two cases is evident. This difference in formal potentials should reflect the difference in the strength of the binding of each half of the redox couple to the polyelectrolyte coating. For example, if $[\text{O}]_s/[\text{R}]_s$ and $[\text{O}]_p/[\text{R}]_p$ are the equilibrium ratios of the concentrations of the oxidized and reduced forms of a couple in the solution (s) and polyelectrolyte (p) phases, respectively, the difference in the formal potentials observed in the two phases should be given by Eq. [1]

$$E_p^f - E_s^f = \frac{RT}{F} \left(\ln \frac{[\text{O}]_s}{[\text{R}]_s} - \ln \frac{[\text{O}]_p}{[\text{R}]_p} \right) \quad [1]$$

Experimental values of E_p^f and E_s^f were obtained from the average of the peak potentials of voltammograms, such as those in Fig. 2. The voltammograms obtained

Fig. 1. Steady-state cyclic voltammograms for $1.0 \text{ mM Ru}(\text{NH}_3)_6^{3+}$ solution at a graphite electrode coated with polyelectrolyte II. Supporting electrolyte: 0.2M KCl at $\text{pH } 5.5$. (A) Coating contained $2.1 \times 10^{-7} \text{ mol cm}^{-2}$ of carboxylate groups. Scan rate: $10, 20, 50 \text{ mV s}^{-1}$. (B) Scan rate: 100 mV s^{-1} . Coatings contained $4.2, 8.4,$ and $21 \times 10^{-8} \text{ mol cm}^{-2}$ of carboxylate groups.

Fig. 2. (A) Cyclic voltammograms for 0.5 mM $\text{Ru}(\text{NH}_3)_6^{3+}$ at a bare graphite electrode. (B) Repeat after the electrode was coated with polyelectrolyte II (8.4×10^{-8} mol cm^{-2} of carboxylate groups), soaked in the $\text{Ru}(\text{NH}_3)_6^{3+}$ solution for 5 min and transferred to pure supporting electrolyte (0.02M CH_3COONa at pH 5.5). Scan rate: 5 mV s^{-1} for both curves.

with the polyelectrolyte coatings were recorded at scan rates sufficiently small ($< 5 \text{ mV s}^{-1}$) so that all of incorporated complex was reduced or oxidized during each half-cycle. The peak currents were proportional to scan rate, as expected under these conditions (11), and the formal potential was taken as the simple average of the peak potentials, which were typically separated by 10 to 30 mV by residual ohmic potentials present in the cell and coating. At bare electrodes, the peak potentials were usually separated by 60-70 mV, as expected (12). The formal potential (E_s^f) was obtained from the average of the peak potentials corrected for the difference in the solution diffusion coefficients of the two halves of the redox couple (12). This correction typically amounted to 1 to 2 mV.

The open-circuit equilibrium potential assumed by bare (or coated) electrodes in solutions containing both O and R is given by

$$E_{\text{eq}} = E_s^f - \frac{RT}{F} \ln \frac{[\text{R}]_s}{[\text{O}]_s} \quad [2]$$

Thus, Eq. [1] can be rewritten as

$$E_p^f = E_{\text{eq}} + \frac{RT}{F} \ln \frac{[\text{R}]_p}{[\text{O}]_p} \quad [3]$$

where E_{eq} is the equilibrium potential of the coated (or bare) electrode in an incorporation solution which leads to the concentration ratio $[\text{R}]_p/[\text{O}]_p$ in the polyelectrolyte phase. Thus, to test Eq. [1], coated electrodes were equilibrated in incorporation solutions containing various ratios of the oxidized to reduced form of the redox couple. The formal potentials of the redox couple in the coating (E_p^f) were then compared with the sum $E_{\text{eq}} + RT/F \ln [\text{R}]_p/[\text{O}]_p$ calculated from the observed values of E_{eq} and the measured concentrations of R and O in the polyelectrolyte phase. The latter were determined chronopotentiometrically (8) after the equilibrated electrode was transferred to a pure supporting electrolyte solution. The constant current densities (i) utilized in the chronopotentiometric measurements were kept small enough to be sure that all of the incorporated reactant in the coatings had

been oxidized or reduced at the transition time (τ), so that the quantity of reactant could be calculated as $i\tau/nF$.

At the transition time, a constant current in the opposite direction was passed through the coating until a second transition corresponding to the sum of the oxidized and reduced reactant initially present in the coatings resulted. Thus, if the first transition time (τ_1) was obtained with an anodic current (i_1), and the second, (τ_2) resulted from a subsequent cathodic current (i_2)

$$\frac{[\text{O}]_p}{[\text{R}]_p} = \frac{i_2\tau_2 - i_1\tau_1}{i_1\tau_1} \quad [4]$$

Figure 3 shows two representative chronopotentiograms for coatings in which the $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ or $\text{Os}(\text{bpy})_3^{3+/2+}$ redox couples had been incorporated. Table I summarizes the results of a series of such experiments with three redox couples to test whether Eq. [1] and [3] provide an adequate description of the behavior of the coated electrodes. The agreement between the calculated and observed potentials in the last two columns of Table I is, in most cases, within the experimental precision of $\pm 5 \text{ mV}$, so that Eq. [1] and [3] appear to be obeyed over a reasonably wide range of $[\text{R}]_p/[\text{O}]_p$ ratios. Thus, it may be concluded that the difference in measured formal potentials of redox couples in solution and incorporated within poly-

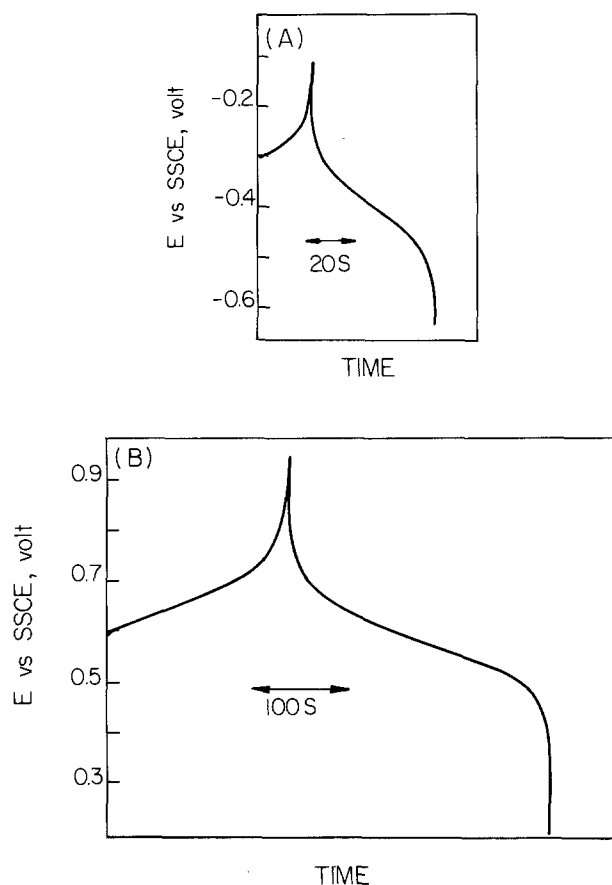

Fig. 3. Chronopotentiograms for the $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ and $\text{Os}(\text{bpy})_3^{3+/2+}$ couples in coatings of polyelectrolyte II. (A) Electrode coated with 2.1×10^{-7} mol cm^{-2} of carboxylate group equilibrated with a solution containing $\text{Ru}(\text{NH}_3)_6^{3+}$ and $\text{Ru}(\text{NH}_3)_6^{2+}$ ($E_{\text{eq}} = 312 \text{ mV}$; $[\text{Ru}(\text{NH}_3)_6^{3+}] + [\text{Ru}(\text{NH}_3)_6^{2+}] = 1.0 \text{ mM}$) before transfer to pure supporting electrolyte solution (0.02M CH_3COONa at pH 5.5). Constant current density = $1.15 \mu\text{A cm}^{-2}$ for oxidation of Ru(II) and $23.0 \mu\text{A cm}^{-2}$ for reduction of Ru(III). (B) Electrode coated with 8.4×10^{-8} mol cm^{-2} of carboxylate groups equilibrated with a solution of $\text{Os}(\text{bpy})_3^{3+}$ and $\text{Os}(\text{bpy})_3^{2+}$ ($E_{\text{eq}} = 602 \text{ mV}$; $[\text{Os}(\text{bpy})_3^{3+}] + [\text{Os}(\text{bpy})_3^{2+}] = 0.5 \text{ mM}$). Constant current density = $2.87 \mu\text{A cm}^{-2}$ throughout.

electrolyte II reliably reflects the difference between the free energy changes associated with the incorporation of the two halves of the redox couple by the polyelectrolyte.

Effect of changes in ionic strength.—The incorporation of cationic redox couples by polyelectrolyte II is an ion exchange process involving displacement of equivalent quantities of the unipositive counterions initially present in the polyelectrolyte. For this reason, the extent of incorporation for each half of a redox couple would be expected to exhibit a dependence on the ionic strength of the incorporation solution. This expectation was tested by measuring the differences between the formal potentials of several redox couples in solution and within the polyelectrolyte coating as a function of ionic strength. The results, summarized in Table II, show that the difference in formal potentials measured inside and outside of the polyelectrolyte coatings is strongly dependent on ionic strength and on the nature of the redox couple.

Temperature dependence of the formal potential.—To obtain additional insight into the factors responsible

for the opposite shifts in formal potential of the Ru(NH₃)₆^{3+/2+} and Os(bpy)₃^{3+/2+} couples upon their incorporation in the polyelectrolyte coatings, the temperature dependences of the formal potentials of the two couples were measured within the coatings and at a bare electrode. The results, plotted in Fig. 4, show that increases in temperature cause the formal potentials for both couples to shift to more negative values within coatings of polyelectrolyte II but in the opposite direction in homogeneous solutions.

The formalism of Weaver *et al.* (9) can be used to evaluate half-reaction entropies for redox couples (ΔS_{rc}°) from the slopes of the lines in Fig. 4. The resulting values are listed in Table III. For Ru(NH₃)₆^{3+/2+}, the value of ΔS_{rc}° at the bare electrode agrees well with that reported by Weaver *et al.* (9), and the value for Os(bpy)₃^{3+/2+} is not far from their value for the isostructural Fe(bpy)₃^{3+/2+} couple (9).

The difference between the values of ΔS_{rc}° at bare and coated electrodes ($\Delta \Delta S_{rc}^\circ$) (Table III) represents the entropy change associated with an overall reaction such as

where $\sim\sim A^-$ represents one of the anionic fixed charge groups of the polyelectrolyte, and (aq) denotes the hydrated ion in the bulk of the solution. The ionic aggregates inside the polyelectrolyte, denoted by $(\sim\sim A^-)_n \text{---Ru(NH}_3)_6^{n+}$, may also be hydrated to an extent that is great enough to affect both their entropies and enthalpies significantly.

The positive values of $\Delta \Delta S_{rc}^\circ$ in Table III show that the substitution for one incorporated cationic complex of its redox partner with the higher charge leads to a net increase in entropy in each case. The corresponding enthalpic differences, $\Delta \Delta H_{298}^\circ$, are positive, strikingly so in the case of polyelectrolyte II. Thus, the preferential incorporation of the more highly charged cations is driven by the large release of entropy.

pH dependence of the incorporation.—The effective pK_a of the carboxylic acid groups in polyelectrolyte II can be inspected by measuring the effect of pH on the incorporation of cations by the polyelectrolyte. Experiments of this type were performed by exposing a coating of polyelectrolyte II to a solution of Ru(NH₃)₆³⁺ which was adjusted to pH values between 1.5 and 5.5. After the incorporation equilibrium had been attained (30 min of exposure proved adequate), the coated electrode was transferred to a pure supporting electrolyte solution at the same pH, and the amount of Ru(NH₃)₆³⁺ retained by the coating was determined by stepping the electrode potential to -0.6V and measuring the total cathodic charge that passed before the current decreased to background levels. The results are shown in Fig. 5. The pH at which the incorporation reaches one-half of its maximum value [only ca. 36% of the total carboxylate groups in the coating bound Ru(NH₃)₆³⁺ cations that were in electronic contact with the electrode] is 2.2. This value is close to the pK_a of 1.9 measured more directly for a similar perfluorocarboxylate polyelectrolyte (13). However, the shape of the plot in Fig. 5 does not match that of a typical pH titration curve. This is presumably because of interactions among the high concentration of carboxylate groups within the polyelectrolyte. Similar behavior was reported recently in coatings of protonated polyvinylpyridine (14). Thus, it is not accurate to identify the pH corresponding to half-maximum incorporation in Fig. 5 with a single pK_a of the functional group. The "effective pK_a " (14) varies with the degree of protonation and with the ionic strength. Nevertheless, it is clear that at pH values as low as 1, protons compete

(B) $\text{Os}(\text{bpy})_3^{3+/2+}$. (■) Bare electrode. (▲) Electrode coated with polyelectrolyte (II). (●) Electrode coated with Nafion. Supporting electrolyte: 0.02M CH_3COONa at pH 5.5.

quite successfully with $\text{Ru}(\text{NH}_3)_6^{3+}$ ions for counter-ionic sites within the polyelectrolyte.

Discussion

The combination of data in Tables I and II shows that the equilibrium constants governing the incorporation of cations by coatings of polyelectrolyte II control the changes in the formal potentials of redox couples extracted into the coatings. The trends in the values of $E_p^f - E_s^f (= \Delta E^f)$ in Table II demonstrate that the relative equilibrium binding constants for two halves of a redox couple are not determined solely by the magnitudes of their positive charges. Thus, the $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ and $\text{Os}(\text{bpy})_3^{3+/2+}$ couples involve the same pair of charge types but, at ionic strengths above ca. 0.05M, the formal potentials of the two couples are shifted in opposite directions by incorporation.

The additional factor affecting the incorporation equilibria seems likely to be hydrophobic interactions

between the large fluorocarbon component of the polyelectrolyte coating and the incorporating cations. Previously cited evidence of such hydrophobic interactions has included the blue shift in the fluorescence of $\text{Ru}(\text{bpy})_3^{2+}$ incorporated in Nafion membranes compared with the red shift observed with other, less hydrophobic, polyelectrolytes (15). In addition, the much smaller diffusion coefficients within Nafion coatings of cations surrounded by hydrophobic ligands has been interpreted in terms of a strong interaction between the diffusing ions and the hydrophobic fluorocarbon portions of the interior of the polyelectrolyte (16).

The trends evident in the data of Table II can be rationalized in terms of the relative importance of hydrophobic and electrostatic interactions between the incorporated cations and the polyelectrolyte. For example, at an ionic strength of 0.2M, ΔE^f is positive for $\text{Os}(\text{bpy})_3^{3+/2+}$, near zero for $\text{CpFeCpCH}_2\text{N}(\text{CH}_3)_3^{2+/+}$ and negative for $\text{Ru}(\text{NH}_3)_6^{3+/2+}$. The less highly

^c, ^d, ^e Differences between ΔS_{rc}° , ΔH_{298}° , and ΔG_{298}° at coated and bare electrodes. Calculated from $\Delta \Delta H^{\circ} = \Delta \Delta G^{\circ} - T \Delta \Delta S_{rc}^{\circ}$; $\Delta \Delta G_{298}^{\circ} = -nF \Delta E^f$.

Fig. 5. Incorporation of $\text{Ru}(\text{NH}_3)_6^{3+}$ by polyelectrolyte II as a function of pH. Electrode coating contained 8.4×10^{-8} mol cm^{-2} of carboxylate groups. Electrode was equilibrated for 30 min with a 5 mM solution of $\text{Ru}(\text{NH}_3)_6^{3+}$ at each pH before transfer to pure supporting electrolyte for measurement of the quantity incorporated. Supporting electrolyte: pH ≥ 4.5 : acetate buffer; $2.25 \leq \text{pH} \leq 3.25$: phosphate buffer; pH ≤ 2 : HCl + NaCl. The ionic strength was maintained at 0.2M.

charged (i.e., reduced) form of each couple would be more hydrophobic and therefore would be expected to be preferentially stabilized by hydrophobic interaction compared with its more highly charged (oxidized) partner. By contrast, purely electrostatic stabilizing interactions would act in the opposite direction. Thus, the values of ΔE^f for the three couples listed above indicate the dominance of hydrophobic interactions for $\text{Os}(\text{bpy})_3^{3+/2+}$ and hydrophilic interactions for $\text{Ru}(\text{NH}_3)_6^{3+/2+}$, with the two factors exerting approximately equal and opposite influences in the case of $\text{CpFeCpCH}_2\text{N}(\text{CH}_3)_3^{2+/+}$. This seems chemically reasonable because the order of increasing hydrophobicity of the three redox couples is very likely to be $\text{Os}(\text{bpy})_3^{3+/2+} > \text{CpFeCpCH}_2\text{N}(\text{CH}_3)_3^{2+/+} > \text{Ru}(\text{NH}_3)_6^{3+/2+}$.

The effects of changes in ionic strength on the values of ΔE^f in Table II for the $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ and $\text{Os}(\text{bpy})_3^{3+/2+}$ couples can be understood on the same basis. Alterations in the intensity of hydrophobic interactions produced by changes in ionic strength are not likely to be as large as the expected (17) decreases in electrostatic interaction as the ionic strength increases. The latter changes can be substantial as the behavior of the $\text{Os}(\text{bpy})_3^{3+/2+}$ couple indicates. In 2M supporting electrolyte, ΔE^f is most positive, pointing to the strongest hydrophobic stabilization, while in 0.02M solutions ΔE^f becomes slightly negative, suggesting that under these conditions the strength of the electrostatic interaction has increased sufficiently to overcome the hydrophobic factors that act in the opposite direction. The much more hydrophilic $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ couple exhibits ΔE^f values that reflect dominance by electrostatic interactions at all ionic strengths. The intensity of these interactions is evidently quite large for this couple, as indicated by the unusually large value of ΔE^f in the 0.02M electrolyte.

ΔE^f was also measured for the $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ couple at 0.2M ionic strength in Nafion coatings. The value observed was -100 mV, compared with -164 mV for polyelectrolyte II under the same conditions. Similar differences exist between the strength of the binding of alkali cations by ion-exchange resins based on sulfonate and carboxylate groups (18). The behavioral difference has been ascribed to differences in the struc-

ture of the primary hydration spheres of the cations induced by the two types of anionic binding groups (18). In the present case, where hydrophobic and electrostatic factors are also believed to influence the strength of cation binding, the difference in ΔE^f for Nafion and polyelectrolyte II for the $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ couple may reflect a greater control by electrostatic binding in the latter coating.

The entropic control of the incorporation equilibria revealed in the data of Table III suggests a primary role for water molecules in the overall incorporation process. This accords with several previous studies of cation binding by polyanionic electrolytes (19), in which evidence was presented for the release of water molecules from both the charged binding sites and the hydration spheres of the bound cations. The large negative value of ΔS_{rc}° for the $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ couple in polyelectrolyte II signals an unusual ionic and solvation environment for the couple in this polyelectrolyte. The binding of the $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ couple by Nafion produces much smaller value of $\Delta \Delta S_{rc}^\circ$ than for binding to the polycarboxylate, II. This may be a reflection of a higher charge density on the fixed anionic sites in II compared with Nafion. This could produce tighter ion pairing with multiply charged cations within polyelectrolyte II and greater loss of water molecules from the outer coordination spheres of the incorporated complexes. Differences in the partial molar volumes of sulfonate and carboxylate bearing polyelectrolytes upon incorporation of cations were explained in similar terms by Tondre and Zana (19d).

The positive value of $\Delta \Delta H^\circ$ for incorporation of the $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ couple by polyelectrolyte II (Table III) represents the net result of a variety of coulombic and dipolar interactions whose individual contribution to the measured values of $\Delta \Delta H_{298}^\circ$ it would be extremely difficult to disentangle. However, it may be worth noting that the behavior we have observed is similar to that reported for the incorporation from aqueous solution of an organic sulfonate (8-anilino-1-naphthalene sulfonate) by the hydrophobic portion of a block copolymer of polyethylene oxide and poly(2-hydroxyethyl methacrylate) (20). The incorporation, which is free of direct electrostatic binding between fixed charge groups and the incorporating ions, is also governed by a positive entropy change that overcomes a corresponding increase in enthalpy. Differences in the ion-dipole interaction energies between the incorporating ion and water molecules inside and outside the polymer may make important contributions to the enthalpy changes in both this instance and the incorporation of the $\text{Ru}(\text{NH}_3)_6^{3+/2+}$ couple by polyelectrolyte II. In any case, the point to be derived from the present study is that the factors governing the relative binding interactions of polyelectrolytes and complex ions can involve much more than the relative charge densities of the latter.

Acknowledgments

This work was supported by the U.S. Army Research Office. Dr. H. Zumbrennen offered many helpful suggestions during early stages of this work. We thank Asahi Glass Company, Tokyo, for a sample of polyelectrolyte II.

Measurements of the Steady-State Activation Overpotential of Chlorine Evolving Electrodes

I. V. Kadija

Olin Corporation, Metals Research Laboratories, New Haven, Connecticut 06511

ABSTRACT

Detailed measurements of interfacial concentration and concentration overpotential of chlorine evolving platinized platinum electrodes were performed in 4.9M NaCl, at 25°C and 1 atm chlorine or 1 atm nitrogen in the cell. Based on these and electrode polarization measurements, steady-state activation overpotential curves were obtained. The applied method enabled for the first time in this field, development of true steady-state activation overpotential curves. Our findings indicated that 30-40 mV/decade slopes typically obtained in nitrogen atmosphere were essentially a sequence of quasi equilibria at the electrode interface. Also, micropolarization data obtained near the open circuit with chlorine atmosphere in the cell were found to be a concentration overpotential phenomenon. The true activation overpotential was found to become a significant part of the electrode polarization only after it exceeded several millivolts in chlorine saturated brine. In nitrogen saturated brine, where the open circuit was undefined, the activation overpotential became significant for polarizations that exceeded two decades of steady-state low current density polarization. In this case, the activation overpotential was observable as a departure from a 32 mV/decade slope. The obtained activation overpotential curves can be used as a base for developing kinetic parameters, however, a considerably greater emphasis than in the past must be given to the corresponding interfacial conditions.

A steady-state electrochemical reaction brings about a concentration gradient across the interface. Assuming a charge transfer reaction virtually at equilibrium, the concentration overpotential is defined (1) as the difference between the steady-state potential and the potential across the interface obtained at the open circuit (equilibrium potential). Using activity terms rather than concentration in the Nernst equation, the concentration overpotential (η_c) for an electronation reaction can be expressed in the following form

$$\eta_c = \frac{RT}{nF} \ln \frac{a_{x=0}}{a^0} \quad [1]$$

where $a_{x=0}$ is the activity of the reacting species at the interface in g ions/l, and a^0 is the activity of the same species in the bulk in g ions/l. According to the Fick's law of steady-state diffusion, assuming a known and virtually constant activity coefficient, $a^0 - a_{x=0}$ is proportional to the current density

$$a^0 - a_{x=0} = - \frac{i\delta}{nFD} \times 10^3 \quad [2]$$

where i is the current density in A/cm², δ is the diffusion layer thickness in cm, and D is the diffusion co-

efficient of the reacting species in cm²/s. By introducing Eq. [2] in Eq. [1], one obtains

$$\eta_c = \frac{RT}{nF} \ln \left(1 + \frac{10^3 i \delta}{nFD a^0} \right) \quad [3]$$

An inherent property¹ of expression [3] is the η_c 's linear dependence on current density for small values of $10^3 \frac{i\delta}{nFD} / a^0$. For such operating conditions, Eq. [3] may be written as

$$\eta_c = i \frac{RT\delta 10^3}{n^2 F^2 D a^0} \quad [4]$$

or

$$\eta_c = K \cdot i$$

where

$$K = \frac{RT\delta 10^3}{n^2 F^2 D a^0}$$

For example, for a single electron charge transfer reaction for $a^0 = 1$ g ion/l, $F = 9.65 \times 10^4$ As/g ion, $D = 10^{-5}$ cm²/s at current density of 10^{-3} A/cm², and

¹ $\ln(1 \pm x) = \pm x$
 $x \rightarrow 0$

$\delta = 10^{-2}$ cm, one obtains $\eta_c = 0.61$ mV. The linear dependence exists up to seven times higher current density giving 4.2 mV. The given example corresponds to a situation frequently encountered in electrochemical investigations, i.e., 1 g ion/l concentration of reacting species, current density of several mA/cm², and depending on the stirring rate, diffusion layer thickness of 50–200 μ . Hence, concentration polarization is present throughout the experiment. Its true value, however, may be determined only by means of retrofitting the necessary information into Eq. [4] or even more accurately, since Fick's law is an approximation, by applying the true value of $a_{x=0}$ in Eq. [1].

In a similar approach, the low field approximation of the Butler-Volmer equation is frequently being used for establishing the kinetic parameters of electrochemical reactions (1)

$$i = \frac{i_0 F \eta_A}{RT} \quad [5]$$

($-0.01 < \eta_A < +0.01$) where η_A is the activation overpotential. Equation [5] expresses the linear relationship between the activation overpotential and the current density if the electrode potential is close to the equilibrium potential established in the particular electrode/electrolyte system.

Now, both Eq. [4] and [5] are applicable to the same system and in the same polarization range. In the presence of both, concentration and activation polarization, there is a linear relationship between the current and the polarization. Clearly, the overall polarization will be the arithmetic sum of the two overpotentials. Eventually, one may make use of Eq. [5] if η_c is measured and its relevance determined.

The role of the concentration overpotential becomes even more important for the investigation of the kinetics of reversible reactions with electrode potential depending on both reactant and product species activity. For example, for a redox couple $A^{n+}/A^{(n-1)+}$ one can write the concentration overpotential expression as

$$\eta_c = \frac{RT}{nF} \left[\ln \frac{a_{A^{(n-1)+}}}{a_{A^{(n-1)+, x=0}}} + \ln \frac{a_{A^{n+}, x=0}}{a_{A^{n+}}} \right] \quad [6]$$

Since in this case the same applied current generates interfacial activity changes for both species, it is necessary to be very accurate in identifying these changes at the instant of taking polarization data. In an example analogous to the one above with both species having a bulk activity of 1 g ion/l, a current of 7×10^{-3} A/cm² will generate 8.4 mV of concentration overpotential. If, however, one of the species is one order of magnitude lower in bulk activity, its interfacial activity change becomes considerable. In that case, we must use Eq. [3] to describe concentration overpotential which in turn follows the logarithmic dependence. For example, by doubling the one species' interfacial activity, one obtains $RT/F \ln 2 = 20$ mV for concentration overpotential. Hence, the species with the lower bulk activity becomes the predominant factor in establishing the concentration overpotential.

Since its measurement introduces considerable complexity to the logistics of the electrochemical investigation, the interfacial activity change of the reacting species is typically presumed to be negligible in the literature. "Sufficient stirring" with a rotating disk, fast flowing electrolytes, or other means is regularly introduced as an *a priori* method to eliminate the concentration gradient. Also typical is the transient method approach where the current-voltage measurements are made prior to the establishment of the steady-state concentration gradient.

However, the above-mentioned methods are usually overestimated concerning their effectiveness in eliminating the concentration polarization. In essence, the interfacial activity deviation from the bulk values is

always present and its relevance to the experimenter's conclusions can be determined only upon detailed measurements of the changes or at least upon a thorough investigation of the mass transport conditions at the interface. Recently, the International Union of Pure and Applied Chemistry, Commission on Electrochemistry, has issued a set of recommendations concerning publishing of the information obtained in investigations of electrode reaction values, transfer coefficients, and rate constants (2). "In view of the complications and confusion which exist in the literature," several suggested basic recommendations put the emphasis on having mass transport and interfacial concentration rigorously controlled and defined.

In the chlor-alkali industry, noble metal-coated titanium anodes provide an excellent substrate for a reversible chlorine/chloride reaction. In such cases, the concentration overpotential can be described with an expression similar to Eq. [6]

$$\eta_c = \frac{RT}{F} \ln \frac{a_{Cl^-}}{a_{Cl^-, x=0}} + \frac{RT}{2F} \ln \frac{a_{Cl_2, x=0}}{a_{Cl_2}} \quad [7]$$

Throughout the existing literature dealing with this subject, in interpreting the current/voltage curves, the electrode equilibrium potential is typically expressed through the chlorine partial pressure, Eq. [8]. By this means, the interfacial chlorine activity $a_{Cl_2, x=0}$ had forever lost its identity being locked into a presumed chlorine equilibrium between the gaseous and the liquid phase. Since the partial pressure over the electrolyzer stays virtually constant throughout the experiment, one may be easily brought to the conclusion that $a_{Cl_2, x=0}$ is always equal to the bulk activity, a_{Cl_2} .

In reality, on a chlorine or any other gas producing surface, one cannot identify the charge transfer sites with gas phase nucleating sites. Typically, the catalytic electrode surface, on an atom scale level, has a density of 10^6 – 10^{12} /cm² of charge transfer sites while the number of gas nucleating sites, on a macroscale, is considerably smaller and ranges from 10^2 to 10^5 /cm². The separation between the two brings up mass transport limitation leading to considerable chlorine supersaturation at the interface (3–8). Clearly, the brine saturation by sparging 1 atm Cl₂ through the electrolyte will have no bearing on the chlorine transport phenomena at the interface in a steady state. Moreover, considerable supersaturation at the interface can cause minor but measurable supersaturation in the bulk since measurably large flux of supersaturated chlorine can diffuse into the bulk without being disengaged by bubbles at the interface. Examples of this mechanism are well demonstrated with high speed movie camera and double ring disk measurements of other gas evolving reactions (4).

In our first contribution (11) we have measured chlorine interfacial concentration in three different sets of chlorine partial pressure and bulk pH conditions; Cl₂ sparged chlor-alkali cell (Cl₂ partial pressure 0.96 atm), N₂ sparged chlor-alkali cell (Cl₂ partial pressure 0.0 atm), and in chlorate cell conditions at pH 7 (Cl₂ partial pressure 0.01 atm). With fixed thickness of diffusion layer at 23 μ , we have shown that the chlorine interfacial concentration follows linearly the current density regardless of the chlorine partial pressure. Furthermore, in the case of a chlorine-saturated chlor-alkali cell, we have measured chlorine bulk activity which exceeded gas/liquid equilibrium. Hence, it was demonstrated that one may not use chlorine partial pressure but only the interfacial chlorine activity as information relevant to the concentration polarization.

This manuscript deals with the chlorine concentration overpotential as a function of the diffusion layer thickness. It also establishes experimentally verified constants applicable to the concentration overpotential measurements for chlorine evolution investiga-

tion at 25°C in 4.9M brine. This information has practical value in establishing the actual activation overpotential if the diffusion layer thickness is known.

Experimental Method

Janssen and Hoogland (9) have shown that diffusion layer thickness is a function of current density that is evidently a result of the varying bubble dynamics. In order to measure the concentration polarization dependence on diffusion layer thickness, one must have a current independent means for controlling the magnitude of the latter. Based on the previous findings (4, 10, 11), we have selected the rotating double ring disk system. Here diffusion layer thickness can be varied independently from the rate of the gas producing reaction. In this perspective, the information given throughout the manuscript is different from the one that may be obtained at a stationary electrode. A diminishing diffusion layer thickness with increasing current density with a stationary system would require diffusion layer thickness analysis from one to another steady state (9).

The experimental method was described earlier (11) in detail. Briefly, it contains the following steps: First, the required diffusion layer thickness was established by fixing the rotating ring disk system at a constant rotation speed. Secondly, from a power supply, an anodic and constant current density was established at the inner ring which served as the operating electrode. Typically, the electrode potential was reached within 1s or less. However, the potential reading was made after at least 3 min have elapsed since the polarographic measurement at the outer ring required 2-3 min to be performed. We have polarographically analyzed the molecular chlorine interfacial concentration by means of the outer ring's independent circuit. The limiting currents for molecular chlorine reduction at the outer ring were proportional to the concentration of molecular chlorine at the operating inner ring's interface (11). An accuracy of $\pm 2\%$ enabled a detailed measurement of the interfacial changes. By means of the activity coefficient and the interfacial concentration, we have calculated the actual steady-state concentration overpotential and used it for establishing the activation overpotential under various hydrodynamic conditions at two rotating ring electrodes.

In experiments performed with the outer ring as an operating electrode, there were no simultaneous measurements of interfacial concentration due to the logistics of the rotating double ring system operation. Presented data are based on the measured polarization and the concentration changes calculated from our previously verified equation [Eq. [7], Ref. (11)].

Since a tenfold increase in chlorine activity gives only 29.5 mV change in the operating electrode potential, we have increased our accuracy by having sets of three Ag/AgCl and three SCE reference electrodes. IR drop corrections were made by current interruption methods. The apparatus was thermostated at $25.0 \pm 0.5^\circ\text{C}$. Special care was taken to avoid supersaturation in the bulk since the analytical outer ring measures the total concentration (11). We restricted our currents to less than 100 mA. We introduced Cl_2 or N_2 bubblers to increase the chlorine disengagement from the bulk. Frequent checks of the limiting current for molecular chlorine reduction at the outer ring at no current from the inner ring was used as a measure of the bulk saturation level (11). Chlorine and nitrogen partial pressure above the solution were 0.95-0.97 atm. All the curves have been reproduced at least three times. Increasing and decreasing current steady-state polarization measurements were within ± 0.7 mV.

Diffusion layer thickness selection.—Janssen and Hoogland (9) have shown that for a range of current densities between 0.1-1.0 A/cm² diffusion layer thick-

ness of a chlorine producing anode at 25°C varies within 60-10 μ , respectively. Hence, we have selected the range of diffusion layer thickness between 15-50 μ since it reflects most accurately the ones obtainable in industrial practice or in experiments with rotating disks.

pH range selection.—In the majority of chlor-alkali operations, the steady-state anolyte pH varies from pH 4.5 to 2.0. Operating with a 95-99% efficiency for chlorine reaction, the interface is typically more acidic than the bulk anolyte due to the 1% to 5% current efficiency in oxygen evolution from water. In view of the potentially variable bulk pH, we have conducted the majority of our chlor-alkali experiments within a pH range of 0.5-2.0. Yokoyama *et al.* (22) have reasonably used a similar range to avoid significant hypochlorite formation. Based on our previous findings (11), however, this change does not introduce any measurable variation in the interfacial saturation phenomena.

Results

The solid N_2 curves in Fig. 1 and 2 are the polarization curves obtained at various rotation speeds on the inner and outer rings, respectively, with N_2 atmosphere in the anolyte. At lower current densities (less than 20 mA/cm²), we have obtained parallel lines with both rings. The average slope of the lines was 32 ± 1 mV/decade.

Solid Cl_2 curves shown in Fig. 1 and 2 describe the polarization curves on the inner and outer rings, respectively, with Cl_2 atmosphere in the anolyte. At higher current densities, these coincide with the N_2 atmosphere curves at corresponding rotation speeds. We have obtained an open-circuit potential of 1.073 ± 0.001 (V) vs. SCE.

Figure 3 shows the change in electrode polarization in N_2 atmosphere as a function of diffusion layer thick-

Fig. 1. Inner ring: steady-state polarization curves. Electrolyte saturated with, N_2 -nitrogen, Cl_2 -chlorine, 0.95-0.97 atm. Full lines are experimental curves, dashed lines are theoretical curves for concentration polarization based on measured interfacial concentration of molecular chlorine for N_2 (Eq. [15]), Cl_2 (Eq. [21]), (a) 518, (b) 1770, and (c) 4628 rpm.

Fig. 2. Outer ring: steady-state polarization curves. Electrolyte saturated with, N_2 -nitrogen, Cl_2 -chlorine, 0.95-0.97 atm. Full lines are experimental curves, dashed lines are theoretical curves based on calculated interfacial concentration of molecular chlorine for N_2 (Eq. [15]), Cl_2 (Eq. [21]), (a) 518, (b) 1770, and (c) 4625 rpm.

ness at constant current density. We have chosen three current densities: 0.7, 2.4, and 9.6 mA/cm^2 .

For the inner ring as an operating anode in both Cl_2 and N_2 saturated anolytes, our measurements of interfacial chlorine concentration have reproduced our previously reported findings and confirmed Eq. [7], Ref. (11).

Discussion

Open-circuit conditions.—The equilibrium potential of a chlorine/chloride electrode can be described by means of the chlorine partial pressure, Eq. [8], as well as by means of the chlorine activity, Eq. [9]

$$E_{Cl_2/Cl^-} = E^{\circ}_{Cl_2 g/Cl^-} + \frac{RT}{2F} \ln P_{Cl_2} - \frac{RT}{F} \ln (m_{Cl^-} \gamma_{Cl^-}) \quad [8]$$

where $E^{\circ}_{Cl_2 g/Cl^-} = 1.3583V$ (12, 13), and

$$E_{Cl_2/Cl^-} = E^{\circ}_{Cl_2 aq/Cl^-} + \frac{RT}{2F} \ln (m_{Cl_2} \gamma_{Cl_2}) - \frac{RT}{F} \ln (m_{Cl^-} \gamma_{Cl^-}) \quad [9]$$

where $E^{\circ}_{Cl_2 aq/Cl^-} = 1.395$ (12)

At the open circuit in a nitrogen-saturated cell, since there is no molecular chlorine, the potential is not defined. The electrode potential fluctuates depending on the electrochemical activity of platinum oxides. However, in a chlorine-saturated cell the reversible chlorine/chloride system is established. By introducing numerical values into Eq. [8], one obtains

$$E_{Cl_2/Cl^-} = 1.3583 + 0.0295 \log (0.96 \pm 0.01) - 0.059 \log (5.45 \times 0.92) \quad [10]$$

$$E_{Cl_2/Cl^-} = 1.317 \pm 0.0005V$$

or,

$$E_{Cl_2/Cl^-} = 1.073 \pm 0.0005V \text{ vs. SCE}$$

where 5.45 is the molality of brine and 0.92 is the coefficient of activity of the chloride ion (14). The experimental value of $1.073 \pm 0.001V$ is in good agreement with the theoretically calculated one based on Cl_2 partial pressure.

Equation [9], however, requires the measurement of the molecular chlorine activity in solution. Three species are conceivably coexisting in a solution where chlorine is being dissolved. These are Cl_2 , $HClO$, and Cl_3^- . Following Sherrill's and Izard's (15) and Yokota's (16) measurements, the $HClO$ concentration presents only 1% or less of the total Cl_2 dissolved in our operating conditions. Concerning Cl_3^- we have given the same treatment as if it were active Cl_2 . This approximation has been made previously by Yokota (16).

We have calculated the activity coefficient from the ratio of chlorine solubility in pure water and brine

Fig. 3. N_2 saturated electrolyte, inner and outer ring. Experimental data of electrode polarization at constant current density and variable diffusion layer thickness, $(dE_c/d \ln \delta)_i$.

assuming the 1.0 atm pressure of chlorine, as recommended by Sherrill and Izard (15)

$$\gamma_{\text{Cl}_2} = \frac{m^w_{\text{Cl}_2}}{m^1_{\text{Cl}_2}} = \frac{0.0592(15)}{0.0256} = 2.31 \quad [11]$$

By introducing numerical values in Eq. [9] one obtains

$$E_{\text{Cl}_2/\text{Cl}^-} = 1.3950 + 0.0295 \log \frac{(0.022 \times 2.31)}{0.894} - 0.059 \log (5.45 \times 0.92) \quad [12]$$

$$E_{\text{Cl}_2/\text{Cl}^-} = 1.3175 \pm 0.0005\text{V} \\ = 1.0735 \pm 0.0005\text{V vs. SCE}$$

The above value is also in a good agreement with the experimentally obtained value, $1.073 \pm 0.001\text{V vs. SCE}$.

Operating conditions.—Once the chlorine production starts in a nitrogen saturated anolyte, the reversible chlorine/chloride reaction can occur even though the bulk chlorine activity and chlorine partial pressure are virtually zero. At any given steady state, the interfacial electrolyte has a certain chlorine activity defined by current density and mass transport conditions. Assuming the bulk chlorine activity to be zero, the interfacial concentration is described by Eq. [7] of Ref. (11) with the first term of the equation equal to zero

$$C_{\text{Cl}_2, x=0} = 4.3 \times 10^2 \cdot i \cdot \delta \quad [13]$$

where i is the current density in A/cm^2 and δ is the diffusion layer thickness in centimeters. Equation [13] is analogous to Eq. [2] with bulk chlorine concentration being zero. To obtain molality of the concentration, one must divide Eq. [13] by 0.894. Furthermore, to calculate the activity of the interfacial chlorine one must apply the activity coefficient that may be applicable for the investigated range of chlorine concentrations. Yokota (16), Smirnov and Aliev (17), and Hine and Inuta (18) have shown for concentrated solutions that the linear dependence between pressure and solubility is preserved for pressure ranging from 0.1 to 6.0 atm. Also, by simulating partial pressure/liquid phase equilibria, we have conducted several calculations with the commercially available computer program (14) and found that the activity coefficient stays within $\pm 1\%$ of 2.11 for our measured range of C_{Cl_2} . Although value 2.11 would not introduce any significant departure in our calculation, we have used our value of activity coefficient $\gamma_{\text{Cl}_2} = 2.31$. Hence, Eq. [13] can be converted to describe chlorine activity change as a function of current density and diffusion layer thickness at the interface

$$m_{\text{Cl}_2} \cdot \gamma_{\text{Cl}_2} = \frac{C_{\text{Cl}_2, x=0}}{0.894} \times 2.31 = (1.11 \pm 0.03) \times 10^3 \cdot i \cdot \delta \left(\frac{M}{1000 \text{ g H}_2\text{O}} \right) \quad [14]$$

In Fig. 1 and 2, the N_2 solid curves show experimental polarization curves on two rings at three different rotation speeds. Dashed lines are drawn based on Eq. [15] obtained by combining Eq. [14] with Eq. [9]

$$E_C = 1.3537 + \frac{RT}{2F} \ln [(1.11 \pm 0.03) \times 10^3 \cdot i \cdot \delta] \quad [15]$$

where E_C is the electrode steady-state potential due to the chlorine activity² at the interface. Dashed lines, Eq. [15], and experimental N_2 curves coincide for each rotation speed indicating that our polarization is essentially a result of an interfacial chlorine activity change with current density and diffusion layer thickness. One may notice, however, that the expression [9] used

² Chloride ion activity term is assumed constant as discussed previously (11). Therefore, $1.395 - 0.041 = 1.354\text{V}$ is the electrode potential for the unit molecular chlorine activity.

in deriving Eq. [15] represents the equilibrium potential dependence on chlorine and chloride species activity. Naturally, since our open circuit is undefined, expression [15] represents the quasi-equilibrium steady-state polarization curves which, in the absence of activation overpotential, can have and indeed have virtually the same values as the ones obtainable in a set of equilibrium conditions with bulk activities identical to the ones at the interface during the steady-state operation. Furthermore, in Table I, we have listed the calculated currents that would, following Eq. [13], give 0.022 M/l chlorine saturation in the adjacent electrolyte. Such concentration exists in the bulk electrolyte if we saturate the solution with chlorine at partial pressure of 0.96 ± 0.01 atm. A dashed vertical line from our open-circuit conditions ($0.96 \pm 0.01 \text{ Cl}_2$, 1.073 vs. SCE) intercepts the polarization curves obtained in N_2 atmosphere with a considerable accuracy at current densities listed in Table I.

In addition, our experimental curves, Fig. 1 and 2 (N_2 lines), and Fig. 3 show polarization slopes of 32 mV/decade and 28.5 mV/decade, respectively. From Eq. [15] one obtains theoretical slopes of 29.5 mV/decade for each

$$\left(\frac{dE_C}{d \ln i} \right) = 29.5 \text{ mV/decade} \quad [16]$$

$$\left(\frac{dE_C}{d \ln \delta} \right) = 29.5 \text{ mV/decade} \quad [17]$$

In a cell equilibrated with the 0.95–0.97 atm Cl_2 , the steady-state interfacial activity is the sum of the bulk chlorine activity and the interfacial activity increment resulting from the electrochemical chlorine generation

$$a_{\text{Cl}_2, x=0} = a^0_{\text{Cl}_2} + (1.11 \pm 0.03) \times 10^3 \cdot i \cdot \delta \quad [18]$$

where $a^0_{\text{Cl}_2} = \frac{0.022 \times 2.31}{0.894}$ from Eq. [12]. Eq. [18] is analogous to Eq. [2].

In this case, expression [7] describes the concentration overpotential. By replacing $a^0_{\text{Cl}^-}/a_{\text{Cl}^-, x=0} = 1$, and

$$\frac{a_{\text{Cl}_2, x=0}}{a_{\text{Cl}_2}} = \frac{a^0_{\text{Cl}_2} + (1.11 \pm 0.03) \times 10^3 \cdot i \cdot \delta}{a_{\text{Cl}_2}} \quad [19]$$

one obtains

$$\eta_c = \frac{RT}{2F} \ln \left[1 + \frac{(1.11 \pm 0.03) \times 10^3 \cdot i \cdot \delta}{0.0568} \right] \quad [20]$$

For the purpose of comparison with the nitrogen-saturated brine data we have plotted the experimental current voltage curves on the same graph (Cl_2 solid curves). The corresponding concentration polarization curve is described with Eq. [21] which is the sum of Eq. [9] and [20]

$$E_C = E_{\text{Cl}_2/\text{Cl}^-} + \eta_c \\ = 1.354 + \frac{RT}{2F} \ln [0.0568 + (1.11 \pm 0.03) \times 10^3 \cdot i \cdot \delta] \quad [21]$$

Up to a polarization of 6–8 mV, the dashed lines, based on Eq. [21], and the full lines (Cl_2 curves) from

Table I. Currents that generate 0.022 M/l molecular chlorine saturation in the anode adjacent electrolyte (N_2 in bulk)

	RPM	Avg δ	i Calculated	i Experimental	% Accuracy
Inner ring	4625	16.3	31.6	28.9 ± 1	92
	1770	26.4	19.4	17.1 ± 0.5	88
	518	49.6	10.3	11.0 ± 0.5	94
Outer ring	4625	15.2	33.6	33.6 ± 1	100
	1770	24.7	20.7	23.1 ± 0.5	90
	518	46.1	11.1	12.4 ± 0.5	90

our experimental measurements are virtually identical. Hence, up to 6-8 mV our polarization is essentially a result of the concentration gradient generated by chlorine evolution from the electrode surface. Furthermore, Table II shows the experimentally obtained polarizations from the open circuit at the same current densities as in Table I. These currents generate a supersaturation of 0.022 M/l of molecular chlorine in the adjacent electrolyte. Theoretically, from Eq. [20], one can calculate a polarization of 8.9 mV due to the interfacial concentration gradient from 0.022 to 0.044 M/l.

At lower rotation speeds and thicker diffusion layers, supersaturation can be reached with lower current densities. Consequently, the activation overpotential is negligible and all of the polarization can be attributed to the excess concentration at the interface. Therefore, at 518 rpm there is a good agreement with 8.9 mV as predicted. At 1770 rpm there is an activation overpotential of 2-3 mV, at 4625 rpm, 3-5 mV.

Clearly, our polarization curves obtained with the platinized platinum electrodes in essence reflect the concentration overpotential for current densities up to 20 mA/cm². For such conditions, a direct application of the low field approximation, Eq. [5], to the micropolarization measurements near the open circuit would evidently be erroneous since the activation overpotential appears only at higher current densities. The situation may be different with electrodes of lower catalytic activity. Activation polarization may become significant at current densities low enough to cause any measurable concentration overpotential. This, however, must be established in each case remembering Eq. [13] and its contribution to the interfacial chlorine activity expressed through Eq. [15] and [20].

Measurements of activation overpotential.—Figure 4 shows the actual activation overpotential curves for both rings. Each data point is obtained by graphical subtraction of the concentration overpotential points on the curves represented by Eq. [21] from the experimental polarization curve obtained in Cl₂-saturated brine. These curves represent the actual activation overpotential free of any remnants of the concentration overpotential.

Surface absorption/desorption, exchange currents, Tafel slopes, and other parameters still bear a strong mark of varying interfacial activity of molecular chlorine. Absorption/desorption phenomena can depend in this case, not only on the chloride ion or Cl radical surface kinetics, but a consideration must be given to the role of molecular chlorine and its absorption/desorption mechanism. Low field approximation, for example, does not follow Eq. [5] predictions for overvoltages higher than 3 mV, suggesting changes in electrode kinetics with increasing current density. In a similar manner, apparent Tafel slopes reflect the surface kinetics parameters as well as interfacial changes. In order to apply these in the mechanism studies of the reaction, one must take into account the molecular chlorine interfacial activity changes occurring in the range of currents used for establishing the slope.

Furthermore, i_0 is a product of the concentration independent rate constant k and the interfacial concentration of the reacting species C_{Cl^-} or $C_{Cl_2, x=0}$ (1)

$$i_0 = Fk C_{Cl_2, x=0} e^{-\beta FE^0/RT} = Fk C_{Cl^-} e^{-(1-\beta)FE^0/RT} \quad [22]$$

Table II. Overpotentials of ring anode in chlorine-saturated solution at 0.022 M/l supersaturation at the interface at respective rotation speed

Ring	4625	1770	518
Inner	14 mV	12 mV	9 mV
Outer	12 mV	11 mV	10 mV

Fig. 4. Cl₂ saturated electrolyte—activation overpotential curves for inner and outer ring. Concentration polarization measured and eliminated. (a) 518, (b) 1770, and (c) 4625 rpm.

In our experiments, however, the measurable activation overpotential falls in the range of $C_{Cl_2, x=0} > 2C_{Cl_2}^0$. Hence, an extrapolation of the curves to the zero η_A gives information pertinent only for particular interfacial conditions. Consequently, it would be erroneous to make comparisons between different catalytic surfaces without considering the interfacial conditions for which extrapolated values were determined. The lower catalytic activity surfaces, of course, may show a predominant charge transfer resistance near the open circuit thus permitting a correlation between the i_0 and the $C_{Cl_2}^0$.

Our activation overpotential curves, Fig. 4, show two distinctive sets of polarization curves for the two rings. This result indicates that the two rings have different catalytic activity.

Distinction in activation polarization within one set of curves can be attributed only to the interfacial concentration variation with rotation since all three curves are obtained on the same ring of identical surface activity but at different mass transport conditions. Table I shows that mass transport conditions, although not identical at the two rings, overlap considerably, i.e., diffusion layer thicknesses for both rings fit in the range of 15.2-49.6 μ with small differentiation in magnitudes for identical rotation speeds. Under operating conditions with a negligibly small difference in surface catalytic activity between the two rings, or, in the absence of an activation overpotential, the polarization curves for both rings should line up in the sequence as expected by mass transport variations (well demonstrated in N₂ curves for lower current densities, Fig. 1, 2, and 3). At higher current densities, where activation overpotential becomes significant, by subtracting the concentration overpotential from our polarization curves, we were able to identify the difference between the surface activities of the two rings.

The outer ring is more active and we attribute this phenomenon to the platinized platinum formation process described in our earlier work (19). Platinum deposition is performed from a chloroplatinic solution under higher than limiting current conditions. This method was developed to provide an active surface with submicronic dendrites which do not interfere with mass transport conditions at the interface. With a

fixed rotation speed, chloroplatinic acid concentration, and deposition time, a larger amount of platinum will be deposited on the outer ring. Hence, a better catalytic activity can be attributed to it. A coulometric oxidation of adsorbed hydrogen, for example, indicates a 12-15% larger adsorption capacity in the outer compared to the inner ring.

We are presently proceeding in establishing the mechanism of chlorine evolution from these surfaces, however, with much greater emphasis on interfacial saturation than encountered in the literature dealing with this subject. Conway and Novak (20), for example, attribute a 42 mV/decade polarization slope in N_2 atmosphere to a Tafel region entirely disregarding the interfacial saturation phenomena. In a similar approach, they make a thorough mechanistic interpretation based on specific adsorption of chloride species assuming an undisturbed interfacial equilibrium of 1 atm Cl_2 with brine. In our opinion, their experiments presented in their Fig. 2 show strong evidence of specific adsorption. However, this may not be only a result of Cl^- ion specific adsorption, as stated by the authors. Other adsorbed intermediate species like Cl_2 , $Cl_2(H_2O)_x$, etc., may as well be in a quasi equilibrium with dissolved molecular chlorine at the interface. At the corresponding current density range, the interfacial chlorine concentration is closer to a several atmosphere supersaturation level rather than to 1 atm as assumed by the authors. Under such conditions, desorption of molecular chlorine or even chlorine hydrate may become the rate-determining step. In a similar fashion, micropolarization data obtained by Tilak (21) and Yokoyama *et al.* (22) on several substrates reflect predominantly the linearity of concentration overpotential with small interfacial chlorine concentration changes as indicated by Eq. [3]. Thus, the extrapolated information about the reaction mechanisms bears an inherent factual error. Furthermore, Fajta *et al.* (23) discussed Tafel slopes assuming interfacial equilibrium of molecular chlorine throughout their experiments. Nevertheless, the current densities they applied were carried well over 100 mA/cm². Krishtalik *et al.* (24), for example, assume interfacial equilibrium of molecular chlorine with 0.057 atm Cl_2 partial pressure in cell atmosphere despite a rate of 1 A/cm² of chlorine evolution. Under such conditions with diffusion layer thickness of approximately 15-20 μ (9), the interfacial chlorine saturation is over an order of magnitude higher than one would expect based on liquid/gas phase equilibrium.

In conclusion, we think that far too much work was done in the past in this field entirely neglecting the interfacial chlorine saturation phenomena. This manuscript points out the potentially erroneous approach and indicates the routes to avoid misleading conclusions. In a well-defined system by means of Eq. [13], (21), or analogous equations, it is possible to establish a sound base for investigation of mechanistic phenomena.

LIST OF SYMBOLS

a° bulk activity of the electrochemically active species ($m^\circ\gamma^\circ$)

$a_{x=0}$	interfacial activity of the electrochemically active species ($m\gamma$)
$A^{n+}/A^{(n-1)+}$	single electron redox couple
$a^\circ Cl^-$	bulk activity of chloride ions ($m^\circ Cl^- \gamma^\circ Cl^-$)
$a^\circ Cl_2$	bulk activity of molecular chlorine ($m^\circ Cl_2 \gamma^\circ Cl_2$)
$a_{Cl^-, x=0}$	interfacial activity of chloride ions, in this manuscript assumed to be the same as $a^\circ Cl^-$, $m^\circ Cl^- \gamma^\circ Cl^- = m_{Cl^-} \gamma_{Cl^-}$
$a_{Cl_2, x=0}$	interfacial activity of molecular chlorine ($m_{Cl_2} \gamma_{Cl_2}$), in this manuscript $m_{Cl_2} \gamma_{Cl_2} \cong m^\circ Cl_2 \gamma^\circ Cl_2$
$C^\circ Cl_2$	bulk concentration of molecular chlorine M/l at the open circuit $C^\circ Cl_2 = C_{Cl_2, x=0}$
$C^\circ Cl^-$	bulk concentration of chloride ions M/l, at the open circuit and concentrated brine solutions $C^\circ Cl^- = C_{Cl^-, x=0}$, Ref. (11)
$C^\circ Cl_2, x=0$	interfacial concentration of molecular chlorine M/l, in nitrogen purged anolite $C_{Cl_2, x=0}$ defined by Eq. [13]
D	diffusion coefficient of the species 10^{-5} cm ² /s
E_{Cl_2/Cl^-}	equilibrium potential of a chlorine/chloride electrode
$E^\circ Cl_2 \text{ g}/Cl^-$	standard potential of chlorine/chloride electrode. Chlorine activity expressed through partial pressure, for 1 atm 1.358V (12, 13)
$E^\circ Cl_2 \text{ aq}/Cl^-$	standard potential of chlorine/chloride electrode for unit chlorine activity 1.395V (12)
E_c	electrode quasi equilibrium or steady-state concentration overpotential, both due to the chlorine activity at the interface $E_c = E_{Cl_2/Cl^-}$ when $\eta_c = 0$ or $E_c = \eta_c$ when E_{Cl_2/Cl^-} is undefined, Eq. [21]
i	average current density on the anode (A/cm ²)
i_0	exchange current density for the couple Cl_2/Cl^-
k	rate constant, cm/s
K	$RT\delta 10^3/n^2F^2Da^\circ$
$m^\circ Cl^-$	molality of Cl^- in the bulk, M/1000 g H_2O
$m^\circ Cl_2$	molality of Cl_2 in the bulk, M/1000 g H_2O
m_{Cl^-}	molality of Cl^- at the interface, M/1000 g H_2O
m_{Cl_2}	molality of Cl_2 at the interface, M/1000 g H_2O
$m^w Cl_2$	molality of Cl_2 in water at 25°C and 1 at Cl_2 , 0.0592 M/1000 g H_2O (15)
$m^l Cl_2$	molality of Cl_2 in brine, 285 g/l NaCl, 25°C and 1 at Cl_2 , 0.0256 M/1000 g H_2O (11)
Greek Symbols	
γ	activity coefficients of the species
$\gamma_{Cl_2} = \gamma^\circ Cl_2$	activity coefficient of Cl_2 , defined as $m^w Cl_2/m^l Cl_2 = 2.31$ or 2.11 by computer program (14)
γ_{Cl^-}	activity coefficient of Cl^- , 0.92 ± 0.015 (14)
δ	average diffusion layer thickness at the anode surface, cm
η_A	anode activation overpotential, V
η_c	anode concentration overpotential, V

Technical Notes

Lead-Acid Battery Cathodes Incorporating Chemically Prepared PbO₂

P. T. Moséley* and N. J. Bridger

AERE Harwell, Materials Development Division, Oxfordshire, OX11 0RA, England

The positive plates of lead-acid starting, lighting, and ignition (SLI) batteries are manufactured according to a time-honored industrial process in which a mixture of finely divided lead, lead oxides, basic lead sulfates, water, and sulfuric acid is pressed, in the form of a paste, into a grid of a lead alloy. The pasted grid is held in an environment of controlled humidity and temperature for a recrystallization process akin to cement curing to take place. The plate is then electrochemically "formed" in a dilute sulfuric acid electrolyte to convert the active material to PbO₂. The forming process involves a complicated sequence of reactions, and it is necessary to carry out the formation in two stages separated by a hold time in order for most of the active mass to be converted. The details of the curing and formation procedures employed may vary from one manufacturer to another, but the whole operation, which is performed on batches of batteries, usually takes about a week.

The manufacture of positive plates for traction batteries differs only in detail: a dry mixture of lead, PbO, and Pb₃O₄ is poured into long thin separator bags which each contain a central lead current collector projecting down from the top of the plate. The formation operation proceeds in a similar way to that for SLI batteries.

These manufacturing processes are rather inefficient, and it would appear that a far less costly product could be obtained through the use of a continuous process in which lead dioxide would be injected directly into the interstices of the lead grid.

Aside from the cost of replacing established plants, one reason why the industry has not yet replaced the batch process with a continuous one is likely to be the published claims that lead dioxide prepared by a chemical method yields little (1) or no (2) capacity as a cathode material in a lead-acid cell. It has been demonstrated by nuclear magnetic resonance (NMR) measurements (3) that there is a difference in the

hydrogen content between chemically prepared and electrochemically prepared PbO₂, and neutron transmission measurements (4) appear to confirm this difference. It has even been suggested (3) that the loss of the hydrogen component is a factor contributing to the progressive loss of capacity observed during the battery life.

High resolution electron microscopy (5) has brought to light a tendency for defect structure and structural intergrowth in PbO₂, but these properties seem to be characteristic of the material regardless of the means adopted to prepare it (4).

It is characteristic of presently available lead-acid positive plates that they generally yield only 1/4-1/3 of the theoretical capacity which would be expected on the basis of the mass of PbO₂ present. It is also found that SLI batteries, which have an energy density much nearer electric vehicle target figures than do tubular batteries, lose capacity after an unacceptably short cycle life.

The published literature is short on evidence to support the claim that chemically prepared PbO₂ cannot be used in a lead-acid cell, and a recent attempt to quantify the effect led to the contrary result (6): that there was no less capacity available from a plate prepared with chemically prepared PbO₂ than from a commercially available plate. Lead dioxide prepared by the action of nitric acid on Pb₃O₄ was mixed with dry polytetrafluoroethylene (PTFE) powder (1 weight percent [w/o]), and pressed into a battery grid from which the commercial product had been removed (6). Capacity measurements were made by low rate discharge through a resistor.

The experiments reported here were designed to extend the testing of chemical PbO₂ capacity to constant current discharge, to explore the range of binder content necessary to perform the function of the conventional curing process in retaining the active material in the grid, and to try to discover at what stage the difference in hydrogen content between chemical and electrochemical PbO₂ develops.

* Electrochemical Society Active Member.
Key words: discharge, cathode.

Lead dioxide was prepared by suspending Pb_3O_4 in hot nitric acid, according to a procedure given in the literature (7). The product varied slightly in color between dark brown and black, but always yielded the x-ray powder diffraction pattern of beta PbO_2 (tetragonal).

A commercial battery was dismantled to provide a hard rubber case to hold plates for charge/discharge cycling. One positive plate from the battery was used to provide benchmark capacity data with which the experimental plates could be compared, and others were stripped of their active material and repasted with mixes based on chemical PbO_2 .

Positive plates were charge/discharge cycled one at a time at constant current against a commercial negative plate. The two plates were kept apart by a perforated sheet of perspex. The mean plate separation was about 5 cm. No other separator was used.

The active material was mixed with varying proportions of PTFE and, in some cases, graphite powder. This mixture was then pressed into the commercial plate and placed into the cell in the battery case for cycling and capacity tests.

Initially, a commercial positive plate was discharged at 30 A/m² to a cutoff limit of 1.0V. The plate, which contained 130g PbO_2 , afforded a discharge capacity of 7 Ah, which corresponds to a utilization of 25%.

Three mixtures of chemical PbO_2 , PTFE, and graphite were tested under similar conditions for initial discharge capacity and polarization characteristics, as shown in Table I.

All three mixtures adhered to the lead grid well, but mixture 3 was drier and stiffer than the other two, polarized badly at the outset, and swelled in thickness during use by a factor of about three. All three compositions were much richer in the highly resistive PTFE component than the mixtures that had been made earlier (6) with dry PTFE powder. So, it is scarcely surprising that the utilization, which in the earlier case was similar to that for commercial plates (25%), was rather less (up to 15%) in the present work.

The highest utilization was demonstrated by plate 1. The active material mix was insufficient to cover the whole plate, but no material appeared to be shed, and the capacity was steady through 40 deep discharge/charge cycles until the plate was removed to make way for tests on other mixtures. A typical discharge/charge cycle for plate 1 is shown in Fig. 1.

Table I also shows that the neutron scattering cross sections of two of the mixtures after drying for 24h at 120°C are much greater than that for the dry beta PbO_2 (4) with which they were prepared. This difference signifies a greater hydrogen content, but may be due to an increase in moisture retention caused by the presence of the PTFE. No neutron scattering measurements had been made on the material mixed with dry PTFE during the earlier work (6).

The influence on the ultimate capacity of variation in the details of the preparation of lead dioxide was investigated. As shown in Table II, variation in acid

Table I. Composition, initial discharge characteristics, and neutron cross-sections of synthetic active masses made using chemically prepared PbO_2

Plate	Composition (g)			Utilization (% of theoretical)	Neutron cross section (b)

strength did not alter the utilization. However, the temperature may be important.

The grain size of the PbO_2 product in all cases (measured by x-ray diffraction line breadth) was of the order of 500Å. Mixtures for measurement of capacity of materials shown in Table II were composed of 17g PbO_2 , 7g graphite, and 10g PTFE.

In a further experiment, there was shown to be little variation in utilization over a wide range of PTFE content, as shown in Table III.

The mixture made without PTFE showed that capacity does not depend on the presence of the polymer. The material was completely shed from the plate after one cycle. It is clear from the rest of Table III that even a rather small quantity of PTFE in the mixture is sufficient to overcome this problem.

The present experiments, carried out at constant current, confirm the earlier report (6) that chemical PbO_2 can be used to obtain electrochemical capacity. The range of PTFE content that has been successfully used to prepare battery positives with chemical PbO_2 is now quite wide. Further, it has been shown (Table III) that neither of the additives (PTFE, graphite) is essential for electrochemical capacity to be obtained from chemically prepared PbO_2 .

The grids used in these tests were all partly corroded, and x-ray diffraction showed a substantial layer

Table II. Variation of conditions of preparation of PbO_2

10.0	20.0	13
20.0	20.0	15

^a All the active material was shed from this plate after one complete discharge.

of PbSO_4 on the surface of the grid members. This layer probably constituted an unnecessary impediment to the achievement of high utilization figures so that there may be prospects for improvement.

The achievement of greater utilizations will depend on the availability of a grid in which (i) regions of active material are not eliminated from participating in the discharge reaction by an insulating layer of PbSO_4 , and (ii) acid access to the active material is maintained at all states of charge.

These are the only ultimate limitations on the utilization of electrochemical or chemical PbO_2 which are imposed by the plate itself.

The key as to whether or not chemical PbO_2 electrodes can be developed to give longer lived batteries may lie in the possible microstructures that can be developed. Recently, it was observed (8) that capacity loss is largely due to resistance increase of intergranular contact.

The demonstration that chemically prepared PbO_2 can be used for the manufacture of positive plates for lead-acid batteries opens the way to the development of continuous processes for commercial manufacture. In the case of flat plates, the function of the curing process will need to be replaced by a binder to hold the active material in place, but for tubular cells it should be possible to pour neat PbO_2 powder into the separator bags, which will retain the active material in position (9). In each case, the curing and formation stages can be omitted from the production time, and after a few discharge/charge cycles the strength of the plates will be decided by the morphology developed by the recrystallization of a large part of the active mass.

After the present work was carried out, a note was published from another lab (10) which appears to support the central contention of this paper.

Acknowledgments

The authors are grateful to Mr. M. A. M. Bourke for experimental assistance and to Dr. C. J. Wright for neutron scattering cross-section measurements.

Lithium-Copper Molybdate Voltage Compatible Battery

F. Bonino and M. Lazzari

Polytechnic of Milan, Centro Studio Processi Elettrodici del CNR, Milano, Italy

B. Scrosati*

University of Rome, Dipartimento di Chimica, Rome, Italy

Because of the popularity of portable microelectronic devices, interest has risen in high energy, long-life power sources having working voltages around 1.5V. These improved systems are usually termed "compatible" batteries, since they may directly be interchanged with conventional zinc and mercury dry cells, with great advantages in terms of reliability and longevity.

Among the most promising compatible high energy power sources of this type are the lithium organic-electrolyte batteries with copper-based (1), lead-based (2), or bismuth-based (3) cathodes.

As alternative cathode material, we have considered copper molybdate (CuMoO_4), which offers good characteristics of specific capacity and specific energy. The performance of this material in a typical lithium-organic electrolyte cell is described and discussed here.

Experimental

The preparation of CuMoO_4 was reported in detail in a previous paper (4). Basically, the compound was obtained by direct reaction between reagent-grade MoO_3 and CuO . The structure of CuMoO_4 prepared in

this way was characterized by x-ray analysis (see Table I).

Copper sulfide, Cu_2S (chalcocite), used here for comparison purposes, was prepared by annealing for 24h at 475°C a stoichiometric Cu and S mixture, maintained in an evacuated two-chamber glass envelope. The structure of the final compound was again char-

acterized by x-ray analysis: the reflections obtained matched those listed in the ASTM card 23-961.

The solvents used, *i.e.*, propylene carbonate (PC) and butyrolactone (BL) were purified by fractional distillation, followed by treatment with molecular sieves (4Å).

All the lithium salts, LiAsF₆ (USS Agri-Chemicals), LiCF₃SO₃ (3M), and LiClO₄ (Merck), were pure products. The latter was dried at 240°C under vacuum.

Typical laboratory cells were used for the discharge tests. These cells consisted of a lithium pellet, a glass-wool separator soaked with the electrolyte, and a cathode pellet (supported on a copper substrate), housed in a plastic container having stainless-steel terminals.

Results and Discussion

The basic electrochemical characteristics of the Li/CuMoO₄ couple in typical organic electrolytes were originally studied, and the results were reported in previous papers (4, 5). Here, attention is given to the discharge behavior in relation to the power requirements of portable microelectronic devices.

Initially, the influence of the type of lithium salt dissolved in the organic solvent (here propylene carbonate) was evaluated. Figure 1 shows typical discharge curves at 0.5 mA/cm² for the Li/CuMoO₄ couple in the LiClO₄-PC and LiCF₃SO₃-PC electrolytes. Both the electrolytes behave satisfactorily, showing flat discharges with working plateaus around 1.5V. The initial spike between 2 and 1.5V could be due to residual traces of unreacted MoO₃ in the CuMoO₄ cathodic material. However, since these traces could

not be detected by x-ray analysis, other explanations (*e.g.*, unknown impurities, surface effects, etc.) could also apply. In any case, the spike is completely eliminated by a predischARGE in all the cells using the CuMoO₄ cathodic material.

The role of the electrolyte is illustrated in Fig. 2, where two discharge curves at 0.5 mA/cm² for LiClO₄-PC and LiAsF₆-BL are compared. The test clearly indicates that LiClO₄-PC is more effective in terms of average voltage and overall performance. This result points out the superior characteristics of the LiClO₄-PC solution as an electrolyte in lithium power sources. Indeed, these characteristics, which follow from a favorable compromise between conductivity and stability, make the LiClO₄-PC the preferred electrolyte medium in various established lithium primary batteries. Therefore, this electrolyte has been also selected for the final evaluation of the Li/CuMoO₄ system discussed here.

Typical discharge curves of the Li/LiClO₄-PC/CuMoO₄ cell at various rates are shown in Fig. 3. The promising behavior of this cell is further indicated by the trend of the discharge plateaus, which remain flat even at currents much higher than those usually required for microelectronic applications.

The discharge mechanism of the cell was investigated by x-ray analysis. Spectra taken on cathodes discharged to a 1V cutoff revealed the presence of metallic copper. Therefore, one can propose that the discharge reaction, which involves 2F per mol of CuMoO₄, results in the displacement of copper by lithium, that is

Fig. 1. Typical discharge curves at room temperature and at 0.5 mA/cm² of the Li/CuMoO₄ couple in two electrolytes.

Fig. 2. Typical discharge curves at room temperature and at 0.5 mA/cm² of the Li/CuMoO₄ couple in two electrolytes.

Fig. 3. Typical discharge curves of the Li/LiClO₄-PC/CuMoO₄ cell at room temperature and at various rates.

Fig. 4. Typical discharge curves at room temperature and at 0.5 mA/cm² of the Li/LiClO₄-PC/CuMoO₄ and the Li/LiClO₄-PC/Cu₂S cells.

The formation of copper during discharge is a desirable event, since it gives the cathode sufficient electronic conductivity to be used without additives (graphite). This result is beneficial in terms of overall energy density.

In Fig. 4 the performance of the CuMoO_4 cathode is compared in the same type of Li cell with that of Cu_2S , i.e., a cathodic material proposed for the commercial production of compatible batteries (1). The result indicates that the performances of the two cathodes are comparable, thus showing that copper molybdate may indeed be considered as a valid candidate for 1.5V lithium batteries. The energy density of this material, when discharged at 0.3 mA/cm² to a 1V cutoff, is 440 Wh/kg. Work is progressing in our laboratories on the Li/CuMoO₄ couple in button cells having a size more commonly used in popular portable devices, such as electronic watches and pocket calculators.

Gas Evolution in Aluminum Electrolytic Capacitors

C. Gómez-Aleixandre, J. M. Albella,* and J. M. Martínez-Duart

Universidad Autónoma, Instituto de Física del Estado Sólido, CSIC, and Departamento de Física Aplicada, Cantoblanco, Madrid-34, Spain

Gas evolution in aluminum electrolytic capacitors constitutes one of their main drawbacks in comparison to other types of capacitors lacking a liquid electrolyte. In this respect, one of the most common causes of failure shown by liquid electrolyte capacitors is electrolyte leakage through the seal or even explosions produced by internal pressure buildup. In order to prevent these hazards, some substances, known as depolarizers, are usually added to the capacitor electrolyte with the purpose of absorbing the hydrogen evolved at the cathode (1, 2). Although the gas evolution problem in electrolytic capacitors has been known for a long time, there is a lack of literature on both direct measurements of the gas evolved and assessments of the amount of depolarizer active for the hydrogen absorption process.

Aluminum electrolytic capacitors of 100 μF and 40V nominal voltage, miniature type (diam 8 mm, height 18.5 mm), were manufactured under standard specifications. The capacitors were filled with about 0.5 ml of an electrolyte consisting essentially of a solution of boric, adipic, and phosphoric acids in ethylene glycol. Picric acid and p-benzoquinone in molar concentrations of 0.01M and 0.05M, respectively, were added as depolarizers, yielding an electrolyte with a resistivity of about 80 $\Omega\text{-cm}$ and a pH of 5.1. The pressure inside the capacitors was monitored by a conventional U-shaped manometer made from a capillary glass tube filled with distilled water. The number of mols of gas generated in the capacitor (n_g) was calculated from the measured pressure (sensitivity 0.1 mm Hg) and the value of the internal volume of the manometer-capacitor system.

The gas evolution processes can be better interpreted if a constant current is applied to the capacitor. The magnitude of the current, provided by an operational power supply (Kepco-OPS-2000), was varied in the range from 100 to 1000 μA . The reason for using currents larger than the capacitor leakage current (28 μA) was to accelerate the generation of gas and therefore carry out the experiments in a reasonable time (2-3h for each constant current run). Under these circumstances, the voltage developed across the

capacitor increased to about 60V for the highest currents employed. Between each run, the capacitor dielectric properties (capacitance and loss factor) remained essentially unaltered, as shown in a previous paper (3). Simultaneously, no pressure drops were detected after each run with the capacitors in open circuit.

Figure 1 shows the variation of the mol number of gas generated as a function of the polarization time (t) for different values of the current (I) through the capacitor. Two linear stages are observed for each curve, the slopes in every stage increasing as the currents increase. Besides, for currents below a certain critical value I_c , the amount of gas evolved is practically zero even after long polarization times (see the 100 μA curve in Fig. 1).

To get further information on the gas evolution process, experiments were carried out for each constant current at different temperatures in the range 20°-80°C. Figure 2 shows the variation of n_g with time for a current $I = 500 \mu\text{A}$ and several temperatures. It can be appreciated that, as the temperature increases, the slope of the first linear stage of the curves gets successively smaller until, for $T \sim 35^\circ\text{C}$, it becomes zero. Simultaneously, the slopes of the second linear stages, and therefore the corresponding gas evolution rates, slightly increase with the temperature.

For the interpretation of the results of Fig. 1 and 2, we can assume that the only gas that contributes significantly to the pressure buildup is hydrogen electrochemically generated at the cathode following Faraday's law, i.e., $n_g = Kit$, where K is the gas mol number generated per unit charge. This assumption is based on the experiments of Burger and Wiswanathan carried out in an open cell with an electrolyte similar to the one employed in this work (1). Furthermore, the presence of other gasses in large quantities would not be consistent with the zero slope observed in the first part of the curves of Fig. 2 for $T \sim 35^\circ\text{C}$.

The linear dependence of n_g on the polarization time, shown in the curves of Fig. 1, and the change in the slopes at some definite times t_e , suggest that, in the first stage of the curves, the gas evolution rate is diminished by the absorption of hydrogen by the depolarizer.

Fig. 1. Mol number of generated gas as a function of polarization time, for different currents through the capacitors.

Fig. 2. Mol number of generated gas as a function of time for a current of 500 μA and several temperatures.

The hydrogen absorption, assumed to proceed at a constant rate v , is carried out through a reduction reaction of the quinone and the picric acid, this last compound undergoing a multistage reduction of the nitro radicals (4, 5). The slope changes observed at time t_e in the curves of Fig. 1 and 2 could then be associated with a diminution of the reaction rate v due to the exhaustion, at a given temperature, of that portion of the depolarizer in contact with the surface of the cathode.

Within the above simple model, one can assume that for $t > t_e$, $v \approx 0$, and therefore write: $n_g = Kit - n_d$, where n_d represents the number of hydrogen mols which have reacted with the depolarizer during the time t_e . The value of n_d can then be directly obtained from the intersect of the second linear part of the curves of Fig. 1 with the ordinate axis. As expected from our model, all the curves converge to the same point, yielding a value of $n_d = (1.56 \pm 0.15) \cdot 10^{-6}$ mol. The variation of n_d with temperature can also be obtained by applying the same procedure to the curves of Fig. 2. It is then found that n_d varies from a value of 1.45×10^{-6} mols at 22°C to a value of 10.5×10^{-6} mols at 80°C (see Table I).

The large increase in the number of hydrogen mols reacting with the depolarizer as the temperature is raised implies, in the first place, that at low temperatures (about 20°C), the reduction reaction is strongly inhibited, probably because of the slow diffusion mechanism of the reactants towards the surface of the cathode. In addition, it is also suggested that we are dealing with a thermally activated reaction mechanism. An Arrhenius plot of the values of n_d gives an activation energy $\Delta E = 6.1$ kcal/mol, which is similar to the 7.0 kcal/mol reported in the literature for another typical depolarizer, p-nitrobenzoic acid (1). In this context, ΔE can be considered as the activation

Table I. Number of mols of hydrogen reacting with the depolarizer as a function of temperature

T (°C)	n_d (mols)
22	1.45×10^{-6}
30	3.31×10^{-6}
37	4.23×10^{-6}
55	6.21×10^{-6}
80	10.50×10^{-6}

energy for the slowest step controlling the reduction reaction, e.g., diffusion of the reactants to the cathode, adsorption of hydrogen, etc.

From the results of this work we can conclude that the internal gas generation, observed in aluminum miniature electrolytic capacitors subjected to stressed electrical conditions, is controlled by two competitive processes: (i) gas generation at the cathode following Faraday's laws, and (ii) hydrogen absorption by the depolarizer following a thermally activated reaction mechanism. Both reactions are favored by the temperature, especially the second one. As a consequence, the internal gas evolution might get smaller when the electrolytic capacitors operate at moderate temperatures. Since the nominal leakage current of a capacitor is well below the value of the critical current I_c found in this work, it can also be concluded that the efficiency of the depolarizer is high in preventing the evolution of gas in a capacitor operating under normal working conditions.

Identification of Electrolyte Salts in Thionyl Chloride Relevant to Voltage Delay

James M. Chen, David R. Damian, Jr., Richard M. Stepnowski, and Clifton A. Young*

The University of Dallas, Chemistry Department, Irving Texas 75061

Thionyl chloride is used as the electrolyte solvent in lithium/thionyl chloride batteries. The thionyl chloride in the battery is also reduced at the catalytic carbon cathode of the battery. The standard electrolyte salt for this battery is LiAlCl_4 (1). One of the problems with this battery is the so-called voltage delay phenomenon. After storage there will be a delay before these batteries deliver their full voltage when put on load (2, 3). Two proposals have been made to alleviate or solve this problem by replacing the standard electrolyte salt with another different salt (4, 5). However, in both cases, subsequent workers have questioned whether the described salts were the actual species in solution (6, 7). Clearly, a technique for isolating and identifying the salts in these solutions is desirable. The importance of analyzing thionyl chloride electrolytes has been shown before by others (8, 9).

We report here on the development of a technique for isolating lithium salts from solution and on its application to systems of significance to thionyl chloride batteries. This technique entails addition of dimethoxyethane to the solution to precipitate the salt. It eliminates the possible use of rigorous conditions, such as evaporation of the solvent, which leaves an intractable, amorphous material.

LiAlCl_4 electrolyte is frequently made *in situ* by reacting LiCl , a Lewis base, with AlCl_3 , a Lewis acid, dissolved in thionyl chloride. One of the proposals was to replace the Lewis base LiCl with an alternative Lewis base Li_2O (4). It was proposed that the electrolyte salt was $\text{Li}_2\text{O} \cdot 2\text{AlCl}_3$ (4). Subsequently, this claim was modified, and it was proposed that the salt was a mixture of LiAlCl_4 and $\text{AlCl} \cdot \text{SO}_2$ (6). Interest in this electrolyte has continued (10). Li_2S has also been proposed as an alternative Lewis base (11).

Carbonates have been used as sources for oxides in chloroaluminate melts (12, 13). Sulfite ion might be expected to behave in a similar manner; however, it has been found to slowly react with chloroaluminate melts to produce thionyl chloride and sulfur dioxide

(14). There has also been an attempt to form Lewis acid adducts with a whole series of oxoanions using BF_3 (15). In the course of that work, it was found that both carbonate and sulfite reacted with BF_3 (15). By analogy with Li_2O , we examined possible Lewis acid-base interactions with these sources of oxide, namely, sulfite and carbonate.

Halogen exchange in thionyl chloride is well known (16). AlCl_3 has been observed to exchange with COCl_2 when AlCl_3 is dissolved in that solvent (17). Halogen exchange by tetrahaloaluminate ions with methylene chloride has also been observed to occur (18). This exchange was observed to be catalyzed by AlCl_3 (18). It is therefore to be expected that AlCl_4^- ion exchanges halogen when dissolved in thionyl chloride (19). Using our technique, we tested this expectation.

Experimental

Preparation of $\text{LiAlCl}_4/\text{SOCl}_2$ electrolyte.—Anhydrous AlCl_3 was dissolved in 50 ml SOCl_2 . This solution was stirred with excess LiCl for 3h. The solution was filtered through an enclosed glass frit (Kontes K-956250) to remove unreacted LiCl . We had some difficulty with preparing this known electrolyte. We attributed the difficulty to unpredictable reaction between two phases (solid and liquid). We recommend that the reaction mixture be refluxed, as our other preparations were, and that careful analytical quality control be exercised over electrolytes used in actual batteries.

Preparation of other electrolytes.—All remaining electrolytes were made in an analogous manner. Aluminum chloride was the limiting reagent. The salt being used as a Lewis base was added in excess to the AlCl_3 in about 50 ml of thionyl chloride. The mixture was refluxed for 3h and filtered as described above.

Isolation of electrolytes and preparation of analytical samples.—Equimolar (to Al) amounts of dimethoxyethane (measured by volume) were added to the electrolyte solutions. The precipitate was isolated by filtering in the enclosed glass frit described above using a

* Electrochemical Society Active Member.

Key words: battery, electrolyte, analysis, chelation.

mechanical vacuum pump. The precipitate was washed once with thionyl chloride. The sidearm flask into which the filtrate and thionyl chloride had drained was replaced with a sealed tube, and the precipitate was pumped dry through a stopcock at the top of the enclosed frit for 0.5h. The extremely hygroscopic salt, while still under vacuum, was immediately hydrolyzed by adding water through the stopcock. To minimize loss of HCl, the water was added from a trap. The water solution of the salt was diluted to a measured volume.

Standard taper glassware gasketed with Teflon sleeves was used for all the above manipulations. When the remaining thionyl chloride was pumped off, the sleeves were supplemented by vacuum grease applied to the outsides of the joints. Teflon sleeves were necessary because of the reactivity of thionyl chloride. The grease prevented a slow leak from destroying the hygroscopic solid. Unfortunately, it also prevented us from obtaining a total weight of the precipitate. The drying is the most critical step of the procedure, at all other times the thionyl chloride protects the salt from moisture. All manipulations should be done in a hood.

Isolation of AlCl₃ from thionyl chloride.—Equimolar amounts of dimethoxyethane were added to these solutions. The precipitates were treated exactly as described above.

Analysis of the hydrolyzed salt.—All analyses were carried out on aliquots of the volumetric solution. Aluminum was determined gravimetrically by the method of Howick and Jones (20). We found it essential to distill the acetone used in this procedure, as suggested by those authors (20). Chloride was determined by argentimetric titration (21). This technique will determine any bromide at the same time. The cation (usually lithium) was determined from an ion exchange total cation determination (22), from which the aluminum determination was subtracted. The titration was carried out using a pH meter, so that if the thionyl chloride had not been completely removed in drying, endpoints due to SO₂ titration would also be observed. All of these literature techniques were verified on control samples of LiCl and anhydrous AlCl₃ and their combinations dissolved in water. The aluminum gravimetric method was further verified on primary standard aluminum wire dissolved in HCl.

Tetrabromoaluminate exchange.—Tetramethylammonium tetrabromoaluminate was made by the method of Bradley *et al.* (23). Their synthesis was verified by analysis. This salt was dissolved in thionyl chloride. The thionyl chloride immediately turned brown. The solvent was removed by vacuum distillation to a dry ice-acetone trap. The solid salt was hydrolyzed and

analyzed as above. SOCl₂ which had exchanged with bromide was hydrolyzed immediately and discarded, since thionyl bromide had been implicated in an unexplained explosion (24).

Results and Discussion

The results of our analyses of a number of electrolytes of interest either chemically or in batteries are presented in Table I.

Identification of the precipitate.—Notwithstanding the fact that aluminum chloride is also precipitated by dimethoxyethane (second item in Table I), we believe that the precipitates of the lithium salts are chelates of lithium, and not the result of chloride displacement from the aluminum by the dimethoxyethane. The two possible reactions in their expected stoichiometries are as follows

The evidence in the literature indicates very strongly that the stoichiometry of reaction [2] would be two aluminum chlorides to one dimethoxyethane (25). In an experiment where dimethoxyethane was the limiting reagent, the yield would indicate that the stoichiometry was one to one (first item in Table I).

In order to resolve the question of which reaction took place, we added dimethoxyethane to a solution of tetramethylammonium tetrachloroaluminate in thionyl chloride. Dimethoxyethane would not be expected to interact with tetramethylammonium. The solution was made by adding a two-to-one excess of tetramethylammonium chloride to aluminum chloride in thionyl chloride. The excess was to insure that there was no uncombined aluminum chloride present. Addition of 60% excess of dimethoxyethane to this solution gave a precipitate, which redissolved upon mixing. Addition of a 200% excess gave a permanent precipitate. We conclude that formation of the aluminum chloride-ether complex is reversible, and, clearly, excess chloride will suppress the reaction. When sufficient dimethoxyethane is added to force the reaction, a permanent precipitate is formed, and this precipitate is insoluble in a solution containing excess dimethoxyethane. However, we had already observed that when twice as many mols of dimethoxyethane as salt were added to a solution of a lithium salt, the precipitate

redissolved. We conclude that there are two different precipitates and that the precipitate of lithium tetrachloroaluminate is probably a salt of an ether chelate of the lithium ion which is soluble in a solution containing excess dimethoxyethane.

Analysis of the electrolytes.—We found that when oxide or a source of oxide (third, fourth, and fifth items in Table I) were refluxed with aluminum chloride and thionyl chloride, they reacted completely to form tetrachloroaluminate ion. This is not surprising, since thionyl chloride is a strong inorganic as well as organic chlorinating reagent (26). The probable reactions are

AlCl_3 has been observed to catalyze reactions of thionyl chloride with a variety of metals (27) and it might also catalyze the already observed reaction of SOCl_2 with oxides (28).

Our results on the electrolyte based on Li_2O are in agreement with those reported by J. P. Gabano. He found, as we did, that when Li_2O was refluxed it reacted completely to form LiAlCl_4 and presumably SO_2 (third item in Table I) (29). We did not attempt to characterize the products of the reaction of Li_2O with AlCl_3 and SOCl_2 at room temperature because our isolation technique does not work on a mixture. In our opinion, the results obtained by Gabano in this reaction at room temperature (6) can be ascribed to incompleteness of reaction. While AlCl_3 forms complexes with both SO_2 (30) and SOCl_2 (31), the complexes formed with SOCl_2 have been isolated from mixtures (31), while that formed with SO_2 was made from an equimolar mixture of AlCl_3 and SO_2 (30). Also, AlCl_4^- can be isolated from solution in sulfur dioxide (32). Therefore, we do not feel $\text{AlCl}_3 \cdot \text{SO}_2$ is an important constituent of this system.

Our results when Li_2S is used as a Lewis base are in agreement with a suggestion made by Abraham *et al.* (11) that elemental sulfur might be formed (sixth item in the Table I). AlCl_3 catalyzes reaction between thionyl chloride (containing oxidized sulfur) and lithium sulfide (containing reduced sulfur), a possibility clearly recognized by those who originally worked on this system (11).

Our observation of halogen exchange on both AlBr_3 and AlBr_4^- is not surprising in view of the well-known halogen lability of thionyl chloride (16) and the previously observed lability of halogen on aluminum (18) (items seven and eight in Table I).

Conclusions

This isolation technique can be and here has been used to isolate and characterize the anions of salts in solution in thionyl chloride. It is not limited to lithium; we found that sodium worked also (fourth item in Table I). There are definite limitations to this technique. It cannot be used on mixtures, and it cannot be used quantitatively to establish the total concentration of salt in the electrolyte. Nonetheless, it may be possible that this kind of technique is usable in other solvents also.

Finally, our work shows that it is important that the reactivity of thionyl chloride be considered when attempts are made to synthesize or dissolve new salts in this solvent. Both the Li_2O -based (6) electrolyte and $\text{Li}_2\text{B}_{10}\text{Cl}_{10}$ (5) have been proposed as solutions to the voltage delay problem in lithium/thionyl chloride batteries. The evidence above and elsewhere (6, 7, 29) now indicates that both of these salts react with thionyl chloride to produce SO_2 . SO_2 has already been shown to alleviate voltage delay (33). This means that every

publicly proposed solution to this problem of which we are aware inadvertently or advertently adds SO_2 to the electrolyte except where reserve cell configurations are used (34), and SO_2 may be the cause of improved battery performance observed with these electrolytes. Clearly there needs to be a thoughtful reevaluation of research on this problem.

Photoelectrochemical Investigation of a Poly(Ethylene Oxide) Cell

Anthony F. Sammells* and Peter G. P. Ang*

Eltron Research, Incorporated, Naperville, Illinois 60540

The modification of poly(ethylene oxide) (PEO) into an alkali ion conducting polymer solid electrolyte by its formation of solid solutions with several alkali metal salts has been well documented over the last few years (1-5). Although the ionic conductivities of such materials are quite low ($\approx 10^{-5} \Omega^{-1} \text{cm}^{-1}$ at ambient temperature), particularly in comparison to aqueous electrolytes, this in part can be compensated for by their fabrication into thin electrolyte samples. Such solid polymer electrolyte materials can conveniently be prepared by evaporation of methanol from solutions containing PEO and an appropriate alkali ion salt onto a suitable substrate. Formation of a thin solid polymer electrolyte layer is then achieved typically by annealing under vacuum at temperatures below 120°C. Transference number (t) measurements for PEO/NaSCN-based solid polymer electrolytes have shown predominantly alkali ion conductivity.

Recently, some preliminary photocurrent/voltage data were reported (7) on a solid-state photoelectrochemical (PEC) cell consisting of PEO/KI, I_2 as a solid polymer redox electrolyte prepared on a tin oxide conducting substrate in intimate contact with an n-Si photoanode. This photoanode was initially coated with platinum and subsequently protected from photoanodic corrosion effects by a layer of polypyrrole. The substitution of alternate redox electrolytes for the aqueous systems predominantly pursued in photoelectrochemical cells is one approach to address photoanodic corrosion effects at the illuminated photoelectrode/electrolyte interface. Alternative redox electrolytes have included organic nonaqueous (8) ambient-temperature molten salts (9) and inorganic solid electrolytes (10). These latter electrolytes have been previously discussed by us at the solid-state interface of n-CdSe with the silver-ion conducting solid electrolyte RbAg_4I_5 . With this solid electrolyte, however, photoactivity was detected even in the absence of a semiconductor junction, a probable consequence of the spontaneous photoreduction of Ag^+ and/or the presence of a Demer-type photovoltage (11). Because of this interfering photoeffect with silver-ion conducting solid electrolytes, there is an obvious incentive to investigate PEC phenomena using alternative redox solid electrolytes where the opportunity for photoeffects by the solid electrolyte is less likely to occur.

In work discussed here, PEC measurements have been made on the solid polymer electrolyte PEO/NaSCN, containing $\text{Na}_2\text{S}/\text{S}$ as an introduced redox species. The fact that various redox couples can be incorporated into these alkali-ion conducting poly-

meric materials may give us the opportunity to use such modified materials in photoelectrochemically rechargeable cells where the stored energy, via oxidized or reduced species within the electrolyte and close to the photoelectrode, could be later electrochemically discharged. This would require that the redox species incorporated within the polymer be essentially immobile. In mainly crystalline PEO electrolyte, ionic conduction is predominantly via an alkali ion transport mechanism along polymer helical chains; for more amorphous PEO materials, a configurational entropy-dominated transport process is likely (12).

Aqueous liquid-junction PEC cells with storage, having the general configuration p-InP/ S^{2-} , $\text{S}_n^{2-}/\text{I}^-$, $\text{I}_2/\text{n-WSe}_2$ have previously been investigated (13). Here the relatively high ionic conductivity of the aqueous electrolytes used allowed large interelectrode distances to be tolerated. For PEO-based cells, however, small interelectrode distances are essential to minimize internal resistance losses. To identify an analogous two-photoelectrode solid-state cell based upon PEO requires that one of the photoelectrodes be transparent, to ensure illumination of both electrode/redox electrolyte interfaces. The use of p-InP as a photocathode in such devices would, consequently, preclude the use of n-WSe₂ as the second photoelectrode.

The PEO-based redox electrolyte was prepared by introducing PEO (Aldrich Chemical Company, MW 600,000) and NaSCN into anhydrous methanol in a 4.5:1 molar ratio of the polymer repeat unit, as discussed by others (6). With continuous stirring an equimolar (0.1M) solution of Na_2S and S up to a sulfide concentration corresponding to 1/10 that of NaSCN was slowly added. During addition of the sulfide species to the PEO · NaSCN solution, the mixture was initially yellow, but became colorless after stirring for 30 min. Upon standing for several weeks, some precipitation became evident in this solution. A PEC cell was prepared by initially placing a drop of freshly prepared PEO · NaSCN/ Na_2S solution onto the surface of a Nesatron tin-doped indium oxide conducting glass electrode and allowed to dry in the atmosphere. This was then treated under vacuum at 75°C for 1h. The p-InP photocathode was obtained from Crysta Communications, Incorporated, (Zn-doped $6 \times 10^{16} \text{cm}^{-3}$, $\langle 111 \rangle$ surface used) and had a resistivity of 0.6 Ωcm . Ohmic contact was made by first sputtering a thin layer of gold, followed by electrodeposited Zn, and later another layer of sputtered gold. The electrode was annealed at 465°C for 1 min. Initial attempts to make contact of this photoelectrode to the solid polymer redox electrolyte on the conducting glass met with mixed results. Reproducible

Key words: poly(ethylene oxide), indium phosphide, solid-state photoelectrochemical cell.

contact was made by introducing a drop of the PEO containing methanol solution onto the photocathode, and after drying, lightly pressing onto the already cured polymer electrolyte present on the conducting glass surface. Final curing of this cell was performed under vacuum for 2h at 75°C.

The initial photoelectrochemical performance of the cell p-InP/PEO · NaSCN, Na₂S, S/cond. glass at 25°C is shown in Fig. 1 under 100 mW/cm² quartz iodine illumination. Positive photopotentials of 200 mV were observed. Upon potentiostating, the p-InP at -1.2V vs. its dark potential, cathodic photocurrents of ≈10 μA/cm² were observed. The rather high photoelectrode bias voltage required to achieve such photocurrents and poor fill factor are in part symptomatic of the highly resistant polymer electrolyte used. Cell resistances could be significantly reduced by increasing temperature, thereby resulting in higher currents. Cells prepared, however, were mechanically stabilized by the use of a wax support between the photoelectrode current collector and a glass substrate. Because of this, cell temperature excursions were avoided.

The photoelectrochemical oxidation of the Na₂S/S couple incorporated into PEO was also investigated on n-GaAs. The n-GaAs single crystal was obtained from Crystal Specialties Incorporated, and had a carrier density of 10¹⁶/cm³ after silicon doping. Ohmic contact to the semiconductor was made by thin-film evaporation of an 88Au/12Ge alloy. The <111> face was used in these experiments after initially etching in H₂SO₄/H₂O₂ before drying and coating with PEO · NaSCN, Na₂S, S. This photoanode was contacted to a Nesatron conducting glass electrode and annealed in an analogous manner to that discussed previously for p-InP. A photocurrent/potential curve for this cell is shown in Fig. 2. Here the initial photopotential obtained was -150 mV using 100 mW/cm² quartz iodine illumination. Anodic photocurrents of 9 μA/cm² were obtained after subjecting the cell to a 1.5V positive bias. Because of the opaque nature of gallium arsenide, however, this photoanode cannot be used in a two-photoelectrode cell where p-InP is used as a photocathode. Similar cells prepared using single-crystal n-CdS typically gave negative photopotentials in the -200 to -250 mV range.

Fig. 1. Current-voltage curve for the cell p-InP/PEO.NaSCN, Na₂S,S/cond. Glass with and without 100 mW/cm² quartz iodine illumination.

Fig. 2. Current-voltage curve for the cell n-GaAs/PEO.NaSCN, Na₂S,S/cond. Glass with and without 100 mW/cm² quartz iodine illumination.

It is necessary for a two-photoelectrode solid-state PEC cell using a solid polymer electrolyte not only that one of the photoelectrodes be transparent, but also that the redox species incorporated into the PEO not corrode the photoelectrodes during illumination. Although we have found the redox kinetics of halogens introduced into PEO, in general, higher than for the Na₂S/S couple, we have not yet been able to fabricate a two-photoelectrode cell which fulfills the above requirements using a halogen as one of the redox couples.

As a result, we have fabricated the solid-state two-photoelectrode cell p-InP/PEO · NaSCN, Na₂S, S/n-CdS using single-crystal photoelectrodes. The n-CdS single crystal was obtained from Cleveland Crystal. Ohmic contact to the material was made by initially contacting with a gallium-indium eutectic followed by silver epoxy and curing at 150°C for 1h. The two-photoelectrode cell was prepared by placing a drop of the PEO redox electrolyte onto the surface of each electrode, allowing to dry in the atmosphere, and partially curing at 60°C under vacuum for 1h. The two electrodes were lightly pressed together to make effective contact and then finally cured at 75°C for 1h. The cell is shown schematically in Fig. 3. The dark open-circuit voltage was 560 mV, presumably due to some nonequilibrium effects between the photoelectrodes and PEO. Upon illumination through the n-CdS photoanode to the solid-state junctions of the redox PEO with both these photoelectrodes under 100 mW/cm² quartz iodine illumination, photopotentials up to 540 mV could be initially generated. Hence initial overall cell voltages in excess of 1000 mV could be achieved between the two photoelectrodes. After several hours, the photopotential realized with this cell reduced to ≈400 mV. The photoresponse of this cell is shown in Fig. 4. Potentiostating the cell to 0.0V in the dark resulted in the passage of insignificant currents. Even when this cell was potentiostated at 0.0V under illumination, currents only in the 0.3 μA range were observed as a result of the high resistivity of the electrolyte under ambient conditions.

We conclude that although PEO-based redox electrolytes offer the opportunity to fabricate solid-state PEC cells, their eventual practicality into small devices is contingent upon increasing PEO ionic conductivity. Compensation of this present limitation by the use of small interelectrode spacing greatly increases the susceptibility to cell shorting during fabrication.

Utility of Surface Reaction Entropies for Examining Reactant-Solvent Interactions at Electrochemical Interfaces. Ferricinium-Ferrocene Attached to Platinum Electrodes

Joseph T. Hupp and Michael J. Weaver*

Department of Chemistry, Purdue University, West Lafayette, Indiana 47907

Reactant-solvent interactions are of prime importance to both the kinetics and thermodynamics of electrode processes. Since electrochemical reactions inevitably occur within the interfacial region, it is desirable to gain information on the nature of reactant solvation at the electrode surface as well as in bulk solution. We have demonstrated that useful information on the latter for simple redox couples can be obtained from the so-called reaction entropy (ΔS°_{rc}) determined from the temperature dependence of the formal potential (E^f) using a nonisothermal cell arrangement (1)

$$\Delta S^{\circ}_{rc} = F(dE^f/dT)_{ni} \quad [1]$$

Since the temperature dependence of the thermal liquid junction potential in such a cell can be arranged to be negligibly small, ΔS°_{rc} essentially equals the difference ($\bar{S}^{\circ}_{red} - \bar{S}^{\circ}_{ox}$) between the ionic entropies of the reduced and oxidized forms of the redox couple in the bulk solution. The reaction entropies of simple transition-metal redox couples have been found to be extremely sensitive to the chemical nature of the coordinated ligands and the surrounding solvent, illustrating the importance of specific ligand-solvent interactions to the overall redox thermodynamics (1-5).

It would clearly be desirable additionally to determine reaction entropies for redox couples residing in the interfacial region. Such surface reaction entropies ($\Delta S^{\circ}_{rc,s}$) would yield insight into the solvation changes accompanying the elementary electron-transfer step

for the redox couple in a particular interfacial environment. For redox couples present at sufficiently high concentrations at the interface to enable the formal potential for the interfacial (adsorbed) redox couple (E_a^f) to be measured, values of $\Delta S^{\circ}_{rc,s}$ can be obtained directly from (cf. Eq. [1])

$$\Delta S^{\circ}_{rc,s} = F(dE_a^f/dT)_{ni} \quad [2]$$

Whereas ΔS°_{rc} corresponds to the overall entropy driving force for transforming the bulk-solution reactant to product, $\Delta S^{\circ}_{rc,s}$ equals the thermodynamic entropy change for the heterogeneous electron-transfer step itself (6). Thus $\Delta S^{\circ}_{rc,s}$ and ΔS°_{rc} are related by

$$\Delta S^{\circ}_{rc,s} = \Delta S^{\circ}_{rc} + \Delta S^{\circ}_p - \Delta S^{\circ}_s \quad [3]$$

where ΔS°_p and ΔS°_s are the entropic work terms associated with forming the "precursor" state for electron transfer from the bulk reactant, and the "successor" state from the bulk product, respectively (6). We report here values of $\Delta S^{\circ}_{rc,s}$ for a surface-attached ferricinium-ferrocene couple in several solvents in order to illustrate the virtues of such measurements for elucidating the nature of reactant-solvent interactions at electrochemical interfaces.

For surface redox couples where the redox center lies within the inner layer, ΔS°_p and ΔS°_s are expected to be both nonzero and different, so that $\Delta S^{\circ}_{rc,s} \neq \Delta S^{\circ}_{rc}$. Indeed, we have recently obtained such a result for a specifically adsorbed Co(III)/(II) sepulchrate couple vs. the corresponding bulk solution couple (7). For electrode reactions where the redox center is present in the diffuse layer or at the outer Helmholtz plane, it

* Electrochemical Society Active Member.

is conventional to assume that the work terms are purely coulombic in nature (8) so that $\Delta S_p \approx \Delta S_s \approx 0$ and hence $\Delta S_{rc,s} \approx \Delta S_{rc}$. This assumption is required in order to extract true frequency factors for electron transfer from the temperature dependence of electrochemical kinetics (6, 9). However, in actuality even $\Delta S_{rc,s}$ for an outer-sphere reaction might be expected to differ significantly from ΔS_{rc} in a given solvent medium, bearing in mind the structure sensitivity of ionic entropies (1-5) and the possibility that the solvating environment in the vicinity of the surface may differ significantly from that in the bulk solution. Indeed, one reason for pursuing the present study was to discover whether differences which we have recently observed between the energetics of structurally similar electrochemical reactions involving surface-bound and solution-phase redox couples (10) could be rationalized in terms of differences between the bulk and interfacial solvation environments.

Measurement of Surface Reaction Entropies

Although it is not feasible to evaluate $\Delta S_{rc,s}$ for outer-sphere (*i.e.*, unadsorbed) redox couples, a suitably high interfacial concentration of normally unadsorbed, and, presumably, fully solvated, reactant can be achieved by attaching the redox center to the electrode surface via an inert covalent linkage. As a model system, we studied the ferricinium-ferrocene redox couple attached to a platinum electrode, as shown in Fig. 1. We prepared the surface-bound ferrocene by using the chemical modification procedure described by Sharp *et al.* (11). This system was selected since both the bond to the platinum surface and the electroactive center itself are exceptionally stable, placing the redox center about 6-8Å from the electrode surface (11). In addition, it was anticipated that the surface-attached couple would exhibit reversible behavior in a variety of solvents.

Efforts to prepare the same ferrocene derivative in solution were unsuccessful. Nevertheless, *n*-ferrocenemethylene-*p*-toluidine (Alfred Bader Chemicals), shown in Fig. 2, was selected as a reasonably close analog of the surface-attached complex, since in the vicinity of the redox center the structures of the two substituents are closely similar. Formal potentials for either the surface-attached or bulk-solution redox couples were obtained from the average peak potentials of the cyclic voltammograms. [Quasi-reversible, rather than reversible, behavior was typically observed for the surface-attached, as well as bulk-solution, couples, with anodic-cathodic peak separations up to *ca.* 50 mV even in the presence of IR compensation; cf. Ref. (11)]. Values of E_a^f for the reduction of the surface-bound ferricinium derivative could be measured with sufficient accuracy to enable $\Delta S_{rc,s}$ to be determined to within about $6 \text{ J} \cdot \text{deg}^{-1} \cdot \text{mol}^{-1}$. Representative E_a^f data obtained in aqueous solution are plotted against temperature in Fig. 3. Data also were obtained in methanol, acetonitrile, dimethylsulfoxide, and sulfolane. Attempts were made to measure $\Delta S_{rc,s}$ in

Fig. 1. Mode of attachment of ferrocene to platinum surface

Fig. 2. Ferrocene derivative (*n*-ferrocenemethylene-*p*-toluidine) used as solution analog of surface-attached ferrocene in Fig. 1.

Fig. 3. Representative plot of E_a^f vs. temperature in aqueous 0.1M TEAP. Potentials vs. saturated calomel electrode at 24°C, using nonisothermal cell arrangement (1).

formamide, nitromethane, and acetone, but were unsuccessful with the first solvent due to instability of the surface complex, and with the other two because of irreproducible behavior. Either 0.1M tetraethylammonium perchlorate or 0.2M LiClO₄ was used as the supporting electrolyte. Additional experimental details are given in Ref. (3).

The resulting values of $\Delta S_{rc,s}$ and E_a^f are summarized in Table I, together with ΔS_{rc} data for the ferrocene and *n*-ferrocenemethylene-*p*-toluidine couples in bulk solution. Contrary to our initial expectations, the reaction entropies for the surface couple and its solution analog were found to be in reasonable agreement in each solvent. Evidently, the solvent interactions experienced by the surface-attached couple are not noticeably different from the reactant-solvent interactions occurring in bulk solution. At least for this couple, therefore, it appears that differences between solvent structure in bulk solution and in the double layer where the surface redox site is located do not greatly influence the electron-transfer energetics.

Interpretation of Surface Reaction Entropy Values

Although the two derivatized ferrocene couples (Fig. 1 and 2) yield similar reaction entropies, these tend to be less positive than the ΔS_{rc} values for the unsubstituted ferricinium-ferrocene couple (Table I). Furthermore, the formal potentials for the surface-attached couple in various solvents are positive of those for ferrocene itself, while the E^f values for the *n*-ferrocenemethylene-*p*-toluidine couple are still more positive (Table I; note that the E^f values quoted are *vs.* that for ferrocene itself in the same solvent). The differences in formal potentials between ferrocene and its derivatives are probably manifestations of the greater electron withdrawing capabilities of carbon-nitrogen double bonds as compared to hydrogen (12). Thus, such an electron withdrawing substituent would tend to stabilize the relatively electron-rich ferrocene re-

dox center to a greater extent than for ferricinium, leaving the former more difficult to oxidize, and thereby yielding a positive shift in the formal potential. The systematic differences in reaction entropies seen between ferrocene and the derivatized couples can also be rationalized on this basis. Whether the differences in formal potentials between the adsorbed couple and its solution analog result from surface attachment or from differences in substituent properties is not entirely clear. A detailed study of substituent effects on the redox thermodynamics and kinetics of several solution ferrocene derivatives is in progress.

A curious aspect of the results is the marked solvent dependence of both the $\Delta S^{\circ}_{rc,s}$ and ΔS°_{rc} values. The magnitude of these quantities expected from purely continuum electrostatic considerations is given by (3)

$$\Delta S^{\circ}_{rc,s} (= \Delta S^{\circ}_{rc}) = - (e^2 N / 2r\epsilon T) (d \ln \epsilon / d \ln T) \quad [4]$$

where e is the electronic charge, N is Avogadro's number, ϵ is the dielectric constant of the solvent, and r is the radius of the ferricinium cation. The $\Delta S^{\circ}_{rc,s}$ values listed in the last column of Table I are obtained from Eq. [4] using literature values of ϵ and assuming that $r = 3.8\text{\AA}$ (13). There is clearly no general pattern of agreement between the experimental and these calculated quantities, the Born treatment predicting a much milder solvent dependence of $\Delta S^{\circ}_{rc,s}$ than is observed. Similar breakdowns of the dielectric continuum model in predicting reaction entropies have

been found for several bulk solution couples in a number of solvents (1-5).

A probable reason for the failure of Eq. [4] is that the major property determining the entropy of charge-induced solvent reorientation is the degree of "internal order" of the solvent (i.e., self-association and long-range structuring induced by hydrogen bonding), rather than the macroscopic dielectric properties (14, 15). Thus, a solvent having a high degree of internal order would be relatively unperturbed by a charged molecule, whereas considerable solvent ordering around the ion would occur in a medium having little intermolecular structure. Since such charge-dipole interactions will be absent for neutral ferrocene, a positive contribution to the reaction entropy ($\bar{S}^{\circ}_{red} - \bar{S}^{\circ}_{ox}$) would be anticipated for the present redox couples, especially in relatively nonassociated solvents. Criss *et al.* (14, 15) have suggested estimating the degree of internal order of a solvent from the difference in boiling point (ΔT_{bp}) compared to that for a structurally analogous hydrocarbon. These values of ΔT_{bp} are also listed in Table I. Indeed, the $\Delta S^{\circ}_{rc,s}$ values for the surface-attached ferrocene couple do for the most part vary as expected with the corresponding values of ΔT_{bp} .

An unusual result which merits comment is the large negative value of $\Delta S^{\circ}_{rc,s}$ ($-50 \text{ J deg}^{-1} \text{ mol}^{-1}$) found in water (Table I). A small negative value of ΔS°_{rc} has previously been observed for the bulk-solu-

Fig. 4. Plot of reaction entropies for surface-attached and solution-phase ferricinium-ferrocene couples in various solvents vs. solvent Acceptor Number (16). Filled triangles: surface-attached ferrocene (Fig. 1). Open triangles: bulk-solution derivatized ferrocene (Fig. 2). Open circles: bulk-solution ferrocene. Key to solvents: 1: acetone. 2: dimethylformamide. 3: propylene carbonate. 4: acetonitrile. 5: dimethylsulfoxide. 6: nitromethane. 7: N-methylformamide. 8: formamide. 9: methanol. 10: water.

tion ferrocene couple, also in water (3). This suggests that the net solvent ordering in the vicinity of the surface-attached redox center is less extensive in the cationic than in the neutral state, in qualitative disagreement with the expectations from an electrostatic treatment. These negative reaction entropy values possibly result from donor-acceptor interactions between the cyclopentadienyl rings and the acidic water hydrogens (3). Since the electron density on the cyclopentadienyl rings will be greater in the reduced state, such specific solvent interactions should be enhanced, leading to increased solvent ordering and a decrease in entropy compared with that for the oxidized state. If such an explanation were correct a correlation between $\Delta S^{\circ}_{rc,s}$ and the acidity of the solvent might be expected. Figure 4 shows a plot of the reaction entropies for the adsorbed couple and its solution analog as well, as for unsubstituted ferrocene vs. the solvent "acceptor number," which is an empirical measure of the electron accepting capabilities of the solvent (16). A reasonable correlation is indeed observed. Alternatively, both the negative reaction entropies in water and methanol and the dependence upon the solvent acceptor numbers can be rationalized in terms of a negative contribution to ΔS°_{rc} arising from disruption of the surrounding solvent structure by the charged solute (17). Regardless of the detailed explanations, similar solvation factors are clearly important in determining the redox properties of the surface-attached and solution ferrocene couples.

The present work demonstrates the feasibility of determining surface reaction entropies and illustrates the utility of these measurements for elucidating the various elements of interfacial reactant-solvent interactions. Given the sensitivity of $\Delta S^{\circ}_{rc,s}$ measurements to the solvent structure, we suggest that this approach might also usefully be employed to gain insight into reactant solvation in polymer film electrodes, for which the question of solvent penetration within the film is of current interest.

Structural Analysis of Silicon-Implanted Polymethyl Methacrylate Films on Glass

Carl E. Bleil and Bernard A. MacIver

General Motors Research Laboratories, Electronics Department, Warren, Michigan 48090-9055

ABSTRACT

Electron diffraction and microscopic analyses of silicon-implanted polymethyl methacrylate (PMMA) films deposited on glass substrates have been carried out with the aid of differential etching. Results show the films to consist of amorphous and polycrystalline graphite structures incorporating diamond-like structure in the bulk of the film and silicon carbide crystallites near the film-glass interface. Particle size is typically less than 50 nm with some crystallites as large as 0.5 μm .

The preparation of thin films with diamond-like properties has intrigued investigators for many years. Such properties as chemical inertness, hardness, and high electrical resistance are only a few of commercial interest. In the past, many attempts to thermally deposit films with diamond-like properties met with only limited success. However, extensive research over the past decade shows considerable promise for diamond-like carbon coatings for a wide variety of applications (1).

Recent developments in our laboratory (2) to produce special films for photolithography which were harder and more chemically inert than chromium, the standard hard surface photomask material of the semiconductor industry, led to processed films of polymethyl methacrylate (PMMA). Interestingly, these films showed properties similar to those reported by Aisenberg and Chabot (3) who used a beam of positively charged carbon ions to prepare their films. In 1976, Spencer *et al.* (4) analyzed films prepared in a manner similar to that of Aisenberg and reported them to contain polycrystalline diamond-like structures. Similarly, the earlier analysis of our films (2) showed that the composition was mainly carbon and suggested that diamond-like structures might exist but the results were not conclusive. Indeed, it is very likely that the silicon-implanted PMMA simply represents one class of the so-called diamond-like carbon, or i-C films (5).

In this paper, we present a detailed analysis of the structure of Si⁺-implanted PMMA films on glass. This was accomplished through the use of differential etching, scanning electron microscopy (SEM), and reflection electron diffraction (RED).

Experimental

Samples of processed PMMA films were prepared by first spinning PMMA dissolved in chlorobenzene onto a glass substrate and baking the film for 30 min at 180°C to remove solvent, leaving a 0.5 μm thick film of PMMA. The PMMA films were then implanted with silicon in two steps. In the first implant step, the dose was 3×10^{15} ions/cm² at 200 keV to ensure a good bond with the glass substrate and to break down C—O—H bonds, leaving mainly carbon. A second im-

Key words: hard carbon films, silicon carbide, differential etching.

plant of silicon, this time with a dose of 5×10^{15} ions/cm² at 150 keV, was used to alter the bonding of the residual carbon and to continue implanting near the film glass interface to improve adhesion. The dose rate was 2 $\mu\text{A}/\text{cm}^2$ for both implants. During this total processing, the film thickness was reduced from 0.5 μm to about 0.1 μm . The substrate temperature was assumed to be about 600 K (6). The resulting films appeared quite opaque, and when subjected to various solvents, including acids, bases, and organics, were found to be chemically inert. Similarly, scratch tests showed the films to be at least as hard as chromium films normally used for photolithography.

Transmission electron diffraction of films removed from the glass substrates with hydrofluoric acid showed only very diffuse rings normally ascribed to amorphous materials. X-ray diffraction was not tried because of the very low absorption coefficient of carbon and the fact that the films were only about 0.1 μm thick. However, reflection electron diffraction provided interesting clues to the film structure. In the earliest attempts to do RED, both spotty rings and spot patterns were observed, which suggested the presence of both polycrystalline graphite and the hexagonal diamond structure.

Based on these early results it was proposed that, if the diamond phase existed, it should exhibit an etch rate in an oxygen plasma somewhat different from the graphite structure. Such differential etching should allow RED to delineate the composition of the film with depth. Additional samples were prepared by oxygen plasma etching for various times and both SEM and RED were used to analyze the resulting samples.

Results

Typical SEM observations of the prepared samples are shown in Fig. 1. From the resulting relief patterns, it is quite clear that as the etch time increases, the concentration and the size of the particles in relief have generally increased. In a few instances, as shown in Fig. 2, these particles exhibited geometric structure, characteristic of single crystals. The largest of these appears to be greater than 0.5 μm in breadth and as thick as the residual film.

The optical density of the films is also observed to decrease with increasing etch time, which would be

Fig. 1. Scanning electron micrographs of silicon-implanted PMMA films etched in an oxygen plasma for various times.

expected if the graphite structure were preferentially removed. Moreover, while the films were very hard and scratch resistant before etching, rubbing them against smooth glass was not observed to scratch the glass. After etching, the surface could be made to scratch smooth glass by a simple rubbing operation. Thus, the relief structure is not simply etched glass but is somewhat harder.

Reflection electron diffraction of the oxygen plasma etched samples produced numerous patterns, some of which were different from those found earlier (see Fig. 3a). As we analyzed the many diffraction patterns obtained, we observed that the unetched samples were mostly of amorphous carbon. Better defined patterns of both graphite and diamond-like structures were obtained in the lightly and moderately etched films but no silicon carbide patterns were observed except for the heavily etched samples (i.e., near the film-glass interface). While all three structures were possibly present near the interface, the frequency of clearly defined silicon carbide structure overwhelmingly

dominated the patterns observed. The patterns were analyzed using an independent gold film as a standard (Fig. 3b), and the corresponding lattice spacing (*d*-values) are listed in Table I. The accepted *d*-values for graphite, diamond, and silicon carbide are also listed (7). Initially, for many samples, charging by the electron beam produced "blooming" and resulted in unacceptable distortion of the diffraction pattern. This problem was almost completely removed with a thin conductive palladium film deposited on the sample. It was noted that the samples that had not been etched showed significantly less charging than the etched samples. We presume that the incorporated graphite in the unetched samples served to discharge the surface because the graphite is fairly conductive. No blooming occurred with the gold standard.

The general agreement between the observed and the accepted *d*-values for the gold standard provides a measure of the precision of these results. The internal consistency of the patterns from our test specimens is sufficient so that, even with some distortion due to charging, the several patterns can be identified and the result provides clear evidence for the presence of SiC, graphite, and diamond-like phases.

Discussion

The shrinkage of the PMMA film during implantation is clear evidence of material loss which, from Auger analysis (2), appears to have been primarily the oxygen and hydrogen from the polymer. The bulk of the remaining film is carbon except in the region of the interface where the concentration of silicon increases significantly. Nevertheless, the observation of silicon carbide only at the interface is particularly interesting since the total silicon implant is sufficiently small that it cannot reasonably account for the silicon carbide formation directly unless all the silicon is deposited at the interface. Therefore, we propose that the high energy implant into the interface actually induces decomposition of the glass, producing a silicon-rich layer. The process leads to significant atomic mixing in the manner described by Liau and Mayer (8). The

Fig. 2. Scanning electron micrograph of a large crystallite near the film-glass interface.

Fig. 3. Typical electron diffraction patterns of (a, top) silicon carbide and (b, bottom) gold standard.

recrystallization of this layer could then produce the silicon carbide we observe and undoubtedly accounts for the very strong bond to the substrate.

One might expect, as suggested by Spencer *et al* (4), that during the reordering of the carbon bonds after the disruption by an adsorbed ion, any of the possible carbon bonding configurations might occur. Even if this were the case, it is most likely that the strongest bonds would form first. Moreover, in subsequent absorption events, the weakest bonds would be removed preferentially. Thus, the allotropes of carbon which

form weakest bonds, would most likely be absent or appear only on the top surface of the film. Hexagonal graphite would be formed at greater film depth because of the stronger planar bonding. Cubic and hexagonal diamond with tetrahedral bonding would also most likely form in the bulk film or near the interface.

To account for the formation of the silicon carbide at the interface or perhaps even the diamond structure in the bulk film, a brief description of the expected energy transfer is probably adequate. The energy of an individual silicon ion entering the film is from 150 to

200 keV and this energy is transferred to the film in less than 10^{-11} s. The volume in which this energy is deposited, assuming a 10 nm diam, is of the order of 10^{-23} m³. Even though there is undoubtedly extensive ionization in this volume, the electron cloud loses its energy to the lattice according to Liu *et al.* (9) in about 10^{-11} s. Based on the spontaneous recrystallization rate of silicon (10), for example, it would require about 10^{-9} s for a crystallite of some 20 nm to grow. It seems reasonable to expect the thermal and pressure spikes produced by the absorption of a single ion to exist for as long as 10^{-10} s or longer (11). Hence, even at this rate of energy dispersal a seed crystal encompassing some 5-10 unit cells could be produced in the time available. For longer dwell times, larger crystallites could be produced, even without postulating secondary epitaxial growth from a nearby ion absorption. Since, for the implant dose used here, there are, on the average, several absorbed ions for each 0.1 nm², the probability of producing 50 nm crystallites by secondary epitaxial growth is reasonably high. Increased implant dose should increase the probability of occurrence of large crystallites and/or produce a higher density of crystallites.

Based on the observations of composition with film thickness and the above-generalized picture, one might explain the material properties. For example, the weakly bonded graphite at the surface would provide good opacity while the film hardness is provided by the planar or tetrahedral bonding in the bulk form.

The adhesion to the glass substrate is very likely related to the strong SiC bonding to the surface.

Conclusions

We believe our results clearly show that etching prepared films in an oxygen plasma reveals a differential etching structure with the concentration of slowly etching particles increasing with film depth.

Moreover, under our conditions for preparation, scanning electron microscopy shows the typical particle size of the slower etching species to be less than 50 nm with some crystallites as large as 0.5 μm.

Reflection electron diffraction with depth shows the following. (i) At the surface, the film is mainly amorphous carbon and fine grain polycrystalline graphite. (ii) In the bulk, there is evidence of polycrystalline graphite and diamond-life structure. (iii) Silicon carbide dominates in the region of the film-glass interface. Thus, all of these observations are consistent with our hypothesis of film formation.

Finally, the bonding observed in the structures of silicon-implanted PMMA films could account for their opacity, extreme hardness, and adhesion.

Tolpography Modeling in Dry Etching Processes

Yoshio Sakai,^{*1} John L. Reynolds,^{*2} and Andrew R. Neureuther*

Department of Electrical Engineering and Computer Sciences, and the Electronics Research Laboratory, University of California, Berkeley, California 94720

ABSTRACT

Some aspects of the interaction among wafer topography and the thin film processes of directional dry etching and deposition are presented in experiment and simulation. The anisotropy of dry etching, which has helped make VLSI possible, increases the interdependence of processing steps and opens the possibility of creative uses of topographical effects in fabricating devices. Examples illustrate the importance of these effects and the basic mechanisms involved. Simulation is particularly well suited for systematically examining the trade-offs among processing steps. Design graphs characterize the effect of anisotropy on line-width loss and oxide removal in polysilicon gate etching, and on thin film resistance in tapered oxide etching. Guidelines for planarization by isotropic deposition and anisotropic etching are suggested. Comparisons with experiments show that the reported planarizing effect is better than expected.

The advent of dry etching and new deposition techniques helps make possible the reduced size and increased complexity in integrated circuit devices. The directionality of dry etching allows feature sizes in devices down to 1 μm (1, 2), and provides a flexible medium for creative processing solutions to device performance problems (3, 4). Novel deposition techniques contribute to higher packing densities (5-7). Simulation (8-10) is useful in characterizing and optimizing the individual deposition and etching processing steps. This paper extends simulation to several new topography control techniques and explains several situations which involve optimization of the interaction between processing steps.

The interaction between process steps is important in anisotropic dry etching. Simple directional etching forms steep, fine patterns which lead to poor coverage in the subsequent deposition of thin films. When followed by deposition and a second directional etch, a residue remains in the vicinity of the abrupt topographic steps. This unetched residue can lead to detrimental effects such as electrical shorts when it is a conductor, but when it is an insulator, it also serves to planarize the topography and can be used in a creative manner as a temporary ion implantation mask (4). Many of these topography creation and interaction problems can be effectively characterized through simulation. The process simulator, simulation and modelling of profiles in lithography and etching (SAMPLE) (9), models the time evolution of an etched line-edge profile. The program uses weighted rate

components and topographical information to produce a two-dimensional line graph of the expected cross section. This paper uses SAMPLE and scanning electron micrographs (SEM's) of laboratory test structures to study these wafer topography issues.

Anisotropic Etching at Steps

Figure 1 illustrates how the underlying topography in a double-level polycrystalline silicon process affects the percentage of electrical shorts in the second-level

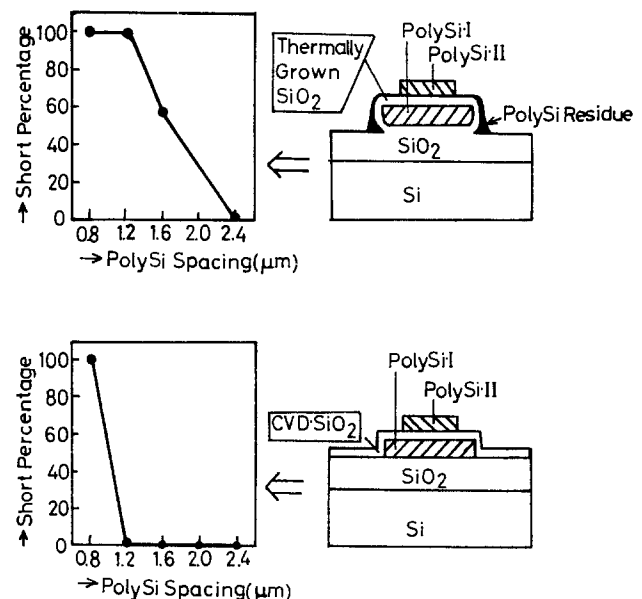

Fig. 1. Percentage of electrical shorts between parallel lines of polysilicon vs. line spacing.

Fig. 2. Simulation of residue removal and gate definition using directional etching and isotropic overetching.

polysilicon lines. In Fig. 1a, a thermally oxidized insulating layer produces a topography undesirable because of its indented structure at the base. After anisotropic etching of the second level of polysilicon, the indentation remains full of unetched polysilicon. The residue causes the electrical shorts in parallel lines of a second layer of silicon. The percentage of shorts increases rapidly for parallel lines separated by less than $2 \mu\text{m}$ because the filaments can form continuous bridges at close spacing. Changing the method of applying the insulator provides a more suitable topography for the dry etching of the second conductor level. As shown in the second part of Fig. 1, silicon dioxide chemically vapor deposited (CVD) at a high temperature makes a better step without indentation. In this case, the percentage of shorts in the second level of polysilicon lines is almost zero above $1 \mu\text{m}$ spacing.

A problem related to the unetched residue at steps also occurs in patterning the first level of polysilicon. The gate electrode material is undercut, while the residue is being etched, as shown in the simulation of Fig. 2. Here, the overlying layer is etched directionally to an end point, and the residue is then removed by introducing an isotropic component during overetching. Simultaneously, in the gate mask region the isotropic overetching undercuts the line, as on the right in Fig. 2. The line width lost depends on the residue thickness and the amount of isotropy in the second etching step. In addition to this undercutting problem, the underlying film, such as the gate oxide, is also attacked during the overetching residue removal process.

An alternative to this double-step process is the use of mixture etching in which a directional and an isotropic component are used throughout a single step.

With this mixed process, the undercutting can be reduced, but the residue thickness remains larger and longer overetching is required. Unfortunately, the anisotropic conditions which reduce the line-width loss have lower selectivity (etch-rate ratio) between the polysilicon and the oxide underneath. Anisotropy thus results in more oxide thickness loss. An example of the relationship between the etch-rate ratio of polysilicon to oxide and anisotropy is shown in Fig. 3a [from Ref. (11)]. The etching selectivity is drastically reduced as the anisotropic ratio increases to the more directional extreme. The relationship between selectivity and anisotropy can be used to explore the basic trade-off between line-width loss and underlying oxide thickness loss. The graph in Fig. 3b compares the polysilicon line-width loss and the oxide etched during the overetching process as a function of anisotropy. The assumed step height is $0.5 \mu\text{m}$, and the deposited thickness of polysilicon is 200 nm . The broken curve corresponds to a single-step etching process where a mixture of isotropic and directional components are used throughout. The solid curve corresponds to a two-step etching process where the first step uses directional etching to an end point, then uses a mixture etching during the overetch time. In both processes, the line-width loss is large in the isotropic region, while the oxide attacked is large in the anisotropic region. The oxide gets etched more in the two-step process because of the need for a longer overetching time. However, the polysilicon line-width loss is less in the double-step process. These curves aid as design guides for determining the optimal etching conditions. A process can be chosen depending upon how much line-width or oxide loss can be tolerated. For instance, if the maximum allowable polysilicon undercut and oxide etched

Fig. 3. (a) Etch rate ratio of poly-Si to SiO_2 [from Ref. (11)]. (b) Line-width lost and oxide etched during over etching time to remove residue at a $0.5 \mu\text{m}$ step.

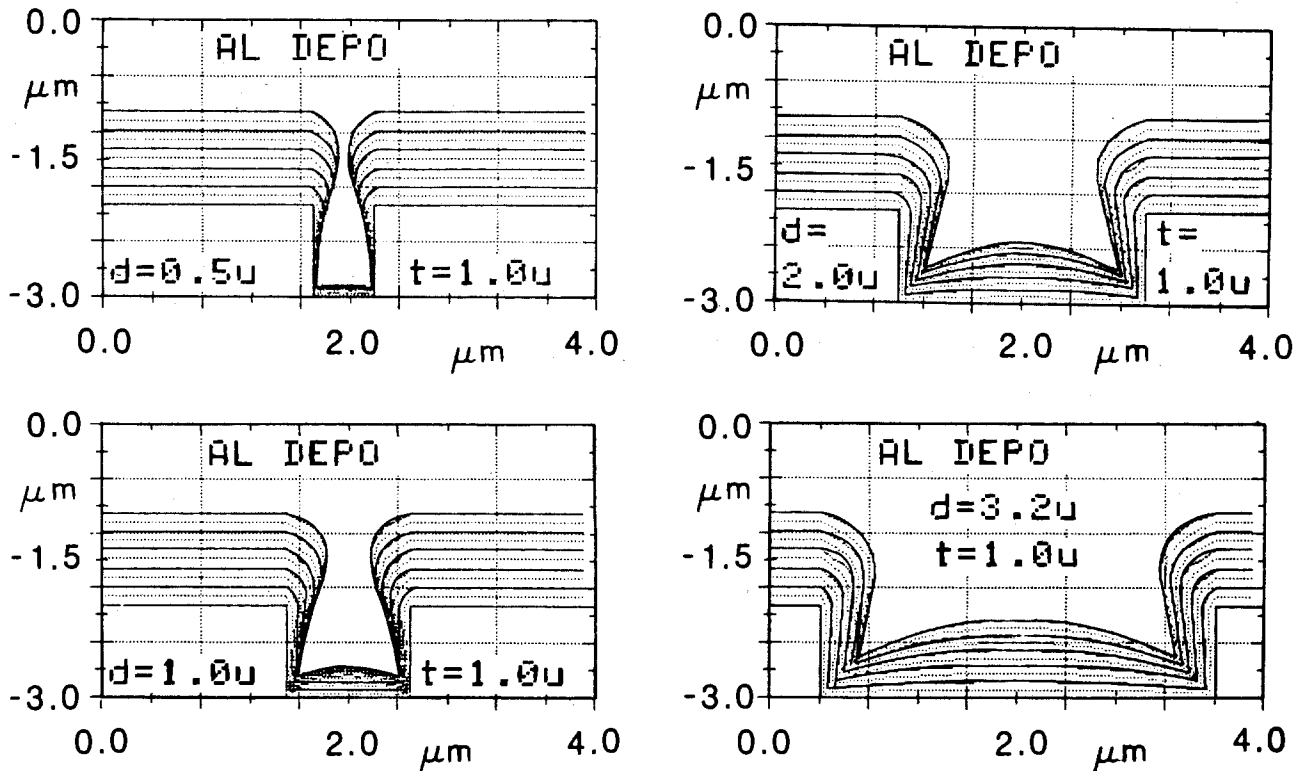

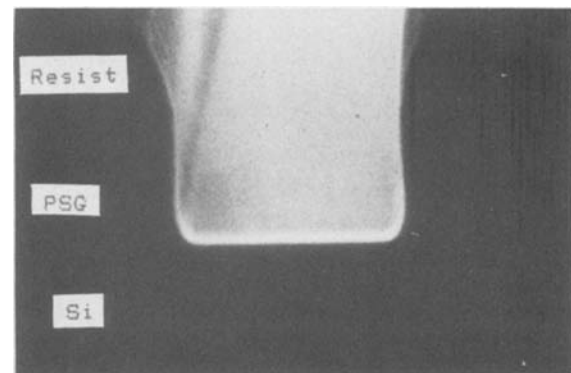

Fig. 4. Simulation of Al deposition in varying window sizes

are $0.2\ \mu\text{m}$ and $30\ \text{nm}$, respectively, the etching condition would fall into the 0%-40% anisotropy ratio for two-step processing. In this case, a good single-step process cannot be found, since such results in large line-width loss.

Step Coverage

Another topography problem is depositional film coverage of dry etched steps. The directional dry etching provides good line-width control and tight layout tolerances, but it results in profiles with steep edges and high aspect ratios, which cause poor coverage when thin films are later deposited. The trade-offs in depositing over dry-etched steps are easily explored using simulation. Figure 4 shows the sputtered aluminum film coverage in contact windows and narrow gaps. Due to the two-dimensional shadowing effect during Al deposition (8), the Al thickness at the bottom corner is much less than the nominal thickness. The shadowing effect becomes more pronounced as the gap dimension is reduced. The Al thickness in a $1\ \mu\text{m}$ wide contact with $1\ \mu\text{m}$ tall vertical walls is only 10% of that of the deposited-film thickness. Even though dry etching would allow reduction to submicron size contact holes, the conventional deposition techniques could not be used to form contact electrodes.

To improve the aluminum coverage of steps with conventional sputter deposition, the contact hole may be tapered (15). A sloped edge provides good coverage, but unnecessarily gradual slopes reduce the tight layout tolerance. Therefore, a compromise in slope and coverage is desirable. Figure 5 demonstrates how photoresist erosion during the etching process can be utilized to give a sloped edge profile. When the photoresist with a steep edge is used as an etching mask in conventional etching steps, the contact window reflects the steepness, because the horizontal resist erosion rate is small. A slightly tapered edge profile can be obtained when tapered photoresist is used as the etching mask. The thinner edge of the mask erodes away, transferring a slope to the contact window edge in the etching process. Postbaking the resist after development is commonly used to taper the resist edge, as shown in the bottom of Fig. 5. Figure 6 illustrates

(a)

(b)

Fig. 5. Profiles of dry etched silicon dioxide using nonreflow and reflow (angled) resist masks.

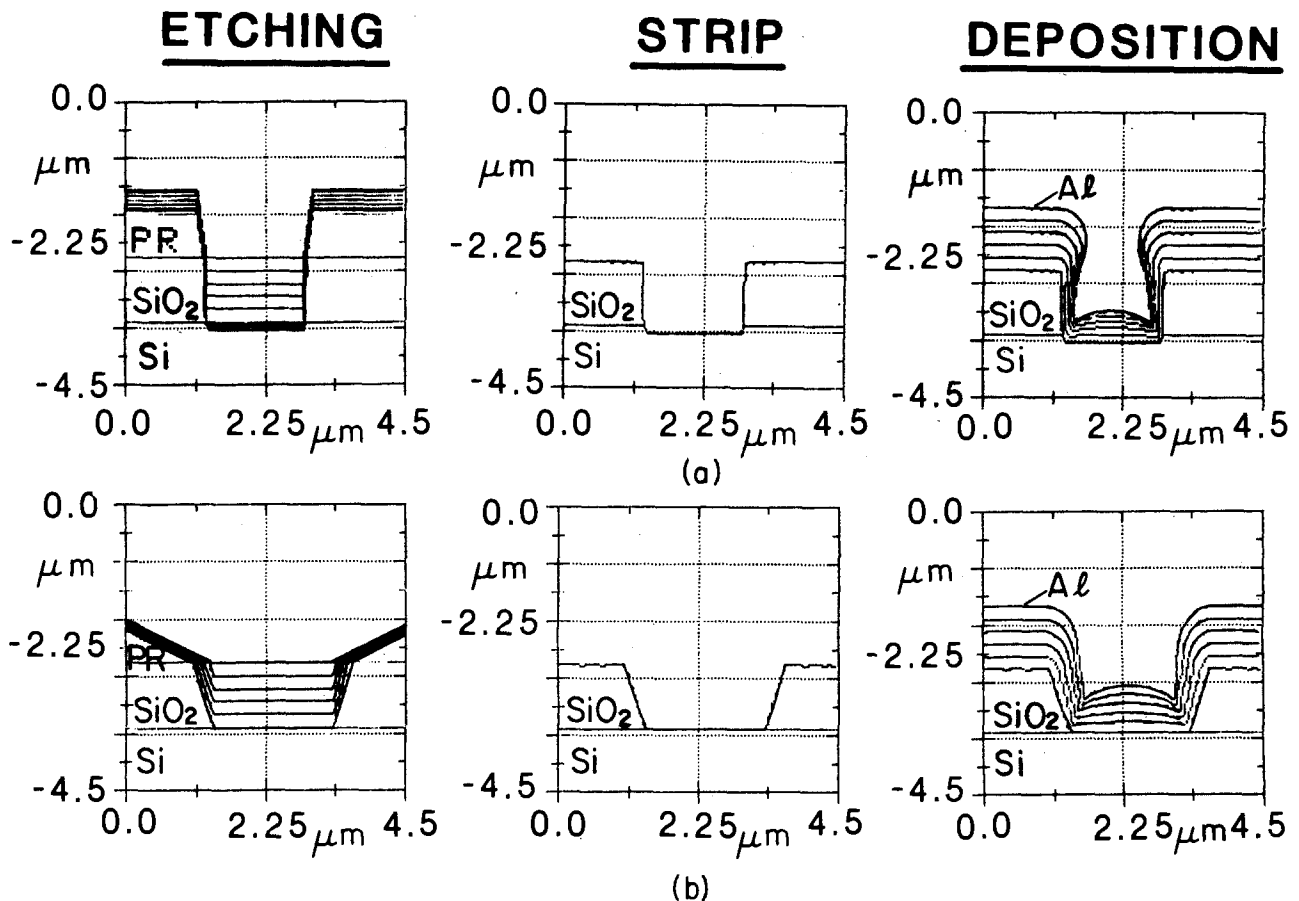

Fig. 6. Simulation of the dry etching of SiO₂ followed by Al deposition using straight and angled masks

the corresponding simulated sequential processing steps. The steep photoresist profile coupled with the vertical etching makes a steep profile that it is difficult for the aluminum to cover. The tapered photoresist with some lateral expansion of the contact hole produces a slightly sloped edge, which provides better step coverage.

The effect of the resist-to-oxide selectivity on the resulting contact-hole size and on the depositional film resistivity can be characterized. A photoresist mask with an initial sidewall taper angle that is etched anisotropically produces a tapered opening in the sili-

con dioxide layer. The oxide sidewall angle depends on the initial resist profile angle and the etch selectivity between the resist and the oxide. The taper in the oxide results in an expansion of the contact hole size, though. This is shown in Fig. 7 for nonreflowed resist of 80° and reflowed resist of 45° as a function of selectivity. The oxide taper angle also affects the subsequent metal coverage. The relative resistivity of the metal line crossing the gap is used to specify the quality of the deposited line. A relationship between resistance and sidewall taper has been generated for a 1 μm gap in a 1 μm thickness of oxide with a 1 μm of sputtered

Fig. 7. Relative resistance of aluminum across gaps and contact window expansion vs. selectivity for two mask angles. (a) 80°, nonreflowed. (b) 45°, reflowed.

Fig. 8. Simulation of a multi-step process planarizing an edge by successively leaving residue. (a) Initial profile, a 0.3 μm rectangular step. (b) Profile after the initial deposition/anisotropic etch cycle. (c) Profile after the second deposition/anisotropic etch cycle. (d) Profile after the third deposition/anisotropic etch cycle.

Al in Ref. (12). This relation between angle and resistance is used for the relative resistance vs. selectivity plotted in Fig. 7. The graph shows how the combination of reflow angle and selectivity can be chosen for the trade-off between resistance and contact window expansion. An oxide sidewall angle of about 60° is a reasonable compromise for sputter deposition without bias. For reflow resist, initially tapered to 45°, a process with 2:1 oxide selectivity achieves the 60° oxide sidewall angle. The use of reflow produced a profile of 63° in Fig. 5, while without reflow, the sidewall angle was steeper than 85°.

Planarization

Now we examine the constructive use of dry etching in planarizing nonuniform surfaces. If a residue is left at steps intentionally, it can be used to ease step coverage in later processing steps. One way is to deposit a thick oxide by CVD at high temperature or at low pressures to obtain a completely isotropic covering of the nonuniform topography. This deposited oxide is then etched back anisotropically to leave a rounded residue at every vertical step. Several isotropic depo-

sition/anisotropic etch steps will leave a larger and larger amount of residue at the concave edge, giving a gradual slope to the edge, as shown in the simulation in Fig. 8. This residue is the basis for the lowly doped drain and offset gate technologies (4).

If, however, the deposited oxide film thickness exceeds one-half the gap spacing, as in Fig. 9, the oxide fills the gap and tends to planarize the surface. The nonplanar dip remaining in the oxide surface decreases as the thickness-to-gap-width ratio is increased. From simulation it can be seen that the oxide surface dip in a 2 μm gap with 2 μm of deposited and etched oxide amounts to only 0.1 μm. This eliminates the problem of sputtering over narrow, deep channels.

Figure 10 illustrates experimentally the isotropic deposition/anisotropic etching method for several test structures. Gaps were directionally etched in silicon. A thin layer of oxide was grown before deposition for later underetching to distinguish between the layers. Then a layer of CVD polysilicon was deposited and etched anisotropically in a sulfur hexafluoride and oxygen mixture (SF₆/10% O₂). After dry etching each layer of the polysilicon, a new distinguishing layer of

oxide was grown. This process was repeated several times. The back-etching of these thin oxide layers reveals the history of the surface shape at various steps (13, 14). The first two micrographs show that isotropical deposition followed by anisotropic etching preferentially leaves a smoothing residue at step edges. These correspond well to the simulation in Fig. 8. The third photo demonstrates how a narrow ($2 \mu\text{m}$) gap is planarized by filling with CVD material and etching. The final photo in Fig. 10 shows that the same effect occurs in a wider $7 \mu\text{m}$ space. This structure has the dip predicted by simulation in Fig. 9, but shows experimentally that the planarization effect is greater than expected.

The simulated aluminum deposition across the top of planarized structures is shown in Fig. 11. Planarization remarkably improves the Al film coverage. The aluminum line resistance is estimated to be almost one order of magnitude less than that of the nonplanarized structure. Therefore, the planarization process for gaps and steps can be useful in reducing interconnection resistance in VLSI technology.

Conclusion

Experiment and simulation are used to explore topographical interaction between etching and deposi-

tion processing steps. Experimental data are included to document the importance of these process interactions and to illustrate the physical mechanisms producing the topographic effects. Design graphs have been generated to illustrate the process options in several current thin film processing technologies.

Simulation and experimental verification lead to several important conclusions. A single-step mixture of isotropic and anisotropic etching removes less gate oxide while removing residue than a double-step process for the same amount of undercut at the polysilicon gate. When considering the resistance of sputtered Al lines into contact windows, tapering the oxide sidewall to 60° by resist reflow and appropriate etching selectivity is a reasonable compromise of layout tolerances. For planarization, an isotropic deposition of material of thickness one-half the narrow gap widths is adequate, but further experimentation shows that the smoothing is better than expected.

The Characterization of Heteroepitaxial Silicon by Surface Photovoltage Technique

Improved Properties in SOS Films Resulting from Implant Damage and Solid-State Regrowth

ABSTRACT

Electronic properties of ion implanted and recrystallized silicon-on-sapphire films were studied by surface photovoltage as a function of implantation dose (varied from 10^{15} to 10^{16} cm^{-2}). It has been found that all essential characteristics of SOS films undergo a pronounced improvement as a result of high dose (4.8×10^{15} cm^{-2}) implantation with Si ions followed by a brief annealing (4h at 600°C). The most important improvement has been found with respect to reduction (about two orders of magnitude) in deep-level concentration situated at the middle of the energy gap, and a significant increase in the minority carrier lifetime.

Ion implantation and subsequent thermal annealing have recently been used as processing steps leading to solid-state recrystallization of heteroepitaxial silicon films on sapphire (1). It has been demonstrated that such processing can improve the crystalline perfection of the films, particularly in the vicinity of the silicon-sapphire interface (2). In the present study, we examine the effects of solid-state recrystallization on the electrical properties of SOS films implanted with Si ions. The films were $\sim 5000\text{\AA}$ thick. Implantation was carried out at 380 keV with a dose ranging from 1 to 8×10^{15} Si^{++} cm^{-2} . Implanted films were annealed at 600°C for 4h. As verified by x-ray measurements, the amorphous-like damage of SOS wafers caused by implantation was effectively removed during annealing, evidently as a result of the solid-state recrystallization process.

X-ray pole-figure measurements (3) were made on the films before implantation, after implantation, and after annealing. The volume percent (v/o) concentrations of (100) and {221} were determined after each processing step relative to the initial concentrations of the (100) parent and {221} twins. The extent of amorphization by implantation and the extent of recrystallization after annealing were deduced from these measurements.

The distribution of Al in the implanted SOS films was measured by SIMS. The electrical properties of the SOS films were measured using photovoltage spectroscopy for macroscale characterization and laser scanning photovoltage microprofiling for the determination of electrical inhomogeneities (4-7). The metal-semiconductor (MS) structures employed in the photovoltage spectroscopy measurements were prepared by evaporation of a semitransparent Al layer on freshly etched (30s in HF) epilayer surfaces. Measurements were carried out at temperatures of 100-300 K utilizing chopped monochromatic light and phase-sensitive detection or signal averaging for spectral response and relaxation time measurements, respectively. Four samples with Si implant doses of 1, 2, 4, and 8×10^{15} ions- cm^{-2} were prepared and measured simultaneously to assure the reliability of this comparative study.

The effect of solid-state recrystallization on the photovoltage spectra of SOS is shown in Fig. 1, where photovoltages of Si-implanted and annealed films are plotted for different implantation doses. These spectra are normalized to the photovoltage value at $h\nu = 2$ eV. In the subbandgap region ($h\nu < E_g$) where the most significant differences are seen, the photovoltage is due to photoionization transitions involving deep

levels (4). The low energy photovoltage threshold can be considered to be a typical feature of heteroepitaxial silicon. According to our recent study, the deep levels E_{t1} located in the vicinity of midgap are involved in these photoionization transitions. They apparently originate from dangling bonds of structural defects

(5, 6), providing a sensitive electronic measure of the crystalline perfection of SOS films.

For photon energy in the range 0.9-1.0 eV, a second photovoltage threshold is observed, indicating the presence of E_{t2} levels (4). In the region $h\nu \gtrsim 1.1$ the band-to-band generation of excess carrier takes place and the photovoltage becomes sensitive to interband optical transitions. A typical feature of these transitions is the presence of a high energy shoulder around $h\nu \simeq E_0$, not observed for bulk single crystalline Si, but an inherent characteristic of amorphous Si. In our previous study (4), we have assigned the structure around $h\nu \simeq E_0$ to a slight amorphization of the SOS films, most likely originating from a region of inferior crystalline quality in the vicinity of the silicon-sapphire interface. For thin SOS films (typically 0.6 μm), the photovoltage exhibits a series of interference maxima-minima (4). In the spectra of Fig. 1, the interference maxima-minima were averaged, since they are of no interest in the present study.

It is seen from Fig. 1 that the subbandgap photoionization transitions are reduced by as much as two orders of magnitude in the SOS films which received a high implantation dose. This effect is clearly seen in Fig. 2, in which the deep level (E_{t1}) concentration is plotted vs. the Si-implantation dose [the deep level concentration in arbitrary units was determined from the values of $V(h\nu = 0.8 \text{ eV})/V(h\nu = 2 \text{ eV})$ (5)]. The results in Fig. 2 indicate that a threshold Si-implant concentration greater than $2 \times 10^{15} \text{ ions-cm}^{-2}$ is required to suppress deep levels in SOS films. The improvement in electronic properties caused by Si-implantation and subsequent annealing was also observed in photovoltage relaxation measurements at low temperatures ($\sim 200 \text{ K}$). As discussed previously (4), the photovoltage transient, caused by interrupting the illumination, exhibits an exponential time dependence with a time constant which is inversely proportional to the concentration of minority carrier traps. The time constant in films annealed after an Si-dose of

Fig. 2. Concentration of deep levels as a function of the implantation dose.

Fig. 3. Photovoltage scans of deposits exposed to (a) 1×10^{15} and (b) $8 \times 10^{15} \text{ ions-cm}^{-2}$ Si implantation.

$8 \times 10^{15} \text{ ions-cm}^{-2}$ was higher by as much as a factor of four than for a low implantation dose of $1 \times 10^{15} \text{ ions-cm}^{-2}$. Accordingly, it can be concluded that solid-state recrystallization reduces the concentration of minority carrier trapping centers.

The above results show the effects of recrystallization on the average (macroscopic) properties of silicon-on-sapphire. Improvement in the electrical homogeneity of heteroepitaxial silicon is observed with photovoltage measurements carried out with a very small focused light spot (15 μm diam). These types of measurements constitute a powerful technique for detection of inhomogeneities in semiconductors (7). In this technique, localized excitation of excess carriers by a focused He-Ne laser beam generates a differential photovoltage between two contacts which are located away from the excitation point and kept in the dark (7). The photovoltage signal is due to the presence of a horizontal gradient in carrier concentration, diffusion length, or the concentration of trapping centers. A localized potential barrier (e.g., an electrically active grain boundary) constitutes a typical example of an inhomogeneity that leads to pronounced photovoltaic signals. In a perfectly homogeneous material, no photovoltage signal is observed.

Typical high resolution photovoltage scans of the central portion of SOS wafers with the lowest ($1 \times 10^{15} \text{ ions-cm}^{-2}$) and the highest ($8 \times 10^{15} \text{ ions-cm}^{-2}$) Si-implantation doses are shown in Fig. 3a and 3b, respec-

Fig. 4. Distribution of Al in the vicinity of sapphire interface for various doses of implantation: (a) $1 \times 10^{15} \text{ cm}^{-2}$, (b) $4 \times 10^{15} \text{ cm}^{-2}$, and (c) $8 \times 10^{15} \text{ cm}^{-2}$. The distance on which Al concentration is reduced to 10^{17} cm^{-3} is marked on the figures.

Table I. Result of x-ray pole-figure analysis of ion-implanted and annealed heteroepitaxial silicon

Dose (ions-cm ⁻²)	Amorphization of (100) (% by vol)	Recrystallization of (100) (% by vol)
1 × 10 ¹⁵	20	100
2 × 10 ¹⁵	55	100
4 × 10 ¹⁵	90	105
8 × 10 ¹⁵	95	105

tively. It is evident that the film which received the high implantation dose was much more homogeneous than the film which received the low implantation dose.

The results of x-ray pole-figure analysis on silicon films implanted and annealed simultaneously with the samples used in the photovoltage measurements are given in Table I.

It can be seen from Table I that at the higher implant doses, more (100)-oriented silicon was present after the recrystallization process than had been present initially. This results from the conversion of {221} twin material, initially present in the films mostly in the interfacial region, to the (100) orientation as a result of amorphization and recrystallization. A corresponding decrease in the {221} concentration of the films was simultaneously observed. It should be noted, however, that these measurements are reproducible to no better than about 5%. Consequently, it is not possible to state conclusively that recrystallization is complete. Some small amount of amorphous material, not detectable by x-ray analysis, may still remain after annealing.

SIMS profiles of the Al distribution in the implanted SOS films are shown in Fig. 4. It is evident that the amount of aluminum which has been displaced into the silicon from the sapphire increases with increasing implantation dose. The aluminum concentration drops to a value of 10¹⁷ atoms-cm⁻³ in the distance of 0.05, 0.06, and 0.08 μm from the sapphire interface in the samples implanted with silicon doses of 1, 4, and 8 × 10¹⁵ ions-cm⁻², respectively. It is evident from the above results that the chemical nature of the interfacial region is significantly changed by ion implantation.

It has been shown recently that the density of electrically active defects is related to the concentration of {221} twins in heteroepitaxial silicon (5). TEM cross-section micrographs indicate that the highest concentration of crystallographic defects is in the interfacial region (8). Therefore, it should not be surprising that the largest reduction in the concentration of electrically

active defects has been observed in the samples with the largest changes in the interfacial region. The reduction observed in the concentration of electrical inhomogeneities probably results from the homogenization of the interfacial region by ion implantation and recrystallization.

It is of interest to note that improvements caused by the solid-state recrystallization are similar to those caused by the hydrogenation of SOS films. As we have recently shown, (6) atomic hydrogen introduced into SOS films suppresses the concentration of E_{t1} levels, reduces trapping effects, and decreases the magnitude of microscopic inhomogeneities. These beneficial effects of atomic hydrogen were attributed to saturation of the dangling bonds of structural defects located mostly at the interface by hydrogen. This led to passivation of their electrical activity.

We believe that the effects reported here are related to reduction of the concentration of structural defects, especially in the interfacial region, as a result of the recrystallization process and/or their passivation by interaction with point defects or impurities, e.g., aluminum. Further study is needed to assess the effect of lower energy implants (which would reduce damage of sapphire) on the electronic properties of SOS films subjected to the solid-state regrowth procedure.

ABSTRACT

Thick oxide films (≈ 220 nm) have been nitrided heavily in ammonia. Dispersion analysis was performed on infrared transmission spectra of oxide, nitrided oxide, and CVD nitride films. The following conclusions may be drawn from the spectra: nitrided oxide is not the same material as CVD silicon nitride; nitridation results in significant loss of Si-O asymmetric stretch intensity; and nitridation leads to the appearance of a spectral peak for planar triply bonded N-Si asymmetric stretch analogous to that in trisilylamine. About 43% of the oxygen was replaced by nitrogen.

The high temperature nitridation of thermal silicon dioxide films in ammonia has been shown to have a profound effect on the radiation resistance of thin (10-20 nm) oxides (1, 2). The primary locus of failure due to radiation in NMOS circuitry is the field oxide, and recent studies have shown that the radiation resistance of thick (200-400 nm) oxides is also affected by nitridation (3). Thick nitrided oxides have been shown by Auger spectroscopy to have incorporated significant amounts of nitrogen in their outer layers and smaller amounts at their silicon interfaces (4-7). In this study, infrared spectroscopy was used to evaluate the nature of the incorporated nitrogen. We find that it is planar trigonally bonded, and we show quantitatively the degree of conversion to nitride.

Experimental

Lightly doped silicon wafers, 5 cm diam, were lapped and polished on both sides to provide a taper of 0.0025-0.020 cm; this taper is required to prevent interference effects in the silicon from obscuring the results. A set of wafers were oxidized at 1000°C using a cycle consisting of 10 min of oxygen, 30 min of steam, and 20 min of nitrogen, to provide oxide films about 220 nm thick on each side. Some of these oxidized wafers were then nitrided in ammonia at 1 atm pressure for 6h at 1100°C. A second set of wafers were coated with 200 nm of LPCVD silicon nitride. The pertinent characteristics of these films are given in Table I.

Infrared transmission spectra of the various samples were measured in the spectral range of 1400-800 inverse centimeters using a Beckman 4250 infrared spectrophotometer. The slit width, under program control, varied from 0.5 mm at 1400 cm^{-1} to 2.1 mm at 800 cm^{-1} . The period was 1s, and the scan speed 50 $\text{cm}^{-1}/\text{min}$. The indicated resolution is a few inverse centimeters, and the photometric error is less than 1%. The spectra were measured using uncoated but tapered silicon wafers as references. The data for each spectrum were digitized and normalized (9). The higher energy portions (asymmetric stretch modes) of each spectrum were decomposed into their constituents; the lower energy peaks (symmetric stretch and rocking modes around 850 cm^{-1} and below for oxide and nitrided oxide, and around 600 cm^{-1} and below for CVD nitride) were ignored.

Dispersion Analysis

Dispersion analysis is a process wherein a set of oscillators is specified which will allow the synthesis of curves having reasonable agreement with the optical data. It has been applied in the past to bulk quartz (10) and crystalline Si_3N_4 (11), but has not to our knowledge been used for films of either silicon oxide or nitride. SiO_2 films have been studied by Kramers-

Kronig analysis (12), which yields values for the optical constants n and k . Dispersion analysis provides information not only on the optical constants n and k , but also on the oscillators which induce changes in these constants. The oscillators can be related, in turn, to the molecular structure of the material.

Our analysis follows that used by Spitzer and Kleinman (10). Following Seitz (13), the classical dispersion theory of crystals leads to these equations for the refractive index n and the extinction coefficient k at optical frequency ν

$$n^2 - k^2 = \epsilon_0 + \sum_j 4\pi\rho_j\nu_j^2 \frac{\nu_j^2 - \nu^2}{(\nu_j^2 - \nu^2)^2 + \gamma_j^2 \nu_j^2 \nu^2} \quad [1]$$

$$nk = \sum_j 2\pi\rho_j\nu_j^2 \frac{\gamma_j\nu\nu_j}{(\nu_j^2 - \nu^2)^2 + \gamma_j^2 \nu_j^2 \nu^2}$$

where the summation is over the lattice oscillators and each oscillator is characterized by its polarization ρ_j , width $\gamma_j\nu_j$, and frequency ν_j .

The quantity ρ_j is related to the oscillator strength f_j by

$$\rho_j = (Ne^2/4\pi^2m\nu_j^2)f_j$$

where N is the oscillator concentration and e and m are the charge and mass of the electron. The long wavelength dielectric constant is given by

$$\epsilon = \epsilon_0 + \sum_j 4\pi\rho_j$$

where ϵ_0 is the short wavelength dielectric constant.

The accommodation required to change from a crystalline to an amorphous structure introduces a distribution in bond strengths and thereby a distribution in oscillator frequencies. We take this distribution to be gaussian and hence replace ρ_j in Eq. [1] by

$$\rho_j \rightarrow \rho_j \frac{1}{1.201 \delta_j \sqrt{\pi}} \int \{\exp - [(\nu_i - \nu_j)/1.201 \delta_j]^2\} d\nu_i \quad [2]$$

where δ_j is the gaussian half width at half maximum for the j -th oscillator distribution ($1.201\delta_j = \sqrt{2} \sigma_j$).

Table I. Ellipsometric characteristics of films
 $\lambda = 632.8$ nm

where σ_j is the standard deviation). Equations [1] now become

$$n^2 - k^2 = \epsilon_0 + \sum_j \frac{4\sqrt{\pi}}{1.201\delta_j} \rho_j \nu_j^2 \int \frac{\{\exp - [(\nu_1 - \nu_j)/1.201\delta_j]^2\} (\nu_1^2 - \nu^2)}{(\nu_1^2 - \nu^2)^2 + (\gamma_j \nu \nu_1)^2} d\nu_1$$

$$nk = \sum_j \frac{2\sqrt{\pi}}{1.201\delta_j} \rho_j \nu_j^2 \int \frac{\{\exp - [(\nu_1 - \nu_j)/1.201\delta_j]^2\} \gamma_j \nu \nu_1}{(\nu_1^2 - \nu^2)^2 + (\gamma_j \nu \nu_1)^2} d\nu_1 \quad [3]$$

Analysis of a film consists of tentatively identifying a set of oscillators, each characterized by parameters ρ_j , δ_j , ν_j , γ_j , which, when inserted into Eq. [3], and then into the equations for optical transmission through the sample (see below), yield a best fit to the experimental data.

For a film on a supporting wafer the effective transmission is mediated by the silicon layer. The equations for transmission rapidly become intractable as the number of films increases; however, because of symmetry, they can be somewhat simplified by having films on both sides of the substrate, and by treating the wafer as lossless. All our results are for wafers with films on both sides.

Heavens (14) gives for the transmission of a single film on an absorbing substrate

$$T_1 = \frac{n_2}{n_0} \frac{[(1 + g_1)^2 + h_1^2] [(1 + g_2)^2 + h_2^2]}{[\exp(2\alpha)] + (g_1^2 + h_1^2)(g_2^2 + h_2^2) [\exp(-2\alpha)] + C \cos 2\theta + D \sin 2\theta}$$

where

$$g_1 = \frac{n_0^2 - n_1^2 - k_1^2}{(n_0 + n_1)^2 + k_1^2} \quad h_1 = \frac{2n_0k_1}{(n_0 + n_1)^2 + k_1^2}$$

$$g_2 = \frac{n_1^2 - n_2^2 + k_1^2 - k_2^2}{(n_1 + n_2)^2 + (k_1 + k_2)^2} \quad h_2 = \frac{2(n_1k_2 - n_2k_1)}{(n_1 + n_2)^2 + (k_1 + k_2)^2}$$

$$\alpha = \frac{2\pi k_1 d_1}{\lambda} \quad \theta = \frac{2\pi n_1 d_1}{\lambda}$$

$$C = 2(g_1g_2 - h_1h_2) \quad D = 2(g_1h_2 + g_2h_1)$$

and n_0 is the index of air, $n_1 = n_1 - ik_1$ and d_1 are the index and thickness of the film, and $n_2 = n_2 - ik_2$ is the index of the silicon wafer.

For a tapered wafer, all phases of the light reflected inside the wafer are added, thereby canceling the resonance effects. If the silicon is perfectly lossless, i.e., $k_2 = 0$, then the transmission of the structure with films on both sides is, with the correction for the change of n on exit, simply the square of the above

$$T_2 = \left(\frac{[(1 + g_1)^2 + h_1^2] [(1 + g_2)^2 + h_2^2]}{[\exp(2\alpha)] + (g_1^2 + h_1^2)(g_2^2 + h_2^2) [\exp(-2\alpha)] + C \cos 2\theta + D \sin 2\theta} \right)^2 \quad [4]$$

We take the index of silicon to be $n_2 = 3.42 + i0$ (15). The dispersion in this frequency range is negligible. The small absorption actually present in the silicon is partially compensated by the reference wafer and by the normalization procedure. The effect of the oxygen content of the silicon, which is measurable both in its dissolved and cristobalite forms, is discussed below.

Results

The spectra for oxide, nitrided oxide, and CVD nitride are shown as the top traces in Fig. 1, 2, and 3, respectively. The fit is achieved iteratively by choosing values for ν_j , ρ_j , γ_j , and δ_j for the several peaks, computing $n^2 - k^2$ and nk from Eq. [3], and then T_2 from Eq. [4]. Each measured curve was normalized at the high and low frequency ends to the computed values.

The results of the spectral analysis of the data are presented in Table II, together with selected literature data from the crystalline compounds and trisilylamine

(vapor) (16), the latter being the simplest trigonally bonded N—Si₃ compound. The bottom traces of Fig.

1, 2, and 3 show the difference between the experimental spectra and the spectra computed from the oscillators of Table II.

The main peak, at 1065 cm⁻¹ in oxide and nitrided oxide, is discussed in detail below. The line at about 1090 inverse centimeters may be attributed to interstitial oxygen in the wafer (17). The line disappears when the films are etched off and reappears when the spectra are recorded without a reference wafer. The appearance is due to the interaction of the lossy wafer and the lossy film in this frequency range, which is not taken into account in our calculations. Note that this is the only sharp line in the spectra; it is similarly sharp in the bare wafers. The presence of this line leads to an uncertainty of 1 or 2 cm⁻¹ in the width and position and a small fraction in the height of the main

(1065) peak. The 1220 line is presumed due to cristobalite in the wafer (17); the 1165 line has been variously attributed to mixed and longitudinal modes (10).

The other lines are presumed to be due to asymmetric stretch of the O—Si or N—Si bonds. The strong line about 1070 cm⁻¹ attributed to the TO mode is dominant in α -quartz, thermal oxide, and nitrided thermal oxide. The width of this line more than

quadruples in going from α -quartz to thermal oxide because bond strengths are altered in forcing the Si—O tetrahedra to accommodate to more random orientations in the vitreous structure.

A new peak at 1000 cm⁻¹ has appeared in the nitrided oxide spectrum, while the main Si—O peak has been reduced and broadened. We attribute this new peak to planar, trigonally bonded nitrogen, because it is close in frequency to the peak for trisilylamine (16).

If the number of silicon bonds is constant during nitridation, then the supplanting of doubly coordinated oxygen by triply coordinated nitrogen should reduce the concentration of oscillators N by a factor of 2/3. However, if the nitrogen is trigonally bonded, the in-plane asymmetric stretch mode is doubly degenerate, doubling the oscillator strength f_j in that mode. Hence, nitridation should result in a factor of $2 \times 2/3 = 1.33$ increase in the product of density and oscillator strength Nf_j for the nitrogen oscillators compared to the loss in Nf_j for the oxygen oscillators. The product

Fig. 1. Infrared spectra of thermal oxide. Top curve: A = Experimental, B = Calculated. Bottom curve: A minus B.

Nf_j is proportional to the polarization $\rho_j \nu_j^2$, so we would expect that the ratio $\rho_{N\nu N^2} / \rho_{O\nu O^2} = 1.33$. As shown in Table II, the scaled polarization for the oxide line decreased by $32,000 - 18,000 = 14,000$, while the mea-

decomposed into oscillators that correspond to α - Si_3N_4 , except for a general shift to lower frequency by 1-5%.

Conclusions

We find, as did Habraken *et al.* (7), that nitridation decreases the amplitude and increases the width of the main thermal oxide peak. Decomposing the peaks shows a new line at 1000 cm^{-1} in the nitrated oxide; about 43% of the oscillators have been converted to the new peak. The near coincidence in frequency to the trisilylamine peak, which has been shown to be due to planar trigonal N—Si₃ bonds, leads us to ascribe the new peak to planar trigonally bonded nitrogen. Note that this peak does not occupy a dominant position in either the crystalline or amorphous (CVD) silicon nitride spectrum. The line width of the new peak again increases as the nitride structure is made compatible to the oxide matrix.

ABSTRACT

The agyrodite $\text{Cu}_6-x\text{PS}_5\text{I}$ is simultaneously a copper ion conductor and a p-type electronic semiconductor. With an energy gap of $\Delta E_G = 2.05\text{ eV}$, the compound intercalates copper upon illumination as demonstrated in photoelectrochemical experiments. The intercalation of copper is accompanied by a color change which is believed to be due to an annihilation of I_2^- color centers. In experiments in which Cu was partially replaced by Ag, photointercalation was verified by means of x-ray fluorescence measurements. It is shown how such a photointercalation reaction could be used to store optical information.

Since the proposal of light-induced intercalation and deintercalation as a possible mechanism for solar energy and optical information storage, several semiconducting host materials have been investigated. Light-induced topotactical reactions have been investigated on p-ZrSe₂ [intercalation of metal ions (1)], n-HfSe₂ [deintercalation of metal ions (2)], and TiO₂(B) [deintercalation of protons (3)]. In the last case, the studies could be made using aqueous electrolytes because of the high stability of the material. In all other cases, organic electrolytes were required to avoid rapid corrosion as a consequence of an intercalation of aqueous species. Preliminary experiments with other materials such as p-ZrS₂ (4), p-FePS₃ (5), and n-InSe (6) have shown that semiconducting host materials of good photocurrent efficiency, corrosion stability, reversibility, and high ionic conductivity are not abundant. Also crucial is the question where the electronic energy levels of the guest atoms have to be placed in an energy scheme. Only those systems are of practical interest which maintain semiconducting properties during intercalation at high concentrations of intercalated guest atoms. Therefore, it appears reasonable to select systems which are semiconducting when fully intercalated. Such a system is $\text{Cu}_6\text{PS}_5\text{I}$ ($\Delta E_G =$

2.05 eV) which can be deintercalated to become a $\text{Cu}_{6-x}\text{PS}_5\text{I}$ compound.

Experimental

Material.—Crystals of $\text{Cu}_6\text{PS}_5\text{I}$ grown by chemical vapor transport in the presence of liquid CuI (7) have a cubic high temperature structure (SG: $F\bar{4}3m$; $Z = 4$) with a disordered Cu-cation sublattice. The idealized anion sublattice, consisting of S and I, forms a framework of interpenetrating centered icosahedra providing ideal and distorted tetrahedral cation sites (Fig. 1) (8). The P atoms reside in the perfect tetrahedral sites surrounded by four S atoms.

The 24 Cu atoms are distributed on a 48-fold split position in distorted anion tetrahedra. Two of these tetrahedra always have a common face. In Fig. 1, a double tetrahedron is outlined and the possible positions which are normally occupied by one Cu atom are marked (9). One Cu position is situated near the common tetrahedral face and exhibits a trigonal planar coordination, while the other is within the tetrahedron (7, 9). Since the resulting double tetrahedra (24 per unit cell) are interconnected by cornersharing and edgesharing to a three-dimensional framework, the observed copper ion conduction (10) can be under-

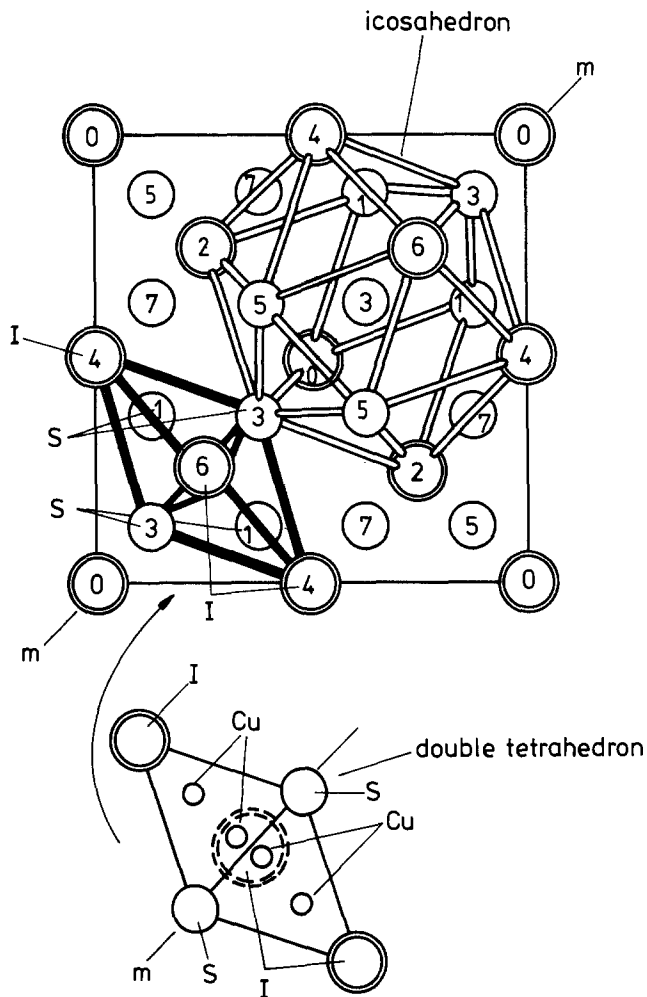

Fig. 1. Projection of the idealized anion sublattice of $\text{Cu}_6\text{PS}_5\text{I}$ along $[100]$ with an anion icosahedron outlined (7). The crystal structure of $\text{Cu}_6\text{PS}_5\text{I}$ can also be built up with double tetrahedra as building units. The numbers are heights in eighths of the unit cell. One of the 24 double tetrahedra which contains one Cu atom is also outlined. The Cu atom is able to migrate between the marked positions.

stood as a hopping process of Cu atoms from one double tetrahedron to a neighboring one. It is assumed that during the Cu migration one double tetrahedron can contain two copper atoms in the tetrahedral positions.

The $\text{Cu}_6\text{PS}_5\text{I}$ crystals were red and transparent. With a Seebeck effect device (GCA Solid State Measurements) the material was identified as a p-type semiconductor. The bandgap is 2.05 eV (11).

Sample preparation.—The crystals used in the experiments were plates with an area of 2–3 mm². Some of the crystals were treated in concentrated nitric acid at 50°C for 20 min to partially remove copper from the $\text{Cu}_6\text{PS}_5\text{I}$ lattice. The nitric acid oxidizes the $\text{Cu}_6\text{PS}_5\text{I}$ by forming $\text{Cu}(\text{NO}_3)_2$ (12). As a consequence of this treatment, the surface is etched and cracks may occur.

A 500Å gold layer was evaporated onto the back face of both the treated and the untreated crystals. The back contact was made by gluing the contacted crystal with Ag epoxy onto a brass electrode holder which was electrically isolated with silicon rubber.

Experimental setup.—Photoelectrochemical experiments were performed in a standard three-electrode cell with an Ag/AgNO₃ electrode as a reference electrode and a copper or silver wire as counterelectrode. The experiments were done in a 0.1M tetraethylammonium perchlorate (TEAPC) acetonitrile solution

containing either 0.01M CuCl or 0.02M AgNO₃. Oxygen and water were removed from the acetonitrile with Cr-HMDS (hexamethyldisiloxane) bound to the surface of silicagel (13).

The CuCl was dried by chemical transport with HCl and N₂ at 600°C. The AgNO₃ and the TEAPC were dried by heating under vacuum. The experiments were carried out in a glove box.

Cyclic voltammograms were obtained with a potentiostat (PAR 179) equipped with a coulometer and a scanning device (PAR 175). A 450W Xe lamp (Oriel) served as a light source. Photocurrent spectra were obtained with a high intensity monochromator (Bausch and Lomb) equipped with a grating blazed at 700 nm.

Results

Figure 2 shows that if the electrolyte contains merely TEAPC as a conducting salt there is only a negligibly small cathodic photocurrent in the negative potential region (probably due to traces of copper). Adding 0.01M CuCl, the cathodic photocurrent is increased by an order of magnitude. Both the cathodic photocurrent and the cathodic dark current decrease when the electrode potential is kept at a constant negative potential. This causes the hysteresis in the cyclic voltammogram of Fig. 3a. When the scan direction is reversed at negative potential values, an anodic discharge current starts to flow which also decreases with time. When the potential is again swept into the negative direction, the onset of the cathodic photocurrent occurs more positive (Fig. 3a). Figure 3b shows the photo- and dark-current after an anodic charge of 16.5 mC/cm² had passed through the electrode at a potential of +0.4V vs. Ag/AgNO₃. In this case, there is clearly an additional increase of cathodic photocurrents. The onset of photocurrents is shifted further towards positive potential values. There is a similar increase in the photocurrent density when the crystal is pretreated with concentrated nitric acid to remove copper.

Color changes from red to black have been attributed to differences of the Cu content in the material (12). An electrode that had been treated before in concentrated nitric acid was illuminated to reintercalate copper with light. The surface of the crystal, which had turned opaque after treatment in concentrated nitric acid ($\text{Cu}_{6-x}\text{PS}_5\text{I}$), regained its red color and transparency ($\text{Cu}_6\text{PS}_5\text{I}$) in the neighborhood of the

Fig. 2. Photocurrent and dark current density as a function of the electrode potential applied on $\text{Cu}_{6-x}\text{PS}_5\text{I}$ (sweep rate: 20 mV sec⁻¹). (1) 0.01M TEAPC-acetonitrile, (2) after addition of 0.01M CuCl.

Fig. 3. Photocurrent and dark current density as a function of the electrode potential (sweep rate: 20 mV sec^{-1}). The electrolyte is $0.01\text{M CuCl}/0.01\text{M TEAPC}/\text{acetonitrile}$. cracks in the surface. These places are in general more favorable for intercalation than the smooth surface. The surface of the originally black electrode after illumination and passage of 54 mC/cm^2 photocurrent is shown in Fig. 4.

The intercalation of foreign guest ions can be conveniently monitored by x-ray fluorescence. Because of restrictions in lattice parameters, we tried to intercalate the small guest ion Ag^+ into a $\text{Cu}_{6-x}\text{PS}_5\text{I}$ electrode. The experiment was performed in a 0.02M AgNO_3 solution with a silver foil as counterelectrode. The potential was fixed at $E = -0.1\text{V vs. Ag/AgNO}_3$. A cathodic charge of 24 mC/cm^2 passed through the electrode which had been pretreated in HNO_3 . The outer part of the electrode broke away as a consequence

Fig. 4. Brightening up of regions along fracture lines ($\text{Cu}_6\text{PS}_5\text{I}$) of a copper-depleted material ($\text{Cu}_{6-x}\text{PS}_5\text{I}$) as a result of photo-intercalation.

of excessive intercalation far away from equilibrium. It contained 70% Ag. Within a layer of $25\text{-}30\mu$ beneath the surface of the electrode, the silver content was up to 20%. Figure 5 shows the distribution of silver perpendicular to the electrode surface.

To check whether this photointercalation mechanism allows the conversion of light energy into electrical energy we built a photoelectrochemical cell with a $\text{Cu}_{6-x}\text{PS}_5\text{I}$ crystal as the photoactive electrode and a silver foil as counterelectrode. No external potential was applied in this experiment. When illuminating the $\text{Cu}_{6-x}\text{PS}_5\text{I}$ electrode, there was a cathodic current flow as shown in Fig. 6. In the dark, the direction of the current did not reverse as it should have if the discharge reaction would have taken place. Also in the corresponding setup with copper, no discharge current was found in the dark.

Photocurrent spectra were recorded to prove whether the color change by chemical and electrochemical treatment is accompanied by a change in the bandgap of the material. Figure 7 shows the photocurrent spectra before, 1, and after treatment, 2, with HNO_3 . As a comparison, we show the absorption spectra before (b) and after (a) treatment with Br_2 , which also leads to the removal of copper from the $\text{Cu}_6\text{PS}_5\text{I}$ crystals (12).

Figure 8 shows the photocurrent spectra before, 1, and after, 2, passing an anodic charge of 10.6 C/cm^2 through the electrode at a potential of $E = 0.4\text{V vs. Ag/AgNO}_3$. The surface of the electrode turned black as a consequence of this electrochemical treatment.

Discussion

The mixed Cu ion conducting and electronic p-type semiconducting properties of $\text{Cu}_6\text{PS}_5\text{I}$ suggest photo-

Fig. 7. Photocurrent spectra (1, 2) and absorption spectra (a,b) of untreated $\text{Cu}_6\text{PS}_5\text{I}$ (1, b) and after passage of anodic charge ($10, 5 \text{ Ccm}^{-2}$) (2, a).

Fig. 8. Photocurrent spectra (1, 2) and absorption spectra (a, b) of untreated $\text{Cu}_6\text{PS}_5\text{I}$ (1, b) and after chemical deintercalation (2, a) (HNO_3 20 min at 50°C).

intercalation of Cu^+ ions as a possible photoreaction in the presence of Cu^+ ions. Figure 2 demonstrates that the presence of Cu^+ ions is responsible for the photocurrents observed in the $\text{Cu}_{6-x}\text{PS}_5\text{I}/0.1\text{M TEAPC-acetonitrile}$ (0.01M CuCl)/ Cu cell. Since in the potential region of this experiment Cu^{2+} does not exist (14), the only possible redox reactions of $\text{Cu}_{6-x}\text{PS}_5\text{I}$ with copper are plating of copper on the surface or intercalation of copper. We excluded the possibility that Cu is plated in this potential region in a separate experiment. At an electrode potential of $-0.65 \text{ vs. Ag/Ag}^+$, we passed a cathodic charge of 0.1 C/cm^2 through the electrode. This corresponds to about 300 monolayers of copper. But no copper layer could be observed on the electrode surface. Correspondingly, the x-ray fluorescence measurements show that in a photoreaction with Ag as a foreign guest atom, silver

is not plated on the surface of $\text{Cu}_{6-x}\text{PS}_5\text{I}$, but is incorporated into the bulk (Fig. 5). The fact that a black copper-deficient electrode regains the color and transparency of the copper-rich material upon illumination (Fig. 4) demonstrates that the removed copper is again inserted by light. The current-voltage behavior of Fig. 3 can be interpreted in terms of intercalation and deintercalation of Cu^+ ions. At positive electrode potential values, copper is deintercalated from the $\text{Cu}_6\text{PS}_5\text{I}$ lattice to give $\text{Cu}_{6-x}\text{PS}_5\text{I}$. Thus, the photocurrent density at a negative electrode potential increases because there are more unoccupied positions for the photointercalation of Cu^+ ions. The shift of the onset of cathodic currents after sweeping to positive potential values is also typical for an electrochemical charging/discharging reaction (15).

We think that our experiments demonstrate that intercalation of copper is the actual light reaction. A description of the photointercalation mechanism of Cu in terms of an energy band scheme is presented in Fig. 9. The electron created upon optical excitation within the space charge layer reduces the copper ion for intercalation into the $\text{Cu}_{6-x}\text{PS}_5\text{I}$ host lattice. The color change of $\text{Cu}_6\text{PS}_5\text{I}$ which is connected with the removal of Cu^+ ions from the $\text{Cu}_6\text{PS}_5\text{I}$ host lattice is not due to a change in the bandgap of the material. This can be concluded from the photocurrent spectra shown in Fig. 7 and 8. In both cases, there is no significant change in the bandgap that could explain the color change.

We assume that the creation of I_2^- color centers by the removal of Cu atoms is responsible for the in-

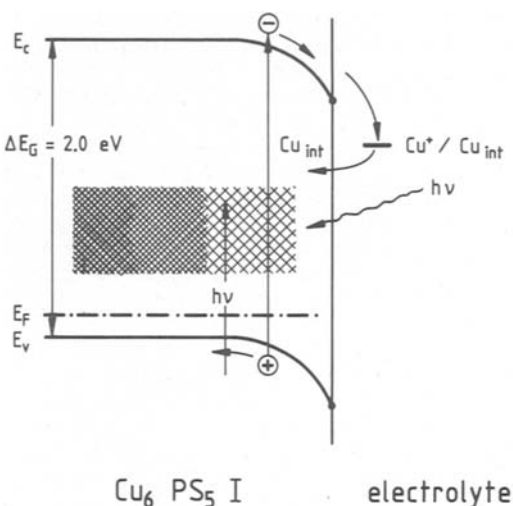

Fig. 9. Energy scheme of $\text{Cu}_{6-x}\text{PS}_5\text{I}$ showing electronic states of color centers (shaded area within the energy gap) and their annihilation as a consequence of photointercalation of copper (above).

Fig. 10. Principle of optical information storage device based on color center annihilation in $\text{Cu}_{6-x}\text{PS}_5\text{I}$ through photointercalation of Cu.

creased optical absorption in $\text{Cu}_{6-x}\text{PS}_5\text{I}$. When copper atoms are removed from the lattice iodine atoms are left behind. These atoms together with normal I^- ions form I_2^- color centers. Similar color centers can also be found in LiF crystals (16). The energetic positions of the electrons that can be excited optically from these color centers are shown in Fig. 9a as a shaded area. When copper is intercalated into $\text{Cu}_{6-x}\text{PS}_5\text{I}$, the color centers disappear. The opaque crystal brightens to a red color.

Though photointercalation reaction with suitable materials provide, in principle, means to convert and store light energy as chemical energy, the photointercalation reactions studied are not suited for energy conversion because there is little tendency for a discharge reaction in the dark (Fig. 6). The color change associated with the photointercalation of copper could, however, in principle, be used to store optical information. Such an optical storage element for one bit is shown in Fig. 10. It consists of a grain of $\text{Cu}_6\text{PS}_5\text{I}$ in contact with a Cu ion conducting material which has to be transparent in the region of interest. At the front there is a ring-shaped copper counterelectrode. An external voltage can be applied between the copper electrode and the ohmic back contact.

The red transparent copper-rich crystal symbolizes a logical "1" the opaque crystal a logical "0". When this element is illuminated with light of an energy $h\nu > \Delta E_G$, copper can be photointercalated into the $\text{Cu}_6\text{PS}_5\text{I}$ lattice. Since the opaque crystal regains its transparency in this way, one has written a "1" into the element. The information can be read out with light of an energy $h\nu < \Delta E_G$.

To delete the stored "1," one has to apply a positive voltage at the $\text{Cu}_6\text{PS}_5\text{I}$ electrode. The crystal becomes opaque when the copper ions are released from the crystal into the electrolyte. This element has the advantage of the stored information not being lost when the external voltage is switched off.

To make such an element technologically applicable further studies concerning the reversibility and stability of such a device are necessary.

ABSTRACT

Interdiffusion between thin films of aluminum (Al) and polycrystalline silicon (poly-Si) has been studied with the purpose of obtaining a stable interface upon sintering for IC metallization. The solid-phase crystal regrowth of Si due to this low temperature interdiffusion has also been investigated. Dopant segregation towards the interfaces and the grain boundaries of arsenic-implanted poly-Si was used successfully to control the kinetics of Al-poly-Si interactions. The correlation between the arsenic depth profiles, the Si-layer microstructure, and the sintering behavior of the Al-poly-Si interface was measured by RBS, (scanning) AES, SEM, TEM, and grazing incidence x-rays. Quantitative results and discussion of the diffusion mechanisms at work are presented. It is shown that the presence of an arsenic segregation peak on top of the poly-Si layer stabilizes Al/poly-Si interface. A concentration of 10^{19} atom/cm³ appears to be a minimum threshold for sintering at 465°C.

The aluminum-silicon (Al-Si) contact, which is extensively used in semiconductor technology, is a limiting factor in scaling down integrated circuit components. The sintering of the Al-Si interface, necessary to obtain good ohmic contacts, introduces reliability problems due to interdiffusion between Al and Si and crystal regrowth of the dissolved material. These interactions may appear for any structural morphology of the Si substrate: single-crystal Si (1, 2), polycrystalline Si (poly-Si) (3), or amorphous Si (4, 5). The low temperature enhancement of Si crystal regrowth, due to the diffusion of Al atoms, presents interesting prospects for solid-phase epitaxy (6, 7).

Because of the extensive use of LPCVD poly-Si in integrated circuits, poly-Si-Al interfaces command particular attention. Forming contacts by means of Al-poly-Si structures has been shown to reduce diode reverse current by a factor of 10 and enhances bipolar transistor gain (8). In addition, MOS circuit density might be increased if the Al-contact were made directly on the poly-Si gate.

Such Al-poly-Si structures require well-defined, stable interfaces. This requirement is not fulfilled by classical Al-metallization, justifying the use of sophisticated technologies to create diffusion barriers between Al and Si. In the present work, a good stability of the Al-poly-Si contact has been brought about by taking advantage of the presence of arsenic, which segregates to the grain boundaries (GB's) and to the interfaces of the poly-Si film. Indeed, Al diffuses mainly along the GB's in the poly-Si layer (9, 11), while Si atoms are mainly extracted from the poly-Si GB's (10, 11), and solute atoms within the GB's of polycrystalline films are known to decrease the diffusivities within the layers involved (12) both for self-diffusion and impurity diffusion.

This paper shows that Al-poly-Si interdiffusion strongly depends upon the dose of dopant in Al-poly-Si and the location of this dopant within the microstructure; it gives evidence that dopant segregation can reduce Al diffusivity in poly-Si, and that this segregation effect, if present at the Al-poly-Si interface, can totally inhibit interdiffusion between the two films at usual sintering temperatures (465°C in this work). In the present work, ion implantation and thermal annealing were used to introduce the arsenic

into the desired sites, while several solid surface analysis techniques were combined to study the interface behavior. The results show that an arsenic segregation peak on top of the poly-Si layer must be preserved to obtain interface stability. A peak concentration of 10^{19} atom/cm³ appears to be a minimum threshold. Since interconnection stripes of poly-Si must always be heavily doped, this condition can be fulfilled in any standard technology, if special attention is paid to the treatment of the poly-Si surface layer before metallization.

Experimental Procedure

From among the standard dopants of Si, arsenic was chosen because of its attractive features: high solid solubility in Si, low thermal diffusivity, and easy detectability in solid surface analysis. To enhance the arsenic influence upon the Al-poly-Si contact, a peak concentration was created in the top region of the poly-Si layers by using low energy ion implantation or adjusted thermal annealing schedules.

Identification of key parameters.—Several parameters influence thin film interfaces during thermal treatment. These are layer thickness, grain size, crystalline defect density, interface quality, and the presence of a native oxide between the layers. Their roles are usually linked together in technological processes. Consequently, five sets of samples were prepared to set apart the influence of the dopant from the other factors (Fig. 1). In each set of samples, the influence from the single-crystal substrate was avoided by growing a SiO₂ layer on it before poly-Si deposition. Such an Al/poly-Si/SiO₂/Si structure appears in MOSFET circuits when an Al contact is made on the poly-Si gate.

In the samples of set I, no implantation was made to provide comparison with doped samples and previous works using intrinsic poly-Si (3). The next four sets of samples were As implanted, but various poly-Si microstructures were created in order to analyze effects related to crystallinity. In the samples of set II, the implantation damage was not removed; a thin amorphous layer, (0.035 μ) containing most of the As, was formed near the poly-Si/Al interface. A high As concentration was thus present near the contact, but without segregation within the Si structure. In set III, a totally amorphous layer of Si was used, to compare the behavior of these samples with the one having a poly-Si layer amorphous only within a thin surface

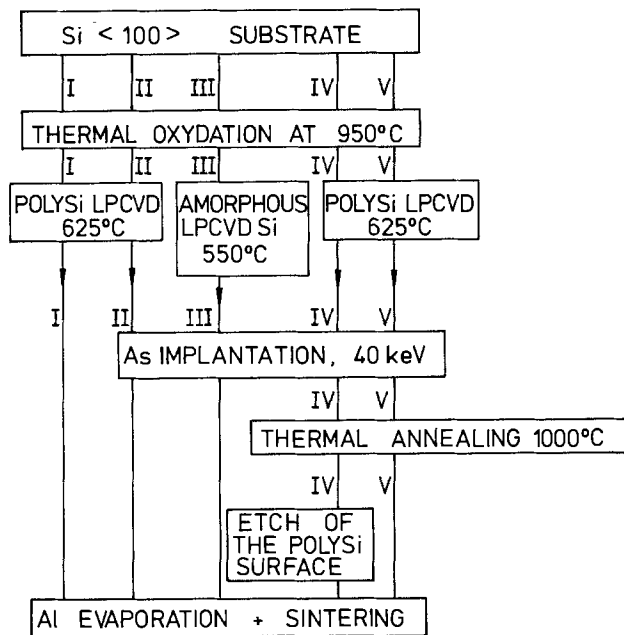

Fig. 1. Flowchart of the technological steps undergone by the samples.

region (set II). In the samples of set IV and V, the polycrystalline structure of the Si layer was restored after implantation, by annealing. In the two sets of samples, the As was expected to have segregated to the interfaces and the GB's (13, 14). A fraction of the implanted dose, thus accumulated at the poly-Si surface, was removed before Al deposition in the samples of set IV, while it was kept in the samples of set V to study its effect upon an interdiffusion at the Al/poly-Si contact independently of the influence of the segregation at the GB's.

Sintering duration ranged between a few minutes and tens of hours. In those cases where interdiffusion takes place, a characteristic duration of interaction can thus be determined.

Sample preparation.—Wafers of N-type <100> single-crystal Si were thermally oxidized and divided into five sets. The oxide thickness was $0.1 \pm 0.005 \mu$, and the substrate resistivity 11–18 Ω cm. Sets I, II, IV, and V were capped with a poly-Si film deposition in an LPCVD reactor at 180 mtorr, at 625°C, with thicknesses ranging between 0.1 and $0.45 \pm 0.01 \mu$. Set I consisted of intrinsic poly-Si layers to reproduce Nakamura's experiment (3) in order to provide a reference for comparison with doped samples. Sets II, IV, and V received a shallow implantation of As (40 keV), at three different doses: $5 \cdot 10^{15}$ atom/cm², $5 \cdot 10^{14}$ atom/cm², and $5 \cdot 10^{13}$ atom/cm². In sets IV and V, the implantation damage was removed by a 1000°C¹ annealing under a N₂ ambient for 45 min, resulting in both As diffusion within the grains of the films and As segregation towards the GB's. The grain size at the poly-Si surface increased from 0.04 μ , which is the usual size for a 625°C deposit (15), to 0.1 μ for doses of $5 \cdot 10^{15}$ atom/cm² and $5 \cdot 10^{13}$ atom/cm², and to 0.15 μ for $5 \cdot 10^{14}$ atom/cm². The wafers of set IV were etched in a diluted solution of hydrofluoric acid (2%) for 5 min to remove the accumulated As at the surface. Tests showed that several minutes are necessary to completely remove the accumulated As. Amorphous Si was deposited on set III (550°C LPCVD) and implanted like the previous samples (but without any further high temperature annealing step). Al layers with thickness ranging between 0.3 and 1.1 μ were then

¹ The temperature chosen constitutes a practical compromise to obtain high electrical activation, to remove implantation damage, and to induce As segregation.

evaporated by electron gun at a rate of 0.0025 μ /s under a working pressure of 10^{-6} torr. Figure 1 summarizes the characteristics of the five sets of samples. Every set of samples was sintered at 465°C in both forming gas (90% N₂ and 10% H₂) and N₂ ambient.

Analytical techniques.—RBS measurements were made on each sample, since this technique provides a quick diagnosis of compositional changes, layer thickness, and interface modifications. A 2 MeV helium beam, delivered by the University of Louvain Van der Graaff accelerator and having a cross-sectional area of approximately 1 mm², impinged upon the targets under working pressure of 10^{-6} torr. Backscattered particles were counted by a solid-state detector having a 15 keV resolution. Measurements were laterally averaged over the dimensions of the spot.

Auger electron spectroscopy (AES), performed with a 3 keV electron beam, was used under a working pressure lower than 10^{-9} torr to study more accurately the compositional changes at the surface and resolve some ambiguities in the RBS spectra. Scanning and transmission electron micrographs (SEM and TEM) provided further information, such as grain size and surface topology. X-rays at grazing incidence were used to verify the composition and crystallinity of the layers.

Experimental Results

Table I summarizes the results obtained in the present work by specifying the annealing time at which interdiffusion takes place for each set, and thus each microstructure, for each dose and for Al and Si thicknesses of 0.3 μ .

Similar results were obtained for the Al/poly-Si interface stability for the next combination: 1.1 μ Al on 0.3 μ poly-Si, 0.5 μ Al on 0.3 μ poly-Si, 0.3 μ Al on 0.5 μ poly-Si, and 0.3 μ Al on 0.1 μ poly-Si (see Fig. 4 below).

For each sample, the figures showing the corresponding RBS spectrum and micrographs are given in cases where the measurements are specifically presented in the paper. Otherwise, samples having features identical to those already illustrated are not shown, but are specified by "as in Fig. . . ."

Microstructural effects.—As previous work has shown (5), increasing the grain size of the poly-Si layer reduces interdiffusion between Al and poly-Si. In the present study, it was found that the structure of the poly-Si layer near the Al-poly-Si interface can have an effect upon the interdiffusion kinetics stronger than that of the average microstructure. This becomes obvious when comparing the sintering behavior of the samples of sets II and III. In the samples of set II, the top of the 0.3 μ poly-Si layer is highly amorphized by ion implantation within a thickness of 0.04 μ .² In the samples of set III, the whole Si layer is amorphous. Even after the shortest annealing time (5 min), both sets of samples exhibited the same level of strong interdiffusion; RBS analysis (Fig. 2a) show that the original Al/poly-Si interface completely disappears, and that a new interface is formed at the same place. This fact shows that most of the Si migrates towards the free surface, while the Al goes down towards the oxide. AES confirms that Si is present in concentration as high as 75 atomic percent (a/o) (Fig. 2b) within the first monolayers of the sample surface, for both sets. Since more than 50 a/o of the original Al layer has been replaced by Si, such an interdiffusion may be called "layer inversion."

Most of the implanted arsenic appears to be trapped at the new interface region, while a fraction of it

² The dose threshold making mono-Si amorphous at 40 keV is $2 \cdot 10^{14}$ atom/cm² for P (mass = 29 amu) and $8 \cdot 10^{13}$ atom/cm² for Ga (mass = 70 amu) (16). Since poly-Si layers contain already much more disorder than mono-Si, a dose of $5 \cdot 10^{13}$ atom/cm² of As (mass 75 amu) is enough to amorphize the region being implanted.

segregates at the new Si surface, this fraction being independent of the original dose, as is clearly seen for the profile ϕ_2 (As dose = $5 \cdot 10^{14}$ atom/cm²), at $50\times$ in Fig. 2a. No measurable concentration of arsenic appears near the oxide.³ Thus, comparable compositional changes occur at the same rate in both sets of samples, although 90 a/o of the Si-layer of samples of set II (shallow implanted poly-Si) is polycrystalline. In addition, the presence of an amorphized top region enhances by at least two orders of magnitude the rate of interdiffusion between Al and poly-Si, as compared to undamaged poly-Si layers. The sintering time needed to get the same level of interdiffusion with intrinsic poly-Si (set I) appears to be 10h at 465°C. These results for intrinsic poly-Si (set I) are consistent with Nakamura's work (3).

The difference in microstructure between set I (intrinsic poly-Si), set II (implanted poly-Si), and set III (amorphous Si) determines the morphology of the inverted layers (Fig. 3). Intrinsic poly-Si (set I) and implanted poly-Si (set II), in spite of different sintering durations, evolve to the same microstructure (Fig. 3c) when reaching "inversion." The new Si layer, formed on the top of the structure, consists of large, flat crystallites, several microns wide, for poly-Si layers 0.3μ thick and Al layers 0.3μ , 0.5μ , and 1.1μ thick. Segregated Al is found between the crystallites, in quantities corresponding to the concentration measured by AES when averaged on 1 mm² spot (between 25 and 30 a/o). Spatially resolved AES (Fig. 3a) shows that the Al concentration within the Si crystallites falls below the detectability limit (0.1%), and that the Si concentration within the Al region does also.

Micrographs also reveal certain aspects of the interdiffusion mechanisms. Some of the largest grains (0.1μ) of the original poly-Si layer are left undissolved under the new crystallites. TEM and SEM photographs show that the Si layers have evolved a step further than in Nakamura's work (3). The original state of the layers is depicted in Fig. 4a. Figure 4b shows Nakamura's results (3). In the present case, the original Si layers

³The original measurable dose of arsenic is found by adding the interface and surface signals in the RBS spectra.

have been nearly consumed. The reaction scheme can thus be completed (Fig. 4c). New crystallites reach the surface and can grow up to 60μ wide. The thickness of both films affects the final microstructure of the reacted films, as Nakamura has previously shown for intrinsic poly-Si (3), and as depicted in Fig. 4b. Figure 4c of the present work shows that the relative thickness of the layers fixes the final microstructure of the inverted layers, but does not affect the interdiffusion at the interface. Since this fact was observed for each set of samples, only results for Al and Si layers 0.3μ thick are presented. When the Al layer dissolves in the Si, a coalescence effect appears, due to the surface tension within the Al film, so that flattened Al globules are formed on the new Si surface (Fig. 3b, 3c).

The persistent coloration of the sintered Al layers is due to the effective dielectric constant of the inverted layers. A characteristic resonance appears at a given wavelength, depending on the distribution and the geometrical factors of the Al globules (16), so that different colors were observed for samples having different microstructures.

If Si crystallites formed from an amorphous layer (set III) are compared with those formed from poly-Si (sets I and II), they appear to be smaller (1μ) for the same level of inversion (Fig. 3c). As compared to samples of set II, they are smaller by one order of magnitude for the same sintering time. They are regular, hexagonal, and interconnected in chain, which is not the case for the large islands of Si formed in samples of sets I and II. Hence, the state of the Si top region is responsible for a sudden interdiffusion, but the morphology of the whole layer fixes the microstructure of the new Si crystallites.

Effect of dopant location in the microstructure.—As can be inferred from Fig. 2a and Table I, (columns II and III), dopants introduced in the Si layer do not affect interdiffusion if they do not interact with the microstructure. The samples of sets II and III are not found to be dose dependent. Arsenic in concentrations as high as 10^{21} atom/cm³ near the surface has no effect upon the interdiffusion kinetics in an amorphous environment at the sintering temperature used

Fig. 2. A, top: RBS spectra of samples of set II and III, before and after 5 min of sintering at 465°C in forming gas, for a dose of $5 \cdot 10^{15}$ atom/cm² (ϕ_1) and of $5 \cdot 10^{14}$ atom/cm² (ϕ_2). (Structure of sample depicted in upper corner, $t_{Al} = t_{poly-Si} = 0.3\mu$). After annealing, Si and arsenic are detected on the surface, while the Al/poly-Si interface is inverted. B, bottom: Typical AES spectra of the sintered samples of (a), shown here for the case $\phi_1 = 5 \cdot 10^{15}$ atom/cm², set II.

here (465°C). In the samples of sets IV and V, where the polycrystalline structure of Si is restored by thermal annealing after ion implantation, the dopant diffused within the whole layer. The As profile is flat except at the poly-Si/Al and at the poly-Si/SiO₂ interfaces, where accumulation of the dopant due to segregation occurred during annealing. As can be seen from Fig. 5, curve V, for an As dose of $5 \cdot 10^{15}$ atom/cm² implanted in a 0.3- μ -thick poly-Si layer, As concentration at both interfaces is $1.4 \cdot 10^{20}$ atom/cm³, while the mean concentration within the film is $6.8 \cdot 10^{19}$ atom/cm³. Grazing angle RBS measurements with a depth resolution of 40Å showed that As pile-up is confined within a 150Å region. After etching (curve IV, Fig. 5), the segregation peak at the poly-Si surface disappears, and the As concentration appears to be less in this region than within the film, showing clearly that the poly-Si surface has been depleted in As. Thus, in samples of set IV, where the surface peak is removed (Fig. 5b, IV), only the As diffused within the grains and the As segregated at the GB's play a role.

During sintering tests, the Al/poly-Si interface evolution is strongly dose dependent. After 30 min of sintering, only the samples implanted with the lowest dose ($5 \cdot 10^{13}$ atom/cm²) lose their interface definition (Fig. 6). Hence, the annealing treatment after ion implantation has increased the interdiffusion time by one order of magnitude, as compared to samples of sets II and III. The dose dependence is not related to a large increase of the grain size following the enhancement of poly-Si grain growth rate by As doping. Indeed, at concentrations above 10^{19} atom/cm³, the presence of As decreases this rate (14), and it is precisely above this level that As segregation at the GB's inhibits interdiffusion in this experiment (Fig. 6). Moreover, SEM micrographs show that grain size increase was about the same for both the lowest and the highest dose used (0.1 μ).

In the samples of set V, the As has segregated at the poly-Si surface before Al deposition. Due to the presence of As, samples could withstand 65h of sintering without significant interdiffusion at the Al/poly-Si

Fig. 3. A, above: Scanning AES spectra of the sample of Fig. 2b, $t_{Al} = t_{Si} = 0.3\mu$, $\phi_1 = 5 \cdot 10^{15}$ atom/cm², $t = 5$ min, $T = 465^\circ\text{C}$, in forming gas (set II). This distribution is typical for inverted layers. B, right: Typical SEM micrograph of the surface of inverted poly-Si; on the left for the same sample in Fig. 3a; on the right for an undoped sample of set I, with $0.3\mu = 0.3\mu$ for $t = 10$ h, $T = 465^\circ\text{C}$ in forming gas, after Al was etched to put in evidence the grain structure. Comparison of both pictures shows that the grain size is the same. The right one shows some undissolved poly-Si under the new crystallites. C, right: Typical optical micrograph of the surface of inverted layers, obtained from amorphous Si (set III), here for the case $5 \cdot 10^{15}$ atom/cm², $t_{Al} = t_{poly-Si} = 0.3\mu$, $t = 5$ min, $T = 465^\circ\text{C}$ in forming gas, before (left) Al was etched. Right: SEM micrograph of the same layer after Al etch. D, right: TEM micrographs of the Si crystallites as in B, after Al etch. The electron diffraction pattern shows that they consist of single-crystal Si. E, right: TEM micrographs of the Si crystallites as in C after Al etch. The electron diffraction pattern shows that they consist of small-sized Si crystals.

interface (Fig. 7, V) while the samples of set IV (etched poly-Si) experienced interdiffusion for the same annealing time. The inversion effect decreased as dose increased in this last set of samples, in contrast with the unannealed samples of sets II and III, which did not show dose dependence (Fig. 2). However, the inverted layers of samples of set IV had the same microstructure as the other poly-Si samples of sets I and II (Fig. 3b). For the highest dose, the As profile moved from a flat line (Fig. 5, IV) to an exponential decay (Fig. 7, IV), with an identical accumulation on the surface, as in the case of samples of sets II and III (Fig. 2).

Discussion

According to the present results, the interdiffusion between thin films of Al and poly-Si appears to reach thermodynamic equilibrium under annealing by a complex mechanism, the kinetics of which can be controlled. During the establishment of thermodynamic equilibrium, the extent to which Al and poly-Si dissolve into each other cannot be predicted from the Al-Si phase diagram for bulk material (19). Moreover, this dissolution is accompanied by two complex phenomena: the segregation of a significant amount of Si to the free surface of the layered structure and the enhancement of Si crystal regrowth at low temperatures.

Kinetics of the interdiffusion between Al and poly-Si layers.—The extensive interdiffusion between Al and

poly-Si is consistent with some of their properties affecting the kinetics of the Al-Si system. Al and Si have about the same atomic radius, 1.43 and 1.32Å, respectively.

The Al is a p-dopant for Si. The radius of a positively ionized Si atom decreases down to 0.41Å and diffuses more easily in Al. This effect will especially be important in poly-Si, because GB's offer additional Al-Si contact sites. Since Al penetrates extensively within the disordered structure of the poly-Si GB's (9, 11), more Si atoms will tend to be ionized in poly-Si than in mono-Si.

In the case of amorphous Si (sets II, III) the diffusion of Al is enhanced by the higher density of defects. On average, many more Si atoms will be in contact with Al atoms, so that the interdiffusion rate will be increased.

An As-rich poly-Si/Al contact and As-rich GB's will induce an increase of the size of the Si atoms, radius (2.71Å), implying a slowing down of the diffusion, as observed for sets IV and V (Fig. 6 and 7, curve V).

The modification of the electronic environment of semiconductor atoms by a metallic contact has also been proposed by Hiraki to explain the migration of Si atoms from a mono-Si substrate through a metal layer towards the free surface, in ultrahigh vacuum, under low temperature annealing. He proposed that Si atoms turn to a metallic state, where they form bonds with the metal atoms at the interface (20). In

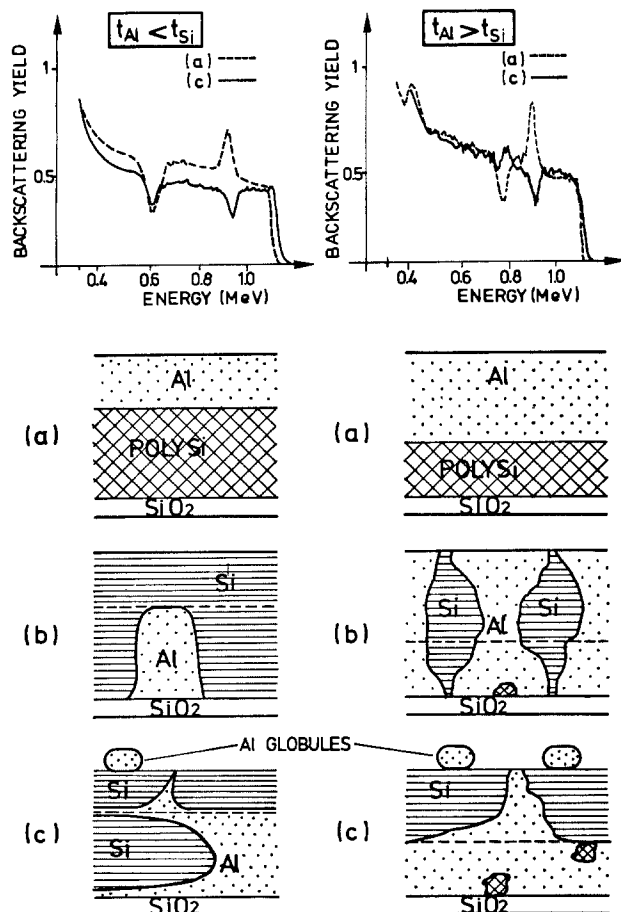

Fig. 4. Scheme of the interdiffusion phenomenon between Al and poly-Si, with corresponding RBS spectra, in the case of a thicker (left) and a thinner (right) Al layer. Diagram (b) is from Ref. (3) and shows mixing between Al and poly-Si. Diagram (c) is more detailed because more analyses were made in the present work.

the present work, we propose further that this effect induces a decrease of the size of the Si atoms, and thus facilitates the Si diffusion within the Al film.

Moreover, the presence in poly-Si and in amorphous Si layers of more Si atoms in a metallic state explains the extensive interdiffusion observed in those disordered microstructures.

We extend Hiraki's results obtained in UHV to real processing conditions for non-monocrystalline Si. Indeed, Hiraki's metal-deposition, annealing, and AES measurements in UHV lead to a final surface composition with Si present in the first monolayer. In the present work, AES measurements depict the surface as contaminated by a first monolayer of carbon, under which an oxygen layer was found chemically bonded to a third monolayer of Al, thus forming Al_2O_3 . Si was detected under this native oxide, which probably inhibits the last step of segregation.⁴

On the other hand, we have shown that by saturating with As the interface and GB's of poly-Si, the interdiffusion mechanisms could be inhibited in agreement with the proposed model.

Thermodynamics of the Al/poly-Si system.—The diffusion mechanism induced by the modification of the electronic environment of Si atoms is thermodynamically favored by the following properties of Al and Si.

1. The bonding energy of an Al-Si atomic pair is lower than that of an Al-Al or of a Si-Si pair, implying that the formation of Al-Si pairs is actually promoted at the Al/Si contact sites.

2. The segregation of the liberated Si atoms at the surface is then induced by the lower free surface energy of Si (0.6 J/m^2) (21), as compared to that of Al (1.2 J/m^2) (22).

3. The enhancement of Si crystal regrowth on an amorphous substrate (SiO_2) depends on the original crystalline state of the layer. In the case of amorphous Si (set III), crystallites appear on the sample surface, but are smaller than in the case of poly-Si (sets I, II, IV). Since the larger crystallites of the original layer are the last to disappear, it can be assumed that Si first dissolves in Al, then segregates to the surface and crystallizes. The dependence on the original state of the layer may be explained by a transfer of the dissolution energy into crystallization energy, since for equally

⁴This may explain the results obtained by Faith who stabilized Al/Si contacts by an alternate deposition of Al and Al_2O_3 (23).

Fig. 5. RBS spectra of samples of sets IV and V before sintering for a dose of $5 \cdot 10^{15} \text{ atom/cm}^2$. $t_{\text{Al}} = t_{\text{poly-Si}} = 0.3 \mu$. The arsenic profile of V reveals segregation to both interfaces of the poly-Si layer. In the case of IV, the segregation peak at the Al/poly-Si interface has been etched and the poly-Si surface is depleted in As. Otherwise, both spectra are identical.

Fig. 6. RBS spectra of samples of set IV, $t_{\text{poly-Si}} = 0.3\mu$, $t_{\text{Al}} = 0.5\mu$, after 30 min of sintering in forming gas showing the dose dependence of the interface stability. The sample which is arsenic implanted with a dose of $5 \cdot 10^{13}$ atom/cm² has lost its interface definition and intermixing of the layers has occurred, while the samples implanted with a higher dose show a good stability.

fast diffusing layers (set II and III, Table I), there is a difference of one order of magnitude between the size of the resulting crystallites.

Inhibiting As concentration.—The threshold concentration of 10^{19} atom/cm³ found here to inhibit interdiffusion appears in other diffusion-in-poly-Si effects (18).

In order to explain the dependence of the poly-Si grain growth on the dose and nature of dopants, Mei assumed a diffusion controlled process (18). In the case of As, he quantitatively accounted for the fact that the poly-Si grain growth, enhanced at low doses, decreases for concentrations above 10^{19} atom/cm³. Therefore, he used a diffusion model including segregation. The Al diffusion in poly-Si studied here is in-

hibited by the same dopant at the same threshold concentration, but only if segregation has occurred in the poly-Si.

Thus, we may conclude that the steric configuration of negatively ionized Si atoms at the GB's and interfaces in As-doped poly-Si slows down both the Si diffusion and the Al diffusion in the layer.

An additional reason for Al-Si bonds not to be formed may be the saturation by As of the dangling bonds (DB) at the interface and GB's, under thermal annealing (set IV and V). A concentration of 10^{19} atom/cm³ should then be enough to passivate the majority of DB at the poly-Si surface, an estimate which is difficult to ascertain by measurement of the poly-Si surface structure and its concentration of DB.

Fig. 7. RBS spectra of the samples of sets IV and V, $t_{\text{Al}} = t_{\text{poly-Si}} = 0.3\mu$ for a dose of $5 \cdot 10^{15}$ atom/cm² after 65h of sintering, showing the correlation between the poly-Si-Al interface stability and the arsenic depth profiles within the poly-Si layers. Sample V has kept a good interface definition because of the presence of the As segregation peak, while sample IV is inverted.

Conclusions

The sintering behavior of the poly-Si/Al interface has been investigated. Our aim was to stabilize this interface. Since solute atoms within GB's of polycrystalline films can decrease the diffusivity within the layer, advantage has been taken from the fact that poly-Si must be heavily doped to obtain a high conductivity, as it is the case in a standard IC fabrication. A systematic procedure was conceived to observe the mechanisms at work. Several solid-state surface analysis techniques were combined to obtain a detailed picture of the sintered layers. Results may be summarized as follow.

1. Dopant segregation is effective in reducing the Al diffusivity within the poly-Si film (set IV, V).

2. The microstructure at the top of the poly-Si layer appears to have more influence upon the interface behavior than the morphology of the whole layer (set II).

3. The top region of the poly-Si layer also plays a basic role when a dopant is present. Segregation of the dopant to this surface has a greater inhibition effect upon the Al/poly-Si interdiffusion than the segregation to GB's.

4. Both the microstructure of the poly-Si surface and the dopant segregation within the first monolayers appear to control the diffusion to such an extent that they can inhibit diffusion through layers as thick as 1μ , (set V). Generally, this fact shows that interface and surface properties can totally determine the behavior of thin films.

5. Understanding the mechanisms at work allows controlling the kinetics of thin film interaction by inhibiting the initiating phenomenon at a monolayer scale.

6. The effects observed in this work could be explained by several physical considerations, which were shown to complete existing models.

Further electrical measurements are presently being made upon stabilized contacts and will be published shortly. The entire experiment will be repeated with other segregating dopants.

Dry Developable Multilayer Resist Using Direct Pattern Formation by Electron Beam-Induced Vapor-Phase Polymerization

Masao Morita, Saburo Imamura, Toshiaki Tamamura, Osamu Kogure, and Kei Murase

Nippon Telegraph and Telephone Public Corporation, Ibaraki Electrical Communication Laboratory, Polymer Section, Tokai, Ibaraki, 319-11, Japan

ABSTRACT

A new technique for high resolution lithography with a dry-developed multilayer resist system is demonstrated. The technique involves a direct pattern fabrication by electron beam-induced vapor-phase graft-polymerization. No wet process was included in the pattern fabrication. The use of a double-layer base film consisting of a thin silicone resin as a top layer and a thick AZ-1350J film as a bottom layer enabled the transfer of graft-polymerized polystyrene patterns on the silicone resin to thick resist with submicron-sized feature.

As the minimum feature of semiconductor devices becomes smaller, the fabrication process becomes more difficult when achieving high resolution lithography. Recently, two kinds of approaches were extensively studied to solve the difficulties. One is the dry development of resists, which can eliminate various problems involved in wet development, such as a resolution loss by resist swelling (particularly in negative-type resists), the treatment of large volumes of organic or inorganic solvents, and poor adaptability to automatic line fabrication processes (1, 2). However, it is not easy to obtain sufficiently large differences in dry etching rates for dry developable resist systems. This often causes the serious reduction in patterned resist thickness.

Another is the multilayer resist system, which realizes submicron resist patterns with a high aspect ratio. This method is extremely effective and becomes inevitable for high resolution lithography on uneven substrates (3-6). However, almost all multilayer resist systems reported so far employ the wet development to define the exposed patterns in top thin resist (7). In this paper we report a novel technique for a dry-developed multilayer resist.

Our principle for dry development is direct pattern formation by electron-beam-induced polymerization. In polymer chemistry, this process is called graft polymerization. When polymer films are subjected to an organic monomer gas after or during high energy beam exposure, polymeric materials are deposited on exposed areas of film (8-10). If a significant difference in dry etching characteristics between deposited graft-polymer and the base polymer film obtains, dry development is possible by etching the base film using the patterned graft-polymer as a mask. We have found that a class of silicone resins can initiate electron-beam-induced graftpolymerization with a reasonable sensitivity and can be applied to this multilayer resist system.

Figure 1 shows our process for dry-developed multilayer resist. A thick organic polymer layer, 1.0 μm of AZ-1350J photoresist (Shipley), was coated on a silicon wafer and baked at 230°C for 1h. The baking makes the film insoluble in organic solvents. The room temperature vulcanizing silicone varnish (Toray Silicone) was spun at 2000 rpm on the AZ layer. The varnish is instantly cured by moisture in the air during the spinning and makes about 0.5 μm thick film.

The wafer was then exposed with an electron beam exposure machine ESM-301 (Elionix) operating at 20 kV, which was modified to allow the exposed wafer to be subjected to vapor-phase graft polymerization. The exposed wafer was transferred from the exposure chamber to the grafting chamber through a gate valve without contacting the air. The grafting chamber was in vacuum so that the graft monomer could be easily vaporized and introduced to the grafting chamber

when the valve connecting the chamber and monomer vessel was opened. The temperature of the wafer was controlled at a slightly higher temperature than that of the monomer in the vessel, in order to prevent the monomer gas from condensing on the wafer. Grafting time was 60 min, and monomer pressure was 3 torr. Styrene was selected as a graft monomer because it is known to have a relatively high dry-etch resistance. The monomer was purified by fractional distillation and degassed to remove dissolved oxygen. After grafting, the wafer was removed from the grafting chamber.

The graft-polymerized patterns were transferred to the silicone layer by means of reactive ion etching using CF_4/H_2 gas with a parallel-plate etching machine DEM-451 (ANELVA). The etch rate of the silicone layer was 100 nm/min, whereas that of the graft polymerized polystyrene was less than 70 nm/min. Using the obtained silicone patterns as a mask, the AZ-1350J layer was reactive ion etched with oxygen

Fig. 1. Processing sequence schematic for direct pattern formation by electron-beam-induced vapor-phase polymerization. (a) Bottom layer coating. (b) Top layer coating. (c) Electron beam exposure. (d) Vapor phase polymerization. (e) Transfer of graft-polymerized pattern to silicone. (f) Transfer of silicone pattern to AZ.

Fig. 2. Sensitivity curves of silicone resin grafted with styrene for 60 min. (a) Silicone varnish (polydimethylsiloxane). (b) Silicone varnish containing 7% vinyl groups.

gas. The oxygen ion etching rate of AZ-1350J at 200 mtorr is 110 nm/min. As the silicone layer does not show any thickness reduction by O_2 gas etching, thick resist patterns can be fabricated without any wet process in our system.

A typical sensitivity curve is given for an electron-beam-initiated graft polymerization in Fig. 2a, where styrene monomer was grafted on $0.5 \mu\text{m}$ silicone resin for 60 min. The Y-axis of Fig. 2 indicates the observed thickness increase in the exposed areas.

Figure 3 shows an SEM picture of thick resist patterns fabricated by our method, where $0.5 \mu\text{m}$ wide lines were obtained with $1.0 \mu\text{m}$ spaces. The resulting resist patterns have vertical walls with a linewidth loss less than $0.1 \mu\text{m}$ in a sidewall. The surface residue resulting from unetched silicone resin in the unexposed region would be removed if the silicone resin was slightly overetched.

The electron beam sensitivity can be significantly improved by introducing vinyl groups into silicone resin, as shown in Fig. 2b. In the lower dose region, the sensitivity curve has a rather long tail, but shows a substantial thickness rise beyond $10 \mu\text{C}/\text{cm}^2$. This long tail does not affect the resolution of this system, because a slight overetching of the silicone layer can easily remove the thinly grafted polystyrene in the tailing region. This means that the steep rise in the sensitivity curve beyond $10 \mu\text{C}/\text{cm}^2$ defines the high resolution of the system.

The use of multilayer system is essential with respect to the resolution. As the film deposition by graft polymerization has no anisotropic characteristics, the grafted polymer should be as thin as possible to minimize a pattern broadening. This means that the base film thickness to be directly etched with the mask of graft-polymerized film is severely limited by the resolution to be achieved. The combination of thin silicone resin as a directly etched layer using graft-polymerized film and thick organic polymer as the bottom layer can resolve the conflict between resolution and the overall resist thickness with this new technique.

Fig. 3. SEM of reactive-ion-etched AZ pattern showing a $1.0 \mu\text{m}$ wide line in $1.0 \mu\text{m}$ thickness using direct pattern formation by electron-beam-induced vapor-phase polymerization. Upper resist: polydimethylsiloxane. Dose: $80 \mu\text{C}/\text{cm}^2$. Grafting time: 60 min.

In summary, a new technique for high resolution lithography with a dry-developed multilayer resist system was demonstrated. The technique involves a direct pattern formation by electron-beam-induced vapor-phase polymerization. The use of a double-layer base film consisting of a thin silicone resin as a top layer and thick AZ-1350J film as a bottom layer enables the transfer of graft-polymerized polystyrene patterns to thick resist patterns with submicron-sized feature. No wet process is included in the pattern fabrication. Furthermore, our processes suggest the possibility of the use of very low energy electron beam or ion beam, which can diminish the device damage caused by the high energy beam exposure, because only the surface layer of base film could be involved with film deposition by graft polymerization.

Carrier Lifetime Reduction by Argon Implantation into Silicon

A. Mogro-Campero* and R. P. Love

General Electric Research and Development Center, Schenectady, New York 12301

ABSTRACT

The reduction of carrier generation lifetime caused by argon implantation into silicon has been studied as a function of argon dose and annealing treatments. The capacitance transient technique was used to deduce that: (i) carrier generation lifetime in the depletion region decreases by four orders of magnitude with doses up to 10^{14} cm⁻², and varies inversely with dose; (ii) the separable contribution to capacitance relaxation due to surface generation and diffusion varies as the square of the dose. The region of low lifetime appears to remain localized within 1 μ m from the surface even after annealing for 1h at 1200°C. Partial recovery of generation lifetime occurs after annealing for 1h at 1100° or 1200°C. Complete recovery was observed only after several hours at 1200°C, and slow cooling (2°C min⁻¹). The resistance to high temperature treatment implies that regions of low lifetime can be incorporated with three-dimensional control into device structures.

Carrier recombination and generation in silicon occurs by various processes. Because silicon is an indirect gap semiconductor, band-to-band recombination and generation are very improbable, and at low carrier-injection levels the dominant mechanism is phonon-assisted events via deep level defects. These defects can be crystalline imperfections such as those induced by radiation damage, impurities such as gold atoms, and/or a combination of both, such as the oxygen-vacancy complex. At large carrier concentrations, other processes may dominate recombination, and these may be important in devices handling large currents. For example, in a p-i-n structure, such as in a p-i-n diode or thyristor, recombination involving three carriers (Auger events) becomes significant at carrier densities in excess of 10^{17} cm⁻³ (1). We will not be concerned here with this recombination mechanism. In such devices, a decrease in the recombination lifetime results in an increase in forward voltage drop and a decrease in the reverse recovery time. Since low values of these device parameters are usually desirable, a compromise must be achieved. In addition, the leakage current is also a function of lifetime. Thus, adjustment of device parameter values requires tailoring the carrier lifetime.

The values of recombination and generation lifetimes are determined by the temperature and properties of the deep levels (their energy, concentration, and electron and hole capture cross sections). In addition, recombination lifetime depends on the doping and injection levels. The relative values of the high level injection recombination lifetime, the low level injection recombination lifetime, and the generation lifetime will be different for different deep levels, and will thus lead to a variety of possible device parameter adjustments. This reason alone serves as justification for the search of new methods of lifetime control. In addition to the differences in deep level properties, the techniques currently in use (electron irradiation, gold and platinum diffusion) have distinct advantages and disadvantages which we shall not discuss. One property which they share in practice is that with them lifetime reduction is achieved throughout the silicon, with very limited spatial localization allowed. Localized lifetime control would offer the device designer an additional degree of freedom, and becomes imperative in high voltage integrated circuitry.

We have been investigating ion implantation as a lifetime-control technique. In a general case, deep levels are provided both by the damage produced by the implantation process, and by the implanted species itself. A distinct advantage of this method is that localized lifetime control on a very small scale is made possible. The shallow range of implanted ions provides the simple solution to spatial planar control by the usual masking procedures. It is, of course, necessary

that lifetime reduction persist after the ensuing high temperature treatments used in device processing. If three-dimensional spatial localization is desired, lifetime reduction must survive the high temperature epitaxial growth process.

We report here on the use of argon implantation for lifetime reduction. A deep level has been reported at 0.5 eV below the conduction band for samples of silicon implanted with argon (2). It seems that this may be a true impurity level rather than one associated with implantation damage, since no similar deep level was found for neon or xenon. In addition, in a study of the relative effectiveness of argon and silicon implantation into silicon (3), it was found that whereas silicon implantation had no effect on the lifetime at doses $< 10^{14}$ cm⁻², argon implantation produced lifetime reduction at doses $> 10^{11}$ cm⁻². This result for argon is consistent with the work to be presented here.

Procedure

n-Type CZ silicon wafers of (111) orientation and doping density 2×10^{15} cm⁻³ were used. The backs of the wafers were implanted with 10^{15} cm⁻² phosphorus of 100 keV to ensure a low resistance contact to aluminum. The front surfaces were implanted with 200 keV argon. A portion of the top surface of each wafer remained unimplanted for control measurements. 60 nm of dry oxide were grown at 1000°C for 50 min with subsequent anneals in nitrogen. A multidiameter set of aluminum dots was then evaporated to form MOS capacitors and sintered at 450°C in nitrogen for 30 min. The range of 200 keV argon ions in silicon is 203 ± 82 nm (4). The sputtering coefficient at this energy is unity (5), so that only about one monolayer is removed by an argon dose of 10^{15} cm⁻².

Ghandhi's definition of generation lifetime (1) was used. This differs from the definition used by some authors by a factor of two. The carrier generation rate (carriers per unit volume per unit time) is given by $n_i/(2\tau_g)$, where τ_g is the generation lifetime and n_i is the intrinsic carrier concentration. Lifetime measurements at room temperature were carried out by a capacitance transient technique (the Zerbst method). The voltage is suddenly changed into the deep depletion regime, and the formation of the inversion layer by carrier generation is observed via the capacitance transient (6). Capacitance was measured at 1 MHz.

Although this method is relatively laborious, it is possible to deduce separately the generation lifetime in the depleted zone (τ_g) and the parameter s due to the combined effect of near-surface generation and minority carrier diffusion into the depletion region from the quasi-neutral bulk. The separation is essentially achieved by dividing carrier generation into two components: those that are independent of the time varying depletion depth are lumped into the parameter s , and generation within the time varying depletion

* Electrochemical Society Active Member

zone is associated with the generation lifetime τ_g . For samples of doping density 10^{15} cm^{-3} , the shallow boundary of the generation volume within the depletion region sweeps by the implant range ($0.2 \mu\text{m}$) during the time period of validity of the Zerbst analysis (7). Therefore, at least some of the implant-related defects contribute to the effective generation lifetime deduced by the Zerbst technique. The parameter s consists of the sum of the surface generation velocity under inversion, near-surface generation which is independent of depletion depth, and the diffusion component $(n_i/N)(D/\tau)^{1/2}$ (8), where N is the shallow donor or acceptor doping density, and D and τ are the minority carrier diffusion coefficient and carrier lifetime in the quasi-neutral bulk. A typical variation of generation lifetime and parameter s of a factor of two was found on a single wafer.

The surface contribution can result from two components: the surface generation velocity under the inversion layer (included in the parameter s), and the surface generation velocity in the uninverted region at the dot perimeter (s_0). The contribution of s_0 was estimated by following the analysis in (6), where it is shown that $\tau_Z^{-1} = \tau_g^{-1} + 8s_0/d$, where τ_Z is the generation lifetime given by the Zerbst analysis, τ_g is the corrected generation lifetime, and d is the diameter of the test dot. Therefore, a plot of τ_Z^{-1} vs. d^{-1} should be linear, and an extrapolation to $d^{-1} = 0$ gives the value of τ_g . In attempting to implement this technique, the main difficulty found was scatter in the data. An example is given in Fig. 1. From such data we estimate that the use of a 1 mm dot results in a finite diameter correction factor $1.0 < C < 1.7$. For simplicity, we assume henceforth that $C = 1$.

Results

The generation lifetime deduced from the capacitance transient analysis is its average value over a portion of the depletion volume (7) which we call the sampling volume. The sampling volume increases with increasing depletion voltage, so that if the generation lifetime τ_g is constant with depth, one expects it to be constant as a function of depletion voltage. This is seen to be true for an unimplanted area (top of Fig. 2). If a region of low lifetime lies below the sampling volume, the measured lifetime should decrease as the sampling depth is increased and penetrates the low lifetime region. Once the sampling depth is such that the entire region of low lifetime is contained within the sampling depth, the measured lifetime should increase with a further increase in sampling

Fig. 1. τ_Z is the generation lifetime measured by the Zerbst technique on a dot of diameter d . The silicon sample was implanted with $10^{14} \text{ Ar cm}^{-2}$ and annealed at 1200°C for 50 min.

Fig. 2. Generation lifetime τ_g vs. depletion voltage for a sample implanted with $10^{14} \text{ Ar cm}^{-2}$ and annealed at 1200°C for 50 min.

depth. The behavior observed for τ_g vs. depletion voltage is shown in the lower portion of Fig. 2. For this sample, the maximum depletion depths at depletion voltages of -5 and -10V are $1.5 \mu\text{m}$ and $2.3 \mu\text{m}$, respectively. The increase of τ_g with depletion voltage in the implanted region means that the region of reduced lifetime is entirely contained within $1 \mu\text{m}$ from the surface. Therefore, depth localization has been preserved even after an annealing treatment of 1200°C for 50 min. Since τ_g in the implanted regions is a function of depletion voltage, we adopt standard pulsing voltages for lifetime determination ($+10$ to -10V). However, it must be kept in mind that the actual value of τ_g within the region of reduced lifetime is at least a factor of ten lower (as can be seen from the lower portion of Fig. 2).

Generation lifetime as a function of argon dose is shown in Fig. 3; τ_g can be decreased by four orders of magnitude. These results are consistent with a study using similar experimental conditions (3). An inverse dose relationship is apparent; this can be understood by noting that lifetime is inversely proportional to the density of deep levels (1), which in this case are introduced by implantation. The parameter s derived from the capacitance transient analysis is shown in Fig. 4 as a function of argon dose, and is seen to increase as the square of the dose. As mentioned previously, the parameter s contains contributions due to near-surface generation and diffusion. The diffusion component can become important when a region of low lifetime lies within a diffusion length of the depletion region; specific cases related to denuded zones and intrinsic gettering have been recently discussed (9, 10). The diffusion contribution may be important in our case due to the low lifetime region which extends beyond the depletion zone in the lateral direction. The strongest dependence on implant dose in this diffusion term is probably via the lifetime, which leads to $s \propto (\text{DOSE})^{0.5}$. The contribution due to surface generation may be important in the present case because of a radiation-related increase in near-surface deep levels, whose density is

Fig. 3. Generation lifetime τ_g vs. argon dose for samples subjected to 1000°C for 50 min to grow 60 nm of oxide after implantation into the silicon.

proportional to the surface generation velocity (11). The dominance of the surface contribution thus leads to $s \propto \text{DOSE}$. In our case the observed dependence $s \propto (\text{DOSE})^2$ could be due to a combination of two irradiation-related defects which have subsequently become paired.

The rapid increase of the parameters s with dose prompts the question of the relative contributions of generation mechanisms to inversion layer charge during the capacitance transient. Using the standard expression (6) for the rate of change of inversion layer charge, it follows that the ratio of the contributions from s to that from generation within the sampling volume in the depletion region is $R \cong 2s\tau_g/(W - W_F)$, where W is the time-dependent depletion depth of final value W_F . The maximum contribution from the depleted zone occurs during the early portions of the capacitance transient. For the experimental conditions here, the contributions due to s will be dominant for $\tau_g s \gtrsim 1 \mu\text{m}$. From Fig. 5, this is satisfied for argon doses $\gtrsim 4 \cdot 10^{12} \text{ cm}^{-2}$. For the purposes of the next figure, let τ_z be the generation lifetime determined by the Zerbst technique. By neglecting the surface and diffusion contributions, a simpler analysis of the capacitance transient (12) has been used in the literature to obtain the generation lifetime; let τ_H be the generation lifetime determined by this method. In our case, this method becomes inadequate with increasing dose, as shown in Fig. 6. The discrepancy becomes larger than a factor of 2 for doses in the 10^{12} cm^{-2} range, which corresponds to a dominant contribution from s as deduced above from examining Fig. 5. The total charge density associated with the oxide which was grown after implantation was evaluated from flatband voltage shift of C-V curves. The measured charge density of 10^{11} cm^{-2} was independent of argon dose.

The ionized doping density was determined by the maximum-minimum capacitance method (13). This method gives an average doping density up to the

Fig. 4. Parameter s vs. argon dose for samples subjected to 1000°C for 50 min to grow 60 nm of oxide after implantation into silicon.

equilibrium depletion depth under inversion ($0.6 \mu\text{m}$ in our case), so that the results should be sensitive to possible doping changes introduced by the argon implantation (range of $0.2 \mu\text{m}$). No changes in doping density were observed up to at least $10^{13} \text{ Ar cm}^{-2}$.

Of the three energy levels associated with argon implantation (2), two are donors (at 0.22 and 0.5 eV from the conduction band), and one is an acceptor state (at 0.18 eV from the valence band). Thus, one might expect doping density changes due to strong compensation to be significant when the density of the electrically active fraction of argon-related deep levels approaches the shallow donor level density. Within a standard deviation from the peak of the

Fig. 5. $\tau_g s$ vs. argon dose from the data in Fig. 3 and 4

Fig. 6. The ratio of generation lifetimes determined by capacitance transient analysis. τ_z and τ_H are defined in the text.

implanted argon, its average density for a dose of 10^{13} cm^{-2} is $4 \cdot 10^{17}$ cm^{-3} , far in excess of the shallow doping density of 10^{15} cm^{-3} . Thus, the effective electrically active fraction of argon atoms seems to be low. This may be related to the aggregation of argon atoms, which produce detectable bubbles of 3 nm diam at a dose of 10^{14} cm^{-2} under similar experimental conditions (3). Other contributions to effective recombination-generation centers as well as donor and acceptor levels may be provided by implantation-induced defects and resident impurities (such as oxygen, which is present at levels of about 10^{18} cm^{-3} in CZ crystals). Interactions between the argon and such defects may be important, particularly since it is known that implanted argon is an effective gettering agent in silicon (14).

We now turn our attention to the effects of higher temperature annealing. The generation lifetime as a function of annealing temperature is shown in Fig. 7; the lifetime recovers to within a factor of about 100. The behavior of the parameter s for these samples is shown in Fig. 8. The value of s decreases, but even at 1200°C, it is still a factor of about 1000 higher than in the unimplanted areas.

The highest annealing temperature tested (1200°C) is close to the highest processing temperature used. These high temperatures are used, for example, to grow thick oxide layers and thick epitaxial layers of Si on Si by chemical vapor deposition (CVD). The behavior of generation lifetime as a function of annealing time at 1200°C is shown in Fig. 9. The sharp decrease of τ_g in the implanted area at 2h, before proceeding to recover, is interesting. A corresponding maximum in the parameter s was also found. This behavior may indicate the predominance of a different type of deep level produced by high temperature annealing, perhaps involving defect interactions as discussed above. All the annealing experiments discussed so far were terminated by relatively rapid cooling (the wafers are pulled out from the hot zone to an ambient at 300°C within a few seconds). To investigate the effect of slow cooling, some samples were cooled at a controlled rate of 2°min^{-1} . The results are shown in Fig. 10. Cooling rate is seen to have a

noticeable effect. The decrease in lifetime at 2h is again present, but at a reduced magnitude. After 5h,

Fig. 7. Generation lifetime as a function of annealing temperature. Annealing time is 50 min in all cases. The argon dose was 10^{14} cm^{-2} .

Fig. 8. Parameter s as a function of annealing temperature for conditions as in Fig. 7.

Fig. 9. τ_g vs. annealing time at 1200°C. Implanted areas contain 10^{14} Ar cm^{-2} . The arrow indicates the lifetime for a sample with minimum heat-treatment (1000°C for 50 min). The samples were cooled rapidly (hundreds of degrees s^{-1}).

the lifetimes in the implanted and unimplanted areas are indistinguishable, which was also found to be true for s .

The work reported here includes argon doses of $\leq 10^{14}$ cm^{-2} . In order to make detection of argon by the SIMS technique possible, some samples were implanted with higher doses (10^{15} - 10^{16} cm^{-2}). The depth profiles of mass 40 from these samples showed an erratic behavior of unknown origin, *i.e.*, the shapes of depth profiles were sometimes inconsistent with tabulated values.

Conclusions

The perimeter effect in the measurement of lifetime by the Zerbst method was shown to be small when using 1 mm diam capacitors. A more simplified treatment of the capacitance transient which neglects the surface and diffusion contributions (12), has been found to be inadequate for the samples with higher argon doses studied here. We have found that values of generation lifetime can be controlled over several orders of magnitude by argon doses up to 10^{14} cm^{-2} followed by a thermal treatment at 1000°C for 1h. The reported values of τ_g are conservative, since we have shown that the actual localized minimum values of τ_g are at least a factor of ten lower. The bulk generation rate within the sampling volume in the depletion region varies as the argon dose, but generation due to the combined effect of the surface and diffusion varies as dose squared. This latter dependence suggests that generation-recombination centers near the surface in-

Fig. 10. Same as Fig. 9, but with a controlled cooling rate of 2°min^{-1} .

volve a pairing of two irradiation-related defects. Doping density was found to be unaffected by argon implantation at least up to a dose of 10^{13} cm^{-2} . Higher temperature annealing (up to 1h at 1200°C) induces partial recovery of the generation lifetime. The region of low lifetime appears to remain localized within 1 μm from the surface even after annealing for 1h at 1200°C. Complete lifetime recovery was observed after several hours at 1200°C followed by slow cooling.

These results show that argon implantation can be used to decrease carrier lifetime substantially in silicon. Localization in the x-y plane can be easily implemented by selective oxide masking. Si on Si epitaxial growth by CVD can be used to effectively bury the argon, and therefore to achieve three-dimensional localization of low lifetime regions, thus allowing these to be introduced into device structures (*e.g.*, into fast switching devices).

Acknowledgments

We thank P. Cerniglia, G. Gidley, B. Hatch, and M. Lazzeri for ably carrying out various wafer processing steps; ion implantations were performed by R. Reihl and W. Whitney. We are grateful to D. Schroder for pointing out the possible importance of the lateral diffusion contribution to the relaxation of the capacitance transient in this experiment, and to W. Katz for the SIMS runs. We are indebted to A. Sears for information on the equipment for measuring capacitance, and to S. Ashok for making us aware of Ref. (2). Discussions on radiation damage with W. Johnston, C. Bean, and R. Fleischer are gratefully acknowledged.

Fines in Fluidized Bed Silane Pyrolysis

G. Hsu, R. Hogle,¹ N. Rohatgi, and A. Morrison*

Jet Propulsion Laboratory, California Institute of Technology, Pasadena, California 91109

ABSTRACT

Silicon deposition on silicon seed particles by silane pyrolysis in a fluidized bed reactor is being investigated as a low cost, high throughput method to produce high purity polysilicon for solar cell applications. Studies of fines, particles 0.1-10 μ diam, initiated from homogeneous decomposition in the reactor were conducted using 2 and 6 in. diam fluidized beds. The studies show functional dependences of fines elutriation on operating parameters such as silane feed concentration, temperature, gas velocity, and bubble size. The observation that the fines elutriation is generally below 10% of the silicon-in-silane feed is explained using a concept of scavenging by large particles in an environment of less free space for homogeneous nucleation. Preliminary results suggest that, with proper conditions and distributor design, high silane concentration (>50% SiH₄ in H₂) feed may be used for silicon production in fluidized bed reactors.

Silicon deposition in a fluidized bed reactor (FBR) was first tested in the early 1960's (1) using chlorosilane for producing semiconductor purity polysilicon. However, the success of the alternative Siemens process (2, 3) led to its universal utilization for commercial production and the de-emphasis of FBR process development. Since 1975, the new potential market for semiconductor grade silicon for photovoltaic applications made a production reactor like the FBR, with the capabilities of continuous high throughput operation and low energy cost, very attractive. Silane is used in this FBR process because of its advantages in low deposition temperature, complete conversion in the irreversible reaction, noncorrosive atmosphere, and the ease of recycling the by-product hydrogen.

In a conventional chemical vapor deposition type of reactor using silane for silicon production, there is a limit of silane concentration in hydrogen [the "critical silane concentration" (4, 5)] beyond which unwanted fines are homogeneously nucleated. In addition to the desirable chemical vapor deposition on the substrate, silicon powders or fines, in the size from submicron to ~10 μ , form in the gas phase. These fines present mechanical problems to the operation of the reactor, and are difficult to transport. They are considered losses to the process. The major reason the chemical vapor deposition type of reactor is operated at low silane concentration is to prevent excessive fines formation; thus, this type of operation is limited in throughput. In a fluidized bed reactor, less fines are generated because (i) less free space is available for homogeneous nucleation and (ii) the silicon seed particles scavenge the homogeneously nucleated fines and incorporate them into the deposition growth (6). Consequently, the net amount of fines becomes much less than that in a chemical vapor deposition reactor at the same silane concentration. A fluidized bed reactor, therefore, can be operated at a much higher silane concentration and the FBR process economics are greatly improved, relative to the Siemens type of chemical vapor deposition process.

In a forthcoming paper, we shall discuss the overall deposition growth mechanism and the details of the phe-

nomena involved in the operation of a silane-fluidized bed reactor. In this study, we shall concentrate on the experimental results of fines elutriation and the functional dependence of fines elutriation on operation parameters.

Experimental

Apparatus.—The experimental data on fines elutriation were collected from both 2 and 6 in. diam fluidized bed reactors. The 2 in. reactor was designed for establishing basic feasibility in the fluidized bed approach, while 6 in. FBR represents the smallest size of a practical engineering reactor to remove the wall effect. Experiments using these two FBR systems provided a means for testing of fines elutriation behavior in a fluidized bed silane pyrolysis system over a wide range of conditions.

The schematic diagram of a fluidized bed reactor is depicted in Fig. 1. The 2 in. id reactor is 36 in. high with an expanded head of 4 in. id \times 6 in. high. The reactor is externally heated with three zones of clamshell-type electrical resistance heaters with an overall height of 18 in. and a total output of 2.2 kW. The temperature was monitored by iron-constantan type K thermocouples located at various heights both outside and inside the reactor wall as well as at the distributor plate. The flows of hydrogen and silane were measured by rotameters. The gases were premixed and preheated to 300°-350°C before being injected into the reactor. The bottom of the reactor was a 30° cone with a 1/2 in. orifice gas distributor or a distributor fabricated from a 200 mesh stainless steel screen supported by a 1/8 in. stainless steel plate perforated with multiple 1/32 in. holes. The temperature of the distributor was kept below 400°C by blowing room temperature nitrogen onto the distributor. The compositions of the inlet and outlet silane-hydrogen gas mixtures were analyzed by a Hewlett Packard Model 5710A gas chromatograph.

The exit gas from the reactor was passed through MICROPORE filters (porosity 0.1 μ m) before being flared off. The pressure in the reactor was maintained at 5 psig with the help of a back pressure regulator. The pressure drop fluctuation across the bed was continuously monitored by a differential pressure transducer. The pressure difference signal was used to indicate the fluidization behavior of the bed.

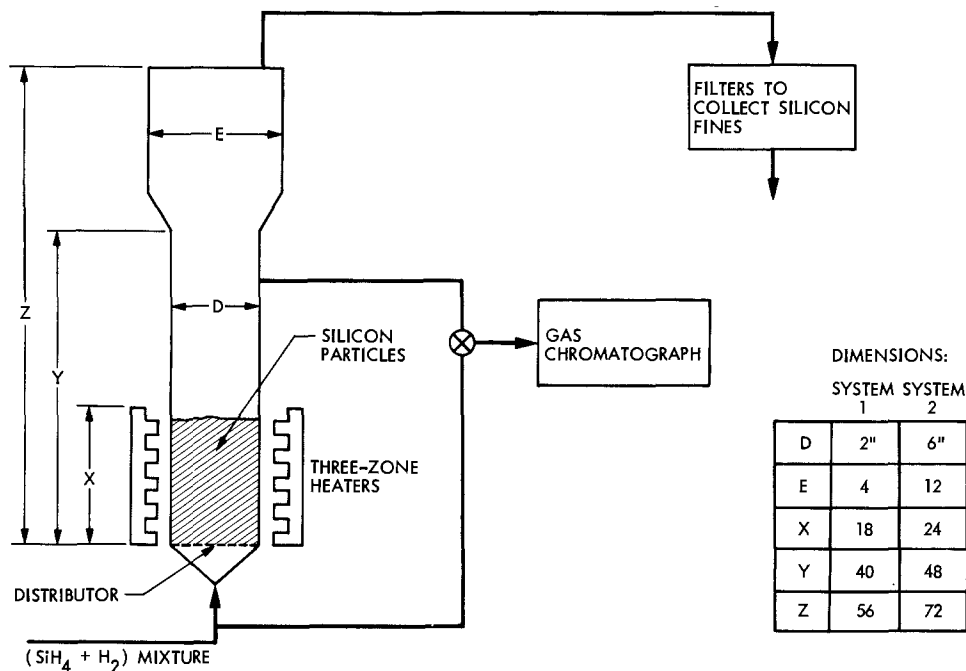

Fig. 1. Fluidized bed reactor systems for fines studies.

The 6 in. diam reactor was fabricated from a 6 in. Schedule 40 type 316 stainless steel pipe. The reactor dimensions are 6 in. id \times 48 in. high with an expanded head of 12 in. id \times 24 in. high. The reactor is externally heated with three independently controlled heaters. The bottom two heaters are made of silicon carbide heating rods, and the top one is a clamshell-type electrical resistance heater with total output of 18 kW. With proper heating, no deposition on the reactor wall is observed. The reactor was fluidized with a multilayer screen (trade name DYNAPORE) gas distributor, or a distributor fabricated from no. 325 mesh screen supported by the 1/20 in. thick plate perforated with 1/8 in. holes. In order to keep the distributor temperature less than 400°C and to avoid premature silane decomposition and plugging of the distributor screen, water cooling was employed both at the periphery of the distributor and beneath the distributor screen.

In all of the experiments, the silicon fines were collected in filters located at the exit line of the reactor expanded head (Fig. 1). For the 2 in. reactor, a 5 in. diam MICROPORE filter was used, and a submicron size cartridge-type of filter was used for the 6 in. reactor.

Procedure.—The silicon dust was collected for at least 15 min after steady-state operation was achieved for a selected bed temperature, silane concentration, and fluidization velocity. The silicon fines collected on the filter were weighed and transferred into a polyethylene bag and sealed in order to avoid oxidation of silicon. The percent of fines elutriated was defined as the ratio of fines collected in the filter to the corresponding silicon-silane feed during that period.

Seed particle sizes of 150-300 μm were used. For the 2 in. diam FBR, a typical bed height of 6 in. was used, whereas a 2 ft height was used for the 6 in. FBR. The fluidization gas velocity ratio, u/u_{mf} (where u is the superficial gas velocity and u_{mf} is the minimum fluidization velocity) was varied from 1 to 10, with a typical number of 5. Seed particles were prepared by crushing and grinding semiconductor grade polysilicon, screening to the specific mesh sizes, and leaching with a mixture of HF, H₂O₂, and deionized water to remove oxide and metal impurities.

Discussion of Results

The fine particles formed by the pyrolysis of silane in a fluidized bed are clusters of submicron size nuclei formed from homogeneous gas phase decomposition, nucleation, and coagulation; this is depicted in Fig. 2. The size range for the clusters is about 1-10 μm . The x-ray diffraction analysis showed that the silicon fines are of crystalline structure. Under the conditions employed, no significant attrition of particles was observed.

Fig. 2. SEM examination of FBR fines

Silane concentration.—Since the first step in fines formation is gas phase decomposition, the maximum fines level can be estimated from the percentage of homogeneous decomposition in the overall reaction scheme. The following simplified calculation of the maximum expected fines is based on the assumption that homogeneous decomposition leads to fines formation at all concentration levels. Since, generally, homogeneous decomposition and heterogeneous deposition are first order with respect to silane concentration, the percentage of fines formation in terms of the feed silicon content is the ratio of the homogeneous rate constant to the sum of the homogeneous and heterogeneous rate constants. In the literature, an expression for the homogeneous first-order rate constant was approximated by (7)

$$k_r = 2.0 \times 10^{13} \exp(-51,700/RT) \quad [1]$$

whereas the heterogeneous rate constant for a fixed particle bed operated under conditions similar to those used in this work was given as (8)

$$K_s = 5.14 \times 10^9 \exp(-38,800/RT) \quad [2]$$

Thus, at 650°-700°C, the maximum calculated percentages of fines formation are 77-83%. In a fluidized bed, the fines are less to begin with because of less free space

available for homogeneous nucleation; and they are further scavenged and incorporated into the deposition. These combined phenomena result in a very low residual fines level, generally less than 10% of the silicon in silane feed as shown in Fig. 3. For a feed silane concentration below 10%, the fines elutriation level is almost negligible.

Temperature.—As the temperature is increased, calculations using the Arrhenius rate constant dependence show that the rate of the homogeneous reaction rises faster than that of heterogeneous deposition. Figure 4 shows the difference between the theoretical fines formation calculated from the assumption that homogeneous decomposition produces fines and the experimental level measured from the effluent filter. These data indicate substantial reduction in fines elutriation. The concept of scavenging is involved to explain the decrease.

There is an optimum temperature range for FBR reactor operation. The effect of the temperature is illustrated in the scanning electron microscope (SEM) pictures presented in Fig. 5. There is a lower limit of operation temperature set by the deposition quality. At $\sim 550^\circ\text{C}$, the product appears to adhere loosely and to be granular in nature. As the temperature is increased past 600°C to 650°C ,

Fig. 5. Deposit surface quality (SEM) vs. temperature

Fig. 3. Fines elutriation vs. silane feed concentration

Fig. 4. Fines elutriation vs. temperature

the deposit appears to be more coherent and dense. At 700°C , the deposit is very coherent and dense. It is evident from the SEM pictures that the silicon deposits have a nodular shape. It is believed that these nodules are formed as a result of the combined actions of the collection of the very small particles (created by homogeneous gas phase decomposition and nucleation) on the surface of seed particles and of heterogeneous CVD-type deposition. The morphology was found to be dependent on the deposition rate and the particle surface temperature. Based on the product morphology, the lower limit for operating the fluidized bed reactor in silane pyrolysis is 600°C and the optimal temperature region is $\sim 700^\circ\text{C}$. Above $\sim 800^\circ\text{C}$, economically intolerable levels of fines are formed.

Gas bubble size.—In a fluidized bed reactor, the gas void space between the fluidized solid particles directly influences the ratio of the fines formation to the heterogeneous deposition. When large gas bubbles occur at the grid of the distributor plate, large amounts of fines are generated in the bubbles.

The data which demonstrates this effect of gas bubble size is shown in Table I in terms of the distributor effect on fines elutriation. Thus, it is essential in fluidized bed design to maintain the gas distribution so as to produce uniform tiny bubbles. This can be achieved either by using a distributor with small openings or a multilayer screen. A very poor situation is one in which the fluidized bed operates in a slugging mode to favor a large amount of homogeneous decomposition and thus high fines production.

Gas velocity.—Other parameters that affect the fines elutriation in a fluidized bed are the bed height and the gas velocity. Bed height affects the residence time for the fines in the bed and thus influences the efficiency of trapping the fines. Gas velocity or retention time can be translated into the retention time of the gas in the bed; as this factor is increased the time for incorporating the fines onto the seed particles increases.

The dependence of elutriation on gas velocity was illustrated, for example, in the data: the dust level of $u/u_{mf} = 3$

Table I. Distributor effect on fines elutriation

Silane concentration (C%)	Temperature (T, °C)	Opening of distributor to bed diameter ratio (d/D)	Fines elutriation (%)
20	700	2.00×10^{-4} **	4.6
20	700	0.25**	6.5
60	650	2.83×10^{-4}	9.5
65***	650	1.45×10^{-3}	12.2

* Estimated equivalent ratio of a multilayer screen distributor.

** Nozzle type of distributor.

*** Note that silane concentration increases from 60 to 65%, which may also increase the level of fines.

was 6% and the level for $u/u_{mf}=6$ was 10% at a bed temperature of 700°C and a 65% silane concentration. However, care must be taken to avoid the use of gas velocities below the limit at which the reaction region spread out by the fluidizing gas will be too narrow. In this case, the resulting high reaction density causes undesirable bed agglomeration. In an earlier study (6), the lower limit for gas velocity, expressed by the parameter u/u_{mf} , was experimentally determined to be 3. The upper limit for velocity was reached when the bed slugged in an uncontrollable mode; this was found to be at $u/u_{mf}=8$.

Conclusions

Key operating guidelines for fluidized bed silicon production from silane have been defined. A scavenging mechanism has been proposed to account for the low fines elutriation in the temperature range of 600°-800°C. Below 600°C, the deposits are relatively poor and loosely adhered to the particle surface. Above 800°C, fines level starts to increase rapidly. Bed agglomeration appears to be avoidable by keeping $u/u_{mf}>3$. Beds have been operated at velocities as high as $u/u_{mf}=8$ without problems, such as excessive dust entrainment and erratic bed behavior.

Based on the above empirical guidelines for temperature and fluidization velocity, the operating envelope for fluidized bed silane pyrolysis systems is thus identified as follows

$$\begin{aligned} 600^{\circ}\text{C} \leq T \leq 800^{\circ}\text{C} \\ 3 \leq u/u_{mf} \leq 8 \end{aligned} \quad [3]$$

The optimal operating condition from fines elutriation and morphology point of view is $T=700^{\circ}\text{C}$ and $u/u_{mf}=5$. Within the identified operating envelope, the fines elutriation percentage is generally below 10% of the silicon-in-silane feed. The preliminary results suggest that high silane concentration (>50%) feed can be used with-

out excessive fines generation if this set of operating conditions can be maintained.

Plasma Anodic Nitridation of Silicon in N₂-H₂ System

M. Hirayama, T. Matsukawa, H. Arima, Y. Ohno, N. Tsubouchi, and H. Nakata

Mitsubishi Electric Corporation, LSI Research and Development Laboratory, Itami, Hyogo 664 Japan

ABSTRACT

Silicon nitride films were directly formed on silicon by plasma anodic nitridation within nitrogen and hydrogen. The nitridation pressure ranged from 0.5 to 2.0 torr, at temperatures from 700° to 900°C. The growth rate of silicon nitride increased with an increase of the dc bias voltage to the silicon wafers. The refractive index of the films was measured to be about 2.00-2.30 by ellipsometry. Film composition was analyzed with Auger electron spectroscopy. Dielectric breakdown strength of the silicon nitride films was about 6.0 MV/cm after oxygen heat-treatment.

Direct nitridation of silicon has been an attractive technique for VLSI device fabrications for the last few years. The dielectric constant of the silicon nitride film is larger than that of the oxide film, and impurities in the gate poly-Si are prevented from diffusing through the silicon nitride film to the channel region. Unfortunately, the silicon nitride deposited on silicon wafers by LPCVD has interfacial instabilities between the silicon nitride and the silicon substrate. Many efforts have tried to obtain the silicon nitride film by direct reaction of silicon in a nitrogen ambient. Although thermal nitridation and plasma-enhanced thermal nitridation were previously reported, the film thickness is only about 100Å even at high reaction temperatures (1, 2). Using nitrogen ambient and pure ammonia for the thermal nitridation (3), the films were very thin because of the slow diffusion of nitridant species through the nitride film. The growth kinetics of thermal nitridation for films below a thickness of 100Å has been analyzed (4). From previous works, the process limitations of thermal nitridation prevent using it for formation gate films for MOSFET's. The nitridation technique was used to form thin gate dielectric films such as nitrided oxide or oxy-nitride films (5). In fact, VLSI devices such as high density single-transistor dynamic

Key words: plasma nitridation, anodization, silicon nitride gate insulator film.

RAM's or electrical erasable and programable ROM's use these nitrided films as a gate insulator film.

Attempts to improve the growth rate and the electrical properties of nitrided films was made using plasma anodic nitridation. Anodization of silicon or anodic oxidation of silicon is a promising approach to accelerate the oxidation rate in semiconductor processing (6). Similarly, plasma anodic nitridation is expected to be useful for nitridation of silicon. The method has the advantage of lower temperature in fabrication of VLSI devices and is expected to improve the interfacial characteristics and electrical properties of the nitride films.

This paper reports some nitridation characteristics of silicon using only nitrogen and hydrogen and a new plasma anodization technique. Some properties of the silicon nitride film obtained by this new technique are also described. We studied plasma anodic nitridation of silicon in the temperature range of 700°-900°C, instead of the conventional thermal nitridation process requiring temperatures above 1000°C.

Experimental Procedure

The starting material was (100) oriented CZ silicon wafers with n-type resistivity of 1-5 Ω-cm. Wafers were chemically cleaned in sulfuric acid and hydrochloric acid and rinsed with deionized water. They were then dipped

Fig. 1. Schematic diagram of experimental apparatus for plasma anodic nitridation.

in 2% hydrofluoric acid for 30s, rinsed with deionized water, and dried in flowing nitrogen gas. The experimental apparatus, shown schematically in Fig. 1, was a horizontal 150 mm diam quartz tube heated to temperatures between 700°-900°C. Cleaned wafers were loaded onto a silicon carbide (SiC) susceptor in the cold zone. After the insertion of the boat, the reaction tube was capped and evacuated with a mechanical booster pump. High purity hydrogen and nitrogen gases were used for the nitridation and flow rates controlled with a mass flow controller. Carbon fluoride (CF_4) and hydrogen were used for pre-etching of silicon surface at a pressure of 0.05 torr for 1 min to remove the native oxide on the silicon surface. Before nitridation in hydrogen and nitrogen plasma, the system was pumped down to 1×10^{-4} torr with a turbo molecular pump to minimize the residual gases. The gas mixture was admitted to vacuum tube through a variable leak valve while a mechanical pump kept the pressure in the reaction tube at 0.5-2.0 torr under flow condition. Once the pressure became stable, a 13.56 MHz RF power was supplied to the silicon carbide rods so that a plasma discharge was excited between the alternate susceptors. In addition, dc bias was applied to the anode (maximum voltage was 250V). This method differs significantly from the previous works.

The thickness and refractive index of as-grown films were determined by the ellipsometry. These were consistently calculated by a computer. The chemical compositions of the films were measured using Auger electron spectroscopy (AES) with a cylindrical mirror analyzer. To measure the dielectric breakdown voltages, polycrystalline silicon electrodes were formed onto the film to make MOS capacitors.

Results

Growth conditions.—Figure 2 shows the relation between film thickness and reaction time at 900°C, 1:1 nitrogen:hydrogen, 1.00 torr, and 150V dc bias voltage on the SiC electrodes. Silicon wafers loaded on the positive electrode nitrided faster than those on the negative electrode. Typical growth rate on the positive electrode was about 1.5 Å/min, and the nitride film was 623Å thick after 7 hr nitridation. Previously, silicon nitride films were limited to about 100Å for thermal nitridation or the plasma-enhanced nitridation (1-3), due to slow diffusion of the nitridant species across the thermal nitride film below 1100°C. These experimental results suggest that the film growth kinetics of the plasma anodic nitridation is different from those of thermal nitridation systems.

Under the same nitridation conditions, film thickness increases with temperature as shown in Fig. 3. The growth rate of the nitride film on silicon loaded onto the negative electrode was smaller. Below 200°C, the nitride film was scarcely visible. Dependence of film thickness on nitridation pressure was minimal in the range from 0.5 to 2.0 torr as shown in Fig. 4. At a nitridation pressure below 0.1 torr, the growth rate of the nitride film abruptly decreased.

The most interesting experimental result is the dependence of film thickness on dc bias voltage as shown in Fig. 5. The nitridation temperature and pressure were 900°C and 1.0 torr, respectively, for 150 min. It is clear that the film thickness increases linearly with the increase of the applied dc bias voltage. On the negative electrode SiC rods, the nitridation was slightly accelerated by the bias voltage. The dc bias voltage was limited at any specific pressure, and the maximum voltage value was 178V at 2.0 torr. Even though the silicon wafers and the SiC disk susceptors were isolated by quartz insulators on SiC rods, at a low bias voltage, the plasma anomalous discharge occurred unexpectedly at low pressures.

Film composition.—The refractive index, as measured by ellipsometry, ranged from 2.0 to 2.3, which was slightly larger than silicon nitride films formed by LPCVD. This may be due to deviation of stoichiometry of silicon nitride. For films below 100Å thick, it is difficult to determine both the refractive index and the film thickness by ellipsometry.

The as-grown film composition was analyzed by Auger electron spectroscopy. The films contained only silicon, nitrogen, and oxygen, and the compositions were consistent with mixtures of Si_3N_4 and SiO_2 . Since hydrogen is not detectable with Auger spectroscopy, the hydrogen

Fig. 6. Typical Auger depth profiles of plasma anodic nitridation film

content of these films is not known. Sputter etching was accomplished with a 1.0 keV argon beam to obtain depth profiles. Depth profiles of components of films grown at 150 min, 1 torr hydrogen and nitrogen, and 900°C are shown in Fig. 6. Thickness of this sample was 120Å. Nitrogen and oxygen concentrations (closed and open circles, respectively) were calculated from the peak height of the KLL transition spectrum. The relatively flat nitrogen and oxygen profiles show that the film was a silicon oxynitride. The most striking feature of Fig. 6 is the nitrogen profile in silicon substrate beyond the interface. Nitrogen apparently diffused into silicon more easily than oxygen even though it is said that the nitriding species diffuses slower through nitride compared to oxygen through oxide. However, reaction of nitrogen on the silicon surface seems to have occurred more easily than oxygen.

Dielectric breakdown strength.—To measure the dielectric breakdown strength of the nitride films, MOS capacitors were fabricated by Si gate MOS technology. A thick oxide film was formed at the field region by conventional photolithography and etching. The gate area was 1 mm². After the nitridation, phosphorus-doped polycrystalline silicon was deposited in an LPCVD system in electrodes and interconnection regions. The breakdown strength of the gate dielectric was measured by the voltage ramping at 100 V/s, and breakdown identified when the gate leakage current exceeded 1 μA. The average breakdown of as-grown nitrided films occurred at about 3.2 MV/cm. The value is rather low in comparison with that of the oxide films obtained at the same temperature, 900°C. Shown in Fig. 7 are typical distributions of the dielectric breakdown strength of the nitride films after heat-treatment in nitrogen and oxygen. The nitride film was formed at 900°C, dc bias of 150V in nitrogen and hydrogen at 1.5 torr. The oxygen ambient was more effective in improving the dielectric breakdown strength. The average dielectric breakdown strength was 6.5 MV/cm after

Fig. 8. Auger depth profiles of LPCVD silicon nitride film

postannealing in oxygen for 20 min at 1000°C, and 5.1 MV/cm in nitrogen ambient for 30 min at 1000°C.

Discussion

The object of this work is to obtain thick silicon nitride films by direct nitridation of silicon. The nitride film must be stable and reliable for VLSI devices. According to the previous reports about thermal nitridation or plasma-enhanced nitridation, the growth rate of silicon nitride was low and a maximum film thickness was 120Å. The reason is believed to be the presence of oxidant species such as oxygen and water in reaction ambient apparently prevents the nitridation of silicon surface. The nitridation rate of silicon is limited by diffusion of the nitridant species across the nitride film, and is further inhibited by diffusion through the oxide film. It is necessary to reduce the amount of oxidant species to less than 1 ppm water and 0.1 ppm oxygen.

To reduce the oxidant species in the nitridation ambient, the background pressure before nitridation was reduced to below 1×10^{-4} torr by a 500 liter/s turbo molecular pump in our experimental apparatus. Furthermore, ultrahigh purity hydrogen and nitrogen gases flowed to the quartz reaction tube through stainless piping using Swedgelock connectors. Ammonia was not used in the nitridation process because it was difficult to purify it to the semiconductor grade. It may be useful to etch the silicon surface for a few minutes with $\text{CF}_4\text{-H}_2$ plasma prior to the nitridation, since the native oxide on the silicon could obstruct nitridation. To confirm the above expectation, a silicon nitride film of 100Å thick was deposited by LPCVD on the silicon surface. From the Auger depth profile of LPCVD film shown in Fig. 8, oxygen was detected in the silicon nitride region and a strong oxygen pile up at the interface between the silicon nitride and the silicon substrate. The pile up may indicate a native oxide layer on the initial silicon. Also, the oxygen profile extends into the silicon substrate beyond the nitrogen

profile. This film is composed of three elements; silicon (29%), nitrogen (65%), and oxygen (6%). It also has about a one third oxygen content compared with the plasma nitride film. From these results, the pre-etching process before nitridation is necessary and effective in excluding the native oxide. The oxygen level was lower in the LPCVD film than in the plasma anodic nitridation film. It is possible that the origin of the oxygen is from the wall of the quartz reaction tube at the plasma nitridation. In plasma nitridation, oxygen is sputtered by ions to a higher level than that of the LPCVD, even though the background pressure was lower than that of the LPCVD.

In spite of limited diffusion of the nitridant species, the growth rate was kept constant during the thick nitride film formation when the dc bias voltage was applied to the silicon wafers. The nitridation mechanism can be analogized with the anodic oxidation of Si (6). Similar to oxidation, nitridation proceeds at both plasma/nitride and nitride/silicon interfaces. Ions of N and Si and/or their vacancies move across the nitride film with an electric field, and nitridation proceeds linearly with growth time, as observed. The nitridation process was also considered as the results of the ion drift process (7). In fact, the growth rate of the nitride film was linearly increased with the increase of the dc bias voltage and the film thickness up to about 630Å in 390 min nitridation was obtained.

Conclusions

Formation of thick silicon nitride films was possible by direct plasma anodic nitridation of silicon. A nitrogen and hydrogen mixture gas was effective for nitridation without an ammonia ambient. The growth rate of the nitride films depended on the nitridation temperature, pressure, and dc bias voltage on the silicon wafers. In 390 min nitridation of silicon at 900°C, a nitride film thickness over 630Å was obtained with a dc bias voltage of 150V. The index of the refraction of films ranged from 2.00 to 2.30, slightly smaller than films by LPCVD because of higher oxygen content. The dielectric breakdown strength of the nitride film was 6.0 MV/cm after annealing in oxygen.

A New Defect Etch for Polycrystalline Silicon

B. L. Sopori

Solavolt International,¹ Phoenix, Arizona 85062

Currently, there is considerable interest in using polycrystalline silicon for solar cells. Several techniques are being developed for growing polycrystalline silicon at high speeds, in particular, as thin ribbons (or sheets). Characterization of defects in these materials is essential. Chemical etching has been applied extensively for defect delineation in single-crystal silicon. Several etchants, such as the Dash, Sirtl, Secco, Wright, and Schimmel etchants, have been developed for revealing defects in single-crystal silicon wafers (1-5). Although these etches have also been used, with some success, for defect delineation in polycrystalline silicon, the general requirements of a defect etch for polycrystalline silicon are somewhat different than those for single-crystalline silicon. The requirements are: (i) Etching characteristics should be isotropic, *i.e.*, defects in all orientations should be delineated and the size of etch pits should be nearly the same. (ii) The etch pits should indicate the direction of defect propagation. This is an important property which permits one to determine if defects, such as dislocations, follow crystallographic slip planes or form networks crossing the slip planes. These features can help determine the mechanisms causing defect generation. (iii) The etch rate should be rapid. (iv) The etchant should not leave a residue of metallic ions. This last requirement allows device fabrication in regions adjacent to defect-etched regions, thus permitting one to correlate device performance with crystal characteristics. Furthermore, because of contamination, it is undesirable to have etchants containing metals in clean processing areas.

Clearly, many defect etchants developed for single-crystal wafers do not satisfy the first two requirements. This is because the quality of defect delineation depends on surface orientation. For example, Sirtl etch works well on (111) surfaces, but leads to the formation of an ambiguous morphology on (100) surfaces. Wright etch appears to work well on many orientations; however, because of the preferential nature of the etch, difficulties arise in defect delineation due to the formation of different size etch pits on different grain orientations. Furthermore, the shapes of the etch pits are strongly controlled by grain orientations rather than by the direction of the defect. Although Dash etch reveals dislocations in all orientations, it requires long etch times. In many applications Secco etch is suitable for polycrystalline silicon etching; however, it does not meet the last requirement indicated above. Schimmel etch has shown only limited success, mainly because the etch leaves a heavy stain on the samples.

This paper describes an optimized isotropic etch designed for revealing defects in polycrystalline silicon. Additional features of the etch are that it does not contain metallic ions and is compatible with photoresist masking. Variations in the etch composition may be used for better delineation in high defect density regions.

Etch Composition

The etch (hereafter called Sopori etch) consists of a mixture of 36 parts HF (49%), 20 parts CH₃COOH (glacial), and α parts HNO₃ (70%), where α may be varied between 1 and 2. Detailed kinetics of HF:CH₃COOH:HNO₃ etches

Key word: polycrystalline silicon, crystal defects, dislocations, defect delineation, defect etch.

have been discussed by Schwartz and Robbins (6, 7). They have divided these etches into two groups based on the rate-controlling mechanisms. According to their classification, this etch is in the regime of high HF concentration where the etch rate is limited by the concentration of the oxidizing species, *i.e.*, HNO₃. Isotropic etching characteristics of high HF concentration etches have also been observed previously (6) and applied to etching mesa diodes in polycrystalline silicon (8, 9).

Experimental

The substrate material consisted of 0.1-16 Ω -cm n- and p-type RTR² ribbons grown by laser or electron beam melting, 1 Ω -cm p-type Wacker Silso³, and Czochralski-grown (Cz) single-crystal wafers. Cz and Wacker Silso were chemically/mechanically polished on one side, whereas RTR ribbons were used with as-grown surfaces. All samples were cleaned in H₂SO₄:H₂O₂ (3:1) at 90°C, followed by a DI water rinse, and dried with nitrogen. Etch solutions were freshly mixed, and etching was done with samples held vertically in a Teflon⁴ holder while the samples were mechanically agitated. Etched samples were rinsed in DI water, dried with nitrogen, and examined under optical (VIS/IR) microscopes. It should be pointed out that etching in 36:20:1, to obtain low etch rates and/or small etch pits, may cause a light bluish stain on the sample. This stain does not interfere with defect inspection and identification, and may be readily dissolved in H₂SO₄:H₂O₂ solutions.

To determine the bulk etch rate, samples were partly masked by photoresist (Waycoat 450)⁵ using conventional photolithography and etched for different times. After removing the photoresist, the step heights were measured using a surface profilometer.

To study defect delineation characteristics for different orientations, single-crystal Cz wafers of different orientations, *viz.*, (100), (110), (111), and polycrystalline substrates whose grain orientations were determined by an optical diffraction technique (10) were used.

Results

The photograph in Figure 1 shows the defect distribution in various grains of a section of RTR ribbon that has been etched for 30s in 36:20:2. The sample was etched without any surface preparation. Various twins and grain boundaries delineated by the etch are marked in the figure.

Figure 2 shows magnified photographs of several regions of the same sample. Etch pits seen in this figure are mostly either circular or elliptical in shape and are due to dislocations propagating along (or at small angles away from) the normal to the surface. Various defects are identified. The grating-like pattern seen in these pictures is a characteristic of the as-grown ribbon surface.

Figures 1 and 2 clearly show delineation of dislocations in a variety of grain orientations in RTR ribbons.

Fig. 1. Photograph of a section of an RTR ribbon etched for 30s in Sopori etch [36:20:2 (HF:CH₃COOH:HNO₃)].

To demonstrate defect delineation on a wide variety of orientations, Fig. 3 shows photographs of two adjacent samples from an RTR ribbon. One of the samples was texture etched to show different grain orientations by reflection contrast, and the other etched in Sopori etch. The large grains were found to be misoriented with respect to the (110) plane by $\pm 15^\circ$ about the x -axis and $\pm 11^\circ$ about the Y -axis. Small grains (not identified in the

Fig. 2. Several typical regions of a defect-etched ribbon

figure) possess other orientations, such as (111) and (100). Defect delineation is clearly seen from the accompanying photograph. The effectiveness of defect delineation on different orientation samples was further confirmed by (i) the use of single-crystal Cz wafers of (100), (110), and (111) orientation into which defects were introduced by nonisothermal heating, and (ii) the use of polycrystalline substrates of other preferred grain orientations, e.g., Wacker Silso, which was found to have most grains close to (111). This extensive study did not reveal any difficulties in delineating crystallographic defects on any grain orientations. Furthermore, the etch pit size does not vary significantly for different orientations.

Defect delineation characteristics of this etch were compared with several other etches. To permit a direct comparison of the effect of these etches on different grain orientations, polycrystalline ribbons, which have nearly longitudinal grains, were scribed into samples such that they possessed many common grains. Figure 4 shows typical examples of etch pits formed by different etchants on the same grain. These samples were cleaned in the manner previously described.

A detailed comparison of different etches for polycrystalline silicon will be given elsewhere (11). Here we may briefly summarize the results as seen in Fig. 4 as follows: (i) The etching characteristics of Sopori etch are very similar to that of Secco etch (which is isotropic). (ii) Although Schimmel etch also produces etch pits similar to Sopori etch, it results in excessive stains and, additionally, delineates defects only in p-type substrates, Schimmel etch also generates different etch-pit sizes on different orientations and has been reported to have defect delineation characteristics which are dependent on the ambient light level. (iii) The post-etch surface quality of samples etched in Sopori etch is similar to that of Secco etch. However, the best surface quality is obtained from the Wright etch.

It is of particular interest to compare the advantages of Sopori etch with a preferential etch such as Wright etch,

Fig. 4. Etch pits formed by different etchants on the same grain. All samples $0.4 \Omega\text{-cm}$, p-type. A (top left): 30s Sopori etch. B (top right): 2 min Sirtl etch. C (middle left): 2 min Secco etch. D (middle right): 5 min Schimmel etch. E (bottom left): 15 min Dash etch. F (bottom right): 5 min Wright etch.

which has recently been used quite extensively for polycrystalline silicon. For this purpose, two adjacent samples having the same grain structure were laser scribed from a ribbon. One of the samples was etched in Sopori etch for 30s, and the other in Wright etch for 5 min. Figure 5 shows a comparison of dislocation configurations revealed by the Wright and Sopori etches. The etch pit shapes of simple slip dislocations in a grain whose surface orientation is (110) are shown in Fig. 5a and 5b. The etch pits due to Wright etch are square, indicative of the

two-fold symmetry of (110), and do not indicate directly the direction of defect propagation. From Fig. 5a, the elliptical etch pits clearly indicate that the dislocations are at an angle to the surface and parallel to the twin boundary, *i.e.*, the (111) plane. Some other regions having dislocation loops and networks are shown in Fig. 5c and 5d. The comet shapes of individual etch pits and interconnected etch pits seen in the Sopori-etched sample are indicative of dislocation loops and networks, respectively. However, looking at the Wright etched section, it is not, in

Fig. 5. Comparison of defect delineation by 30s Sopori etch and 5 min Wright etch. A (top left) and B (top right): (100) grain orientation with simple slip dislocations for Sopori etch and Wright etch, respectively. C (middle left) and D (middle right): grain with dislocation networks for Sopori etch and Wright etch, respectively. E (bottom left) and F (bottom right): dislocation delineation on a (100)-oriented grain for Sopori etch and Wright etch, respectively.

general, possible to determine the nature and direction of dislocations, although the presence of different pit shapes in the same grain (as seen in Fig. 5d) would imply dislocation propagation at different angles. Another disadvantage of a preferential etch is that the etch-pit size varies with grain orientation. This is seen by comparing the etch pit sizes of Fig. 5c and 5f, which show dislocations on a (100) grain revealed by the Sopori and Wright etches, respectively, with those of Fig. 5a-5d. Clearly, the etch pit

size on (100) due to Wright etch is much smaller than that on (110). Consequently, we believe that the advantages of using a preferential defect etch for generating well-defined geometric etch-pit shapes on single-crystal substrates (for easy identification of the nature of the defect and the crystal orientation) are diminished for polycrystalline substrates.

The relationship between the shape of the etch pit and the direction of defect propagation can be demonstrated

Fig. 6. IR photographs of a ribbon etched in 36:20:2 showing a correspondence between etch pits on the top and bottom surfaces due to each dislocation. Ellipticity of each etch pit is related to angle at which dislocation propagates. A (top): transmission mode, top surface focused. B (middle); reflection mode. C (bottom): transmission mode, bottom surface focused.

by viewing a sample, etched with Sopori etch, under an infrared (IR) microscope. Figure 6 shows IR photographs of a sample taken under different viewing conditions. In Fig. 6a, the well-defined dark images are due to etch pits on the top surface, and the blurred images are due to etch

pits on the back surface (away from the objective). To help identify the top surface etch pits in Fig. 6a, a photograph of the same region taken in reflection is shown in Fig. 6b. A correspondence between the top and the bottom etch pits of the same dislocation can be easily recognized for most cases. It is obvious from the photos in Fig. 6 that an increase in the ellipticity of an etch pit is accompanied by an increase in the separation between the top and the bottom etch pits of the same dislocation. For ease in recognition of etch pits on the bottom side, a photograph of the back side (focused in transmission mode) is given in Fig. 6c.

Sopori etch also works well for delineation of stacking faults, as shown in Fig. 7.

Discussion

Sopori etch shows excellent delineation characteristics with etch rates that are the same for all orientations. Figure 8 shows bulk etch rates using two compositions de-

Fig. 7. Sopori etch delineations of stacking faults. A (top): oxidation-induced faults on a (111)-oriented Cz wafer. B (bottom): bulk stacking faults in an oxygen-rich RTR ribbon.

Fig. 8. Bulk etch rates for (A) 36:20:1 and (B) 36:20:2

Fig. 9. 50 mil mesa diode formed by Sopori etch, with underlying defect structure. Diode width = 1270 nm.

scribed in this paper. Although etch rates are higher than for other defect etches, we have found that no appreciable degradation of surface quality occurs, and the etch rates are quite controllable. These features of the etch, along with the capability of masking with conventional photoresists, have been used to fabricate mesa devices. The advantage of using this etch is that substrate structure is revealed during mesa etching. This offers a convenient way of correlating device performance with substrate structure. The underlying defect structure of a 1270 mm diam. mesa diode, formed by the 36:15:1 etch, is shown in Fig. 9. Etch rates can be adjusted between the two cases shown in Fig. 8 by further dilution of 36:20:2 by CH_3COOH up to 36:25:2 without affecting the quality of defect delineation.

Alternatively, by cooling the etch (to 10°C), the etching time was increased to 2 min. The cooled etch also improves surface quality and eliminates the formation of any occasional stains. For everyday purposes, the etch (36:20:2) is premixed in the desired quantities (10 to 50 gal) and stored in 1 gal containers for use over a period of up to a few months. The etch is routinely used for defect delineation in a variety of polycrystalline silicon substrates of different grain sizes and grown by different techniques.

Acknowledgments

The author would like to thank Dr. F. Secco and Ms. M. Wright Jenkins for many helpful suggestions regarding this work and for critical reading of the manuscript. I would also like to thank the reviewers for pointing out Ref. 5. Technical help from Tom Nilsson, Marge McClure, and Jan Markham is greatly appreciated.

Amorphous Silicon Produced by Ion Implantation

Etching Rate in HF Solution and Effect of Annealing

L. Liou and W. G. Spitzer

Departments of Materials Science and Physics, University of Southern California, Los Angeles, California 90089-0241

S. Prussin*

TRW Electronics Systems Group, Redondo Beach, California 90278

This study is an investigation of the effect of the state of amorphous Si on the etching rates in HF acid. Recently, two different metastable amorphous states have been identified for Si (1). Measurements of several different physical properties of amorphous Si produced by high fluence ion implantation have indicated that the as-implanted state, called a-I, is essentially unique in that the properties have nearly the same values for a wide range of implantation parameters (1, 2). The second state, called a-II, is produced by thermal annealing an a-I sample for a short time in the temperature range 400°-600°C. After reaching the a-II state, further annealing does not significantly change any of the measured properties until the material recrystallizes (1-3). The properties which change for a-I → a-II have values in the a-II state which are between those for a-I and crystalline Si.

One of the properties used to characterize the a-I and a-II states was the "dangling bond density" as determined from an ESR measurement (total number of unpaired spins) and the infrared reflection interference spectrum (layer thickness). The dangling bond density was ob-

served to decrease (1, 2) by a factor of about two for a-I → a-II, which suggests that one might observe a difference in chemical behavior for the two states. It is known that crystalline Si is not etched by a 48% HF solution (4, 5) while amorphous Si is etched. However, two different reports place the near-room-temperature rate at about 600 Å/h in one case (6) and 32 Å/h in the other (7). The thermal histories of the amorphous Si in these prior studies is uncertain.

In the present work, two sets of ion-implanted Si samples were used. In one set, the samples were cut from a wafer section having a polished (100) surface which was implanted at room temperature with 5×10^{14} As⁺ ions/cm² having an incident energy of 100 keV. The Si was cut from a p-type ingot having a resistivity between 20 and 40 Ωcm. The second set was taken from another section of the same wafer in which the implantation was done with 5×10^{15} ions/cm² of 200 keV Si⁺ ions. During the implantation, a retaining ring shielded a portion of the wafer section from the implantation beam. In each case, samples were cut so that a small portion of the surface area at one end was nonimplanted material. The thickness of the layer removed in the etching was determined in two

Key words: amorphous, semiconductors, etching, anneal.

ways: (i) infrared reflection as a function of frequency shows interference fringes which can be used to measure the thickness of the amorphous layer before and after etching, and (ii) the step height on the surface, introduced by the etching at the amorphous-crystalline (a-c) interface as measured by a Sloan Dektak Profilometer. The use of infrared reflection measurements to characterize implantation-produced amorphous Si layers has been discussed in detail in the literature (1-3, 8). The infrared measurements indicated that the amorphous layers extended from the top surface to a uniformly deep a-c interface.

The as-implanted samples were all cleaned carefully by washing sequentially in DI water, trichloroethylene, acetone, methanol, and DI water. All containers were similarly cleaned after a preliminary wash with detergent solution. In one case, the sample surface was also cleaned by an oxygen plasma etch which removed $<50\text{\AA}$ of material. In this case, the surface was rinsed in HF to remove residual oxide, and photoemission (XPS) measurements indicated only traces of residual carbon, oxygen, and fluorine on the surface.¹

Three methods were used to etch the samples in 48% HF solution: (i) quiescent (the sample simply immersed in the etchant), (ii) the sample plus etchant in an ultrasonic bath, and (iii) stirring of the etching solution (stirring rod rotating at approximately 200 rpm).

The etching of the a-I material was nonuniform; so, meaningful etching rates cannot be given. This was the result for all samples and all etching techniques. The pre-etching thickness of the a-I layer was determined from the infrared measurements to be $0.128 \pm 0.004\ \mu\text{m}$ for the As⁺-implanted samples, hereafter called group 1, and $0.395 \pm 0.003\ \mu\text{m}$ for the group 2 (Si⁺-implanted samples). An example of the etching of a-I material is given in Fig. 1a, which is a photograph of surface of a group 1 sample after quiescent etching for 3h. The gross nonuniformity is apparent. The Dektak profile shown in Fig. 1b shows substantial portions of the path are close to the crystalline substrate in depth. The plateau regions, where a-I material still remains, indicate a removal rate of $>100\ \text{\AA}/\text{h}$. Since the area of the infrared beam spans the inhomogeneities, the infrared measurements are not meaningful in such a case. Increasing the etching time to 5h results in the a-I material being largely gone, and after 7h, it is

¹ R. P. Vesquez of Jet Propulsion Laboratories performed the plasma etch and made the photoemission measurement.

Fig. 1. Top: a (100) Si surface implanted with $100\ \text{keV}$, $5 \times 10^{14}\ \text{As}^+/\text{cm}^2$ ions and in o-l (as-implanted) state after quiescent etching for 3h in 48% HF. Bottom: a Dektak profilometer recording for traverse of a section of a sample similar to that shown at top. Arrow indicates the amorphous and crystalline interface step.

totally removed. The measured step height after 7h is 1240\AA . Since the density change produced by the implantation-induced $c \rightarrow a$ transition results in a $\sim 2\%$ swelling of the amorphous layer (1, 2), the step height anticipated from the initial infrared measurement is $0.98\ (0.128\ \mu\text{m})$ or $0.125 \pm 0.004\ \mu\text{m}$, which is in good agreement with the Dektak result.

The a-II material showed a very different etching behavior than that just described for the a-I material. The a-I \rightarrow a-II transition was produced by annealing several samples from both groups at 400° and 500°C in a quartz tube furnace at diffusion pump vacuum. The infrared reflection spectrum verified that the annealing was sufficient to produce a change in the refractive index of the amorphous layer (1-3); which indicated a-I \rightarrow a-II, i.e., $n(c) = 3.44$, $n(a-I) = 3.84$, and $n(a-II) = 3.70$; all at a frequency of $\nu = 4000\ \text{cm}^{-1}$. The cleaning procedures were the same as those described above. An example of some of the results are shown for two samples in Fig. 2, where one observes uniform etching for as long as 6h and the infrared and Dektak measurements give similar removal rates. The nonuniformity is increasing at the longer times, as indicated by the increasing error bars for the step-height measurements. For still longer etching times, the measurements indicated progressively more inhomogeneous removal, and frequently staining was observed.

The results of all the etching measurements are summarized in Table I. It is worthwhile to make several observations concerning the information in the table.

1. The etching characteristics are completely different for a-I and a-II materials, but appear to be largely inde-

Table I. Summary of etching results for a-Si samples

Sample no.	Group	Amorphous Si state	Anneal condition	Etching procedure	Rate (Å/h)	Comments
1	1	a-I	none	quiescent	$\approx 1 \times 10^2$ (sh)	Highly nonuniform. Rate specified is for plateau of a-I material (see text). Surface cleaned by rinsing in HF and methanol, before and after plasma etching. Surface is nonuniform but not as much as sample 1.
2						
3	2	a-I	none	quiescent	$\approx 1 \times 10^2$ (sh)	
4	1	a-I	none	ultrasonic bath	$\approx 1 \times 10^2$ (sh)	Highly nonuniform, rate larger than that for quiescent case.
5						
6	1	a-I	none	stirring	~ 3 to 4×10^2 (sh)	Not so nonuniform as other a-I etching methods but rate not constant in time.
7	1	a-II	400°C/2h	quiescent	41 (ir)* 40 (sh)	Uniform, measurements in 1h intervals for 7h.
8	1	a-II	400°C/2h	quiescent	38 (ir) 40 (sh)	Uniform, measurements in 1h intervals for 7h.
9	1	a-II	400°C/2h	quiescent	40 (sh)	Less uniform than samples 7 and 8.
10	2	a-II	400°C/2h	quiescent	40 (ir)	
11	2	a-II	400°C/2h	quiescent	~ 50 (ir) ~ 60 (sh)	Surface layer etched at a more rapid rate than material at depths $>200\text{Å}$. Same procedure as sample 9, but with initial plasma etch and HF and methanol rinse.
12	2	a-II	400°C/2h	quiescent	36 (ir)	
13	2	a-II	500°C/1h	quiescent	~ 50 (ir) ~ 50 (sh)	Pronounced stain develops after 2h.
14	1	a-II	400°C/1h	ultrasonic bath	~ 70 (sh) ~ 67 (ir)	
15	1	a-II	400°C/2h	ultrasonic bath	~ 70 (sh) ~ 67 (ir)	Uniform, measurements in 1h intervals for 7h.
16	1	a-II	400°C/2h	stirring	~ 80 (ir) ~ 77 (sh)	

*(sh) means step height measured value; (ir) means infrared interference determined value.

pendent of whether the sample is from group 1 (As⁺-implanted) or group 2 (Si⁺-implanted).

2. While the etching of the a-I material is grossly nonuniform, the rates for the plateaus are substantially larger than those observed for the a-II material. This result is qualitatively consistent with the anticipated difference in behavior based on the change observed in the dangling bond density.

3. While there is some spread in the experimental removal rates for the a-II material, there is an indication that the rate is lowest for quiescent and largest for stirring, not an unexpected result. The average value for the quiescent rate is 42.5 Å/h with a standard deviation of ± 8.5 Å/h, while the rate for stirring is almost twice as large. In many cases the surfaces show some staining during the prolonged etching procedures.

4. Comparison with previously reported rates indicates that the 33 Å/h value given by Tsai *et al.* (7) is close to that observed here for a-II material (quiescent). The approximately 600 Å/h value reported by Gerasimko *et al.* (6) would indicate they were etching a-I material, even though they did not indicate the nonuniformity observed here.

Gibbons *et al.* (9) observed that quiescent etching rates can be highly variable, and Tsai *et al.* indicated that surface contamination may be responsible in part for nonuniform etching. If the amorphous layers contain microvoids, a common occurrence in deposited layers, or if the implantation leaves a thin crystalline surface layer, then one may also observe highly variable etch rates. However, it is clear from the above measurements that the state of the amorphous Si also influences the etch rate. Recently, Prussin (11) indicated that dynamic annealing may occur during ion implantation of the specimen if high beam current densities are used and the samples are not in good contact with a heat sink. Our preliminary measurements of the IR reflection spectrum show that when dynamic annealing occurs, the amorphous material still remaining

has a refractive index between those of state a-I and a-II. Therefore, one might expect different etching rates of the ion-implanted material with different cooling arrangements and ion beam currents.

ABSTRACT

Undoped LPCVD silicon films have been deposited at five temperatures between 560° and 620°C. The films were characterized as grown and after thermal annealing at 900°, 950°, and 1000°C. We used x-ray diffraction, TEM, SEM, Raman and elastic light scattering, optical absorption and reflection, and other techniques in order to obtain information on the grain size, structure, structural perfection, and surface roughness. We found that polysilicon films of good structural perfection, low strain, and small surface roughness are obtained when the films are deposited in the amorphous phase and subsequently crystallized at 900°-1000°C. Such films are superior in all investigated material aspects to films grown in the crystalline phase.

The quality of polycrystalline silicon layers used as MOS gates, load resistors in memory cells, and various other applications in the IC technology is of paramount importance for the device performance. Within the last several years, the technique of low pressure chemical vapor deposition (LPCVD) has become the standard preparation method for polysilicon films in IC manufacturing. A few studies on the structure, morphology, and electrical properties of LPCVD polysilicon films have been reported (1, 2). It was concluded that polycrystalline films formed above 600°C are more stable than the amorphous films deposited at lower temperatures. Amorphous films seemed undesirable because of uncontrolled crystallization in postdeposition heat-treatments. We have reinvestigated this question by a systematic variation of the growth conditions and a comprehensive characterization by x-ray diffraction, electron microscopy, and electrical techniques, and also by several optical methods. The main conclusion from the results presented in this paper is that in contradiction to the previous belief, only films deposited in the amorphous phase and subsequently crystallized have the high quality in terms of structural perfection and surface roughness which is required for critical applications.

Film Deposition and Thermal Annealing

The growth experiments were carried out in a conventional hot wall LPCVD reactor equipped with a 124 mm id quartz tube and a 1 m³min⁻¹ Alcatel double-stage rotary pump. The deposition temperature was measured inside the deposition tube during the film growth. Substrates with a 2 in. diam and placed perpendicularly to the tube axis with a spacing of ¼ in. were used. Sapphire {1102} substrates were chosen for measuring the film thickness. {100} silicon substrates covered with a 300 nm thick thermally grown SiO₂ were chosen for all the electrical, optical, x-ray, and TEM characterization methods, and some quartz substrates were chosen for optical absorption measurements. Films of 0.5 μm thickness were deposited from undiluted silane at temperatures of 560°, 570°, 580°, 600°, and 620°C. Silane gas flow rates from 50 to 200 cm³ min⁻¹ and deposition pressures of 120-350 mtorr were used. The growth rate at 600° and 620°C was limited to 10 nm min⁻¹ by reducing the deposition pressure from 350 to 120 mtorr. The film thickness was measured after growth with a "Dektak" surface profilometer on the films deposited on sapphire substrates. For this purpose, a small window of about 3 × 3 mm was etched in the center of the wafer. The masking was done with Apiezon wax, and the film was etched with an etchant consisting of HF-acetic-HNO₃ with a ratio of 1:1:10 by volume. The growth rate as

a function of deposition temperatures is shown in Fig. 1. The calculated apparent activation energies of 32-39.9 kcal/mol agree well with 32 kcal/mol reported for LPCVD by Gieske and McMullen (3).

After the initial characterization with some of the methods, the Si/SiO₂ substrates were cleaved into four equal parts prior to thermal recrystallization. One part was kept in the as-grown state for further reference while the others were annealed at 900°, 950°, and 1000°C, respectively. The annealing treatments were done in N₂ + 0.5 volume percent (v/o) O₂ for 30 min. The thin SiO₂ film which grows during annealing was not removed before characterization.

X-Ray Diffraction

X-ray diffraction was used to examine the degree of crystallinity and crystallite size and texture of the as-grown and annealed layers. For each layer, the three most intense reflections from the {111}, {220}, and {311} planes were recorded with a Siemens Type F diffractometer (Cu-radiation, 40 kV). The crystallite size was determined from the linewidth (full width at half maximum) by applying the Scherrer formula (4): $D = 0.9\lambda / (B \cos \Theta_B)$ where $\lambda = 1.5405 \text{ \AA}$, Θ_B is the Bragg angle, and B the linewidth corrected for the $K\alpha_1 - K\alpha_2$ line splitting (5) and instrumental broadening (6); the latter had been determined by using an Au standard. Thus, the corrected halfwidth was interpreted as being fully due to a crystallite size effect, neglecting strain influences. The line intensities were corrected for the film thickness and normalized for the strength of the signal expected from a randomly oriented signal (7, 8).

The grain size accuracy and reproducibility expected from this method is about 10-20%. However, with this procedure a single grain size is determined from each diffraction line while in reality there is a wide distribution of grain sizes present (see TEM measurements). Nevertheless, one obtains from x-rays an order of magnitude grain size and relative trends for the polysilicon layers.

The layer properties deduced from the x-ray measurements are given in Table I and Fig. 2. The layers deposited at 560° and 570°C are x-ray amorphous (no line intensities); note the fact, however, that a few small crystallites are observed by TEM (see next section). Layers deposited at 580°C are partly amorphous/partly crystalline as deduced from low line intensities. The high temperature layers appear to be fully crystalline (since for these layers the line intensities do not increase any more with annealing). After annealing ($T_a = 900^\circ\text{-}1000^\circ\text{C}$), all layers are fully polycrystalline.

The grain sizes of the as-grown layers range between 100 and 770 Å and differ because they were obtained from different diffraction lines. A <311> preferred orientation (texture) is found for as-grown layers deposited at 580° and 600°C, while a strong <110> texture is exhibited by the 620°C layers. In the 620°C films, a very pronounced

columnar structure was observed by cross-sectional TEM (9) and the grain dimension D_{220} is by far the largest. A columnar structure similar to our 620°C layers has been reported by Falckenberg *et al.* (10) for poly-Si films deposited by LPCVD at 625°C.

Grain growth seems to take place in a different way when the layers are deposited in the amorphous phase and annealed at 900°-1000°C. It appears that nucleation takes place in randomly oriented grains, but the largest grain dimensions and texture develop in <111> direction. This trend overcomes the original weak <311> texture in the layers deposited at 580°C so that <111> texture becomes dominant by annealing. The structure and morphology of the originally polycrystalline layers is preserved during annealing except for a slight grain growth.

We conclude from the x-ray diffraction that the crystallization of amorphous layers does not lead to unreproducible structures (1). Texture and grain size are remarkably reproducible in the entire deposition temperature range from 560° to 580°C. The average grain size is somewhat larger than in originally polycrystalline films but still small compared to present design rule dimensions and even future submicron scales.

Transmission Electron Microscopy

For TEM investigations, the following sample preparation was performed: a 3 mm diam disk was cut out of the original wafer by ultrasonic techniques. An angle lap of

D_{hkl} = grain size evaluated from the x-ray diffraction line (hkl) according to the Scherrer formula (see text).

about 1° was performed at the surface of this disk, the sample was then thinned by ion etching (HF-HNO_3) starting from the substrate side. The oxide layer was removed by a 1 min etch in HF and finally the poly layer jet-etched until a small hole occurred. This preparation technique permits an examination of the polysilicon layers at various depths. The samples were investigated by bright and dark field techniques and by selected area electron diffraction.

The TEM results for as-grown layers show that the low temperature layers all are found to be partly crystalline (differing partly from x-ray and Raman results due to the testing method) while the high temperature group is fully crystalline (11). The average crystallite size \bar{S} and size distribution was determined by measuring 30-100 crystallites

Fig. 2. X-ray grain size D_{111} as a function of annealing temperature T_a for various deposition temperatures T_d .

from the bright and dark field micrographs (Fig. 3a, b) for relative large grains and from the diffraction micrographs (Fig. 3c) for small particles. The average crystallite size \bar{S} increases approximately linearly with T_d (see Fig. 4) from 50 to 300Å, (neglecting large irregularly shaped crystallites at the 580°C layer surface).

However, there is a wide distribution of grain sizes present in all layers. This is illustrated in Fig. 5, where the distribution of the grain sizes is plotted for a 620°C layer. Many grains are smaller or larger than \bar{S} . Slightly different grain size distributions are found at the substrate-layer interface (I) and at the layer surface (S), indicating a higher crystalline volume fraction at the substrate-layer interface for the 560° and 570°C layers (11).

Annealed layers were studied by TEM exclusively for 1000°C annealing, since x-ray had shown little annealing temperature dependence. The low temperature layers, after annealing, exhibit grain sizes \bar{S} around 800Å while the high temperature layers group around 300Å (Fig. 4). Annealing thus has a large effect on the crystallite size of the low temperature group which is to be expected since these layers are mainly amorphous in the as-grown state. The grain size of the high temperature group, however, increased very little, since the original deposition in crystalline form imposes some constraints on further grain growth. These results, in general, compare well with x-ray and in particular with the grouping for the D_{111} values (see Fig. 2). As already pointed out, the agreement between x-ray and TEM average crystallite size determination is quite satisfactory (11). It should be noted, however, that our TEM technique yields only grain dimensions in the plane of the film. Cross-sectional TEM work (9) has shown that, e.g., our $T_d = 620^\circ\text{C}$ films have a pronounced

Fig. 3. Bright field (a, top), dark field (b, middle), and selected area diffraction (c, bottom) micrographs for an LPCVD layer deposited at $T_d = 560^\circ\text{C}$ and annealed at $T_a = 1000^\circ\text{C}$, taken at the SiO_2 -Si interface.

Fig. 4. Average crystallite size \bar{S} for LPCVD Si-layers, as-grown (\circ : interface, \bullet surface) and annealed at 1000°C (\square : interface, \blacksquare surface) as a function of T_d .

columnar structure such that many grains extend vertically through the entire film.

The grain size distribution of annealed $T_d = 620^\circ\text{C}$ layers is shown in Fig. 5 (note that there is a very small probability for sizes larger than 700Å). It can be seen from Fig. 6 that the annealed low T_d layers, in particular those grown at 560° and 570°C, show a smooth grain size distribution. The distribution is shifted to larger sizes as compared to $T_d = 620^\circ\text{C}$ (Fig. 5) but there are very few grains of a few thousand angstroms in diameter. So the TEM results show in even greater detail than x-ray diffraction that the crystallization of amorphous layers yields a well-defined morphology.

Brown *et al.* (1, 2, 7) have reported on the structure of LPCVD films grown at $T_d \geq 525^\circ\text{C}$ on silicon wafers covered with 1000Å of thermally grown oxide. Their results agree with ours in the sense that polycrystalline films are formed for $T_d \geq 600^\circ\text{C}$. However, average crystallite sizes determined by these authors using TEM were 550-870Å for as-grown layers, nearly three times our values. This may be due to the detailed deposition conditions which, as mentioned elsewhere in this paper, play an important role in this transition temperature region (600°-620°C). For annealed layers, no grain sizes were quoted by Brown *et al.* In terms of texture, the $\langle 110 \rangle$ texture for high temperature as-grown and annealed layers is confirmed by us, while there is a difference for annealed 580°C layers for which Kamins *et al.* find $\langle 311 \rangle$ while we find $\langle 111 \rangle$ texture. Moreover, we have to emphasize again that originally amorphous films can be thermally converted into reproducible stable polycrystalline structures.

Light Scattering

Raman scattering.—Raman scattering can provide the following useful information on the films in the as-grown and annealed state:

Fig. 5. Grain size distribution for an LPCVD layer, deposited at $T_d = 620^\circ\text{C}$, as-grown and annealed at 1000°C . I = interface, S = surface.

1. From the frequency of the line, the degree of crystallization (amorphous, crystalline, or mixed) can be determined in a short time. This makes use of the fact

Fig. 6. Grain size distribution for low T_d LPCVD Si layers annealed at 1000°C . (\bullet) $T_d = 560^\circ, 570^\circ\text{C}$; (\blacktriangle) $T_d = 580^\circ\text{C}$.

that in crystalline silicon the lattice vibration line is observed as a sharp line at 522 cm^{-1} as seen, e.g., in Fig. 7 (top), while in the amorphous state the breakdown of lattice periodicity relaxes the symmetry restrictions and permits scattering from all vibrational modes resulting in a broad line centered at 483 cm^{-1} , as seen, e.g., in Fig. 7 (bottom). Intermediate states between the two forms (i.e., partly crystalline, partly amorphous) are easily recognizable as a superposition as found, e.g., in Fig. 7 (center). One should note that the terms Raman, x-ray, and TEM amorphous are not equivalent due to a different response by the different techniques.

2. From the intensity of the Raman line, after annealing, the crystalline perfection can be judged.
3. From the Raman line shape (or width), after annealing, one can determine the amount of lattice perturbation and internal strain remaining in the layers.

We have made use of the standard Raman scattering technique (12), with a 100 mW laser light of 5145Å focused to a spot of $50\text{ }\mu\text{m} \times 2\text{ mm}$ on the film. We have verified that these conditions are sufficient for avoiding thermal crystallization by the beam. The scattered light is dispersed in a double monochromator and detected by photon counting. Using a fast scanning technique with suitable averaging can provide the results in a few minutes. The light penetration depth amounts to the reciprocal absorption coefficient which is discussed in the next chapter.

The results are presented in Fig. 8 for as-grown and annealed films vs. deposition temperature. For convenience, we have plotted the maximum Raman intensity; any intensity above the 20-25 counts/s amorphous maximum intensity is therefore due to the crystalline contributions. The predominant crystallization state (amorphous, crystalline) is denoted by the appropriate symbol. The as-grown low temperature group ($T_d \leq 580^\circ\text{C}$) is found to be completely Raman amorphous, while the high temperature group ($T_d \geq 600^\circ\text{C}$) is observed to be partly to fully crystalline with a more or less strong amorphous tail in the spectrum. Upon an-

Fig. 7. (Bottom) Raman spectrum of amorphous layer, as deposited at 570°C . (Middle) mixed amorphous-crystalline layer deposited at $590^\circ\text{--}600^\circ\text{C}$. (Top) crystalline layer, deposited at 570°C with subsequent annealing at 900°C .

Fig. 8. Raman peak intensity for as-grown and annealed layers vs. deposition temperature. \circ = amorphous; \times , \square = crystalline, \otimes = mixed.

nealing, we find no particular dependence on temperature within the range 900°-1000°C. However, of interest is the very strong dip observed in the annealed curve of Fig. 8 for $T_d = 600^\circ\text{C}$ for which the strongly deposition temperature-dependent texture of the crystalline grains might be responsible (see under x-ray).

Some more subtle differences between the low ($T_d \leq 580^\circ\text{C}$) and the high ($T_d \geq 600^\circ\text{C}$) group layers can be found by studying the Raman line shape of annealed films. Preliminary results on this have been reported (11) and are considered to be of importance for device applications. It is found [see Fig. 2 of Ref. (11)] that the Raman line of the low temperature grown polysilicon films quite closely resembles the Raman line of bulk single-crystal silicon while the high temperature grown films exhibit a strong line shape distortion, evident mostly as a low frequency tail. This tail, when integrated, exceeds the bulk silicon integrated intensity by as much as 26%. In a different manner, this can be seen in Fig. 9 where the full Raman linewidth at one-tenth peak height is plotted vs. deposition temperature. The difference between the low and the high temperature group films is indeed very striking. An interpretation of this behavior can easily be given, and is in line with the other findings by light scattering (*i.e.*, elastic scattering to be discussed below). Any contributions to Raman scattering in silicon from modes of lower frequency than the first-order Raman line are possible only if the lattice periodicity of the material is seriously disturbed (of which the limit would be a fully noncrystalline structure). Thus, as judging from Fig. 9 [or Fig. 2 of Ref. (11)], there is little or no disturbance for the annealed low temperature group films which can be considered to be excellent. On the contrary, the high temperature group layers ($T_d \geq 600^\circ\text{C}$) after annealing remain in a highly disturbed state of partly well and partly (maybe up to 26 v/o) poorly crystallized material. It is the latter which is highly undesirable for some device applications since it is internally highly strained (dislocations, stacking faults, *etc.*), and this can produce unwanted defects in an active device area.

Elastic scattering.—The technique of elastic light scattering can be used to determine the structural perfection of polysilicon layers. Every material exhibits an intrinsic elastic scattering which is given by temperature or en-

Fig. 9. Raman linewidth of annealed layers (900°-1000°C) vs. deposition temperature. The low temperature group is close to bulk single crystal while the high temperature group exhibits large linewidth distortions.

trophy fluctuations. In addition, extrinsic elastic scattering is produced by all kinds of structural imperfections of the bulk such as mosaic misorientation, twinning, strain, grain boundaries, stacking faults, dislocations (in general all effects resulting in changes in refractive index), as well as local defects. In terms of surface to volume, the elastic scattering can in principle originate (*i*) from the surface roughness, and (*ii*) from the volume structural imperfection to within the light penetration depth (see section on Raman scattering) in the layer.

For cases where the surface is not exceedingly poor, we have found that the second source dominates since the surface represents only a small portion of the scattering volume. We have, *e.g.*, been able to show (13) that the elastic light scattering on SOS (silicon on sapphire) wafers is strongly correlated with UV reflectivity which again has been shown to be correlated (14) with the twinning density and the SOS device yield.

Elastic light scattering measurements on polysilicon layers were performed by means of two methods: the spectrometer and the scanner for dust and defect detection (15) used in the quality control mode (13). In the former, the same arrangement and the same power and spot size was used, as given above for Raman scattering, except for an additional 10^6 - 10^8 attenuation filter inserted in front of the photomultiplier; the scattered elastic intensity is then recorded for the various wafers. In the latter, by using the laser scanner in the quality control mode, laser light is falling onto the spinning wafer while being translated. The scattered elastic light originating from the bulk (*i.e.*, not from dust or individual defects) is used as a measure for the crystalline perfection. Both methods correlate extremely well.

The elastic scattering results from the spectrometer method for as-grown and annealed layers have been published previously (11). As grown, the elastic light scattering intensity of the low temperature group is very low, in fact it is found to be very close to good single-crystal silicon, and it remains that way upon annealing. Therefore, this material is of very good structural perfection. In contrast, the high temperature group exhibits a very high elastic scattering intensity. Also, the variations (scatter of the data) within the high temperature group are considerable, due to the transition regime. This additional scattering observed for the high temperature group must be interpreted as extrinsic in nature, and caused by the very large volume portions of imperfect and poorly crystallized material in this group, as described above, in connection with the linewidth in the Raman scattering section.

A correlation of these elastic scattering results with Raman scattering is presented in Fig. 10 for as-grown

Fig. 10. Correlation between Raman and elastic intensity for different deposition temperatures, as grown. \circ = amorphous, \times = crystalline, and \otimes = mixed.

layers, from where it is seen that these data correlate quite well in the sense that low temperature amorphous grown films are of high structural perfection while high temperature crystalline films are of rather poor structural perfection. It should be mentioned here that the results of the scanner method, which will be published elsewhere (13), are in full agreement with these findings. In fact, this second method, which is very convenient, lends itself to a rapid characterization (in a matter of seconds) of as-grown material in terms of quality.

Optical Absorption and Refractive Index

Optical absorption.—The optical absorption coefficient has been measured in order to determine the light scattering volume involved in Raman and elastic scattering. For convenience, we have grown polysilicon layers on quartz glass substrates concurrent with the layers grown on silicon/silicon oxide substrates. They have been used to determine the absorption coefficient, as-grown and annealed, from the transmitted and reflected laser intensities at 5145 and 4416Å.

The resulting absorption coefficient is given in Fig. 11 for 4416Å vs. the layer deposition temperatures. It is seen that the absorption coefficient of the low temperature group ($T_d \leq 580^\circ\text{C}$) after annealing at 900°C is very close to the absorption coefficient of single-crystal bulk silicon (16). This provides further support for the findings of Raman scattering intensity, in particular linewidth (see above), and of elastic intensity (see above) that the low temperature growth provides material which after annealing closely resembles the single-crystal silicon material properties. The absorption coefficient of the high temperature group ($T_d \geq 600^\circ\text{C}$), on the other hand, is very different from the single-crystal absorption coefficient (Fig. 11) This can easily be understood in terms of the large distorted volume portion discussed in the context of light scattering. The distorted regions of structural imperfection in the high temperature group give rise to a great deal of internal scattering which seemingly reduces the transmitted light and thus increases the apparent absorption coefficient.

Refractive index.—The refractive index is important for routine thickness measurements with the optical thickness monitor described by Sandercock (17). The effective refractive index was measured as a function of the film deposition temperature by relating the optical thickness t_{opt} for $n = 1$ as measured with the optical monitor to the thickness reading with the "Dektak" surface profilometer t_{eff} , according to $n_{eff} = t_{opt}/t_{eff}$. The results in Fig. 12 show two distinct regions with $n_{eff} \approx 3.9 - 4$ for amorphous material deposited at $T_d \leq 580^\circ\text{C}$ and a transition region

Fig. 11. Absorption coefficient of polysilicon vs. deposition temperature, as-grown and annealed (900°C - 1000°C), at 5145Å (top) as pertinent for Raman and elastic using spectrometer method and at 4416Å (bottom) as pertinent for scanner method.

for $T_d > 580^\circ\text{C}$ where the material is deposited with a mixed amorphous/crystalline structure. The anomalous data points around $n \approx 3.23$ (denoted by *) appear to be the result of excessive surface roughness at this deposition temperature. The error originates from the surface profilometer reading as the stylus cannot follow the full

Fig. 12. Effective refractive index n_{eff} for measurements with the thickness monitor as a function of T_d . * See text.

depth contour of the microscopic surface roughness in contrast to the optical thickness monitor. This was independently confirmed by evaluating a 5400Å thick SiO₂ film with a 1600Å thick deep grating on the surface. It is obvious that the large change in refractive index can be used to get rapid information on whether the deposited material is amorphous or polycrystalline.

Surface Roughness

A slightly rough surface is one in which the surface irregularities are small but not negligible compared to the wavelength of the incident radiation. It has been shown (18) that the optical properties of such a surface are determined by two statistical functions, *i.e.*, the probability distribution of height $D(z)$ and the autocorrelation function $A(s)$ connecting two points on the surface. Because of the continuity of the surface, both functions are mutually dependent. They are characterized by the root mean square (rms) roughness σ defined by $\sigma^2 = \langle z^2 \rangle$ relative to the mean surface level, $z = 0$, and by the correlation length, a , respectively. If $D(z)$ is assumed to be a Gaussian distribution function, the peak to peak surface roughness σ_{pp} is in first approximation given by $\sigma_{pp} = 2 \cdot \sqrt{2} \sigma$.

We determined the surface roughness σ of as-grown and annealed films using a technique developed by Cunningham and Braundmeier (19). A silver layer of 700-1000Å thickness is evaporated onto the silicon surface and then the reflectance of the silvered surface is measured in the wavelength region of surface plasmon excitation, *i.e.*, $\lambda = 3500\text{Å}$. Normally, incident light couples to surface plasmons only through surface irregularities such that the loss of reflectance ΔR , compared to that of a smooth silver surface, is a direct measure of σ . Quantitative σ values are based on a correlation between ΔR and σ values obtained by an interferometric method (19).

We found [see Ref. (11)] σ values of less than 15Å for films in the amorphous phase, *i.e.*, at $T_d \leq 580^\circ\text{C}$. Deposition at 620°C yields reproducible values between 50 and 60Å whereas $T_d = 600^\circ\text{C}$ occasionally gives a smooth surface when other runs produce rough films. Similar results have been obtained by Aspnes *et al.* (20) using ellipsometry to characterize the surface quality of LPCVD films deposited at 575° , 740° and 870°C . σ values in excess of 100Å have been reported for deposition temperatures of 880° - 980°C (21).

It is very remarkable that our σ values are not changed by the annealing treatment at 900° - 1000°C (11). The main conclusion to be drawn here is that the surface roughness is not parallel to the average grain size (see Table I). The annealed low temperature films have an average grain size of about 800Å and $\sigma < 15\text{Å}$ whereas the annealed high temperature films have average grain sizes of 200-400Å and $50\text{Å} < \sigma < 60\text{Å}$. This important fact results from the growth history. If the films are grown in the amorphous state, their surface is smooth, and this smoothness is preserved during recrystallization. The crystallites which are formed in this process do not "stick out" from the surface. It seems possible that a crystallization near the surface leads to a distribution and arrangement of grains such that they can be accommodated within the given contour. If, on the other hand, the films grow in the crystalline state, the surface structure results from the shapes of individual grains which can grow fairly uninhibited. Differences within the group of high temperature films may be due to the different type of texture occurring from $T_d = 600^\circ$ or 620°C . It is obvious that for all those critical applications which rely on an extremely smooth polysilicon surface, one has to avoid growth temperatures of 600°C or higher. In terms of surface roughness, they are either irreproducible (600°C) or unacceptable (620°C).

It was also shown that rapid characterization of the surface roughness is possible by measuring the reflectance of the untreated surface at two fixed wavelengths ($\lambda = 280$ and 400 nm). This technique has been used before to measure the near-surface crystallinity of silicon on sapphire (14). Results obtained on the as-grown and annealed silicon films have been published elsewhere (22).

TEM micrographs of surface replica of the polysilicon films have been taken. Shadowing techniques have been used for evaporation of a 10-20Å thick Pt film under 45°

incidence. Figure 12a shows that a film grown at 570°C and annealed at 1000°C has a lateral structure with a typical dimension of about 200Å but a peak to peak surface roughness σ_{pp} smaller than 50Å. The film grown at 620°C in Fig. 13b has a typical lateral dimension from peak to peak or valley to valley corresponding to the correlation length a of the order of 1000Å. The value for σ_{pp} , deduced from the width of the shadow contours visible in Fig. 13b, is about 200-300Å. Keeping in mind that σ_{pp} is a few times σ_{rms} , these values are in good agreement with the roughness values deduced from the optical measurements.

SEM micrographs have been taken directly of the uncoated surface in order to make sure that no artifacts are introduced by the metallization applied in either of the other two techniques. Indeed, the same lateral dimensions have been found as in TEM. Also, when the samples are tilted, the pronounced differences in the surface height distribution between the low temperature group and the high temperature group become clearly visible. It is also worth noting that in the TEM and SEM studies, no increase of the surface roughness by annealing was observed. In conclusion, electron microscopy confirms the optical roughness values and, in addition, gives insight into the lateral structure.

Conclusions

In this detailed investigation, we have shown that the properties and device quality of polysilicon films depend most sensitively on the deposition temperature and, hence, on the structure in the as-grown state. If polysilicon films of high structural perfection, low strain, and small surface roughness are required, then the deposition temperature should not exceed 580°C .

The reason for the high quality of such films seems to lie in the fact that they condense in the amorphous structure. This type of structure leads to a better grain formation in subsequent annealing processes as compared to direct deposition in the crystalline structure. In the postcrystallized, originally amorphous, films, we observe less strain and higher perfection than in growth-crystallized films. Also, the original small surface roughness of less than 20Å (root mean square value) is preserved in the crystallization process although a grain size distribution with an average size of about 800Å develops.

The growth rate increases with increasing temperature and is higher than 50 Å/min at 580°C . Somewhat higher

Fig. 13. TEM micrographs of shadowed surface replica of polysilicon films annealed at 1000°C . (a, top) $T_d = 570^\circ\text{C}$; and (b, bottom) $T_d = 620^\circ\text{C}$.

growth rates can be obtained at $T_d \geq 600^\circ\text{C}$ but only at the cost of lower structural and surface perfection.

The results of our investigation on *in situ* phosphorus-doped LPCVD polysilicon films will be described in a forthcoming publication (23).

Growth and Characterization of Thin Gate Oxides by Dual TCE Process

B. Y. Liu* and Y. C. Cheng

Department of Electrical Engineering, University of Hong Kong, Hong Kong

ABSTRACT

A novel Dual TCE (two step trichloroethylene) oxidation process has been developed to grow thin and highly reliable gate oxides for very large scale MOS application. The main features consist of an initial low temperature oxidation providing a low-defect-density oxide structure and a subsequent high temperature oxidation providing a good interface with passivation ability against mobile ions. Combinations of various percentages of TCE and different oxidation conditions are examined. It is found that thin oxides obtained by Dual TCE process have high dielectric break-down fields and good oxide-silicon interface, similar to those obtained by two step HCl oxidation, but without their associated disadvantages.

INTRODUCTION

The trend of VLSI strategy is to pack as many devices as possible on a single chip. One of the ways to achieve this goal is to shrink the dimensions of the device structure. In MOS technology, the miniaturization procedure calls for scaling down all physical dimensions, among which an important one is the gate oxide. To realize a sub-micron MOS channel, the dimension of the gate oxide must be scaled down to the order of 100 Å or less¹. Therefore, techniques to routinely form very thin and highly reliable oxides must be established, in order to fully exploit the potential of VLSI technology.

Several groups of workers have reported different methods² to grow thin gate oxides. Kamigaki and Itoh² employed low oxygen partial pressures to obtain thin oxides. Raider and Forget³ and Adams et al.⁴ examined the growth kinetics and properties of very thin oxides. More recently, an HCl oxidation technique⁵ has been applied to form thin and highly reliable gate oxides^{6,7}. In both studies, a two-step HCl oxidation process at different temperatures was invoked.

The idea of a two-step⁶ or dual cycle⁷

HCl oxidation to grow reliable thin gate oxides evolves quite naturally from several experimental observations. It has been reported⁸ that oxides grown at a high temperature have a higher defect density than those grown at lower temperatures. Oxides obtained by HCl oxidation show a significant decrease in defect density when grown at lower temperatures around 900 °C. However, on the other hand, it is known⁹ that below 1060 °C the passivation ability of HCl oxides is not effective. Furthermore, charges at the oxide-silicon interface are not at a minimum if the oxides are grown at lower temperatures¹⁰.

Taking the above facts into consideration and noting that the condition of the oxide-silicon interface is primarily dictated by the final stage of oxidation, a two-step oxidation scheme is an obvious strategy to obtain high-quality thin oxides. The first stage of growth at low temperature is to obtain a low-defect-density oxide structure. The second stage is to perform the HCl oxidation at higher temperature so that a good oxide-silicon interface is obtained, in addition to the beneficial properties of the passivation effect.

The two-step HCl oxidation appears to be a good technique to form reliable thin gate oxides. Besides the good quality mentioned above, the thin oxides thus obtained should possess all the other benefits of HCl oxides, such as elimination of stacking faults¹¹ and improved low-frequency noise performance¹². However, the HCl oxidation technique has, after all, several drawbacks due to its insidious side effects. HCl is a very dangerous acid and cannot be handled easily. Furthermore, it is very corrosive and causes the oxide to have a rough surface if the concentration of HCl is too high. The use of trichloroethylene (TCE) has been reported¹³ to be just as effective as HCl, but without its disadvantages.

Indeed, TCE has some distinct advantages over HCl in that it is much easier to handle,

contains sufficient chlorine and is far less corrosive. However, the technique of TCE oxidation has not been reported to apply to grow thin and reliable gate oxides. In the present work, we report the successful application of TCE oxidation to form very thin and reliable gate oxides. Thin oxides ranging from 90 Å to 500 Å were obtained by different TCE oxidation cycles. Relevant properties of these SiO₂ films were compared to those obtained by the standard dry oxidation process in order to determine the most appropriate TCE conditions to grow thin oxides for VLSI application.

TCE OXIDATION CYCLES

For the present studies, p-type, <111> oriented silicon wafers with a resistivity of 2 to 4 Ω-cm were used, and these were cleaned in H₂O₂-NH₄OH-H₂O (2:1:5, volume) and H₂O₂-HCl-H₂O (2:1:7, volume), followed by DI water rinse. After standard cleaning procedure, these were oxidized in a resistance-heated furnace at various temperatures in the presence (or absence) of a small amount of TCE. TCE vapor was added to the oxidizing ambient which consisted of dry oxygen and dry nitrogen. The partial pressure of oxygen was controlled by adjusting the relative proportion of oxygen and nitrogen. The amount of TCE was controlled by varying the flow rate of another dry nitrogen inlet through a bubbler filled with purified liquid TCE kept at 0 °C. Details of quantitative data regarding the oxidation ambients can be found in Table I.

Several TCE oxidation cycles were performed, and resulting oxides were compared with those obtained by the standard dry oxidation procedure. We call the first one 'total TCE process' in which the entire oxidation takes place in an ambient of oxygen and TCE (other than a small amount of nitrogen as the carrier gas) at a high temperature of 1060 °C. Then the oxide was annealed in nitrogen at the same temperature. The second one is called 'partial TCE process' which differs from the total TCE process in having an initial low temperature (900 °C) dry oxidation and a subsequent high temperature TCE oxidation and nitrogen annealing. The last one is the 'dual TCE process' which consists of a low temperature dry oxidation, a low temperature TCE oxidation and a high temperature TCE oxidation with low oxygen partial pressure. This can be followed by nitrogen annealing, which has not been performed in the present studies. The essential features of these processes are summarized in Table I.

Table I : Summary of various oxidation cycles

Steps	Conditions	Total	Partial	Dual	Standard
1	Gas (ml/min)	-	O ₂ :500	O ₂ :500	O ₂ :500
	Temp. (°C)	-	900	900	1060
	Time (min)	-	10	8	13
2	Gas (ml/min)	O ₂ :500	O ₂ :500	O ₂ :500	-
		TCE/N ₂ :40	TCE/N ₂ :40	TCE/N ₂ :40	-
	Temp. (°C)	1060	1060	900	-
	Time (min)	12	11	15	-
3	Gas (ml/min)	N ₂ :500	N ₂ :500	N ₂ :500	N ₂ :500
				O ₂ :50	
				TCE/N ₂ :25	
	Temp. (°C)	1060	1060	1060	1060
	Time (min)	40	40	40	40

Note. TCE/N₂ denotes the flowrate of dry nitrogen bubbling through liquid TCE, and by varying this rate, the amount of TCE can be controlled.

The oxide film thickness was measured by a Rudolph ellipsometer, Model 43603-200E at a wavelength of 5461 Å, taking the silicon refractive index to be 4.040 - 0.031 i⁴. SiO₂ films on the back sides of wafers were carefully etched by HF. Aluminum electrodes were evaporated from a tungsten boat. Al dot electrodes with 0.51 mm, 0.76 mm, 1.02 mm and 1.52 mm diameters were patterned photolithographically, and the back sides of wafers were evaporated with thick Al films. Dielectric breakdown measurement was performed with the aluminum dots biased negatively, i.e., with the p-type silicon in accumulation. The breakdown voltage was measured on these aluminum dots with four different sizes when the current density reached a magnitude of 0.049, 0.022, 0.012 and 0.008 mA/mm² respectively. For each sample, the mean value of breakdown voltages was obtained from one hundred measurements, and the corresponding breakdown field was computed from the breakdown voltage and oxide film thickness. Fixed oxide charges and mobile ions were deduced from the flat band voltages, based on the high frequency capacitance-voltage measurements using MSI Electronics Model 868 C-V plotter.

RESULTS AND DISCUSSIONS

Typical statistical distributions of the average breakdown field for both TCE and standard oxides are summarized in Figure 1.

It is noted that most breakdown occurs at high fields, within a very narrow range for various TCE oxides. The spread in the breakdown field is large in standard oxides. Table II classifies the breakdown strength for various oxides.

Table II : Comparison of percentage of capacitors for various oxidation cycles
(Area of capacitor = 0.204 mm²)

	Standard Oxide (352 Å)	Total TCE Oxide (477 Å)	Partial TCE Oxide (408 Å)	Dual TCE Oxide (499 Å)
> 6 MV/cm	71.6%	89.5%	95.8%	96.1%
> 8 MV/cm	58.9%	82.9%	90.7%	90.3%
< 4 MV/cm (Low Field Breakdown)	14.7%	4.8%	1%	0%

For total TCE oxide, more than 82% of the breakdown field occurs at fields between 8 to 11 MV/cm, while more than 90% of the breakdown field occurs at the same range for partial TCE and dual TCE oxides. These should be contrasted with the standard oxide which has only 58.9% breakdown field larger than 8 MV/cm. Furthermore, 14.7% of low field breakdowns (< 4 MV/cm) is found in the standard oxides, in contrast to the observation that there is practically no occurrence of low field breakdown in dual TCE oxides.

Figure 2 shows the mean value of electric field breakdown versus capacitor area for the various groups of oxides. The breakdown field drops as the electrode area increases, and levels off as the area increases, and reaches a constant value as the area exceeds about 1.5 mm². The slopes of decrease in the breakdown field are less steep in TCE oxides than that of standard oxide. The mean value of breakdown field in dual TCE oxides and partial TCE oxides is higher than that based on other oxidation condition. The value of the dual TCE breakdown is comparable to the published results of breakdown field in two-step HCl oxides^{6,7}. However, it should be pointed out that exhaustive attempts have not been made in the present work to optimize the dual TCE oxidation conditions in order to obtain the best overall oxide quality.

The fixed oxide charge of dual TCE oxide is significantly lower than that in other samples, as shown in Table III. These values are typical of thin oxides¹⁴. Once again, it should be mentioned here, no attempts have been made to minimize the charge density because no

Table III : Q_{ss} of various oxidation cycles

Sample	Standard Oxide (352 Å)	Oxide TCE Oxide (477 Å)	Partial TCE Oxide (408 Å)	Dual TCE Oxide (499 Å)
Q_{ss} (cm ⁻²)	2.6×10^{11}	1.9×10^{11}	1.75×10^{11}	1.4×10^{11}

N₂ annealing was performed in the dual TCE oxide.

For the effect of protection against mobile ions contamination, bias-temperature-stress had been performed, and the shifts in flat-band voltages in dual TCE oxides are at least ten times smaller than those of our standard oxide samples. More detailed information on the fixed oxide charge density, passivation capability against the mobile ions, and dielectric breakdown properties can be found in a separate publication¹⁵.

CONCLUSION

In our search for techniques to grow thin and highly reliable oxides, we have demonstrated that the dual TCE oxidation cycle is a viable method. Samples obtained show all the good qualities as found in the two-step HCl oxidation technique, but without the inherent difficulties and disadvantages associated with HCl. While we have shown the feasibility of the dual TCE oxidation technique, more work is needed to fully characterize and understand this method, in order that an optimal process can be found. The fixed charge density might be minimized if a conscientious effort is made in annealing the sample, and in adjusting the proper percentage of incorporation of chlorine atoms. Attempts should also be made to render the passivation ability more effective by finding the optimum combination of temperature, TCE percentage and time of duration. In conclusion, we believe the dual TCE oxidation technique will provide a reliable but simple method to grow ultra thin gate oxides for VLSI application.

Polymer Films on Electrodes

13. Incorporation of Catalysts into Electronically Conductive Polymers: Iron Phthalocyanine in Polypyrrole

R. A. Bull, F.-R. Fan, and A. J. Bard*

Department of Chemistry, University of Texas at Austin, Austin, Texas 78722

Abstract

Tetrasulfonated iron phthalocyanines (FePcS) can be incorporated into electronically conducting polypyrrole by electrochemical polymerization of pyrrole in the presence of FePcS. The FePcS modified glassy carbon electrodes catalyzed the reduction of O_2 at potentials 250 to 800 mV less negative than at bare glassy carbon or at polypyrrole-coated glassy carbon not containing FePcS. Rotating ring-disk experiments indicated some hydrogen peroxide formation at most pH's. However, at high pH essentially exclusive reduction of O_2 to H_2O was observed at potentials 250 mV less negative than at a non-catalyzed electrode.

(end of abstract)

One of the main motivations for the preparation of modified electrodes, including those covered with polymer films, is the incorporation of electrocatalysts onto the electrode surface. For example, catalysts have been covalently attached to the substrate, irreversibly adsorbed, and introduced into polymer films via electrostatic binding (1). Of particular interest have been electrocatalysts for the reduction of oxygen (2-5); these often are based on metal porphyrins and phthalocyanines. Among the problems arising in the utilization of catalytic modified electrodes are the limited effectiveness on monolayers (6), instability of the attached or adsorbed materials, and low rate of charge transport through non-electronically conductive films. We suggest here the incorporation of a catalyst into a conductive polymer layer by electrochemical polymerization in the presence of catalyst and briefly describe the characteristics of such an electrode for the reduction of oxygen.

Electrochemical Society Active Member *

Key Words: catalysis, polymers, voltammetry, electrodes

The conductive polymer chosen was polypyrrole (PP); a number of electrochemical studies of this material have demonstrated that this can be readily deposited by electrochemical oxidation of pyrrole from nonaqueous or aqueous solutions (7-10). The catalyst was tetrasulfonated phthalocyanine incorporating iron (FePcS) and the substrate was glassy carbon (GC). The advantages of this system include ease of preparation, and both high conductivity and high porosity of the PP film (11), leading to rapid transport of both charge and solution substrate within the electrode structure.

Polypyrrole films were deposited from aqueous 0.05 M sodium trifluoroacetate solutions (NaTFA) (pH 1-7) that were 0.1 M in pyrrole by anodic oxidation at +0.7 V vs. SCE at GC. Polymer film thicknesses were estimated by taking 24 mC/cm² of charge to be equivalent to a 1 μ m film (8c). GC/PP/FePcS films were prepared by an identical procedure except that the solution contained only 1 mM FePcS and 0.1 M pyrrole. Oxidation of pyrrole in the presence of FePcS was necessary for catalyst incorporation. Control experiments in which a GC electrode was held at +0.7 V vs. SCE in a FePcS solution not containing pyrrole showed no O_2 - reduction catalysis. PP films deposited in the absence FePcS and then cycled through the PP redox waves in a solution containing FePcS also showed no catalytic activity.

CV Experiments.--A typical cyclic voltammogram (CV) of a FePcS/PP film (0.1 μ m thick) is shown in Fig. 1a for a 0.1 M NaTFA electrolyte (pH 1.7) saturated with N_2 . The small waves for FePcS reduction and re-oxidation are superimposed on the large PP background; the large background currents have been ascribed to capacitive charging of the highly porous PP film (11). An estimate of the amount of electroactive FePcS in the polymer from the CV, assuming n=1 for Fe(III)/Fe(II) couple

Manuscript submitted Feb. 22, 1983.

is 2 to 6×10^{-11} moles/cm² geometric area. The FePcS redox waves were stable to cycling within the potential limits imposed by PP. Scanning to potentials sufficiently negative for PP reduction (i.e. out to -0.3 to -0.5 V vs. SSCE) resulted in a decrease in the peak currents (i_p) for the FePcS waves. Potentials positive enough for irreversible PP oxidation ($+0.8$ V vs. SSCE at pH 1 to $+0.4$ V at pH 13) also decreased i_p for the FePcS redox waves, although the film still remained on the electrode surface.

In O₂-saturated solutions the current at the FePcS² wave was greatly increased (Fig. 1b); this is attributed to the catalyzed reduction of O₂. In all cases significantly higher reduction currents were found at more positive potentials at GC/PP/FePcS than at GC/PP or bare GC electrodes. For example, under the conditions of Fig. 1b, O₂ reduction at GC/PP occurs at about -0.8 V vs. SSCE. The effect of pH on the potentials for catalyzed O₂-reduction was similar to that found for the FePcS waves themselves. At pH < 3, the shift of E_d was 45 mV/pH unit. As with the FePcS redox waves themselves, the waves attributed to O₂ reduction disappeared upon irreversible PP oxidation.

RRDE Experiments.--Reduction of O₂ at bare and modified GC disk electrodes with detection of products (e.g. H₂O₂) via oxidation at a Pt ring electrode provided additional information about catalysis by incorporated FePcS (Fig. 2). At a bare GC electrode O₂-reduction occurred to produce a mass transfer-controlled wave, with the limiting current, i_L , increasing with angular rotation velocity, ω . For GC/PP electrodes a wave at similar potentials was observed, but i_L reached a limiting value at about 1000 rpm. The collection efficiencies, N, found for GC and GC/PP electrodes (for O₂ reduction at the disk and H₂O₂ oxidation at the ring) were generally 0.26-0.30; this is less than the collection efficiency found with this electrode and a soluble redox couple such as Fe(CN)₆^{3-/4-}, where N = 0.39. For a GC/PP/FePcS disk electrode, the reduction of O₂ essentially coincided with the FePcS reduction wave and occurred at less negative potentials compared to GC and GC/PP electrodes, similar to the CV results. At most pH's anodic ring currents were observed when O₂ was reduced at the disk (e.g. at pH = 6.5, E_d = -0.6 V; E_r = $+1.0$ V vs. SSCE), demonstrating that some H₂O₂ is produced. Typical results for a 0.12 μm PP/FePcS film in O₂-saturated 0.1M NaTFA (pH 6.5) are given in

Fig. 2a. Strict correspondence to the Levich equation (i_p vs. $\omega^{1/2}$) was not found with this electrode, perhaps because of interference from the background processes of PP. The reduction of O₂ at GC/PP/FePcS in 0.1 M NaOH did not lead to anodic ring currents until the disk potential attained values where direct O₂ reduction of GC/PP occurs. Typical RRDE voltammograms are given in Fig. 2b. After an initial "break-in period" during which the reduction current decreased, the current between -0.1 and -0.3 V was independent of ω . No ring currents were observed at these values of E_d. When E_d reached -0.35 V, the onset potential for O₂ reduction at bare GC, anodic current became apparent. Note, however, that even at these potentials the anodic currents were very small, so that N-values in this region were two orders-of-magnitude smaller than for catalyzed O₂ reduction at lower pH. These results suggest that FePcS catalyzes the decomposition of H₂O₂ in 0.1 M NaOH solution.

In general, over the pH range of 1.7 to 13, N-values for GC/PP/FePcS electrodes were always smaller than those for bare GC electrodes at the same pH. However, at lower pH, N was nearly the same as that for the bare electrode. At pH 13, N was two orders of magnitude less than at a bare GC electrode, even at potentials where peroxide is produced at GC.

The stability of FePcS-PP films depended on the pH and the cathodic scan limits. If the PP films were reduced, O₂-reduction activity decreased. As a result, limiting currents and i_p vs. $\omega^{1/2}$ data could not be obtained. This was particularly so at low pH, where PP reduction began at only slightly negative potentials. The stability of the catalyst-film during O₂ reduction and in the presence of reduction products, e.g. H₂O₂, is also of interest. Successive O₂-reduction scans, especially at low pH, resulted in a gradual decrease in the disk current. After prolonged O₂ reduction the initially shiny blue-black FePcS-PP film changed to a gray particulate deposit that was easily removed from the electrode. At this point, little O₂ reduction activity was observed and, after N₂ saturation, no FePcS redox activity was found. The addition of H₂O₂ to the electrolyte also brought about rapid delay of catalytic activity.

In conclusion, this method of incorporation of catalysts via conductive polymers onto an electrode surface appears to be a promising one. For the GC/PP/FePcS electrodes we have observed significant

catalytic activity for O_2 reduction at potentials 250 to 800 mV² less negative (depending on pH) than at bare GC or GC/PP electrodes. Moreover, the observed current densities for O_2 reduction based on the geometric area of the electrode appear to be larger than those reported for similar catalysts adsorbed on electrodes (2,5). This can probably be attributed to the high conductivity and porosity of the PP matrix, making a larger number of catalyst centers accessible per unit area of electrode to dissolved O_2 .

The PP background often hindered the collection of precise peak and limiting current data for quantitative kinetic analysis. As a result, only qualitative aspects of O_2 reduction mechanisms can be discussed. The similarity of the FePcS and catalyzed O_2 reduction potentials suggests a redox-type mechanism (12). However, the voltammetric behavior and the change of N with pH suggest at least two simultaneous O_2 reduction processes. At low pH the reduction is predominantly to peroxide and N is nearly that found for an unmodified GC electrode. As the pH is raised the Tafel slopes increased and N decreased from that at an unmodified electrode. At intermediate pH, the 2e and 4e processes are competitive, but at high pH no peroxide was detected at potentials positive of O_2 reduction at GC, suggesting a direct 4e reduction to H_2O . The 4 electron process probably involves the dismutation of H_2O_2 by FePcS, as suggested for iron porphyrins in methylacrylate polymers (13). Direct reduction of H_2O_2 is also possible; however, H_2O_2 contributes to instability of PP and loss of catalytic activity. The stability of PP/FePcS catalyst increased at higher pH.

The catalytic behavior found here is qualitatively similar to those observed by Zagel et. al. (2) and perhaps involve similar mechanisms. This suggests that incorporation of FePcS into PP has essentially no effect on the mechanism or catalytic behavior. However, the conductive support enhances the effectiveness of the catalyst by providing more surface area and a larger percentage of active centers than are present in adsorbed films or catalysts in non-conducting polymers and provides a convenient method of attaching the catalyst to the substrate (14).

An Admittance Study of the Lead Electrode

S. H. Glarum* and J. H. Marshall

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

Although impedance measurements are recognized as a valuable adjunct to electrochemical studies, the full realization of the power of the technique has been limited by the need for the expeditious creation and interpretation of a large data base involving impedance, frequency, and potential. Complex-plane plots or analogous representations are often used to deduce and parametrize equivalent circuit descriptions. Mathematically these parameters can be described within the context of rather generalized models by partial derivative functions involving current, potential, and concentrations. Fixed potential measurements evaluate these functions at the selected potentials, but often it is the functions themselves rather than their values which are of prime interest. This study endeavors to obtain such partial derivative functions for the electrodeposition of Pb from perchloric acid solutions, using a microcomputer to analyze a large data base gathered with coordinated measuring apparatus. Complex-plane plots suggest a relatively simple model, with the current being an arbitrary function of potential and the local surface concentration of Pb^{++} ions. From this assumption, it has been possible to extract and plot the partial functions directly. A variety of plating additives were also examined. Each revealed distinctive effects in its partial derivative function plots.

Fundamental studies of electrochemical deposition and dissolution are essential for a scientific comprehension of many important technological processes. Quasi-static current-voltage measurements have been widely applied, but their utility is largely restricted to observing the slowest rate-limiting step. Often this step is solute mass transport and uninteresting from the viewpoint of understanding the true surface reaction. Impedance measurements have been often used to probe electrode behavior on shorter time scales. Because of the time consumed in ac measurements, however, such studies have nearly always been restricted to zero current conditions. Exchange currents may be deduced from such data, but the behavior at other potentials can only be inferred through the assumption of an explicit functional relationship.

In more recent years, automated impedance measuring apparatus has extended the state of the art, making possible considerably more sophisticated studies (1-5). Results are normally plotted in the complex admittance or impedance plane. From the shapes of these plots, equivalent circuits may be deduced and parameters evaluated for the circuit elements. Formally, these elements can be expressed in terms of partial derivatives involving parameters such as current, potential, and concentration. Ideally one would like simultaneous impedance measurements at all frequencies and all potentials. Then, instead of measuring numbers, one would be able to extract the functions themselves rather than their values for a single potential. In earlier work, we have found plots of the real and imaginary admittance components useful for studying the variations of electrode reactions with potential (5). These components, however, are themselves nonlinear functions of underlying partial derivative functions, and are most useful when dominated by a single element. For a more complete analysis, one would like to extract the partial derivative functions themselves from the admittance data.

This study attempts such an analysis for lead dissolution and deposition. Several impedance studies

have been previously reported, but all have been restricted to zero current conditions, yielding only an exchange current density (6-10). The lead electrode has proved especially convenient, for over a wide potential range its behavior can be expressed in terms of a double layer capacitance, a Warburg impedance, and a surface resistance. From impedance measurements *vs.* potential at multiple frequencies, we have found it possible to obtain the partial derivatives as continuous functions of potential. Although certain assumptions are still required, they are of a quite general nature, requiring that the current be a function only of potential and the surface concentration of Pb^{++} ions.

These procedures have also been applied to lead solutions containing the additives thiourea, phenolphthalein, and polypropylene glycol. Each turns out to have a quite distinctive effect when analyzed in terms of its partial derivative functions.

Experimental

The majority of experiments used a 10 mM $\text{Pb}(\text{ClO}_4)_2$ (Alfa Products) solution in 1N HClO_4 (Baker Ultrex). The solution was vigorously degassed with argon, and was thermostated at 25°C.

A 1/16 in. diam platinum rotating disk electrode provided the substrate for lead deposition. The surface was polished immediately prior to each experiment. Lead wire fused within glass capillary tubing served as the reference electrode. Open-circuit potential measurements between the reference and fresh lead deposits were always within 1 mV, our measurable limit.

Sweep frequency measurements, 200 kHz-100 Hz, were made at the open-circuit potential for each series of runs to measure electrolyte resistance and check on the double layer capacitance. The results of prime interest in this paper, however, are derived from admittance-potential measurements at fixed frequencies. As described previously, phase detector outputs were first signal-averaged, and then converted to admit-

* Electrochemical Society Active Member.

tance values by a Texas Instrument 960A minicomputer (5).

In a major experimental enhancement, the 500+ points accumulated for each run were then stored on floppy disks through the intervention of an additional microcomputer. Rather than having to process and plot results between runs, the time between successive measurements became minimal, and this proved important for the comparisons between runs required for data reduction to partial derivative functions. Stored data files were accessible to either computer. Existing minicomputer programs did the heavy number crunching involved in current distribution corrections and the separation of electrolyte resistance. These results were then processed by microcomputer BASIC programs to find the partial functions, and results were plotted semilogarithmically on an X-Y recorder. Thus, the full set of data could be analyzed and displayed with a minimum of human intervention. BASIC programs were also used to construct plots for explicit model functions.

Analysis

Formally, the current flowing in an electrodeposition process, $I(\eta, c, q_i)$, may be expressed as a function of potential, η , the concentration of metal ions, c , and a set of other possible parameters, q_i . When the potential is modulated, $\eta = \bar{\eta} + \eta^* \exp(i\omega t)$, the remaining parameters may also be modulated, i.e., $c = \bar{c} + c^* \exp(i\omega t)$, where η^* , c^* , etc., are complex, time-independent variables. Thus

$$I^* = \left(\frac{\partial I}{\partial \eta} \right)_{c, q_i} \eta^* + \left(\frac{\partial I}{\partial c} \right)_{\eta, q_i} c^* + \left(\frac{\partial I}{\partial q_i} \right)_{\eta, c} q_i^* \quad [1]$$

The information to be obtained from modulation experiments can therefore be represented by a set of partial functions.

If we define $c^*(b)$ as the concentration modulation at a plane a distance b from the electrode, beyond which concentration gradients lie normal to the plane, the high frequency Warburg solution is (19)

$$I_s^*(b) = zFA(i\omega D)^{1/2} c^*(b) \quad [2]$$

where $I_s^*(b)$ is the current modulation at this plane due to the solute species represented by c , z , and D are the charge diffusion coefficient of the solute ion, and A is the planar area. For a hypothetically smooth and uniform electrode surface, $b \rightarrow 0$ and $I^* = I_s^*$ if all current is initially transferred from the electrode to a single solute species.

Admittance measurements yield the ratio I^*/η^* , and, with the assumption that $b = 0$, Eq. [1] may be written as

$$I^* = \left(\frac{\partial I}{\partial \eta} \right)_c \eta^* + [(i\omega D)^{1/2} zFA]^{-1} \left(\frac{\partial I}{\partial c} \right)_\eta I^* \quad [3]$$

where the "hidden" variables are incorporated in the modified pair of partial derivative functions. These functions will be frequency independent if these variables are unimportant or not modulated. Should their frequency dependence parallel I^* or η^* , their detection will depend upon a quantitative examination of the derived functions.

Equation [3] constitutes the basis for the analyses in this study and our objective is to extract from experimental data the two partial derivatives and their ratio, $(\partial c/\partial \eta)_I$, as functions of potential. The electrode impedance is given by the ratio η^*/I^* , and Eq. [3] leads to a simple series equivalent circuit composed of a resistance and a Warburg element, i.e., $Z^* = 1/Y^* = A + B/(i\omega)^{1/2}$. Given A and B , the partial derivatives in Eq. [3] can be evaluated. Unfortunately, the double layer capacitance, C_{dl} , introduces a complication, and a single admittance measurement was found to be

insufficient for the evaluation of these parameters. Instead, measurements for at least two frequencies were required.

Results will only be independent of the solution algorithm if the partial functions are frequency independent, and this proves not always to be the case. We therefore sketch the procedure used. Let ω_1 and ω_2 be the two frequencies ($\omega_1 < \omega_2$) and Y_1^* and Y_2^* the associated experimental admittances. We define

$$\begin{aligned} R' &= Y_1' \\ R'' &= Y_1'' - (\omega_1/\omega_2) Y_2'' \end{aligned} \quad [4]$$

thereby eliminating C_{dl} from R^* . Now let

$$\begin{aligned} Q' &= R' \\ Q'' &= R'' + (\omega_1/\omega_2) S(\omega_2, A, B) \end{aligned} \quad [5]$$

and solve $1/Q^* = A + B/(i\omega_1)^{1/2}$ for A and B . Finally let

$$S(\omega_2, A, B) = \text{Im} [A + B/(i\omega_2)^{1/2}]^{-1} \quad [6]$$

and iterate to Eq. [5] until convergence is achieved. In practice, a 4:1 frequency ratio was satisfactory and the 500+ points could be handled by a BASIC program within 2 min. Values for A and B reflect primarily the lower frequency data, while C_{dl} is found from $Y_2'' - S$, and is largely determined by the higher frequency data. A is inversely proportional to $\partial I/\partial \eta$, and B to $\partial c/\partial \eta$. Thus, when current is primarily limited by concentration polarization, the latter partial is more accurately determined, while the former function becomes noise prone. The converse applies when surface resistance dominates. For 10 mM Pb^{++} solutions, both effects are commensurate, hence our attention to this concentration level.

Equation [3] offers a more general basis for the analysis of admittance data than does the assumption of an explicit model function $I(\eta, c)$. Still, one should understand that this equation entails some assumptions regarding additional parameters, and its usefulness depends upon deriving frequency-independent functions which exhibit "reasonable" behavior. By way of illustration, let us consider the hypothetical function

$$\begin{aligned} I &= I_0 [\exp(\beta e \eta / kT) - x \exp(-\alpha e \eta / kT)] \\ x &= 1 + I/I_{lim} \end{aligned} \quad [7]$$

x being the surface concentration normalized to the bulk concentration and I_{lim} the magnitude of the rotating disk limiting current. The function $\partial I/\partial x$ will then have a linear semilog plot vs. potential, with intercept and slope giving I_0 and α . The function $\partial I/\partial \eta$ has a more interesting shape, with a limiting cathodic value of $\alpha e I_{lim} / kT$, exponential anodic behavior, and a possible minimum depending upon the ratio I_0/I_{lim} . Figure 1 depicts a family of plots for this function for different ratios. Note that the experimental partial derivative functions provide several independent means for evaluation of the three parameters.

Results

The experimental procedure for this study paralleled that previously used for tin (11). Plating took place during a cathodic sweep beginning at an anodic overpotential of +80 mV and running to a lower potential of -250 mV. Admittance measurements were made on the anodic retrace to the starting potential. There the electrode was stripped and the cycle repeated four to eight times for signal averaging. Various combinations of sweep rates between 10 and 200 mV/s were explored to establish a reproducibility window for deposit thickness. A sweep rate of 30 mV/s was chosen for the cathodic trace, leading to a nominal 700Å deposit at the start of data acquisition. A 150 mV/s rate was selected for the anodic trace to minimize morphological changes during measurement.

Fig. 1. Theoretical plots for the function $(\partial I/\partial \eta)_c$ given by Eq. [7] with parameters $\alpha = 0.5$, $\beta = 1.0$, $i_{lim} = 11 \text{ mA/cm}^2$, and indicated ratios for I_0/i_{lim} .

With thicknesses greater than 2000 Å, irregular behavior attributable to dendritic growths could be seen in current-voltage curves (12).

A significant hydrogen evolution current was observed for the first two to three sweeps following introduction of the electrode into the bath. This current soon abated and a flat limiting current region was established down to -250 mV . Underpotential deposition of a lead monolayer not removed under the stripping conditions employed is presumed responsible. At the lowest potential, -250 mV , no further evidence for H_2 formation was apparent after the first few cycles. To avoid the formation of higher valence lead species, the overpotential was not allowed to exceed $+80 \text{ mV}$.

A diffusion coefficient of $9.4 \pm 0.4 \times 10^{-6} \text{ cm}^2/\text{s}$ was found from limiting current measurements for disk rotational speeds of 25–400 rad/s. This value agrees satisfactorily with the literature, 9.8×10^{-6} (13) and was used for subsequent analyses.

Upon completion of a series of experiments and after final stripping of bulk lead at $+80 \text{ mV}$, the electrode was removed, quickly dried, and examined under a microscope. Inevitably, there were indications of a film masking the fine platinum polishing scratches normally visible with oblique illumination. Dramatic color changes ensued when a drop of deionized water was added to the surface. In addition to development of an overall yellow cast, we witnessed red, green, and blue sections from optical interferences. After the electrode had been returned to the acid bath and rotated for a minute under open-circuit conditions, all traces of the film and the discoloration disappeared and surface detail returned to that of a freshly polished platinum surface.

Atmospheric oxidation was suspected, for when the bath was saturated with oxygen, the electrode emerged from plating and stripping cycles with no indications of a film residue. Evidently, the film re-

tains a Pb species other than the bulk metal which oxidizes to yellow acid-soluble PbO . The interference colors would seem to rule out the adatom monolayer not removed at the stripping potential. The film and its attendant colorations were also seen with all the addition agents to be discussed presently.

Figures 2a and 2b plot the real and imaginary components of the surface admittance for a $10 \text{ mM Pb}(\text{ClO}_4)_2/1\text{N HClO}_4$ solution after a current distribution correction and the subtraction of the electrolyte resistance (ca. 10Ω). These data constitute the input for the partial derivative analysis. Figures 3a and 3b show the results of this analysis for the three partial derivative functions and the double layer capacitance. All functions were frequency independent above -150 mV , but below this potential both $\partial I/\partial \eta$ and $\partial I/\partial x$, where x is the reduced surface concentration $c(0)/c_0$, showed a definite dispersion.

Qualitatively, above -150 mV these plots conform to the predictions of a model described by Eq. [7]. Both $\partial I/\partial x$ and $\partial x/\partial \eta$ show exponential behavior, while $\partial I/\partial \eta$ exhibits a cathodic plateau. Note that this feature, not evident in the 40 Hz data in Fig. 2a, is clearly extracted at this frequency by the analysis. Further experiments confirmed the plateau level varied as the square root of disk rotational speed varied and thus also as the limiting current varied.

The dispersion below -150 mV reveals an inadequacy of the three parameter equivalent circuit: surface resistance, Warburg impedance, and double layer capacitance. As no dispersion was seen in plots of $\partial x/\partial \eta$, the source of the dispersion appears to lie in $\partial I/\partial \eta$, which is inversely proportional to the surface resistance. In the dispersion region, the Warburg impedance exceeds the plateau resistance by more than an order of magnitude. Empirically, $\partial I/\partial \eta$ appears to vary as $\omega^{1/2}$.

Fig. 2a. Dependence of the real part of the surface admittance, Y' , for a $10 \text{ mM Pb}(\text{ClO}_4)_2$ solution in 1N HClO_4 after current distribution corrections and the subtraction of electrolyte resistance. Curves a-f correspond to measurements at 40, 80, 200, 400, 800, and 2000 Hz.

Fig. 2b. As for Fig. 2a, but for the imaginary part of the surface admittance, Y'' .

Marked changes were observed when phenolphthalein (0.2 mM) was added to the 10 mM solution. Figures 4a and 4b show the results for the partial derivative analysis. An order of magnitude reduction in the exchange current is evident from the functions $\partial I/\partial \eta$ and $\partial I/\partial x$ at $\eta = 0$. The former now has a prominent minimum near -20 mV, which follows from Eq. [7] when $I_0 \ll I_{lim}$. The cathodic plateau remains, however, at nearly the same level. This function was independent of frequency over the range 40–800 Hz, including the slight drop seen below -200 mV.

The remaining partial functions, however, show large dispersions near $\eta = 0$ which increase as the first power of frequency and suggest errors in the evaluation of $\partial x/\partial \eta$, which is inversely proportional to the Warburg impedance. Surface resistance dominates the impedance in this region. In contrast to the results for the additive-free solution, all functions were frequency independent below -150 mV.

Because of the limited solubility of phenolphthalein in water, additions of a 10 mM solution in ethanol were made to the bath. Measurements using an equivalent volume of pure ethanol established that the changes were not due to the alcohol. Moreover, no differences were found when measurements were made immediately after additive addition or following several hours of degassing which might have removed some of the ethanol.

Figure 5 plots analysis results for a 10 mM $Pb(ClO_4)_2/1N$ $HClO_4$ solution with 0.5 mM (monomer) polypropylene glycol (PPG) added. The average molecular weight, 425, leads to an actual polymer concentration of 0.07 mM. Although similar in appearance to the phenolphthalein results (Fig. 4), there are distinctive differences. The minimum for the function $\partial I/\partial \eta$ has shifted to -50 mV, and this function does not approach the previous cathodic plateau level. Plots using 40–800 Hz data showed no dispersion at any potential. Dispersions in the functions $\partial I/\partial x$ and $\partial x/\partial \eta$ appeared above -100 mV, but their magnitudes were

Fig. 3a. The potential dependence of the functions $(\partial I/\partial \eta)_x$ and $(\partial I/\partial x)_\eta$ obtained from the data in Fig. 2. Curves a, b, and c were obtained, respectively, through analysis of 40, 200, and 800 Hz data with 2000 Hz data. (The extension above $+5$ mV is taken from separate measurements.)

somewhat less than in the case of phenolphthalein. The double layer capacitance was reproducibly greater over most of the potential range, 30–48 $\mu F/cm^2$.

The final additive examined in this study was thiourea. Analysis results for a 10 mM $Pb(ClO_4)_2/1N$ $HClO_4$ solution containing 0.5 mM thiourea are shown in Fig. 6a and 6b. The partial functions reflect an order of magnitude increase in the exchange current density. The resistive portion of the surface impedance is now so small that $\partial I/\partial \eta$ and $\partial I/\partial x$ plots are quite noisy below -100 mV. The surface impedance is dominated by the Warburg contribution, and it can be seen that it is the function $\partial x/\partial \eta$ which is most accurately evaluated.

No plateau for $\partial I/\partial \eta$ is evident, although there are indications of an incipient inflection before this function continues to drop off exponentially in a manner similar to the extreme cathodic behavior seen in Fig. 3a. The function $\partial I/\partial x$ also peaks at about the same level in this region, and exponential behavior is only evident over a 100 mV potential range.

Discussion

Our analysis, predicated upon Eq. [3], presumes an equivalent circuit of series-connected resistive and Warburg elements in parallel with the double layer capacitance. The Warburg admittance is directly proportional to the function $\partial x/\partial \eta$, while the resistive admittance is directly proportional to $\partial I/\partial \eta$. The former function characterizes concentration gradients

Fig. 3b. The potential dependence of the functions $(\partial x/\partial \eta)_I$ and C_{dl} obtained from the data in Fig. 2. These functions are frequency independent.

within the Nernst layer, which is about 15μ thick under the prevailing rotating disk conditions. The parameter x represents the Pb^{++} concentration, normalized to its bulk value, at an inner Nernst layer plane. Formally, this plane is a hypothetical surface parallel to the electrode beyond which concentration gradients lie normal to the surface and concentration changes can be described by one-dimensional diffusion kinetics. The Warburg admittance is frequency dependent because, as the frequency decreases, an increasing portion of the Nernst layer is sampled by ions diffusing from the electrode surface. For frequencies 40-1000 Hz, this thickness ranges from 0.2-4.0 μ . At still lower frequencies, which allow sufficient time for a concentration perturbation to propagate through the Nernst layer (ca. 1 Hz), the frequency dependence shifts from a $(i\omega)^{1/2}$ dependence to resistive behavior. At higher frequencies deviations from ideal $(i\omega)^{1/2}$ behavior may be anticipated when the size of the sampled region reduces to the scale of surface roughness.

The resistive contribution to the electrode impedance represents the net result of all kinetic processes occurring between the metal surface and the inner Nernst layer boundary. Lower values for $\partial I/\partial \eta$ reflect increased surface inhibition of the electrode reaction, whereas lower values for $\partial x/\partial \eta$ indicate increased retardation by solute concentration gradients. The ratio of these functions, $\partial I/\partial x$, measures the relative contributions of surface and solute effects, and for a 10 mM solution at 200 Hz, both are of the same magnitude for $\partial I/\partial x \approx 0.2$ A/cm².

Fig. 4a. The potential dependence of $(\partial I/\partial \eta)_x$ and $(\partial I/\partial x)_\eta$ after a 0.2 mM phenolphthalein addition. The former function is frequency independent. Curves a-e were obtained using 40, 80, 200, 400, and 800 Hz data in combination with 2000 Hz data.

The first surface characteristic we consider is the apparent double layer capacitance. For additive-free solutions this function varies from 30 $\mu F/cm^2$ at -250 mV to 37 $\mu F/cm^2$ at 0 mV. With phenolphthalein added, values range from 24 to 29 $\mu F/cm^2$, and for PPG, 30 to 48 $\mu F/cm^2$. Thiourea solutions show a constant 44 $\mu F/cm^2$ value over most of the cathodic potential range with a drop near 0 mV (Fig. 6b). This decrease was atypical, and all other studies involving this additive gave increases above 0 mV to frequency-dependent values ca., 75 $\mu F/cm^2$.

The range of the capacitances for all solutions is characteristic of the metal-electrolyte interface and reveals no untoward behavior. In particular, there is neither a decrease indicative of a surface film blocking ionic migration to the metal surface nor an enhancement due to reversibly adsorbed surface species. The gradual rise with potential may be rationalized by an increase in surface roughness as deposition progresses. The atypical behavior of thiourea solutions suits this interpretation because of the much larger anodic currents encountered with this additive.

Of the partial derivative functions, let us first examine $\partial x/\partial \eta$. As previously mentioned, this function is determined by changes within the Nernst layer and may therefore be less sensitive to surface complications. Additionally, we have established experimentally that this function is frequency independent with well-defined potential regions of log-linear behavior for the additive-free and thiourea solutions. Consider the nature of this function as given by Eq. [7], bearing in mind that it is not our objective to obtain a "best" fit to this equation, but rather to use it as a guide for discussion. From Eq. [7] we obtain

$$\left(\frac{\partial x}{\partial \eta}\right)_I = (e/kT) (\beta \exp[(\alpha + \beta)e\eta/kT] + \alpha x) \quad [8]$$

and note contributions from two terms corresponding to cathodic and anodic partial currents. At sufficiently

Fig. 4b. The potential dependence of $(\partial x/\partial \eta)_I$ and C_{dl} after phenolphthalein addition (cf. Fig. 4a).

Fig. 5. The potential dependence of $(\partial I/\partial \eta)_x$ and $(\partial I/\partial x)_\eta$ after a 0.5 mM (monomer) addition of polypropylene glycol (PPG). The two plots for the latter function are for 80 and 800 Hz data in combination with 2000 Hz data.

cathodic potentials, this function may be anticipated to be proportional to the inner Nernst plane concentration, x . In the limiting current region in the absence

Fig. 6a. The potential dependence of $(\partial I/\partial \eta)_x$ and $(\partial I/\partial x)_\eta$ after a 0.5 mM thiourea addition. These functions are frequency independent.

Fig. 6b. The potential dependence of $(\partial x/\partial \eta)_I$ and C_{dl} after thiourea addition (cf. Fig. 6a). The behavior of the latter function is atypical of other measurements on this system.

of additives, we observe log-linear behavior with a 103 mV/decade slope corresponding to $\alpha = 0.58$. It is noteworthy that experimentally this function is frequency

independent and log-linear over a potential range where the other partial functions show a more complex potential and frequency dependence. Between -75 and -50 mV, an increase in slope to 42 mV/decade occurs. Then, according to Eq. [8], $\alpha + \beta = 1.40$. We note that the function's value at $\eta = 0$ independently also gives a value for $\alpha + \beta$, and from this intercept we obtain 1.35.

In the presence of thiourea, log-linear functional behavior is seen down to -75 mV, beyond which a decrease in slope occurs. Signal-to-noise limitations unfortunately obscure an accurate slope evaluation at the lower potentials. Assuming that the extensive linear portion of Fig. 6b reflects the contribution of the anodic partial current, we find from the slope that $\alpha + \beta = 1.53$, while from the $\eta = 0$ intercept, $\alpha + \beta = 1.55$.

Corresponding analyses for $\partial x/\partial \eta$ with phenolphthalein and PPG present are hampered by the frequency dispersion above -150 mV. Below this potential, a frequency-independent log-linear region with a 120 mV/decade slope ($\alpha = 0.5_0$) is found for the former additive, while a more tenuous 130 mV/decade slope ($\alpha = 0.4_6$) can be ascertained for the latter. Separate PPG experiments at 20 Hz and extending to lower potentials gave 115-125 mV/decade slopes over a full decade. Steeper slopes were also observed with these additives at anodic potentials. Although function values were frequency dependent because of the adjacent dispersion region, slopes were less affected. For PPG, Fig. 5 shows 33-36 mV/decade slopes extending over two decades ($\alpha + \beta \approx 1.6-1.8$). With phenolphthalein present, no distinctly linear region was observed, although the slope increased to values within this range at the upper potentials of measurement. In both cases, function values at $\eta = 0$ were too low, by factors of 4 or more, to be self-consistent with the slopes.

To summarize the information garnered from the experimental $\partial x/\partial \eta$ functions, values for α of 0.5-0.6 and for $\alpha + \beta$ of 1.4-1.7 appear consistent with the potential dependence of this function for all three additives studied as well as for the additive-free case. This function also provides a measure of the actual surface concentration of Pb^{++} ions in the limiting current region. At the minimum potentials examined, this concentration was about 0.5% of its bulk value for the additive-free and thiourea solutions, and 3-5% for the phenolphthalein solutions.

The second function of interest is $(\partial I/\partial x)_\eta$, and from Eq. [7]

$$\left(\frac{\partial I}{\partial x}\right)_\eta = -I_0 \exp(-\alpha e\eta/kT) \quad [9]$$

Provided Eq. [7] is relevant, semilog plots for this function should be linear with a slope giving α and an intercept at $\eta = 0$ yielding the exchange current density, I_0 . Note that the previous function discussed is not explicitly dependent upon this parameter.

For additive-free solutions, linear semilog behavior is found above -150 mV, and for thiourea solutions above -125 mV. In the former case, we deduce $\alpha = 0.63$ and $I_0 = 11$ mA/cm², whereas for the latter, $\alpha = 0.61$ and $I_0 = 86$ mA/cm². At lower potentials, this function, particularly in the former instance, appears to peak at a value ca. 1 A/cm² and then decrease in a frequency-dependent manner. This behavior is not predicted by Eq. [7].

For the phenolphthalein and PPG solutions, a frequency-dependent dispersion hinders an equivalent interpretation. A linear and frequency-independent section for this function is observed in the former case between -200 and -125 mV, giving $\alpha = 0.57$ and $I_0 = 1.6$ mA/cm². Below -125 mV, linear plots also appear for the PPG solutions corresponding to $\alpha = 0.30$ and $I_0 = 3.3$ mA/cm². Although both additives have sub-

stantially lowered the exchange current, their differential influences are evident in α values.

In both of these instances, a dispersion leading to a maximum can be seen at higher frequencies. The position of this maximum is correlated with the minimum of $\partial I/\partial \eta$ and, for frequencies in the range 40-1000 Hz, the maximum value increases linearly with frequency. Discussion of possible sources for this dispersion will be deferred, but we note that as $\omega \rightarrow 0$ the experimental behavior of $\partial I/\partial x$ also appears consistent with Eq. [7].

Except in the case of PPG solutions, α values are also in agreement with those given independently by analysis of the function $\partial x/\partial \eta$. The plots of $\partial I/\partial x$ reveal the major influence of additives upon the exchange current density. Thiourea leads to an 8-fold increase, while phenolphthalein gives an equivalent decrease at the concentrations employed.

The third partial function which can be derived from the analysis of impedance data, $\partial I/\partial \eta$, is given by the ratio of the two functions previously discussed. For the model described by Eq. [7]

$$\left(\frac{\partial I}{\partial \eta}\right)_x = (eI_0/kT) [\beta e\beta e\eta/kT + \alpha x e^{-\alpha e\eta/kT}] \quad [10]$$

We note contributions from both anodic and cathodic partial currents. At anodic potentials, a linear semilog plot is expected with a slope yielding β . In the cathodic limiting current region

$$-I \approx I_{\text{lim}} \approx I_0 x \exp(-\alpha e\eta/kT) \quad [11]$$

and a constant value for the function, $\alpha eI_{\text{lim}}/kT$ is predicted. At $\eta = 0$ the function's value reduces to $(\alpha + \beta)(eI_0/kT)$. The traditional ac determination of exchange currents measures this point of the function and generally assumes that $(\alpha + \beta) = z$.

For the thiourea solutions, plots show anodic slopes of 59 mV/decade or $\beta = 1.01$. Measurements using additive-free solutions consistently also gave linear plots corresponding to $\beta = 0.9-1.0$. For the 10 mM limiting current density of 11 mA/cm² and $\alpha = 0.6$, the expected plateau value is 0.26 mho/cm² and is independent of the exchange current. The function derived for the additive-free solution does exhibit a constant value region near this level, but results for thiourea solutions are ambiguous because of a higher noise level.

The general shape of this partial function is complex and shows a distinct minimum for the phenolphthalein and PPG solutions. Rather than relying upon asymptotic behaviors to evaluate parameters, we prefer to simulate function plots based on Eq. [7]. This lets us examine in greater detail information contained in the shape of the curve without approximation. Four parameters are required for a simulation: the limiting current, the exchange current, and α and β . The first has been determined independently and the second was selected to reproduce the value of the function at $\eta = 0$. Plots were then made for various combinations of α and β . Finally a nominal "best" β value was used to construct a family of cathodic curves for different α . These were then complemented by a family of anodic curves for different β values and a "best" α .

Such a simulation is shown in Fig. 8 for phenolphthalein together with the experimental function. On the anodic side, a β value of 0.90-0.95 seems appropriate. At cathodic potentials the experimental function ranges between the simulations for α equal 0.60 and 0.65, but no single value appears adequate to describe the function's shape. Below -150 mV, the experimental function peaks and then slowly declines. This behavior lies beyond the predictions of Eq. [7] and appears to be frequency independent between 40 and 1000 Hz.

Fig. 7. A comparison of the experimental $(\partial I / \partial \eta)_x$ function in Fig. 3a with theoretical plots based on Eq. [7] for $\alpha = 0.45(0.05)0.70$ and $\beta = 120$.

Corresponding plots for PPG solutions. Fig. 9, suggest $\beta = 1.3$, and in the cathodic region the experimental function lies between simulations for α equals 0.30 and 0.35, with no single value correctly describ-

Fig. 8. A comparison of the experimental $(\partial I / \partial \eta)_x$ function in Fig. 4a (phenolphthalein) with theoretical plots based on Eq. [7] for $\alpha = 0.45(0.05)0.80$ and $\beta = 0.8(0.1)1.2$.

ing its shape. Deviations below -150 mV resemble those for the phenolphthalein solutions.

Simulations for additive-free solutions are shown in Fig. 7. The experimental function lies between the curves for α equals 0.55 and 0.60, but as in the preceding cases, no single value suffices to fit the data. Below -150 mV, a more drastic deviation from model behavior is evident, and the function is proportional to $\omega^{1/2}$ for frequencies between 40 and 1000 Hz.

With the exception of the PPG solutions, the general behavior for all functions is consistent with parameters for Eq. [7] of $\alpha \sim 0.6$ and $\beta \sim 1.0$. These values have been derived from a variety of independent features of the partial functions. The exchange current density is strongly dependent upon the additives present.

Previous work has reported values based on the concentration dependence of the exchange current as measured at equilibrium. For the model represented by Eq. [7]

$$I_0 \propto [c]^{\beta/(\alpha+\beta)} \quad [12]$$

Reported values for the exponent vary substantially, 0.15-0.20 (8), 0.37 (7), and 0.5 (10), all of which imply $\alpha \cong \beta$. The position of the minimum for the function $\partial I / \partial \eta$ also depends upon this ratio. Experimentally, this minimum always lies at cathodic potentials and necessarily we require $\alpha < \beta$. We thus see little chance for reconciling previous reports with our studies of variations with potential. (An identical situation exists results for copper deposition (14).) Exchange current densities from previous work range from 10 to 50 mA/cm² for 10 mM solutions, and agree somewhat better with our 11 mA/cm² value for additive-free solutions.

The value $\alpha = 0.6$ strongly suggests a limiting one-electron cathodic process, implying a Pb(I) surface intermediate. If we surmise

Fig. 9. A comparison of the experimental $(\partial I / \partial \eta)_x$ function in Fig. 5 (PPG) with theoretical plots based on Eq. [7] for $\alpha = 0.2(0.05)0.5$ and $\beta = 1.0(0.1)1.5$.

followed by a rapid second electron transfer

the mechanism would be similar to the Mattson-Bockris interpretation of copper deposition, the primary distinction being in the solubility of the intermediate (14). For this mechanism, the concentration, c_1 , of the surface species will be

$$c_1 = c_{10} \exp(e\eta/kT) \quad [15]$$

and

$$I_2 = I_1 + AF(dc_1/dt) \quad [16]$$

The ac response is therefore given by

$$I^* = I_1^* + I_2^* = i\omega(eAF/kT)c_1\eta^* + 2I_1^* \quad [17]$$

and

$$I_1^* = \left(\frac{\partial I_1}{\partial \eta} + (ex_1/kT) \frac{\partial I_1}{\partial x_1} \right) \eta^* + \left(\frac{\partial I_1}{\partial x_2} \right) x_2^* \quad [18]$$

This two-step model predicts an additional capacitance of $eAFc_1/kT$ in parallel with the double layer capacitance, and this capacitance should increase exponentially with potential. The expected form of $\partial I/\partial \eta$ is also modified. No anomalous behavior was found for the double layer capacitance and, assuming a maximum contribution of order $10 \mu\text{F}/\text{cm}^2$, the maximum surface concentration would be of order $10^{12}/\text{cm}^2$ (0.1%) at any potential. This model further requires that $\alpha + \beta = 2$, somewhat at variance with our results.

An alternative path might involve a rapid surface disproportionation reaction for the second step, *i.e.*

in which case $x_2 = x_1^2$. In this instance

$$I^* = \left(\frac{\partial I}{\partial \eta} \right) \eta^* + \left[\frac{\partial I}{\partial x_2} + (1/2x_1) \left(\frac{\partial I}{\partial x_1} \right) \right] x_2^* \quad [20]$$

and we find the function $\partial I/\partial x$ to be now affected. Simulations show that instead of being log-linear, this function will bend downwards with increasing potential. All experimental deviations lie in the opposite direction. Although a value $\alpha + \beta = 1.5$ can be deduced for this model from slopes, at $\eta = 0$ a value of 2 should still be given by $\partial x/\partial \eta$.

The dispersions observed in plots for phenolphthalein and PPG appear in regions where the resistive surface impedance substantially exceeds the diffusional impedance, whereas the cathodic dispersion for additive-free solutions occurs where the converse situation prevails. Both may be empirically explained by a Warburg-like admittance, $Y = (i\omega)^{1/2}W_x$, in parallel with both the double layer capacitance and the electro-deposition admittance.

Such an element couples the apparent partial functions because of the method of analysis. In the former instance, as a limiting case.

$$\left(\frac{\partial I}{\partial x} \right)_{\text{app}} \simeq \omega zFA\sqrt{D}c_0W_x \left(\frac{\partial I}{\partial \eta} \right)^{-1} \quad [21]$$

The proportionality to frequency and the inverse variation with $\partial I/\partial \eta$ seen in Fig. 4a and 4b are accounted for, as well as the absence of a significant dispersion for $\partial I/\partial \eta$. From Fig. 4, we estimate $W_x = 3 \times 10^{-6}$ mho-s^{1/2} for the true electrode area. In the converse situation, it is $(\partial I/\partial \eta)$ which is most sensitive to W_x and

$$\left(\frac{\partial I}{\partial \eta} \right)_{\text{app}} \simeq \left(\frac{\partial I}{\partial \eta} \right) \left[1 - (2\omega)^{1/2}W_x \left(\frac{\partial I}{\partial \eta} \right)^{-1} \right]^{-1} \quad [22]$$

From the 800 Hz plot in Fig. 3a, we obtain $W_x = 2 \times 10^{-6}$ mho-s^{1/2}. The magnitude of this empirical admittance is a fraction of that of the double layer ca-

pacitance, even at the lowest frequencies, typically 10%. Since similar magnitudes for W_x account for both dispersions, we will not associate it with the deposition process. The dispersions may reflect nonideal double layer capacitance behavior at low frequencies, possibly related to the observed surface film. Electrode imperfections, particularly at the metal-epoxy interface, might also be involved. Although a correction for this effect would increase the value of $\partial x/\partial \eta$, it amounts to only 2% for 40 Hz additive-free data at $\eta = 0$ and does not significantly raise the reported value for $\alpha + \beta$ of 1.35.

The value for $(\partial x/\partial \eta)_{I=0}$ should correspond to the slope of a plot of $(\ln c)$ vs. the equilibrium electrode potential, and for a reversible two-electron process the Nernst equation gives $78 \text{ V}^{-1} = ez/kT$. Experimentally however, we find values ca. 55 V^{-1} . Open-circuit potentials were therefore measured for concentrations between 1 and 50 mM $\text{Pb}(\text{ClO}_4)_2$ in 1N HClO_4 . Plots for both bulk lead electrodes and thin film deposits on platinum gave canonical 30 mV/decade slopes.

Additional experiments were attempted to resolve the difference between ac results and the open-circuit potential measurements. One possibility was that the freshly formed surfaces studied might not be near a state of thermodynamic equilibrium. Changes in ac response were therefore monitored at several frequencies after a plating cycle was halted at -1 mV. Results were subjected to a partial derivative analysis and are shown in Fig. 10.

Over the first several minutes there is a 40% drop in $\partial I/\partial \eta$, and a 15% drop in the double layer capacitance, but $\partial x/\partial \eta$ remains constant at $52 \pm 2 \text{ V}^{-1}$ during the decay period. The capacitance drop probably reflects a roughness decrease by dissolution, while the larger decrease in $\partial I/\partial \eta$ corresponds to a reduction in the exchange current, possibly through a reduction in the

Fig. 10. The decay of partial functions when the potential sweep was halted at -1 mV.

surface density of growth sites. The behavior of $\partial x/\partial \eta$, however, fails to show a relaxation towards its equilibrium value.

Complex plane measurements to a lower frequency of 0.5 Hz were also made using a nonrotating electrode after a 5 min waiting period. Impedance diagrams showed a linear 45° plot below 50 Hz, and from Z'' values below 5 Hz we obtained $\partial x/\partial \eta = 52 \pm 4 \text{ V}^{-1}$, agreeing with fixed frequency measurements.

The ac results appear to be internally self-consistent, but suggest no explanation for their divergence from equilibrium expectations. Evaluation of $\partial x/\partial \eta$ does require known values for the diffusion coefficient, electrode area, and concentration, and does presume that all current crossing the metal/electrolyte interface is initially carried by diffusing Pb^{++} ions. We might speculate among these possibilities, but the fact remains that the $\partial x/\partial \eta$ functions also give values for $\alpha + \beta$ which concur with values obtained independently from the slopes of the various functions.

If we forsake a detailed balance representation for equilibrium electrode behavior at the frequencies employed, the simplest interpretation is a two-step reduction path: the first being a rate-determining charge transfer step, the second a rapid and irreversible step

One interpretation could be electron transfer to a solvated Pb(II) ion followed by the rapid decay of an unstable Pb(I) species. The irreversibility of the second step insures the absence of a detectable capacitance due to the intermediate.

Anodic behavior, characterized by $\beta \simeq 1$, has as its simplest interpretation the direct dissolution of a doubly charged lead ion which acquires its solvation shell within the Helmholtz layer

The drop in $\partial I/\partial \eta$ from its plateau at extreme cathodic potentials is reminiscent of the behavior of tin (11). There we proposed an explanation based on three-dimensional concentration gradients focused upon discrete deposition sites. The essential distinction between one- and three-dimensional diffusion processes is that the latter lead to a resistive or frequency independent contribution to the impedance, whereas the former have a $(i\omega)^{1/2}$ dependence.

To translate this effect into the present formulation, we shall split the diffusion process into two spatial regions, with r being the distance from the electrode. For $a < r < b$ hemispherical diffusion predominates, while for $b < r$ the linear model will be assumed. Solution of the diffusion equation

$$i\omega c^*(r) = D\nabla^2 c^*(r) \quad [25]$$

with fixed boundary conditions for $c^*(r)$ at $r = a$ and $r = b$ leads to

$$\begin{aligned} a < r < b \quad c^*(r) &= c^*(a) \frac{a \sinh[\gamma(b-r)]}{r \sinh[\gamma(b-a)]} \\ &+ c^*(b) \frac{b \sinh[\gamma(r-a)]}{r \sinh[\gamma(b-a)]} \\ b < r \quad c^*(r) &= c^*(b) \exp[-\gamma(r-b)] \end{aligned} \quad [26]$$

where $\gamma = (i\omega/D)^{1/2}$.

Renormalization by equating the hemispherical and planar fluxes at $r = b$ lets us solve for $c^*(a)$ in terms of the current or flux at $r = a$. Omitting a lengthy exercise, we obtain in the low frequency limit, $i\omega b^2 \ll D$.

$$c^*(a) = I^*[(2\pi N a z F A D)^{-1} + (z F A / i\omega D)^{-1}] \quad [27]$$

where N is the density of deposition sites with effective radius a . Substitution into Eq. [1] gives

$$\begin{aligned} Z^* &= \left(\frac{\partial I}{\partial \eta} \right) + \left(2\pi N a z F A D c_0 \frac{\partial x}{\partial \eta} \right)^{-1} \\ &+ \left(\sqrt{i\omega D} z F A c_0 \frac{\partial x}{\partial \eta} \right)^{-1} \end{aligned} \quad [28]$$

The second rhs term is a resistive addition due to constrictive diffusion. When this term dominates the contribution from $\partial I/\partial \eta$

$$\left(\frac{\partial I}{\partial \eta} \right)_{\text{app}} = 2\pi N a z F A D c_0 \left(\frac{\partial x}{\partial \eta} \right) \quad [29]$$

and

$$- \left(\frac{\partial I}{\partial x} \right)_{\text{app}} = 2\pi N a z F A D c_0 \quad [30]$$

Thus, the latter function, as evaluated by our analysis, should show limiting cathodic behavior proportional to the density of deposition sites. For additive-free lead solutions, the experimental function attains a maximum value ca. 0.5 A/cm², corresponding to $N a = 4000$, or estimating $a \simeq 5 \times 10^{-8}$ cm, $N \simeq 8 \times 10^{10}$ /cm². For PPG and phenolphthalein solutions, only minor deviations from linearity for this function were found, but the maximum value reached was but 0.05 A/cm² over the potential range studied. Thiourea solutions show some indications of also limiting at the 0.5 A/cm². Given the thickness of these deposits, this number density may be correlated with grain size, implying that only a small number of growth sites are concurrently active per grain.

Our findings also offer some insights into the manner by which additives influence lead plating. One might postulate their role is either to modify the density of growth sites or the rate-limiting step, or both. Thiourea and phenolphthalein were found to change the exchange current density in opposite directions, but α and β values remained similar to those for additive-free solutions. This suggests that these additives function primarily by altering growth site densities, but not kinetics at these sites. The behavior of PPG, however, differs significantly. Apart from reducing the exchange current density, it markedly reduces α and increases β . Interestingly, $\alpha + \beta$ remains about the same as for the other cases, suggesting a common rate-limiting step, but with the limiting barrier relocated in the Helmholtz region. The shift to a lower α value indicates a greater portion of the bias potential appears between the metal surface and the barrier, as would be the case if an intervening layer of low polarizability were present.

Kohl has examined the morphological and voltammetric effects of phenolphthalein and Triton X-100 on Sn/Pb plating from HBF_4 (12). The latter additive, like PPG a polyglycol, was found to suppress dendritic growth without appreciably changing the surface resistance, whereas phenolphthalein significantly increased this resistance without inhibiting dendrite formation. For the systems we have examined, both additive types increased surface resistance at $\eta = 0$, as indicated by reductions in exchange current densities. However, because of a lower α value, the polyglycol is more effective in maintaining a high surface resistance at cathodic deposition potentials.

Finally, we should comment briefly on the surface film mentioned among our results. The interpretation of impedance measurements has not invoked this film, and were it not for a visual microscopic inspection, its presence would have gone undetected. Normal double layer behavior indicates the film must be quite porous and permeable to the electrolyte. Possibly the film is buried during deposition and only surfaces upon stripping. At the completion of stripping, we have always observed abrupt changes in ac and dc currents, with no lingering tail to indicate slowly oxidizing lead.

We anticipate such behavior should the film contain metallic lead residues.

The visual changes seen during oxidation of the wet film might suggest a Pb(I) species. This, however, runs counter to established lead chemistry, and Pb⁺ ions have only been observed in the gas phase and matrices subjected to ionizing radiation (17). The reported suboxide, Pb₂O, is believed to be a nonstoichiometric mixture of Pb and Pb(II) (18). Our conclusion that Pb⁺⁺ reduction is limited by a one-electron transfer step requires only a transient Pb⁺ state. Indeed, no pseudocapacitance was found which would reveal an equilibrium surface concentration. If the film is related to the suboxide mixture, then why it is not oxidized to PbO during stripping remains an unanswered question.

A Mathematical Model for the Iron/Chromium Redox Battery

Peter S. Fedkiw* and Rick W. Watts

Department of Chemical Engineering, North Carolina State University, Raleigh, North Carolina 27695

ABSTRACT

A mathematical model has been developed to describe the isothermal operation of a single anode-separator-cathode unit cell in a redox-flow battery and has been applied to the NASA iron/chromium system. The model, based on porous electrode theory, incorporates redox kinetics, mass transfer, and ohmic effects as well as the parasitic hydrogen reaction which occurs in the chromium electrode. A numerical parameter study was carried out to predict cell performance to aid in the rational design, scale-up, and operation of the flow battery. The calculations demonstrate: (i) an optimum electrode thickness and electrolyte flow rate exist; (ii) the amount of hydrogen evolved and, hence, cycle faradaic efficiency, can be affected by cell geometry, flow rate, and charging procedure; (iii) countercurrent flow results in enhanced cell performance over cocurrent flow; and (iv) elevated temperature operation enhances cell performance.

A redox cell stores energy in the change of the oxidation state of a fully soluble redox couple. The use of redox reactions in a battery was pointed out by Thaller (1) and the developmental effort has been mainly carried out at NASA-Lewis (2). Cost studies (3, 4) have projected that the redox battery is a promising energy storage system for load leveling. An extensive search by NASA for possible redox couples and electrode materials has led to the present acidified Fe(II)/Fe(III) and Cr(II)/Cr(III) couples carried out on a catalyzed graphite felt electrode. Other redox battery systems have been examined (5-7) as well as hybrid batteries in which one electrode involves a soluble redox couple and the other uses a reactant with a phase change (8-10). The Zn/Cl₂ and Zn/Br₂ cells may be classified as a hybrid redox cell.

The design of the Cr/Fe cell has proceeded mainly by an experimentally guided effort. The technology has progressed to the point where pilot plant evaluations of the battery system are now feasible. The scale up from the laboratory could proceed more efficiently if a predictive mathematical model was available to guide quantitatively the work and aid in the correlation and extrapolation of experimental data. This report discusses such a model which is generated by ap-

plying porous electrode theory to a single iron electrode-separator-chromium electrode unit cell. Optimization of the battery design and operation may be rationally guided with the model, and examples of such results are given. The calculations presented here use parameters which are characteristic of the Fe/Cr system, but the discussion presents guidelines which may be applied to other flow battery systems.

Newman and Trainham have presented a model for the Fe/Ti redox flow cell (11). They compared the flow-through to the flow-by electrode configuration and concluded that the flow-by configuration, as utilized in the NASA cell, was inherently the better of the two. Several assumptions were made in their analysis which limits its utility. They assumed: (i) linear kinetics; (ii) a single electrode reaction in each compartment; and (iii) potential variations in the current flow direction and concentration variations in the streamwise flow direction only. These assumptions were not made in the present analysis and, hence, the effect of geometrical and operational parameters on faradaic efficiency and cell performance can be better examined.

Model Development

Figure 1 shows a schematic diagram of a single anode-separator-cathode unit in the redox battery. In

Fig. 1. Schematic diagram of the Fe-Cr redox cell

an actual battery, a number of these cells are arranged in series in a cell stack. The electrode is a porous graphite felt which is compressed by the bipolar current collectors. The felt in the chromium compartment is coated with an Au/Pb catalyst. The potential and concentration of reactant and product are assumed to vary in both the X and Y coordinate within each electrode. Variations along the cell width are neglected. The fluid enters the cell through a manifold, flows through the electrode, and exits through another manifold. The individual cells in a cell stack share a common inlet and outlet manifold for each electrolyte. The anolyte and catholyte solutions are acidified with HCl and are isotonic to prevent the swelling of the membrane separator. Not shown in the figure are the two storage tanks from which the solutions are recirculated and the potential sensing open-circuit cell and a rebalance cell which are an integral part of a fully functional cell stack (2).

The volume-averaged conservation of charge and mass equations, porous electrode theory, are applied within each electrode under isothermal operating conditions (12). The reaction distribution within the chromium compartment depends upon the reaction distribution within the iron compartment since the charge transferred from one flows to the other across the separator. Consequently, the equations are coupled by the continuity conditions imposed at the separator. The following effects are accounted for: (i) the kinetics of each redox reaction; (ii) the parasitic hydrogen reaction which occurs in the chromium compartment. (Since the Cr(III)/Cr(II) couple is electro-negative, there normally exists a cathodic overpotential for proton reduction which is particularly an acute problem on charge near full state-of-charge conditions. No secondary reactions occur in the Fe electrode.); (iii) cell geometry; (iv) mass-transfer effects; (v) state-of-charge; (vi) separator resistance; and (vii) solution physical properties. The governing equations for each electrode compartment are discussed below.

Conservation

$$\text{of charge: } \kappa_j \nabla^2 \phi_j^l = a_i i_{n,\text{total}} \quad [1]$$

The conservation of charge equation has been written assuming Ohm's law is valid; since the solutions are well supported, the migration flux is neglected. The right side of the balance represents the total charge density per unit electrode volume leaving the matrix phase. In the iron compartment only one reaction occurs, but in the chromium compartment the redox reaction and proton reduction both contribute to this term. The effective solution conductivity in the

electrode is calculated from that of the electrolyte by $\kappa = \epsilon^{1.5} \kappa_0$ (13).

Conservation

$$\text{of mass: } v_j \nabla C^j = \epsilon D_j \nabla^2 C^j + \frac{\alpha_i i_{n,j} s_{R^j}}{n_j F} \quad [2]$$

Dispersion is neglected in the y direction but diffusion is accounted for. Convective transport only occurs in the y direction; it is assumed that there is no fluid velocity in the x direction, but rather diffuse transport of material occurs along this coordinate. A similar equation as used for κ is applied to calculate the effective diffusivity ϵD from the bulk value. It was assumed in the analysis that the diffusivity of the (II) oxidation state of a species was the same as that of the (III) species; consequently, only one differential mass balance was required in each compartment since an algebraic expression gave the concentration of the other redox species. In this work, a balance was written for Fe^{+2} and Cr^{+3} , the reactants in a charge cycle.

$$\text{Surface flux: } \frac{s_{R^j} i_{n,j}}{n_j F} = k_{mj} (C^j - C_s^j) \quad [3]$$

A mass transfer coefficient is used with Faraday's law to relate the local electrochemical reaction rate to the local surface-to-bulk concentration difference of the reactant. The Wilson-Geankoplis correlation for k_m was used (14).

$$\begin{aligned} \text{Kinetics: } i^{\text{Fe}_{n,\text{total}}} = i_{n,\text{Fe}} = i^{\text{Fe}_{o,f}} \left\{ (\text{Fe}_{s^{+2}}/\text{Fe}_{t^{+2}}) \right. \\ \left. \exp \left[\frac{F}{RT} \alpha_{\text{A}^{\text{Fe}}} (\phi_1^{\text{Fe}} - \phi_2^{\text{Fe}}) \right] - (\text{Fe}_{s^{+3}}/\text{Fe}_{t^{+3}}) \right. \\ \left. \exp \left[-\frac{F}{RT} \alpha_{\text{C}^{\text{Fe}}} (\phi_1^{\text{Fe}} - \phi_2^{\text{Fe}}) \right] \right\} \quad [4] \end{aligned}$$

$$\begin{aligned} i^{\text{Cr}_{n,\text{total}}} = i_{n,\text{Cr}} + i_{n,\text{H}_2} = i^{\text{Cr}_{o,f}} \left\{ (\text{Cr}_{s^{+2}}/\text{Cr}_{t^{+2}}) \right. \\ \left. \exp \left[\frac{F}{RT} \alpha_{\text{A}^{\text{Cr}}} (\phi_1^{\text{Cr}} - \phi_2^{\text{Cr}}) \right] - (\text{Cr}_{s^{+3}}/\text{Cr}_{t^{+3}}) \right. \\ \left. \exp \left[-\frac{F}{RT} \alpha_{\text{C}^{\text{Cr}}} (\phi_1^{\text{Cr}} - \phi_2^{\text{Cr}}) \right] \right\} \\ + i_{o,\text{H}_2} \left\{ \exp \left[\frac{F}{RT} \alpha_{\text{A}^{\text{H}}} (\phi_1^{\text{Cr}} - \phi_2^{\text{Cr}} - U_{\text{AH}}) \right] \right. \\ \left. - \exp \left[-\frac{F}{RT} \alpha_{\text{C}^{\text{H}}} (\phi_1^{\text{Cr}} - \phi_2^{\text{Cr}} - U_{\text{AH}}) \right] \right\} \quad [5] \end{aligned}$$

The redox reactions are assumed to occur by simple elementary steps which are characterized by a Butler-Volmer type expression. The chromium redox reaction is actually somewhat more complicated. The Cr(II) and Cr(III) species form complexes with Cl^- ions which effect their reactivity (15). In particular, the monochloride-pentahydrate complex of Cr(III) is easier to reduce than the hexahydrate complex. Both species exist in solution but higher temperature favors the monochloride species.

The electrode potential, ϕ_1^l , is assumed uniform because of the high conductivity of the matrix. The solution potential, ϕ_2^l , is measured with a reference electrode of the same kind as the main reaction in electrode j. The concentrations of reactant and product in this hypothetical reference electrode are at the feed conditions. The exchange current density for the redox reaction is, consequently, evaluated at the feed condition which is dependent upon the state-of-charge as shown below

$$i^{\text{Fe}_{o,f}} = i^{\text{Fe}_{o,\text{ref}}} \left[\frac{\text{Fe}_{t^{+2}}}{\text{Fe}_{\text{ref}^{+2}}} \right]^{\alpha_{\text{C}^{\text{Fe}}}} \left[\frac{\text{Fe}_{t^{+3}}}{\text{Fe}_{\text{ref}^{+3}}} \right]^{\alpha_{\text{A}^{\text{Fe}}}} \quad [6]$$

$$i_{Cr_{o,f}} = i_{Cr_{o,ref}} \left[\frac{Cr_f^{+2}}{Cr_{ref}^{+2}} \right]^{\alpha_{O^{Cr}}} \left[\frac{Cr_f^{+3}}{Cr_{ref}^{+3}} \right]^{\alpha_{A^{Cr}}} \quad [7]$$

The hydrogen reaction occurs in the chromium compartment because of the large driving force for proton reduction. The term U^{AH} in the hydrogen kinetic expression is dependent upon the state-of-charge and accounts for the open-circuit potential difference between the Cr(III) and the proton reduction; it was calculated assuming Nernstein behavior. It was assumed that the proton reduction is kinetically controlled, and since the H^+ concentration is approximately one order of magnitude greater than the total Cr species, a mass balance for H^+ was not required.

The boundary conditions on the potential for each electrolyte were specified as follows

$$y = 0 \quad \frac{\partial \phi_2^j}{\partial y} = 0 \quad [8]$$

$$y = L \quad \frac{\partial \phi_2^j}{\partial y} = 0 \quad [9]$$

$$x = 0 \quad \frac{\partial \phi_2^j}{\partial x} = 0 \quad [10]$$

$$x = d_{Cr} \quad R_{s^{Cr}} \frac{\partial \phi_2^{Cr}}{\partial x} = \phi_2^{Cr} - \phi_2^{Fe} - V_{oc} \quad [11]$$

$$x = d_{Fe} \quad -R_{s^{Fe}} \frac{\partial \phi_2^{Fe}}{\partial x} = \phi_2^{Cr} - \phi_2^{Fe} - V_{oc} \quad [12]$$

Equations [8] and [9] assume no shunt current in the manifold. In a cell stack, a potential difference between electrolytes in adjacent compartments will cause a shunt current. Proper design of the manifold system can reduce the shunt current but not eliminate it. The results presented here can be thought of as a best case where the parasitic loss of shunt current has been totally eliminated. Equation [10] states that all the current is carried by the matrix at the current collector. Equations [11] and [12] express the continuity of current and potential across the electrolyte-separator interface in the chromium and iron electrode, respectively. The separator resistance R_s is assumed to be constant.

The boundary conditions on Cr^{+3} and Fe^{+2} depend upon the electrolyte flow orientation: cocurrent or countercurrent

$$y = 0 \quad \begin{array}{c} \text{Fe} \\ -\epsilon D_{Fe} \frac{\partial C^{+2}}{\partial y} + vC^{+2} = vC_f^{+2} \end{array}$$

$$y = L \quad \frac{\partial C^{+2}}{\partial y} = 0$$

$$x = 0 \quad \frac{\partial C^{+2}}{\partial x} = 0$$

$$x = d \quad \frac{\partial C^{+2}}{\partial x} = 0$$

feed ratio of Fe^{+2} and Cr^{+3} , respectively. Four coupled nonlinear elliptic partial differential equations were generated and made dimensionless, and thereby generating nine dimensionless terms characteristic of each electrode. A finite-difference-collocation numerical procedure (16) was used to solve this nonlinear system by iteration until a relative difference of 10^{-5} was obtained between each iteration for all dependent variables at all points on the solution grid. As a check of the validity of the numerical integration, the cell current was calculated three independent ways: (i) concentration change of Fe^{+2} from inlet to outlet; (ii) integrated membrane current density; and (iii) volumetric integration of local Fe reaction rate or Cr plus H_2 reaction rate. In the worst case, the largest deviation of a current from the average value of the above three methods was 0.2%. The detailed nondimensional equations and parameters and further discussion of the numerical solution scheme are given by Watts (17).

Results and Discussion

It was beyond the scope of this work to optimize the cell design and operation. However, an endeavor has been made to illustrate that optimum design and operational parameters and charge/discharge protocols exist, and the model is a useful aid in finding these optima.

The numerical solution to the model equations has been used to: (i) calculate the cell performance map (current-voltage-flow rate relationship); (ii) investigate the effect of countercurrent and cocurrent arrangement of reactant streams; (iii) study the effect of electrode thickness and length; (iv) study the effect of higher temperature operation; and (v) investigate two different charge/discharge protocols.

The open-circuit voltage varied with the depth of discharge and was calculated by

$$V_{oc} = V_{formal} - (RT/F) \ln [(Cr_f^{+3}Fe_f^{+2}) / (Cr_f^{+2}Fe_f^{+3})] \quad [17]$$

The voltage V_{formal} was set at 1.05V (2). The depth of discharge, f , defines the reactant and product concentrations at any given time and is defined by the following

$$\begin{aligned} Cr_f^{+3} &= fCr_1^{+3} \\ Cr_f^{+2} &= (1-f)Cr_1^{+3} \\ Fe_f^{+2} &= (Fe_1^{+2} - Cr_1^{+3}) + fCr_1^{+3} \\ Fe_f^{+3} &= Fe_1^{+3} + (1-f)Cr_1^{+3} \end{aligned} \quad [18]$$

$$\begin{array}{c} \text{Cr} \\ \text{cocurrent:} \quad -\epsilon D_{Cr} \frac{\partial C^{+3}}{\partial y} + vC^{+3} = vC_f^{+3} \end{array}$$

$$\text{countercurrent:} \quad \frac{\partial C^{+3}}{\partial y} = 0$$

[13]

$$\text{cocurrent:} \quad \frac{\partial C^{+3}}{\partial y} = 0$$

$$\text{countercurrent:} \quad -\epsilon D_{Cr} \frac{\partial C^{+3}}{\partial y} + vC^{+3} = vC_f^{+3}$$

[14]

$$\frac{\partial C^{+3}}{\partial x} = 0 \quad [15]$$

$$\frac{\partial C^{+3}}{\partial x} = 0 \quad [16]$$

Equation [3] was combined with the kinetic expression for $i_{n,Fe}$ or $i_{n,Cr}$ to eliminate the surface-to-

It was assumed that Cr was the limiting reactant as would occur with isotonic electrolytes. The subscript 1

Net power calculations are reported here and represent the gross power from the cell minus the parasitic pumping loss. The pumping loss was calculated by applying the Ergun equation (18) to find the pressure drop across the felt electrode and adding that loss to the pressure drop in the inlet and outlet manifold. The latter was calculated by using an empirical correlation to fit the available hydraulic data (19).

Parameter values used in this study.—The geometric, operational, and physical parameters used in the calculations are presented in Table I. An effort was made to choose values as physically reasonable as possible; however, certain parameters, such as the kinetic constants for the reactions at elevated temperatures, are not yet available. Clearly, the dominant cell resistance is the separator ohmic resistance with the electrolyte resistance of next importance followed by kinetic and mass-transfer resistance. It should be emphasized, however, that these conclusions are valid at the feed conditions, which may not, under all operating conditions, be characteristic of the entire electrode.

Cell performance map.—Figure 2 shows a calculated, so-called, cell performance map for both charge and discharge at three cell polarizations with a countercurrent flow arrangement. The cell current I_c asymptotically approaches a limit at high flow rates at which the intrinsic reaction kinetics and ohmic resistances limit the reaction. At low flow rates, the current is controlled by the supply of reactant. This mass-transfer limited current, indicated by the dashed line labeled Q_{SF} on the figure, is that current which could

be obtained from the cell if all available reactant was consumed. The NASA literature implies that very little can be gained by operating the cell at a flow rate greater than twice the stoichiometric requirement. It can be seen from Fig. 2 that at $2 \times Q_{\text{SF}}$, indicated by the dashed line labeled Q_2 , the cell is indeed operating on the nearly flat portion of the curve. However, it has been predicted in this work, as will be discussed in a following section, that maximizing the net discharge power requires a larger stoichiometric flow multiple which is dependent upon the state-of-charge. In the parameter range studied in this report, this multiple varied from 1.3 to 10.6.

Figure 2 illustrates that mass-transfer resistance apparently is not important except at low unpractical flow rates. However, the kinetic and electrolyte resistance at high flow rates add a small and calculable contribution to the total cell resistance. The separator resistance was set at $4 \Omega \cdot \text{cm}^2$ for Fig. 2. At the high flow rates, the total cell resistance is calculated to be $4.44 \Omega \cdot \text{cm}^2$. As the separator resistance is lowered, the relative importance of the other contributing terms to the total cell resistance will increase.

Electrolyte flow arrangement.—The effect of the electrolyte flow arrangement, cocurrent as compared to countercurrent, has not been experimentally examined. By analogy to heat exchangers and mass-transfer separation devices, it is anticipated that the electrical driving force can be more uniformly distributed with a countercurrent flow arrangement than with cocurrent flow. Consequently, a more effective utilization of the membrane and electrode would result.

The model does indeed predict a more uniform distribution with countercurrent flow. Figure 3 shows the current density at the separator as a function of streamwise position for cocurrent and countercurrent flow at two flow rates. At $Q = 600$ ml/min the membrane current density variation from the inlet to outlet is 2.3 times greater for cocurrent than for countercurrent flow. Similarly, at $Q = 400$ ml/min, the same ratio is 2.8. For both flow rates, the result of countercurrent flow is a smoother current distribution.

Table II compares cell performance under cocurrent and countercurrent flow at various flow rates under charge at a 90% state-of-charge condition. The conversion of Cr^{+3} or Fe^{+2} at any flow rate is always greater with countercurrent flow, but the faradaic efficiency is greater at the low flow rates with cocurrent flow. More H_2 is evolved at the low flow rates with countercurrent flow, which causes the drop in faradaic efficiency. The cause of this seemingly anomalous behavior is due to the excess of Fe^{+2} (in comparison to Cr^{+3}) with isotonic solutions. Since the

Fig. 2. Cell performance map at selected polarizations. Parameter values listed in Table I and $f = 0.5$, $d_{\text{Cr}} = d_{\text{Fe}} = 0.25$ cm, $L = 30.5$ cm, $T = 25^\circ\text{C}$. Q_{SF} indicates the stoichiometric flow and Q_2 indicates twice the stoichiometric flow.

Fig. 3. Separator current density at -300 mV discharge polarization. Parameter values listed in Table I and $f = 0.1$, $d_{Cr} = d_{Fe} = 0.25$ cm, $L = 30.48$ cm, $T = 25^\circ\text{C}$.

countercurrent flow mode is more efficient in reducing Cr^{+3} , the charge which is passed when the excess Fe^{+2} is oxidized is directed to H^+ reduction. The flow rate at which this transition occurs is too low for practical use, but this clearly points out a potential operational problem if unbalanced reactant solutions are used.

Electrode thickness and flow rate.—If the electrode thickness is increased, more surface area is made available and, hence, one might expect a larger reaction rate at any given cell polarization. The increase in chromium conversion and hydrogen production should be asymptotic with increasing thickness. Predicted currents at 25°C for three electrode thicknesses are shown on Fig. 4. The calculations have shown that the cell current ($I_c = I_{Cr} + I_{H_2}$) actually increases with decreasing electrode thickness at a fixed flow rate. For a given flow rate, decreasing the electrode thickness will result in an increase in velocity with an attenuation of the mass-transfer resistance and a consequential increase in current. Eventually, however, as the electrode thickness is decreased below the penetration depth, a drop in cell current will result.

* $d_{Cr} = d_{Fe} = 0.25$ cm, $L = 30.48$ cm, $V_o - V_{oc} = 300$ mV, $f = 0.1$, $T = 25^\circ\text{C}$.

Fig. 4. Current due to chromium and hydrogen reactions at 300 mV charge polarization. Parameter values listed in Table I and $f = 0.5$, $L = 30.48$ cm, $T = 25^\circ\text{C}$. (a) $d_{Cr} = d_{Fe} = 0.1$ cm; (b) $d_{Cr} = d_{Fe} = 0.175$ cm; (c) $d_{Cr} = d_{Fe} = 0.25$ cm.

The penetration depth is defined by the following equation for infinite matrix conductivity (20)

$$d_{j,pen} = \left\{ \frac{RT}{F} \kappa_j / [(\alpha_A^j + \alpha_C^j) a_i^{j_{o,t}}] \right\}^{1/2} \quad [19]$$

The reaction rate decreases by approximately a factor of e for each penetration layer into the electrode. If $d_j \gg d_{j,pen}$, a decrease in electrode thickness initially removes an electrode which is largely unavailable to the main reaction. As $d_j \sim d_{j,pen}$, a further decrease in electrode thickness results in less electrodes available to the main reaction with a subsequent decrease in cell current. For the parameter values used in Fig. 4, the penetration depth at the inlet is 0.026 and 0.066 cm for the chromium and iron electrode, respectively. This indicates the need for a thinner electrode in the chromium than in the iron compartment. For illustrative purposes, the electrode thickness in both compartments was kept identical for all calculations.

In order to examine the effect of electrode thickness alone on cell performance while holding the variation in all other effects to a minimum, it is necessary to vary the flow rate. Table III presents calculations in which the electrode thickness is varied but the flow rate is adjusted to maintain a constant velocity. It can be seen that providing more electrode surface by increasing the cell thickness does result in a higher cell current if the velocity is held constant.

If the flow rate is held constant and the electrode thickness is increased, the pumping loss is decreased and the net power output from the cell, under certain conditions, may be increased. Because of the combination of pumping losses, kinetic, and mass-transfer effects, an optimum electrode thickness exists which maximizes the net power output on discharge. Figures

Table III. Effect of electrode thickness at constant velocity*

d (cm)	Q (ml/min)	I_{Cr} (A)	I_{Fe} (A)	I_{H_2} (A)	η_{Far}

* $V_c - V_{oc} = 300$ mV, $f = 0.5$, $L = 30.48$ cm, $v = 0.879$ cm/s, countercurrent flow, $T = 25^\circ\text{C}$.

Fig. 5. Net cell power and current due to chromium conversion at -300 mV discharge polarization. Parameter values listed in Table I and $f = 0.5$, $L = 30.48$ cm, $T = 25^\circ\text{C}$. (a) $d_{\text{Cr}} = d_{\text{Fe}} = 0.1$ cm; (b) $d_{\text{Cr}} = d_{\text{Fe}} = 0.175$ cm; (c) $d_{\text{Cr}} = d_{\text{Fe}} = 0.25$ cm.

4 and 5 illustrate the effect of varying electrode thickness and flow rate on cell performance for charge and discharge, respectively. An electrode thickness of 0.1 cm is the best of the three shown. Under charge, a cell with 0.1 cm electrodes delivers the greatest chromium conversion and the least hydrogen evolution. Under discharge, the net cell power is nearly maximized

Fig. 6. Net cell power vs. flow rate at various depths of discharge for a -300 mV discharge polarization. Manifold losses included. Stoichiometric flow multiple and cell current at the optimal flow-rate indicated. Parameter values listed in Table I and $d_{\text{Cr}} = d_{\text{Fe}} = 0.25$ cm, $L = 30.48$ cm, $T = 25^\circ\text{C}$. Manifold dimension: 0.2 cm \times 0.4 cm. Arrows indicate twice the stoichiometric flowrate.

Fig. 7. Same as Fig. 6 except $T = 65^\circ\text{C}$

and chromium conversion is the greatest with 0.1 cm thick electrodes. Thinner electrodes would not be of any further advantage because of larger parasitic pumping losses.

Figures 6 and 7 illustrate the net power output as a function of flow rate at three depths of discharge for a -300 mV discharge polarization at low and high temperature, respectively. The current at the power optimum is indicated on the figure as well as the flow rate expressed as a multiple of the stoichiometric flow rate. The optimum flow rate varies with the depth of discharge. At $f = 0.5$, the optimum flow rate is less than that at $f = 0.1$ or $f = 0.9$. The explanation for this trend lies in the nonconstant nature of the chromium and iron exchange current densities. On discharge, at low values of f , the exchange current densities are less than their maximum due to product poisoning. At high values of f , reactant starvation causes the exchange current densities to decrease. Therefore, at extremes of depth of discharge, higher flow rates are needed to overcome the effects of reactant starvation or product poisoning in order to produce the power maximum. At sufficiently high flow rates at any depth of discharge, the reaction is limited by kinetics, and further increase in flow rate will not result in increased cell current and gross power. The decrease in the P_{net} vs. Q curves to the right of the maximum is attributed to the parasitic pumping losses.

It is apparent from the figures that any rule of thumb, such as the optimum flow rate being a multiple of 1.5-2 times the stoichiometric flow rate, does not rigorously apply; however, the power maximums are broad for the parameters used in these calculations. The maximum becomes better defined as the pumping loss increases with longer cells, thinner electrodes, or smaller manifolds. The latter is a particularly important consideration because the smaller the manifold, the lower will be the shunt currents, but with a consequential increase in pumping loss.

Electrode length.—Predictions of cell performance at a fixed polarization and flow rate of a lengthened electrode show that the cell current also increases, but in a diminishing manner. Because of reactant consumption in the inlet region of the cell, more of the electrical driving force is expended near the outlet in

overcoming concentration polarization as the cell length is increased. Therefore, the longer the cell, the more the reactant-starved condition exists over the cell length and, eventually, no increase in reactant conversion will result from increased cell length. The cell polarization may not, in sufficiently long cells, be great enough to overcome the concentration polarization, and the reverse redox reaction may occur. Furthermore, at cell lengths in which the chromium electrode becomes reactant-starved, the hydrogen evolution increases drastically, thereby lowering the faradaic efficiency. These effects are illustrated in Table IV. The advantage of countercurrent flow arrangement is seen for the shorter length cells but not for the longer cells because of the inherent reactant imbalance with the isotonic solutions.

Charge/discharge cycles.—The amount of hydrogen which is produced in an entire cycle will depend on the charge/discharge procedure used. If the cell polarization is varied and all other conditions held constant, both the cell current and the rate of hydrogen evolution will also vary. This is especially true when the cell is nearly charged. An infinite number of charge/discharge protocols can be proposed; in this work only two are examined: (i) a constant cell voltage of 1.35V under charge and 0.75V under discharge, and (ii) a constant cell polarization of +300 mV under charge and -300 mV under discharge. At $f = 0.5$, these two protocols are identical. Figure 8 shows how the cell and hydrogen current vary over a charge cycle for the two polarization protocols. Figure 9 shows the same result but at a higher temperature.

In order to calculate charge and discharge times and energy stored or used, a storage tank volume of 1820 liters/electrolyte was used based on recommendations of a cost study (4). Table V summarizes these results. The cycle energy efficiency is low because of the large polarization used in the calculation. It is seen, however, that less time is required to charge the cell at constant polarization than with a constant cell voltage. There is little difference in the faradaic efficiency at the lower temperature in the two protocols; however, at the higher temperature, the constant cell voltage charge has a higher efficiency because of the dramatic increase of H_2 production near fully charged conditions under constant polarization.

Conclusions

1. A mathematical model of an isothermal redox flow battery has been developed which incorporates redox reaction kinetics and the parasitic H_2 reaction, mass-transfer effects, and ohmic losses in the separator and electrolyte.
2. Optima exist in the design and operation of the redox flow cell. Specifically, the electrode thickness, cell voltage, and electrolyte flow rate can be optimized to maximize the cell current or faradaic efficiency. The model is a useful aid in locating these optima.
3. The separator ohmic resistance is the dominant cell resistance followed by the electrolyte ohmic resistance. Kinetic resistances are much less than separator or electrolyte resistances and mass-transfer resistance is almost negligible at reasonable flow rates.

Charge: $V_c - V_{oc} = 0.3V$	2010	0.966	13.4
Discharge: $V_c - V_{oc} = -0.3V$	1050	0.991	13.1

* $d_{cr} = d_{Fe} = 0.25$ cm, $L = 30.48$ cm, $Q = 400$ ml/min, counter-current flow.

used in this study, the cell is operating on the nearly flat portion of the current-flow rate curve.

5. Countercurrent electrolyte flow is predicted to improve cell performance in comparison to cocurrent flow at all practical flow rates. This increased performance can be attributed to the result of more uniform current distribution.

6. For the range of parameters used in this study, the cell current increased with decreasing electrode thickness at a fixed flow rate. Actually, the decreased electrode surface area tends to decrease the cell current; however, the decreased area of flow results in a higher velocity and enhanced mass transfer within the penetration thickness and, therefore, increases cell current. If the electrode thickness and electrolyte flow rate are simultaneously varied in such a manner as to maintain a constant velocity, the cell current decreases as the electrode becomes thinner.

7. On the discharge cycle, the electrolyte flow rate which results in maximum net power output is lowest at midcycle ($f = 0.5$) and increases at either extreme of depth of discharge as the effects of reactant starvation or product poisoning become more important. A simple rule of thumb such as the optimum flow rate being 1.5 or 2 times the stoichiometric flow rate does not rigorously apply across an entire cycle. The maximum is shallow at $R_s = 4 \Omega \cdot \text{cm}^2$ but becomes better defined as R_s decreases.

8. Increasing the cell length at constant flow rate results in a larger cell current but in a diminishing returns manner. Faradaic efficiency decreases with increasing length, and, eventually, added length supports only the hydrogen reduction with no improvement in chromium conversion.

9. The chromium conversion and cell energy efficiency are functions of the charge/discharge protocol employed. The model provides a means of finding a charge/discharge protocol that gives the maximum chromium conversion while, at the same time, results in minimum hydrogen evolution.

10. An increase in the cell operating temperature from 25° to 65°C results in greater reaction rates, improved electrolyte and membrane conductivities, increased cycle energy efficiency, and reduced charging times.

Discharge Kinetics of the Nickel Electrode

A. H. Zimmerman* and P. K. Effa

The Aerospace Corporation, Chemistry and Physics Laboratory, El Segundo, California 90245

ABSTRACT

The kinetics of nickel electrode discharge are found to be controlled by solid-state proton diffusion under normal high rate discharge conditions. As the nickel electrode is discharged, the conductivity of the active material decreases until eventually mixed kinetics are observed where the electrode impedance has significant contributions from both proton diffusion and charge transfer resistance. Further discharge results in the formation of a semiconductor layer at the metal-active material interface that is depleted in charge carriers and has a relatively high electronic resistance. The depletion layer is responsible for the secondary discharge plateau of the nickel electrode at 0.0 to -0.5 V vs. Hg/HgO. Changes in electrode capacitance during depletion layer formation appear to provide a sensitive measure of the uniformity of electrode discharge. The effects of cobalt additives on the kinetics have been experimentally measured, and while cobalt does not change the discharge mechanism, it does increase the ionic and electronic conductivity of the active material allowing a greater depth of discharge before depletion layer formation.

The oxidation/reduction reactions at the nickel electrode have been the subject of a number of studies during recent years. As more experimental studies have been reported, it has become clear that the electrochemistry of the nickel electrode is quite complex. The early work of Bode *et al.* (1), and the later work of Schrebler-Guzman *et al.* (2) indicated the existence of both α and β phases of Ni(OH)₂. These two phases may be oxidized to γ and β phases of nickel oxyhydroxide, respectively, and may also undergo chemical interconversion. Additional energetically discernible phases have been found in the work of Schrebler-Guzman *et al.* (3) and Barnard *et al.* (4). In light of the growing number of possible phase structures, it is anticipated that the kinetics of the nickel electrode oxidation/reduction processes will be difficult to unravel, particularly in sintered nickel electrodes, where the effects of additives and phase nonuniformities are expected to provide additional kinetic and thermodynamic complexity.

Nickel electrode reduction has been found to follow diffusion kinetics in a number of previous studies (5-8). The limiting diffusion process in the voltage range above 0.2V (vs. Hg/HgO) is the diffusion of protons formed at the electrode/electrolyte interface to the charge transfer site. The reduction process may be represented as

Reaction [1] represents the formation of a proton at catalytic site *s* at the electrode/electrolyte interface; reaction [2] involves diffusion of the proton from site *s* into the electrode to the charge transfer site *s'*; and reaction [3] is the charge transfer process involving the reduction of one of the higher valency species of active material in the lattice, represented here as simply NiOOH. Reactions [1] and [3] are not generally believed to be rate limiting under the operating conditions of the nickel electrode because they would not account for the observed diffusion kinetics. A recent report (9) that reaction [1] may be rate limiting appears to be more consistent with diffusion of OH⁻

between the bulk electrolyte and the active material surface as the rate-limiting step for high rate electrode operation, particularly at reduced concentrations of OH⁻. Reaction [2], proton diffusion, is generally regarded as controlling the rate of nickel electrode discharge at the potential and current densities normally used in battery operation. Barnard (10) has obtained electrochemical evidence that the protons involved in processes [1]-[3] are delocalized throughout the active material lattice, a result that is consistent with spectroscopic data in which the lack of IR absorption bands due to OH in the oxidized active material is reported (11). The proton diffusion rate and proton concentration are expected to depend on the phase composition of the NiOOH, as well as on the presence of additives in the lattice structure (8).

During normal discharge of the nickel electrode in a battery cell, the diffusion process indicated by reaction [2] is rate limiting. However, for some conditions of electrode structure (13) or operation (12), the electrode voltage can prematurely drop to a plateau at 0.0 to -0.5 V (vs. Hg/HgO), and the electrode can discharge a substantial portion of its capacity at the lower potential. The lower voltage discharge has been attributed to effects such as adsorbed oxygen (14-17), lower energy nickel oxides (18-22), and conductivity changes (13, 23). Measurements of the electrode kinetics in the low state of charge region should allow the process(es) causing the low discharge voltage plateau to be identified. Such measurements of the electrochemical kinetics of the nickel electrode are reported here. The kinetics are measured over a wide range of electrode potential for electrodes of flat plate and sintered construction, with and without cobalt additives. The work described here provides evidence indicating that conductivity changes coupled with the formation of an interfacial loss layer are responsible for the premature depletion of nickel electrode capacity at voltages sufficient for battery operation.

Experimental

Nickel electrodes were made by electrochemical deposition (24) of Ni(OH)₂ on either 4 cm² flat nickel plates or 1 cm² sintered nickel substrates. The nickel sinter substrate used was 0.076 cm thick and had a porosity of 79.5%. Cathodic deposition at 4 and 35 mA/cm² was used for the flat plate and sintered elec-

* Electrochemical Society Active Member.

Key words: kinetics, impedance, electrode, battery.

trodes, respectively, using a boiling solution 60% in 2M Ni(NO₃)₂ and 40% in ethanol. Cobalt nitrate was added to the solution to give the desired Ni/Co ratio for studying the effects of cobalt additives. Chemical deposition in a sintered electrode was done by repetitively evacuating the air from the sinter while dipped in a 2M Ni(NO₃)₂ solution and then dipping in a 20% KOH solution. Typically, about 0.1 g/cm² of Ni(OH)₂ was deposited on the sintered electrode (1.60 g/cm³ void), and about 6 mg/cm² was deposited on the flat plate electrodes. All electrodes were cycled prior to experimental use until the capacity stabilized, which was typically five complete charge/discharge cycles. Rated capacities which will be referred to were 20 and 0.14 mAh/cm² for sintered and flat plate electrodes, respectively.

Electrode charge and discharge, impedance measurements, and capacitance monitoring were done automatically using a computer which continuously monitored electrode voltage and controlled the current passing through the electrode. An operational amplifier power supply having a 10 kHz frequency response was used to charge and discharge the electrodes. The electrodes were monitored in a nitrogen-purged, polystyrene test cell that incorporated a nickel sheet counterelectrode, a Hg/HgO reference electrode, and 31% KOH electrolyte. Electrode capacitance could be monitored by the computer through the application of a current step, the capacitance being obtained from the ratio of the magnitude of the current step to the initial slope of the electrode voltage response. Electrode capacitance was only measured at potentials where the initial voltage response to a current step was exponential in time; in potential regions where diffusion dominates the electrode kinetics, capacitance measurements are meaningless. The computer similarly measured the electrode impedance by monitoring the time dependence of the voltage response to a small current step. The method for obtaining the impedance from such transient data has been previously described (25). The time resolution for such transient acquisition was 1 ms. All transient voltage responses for both capacitance and impedance measurements were less than 5 mV in amplitude. Digital filtering of the amplified voltage response gave a typical noise level of less than 25 μ V in the electrode voltage. Capacitance measurements could be automatically done during electrode discharge with a typical precision of $\pm 0.5\%$; the accuracy was generally less than this because the electrode did not act as an ideal RC equivalent circuit. All capacitance measurements reported here are at potentials where the nickel electrode exhibited a nearly exponential time response, and have an accuracy of about $\pm 5\%$. All experiments were done at room temperature, 23 \pm 2 $^{\circ}$ C.

Nickel Electrode Discharge Kinetics

Results.—The Ni electrode voltage typically follows the curve indicated in Fig. 1 when it is discharged first at C/10, then at a lower rate (C/100). The points, a, b, and c indicated in Fig. 1 are the points during discharge at which the measurements in Fig. 2 were made. Figure 2 indicates the kinetic response of this electrode to a small current step at the upper voltage plateau during high rate discharge (point a), during low rate discharge (point b), and on the lower voltage plateau (point c). Also included in Fig. 2 are the electrode impedances calculated from the data at points, a, b, and c during discharge. As has been found by other workers (6-8), the kinetics are diffusion controlled during discharge on the upper voltage plateau at point a. Diffusion control is indicated by the linear region in the plot of transient voltage vs. \sqrt{t} in Fig. 2 at point a, or similarly by the linear dependence rising from the origin with a 45 $^{\circ}$ slope in the impedance plot of Fig. 2 at point a. The electrode at point b, while

Fig. 1. Discharge voltage of a sintered nickel electrode at C/10 rate followed by a C/100 discharge of residual capacity. The points a, b, and c refer to measurement points in Fig. 2.

Fig. 2. Transient impedance measurements at points a, b, and c during the discharge of Fig. 1. The upper curves are the transient responses to current changes, and the lower curves are the impedances calculated from the time transients. The numbers indicate the frequencies of the reactive extremes in Hz. The multipliers indicated have been applied to both coordinates.

still discharging on the upper voltage plateau, exhibits mixed kinetics suggestive of both activation and diffusion-controlled processes influencing the discharge. At point c on the lower plateau, the discharge kinetics are dominated by an activation-controlled process. Activation kinetics are characterized by an exponential transient response in time, which gives a semicircular impedance plot as shown in Fig. 2 for point c. In the discussion that follows, the resistance and capacitance associated with the activation controlled processes at points b and c will be labeled R and C, respectively. The diffusion resistance associated with the diffusion-controlled process at points a and b in Fig. 1 will be referred to as R_d.

Both R and C were measured during constant current discharge as a function of potential and state of charge. These results are indicated in Fig. 3 and 4, respectively. In Fig. 3 log R is plotted vs. potential during the course of a C/100 discharge. Also, at various

Fig. 3. Resistance R , as a function of voltage (solid circles) during $C/100$ discharge of the residual capacity in a sintered nickel electrode. At various times during the $C/100$ discharge the resistance was measured as a function of potential, as indicated by the solid lines.

Fig. 4. Sintered nickel electrode capacitance as a function of voltage (solid line) and capacity discharged (dashed line) during discharges of residual capacity at $C/100$ rate.

times during the discharge in Fig. 3, the current was varied so as to allow measurement of R as a function of voltage at a constant oxidation state. The capacitance of the sintered nickel electrode is indicated as a function of residual capacity Q , and also as a function of electrode voltage in Fig. 4. The capacitance decreases linearly with Q until the lower voltage plateau is reached, after which the capacitance is relatively constant during further discharge. While the capacitance does appear to vary with state of charge in Fig. 4, the variation in the capacitance actually appears to depend only on the electrode voltage in the range -0.3 to 0.25 V. Essentially the same voltage/capacitance curve as in Fig. 4 is obtained at all states of charge if the voltage of the nickel electrode is varied from about -0.3 to 0.25 V vs. Hg/HgO, suggesting that the capacitance may be controlled by a thin surface layer rather than by the properties of the bulk active material.

The results indicated in Fig. 1-4 are for an electrochemically impregnated sintered nickel electrode. Similar results were obtained for chemically deposited active material. Flat plate electrodes also gave similar behavior in that diffusion-controlled kinetics changed into mixed kinetics, and then finally into activation-controlled kinetics as the electrode was discharged. For the flat plate electrodes the current density was scaled down to realize a $C/10$ or a $C/100$ rate.

Discussion of nickel electrode kinetics.—Three processes have been observed that can control reduction

rates at the nickel electrode. The diffusion kinetics that are observed above 0.3 V are consistent with previous results attributed to proton diffusion in Ni electrodes (6-8) and in the NiCd cell (25). For a flat plate electrode, proton diffusion coefficients of about 10^{-10} cm^2s^{-1} are obtained from the measured diffusion times, assuming a film thickness proportional to capacity (about 10^{-4} cm). Deviations from ideal diffusion-controlled behavior are observed at high currents ($> C/2$) and also above about 70% state of charge. It is possible that these deviations are due to nonuniform ionic conduction within the active material; for example, proton diffusion should be predominantly along grain boundaries at the beginning of discharge when reaction is largely at the grain surfaces. The impedance arising from electrolyte diffusion in the pore structure of the sintered electrodes was not significant relative to the solid-state proton diffusion impedance at the discharge rates employed here, but did become significant at higher rates. This conclusion is supported by the similar impedance characteristics measured for flat plate and porous electrodes.

While still on the upper voltage plateau, but at low states of charge, a second process begins to control the kinetics, as indicated by the mixed kinetics at point b in Fig. 1 and 2. This process is activation controlled, and as shown in Fig. 3 has a Tafel slope of about 60 mV/decade. The same slope was observed for all electrodes studied: flat plate electrodes, sintered electrodes, and electrodes in commercial NiCd cells. The slope is consistent with the single-electron transfer process given by reaction [3] becoming rate limiting. Also, since the capacitance decreases linearly with charge transfer site density or electrode state of charge in the region above 0.2 V, reaction [3] appears most likely to control the rate. Therefore, in the region having about a 60 mV/decade Tafel slope, the density of charge transfer sites appears to have decreased to the level where charge transfer has become rate limiting. Discharge in this region continuously decreases the density of higher valency sites and thereby increases the charge transfer resistance of the active material. It should also be noted that the open-circuit voltage of the active material continuously decreases as the density of higher valency sites diminishes.

As the Ni electrode is discharged towards the divalent state, a third process can cause the electrochemical kinetics to change dramatically in the potential range between 0.1 and 0.2 V. While the active material above 0.2 V acts as an electronic conductor, below 0.2 V a layer of active material begins to behave like a semiconductor, exhibiting Tafel slopes (Fig. 3) that continuously increase as the material is reduced. The sudden decrease in capacitance that accompanies the transition to the lower voltage plateau (Fig. 4) is consistent with the formation of a layer of carrier-depleted material at the metal current-collector/active material interface, such that the resistance and capacitance of this layer now dominate the discharge kinetics. Continued discharge on the lower voltage plateau causes the depletion layer to grow in thickness (and resistance) towards the solution interface.

The model presented above is similar to models put forth qualitatively by Klapste *et al.* (13) and somewhat more quantitatively by Barnard *et al.* (23), in that changes in the conductivity of the active material cause the lower voltage plateau. The model of Barnard *et al.* (23) fits the Tafel slope reported here on the upper voltage plateau. However, the Tafel slopes observed on the lower voltage plateau suggest that a poorly conducting semiconductor layer has formed and that the electrode overpotential arises from the space charge voltage across the layer. The layer is kinetically maintained by current flow, and it is therefore expected that both its thickness and its conductivity at a given state of charge will depend on current den-

sity. The kinetics on the lower plateau are clearly activation controlled, indicating that conduction through the depleted layer does not occur through ionic migration.

While it is technically true that a secondary plateau in the voltage is not observed during recharge of a Ni electrode, the increased resistance associated with the depletion layer can be clearly seen in the early stages of Ni electrode oxidation. After generation of a depletion layer by a low rate discharge to low potentials, the electrode voltage goes through an initial high voltage peak when recharge is initiated. It has been well established that after shorting NiCd cells down for long periods, recharge must be initiated at quite a low rate to keep the voltage from initially rising to unacceptably high levels. Such a voltage peak is likely to arise from the ohmic contribution of the depletion layer, which can become quite thick in instances of long-term cell short down.

Electrode capacitance and nonuniformities.—The model described above for the kinetics of the nickel electrode suggests that above about 0.25V the capacitance of the electrode is controlled by the density of higher valency sites available for reduction, giving the linear relationship between capacitance and residual capacity in Fig. 4 below 6C (above 0.25V). Continued discharge to the lower voltage plateau causes a drop in capacitance as it becomes controlled by the space charge capacitance across the depleted layer at the active material/current collector interface. The drop in capacitance should be sensitive to the structure of the active material at this interface. A low interfacial contact area (high interfacial current density) should give a greater drop in capacitance, and any energetic differences in active material at the current collector interface should spread the capacitance drop over a range of discharge capacity and thereby decrease the sharpness of the drop. The manner in which the capacitance varies during discharge of residual capacity can therefore indicate the causes for changes or differences in electrode performance. In Fig. 5, plots of electrode capacitance as a function of residual capacity are shown for a sintered nickel electrode after being cycled 32 times, after being reconditioned, and for a flat plate nickel electrode. The most striking difference between the electrodes is the degree of sharpness of the capacitance drop as electrode voltage drops to the lower discharge plateau. For the sintered electrode that has been cycled many times, the active material at the current collector interface has developed significant nonuniformities, which are likely to be associated with energetic variations between different phases

Fig. 5. Capacitance of nickel electrodes during a C/100 discharge of residual capacity. The solid curve is for an uncycled 1 cm² sintered electrode after formation, dashed curve for a 1 cm² sintered electrode after 32 cycles, and the dash-dot curve is for an uncycled 4 cm² flat plate nickel electrode.

or structures of the active material at the interface. The flat plate electrode, however, has an extremely sharp drop in capacitance in Fig. 5, suggesting a highly uniform active material/current collector interface. The greater relative drop in capacitance for the flat plate electrode is likely to be due to a somewhat higher interfacial current density.

The capacitance on the lower plateau, if due to a perfectly uniform semiconductor layer, would be expected to exhibit a Mott-Schottky dependence on voltage. This relationship is plotted in Fig. 6 for differing amounts of residual capacity discharged for both sintered and flat plate electrodes. At all states of discharge, the relationship is essentially linear above 0.0V for the flat plate electrode, and above 0.05V for the sintered electrodes. The linear ranges are not large because data only extend up to about 0.15V, since the depleted layer cannot be maintained above this voltage under galvanostatic conditions. It is interesting to note that for all states of discharge for both the flat plate and the sintered electrodes, the higher voltage data extrapolate to 0.32V vs. Hg/HgO. A possible explanation for the linear behavior at higher voltages and the pronounced curvature at lower voltages is that at lower voltages the depleted layer becomes quite thick relative to grain sizes and active material nonuniformities, thus giving a highly inhomogeneous space charge region. At high voltages, the depleted layer is extremely thin, and is therefore less likely to exhibit Mott-Schottky deviations.

Cobalt additive effect.—Additives such as cobalt are generally considered to significantly improve nickel electrode performance. Although the effects of additives of this kind on the mechanisms of nickel electrode operation are not completely understood, it is expected that the additives can affect both ionic and electronic conductivity of the active material. The effects of a 10% cobalt additive on the kinetics of the sintered nickel electrode were evaluated, and are given in Fig. 7. The data in Fig. 7 clearly show that the overall discharge mechanisms on the upper and lower voltage plateaus are unchanged by the Co additive. However, the Co additive decreased the diffusion resistance during the C/100 discharge by about an order of magnitude, indicating substantially increased ionic conductivity. The electronic conductivity of the active material is also increased by the higher defect concentration provided by the cobalt. As has been previously reported (26), the increased defect concentration decreases the equilibrium electrode voltage

Fig. 6. Mott-Schottky plots for sintered (solid lines) and flat plate (dashed lines) nickel electrodes at various points of discharge of residual capacity. The percentages of residual capacity discharged are indicated. For flat electrode $1/C^2$ has been scaled down by 10.

Fig. 7. Resistance R , as a function of voltage for a sintered nickel electrode (closed circles) and a sintered nickel electrode with 10% cobalt additive (closed squares) during a C/100 discharge of residual capacity. The open symbols indicate the diffusion resistances R_d , that were also measured at the higher voltages.

about 70 mV. This has significant effects on the rechargeability of the nickel electrode. The high peak in the resistance during the transition from the upper to the lower voltage plateau appears to be eliminated by the cobalt additive. The peak and how cobalt additives act to eliminate it are the subject of continuing study.

ABSTRACT

Passive layers on nickel and their change by the action of fluoride have been studied by surface analyses such as x-ray photoelectron spectroscopy (XPS) and low energy ion scattering (ISS). The thickness of the layers is deduced from the height of the XPS signals Ni2p3/2, O1s, and F1s and their attenuation by covering layers. Argon sputtering gives information on the in-depth structure of the passivating films in combination with XPS and the higher depth resolution of ISS. Their thickness and chemical composition change with the electrode potential and the time of exposure to HF. A multilayer structure is found with an inner oxide and outer hydroxide film and, in a higher potential range, a fluoride layer in between. The layer structure shows a close correspondence to the results of the electrochemical examination.

The thickness and composition of surface layers are of decisive importance for processes at the solid-

electrolyte interface. Especially in the field of corrosion, the analysis of the metal surface is necessary to gain a deeper insight into the phenomena and a better interpretation of the electrochemical results. Therefore, we started a combined study of x-ray photoelec-

* Electrochemical Society Active Member.

tron spectroscopy (XPS), ion scattering spectroscopy (ISS), and electrochemical examinations. In a previous paper, the influence of fluoride on the passive behavior of nickel was studied (1). A profound explanation of the findings was only possible on the basis of the surface analytical results. We examined the films of passivated nickel and those which have been attacked by fluoride. For this purpose, the specimens are prepared under well-defined electrochemical conditions.

Experimental

The specimen preparation was described in detail previously (1). After the individual pretreatment, the specimens were rinsed with triply distilled water and transferred into the vacuum chamber as quickly as possible, typically within 1 min. For the analysis, we used an ESCALAB 5 system (Vacuum Generators, Limited) with a fast entry airlock, a preparation chamber, a main analytical vessel with an optimum pressure of $5 \cdot 10^{-11}$ mbar and an operating pressure of some few 10^{-10} mbar after sample induct. The XPS analysis was run with a Mg $K\alpha$ source with 300 W power. For sputtering and ISS analysis, a fine focusing scanning ion gun was used. For depth profiling, an argon beam with 3 keV primary energy and a controlled specimen current of 0.7 μ A was scanned over an area of 8×8 mm. ISS was performed with a helium beam of 1 keV primary energy and 10 nA current to avoid any changes during analysis. A gas inlet system facilitated the rapid change of gases for the ion gun. Phases of argon sputtering and analysis with helium followed alternatively, thus providing an ISS depth profile. After each sputter period, an XPS analysis of the most relevant peaks was taken. The sputter area was large enough to get only contributions of equally etched parts of the surface. For ISS, the signal was taken from a small part of the sputtered area in the center.

With the ISS spectrum, one may distinguish between the three main elements, Ni, O, and F present at the surface. This method has an in-depth resolution of a monolayer. However, depth profiles are affected by the different changes caused by argon ion sputtering. Therefore, we used ISS only to determine qualitatively the sequence of multilayer structures.

For XPS analysis, we used the O1s signal at the binding energies $E_B = 529.3$ and 531.5 eV to distinguish between oxide and hydroxide, the F1s signal at $E_B = 685$ eV, and the Ni2p3/2 peaks in the range $E_B = 852$ – 868 eV. At $E_B = 852.8$ eV, the metallic Ni peak is found. The peak at 856.5 eV is an overlap of several signals, Ni(OH)₂, NiO, and the "shake up" of the metallic nickel. NiO is found at 853.4 and 855.4 eV and Ni(OH)₂ at 855.8 eV. In the presence of fluoride, a peak at 857.2 eV is attributed to NiF₂ after comparison with standards. The related "shake up" is found at 863.5 eV. As nickel is present simultaneously at the surface in different valence states, the peaks and their satellites overlap to a complicated structure with a base line not well defined. Unfolding this structure is affected with a large error. Therefore, we did not use

this part of the Ni2p3/2 signal for quantitative analysis. The main qualitative and quantitative information was taken from the metallic Ni2p3/2, the O1s, and the F1s peak.

As references, we used a sputter-cleaned Ni specimen, NiO, Ni(OH)₂, and NiF₂ powder pressed in a tin foil to reduce surface charging (2) and a Ni sample oxidized in air at 700°C and so covered with a visible NiO film thick enough to prevent any contribution of the metallic Ni peak. Table I shows the relevant peak positions of different nickel compounds. In cases where surface charging was a problem, the signals were corrected by referring them to the Cls position with $E_B = 284.6$ eV. Carbon was always present in traces because of the inevitable contaminants from the electrolyte and the exposure to the environment. The results of Table I show a good agreement with those from the literature (3–9) and helped in identification of the nature of the surface films. The Ni2p3/2 peak of the Ni₂O₃ specimen is close to the positions of NiO and Ni(OH)₂. The distinction between Ni₂O₃ and NiO in the absence of Ni(OH)₂ is possible by using the different O1s peak positions (7). In presence of Ni(OH)₂ this distinction is impossible on the basis of ESCA measurements. Therefore, we could not find small amounts of Ni₂O₃ in a NiO matrix as postulated for the transpassive potential range for Ni. However, the presence of Ni₂O₃ cannot be ruled out.

Results and Discussion

The XPS spectra of electropolished nickel rinsed with triply distilled water show qualitatively the presence of a NiO film with a Ni(OH)₂ overlayer (Fig. 1). The Ni2p3/2 shows a metallic Ni peak ($E_B = 852.8$ eV) attenuated by the surface film and a peak at $E_B = 856.5$ eV with its origin from NiO, Ni(OH)₂, and a "shake up" contribution. The O1s signal demonstrates the presence of hydroxide ($E_B = 531.5$ eV) and a shoulder at $E_B = 529.9$ eV of oxide. Argon sputtering enlarges the shoulder at lower binding energy with a simultaneously vanishing hydroxylic signal. A change from nickel hydroxide to oxide or even its reduction to nickel metal by preferential sputtering during argon ion bombardment may be excluded by the results of other authors (6, 7) and own tests with Ni(OH)₂ specimens. Consequently, the surface film has a double structure with an inner oxide and an outer hydroxide layer. Sputtering enlarges the metallic Ni2p3/2 signal as a consequence of the thinning of the surface film and, contrary to Ni(OH)₂, by a partial reduction of NiO to Ni metal by preferential sputtering.

ISS shows only a Ni and O peak. Both signals appear after a short argon sputtering of some few minutes corresponding to a removal of less than one monolayer. This is a typical effect of all ISS spectra when water or OH groups are present at the surface. Backscattering of helium at the lighter hydrogen atoms does not occur.

The nickel specimen passivated in 1M HClO₄ ($\epsilon = 1.4V$) showed a similar XPS spectrum (Fig. 2). The Ni metal peak is less pronounced, and at $E_B = 855$ eV

a larger $\text{Ni}2p_{3/2}$ signal is found. This is a consequence of a thicker oxide film. Two distinct $\text{O}1s$ signals indicate the presence of an oxide and hydroxide layer.

Sputtering with argon ions again enlarges the Ni metal peak and reduces the oxide shoulder at $E_B = 855$ eV. The $\text{O}1s$ hydroxide signal also vanishes first within

Fig. 2. XPS and ISS depth profile of a passive film on nickel formed in 1M HClO_4 at $e = 1.4\text{V}$ for 3h.

about 5 min; the O1s oxide signal vanishes within 20 min. The ISS signal does not contain further information. The oxygen signal also disappears within 20 min of sputtering. A comparison with the electropolished Ni specimen shows a hydroxide layer of similar thickness by both the size of the O1s hydroxide signal and its disappearance within the same sputtering time. However, the oxide thickness has doubled after the results for the O1s signal. The XPS depth profile shows again an outer hydroxide and an inner oxide layer for passivated nickel electrodes. Similar results are obtained within the whole passive range of $\epsilon = 0.5$ -1.8V. In the transpassive region for $\epsilon > 1.5$ V, an increase of the oxide thickness is found. A higher valent oxide, i.e., Ni₂O₃, which is postulated from electrochemical results could not be detected. A clear indication of its presence is not possible because of the small chemical shift of the Ni2p3/2 peak (Table I).

To obtain quantitative results, the thickness of the surface layers was calculated from the XPS signals. For base line subtraction the background at both sides of a signal was connected at the peak position (10). With sufficient accuracy the peak heights between the maximum and the base line were taken for a quantitative evaluation instead of the peak areas which were controlled in several cases. The calculation was performed on a relative basis with peak height ratios, which minimized the error. Any changes by unfolding the overlapping peaks causes a larger inaccuracy. The structure of the Ni2p3/2 signal is complicated by the overlapping peaks of the different nickel compounds and their satellites. An unfolding for quantitative evaluation would give rather uncertain results. Therefore, we used only the Ni metal peak at $E_B = 852.8$ eV, and in addition the much simpler O1s signal ($E_B = 829.3$ and 531.5 eV). For the unfolding we assume a symmetrical peak shape with identical leading and tailing edges.

The attenuation of the Ni2p3/2 metal signal is used to get a value for the thickness of the total layer. If y is the thickness of the oxide, x of the hydroxide, and δ of the total layer (Fig. 3), one obtains for the attenuated Ni metal signal

$$I_1^{Me} = KF\sigma^{Me}[\text{Ni}]\lambda_{Me}^{Me} \exp(-\delta/\lambda_o^{Me}) \quad [1]$$

$$\delta = x + y \quad [1a]$$

where F is the intensity of the x-ray source and K a characteristic constant of the spectrometer containing the transmission characteristic of the energy analyzer and the detector and the angular acceptance of the analyzer. σ^{Me} is the photoionization cross section for the Ni2p3/2 signal after Scofield (11), corrected for the anisotropy of the photoelectron emission including the angle between the x-ray source and the energy analyzer (12, 13). $[\text{Ni}] = 0.1516$ mol cm⁻³ is the concentration of the nickel atoms in the metal (14), and λ_{ox}^{Me} the escape depth of the Ni2p3/2 photoelectrons from a NiO matrix. In a first approximation, the escape depth depends only on the kinetic energy after the relation

$$\lambda = B\sqrt{E_{kin}} \quad [2]$$

for kinetic energies $E_{kin} > 100$ eV (15) so that the values of NiO and Ni(OH)₂ do not differ ($\lambda_{ox}^{Me} \approx \lambda_{OH}^{Me}$). λ_{Me}^{Me} is the escape depth for the metal matrix, which is different from that of the oxides when considering the matrix effect to a first approximation (15).

For a clean sputtered nickel surface, one obtains for the Ni metal signal

$$I^{Me} = KF\sigma^{Me}[\text{Ni}]\lambda_{Me}^{Me} \quad [3]$$

Dividing Eq. [1] and [3] yields the following relations for identical experimental conditions for the spectrometer (K, F)

$$\frac{I_1^{Me}}{I^{Me}} = \exp(-\delta/\lambda_o^{Me}) \quad [4]$$

With the measured intensity of the Ni2p3/2 metal signal of the passivated specimen I_1^{Me} and the clean and uncovered standard I^{Me} , one obtains the total thickness $\delta = x + y$ of the double layer after relation [4]. For the subdivision in the two parts x and y , one may use the ratio of the peak heights of the O1s hydroxide and oxide peak

$$\frac{I_{OH}^o}{I_{ox}^o} = \frac{[\text{OH}^-][1 - \exp(-x/\lambda_{OH}^o)]}{[\text{O}^{2-}] \exp(-x/\lambda_{OH}^o)[1 - \exp(-y/\lambda_{ox}^o)]} \quad [5]$$

$[\text{OH}^-] = 0.0896$ mol cm⁻³ and $[\text{O}^{2-}] = 0.0839$ mol cm⁻³ are the molar concentrations of the OH⁻ and O²⁻ ions of NiO and Ni(OH)₂, respectively (14). The factor in brackets takes account of the self-attenuation of the signal with increasing thickness of the hydroxide and oxide layer, respectively. The additional exponential factor in the lower part reflects the attenuation of the O1s oxide signal by the hydroxide overlayer. Equation [5] requires identical experimental conditions for the spectrometer again.

Neglecting the matrix effects on the escape depth with $\lambda_{ox}^o = \lambda_{OH}^o = \lambda^o$, one obtains the relation for the thickness x of the hydroxide layer

$$x = -\lambda^o \ln \frac{I_{ox}^o[\text{OH}^-] + I_{OH}^o[\text{O}^{2-}] \exp(-d/\lambda^o)}{I_{OH}^o[\text{O}^{2-}] + I_{ox}^o[\text{OH}^-]} \quad [6]$$

Equations [4] and [6] permit one to calculate the thickness $\delta = x + y$ of the total layer, and the parts x for the hydroxide and y for the oxide.

The results of this evaluation are depicted in Fig. 4. For a better understanding, the potentiodynamic polarization curve of nickel in 1M HClO₄ is represented together with the total thickness δ and the oxide thickness y . The hydroxide thickness x equals the distance between both curves. The error of these results is most affected by the uncertainty of the escape depth λ of the electrons. This may be estimated to be $\pm 20\%$, thus leading to a similar error for the thickness values after Eq. [4] and [6] with $\delta \sim \lambda$ and $x \sim \lambda$.

Weakly acidic and alkaline solutions.—The passive layer in phthalate (pH 5.0) and borate buffer (pH 8.0) has the same double layer structure and only slight changes in thickness are found. Table II compares some results of the three electrolytes. Marcus *et al.* found the same structure but half the thickness for nickel passivated at $\epsilon = 0.54$ V in 0.1M H₂SO₄ (3). They used, however, the complex Ni2p3/2 signal for their evaluation and did not take into account the attenuation by the covering layers. Ohtsuka and Heusler determined similar values in 1M H₂SO₄ ($\epsilon = 0.6$ -1.6V, $\delta = 14$ -20Å) for the total layer (16) by *in situ* ellipsometry, and Sato in borate buffer pH 8.4 (17).

The thickness of the hydroxide layer does not change with potential and pH and does not seem to have a pronounced influence on the passive behavior. Its constant thickness for all electrolytes suggests that it is

not formed by secondary processes (*i.e.*, by precipitation from the adherent solution during the removal of the samples from the electrolyte or during rinsing with water). Small amounts of Ni²⁺ (passive current density < 1 μ A cm⁻²), especially within an adherent acidic electrolyte are expected to be washed off much more readily than in alkaline buffers with a lesser

Table II. Layer thickness of passivated nickel at different potentials ϵ in 1M HClO₄, phthalate buffer pH 4.9 and borate buffer pH 8.0 and of electropolished nickel

tendency to form precipitates. The oxide layer determines the passivating properties, as shown by its change with potential especially in the transpassive region, where a reduced dissolution, besides the evolution of oxygen, is found (18). The thinner oxide layer on electropolished nickel also supports this conclusion. These specimens are much better protected against aggressive electrolytes when they are prepassivated additionally for a sufficiently long period (19, 20), and achieve smaller stationary current densities with time.

Passive films after fluoride attack.—The addition of HF to 1M HClO₄ causes a pronounced increase of the corrosion current density of a passivated nickel electrode. The current density potential curve has a maximum and two characteristic minima (Fig. 6) (21, 22). To get an explanation for these features of the polarization curve and the effective corrosion mechanisms, we examined the nickel specimen after fluoride attack by surface analysis.

Figure 5 shows a depth profile by XPS and ISS of a nickel electrode prepassivated in 1M HClO₄ for 2h after the attack by 0.1M HF for 30 min at minimum I ($\epsilon = 0.5V$). Before the specimen was transferred from the electrolyte into the UHV chamber, stationary conditions with a constant current density had been achieved. The spectra were qualitatively the same as those without the fluoride addition. No fluoride was

Fig. 5. XPS and ISS depth profile of 2h in 1M HClO₄ prepassivated nickel after 30 min of exposure to 1M HClO₄ + 0.1M HF at $\epsilon = 0.5V$ (minimum I).

found in the surface layer by XPS and ISS after the fluoride attack (1% NiF_2 detection limit). The $\text{O}1s$ signal indicates the double layer structure. The OH signal disappears first during argon sputtering, demonstrating the outside position of the hydroxide. It takes about half the time to remove the passive layer compared to the specimen without fluoride attack, indicating its severe thinning. This is confirmed by the quantita-

tive evaluation of the $\text{Ni}2p_{3/2}$ metal peak and the two $\text{O}1s$ signals with Eq. [4] and [6] (Fig. 6). The thickness of the hydroxide layer is unchanged. These findings demonstrate the importance of the oxide layer and its changes for the passive behavior. Similar results are obtained in the whole potential range of minimum I up to the intermediate maximum ($\epsilon = 0.4$ – 0.9V) (Fig. 6).

More pronounced differences were found for those electrodes which had been exposed to HF containing HClO_4 at potentials of minimum II. At $\epsilon = 1.4\text{V}$, a large $\text{F}1s$ signal indicates the presence of fluoride in the surface film (Fig. 7). The $\text{O}1s$ signal shows the presence of hydroxide; however, oxide cannot be detected on the unspattered specimen. A very small $\text{Ni}2p_{3/2}$ metal signal is caused by a much thicker surface film than on a passive electrode in HClO_4 without HF (see Fig. 2). The signal at $E_B = 857.4\text{ eV}$ refers to NiF_2 , as is seen by comparison with a NiF_2 standard (Table I). This peak is at the position of the Ni metal satellite. However, the Ni shake-up peak is much too small to give any appreciable contribution with the vanishing main Ni metal peak of the unspattered specimen. The height of the satellite is generally about 17% of the total (main peak plus satellite).

During sputtering, a small $\text{O}1s$ oxide signal appears when the hydroxide peak is vanishing (Fig. 7). The fluoride disappears within ca. 1h when the oxide is still present.

ISS gives further information about the structure of the surface film. The increasing peak at $E/E_0 = 0.65$ is attributed to fluoride (Fig. 7). When the fluoride layer disappears after ca. 1h, an oxide signal is found at $E/E_0 = 0.60$, indicating a NiO sublayer. The preferential sputtering of the lighter elements oxygen and fluorine is accompanied by a partial reduction of the nickel compounds NiO and NiF_2 (7), which causes an early increase of the $\text{Ni}2p_{3/2}$ metal signal. This is overcome by its normal increase in later stages as a consequence of the removal of the surface layer.

The XPS and ISS examinations (Fig. 7) suggest a triple-layer structure for nickel electrodes in the range of minimum II. A very thin NiO layer at the metal surface is covered by a much thicker NiF_2 superimposed by a thin Ni(OH)_2 layer. The hydroxide layer is found by the $\text{O}1s$ signal on a non- or short-time (< 15 min) sputtered specimen (Fig. 7). A good ISS

Fig. 7. XPS and ISS depth profile of 2h in 1M HClO_4 prepassivated nickel after 30 min of exposure to 1M HClO_4 + 0.1M HF at $\epsilon = 1.4\text{V}$ (minimum II).

signal is obtained only after some sputtering when hydrogen is removed.

Besides the position of the Ni2p_{3/2} peak at $E_B = 857.4$ eV, the quantitative evaluation of the XPS signals gives information about the chemical nature of the fluoride containing layer. For this purpose the peak heights of F1s and Ni2p_{3/2} are divided by the corrected photoionization cross sections (11-13) $\sigma_F = 5.46$ and $\sigma_{Ni} = 17.03$. The molar ratio is obtained after relation [7]. The energy dependence of the escape depth Eq. [2] cancels with that of the transmission function $T \sim (E_{Kin})^{-1/2}$ of the ESCALAB 5 (10).

$$\frac{n_F}{n_{Ni}} = \frac{I_{F\sigma_{Ni}\lambda_{Ni}T_{Ni}}}{I_{Ni\sigma_F\lambda_F T_F}} = \frac{I_{F\sigma_{Ni}}}{I_{Ni\sigma_F}} \quad [7]$$

Table III gives the molar ratio of fluorine to nickel for prepassivated specimens exposed to 1M HClO₄ + 0.1M HF for 30 min in the potential range of minimum II. The results show sufficient coincidence with those for a NiF₂ standard. The Ni2p_{3/2} fluoride signal is not corrected for the small peak of the nickel hydroxide. However, its contribution is estimated to be less than 5%. Its consideration would enlarge only slightly the n_F/n_{Ni} ratio.

From the position and height of the XPS peaks, we have to conclude that a NiF₂ layer is present at the surface in the potential range $\epsilon = 1.1$ to $<1.8V$; however, small amounts of higher valent nickel compounds (i.e., NiF₃) cannot be excluded. Very small amounts of oxide and hydroxide are also seen in the depth profiles so that some contaminations of the fluoride film seems reasonable. This holds especially for the visible blue-black layers formed at the peak maximum ($\epsilon = 1.15V$) (1). They are apparently much too thick to permit a contribution of the thin NiO sublayer to the O1s signal. Even after 30 min of sputtering a very small O1s is still detected (Fig. 8). Also in this case, the increase of the Ni2p_{3/2} metal signal demonstrates the partial reduction of the surface film (NiO, NiF₂) by preferential sputtering of the lighter elements (O and F). The nickel substrate cannot give any contribution when it is covered by the visible coherent film which only might contain some pores. Appreciable amounts of complexes with a high F content within the film such as [NiF₆]⁴⁻ may be excluded. They would cause a pronounced chemical shift of the Ni2p_{3/2} and

Table III. Molar ratio n_F/n_{Ni} after Eq. [10] from XPS peak heights for surface layers prepared by 30 min exposure to 1M HClO₄ + 0.1M HF at different potentials and NiF₂ standard, $\epsilon = 1.15V \triangleq$ visible fluoride film

ϵ/V	n_F/n_{Ni}

NiF ₂ standard	2.25

F1s signal to $E_B = 861.2$ eV and $E_B = 687.8$ eV as compared to K₂NiF₆ (23), which is not found experimentally.

The thickness of the triple layer may be calculated from the peak heights of the XPS signals similar to the case of an ordinary passive film on nickel. For this more complicated situation, the F1s peak is used as well, leading to the following equation for the peak height ratios

$$\frac{I_{O_{OH}}}{I_F} = \frac{\sigma_o[OH^-] [1 - \exp(-x/\lambda^o)]}{\sigma_F[F^-] \exp(-x/\lambda^o) [1 - \exp(-y/\lambda^F)]} \quad [8]$$

$$\frac{I_{O_{ox}}}{I_F} = \frac{\sigma_o[O^{2-}] \exp(-(x+y)/\lambda^o) [1 - \exp(-z/\lambda^o)]}{\sigma_F[F^-] \exp(-x/\lambda^o) [1 - \exp(-y/\lambda^F)]} \quad [9]$$

where x is the thickness of the hydroxide, y of the fluoride, and z of the oxide layer. The escape depths of the electrons originated at F and O atoms are only slightly different, $\lambda^o = 12\text{\AA}$ and $\lambda^F = 11\text{\AA}$, when the matrix effect is neglected and Eq. [2] is applied. With the approximation $\lambda^o \approx \lambda^F = \lambda$, one obtains the following relations

$$x = -\lambda \ln \left[\frac{b/c + (f/h) \exp(-\delta/\lambda)}{a/c + g/h} \right] \quad [10]$$

$$y = -\lambda \ln [(g/h) + (f/h) \exp(-[\delta - x]/\lambda)] \quad [11]$$

with the following expressions

Fig. 8. XPS and ISS spectra of 2h in 1M HClO₄ prepassivated nickel after different times of exposure to 1M HClO₄ + 0.1M HF at $\epsilon = 1.4V$ (minimum II) after 5 min of argon sputtering (0.7 μA , 3 kV).

$$\begin{aligned}
 a &= I_{\text{OH}\sigma\text{F}}[\text{F}^-] + I_{\text{F}\sigma\text{O}}[\text{OH}^-] \\
 b &= I_{\text{F}\sigma\text{O}}[\text{OH}^-] \\
 c &= I_{\text{OH}\sigma\text{F}}[\text{F}^-] \\
 f &= I_{\text{F}\sigma\text{O}}[\text{O}^{2-}] \\
 g &= I_{\text{Ox}\sigma\text{F}}[\text{F}^-] \\
 h &= I_{\text{F}\sigma\text{O}}[\text{O}^{2-}] + I_{\text{Ox}\sigma\text{F}}[\text{F}^-] \\
 \delta &= x + y + z \text{ (total layer thickness)}
 \end{aligned}
 \quad [12]$$

For the concentrations of the anions, the previously mentioned values of the bulk materials NiO, Ni(OH)₂, or NiF₂ are applied [$[\text{F}^-] = 0.0958 \text{ mol cm}^{-3}$ (14)]. The total layer thickness δ is calculated again from the attenuation of the Ni2p3/2 metal signal. The relatively thick fluoride layer causes problems in the determination of the thickness of the oxide (z) and the total layer thickness (δ). The nickel metal and nickel oxide signals are attenuated to a large extent, so that δ may be determined only with a relatively large error of $\pm 20\%$. After the depth profiles, a small oxygen content within the fluoride was taken into account. This situation enlarges the nickel oxide peak and leads to much too high values for the oxide thickness x . Table IV shows the thickness of the triple layer after exposure to HClO₄ + 0.1M HF for different times at potentials in the range of the minimum II ($\epsilon = 1.2$ -1.8V), where transparent films are formed. The values in the brackets are obtained by direct application of Eq. [4], [10], and [11]. The other more correct values are obtained from the time dependence of the fluoride attack, especially for short-time exposures. This is described below.

Change of the surface layer with time.—The changes of the thickness and composition of the surface layers occur in close coincidence with the features of the current density-time curves (1). Figure 8 depicts the XPS and ISS spectra after different times of attack by 0.1M HF in 1M HClO₄. The specimens are all sputtered for 5 min with identical conditions to get a well-developed ISS spectrum, which is not suppressed by the presence of H atoms at the surface. Consequently, the O1s hydroxide signal is reduced to only a small shoulder close to the oxide peak for a nonattacked sample. With increasing time of HF exposure, the O1s oxide signal gets smaller because the NiO is covered by an increasing fluoride layer and the oxide itself is thinned. The increase of the O1s hydroxide signal for long times of HF exposure is presumably caused by an OH⁻ contamination of the fluoride layer. The HF attack increases the Ni2p3/2 fluoride and the F1s signal and decreases the Ni2p3/2 metal signal.

Similarly, the ISS spectrum reflects the growth of the fluoride layer on NiO. After 24s of attack, a small oxide shoulder is still seen besides the fluoride peak. After 38s, the fluoride film is already thick enough to

cover the oxide completely after 5 min of sputtering. Consequently, a large F peak is found without an oxide shoulder for > 38s of HF exposure. The depth profiles of specimens with increasing fluoride attack are consistent with an increasing intermediate fluoride layer. The sputter time for the detection of the rest of the oxide at the metal surface by ISS increases with the exposure to HF. Similarly it takes more time to remove the fluoride from the surface.

The F1s and the Ni2p3/2 fluoride peaks increase, and the O1s oxide signal decreases with the time of exposure. At 75s of HF attack, the maximum of the F1s and Ni2p3/2 fluoride signal and a minimum of the O1s oxide peak are achieved, and no pronounced change occurs within the following 90 min.

For short times of HF exposure up to 74s, the calculation of the thicknesses x , y , and z of the triple surface layer does not cause major problems. The attenuation of the Ni2p3/2 metal and O1s oxide signal still permits determination of reliable values. After several minutes, however, both peaks are too small to be measured with a large overlapping Ni2p3/2 fluoride and O1s hydroxide signal. A 10 min sputtering, however, gives an estimate of the layer thickness applying relations [4] and [10]-[12]. The hydroxide signal was taken from the unspattered, whereas the oxide and the fluoride signals were taken from the sputtered specimen. During the sputtering process, the hydroxide is mainly removed. To some extent the fluoride is also. This increases the F1s signal because only the self-attenuation of the layer is effective now. The partial reduction of the surface by preferential sputtering leads to a somewhat too small total thickness δ so that these values for 10-90 min should be seen as an estimate.

The results for $\epsilon = 1.4\text{V}$ are depicted in Fig. 9. The changes occur in close relation to the polarization curve. The thinning of the oxide layer occurs during the first 1.5 min. At the same time the fluoride layer is formed. During the first 30s, the oxide thinning is responsible for the current increase; in the following minute, the growth of the fluoride layer reduces its value. After 1.5 min, only minor changes in the layer structure and the current density are found.

The thickness of the three layers are also inserted in the diagram in Fig. 6. The decrease of the current for $\epsilon > 1.0\text{V}$ coincides with the formation of a fluoride film. At the current maximum its protecting properties are still not sufficient. Although a visible film is observed, the corrosion of nickel is not effectively suppressed. This should be seen as a consequence of the layer structure, which presumably is porous or not dense enough to reduce effectively the transfer of the metal ions from the metal into the electrolyte. At the falling edge of the current density up to $\epsilon < 1.2\text{V}$, the surface is covered only partially by a visible film. Current oscillations indicate the instability of this

Table IV. Layer thickness of prepassivated nickel after exposure to HF or KF containing 1M HClO₄, phthalate buffer pH 4.9 and borate buffer pH 8.0 for different times and potentials

Fig. 9. Current density time curve of 2h prepassivated nickel after exposure to 1M HClO₄ + 0.1M HF and the related change of the layer thickness at $\epsilon = 1.4V$ (minimum I1). ●: total layer. ○: oxide layer. △: hydroxide layer. Difference refers to fluoride layer.

layer which may be even removed completely by sufficient stirring (i.e., by rotation of a Ni disk electrode at > 400 rpm). At $\epsilon \geq 1.2V$ the nonvisible, nonporous protecting fluoride films are formed. The change of their physical structure may explain why the current density decreases with the thickness in the range $\epsilon = 1.2-1.4V$, because in most cases of passivity the opposite behavior is found.

Weakly acidic and alkaline solutions.—The effect of HF and F⁻ on the passive current density in more alkaline solutions is less pronounced, as has been described already in detail (1, 19). In phthalate buffer pH 4.9 with 0.1M KF, an intermediate maximum is found in the polarization curve, whereas in borate buffer pH 8.0 with 0.1M KF, the same results are ob-

tained as in fluoride-free solution. In minimum I in phthalate buffer even after more than 120 min of KF exposure, only a very weak F1s signal is found just above the background. This disappears during 10 min of sputtering (Fig. 10). From comparison with the fluoride-covered specimen of Fig. 7, this corresponds to much less than 1 monolayer and should be seen as a quantity adsorbed at the surface of the passive film. This result would support the catalytic effect of HF for the passive current density by the formation of a surface complex at the oxide-electrolyte interface (1). The depth profile for $\epsilon = 0.5V$ shows again an inner oxide and outer hydroxide layer. The quantitative evaluation of the XPS signals (Eq. [4] and [6]) leads to similar results as in 1M HClO₄ (Table IV). At $\epsilon \geq$

Fig. 10. XPS and ISS depth profile of 2h in phthalate buffer pH 4.9 prepassivated nickel after 120 min exposure to additional 0.1M KF at $\epsilon = 0.5V$ (minimum I).

Fig. 11. XPS and ISS depth profile of 2h in 0.1M phthalate buffer pH 4.9 prepassivated nickel after 150 min exposure to additional 0.1M KF at $\epsilon = 0.95V$.

0.95V (maximum and minimum II), a more pronounced F1s signal is found which should be attributed to a fluoride layer (Fig. 11). It is, however, much thinner than in 1M HClO₄ despite the longer exposure to KF (150 min). Its intermediate position is demonstrated again by the depth profile with the O1s signal and the ISS oxygen and fluorine peaks. No visible layer is found at any potential in the weakly acidic fluoride solution.

In borate buffer pH 8.0 no fluoride is detected at the surface within the whole passive range. The layer structure and thickness do not show any major changes. Only the outer hydroxide layer increases (Fig. 12). These results confirm the electrochemical findings that fluoride does not affect appreciably the passive behavior of nickel at pH 8.0 (1).

Conclusion

The application of XPS and ISS is well suited to obtaining information about the chemical and physical structure of passivating layers on metals. The quantitative evaluation of the XPS results permits the calculation of the thickness of surface layers up to 60Å.

The passive layer in fluoride-free solutions of pH 0.0-8.0 consists of an inner oxide and an outer hydroxide layer of 8Å, which does not change with potential and pH, and therefore should not be responsible for the passive behavior. The oxide layer grows, however, with potential, especially in the transpassive range. Its thickness is similar for the solutions of different pH and close to the values of other authors ob-

Fig. 12. XPS and ISS depth profile of 2h in 0.1M borate buffer pH 8.0 prepassivated nickel after 30 min exposure to additional 0.1M KF at $\epsilon = 1.0V$.

tained by other methods. It represents the main barrier for the passive behavior.

In the case of nickel in HF or fluoride containing solutions, a close correlation between the electrochemical and surface analytical results was obtained which helped in interpretation of the mechanism of fluoride attack. In a lower potential range (minimum I), a surface catalytically enhanced dissolution is found which assumes for the mechanism the formation of an intermediate Ni^{2+} fluoride complex at the surface (1). Therefore, no F^- is found for specimens prepared in HClO_4 and rinsed with water. Only in phthalate buffer a very weak F1s signal indicates the presence of adsorbed fluoride, less than one monolayer. The hydroxide layer is unaffected. However, the oxide is thinned.

In the higher potential range (minimum II), a thick fluoride layer is found in $1M \text{HClO}_4 + 0.1M \text{HF}$. It grows with the time of HF exposure and gets thinner with increasing electrode potential. The oxide is thinned to ca. 4Å. It is situated at the metal surface covered by 20-70Å of fluoride followed by 8Å of hydroxide at the outmost position. The fluoride has passivating properties and compensates partly for the thinning of the barrier type of oxide.

In phthalate buffer pH 4.9, the oxide layer is thinned to a smaller extent and less fluoride is formed. This corresponds to a much smaller current increase for this electrolyte.

In borate buffer pH 8.0, no current increase, no fluoride at the surface, and no thinning of the oxide layer is found.

The quantitative evaluation of the XPS peaks shows that the fluoride layer has a composition similar to NiF_2 with some contamination by oxide and hydroxide. Any Ni-F complexes or higher valent nickel compounds could not be detected by XPS. The chemical shift between NiO and Ni_2O_3 is too small to find small amounts of three valent nickel ions in a two valent matrix.

These examinations show that a combined study with electrochemical and surface analytical methods gives a good insight into the processes occurring at the solid-electrolyte interface and is especially suited for the study of surface films passivity and corrosion phenomena.

Electrochemical and Ellipsometric Investigations of Passive Films on Iron in Borate Solutions

III. The Kinetics of Film Growth on Iron at Transpassive Potentials

W. Kozłowski and A. Szklarska-Smiałowska

Institute of Physical Chemistry, Polish Academy of Sciences, Warsaw, Poland

ABSTRACT

Ellipsometric technique has been used to study the oxide film formation on iron in two borate buffer solutions of pH 8.4 in the transpassive region of potentials. At the potential of oxygen evolution ($\sim 1.0 V_{\text{SCE}}$), a slight decrease of the refractive index with respect to its value in the passive region was observed, indicating some changes in the composition or structure of the film. Above $1.4 V_{\text{SCE}}$, a second thicker film grows on the top of the passive film. This outer film, which is probably composed of corrosion products, exhibits a low refractive index. At high anodic potentials (above $1.5 V_{\text{SCE}}$), pitting occurs.

There have been very few studies of the film formation on iron in borate solutions at potentials corresponding to the oxygen evolution reaction or above. Sato *et al.* (1) measured the thickness of films formed in borate solutions of pH 7.45, 8.42, and 9.37 by galvanostatic reduction. The films were reduced in a bo-

rate solution of pH 6.35 containing As_2O_3 as inhibitor. Based on these measurements and analyses of the Fe^{2+} content in solution, it was concluded that in the region of O_2 evolution, up to the potential where transpassive dissolution of iron began to occur ($\sim 1.3 V_{\text{SCE}}$), the thickness of the film increased with increasing

potential. On the other hand, the film thickness was potential independent above 1.3V. Also, the potential for the transpassive iron dissolution was found to be independent of pH. A mechanistic model for film breakdown was developed to interpret these results (2). According to that model, when a certain critical film thickness is attained, mechanical breakdown of the film occurs as a result of the high electrostrictional pressure. This pressure can produce compressive stresses exceeding a critical breakdown stress in the oxide film.

Ellipsometric investigations performed by Sato *et al.* (3) supported the above results and conclusions. The film was found to be composed of two layers: an inner barrier layer of γ -Fe₂O₃, and a deposited outer layer of hydrated iron III oxide. The complex indexes of refraction for the barrier layer were (2.50-0.30i) and (2.50-0.22i) within the potential range of 0.5-1.3V and above 1.3V, respectively. The complex index of refraction of the outer layer was found to be the same in both potential ranges: 2.20-0.10i. The same authors (3) claim that from 0.5V to 1.3 V_{SCE} the state of oxidation of iron in both the barrier and the deposited layer is +3, but above 1.3V, a small amount of Fe²⁺ is also present in the barrier layer. Hence, the composition of the film is probably close to Fe₃O₄. However, in the deposited layer only Fe³⁺ is present. At the boundary between these oxide layers, an excess of iron or iron vacancies occurs.

Electron diffraction studies of the oxide film formed in borate solution of pH 8.5 at 1.25 V_{SCE} indicated that the film is composed of Fe₃O₄ (4). The same film structure was found (4) in NaOH (pH 11.4) and in H₂SO₄ (pH 1.1) solutions.

There are also several papers dealing with the composition and properties of films formed on iron in the transpassive region of potentials, but in solutions other than borate. These studies were conducted to explain the processes occurring during electrochemical machining (ECM) of steel parts. The film formed on mild steel after ECM in NaClO₃ was γ -Fe₂O₃, as determined by reflection electron diffraction (RHEED) and electron probe analysis (5). However, in NaNO₃ solution, it was assumed (6, 7) that electronically conductive Fe₃O₄ is formed because most of the current was consumed by the O₂ evolution reaction instead of metal dissolution.

Cohen *et al.* (8), using RHEED and x-ray emission analysis (XRE), have established that the film formed during electropolishing in a mixture of HClO₄ and CH₃COOH is composed of a mixture of anhydrous Fe₃O₄ and γ -Fe₂O₃.

According to some authors, anodic films may undergo changes at the potential of oxygen evolution. For example, Oshe *et al.* (9), suggested that in the transpassive region of potential, an increase of current that occurs in the Fe-Na₂SO₄ system at the beginning of oxygen evolution is connected with the removal O²⁻ and OH⁻ from the almost stoichiometric γ -Fe₂O₃. The decrease in concentration of O²⁻ and OH⁻ in the film results in an increased current associated with iron dissolution.

Also, Vetter (10) takes into consideration the possibility of oxide film participation in the oxygen evolution reaction. It is worthwhile noting that some experimental evidence obtained for platinum suggests that the anodic film takes part in the oxygen evolution reaction (11). However, the results of studies (12) on anodic oxygen evolution on α -Fe₂O₃ in H₂SO₄ solution seem to exclude any possibility of withdrawal of oxygen from the oxide lattice.

The existing models for breakdown of the passive film in the transpassive region of potentials (3, 6, 13, 14), suggest that the first step consists of anion adsorption on the metal surface. With increasing anion concentration, the efficiency of metal dissolution should

increase. In agreement with this conclusion, Mao and Chin (7) obtained higher current efficiencies for iron dissolution in NaClO₃ with increasing concentration of ClO₃⁻.

The aims of the present work were as follows: (i) to compare the optical properties of film formed in the passive and transpassive state; (ii) to establish the kinetics of film growth in the transpassive region of potentials; (iii) to determine whether the optical parameters or film thickness change before film breakdown occurs; and (iv) to compare the properties of films formed in two borate buffer solutions of the same pH (8.42) but differing in borate concentration.

Experimental

The material, preparation of specimens, and ellipsometric methods have been described in Part I (15) of this series of papers. In this case, the bubbles of oxygen evolving at high anodic potentials were removed from the electrode surface by a stream of argon in order to facilitate the measurements.

Results

The anodic polarization curves obtained for both solutions, with the transpassive region of potentials included, have been given in Part I of this study. These curves show that at high anodic potentials (above 1.2-1.3V) the current densities are higher in the more concentrated solution 2 than in the dilute solution 1.

The changes in current density at constant potentials recorded as a function of time in solution 2 for potentials in the oxygen evolution region are plotted in Fig. 1. It is seen that within the time period examined, the current density continues to decrease only at an applied potential of 1.0V. At higher anodic potentials the current density, after decreasing during the first few minutes, increases until a steady-state value is reached. An increase in the applied potential decreases the time in which a minimum current density is observed. At very high anodic potentials (above 2.0V), a minimum does not appear. Similar results were obtained for solution 1, but the current density minima were less pronounced than for solution 2.

The effects of applied potential on the optical parameters n and k are shown in Fig. 2 for both solutions 1 and 2. A small decrease in n with increasing anodic potential occurs in both solutions at potentials above 1.0V, this effect being more pronounced in solution 2. Figure 2 also includes values of n and k obtained in the passive range of potentials from 0.5 to 0.8V. The real part of refractive index, n , is only slightly lower in the oxygen evolution range than in the passive region of potentials. The absorption coefficient k increases a

Fig. 1. Changes in current density with time at constant potentials in solution 2 (0.15M H₃BO₃ + 0.375M Na₂B₄O₇ · 10 H₂O).

Fig. 2. Dependence of optical parameters (n and k) on potential for films formed during 1h of polarization in both solutions. Optical parameters of the outer layer formed above 1.4V are also given.

little from 0.8 to 1.1V, and at still higher potentials attains a steady-state value. In the lower part of Fig. 2, values of n and k are given for films that form on the outer layer at potentials higher than 1.4V. The optical parameters of these outer layer films are very low and do not exceed 1.57 and 0.27 for n and k , respectively.

It seems that the values of n and k found for the outer layer are potential independent. These parameters have been evaluated assuming that the first (inner) layer does not undergo any change during the outer layer formation, which is a simplification in the data analysis. At these potentials, transpassive dissolution of iron occurs, which can lead to surface roughening. Moreover, pitting takes place in solution 2 at potentials higher than 1.55V, while in solution 1, pitting was only sporadically observed. Therefore, the values of n and k for the outer film layer are affected by some undefined error.

Figures 3 and 4 show the film thickness as a function of time for solution 1 and 2, respectively.

Fig. 3. Thickness of film as a function of time for films formed at different potentials in solution 1.

Fig. 4. Thickness of film as a function of time for films formed at different potentials in solution 2.

At high anodic potentials, the films grow in several stages, similar to films formed in the lower potential range as discussed in Part I of this work. However, the first stage identified previously as stage I appeared only at a potential of 1V in solution 1. Evidently, at higher potentials, stage I lasted for less than 0.1s. Therefore, the first segments of the dependence of film thickness on log time correspond to stage II of film growth. Further stages of film growth identified in Part I of this study as stages III and IV also appear at some definite potentials.

In contrast with the behavior observed in the passive region, above 1.4V a second layer grows rapidly on the top of the passive film. This outer layer, which exhibits low n and k values, is a result of the breakdown of the passive film and consists of corrosion products probably containing borate anions.

As the applied anodic potential increases, the rate of the outer layer growth increases, and the time necessary to start formation of that layer becomes less.

The thicknesses of films formed under the same experimental conditions in solution 2 are always greater compared with films formed in solution 1. On the other hand, by comparing the time at which the outer layer formation becomes significant in solution 2 (Fig. 4) with the minimum current density (i) obtained from the i vs. time relationship (Fig. 1), it can be concluded that the higher is the anodic potential, the shorter is the time of inner layer formation, and that the formation of the outer film begins as the current density increases after attaining its minimum.

Figure 5 gives the results of measurements of film thickness (inner and outer layers) as a function of potential. The film thicknesses are computed after 1h polarization. Here again, thicker films form in solution 2 compared with solution 1.

Discussion

As shown in Fig. 2, at about $-1.0V$, which corresponds to the potential of oxygen evolution, the real part of the index of refraction suddenly decreases and continues to diminish slowly as the anodic potential is increased. These effects are more pronounced in solution 2 compared with solution 1. Sudden changes do not, however, occur in the case of the absorption coefficient k . This suggests that at potentials above that, corresponding to oxygen evolution, the structure of the film tends to be less dense. The above results appear to

Fig. 5. Film thicknesses (inner and outer layer) obtained in both solutions after 1h of polarization at various potentials.

indicate that when the oxygen evolution reaction occurs on the surface of film, the latter undergoes some reconstruction and probably suffers local damage due to the action of the high electric field. Consequently, oxygen begins to be evolved on the metal surface as well, and this leads to further damage of film and to iron dissolution at higher potentials. If a constant potential higher than 1.4V is applied over 1h, a second layer starts to grow on the top of the weakened passive film. This outer layer, which forms by precipitation of corrosion products on the surface of the partially damaged passive film, exhibits a very low n value coupled with a k value close to zero. Corrosion products are probably composed of iron hydroxides and borates, for example, $\text{FeO}(\text{OH})_2$. It should be emphasized that in the 1.4-2.0V potential range, the increment of thickness of the I and II layers of passive film per potential unit is less than at potentials lower than 1.4V, and consequently, the field strength is higher.

From Fig. 3 and 4 it is evident that in the more concentrated solution 2 the layer of corrosion products forms more rapidly and at lower potentials than in solution 1. Presumably, this is due to the less protective character of the film grown in solution 2 (15, 16) and to the larger content of borate anions occluded by this film compared with that formed in solution 1. As a result, the film formed in solution 2 is much more susceptible to localized corrosion. So, in solution 2, pitting was observed to occur within 1h at 1.55V, while in solution 1 pitting was absent at this potential.

These results indicate that pitting of iron may occur in the absence of aggressive anions in the electrolyte if conditions leading to the interruption of passive film

exist, and repassivation is prevented. In the system considered, these conditions were provided by the high electric field which determined the localized breakdown of the film and the concurrent deposition of non-protective corrosion products. These corrosion products seem to be formed by dissolution of the metal substrate, precisely at those locations where the localized breakdown took place.

Conclusions

1. At the potential of oxygen evolution (about 1.0V), the passive film formed in stage I and II exhibits small changes in its optical properties. These changes are more pronounced in the more concentrated boric buffer solution 2 compared with the dilute solution 1.
2. In both solutions, at 1.0 and 1.2V, the film grows in several stages as described in Part I of this work. Because of the high oxidation rate, the first stage can be revealed only in solution 1 at a potential of 1V. Above 1-1.2V, the breakdown of passive film occurs in stages III and IV of film formation, depending on the potential.
3. At potentials higher than 1.4V, an outer layer of corrosion products with a low refractive index grows on the surface of the passive film.
4. Significant pitting commences when the potential reaches 1.5V in the more concentrated solution 2. In solution 1, slight pitting takes place above 1.5V.

Influence of Incorporated Cl^- in NiO on the Pitting Susceptibility of Nickel

B. MacDougall* and M. J. Graham

National Research Council of Canada, Division of Chemistry, Ottawa, Ontario, K1A 0R9, Canada

ABSTRACT

The pitting susceptibility of nickel in 0.08M Cl^- solutions (pH 4.0 Na_2SO_4) has been determined by both potentiodynamic and potentiostatic techniques, the former giving a pitting potential and the latter an induction time, τ_{ind} , for pit initiation. The potentiostatic approach is preferred because of the good reproducibility of results. Samples were prepassivated in non- Cl^- or Cl^- containing solutions and then potentiostatically polarized in 0.08M Cl^- at different potentials and τ_{ind} measured. For either pretreatment, τ_{ind} decreased exponentially as the potential of pitting increased, i.e., $\log 1/\tau \propto V$. Oxides on samples prepassivated in Cl^- solution contain incorporated Cl^- and are significantly more resistant to pitting than those formed in Cl^- -free solutions. This increase in pitting resistance for the Cl^- -treated samples is in contrast to their decreased resistance to open-circuit breakdown. Cl^- incorporation results in $\sim 2\%$ expansion of the NiO lattice leading to a more defective and thus less stable film towards open-circuit breakdown. The τ_{ind} results strongly suggest that Cl^- incorporated in the oxide lattice (as distinct from Cl^- in the electrolyte) is not a precursor to pit initiation since it actually increases the resistance to pitting.

In a previous paper (1), it was shown that formation of the passive oxide film on nickel in a Cl^- containing electrolyte resulted in the incorporation of Cl^- into the oxide lattice. While Auger sputter profiles indicated that the Cl^- was mainly distributed in the outer layers of the oxide film, the results were not compatible with a simple adsorption of Cl^- on the oxide surface (cf. 2-7). Indeed, the Cl^- signal increased substantially as the first oxide layer was sputtered away, and there appeared to be approximately twice as much Cl^- in the second layer as in the first. The amount of chloride in the film was highly dependent on the $[\text{Cl}^-]$ in solution and the potential of anodization. The maximum homogeneous atomic concentration of Cl^- which could be achieved was $\sim 5\%$. (This concentration is determined assuming a uniform layer-by-layer distribution of Cl^- .) The concentration of incorporated Cl^- quickly reached a steady-state value ($\leq 15\text{s}$) if the films were formed in a Cl^- containing solution. On the other hand, incorporation into an initially Cl^- -free NiO film, achieved by subsequent anodization in a Cl^- containing solution, was dependent on the state of perfection of the passive film. The results suggested that Cl^- incorporation into an existing passive film occurred via local breakdown-repair events. These breakdown events were not induced by the presence of Cl^- , but were simply due to chemical dissolution of the oxide at local defects, i.e., the process that gives rise to the corrosion current even in the absence of Cl^- . Local reformation of the film in the Cl^- containing solution therefore resulted in a local Cl^- incorporation. A more perfect oxide film has fewer defects and therefore a slower rate of Cl^- uptake.

While the previous paper (1) indicated that Cl^- can incorporate into the NiO lattice, it did not address the question of the influence of this Cl^- on the pitting susceptibility of nickel. It is known that Cl^- in solution plays a major role in pit initiation [by virtue of its ability to interfere with passive film formation (8)], but the role of Cl^- incorporated in the oxide is not so clear. In the present paper, the influence of previously incorporated Cl^- on the induction time for potentiostatic pit initiation is studied with a view to determining whether Cl^- in the oxide lattice is a precursor to pit initiation.

Experimental

Polycrystalline nickel specimens, 1×2.5 cm, were prepared as described previously (9). All potentials are referred to the saturated calomel electrode, $\text{Hg}/\text{Hg}_2\text{Cl}_2$. Experiments were conducted at 25°C in de-

aerated solutions of pH 4.0 Na_2SO_4 . Chloride was incorporated into passive NiO films by forming the films in pH 4.0 $\text{Na}_2\text{SO}_4 + 1.0\text{M Cl}^-$. Pitting experiments were conducted in pH 4.0 $\text{Na}_2\text{SO}_4 + 0.08\text{M Cl}^-$.

Results and Discussion

Potentiodynamic vs. potentiostatic pitting experiments.—Pitting susceptibility can be determined either potentiodynamically or potentiostatically. The former gives a pitting potential which is usually a function of sweep rate (8), while the latter gives an induction time for pit initiation at a specific potential. The potentiodynamic approach is illustrated in Fig. 1 for a solution without Cl^- and for solutions with 0.1 and 1.0M Cl^- . The profile obtained in the absence of Cl^- is a background sweep showing the passive potential range and the potential region where oxygen evolution begins, the latter giving rise to a gradual increase in anodic current. In the presence of Cl^- (added after the samples were prepassivated), the anodic current abruptly increases at potentials cathodic to oxygen evolution with the pitting potential decreasing with increasing $[\text{Cl}^-]$.

While the pitting potential obtained during a sweep experiment is quite distinct (Fig. 1), the scatter of results from experiment to experiment is too large (± 25 mV) for the technique to be used to quantitatively assess the role of incorporated Cl^- in the pitting process. The considerable scatter of results may possibly be associated with the simultaneous variation during a sweep of both potential and time, these being the two parameters which play key roles in pit initiation. Consequently, small variations in the induction time for pitting (e.g., see Fig. 2) can show up as quite large changes in the pitting potential even at slow sweep rates. Because of this, pitting susceptibilities were determined by holding the potential constant and measuring the induction time for pit initiation, τ_{ind} .

Influence of electrode pretreatment on pitting susceptibility.—The details of the experimental determination of τ_{ind} can be understood by reference to Fig. 3, where nickel electrodes were prepassivated at 0.3V for 15s in pH 4.0 Na_2SO_4 solutions containing either no Cl^- or 1.0M Cl^- . The pretreated electrodes were removed from solution, flushed with doubly distilled water and then reimmersed in a fresh pH 4.0 Na_2SO_4 solution (containing no Cl^-) at 0.3V for 30s. The potential was then increased to the value at which τ_{ind} was to be measured, and after 90s sufficient Cl^- was added (from a 2M NaCl stock solution) to give a $[\text{Cl}^-] = 0.08\text{M}$. Nitrogen bubbling was continued for 30s after adding the Cl^- to ensure complete mixing. τ_{ind} is the time

Fig. 1. Potentiodynamic current-potential profiles for nickel electrodes at 2 mV s^{-1} in pH 4.0 Na_2SO_4 with different $[\text{Cl}^-]$: 0 (solid line); 0.1 (dotted line); and 1.0M (dashed line) Cl^- . In each case, electro-polished nickel was cathodically reduced in pH 4.0 Na_2SO_4 at $20 \mu\text{A cm}^{-2}$ and the potential then stepped to 0V for 60s before initiating the sweep. Cl^- was immediately added to the solution prior to starting the sweep so that the film was always formed in a non- Cl^- solution.

between the addition of Cl^- and the abrupt increase in current indicative of pit initiation. As seen in Fig. 3, the sharp increase of anodic current upon pit initiation, together with the virtual absence of breakdown-repair events prior to sustained pitting, makes it easy to determine τ_{ind} .

Fig. 2. Induction time for pitting, τ_{ind} , vs. potential of anodization for nickel samples pretreated at 0.3V in pH 4.0 Na_2SO_4 either with (—◇—) or without (—○—) 1M Cl^- in solution, and pitted in a 0.08M Cl^- solution. (Details of the induction time measurements are given in Fig. 3).

Figure 2 is a plot of τ_{ind} vs. anodic potential for samples prepassivated in non- Cl^- and Cl^- containing solutions. (The data were obtained from a large number of nickel specimens.) In each case, the induction time for pitting decreases exponentially as the potential of the pitting experiment is increased. The good linearity between $\log(1/\tau)$ and potential is shown in Fig. 4. This type of relationship has been noted by others for the pitting of stainless steel (10, 11) and is taken to indicate that the pitting process involves a step such as the adsorption of Cl^- under electrochemical control. It has been shown previously (8) that Cl^- in solution interferes with oxide formation on nickel, probably because of competitive adsorption and interference with the development of the protective oxide film, and so the exponential relationship between induction time and potential is not surprising. What is surprising, however, is the fact that nickel samples pretreated in 1.0M Cl^- at 0.3V, and thus having ~ 4.0 atom percent (a/o) Cl^- incorporated in the oxide lattice (1), are substantially more resistant to pit initiation than those samples which were pretreated in a non- Cl^- solution. The presence of 4 a/o Cl^- in the oxide lattice as seen in Fig. 2 increases the pitting potential for a particular induction time by ~ 40 mV. Besides the data points shown in Fig. 2, pitting experiments were also performed on Cl^- -treated electrodes at potentials of 0.50, 0.51, and 0.52V, and in all cases the τ_{ind} was $> 5\text{h}$, i.e., the Cl^- -treated samples are resistant to pitting under conditions where the Cl^- -free samples pit anywhere from 2 to 30 min. For some reason, the presence of Cl^- in the oxide film actually increases the resistance to Cl^- -induced pitting.

A possible explanation for the observed behavior in Fig. 2 is that the nickel electrodes passivated in 1.0M Cl^- solution have a substantially rougher surface because of the large amount of nickel dissolution during prepassivation [see Fig. 3 and Ref. (8)]. To determine if surface roughness is the reason for the increased pitting resistance, samples passivated in 1.0M Cl^- were cathodically reduced at $20 \mu\text{A cm}^{-2}$ for 30 min in a fresh pH 4.0 Na_2SO_4 solution prior to the pitting experiment. Auger analysis of the surface oxide indicated that cathodic reduction effectively removed the previously incorporated Cl^- . Table I shows the induction time at three different potentials for samples treated in three different ways: (i) passivated in a Cl^- containing solution, (ii) passivated in a Cl^- containing solution and then cathodically reduced to remove the

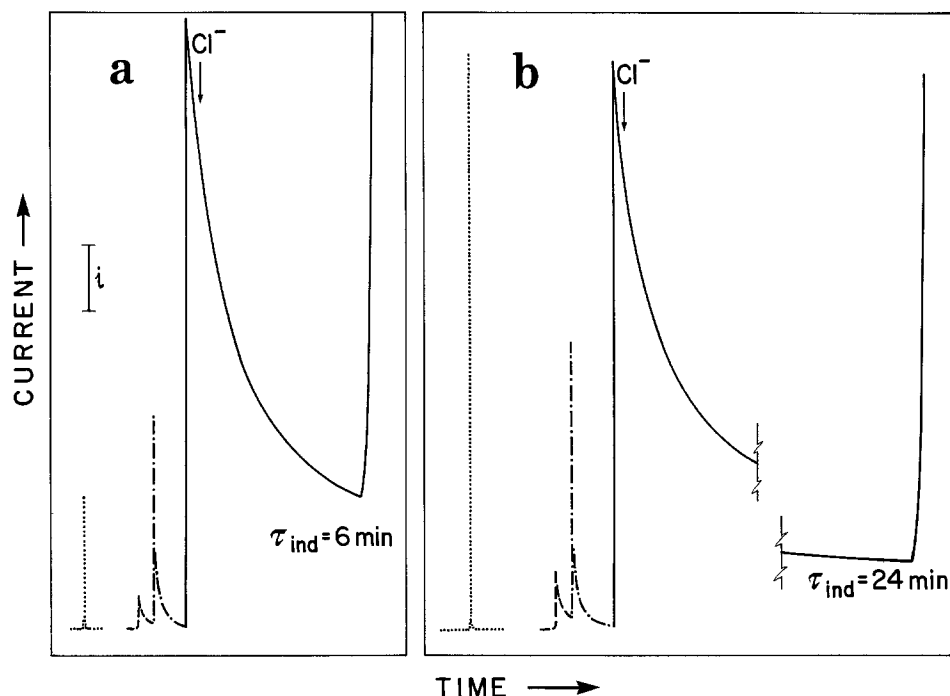

Fig. 3. (a) Current-time profile (dotted line) for electro-polished and cathodically reduced nickel upon stepping the potential to 0.3V in pH 4.0 Na₂SO₄ for 15s. The electrode was then removed and re-immersed in a fresh pH 4.0 Na₂SO₄ solution at 0.3V (dashed line) for 30s, after which time the potential was increased to 0.515V (dash-dot line); 90s later, sufficient Cl⁻ was added to give a concentration of 0.08M. τ_{ind} indicates the induction time for pitting after the addition of Cl⁻. The current sensitivity, in relation to the current marker *i*, is 5 mA cm⁻² (dotted line), 50 μA cm⁻² (dashed line) and (dash-dot line), and 0.5 μA cm⁻² (solid line), i.e., the sensitivity was increased at 0.515V just before Cl⁻ was added. (b) Similar to (a) except the pretreatment was in 1.0M Cl⁻ (dotted line) and the potential at which the induction time was measured was 0.54V [(dash-dot line) and (solid line)].

Cl⁻, and (iii) passivated in a non-Cl⁻ solution. The Cl⁻-treated specimens which were cathodically reduced behave similarly to those treated in non-Cl⁻ solution, suggesting that the increase in τ_{ind} after prior Cl⁻ treatment is not simply due to surface roughening but rather to the presence of Cl⁻ in the film.

Influence of incorporated Cl⁻ on film properties.— To determine the influence of incorporated Cl⁻ on the dissolution stability of oxide films, open-circuit decay profiles were obtained for films formed both in the presence and absence of Cl⁻ in solution. Figure 5 shows the results for oxides formed at 0.4V for 15s with different solution [Cl⁻] and then immersed on

open circuit in a fresh Cl⁻-free pH 4.0 Na₂SO₄ solution. The presence of Cl⁻ in the oxide film does not alter the overall shape of the potential decay profile, but resistance of the film to breakdown does decrease with increasing amounts of Cl⁻ in the film, i.e., the oxide film is more defective with incorporated Cl⁻ (12-17). This is in contrast to the beneficial effect that incorporated Cl⁻ has on pitting resistance.

To determine the structure of the oxide, reflection high energy electron diffraction patterns were obtained from a Ni(111) crystal passivated in 1.0M Cl⁻ at 0.3V. The oxide contained ~4 a/o Cl⁻. The patterns indicated the presence of a thin single-crystal NiO film with a lattice parameter ~2% larger than that expected for stoichiometric NiO. The mean oxide particle size was ~20Å. In contrast, a similar passivation treatment in a Cl⁻-free pH 4.0 Na₂SO₄ solution produced a film of almost stoichiometric NiO, again with a mean particle size of 20Å (9, 12). The lattice expansion for the film containing Cl⁻ is not surprising since the Cl⁻ ion is ~50% larger than the O²⁻ ion and the expansion is similar to that observed for the oxide on electro-polished nickel (9). There appears to be a correlation between lattice expansion and susceptibility to open-

circuit breakdown, with both the film on electropolished Ni and that containing Cl^- breaking down more rapidly on open circuit than the passive film.

The role of incorporated Cl^- in pit initiation.—The fact that incorporated Cl^- simultaneously makes the oxide film more defective and more resistant to pitting suggests that the beneficial effects associated with incorporation overcome the negative influence on film stability. Perhaps incorporated Cl^- changes the conductivity of the film which would result in a shift of the pitting potential in order to achieve the same driving force for pitting. Alternatively, it has been suggested that pitting occurs at islands of adsorbed Cl^- (3, 18-20). The presence of Cl^- incorporated in the oxide could conceivably make it more difficult to achieve these high local surface concentrations so that higher anodic potentials are needed to achieve the critical values for pitting. At this stage, we can only speculate as to the key process(es) in pit initiation on previously passivated nickel surfaces and the mechanism by which incorporated Cl^- influences this initiation. However, the present results clearly indicate that Cl^- incorporation into the oxide increases the resistance to pit initiation and this suggests that such incorporation is not a precursor to initiation. While it may be attractive to propose that Cl^- incorporation into a preformed passive film is the event that triggers local passivity breakdown and subsequent pit initiation, the results of this investigation suggest otherwise.

Electrodeposition of Nickel and Cobalt Oxides onto Platinum and Graphite Electrodes for Alkaline Water Electrolysis

Yih-Wen D. Chen and Rommel N. Noufi*

Solar Energy Research Institute, Golden, Colorado 80401

ABSTRACT

Smooth, compact, and bright films of nickel and cobalt oxides were prepared from 0.5M acetate aqueous solutions and electrodeposited onto platinum and graphite electrodes. Oxygen evolution potentials in 1M NaOH at room temperature were about 150-170 mV lower on nickel(III) oxide [NiO(OH)] and cobalt(III) oxide (Co₂O₃)-coated anodes than on bare anodes. Scanning electron micrographs of NiO(OH) deposits showed no morphological change after extensive electrolysis, and electrocatalytic activity was stable in long-term controlled-potential coulometric electrolysis. However, the electrocatalytic activity of Co₂O₃ showed initial decay followed by a fairly constant behavior. No visible change in the surface of the Co₂O₃ deposit was observed after extensive electrolysis.

The electrochemical properties of metal oxide electrodes have attracted interest over several decades. Early work was oriented toward understanding thick films relevant to battery development (1). The objective of more recent studies has been to develop a fundamental understanding of the redox processes in these films (2, 3). Since hydrogen has recently been considered one of the clean fuels for energy storage (4-6), its production by various methods (7-9) has been proposed. Splitting water to hydrogen and oxygen by electrolysis remains the simplest and most economical method. One drawback in alkaline water electrolysis is the high overvoltage of the oxygen evolution on anodes.

Although metal anodes have been conventionally used for water electrolysis (10-12), their use is not feasible because these anodes [especially nickel anodes (13)] tend to form a nonconducting oxide film, causing oxygen evolution to deteriorate with time. Metal oxides that can provide a catalytic path for oxygen evolution have been recognized (2). Most of the anodic metal oxides studied were formed by anodization of the bare substrates in alkaline solution (14-17). In this paper, we investigate electrodeposition of thin films of nickel and cobalt oxides on platinum and graphite to study an inexpensive method to prepare and characterize these very thin film electrocatalysts. The objective of the above task is to apply the results to semiconductor photoelectrodes in order to bring about or facilitate the photoelectrolysis of water.

Experimental

Reagents.—Sodium acetate and sodium hydroxide are Baker-analyzed reagents. Nickel(II) sulfate was obtained from Johnson Matthey Chemical, Limited, and cobalt(II) acetate was obtained from Alfa Products. All of the reagents were reagent grade and were used without further treatment.

Electrodes.—Rotating platinum disk and graphite disk electrodes (area = 0.20 cm²) were obtained from Pine Instrument Company. The electrodes were polished with 1, 0.3, and finally with 0.05 μm aluminum oxide.

Cells.—All measurements and electrodeposition were performed in a three-electrode cell and are compared with the saturated calomel electrode (SCE) results. The cell assembly is simply a beaker with 250 ml capacity and a Teflon cap with four holes for the rotating disk electrode, reference electrode, counterelectrode, and gas dispersing tube. To keep the reference electrode from contaminating the electrolyte, a Beckman junction tube (no. 531041) was used to fill the support-

ing electrolyte. All experiments were conducted at room temperature and under argon atmosphere.

Apparatus.—A PAR Model 173 potentiostat with Model 175 Universal programmer and Model 179 Digital coulometer was used to control potential electrodeposition, cyclic voltammetric measurements, and potential coulometric electrolysis of water. A Houston Model 200 X-Y recorder registered the data.

Analysis of the film.—The nickel and cobalt contents in the film were determined by dissolving the metal oxides in 1% HNO₃ and measuring by atomic absorption.

Results and Discussion

Electrodeposition of nickel(III) oxide on platinum and graphite electrodes.—The nickel(III) oxide, NiO(OH), was previously formed when nickel(II) oxide was electrochemically oxidized to the +3 oxidation state (14-16). In this investigation, NiO(OH) was prepared directly from 0.5M sodium acetate aqueous solution with 0.05M NiSO₄. Figure 1 illustrates the cyclic voltammogram for the oxidation of nickel(II) ion onto platinum. On the first anodic scan, no obvious anodic peak was observed; however, on the subsequent cycles, anodic peaks were easily identified. Upon scan reversal, reduction waves of the oxide were observed. The increase in redox peaks with each cycle indicates the

Fig. 2. Controlled potential coulometric electrodeposition of NiO(OH) on rotating (900 rpm) platinum disk electrode (0.20 cm^2) in aqueous solution containing 0.05 M NiSO_4 and 0.5 M sodium acetate at (a) 1.025 V , (b) 1.050 V , (c) 1.075 V , and (d) 1.100 V vs. SCE.

growth of the deposit. At potentials $>1.0 \text{ V}$, anodic currents [the result of electrocatalytic evolution of oxygen at the NiO(OH) film] increase with each cycle. This increase is seen again in Fig. 2, which illustrates controlled potential coulometric electrodeposition at different anodic limits. At each anodic limit, the anodic current decreases initially until $\sim 0.06 \text{ mC}$ had passed, which is the estimated quantity needed for monolayer deposition ($\sim 0.30 \text{ mC/cm}^2$) (18). After monolayer formation, the current density increases during the extensive electrodeposition because of electrocatalytic

Fig. 4. Cyclic voltammograms at 50 mV/s for a rotating (900 rpm) platinum disk electrode (0.20 cm^2) in 1 M NaOH aqueous solution. Curve a: uncoated platinum electrode. Curve b: NiO(OH)-coated platinum electrode electrodeposited at $+1.10 \text{ V}$ with 15 mC passed, on rotating (900 rpm) platinum disk electrode, in an aqueous solution containing 0.05 M NiSO_4 and 0.5 M sodium acetate.

oxidation of water. Through x-ray photoelectron spectroscopy (XPS), the deposition product was identified as predominantly NiO(OH) (see Fig. 3), which is similar to the results obtained from the anodic oxidation of the Ni(OH)₂ film (14-16). Therefore, the NiO(OH) species seems essentially responsible for the catalyzed oxygen evolution. The oxygen evolution occurring with the anodic electrodeposition of NiO(OH) film is also evident from the analysis of the nickel content in the film (measured by atomic absorption, as shown in Table I). The coulometric efficiency of the deposition decreases with increase in applied potential.

The controlled potential coulometric electrodeposition of NiO(OH) on platinum and graphite electrodes yields reproducible, compact, and smooth films. With this method, thick conducting films can be deposited over 1 C/cm^2 . In comparison, passive oxide films were normally grown on nickel electrodes with limited thickness (19-21).

The electrocatalytic evolution of oxygen was also observed in 1 M NaOH aqueous solution, where the

Fig. 3. XPS spectra of NiO(OH) electrodeposited on platinum (0.25 cm^2) at a potential, $E_a = 1.10 \text{ V}$ with $Q = 3.7 \text{ mC}$ in an aqueous solution containing 0.5 M sodium acetate and 0.05 M NiSO_4 . A, left: XPS spectrum of the immediate surface. B, right: XPS spectrum of the bulk.

Fig. 5. Oxygen evolution at NiO(OH)-coated platinum electrode (0.20 cm^2) at $+0.55 \text{ V}$ in 1 M NaOH aqueous solution. Curve a: current-time curve for initial electrolysis. Curve b: current-time curve for continuous electrolysis after 3 days. The NiO(OH)-coated anode was prepared by electrodeposition on rotating (900 rpm) platinum disk electrode (0.20 cm^2) at $+1.0 \text{ V}$ with 10 mC passed in an aqueous solution containing 0.05 M NiSO_4 and 0.5 M sodium acetate.

oxygen evolution potential was about 150 mV lower on the NiO(OH) electrode than on the platinum anode (as shown in Fig. 4). The long-term stability of oxygen evolution on NiO(OH) film was tested in 1 M NaOH , and the film showed good stability. Initially, the catalytic current increased sharply, and then reached steady state after a few minutes (Fig. 5). The electrolysis continued for 3 days with no decay in current. Therefore, no passive oxide film formed, and there was also no morphological change in the NiO(OH) film (Fig. 6).

Electrodeposition of cobalt(III) oxide onto platinum and graphite electrodes.—Cobalt(III) oxide films were prepared by electrodeposition onto platinum and

Fig. 6. Scanning electron micrographs of NiO(OH)-coated platinum electrode (times 2000) for (a, top) before and (b, bottom) after oxygen evolution in 1 M NaOH aqueous solution.

Fig. 7. Cyclic voltammograms at 50 mV/s for a (a, left) rotating (900 rpm) platinum disk electrode (0.20 cm^2) and (b, right) rotating (900 rpm) graphite disk electrode (0.20 cm^2) in aqueous solution containing 0.05 M Co(OAc)_2 and 0.5 M sodium acetate.

graphite electrodes in essentially the same way as the NiO(OH)-coated electrodes. Cyclic voltammograms of the oxidation of cobalt(II) ion onto platinum and graphite electrodes were basically the same for both electrodes (Fig. 7). On the first anodic scan, no obvious anodic peak was observed; however, on the subsequent cycles, anodic peaks were observed. On the scan reversal, broad and relatively small reduction waves were observed. The increase in peak height with each cycle indicates the growth of the film. The oxidation currents at the anodic limit increase while the film is continuously deposited, indicating the electrocatalytic evolution of oxygen. However, the catalytic effect by the cobalt oxide is not as clear as it is with NiO(OH); a more complicated film growth behavior is observed (Fig. 8). At each anodic limit, the oxidation current decreases initially until ~ 0.10 mC had passed, which is the estimated quantity (~ 0.5 mC/cm²) required for

monolayer deposition (21). After the monolayer formation, the current density increases and then decreases during bulk electrodeposition. The increase in the current density might indicate catalytic oxygen evolution, followed by a decrease in current density due to the less conducting character of the film. The electrodeposited film was not stable in air. The orange film gradually changes to green on the surface and becomes soluble in 1M NaOH. However, the underlayer of the green film stays orange and stable in 1M NaOH. XPS measurements were not sensitive enough to distinguish between the binding energies of Co₂O₃, Co₃O₄, and CoO (Fig. 9). However, Co₂O₃ is most likely the cobalt oxide deposited because the stoichiometry fits the analytical results of coulometric efficiency of the electrodeposition at lower applied anodic potential (Table I). At the lower potential, over 90% coulometric efficiency based on Co₂O₃ film formation is observed.

Table I. Coulometric efficiency of electrodeposition of nickel(III) and cobalt(III) oxides^a

Sample number	Metal analyzed	Q _a ^b (mC)	E _a ^c (V)	C ^d (ppm)	Coulometric efficiency (%)
1	Ni	30	1.10	0.47	28
2	Ni	30	1.07	0.55	32
3	Ni	30	1.00	0.62	36
4	Co	30	0.80	1.65	93
5	Co	30	0.90	1.55	88
6	Co	30	1.05	1.32	75
7	Co	30	1.10	1.12	63

^a An aqueous solution of 0.5M sodium acetate and 0.05M NiSO₄ was used to electrodeposit NiO(OH) on a rotating (900 rpm) platinum disk electrode. An aqueous solution of 0.5M sodium acetate and 0.05M Co(OAc)₂ was used to electrodeposit cobalt(III) oxide on a rotating (900 rpm) graphite disk electrode.

^b The number of coulombs applied for electrodeposition.

^c The constant anodic potential applied for electrodeposition.

^d Metal oxides were dissolved in 10 ml 1% HNO₃ and were measured by atomic absorption.

^e Coulometric efficiency is based on NiO(OH) and Co₂O₃ formation.

The electrocatalytic evolution of oxygen was evident in 1M NaOH aqueous solution where the oxygen evolution potential was about 170 mV lower on Co₂O₃ than uncoated anodes (see Fig. 10). The long-term stability of oxygen evolution on Co₂O₃ film was tested in 1M NaOH, and this film also showed good stability (Fig. 11). Contrary to NiO(OH), the catalytic current initially decreases sharply and stays fairly constant during extensive electrolysis. Initially, the catalytic current of Co₂O₃ is larger than that of NiO(OH). However, after extensive electrolysis, the catalytic current of Co₂O₃ becomes less than that of NiO(OH). Essentially, no visible change in the cobalt(III) oxide film was observed after long-term oxygen evolution experiment.

ABSTRACT

Electroreflectance was used to evaluate the optical properties of CdIn₂Se₄ in polysulfide solution, before and after photoetching. The variations of signal intensity with electrode potential were used to trace the band position as a function of potential. It was found that the optical transition fits a three-dimensional parabolic model of the density of states, with direct transition at 1.825 eV. When the crystal is photoetched, there is a shift of 98° in the phase factor and a decrease in the broadening parameter from 0.42 to 0.32 eV. By monitoring the signal intensity with potential, it was shown that, irrespective of photoetching, the Fermi level is pinned as reverse bias conditions are approached. The pinning is ascribed to surface states that most likely originate from the adsorption of the electrolyte. The variation of the flatband potential with electrode potentials was calculated and was determined to occur because of the changes in the potential of the Helmholtz layer; the energy distribution and the density of states, which are responsible for those changes in potential of the Helmholtz layer, were also calculated.

II-VI materials, especially Cd-chalcogenides, are among the most often-considered photoelectrodes for use in photoelectrochemical solar cells (1). Because the electropositive constituent can be cross-substituted to obtain better optical and electrical properties, ternary chalcogenides are particularly attractive as electrodes in photoelectrochemical devices. These considerations led to a study of single-crystal CdIn₂Se₄ as an electrode in photoelectrochemical solar cell; the study results were not promising (2). It was clear from that study that although the bandgap of CdIn₂Se₄ is high making suitability as a photoelectrode questionable, that deficiency can be modified easily by controlling the In-to-Cd ratio (3). The low photovoltaic response of CdIn₂Se₄ was attributed primarily to poor surface conditions, which give rise to surface recombination and excessive dark currents under forward bias and reverse bias conditions. In an effort to alleviate some of these problems, various chemical etching methods were attempted, but with little effect. Photoetching proved to be more successful and resulted in a significant increase in the performance of the electrode.

In view of the significant improvements in the performance of binary chalcogenides such as CdSe and CdTe due to photoetching (4), it became increasingly important to understand the mechanisms by which this kind of "surface" treatment can improve the photoresponse of the electrode. In an effort to understand the photoresponse of CdIn₂Se₄ and the effect of photoetching on its response, differentiation between static, energetic factors (such as composition, potential distribution, etc.), and kinetic factors (such as recombination mechanisms) was attempted.

The use of electrolyte electroreflectance (EER) to determine some of the optical properties that are of key importance in determining the photoelectrochemical activity of the crystal is made. The changes in some of these parameters due to photoetching and the variations of the position of the bandedges with electrode potential are determined. The use of EER is then quantified to determine the degree of Fermi level pinning (5). The Fermi level pinning is correlated with a quantitative description of the surface states that give rise to the pinning, and those findings are correlated with some of the dynamic performance characteristics of CdIn₂Se₄ crystals.

Key words: semiconductor, reflectance, solar, interfaces.

Experimental

A CdIn₂Se₄ crystal, synthesized from the constituent elements,¹ was polished to a 1 μm finish and etched with fresh aqua regia (1:4 HNO₃:HCl mixture). Ohmic contact was made by rubbing In-Ga alloy on the back surface of the crystal, and a copper wire was attached to the crystal with silver epoxy. The electrode was sealed with an insulating epoxy, with the front surface exposed, and mounted in a N₂-purged solution of Na₂S:S:NaOH 1/1/1M within a sealed plastic cell. A Pt foil was used as the counterelectrode. Photoetching was carried out in ten times diluted aqua regia by connecting the photoelectrode, a Pt foil as the reference electrode, and a carbon electrode to a potentiostat, and illuminating the photoelectrode with a W/X light source at an intensity of ~ AM1. The electrode was photoetched potentiostatically at 1V vs. Pt for 30s.

The EER spectra were measured *in situ* in the PEC cell configuration using apparatus described elsewhere (5). A PAR Model 173 potentiostat was used to operate the cell in the potentiostatic mode during photoetching.

Only one small wafer was available for the experiments that are described here. This was unfortunate, because at the conclusion of the theoretical treatment additional parameters were necessary to make complete measurements. The crystal, which was kept in the polysulfide solution for a few months, suffered severe dark corrosion, probably because of leaching of In and dissolutions of In₂S₃. The corrosion relates to the short-term stability (few hours) reported with regard to the photocorrosion of this material (2).

Results and Discussion

The spectra.—Figure 1 shows the EER spectra for CdIn₂Se₄ in aqueous polysulfide, at a dc bias of -0.2V vs. Pt and a modulating voltage of 0.2V P.P. at a frequency of 70 Hz. Figure 1a and 1b are the spectra before and after photoetching, respectively.

The lineshape of the electroreflectance signal sharpens considerably due to photoetching, and the characteristic third derivative (6) lineshape appears after the surface treatment. The intensity of the EER signal is enhanced due to the KCN washing, but there is very little effect on the lineshape, and this was not analyzed further.

¹The crystal was grown and doped by W. Girit, Centro de Física, Instituto Venezuela de Investigación Cient., Caracas, Venezuela.

Fig. 1. EER spectra for CdIn₂Se₄ in aqueous polysulfide, at a dc bias of $-0.2V$ vs. Pt and a modulating voltage of $0.2V$ (peak to peak). a: before photoetching. Experiment (dotted curve) and theory (solid curve) with the following parameters: $n = 2.5$, $E_g = 1.825$ eV, $\theta = 217.5^\circ$, and $\Gamma = 0.416$ eV. b: after photoetching. Experiment (dotted curve) and theory (solid curve) with the following parameters: $n = 2.5$, $E_g = 1.825$ eV, $\theta = 315.5^\circ$, and $\Gamma = 0.316$ eV.

In view of the gross differences between the lineshape of the EER before and after photoetching and the apparent shift in the position of the peak, the main question was whether chemical changes occur during the photoetching process. Such changes occur due to selective photoetching and give rise to different band structure parameters. Changes in electroreflectance might be accounted for by selective photoetching of defects. These will manifest in terms of changes in the field distribution at the surface and the intrinsic linewidth of the EER signal. Electroreflectance spectra exhibit one positive and one negative extremum for each critical point. This can be expressed in terms of a general lineshape function of the form (6)

$$\frac{\Delta R}{R} = \text{Re} [C e^{i\theta} (E - E_g + i\Gamma)^{-n}] \quad [1]$$

where C and θ are amplitude and phase factors; $n \geq 2$ is characteristic of the critical points such that for simple parabolic models, $n = 3$ for a two-dimensional model, $n = 5/2$ for a three-dimensional model, and $n = 2$ for exciton; E_g is the energy gap; and Γ is a broadening parameter related to the lifetime. The phase factor θ , in addition to a contribution from the Seraphin coefficients (7), will contain contributions from electron-hole coulomb interaction and from inhomogeneities in the electric field distribution in depth determined by the penetration depth of the light (8). If photoetching does not alter the chemical composition of the surface through selective etching but does change drastically the defect concentration, θ will probably be the most sensitive parameter that will be modified by the treatment, and n and E_g will remain unchanged.

The four parameters that determine the lineshape were fitted to the spectra of the samples after the photoetching. The best fit of the experimental data to the theoretical lineshape function is shown in Fig. 1b with the following parameters: $n = 2.5$, $E_g = 1.825$ eV, $\theta = 315.5^\circ$, and $\Gamma = 0.316$ eV.

The fitting of Eq. [1] to the spectrum of the sample before photoetching was done by keeping E_g and n constant and changing only θ and Γ . The experimental

and the theoretical curves for this sample are shown in Fig. 1a. A shift of 98° - 217.5° is shown in θ , while the broadening parameter increases by about 30%, to 0.416 eV. Because the Seraphin coefficients and the electron-hole coulombic interactions normally do not change with surface treatment, it is believed that this large change in θ is due entirely to changes in the inhomogeneities in the electric field distribution due to the surface treatment. This conclusion is supported by the drastic improvement in the performance characteristics being achieved by photoetching (2). The energy gap found here is on the high energy side of previously reported values, which were evaluated by photoresponse (2), absorption measurements (9), and thermoreflectance (9).

Fermi level pinning.—Figure 2 shows the variation of the intensity of the electroreflectance signals with electrode potential. In both cases, the signal decreases dramatically toward the reverse bias. This behavior was found to occur in polycrystalline CdSe (5) and was interpreted to be due to Fermi-level pinning due to surface states that are fast enough to equilibrate at the modulation frequency. This causes part of the potential drop to fall across the Helmholtz layer, thus modulating the position of the bandedges relative to the reference electrode, resulting in a decreased modulation amplitude on the space charge layer and, hence, a decreased electroreflectance signal.

In the "low field" regime, the electroreflectance signal is given by (6)

$$\frac{\Delta R}{R} = - \left(\frac{2eN_D V_{sc}}{\epsilon_s} \right) L(\hbar\omega) \quad [2]$$

where $L(\hbar\omega)$ is a spectral lineshape function, which was discussed previously; V_{sc} is the modulated voltage across the space charge layer; N_D is the density of the

Fig. 2. Variation of the EER signal with the potential for CdIn₂Se₄ in aqueous polysulfide. A: before photoetching (photon energy = 1.8 eV). B: after photoetching (photon energy = 2.0 eV). Modulating voltage = $0.2V$ (peak to peak).

ionized donors; ϵ_s is the static permittivity; and e is the electronic charge. The potential drop across the space charge layer can be expressed as

$$\Delta\phi_s = U - U_{FB} \quad [3]$$

where U is the electrode potential, and U_{FB} is the flatband potential. Assuming no IR drop, the change in electrode potential due to the modulation will be divided between the space charge layer and the Helmholtz layer according to (10)

$$\delta U = \delta\Delta\phi_s + \delta\phi_o = V_{sc} + \delta\phi_o \quad [4]$$

where ϕ_o is the potential drop across the Helmholtz layer. The change in the potential of the Helmholtz layer due to a change in the number of ionized surface states is given by (11)

$$\delta\phi_o = \frac{e}{C_H} \delta N_{ss}^+ \quad [5]$$

where C_H is the capacitance of the Helmholtz layer, and N_{ss}^+ is the area concentration of the ionized surface states. Combining Eq. [2], [3], [4], and [5] results in

$$\frac{\Delta R}{R} = K \left(1 - \frac{e}{C_H} \frac{dN_{ss}^+}{dU} \right) dU \quad [6]$$

where

$$K = -\frac{2eN_D}{\epsilon_s} L(\hbar\omega) \quad [7]$$

and dU is the modulating potential (taken here to be a small displacement of the dc electrode potential). Within the low field regime, $\Delta R/R$ should be independent of the dc potential, which will decrease for $dN_{ss}^+/dU > 0$, namely, for an n-type semiconductor anodic shift of the electrode potential will result in incremental ionization of the surface states. Within this regime, $\Delta R/R$ will be maximum for $dN_{ss}^+/dU = 0$ and will decrease when dN_{ss}^+/dU increases. This can be expressed in close form as

$$\Gamma = \frac{e}{C_H} \frac{dN_{ss}^+}{dU} = 1 - \frac{\Delta R/R}{(\Delta R/R)_{\max}} \quad [8]$$

Equation [8] is valid provided that $(\Delta R/R)_{\max}$ occurs when $dN_{ss}^+/dU = 0$, still within the low field regime. If this condition is satisfied, the electroreflectance will provide direct measurement of $\frac{1}{C_H} \frac{dN_{ss}^+}{dU}$, which facilitates capacitance measurement by providing direct differential measurement, in contrast to the total system response of the impedance measurements.

Quantitative correlations between the two techniques have been described (5). Because changes in the flatband potential originate from changes in the potential drop across the Helmholtz layer, i.e., $\delta\phi_o = \delta U_{FB}$, it follows from Eq. [5] and [8] that

$$\Gamma = \frac{dU_{FB}}{dU} \quad [9]$$

$$U_{FB} = U_{FB}^0 + \int_{U_{\max}}^U \Gamma dU \quad [10]$$

where U_{\max} is the potential at which $\Delta R/R$ is maximum.

Equation [10] is valid within the assumptions that led to Eq. [8]: in terms of U_{FB} , at $U = U_{\max}$ the flatband potential is still U_{FB}^0 because $dN_{ss}^+/dU = 0$. Because $\int_{U_{\max}}^U \Gamma dU$ can be directly evaluated from the electroreflectance data, Eq. [10] provides an experimentally accessible way to determine U_{FB} as a function of electrode potential.

Because in all cases of interest here the Fermi level is not pinned when U is close to U_{FB}^0 , the latter can be determined independently either from the forward

bias portion of the electroreflectance [not a low field regime (12)] or by an alternative technique such as capacitance (13) or modulated light-induced current voltage response, which will determine the turn-on potential of the system. The Fermi level is completely pinned when $\Gamma = 1$. The potential drop across the space charge layer at this potential can be measured directly by using the same methodology as previously described. The potential drop will remain constant upon further increase in the potential in the reverse bias direction. A parameter that might prove to be useful in describing the pinning process is defined in Eq. [11]

$$\gamma = \frac{U_{FB} - U_{FB}^0}{U_{FB}^P - U_{FB}^0} \quad [11]$$

where U_{FB}^P is the flatband potential at the electrode potential in which the Fermi level is completely pinned, i.e., when $\Gamma = 1$. By definition, γ will vary from 0 to 1 and will provide direct measure of the pinning process. γ is a function of the electrode potential and the density and rate of the surface states.

Figure 3 shows the shift in the flatband potential of CdIn₂Se₄ before and after the photoetching experiment. Consistent with Fig. 2, the photoetching increased the Fermi level pinning. Before photoetching, the Fermi level pinning appears only in reverse bias; thus, it has no effect on the performance of the electrode in a photovoltaic device. The breakdown at 0.4V reverse bias, for both the chemically etched and the photoetched samples (2), which results in enhanced anodic dark current, can be a manifestation of this phenomena. The Fermi level pinning increase upon photoetching is surprising. No satisfactory explanation can be made of this phenomenon. This interpretation is based on the assumption that the potential, U_{\max} in which $\Delta R/R$ is maximum, $U_{FB} = U_{FB}^0$, no Fermi-level pinning occurs under these conditions. If this assumption is incorrect, and at $U = U_{\max}$ the Fermi-level pinning has already occurred—to different degrees with the two samples—then Fig. 3 must be modified and the conclusions derived from this figure, reevaluated.

Fig. 3. Shift in the flatband potential with the potential for CdIn₂Se₄ in aqueous polysulfide, before (a) and after (b) photoetching.

Characterization of the surface states responsible for the pinning.—Assuming Gaussian energy density distribution for the surface states (13)

$$N_{ss}(E) = \frac{N_t}{\sigma e (2\pi)^{1/2}} \exp[-(E_t - E)^2 / 2(\sigma e)^2] \quad [12]$$

where σe is the standard deviation in energy, E is the energy of the surface states, E_t is the energy at maximum density, and N_t is the total concentration. The number of ionized states is given by (13)

$$N_{ss}^+(E_F) = \frac{N_t}{2} \left[\operatorname{erf} \left(\frac{E_t - E_F}{\sigma\sqrt{2}} \right) - \operatorname{erf} \left(\frac{E_t - E_c}{\sigma\sqrt{2}} \right) \right] \quad [13]$$

Neglecting the energy difference between the Fermi level and the bottom of the conduction band in the bulk of the semiconductor and using Eq. [10], the variables in Eq. [13] can be transformed to electrochemical potentials by using the following identities

$$\begin{aligned} E_F &= -eU \\ E_c &= -eU_{FB} = -eU_{FB}^0 - e \int_{U_{max}}^U \Gamma dU \\ E_t - E_c &= E_t^0 - E_c^0 = -eU_t^0 + eU_{FB}^0 \end{aligned} \quad [14]$$

This will lead to

$$N_{ss}^+(U) = \frac{N_t}{2} \left[\operatorname{erf} \left(\frac{-U_t^0 + U - \int_{U_{max}}^U \Gamma dU}{\sigma\sqrt{2}} \right) - \operatorname{erf} \left(\frac{-U_t^0 + U_{FB}^0}{\sigma\sqrt{2}} \right) \right] \quad [15]$$

Differentiation of Eq. [15] with respect to U and application of Eq. [8] and [9] yields

$$\frac{\Gamma}{1 - \Gamma} = \frac{eN_t}{C_H \sigma (2\pi)^{1/2}} \left[\exp \frac{-1}{2\sigma^2} \left(U_t^0 - U + \int_{U_{max}}^U \Gamma dU \right)^2 \right] \quad [16]$$

The three unknown parameters in Eq. [16] are U_t^0 , σ , and N_t/C_H . The solid lines in Fig. 4 are the best fit of Eq. [16] to the experimental results, which were cal-

culated based on the data in Fig. 2. The parameters which were evaluated from this fit are Before photoetching:

$$U_t^0 = 0.823V \text{ vs. Pt}$$

$$\sigma = 0.4V$$

$$\frac{eN_t}{C_H} = 0.88V$$

After photoetching:

$$U_t^0 = 0.172V \text{ vs. Pt}$$

$$\sigma = 0.1V$$

$$\frac{eN_t}{C_H} = 6.88V$$

The fit is good in both cases for the reverse bias conditions. The fit is not good under forward bias conditions, where the degree of pinning is small because $\Gamma/1 - \Gamma$ is less sensitive to $[(\Delta R/R)_{max}]$ as it approaches reverse bias, and the low field regime assumption breaks as it approaches bias when the penetration depth of the light exceeds the penetration of the electric field. Assuming $C_H = 30 \mu\text{F}/\text{cm}^2$ (13), then $N_t = 1.7 \times 10^{14}/\text{cm}^2$ for the chemically etched surface and $N_t = 1.3 \times 10^{15}/\text{cm}^2$ for the photoetched surface. Because this analysis is based on the data used in Fig. 3, it is not surprising that the coverage of surface states has increased upon photoetching. For the chemically etched surface the total coverage is smaller but the width is considerably greater than the coverage and width of the photoetched surface. This suggests that the origin of the width of the surface state band is not due to overlap (14) or reorganization of the solvent (15) but more likely due to surface heterogeneity, which is more pronounced on the chemically etched surface than on the photoetched one. This is consistent with the lineshape parameters described in the discussion of spectra.

Because surface heterogeneity plays a minor role in the photoetched sample, identifying the nature of the surface states from that sample is easier. U_t^0 in that case agrees well with the rest potential of the electrode, which is determined by oxidation-reduction of the adsorbed ions according to the following reaction

which is also the potential of counterelectrode.

If the adsorbed polysulfide constitutes the surface states responsible for the Fermi-level pinning, it will be impossible to remove them and retain the photovoltaic properties of the cell. Thus, the only way to remove Fermi-level pinning is to slow down the dark reaction responsible for ionization of these states. It was demonstrated, in the case of CdSe, that this is possible because single-crystal CdSe in the same electrolyte does not have a tendency toward Fermi-level pinning; however, strong pinning effects, similar to those observed in this analysis, were demonstrated with polycrystalline CdSe (5) in the same solution.

Conclusions

Electroreflectance was used to evaluate the optical properties of CdIn₂Se₄ in polysulfide solution before and after photoetching. The variations of the signal intensity with electrode potential were used to trace the band position as a function of potential.

It was found that the optical transition fits a three-dimension parabolic model of the density of states with direct transition at 1.825 eV. There is a shift of $\sim 100^\circ$ in the phase factor and a decrease of 25% in the broadening parameter, from 0.42 to 0.32 eV, when the sample is photoetched. This result indicates that the photoetching does not alter the chemical composition of the surface through selective photoetching but strongly affects the potential distribution at depths character-

Fig. 4. $\Gamma/(1 - \Gamma)$ vs. potential. A: before photoetching. Experiment ($\blacktriangle\blacktriangle\blacktriangle$) and theory (—) with the following parameters: $U_t^0 = 0.823V$ vs. Pt, $\sigma = 0.4V$, and $eN_t/C_H = 0.88V$. B: after photoetching. Experiment ($\bullet\bullet\bullet$) and theory (—) with the following parameters: $U_t^0 = 0.172V$ vs. Pt, $\sigma = 0.1V$, and $eN_t/C_H = 6.88V$. For more details see Eq. [16].

ized by the penetration depth of the light. The effects on the potential distribution probably originate from selective etching defects.

It was shown that by monitoring the variation of the signal intensity with potential, irrespective of photoetching, the Fermi level starts to be pinned as reverse bias conditions are approached. Photoetching apparently enhances the pinning, due to the increased number of surface states. The energy and density of the surface state most likely originate from the absorbed polysulfide ions.

The experimental results presented here suffer from deficiencies that make some of the conclusions conditional. The quantitative evaluation of the shift in the bandedges with the electrode potential is based on comparison to conditions in which the Fermi level is not pinned. There is no direct evidence to support the contention that the Fermi level of CdIn₂Se₄ in polysulfide solutions unpins at any potential. The potential of reference used was where the electroreflectance signal is maximum. In addition to the uncertainty in whether the Fermi level is unpinned at this potential, there is uncertainty in whether the electroreflectance is in the low field regime at this potential, although the signal does fit the third derivative lineshape.

To clarify whether the Fermi level is unpinned at the potential of maximum electroreflectance signal, where and under what conditions Fermi level is unpinned throughout the potential regime must be determined. In addition, an independent evaluation of U_{FB}^0 and the doping level will have to be made, and the variations in those parameters with photoetching evaluated. Such data are necessary for the determination of the absolute position of the bandedges as a function of potential and not just the shift in position, as occurred in this analysis. As noted, it was impossible to carry out further required experiments.

Electroactive Properties of Polyaromatic Molecules

Robert J. Waltman, A. F. Diaz,* and Joachim Bargon¹

IBM Research Laboratory, San Jose, California 95193

ABSTRACT

Electroactive and electrochromic films of electropolymerized polyazulene and polythiophene have been found to be surprisingly insensitive to common solvents and temperature. As electrodes in all-organic batteries these thin polymeric films allow current densities of 2 mA/cm² at open-circuit voltages of 2.3V. The electrochromic properties suggest application in electro-optical displays.

The variety of compounds which have been found to undergo electrochemical polymerization have demonstrated the facility of the electrochemical approach to synthesis of electrically conducting polymeric films. Such films have been prepared from molecules which represent all pertinent classes of aromatic compounds. They include the heterocyclic pyrroles (1, 2), thiophenes (3-5), furan (5), carbazoles (6, 7), the polynuclear aromatic hydrocarbons pyrene or fluorene (8), and even the nonbenzenoid aromatic hydrocarbon azulene (9). When in the oxidized form, all of these polymers are semiconducting (10^{-6} - $10^2 \Omega^{-1}$

cm⁻¹), with polypyrrole exhibiting the highest conductivities of $10^2 \Omega^{-1} \text{ cm}^{-1}$. Thin films from polypyrrole, polythiophene, and polyazulene which are supported by a Pt surface are also attractive, because they exhibit electroactive and electrochromic properties. Thus, electrically conducting polymers become suitable for application in electro-optic display devices (10) or as electrode materials (11). Successful application in the latter has been demonstrated by the fabrication of a lightweight, rechargeable battery employing a polyacetylene electrode, whereby large power and energy densities were obtained (12). The fact that electrochemically prepared polymers, such as polythiophene or polyazulene, have similar properties, points to their potential application in energy tech-

nology as well. Accordingly, we report herein some properties of these materials relevant to their applications in battery technology.

Experimental

All compounds were obtained from commercial sources. Polythiophene and poly- β -substituted thiophenes were prepared by the electrochemical oxidation of the appropriate thiophene monomers in a three-electrode, single- or two-compartment cell. Platinum, gold, and sodium chloride calomel (SSCE) were used as the working, counter, and reference electrodes, respectively. The solutions were typically 10^{-4} - 10^{-3} M in monomer, in a 0.1M electrolyte/acetonitrile solution. The electrolyte, usually tetraethylammonium tetrafluoroborate (TEAFB), was recrystallized from alcohol-ethyl acetate and dried under vacuum. The acetonitrile (Burdick and Jackson, spectrometric grade) was used directly without further purification. The solutions were bubbled with argon for 5-10 min, and protected by an argon blanket. Cyclic voltammograms of polymer films were measured in electrolyte solutions containing no other electroactive species. All electrochemical measurements were performed with an IBM EC225 Voltammeter Analyzer.

Results and Discussion

Electrochemical data.—Cyclic voltammetric data for some thiophene monomers and their corresponding polymers are given in Table I. All of the monomers show irreversible oxidation peaks and give rise to colored solutions upon electro-oxidation. The value of n for the oxidation reaction was estimated from the Nicholson and Shain treatment for a totally irreversible electron-transfer process which provides $n^{3/2}D^{1/2}$, where D was assumed equal to 10^{-5} cm² s⁻¹. In general, the reaction of compounds which produce polymer films occurs on the electrode surface and has n values between 2 and 3, as estimated from cyclic voltammetry. From elemental analysis, n values between 2.07 and 2.17 are obtained for some of these polymers. The reaction of compounds which produce soluble products and, therefore, occur away from the electrode, has n values between 1 and 2, depending upon whether monomeric ($n = 2$) or dimeric ($n = 1$) products are formed (13). Accordingly, the α,α' -blocked 2,5-dimethylthiophene has an n value of 1.2, similar to 2,5-dimethylpyrrole (13).

Whereas low molecular weight products are obtained from α -substituted heterocycles, polymeric films are indeed obtained from certain β -substituted monomers. The cyclic voltammogram of a typical 60 nm thin film of polythiophene on a Pt surface obtained from the electropolymerization of 2,2'-bithiophene is shown in Fig. 1.

The details of the electroactive properties of these films have been previously considered (4), and no reiteration is necessary here. However, it is important to

point out that these films can be cycled repeatedly between the oxidized, conducting state and the neutral, nonconducting state, an event which is accompanied by a reversible color change from green-back to a pale-copper color, respectively. The cycling behavior is observed for polythiophene films derived from either the monomer or the 2,2'-dimer. The anodic peaks obtained from the dimer derived polymer films, however, are noticeably sharper with peak widths at half height (PWHH) of ca. 90 mV for 60 nm films, while monomer derived films of the same thickness have PWHH of ca. 300-350 mV. Since it is known that the oxidation and reduction reaction is controlled by the diffusion of counteranions into and out of the surface-localized film, diffusion of ions through the dimer-derived film is less limiting. This may also reflect the more regularly α,α' -linked monomer units in the dimer-derived film. The sensitivity of the electrical properties of polythiophene to linkages between monomer units other than α,α' -bonds has been pointed out by Sanechika *et al.* (14). In particular, they found that the electrical conductivity of polythiophene decreases with increasing β -linkages introduced between monomer units.

Figure 1 also shows that the peak oxidation potential of polythiophene occurs at +1.0V. This is far anodic of the peak oxidation potential of polypyrrole (-0.15V), with the important consequence that polythiophene films are much more stable, especially to the presence of oxygen. Thus, unlike polypyrrole, neutral or electrochemically oxidized polythiophene films can be exposed to air, or even passed under a stream of oxygen, yet when put back into an electrolyte solution and cycled electrochemically, they retain their switching capabilities. However, ESCA studies of the neutral films reveal the presence of bonded oxygen at the surface of these materials. For neutral polythiophene films exposed to air for 24h, the C:S:O ratio is 4.0:0.55:1.0, respectively, while a 14 day exposure reveals a C:S:O ratio of 4.0:0.5:1, respectively (15). However, the surface properties are not representative of the bulk properties of the film, as is evidenced by its ability to retain electrochemical switching.

The electrochemical behavior of polyazulene films is similar to that of polythiophene films insofar that they too are electroactive and electrochromic (Fig. 2). The peak oxidation potential of the polymer film occurs at +0.650V, *i.e.*, lower than the polythiophene counterpart but still anodic of polypyrrole.

Stability of films.—For successful performance of these materials in various applications, such as in batteries, apart from the desirable electroactivity of the films, their stability under different conditions be-

Fig. 2. Cyclic voltammogram of [Pt]-polyazulene- BF_4 film in 0.1M TEAFB/ CH_3CN solution.

comes of paramount importance. Thus, thicker films from polythiophene and polyazulene can be peeled off from the Pt anode. These are flexible, continuous, free standing films which are electrically conducting to the extent of $1 \Omega^{-1} \text{cm}^{-1}$. The oxidized, conducting forms of these polymer films are also remarkably stable

Fig. 4. The shift in the peak oxidation potential of polythiophene as a function of temperature.

Fig. 3. Cyclic voltammograms of [Pt]-polythiophene- BF_4 as a function of temperature in 0.1M TEAFB/ CH_3CN .

under different conditions. They are insoluble in strong acids, bases, or common organic solvents. For example, when oxidized films are placed in 6M HCl or NaOH, or in a solvent such as dichloromethane for 1h, they retain their electroactive properties when subsequently electrochemically cycled. The thicker films are also thermally stable to heating at 80°C for several hours. When kept for 3h at this temperature, polyazulene and polythiophene show a decrease in conductivity from 0.4 to $0.2 \Omega^{-1} \text{cm}^{-1}$, and from 0.1 to $0.04 \Omega^{-1} \text{cm}^{-1}$, respectively, while heating for 20h results in a ten-fold decrease in their conductivities. Whereas the thick films show moderate stability to heating, the thin films display a sensitivity of the switching behavior to changes in temperature. Thin films were cycled repeatedly in the temperature range between 0.0° and 80°C , and were found to be stable under these conditions for at least several hours. The electroactive properties are still retained (Fig. 3), and the peak oxidation potential shifts cathodically by 0.88 mV deg^{-1} with increasing temperature (Fig. 4). The 70 mV shift in the oxidation potential is reversible in this range, and a noticeable sharpening of the anodic peak is observed at higher temperatures (Fig. 3).

Apart from the demonstrated temperature stability, these data also allow information concerning the energetics of the switching reaction in this temperature range. The reaction is electrochemically irreversible and thus the relation $dG = -nFE$ cannot be applied. However, the dE/dT dependence is real and can be related to $d(dG)/dT$, which provides $-dS$. Thus, $dS = nF(dE/dT) = -3.4 \text{ cal deg}^{-1}$, whereby $n = 0.17$, i.e., the amount of charge consumed in the partial oxidation of the film, as can be derived from elemental analysis data. This change of state also involves a change in composition where anions are incorporated into the film in order to balance the positive charges along the polymer chain. The sign and magnitude for the entropy term dS is consistent with what is characteristic for molecular complex formation (16). The sign for dS suggests that as the film switches from the neutral to the oxidized state, accommodation of counter-anions (which is necessary to balance the positive charge induced in the polymer chain) results in a structure more rigid than in the neutral state of the film.

Fig. 5. Electrochemical peak oxidation potential of thiophene monomers vs. their respective Hammett substituent constants.

Substituent effects.—The eventual application of these materials in energy technology or in other fields will demand some chemical modifications in order to meet particular criteria. For example, we have demonstrated previously that the conductivity of polythiophene can be increased 100-fold with the introduction of a single β substituent (4). The fraction of counteranions in the film can also vary depending on which substituent is introduced into the parent polymer. Correspondingly, an investigation of polythiophene films with appropriate β substituents showed that when the peak oxidation potential of some β -substituted monomers are plotted against their respective Hammett substituent constants, a linear correlation is obtained (Fig. 5). The shift in the peak oxidation potentials of the series of β -substituted thiophenes is dependent on three parameters: namely, their polar, steric, and mesomeric effects, which are exerted by the substituents (17). This behavior can be described by the usual Hammett-Taft

$$E = \rho_{\pi\sigma} + S$$

equation where $\rho_{\pi\sigma}$ describes the polar-mesomeric parameters, and S accounts for the steric factor (17). Accordingly, Fig. 5 allows three conclusions to be drawn. First, the straight-line fit indicates that all of the monomers are oxidized by the same mechanism, *i.e.*, electro-oxidation results in the removal of a π electron from the thiophene ring. Second, the positive sign for the substituent constant ρ_{π} reveals that as the substituents take on more electrophilic character, the oxidation of the corresponding thiophenes proceed more difficultly. Finally, the steric term S appears to be minimal since for the substituents chosen here, a straight-line fit is obtained. Thus, the primary effect exerted by the β substituents is electronic and described by the $\rho_{\pi\sigma}$ term. One possible interpretation of these facts (Fig. 5) suggests that there is an optimum potential range, *i.e.*, reactivity of the radical cation intermediate, which favors radical cation coupling in the follow-up reaction to yield polymeric films. Thus, under these conditions, polymerization occurs only for the parent thiophene, and the methyl-, bromo-, and iodo-substituted thiophenes. The latter two monomers yield poorly conducting films, while the other two polymers, polythiophene and poly(3-methylthiophene), have conductivities of *ca.* 10^{-2} – 10^{-1} , and $1 \Omega^{-1} \text{ cm}^{-1}$, respectively. 3-Thiophene carboxylic acid,

3-cyano-, and 3-nitro-thiophene yield no polymers on electro-oxidation under these conditions. Several reasons may be attributed to the lack of polymers obtained from the latter three monomers. One interpretation postulates that the stability (or reactivity) of these monomers is affected by the β substituents. Thus, as the reactivity of the radical cation intermediates increases, as reflected in their increasing oxidation potentials (Fig. 5), the more reactive these intermediates become with respect to nucleophiles, or they undergo other "escape" reactions, *e.g.*, with the solvent or other nucleophilic species in the vicinity of the Pt surface. Thus, one possible effect of these strongly electron withdrawing groups is to destabilize the radical cation intermediate to the extent that radical cation coupling reactions become unfavorable when compared with other reaction pathways. Another reason for their failure to promote electropolymerization may be due to a breakdown of the solvent, since the anodic potentials applied become rather high for the nitro- and cyano-substituted monomers (Table I).

While steric factors do not seem to play any appreciable role in the primary electro-oxidation of the monomer (Fig. 5), their subsequent follow-up reactions (radical cation polymerization) are more susceptible to steric effects, which, therefore, may well play a role in deciding whether polymerization can compete favorably with other potential follow-up reactions, such as with nucleophiles. This may explain the overall inferior quality of the polymer films derived from the 3-bromo- and 3-iodo-thiophenes, even though their oxidation potentials do not differ greatly from that of the parent thiophene monomer. It is, however, interesting to note that while a bulky substituent, such as iodo, allows polymerization (albeit of poor quality), a sterically smaller cyano group does not.

Another example of a property-structure correlation between thiophene monomers and their corresponding polymers is reflected in Fig. 6, where the peak oxidation potentials of some thiophene monomers are plotted against their respective polymers. The straight-line fit suggests that β -substituted monomers and their respective polymers are made up of a related system of π electrons, *i.e.*, the electronic structures of the monomers and their corresponding polymers must be alike. This is consistent with the fact that polythiophene (and polypyrrole) consists primarily of α,α' -linked monomer units (3, 4).

Battery applications.—The stability of polythiophene and polyazulene films as described above suggests application of these materials as battery electrodes. Of particular importance is the high extent of

Fig. 6. Peak oxidation potential of thiophene monomers vs. their respective polymers in 0.1M TEAFB/CH₃CN.

Fig. 7. A simple "all polymer" battery cell

Fig. 8. A typical voltage change during 0.15 mA constant-current discharge of a polyazulene battery cell.

counteranions which can be incorporated into these polymer films, especially into polyazulene, whereby one counteranion is shared by four azulene monomer units (Table II). Polythiophenes are additionally attractive from the standpoint that their film properties are readily altered via substituent groups. Thus, a simple battery cell (as shown in Fig. 7) was assembled utilizing oxidized and neutral polymer films adhered onto Pt as the two terminals. The films were typically $1 \times 2 \text{ cm}^2$ with a thickness of ca. 10^{-3} cm , corresponding to a film weight of about 1-2 mg. These were immersed into a 0.1M TEAFB acetonitrile solution containing no other electroactive species. The arrows in Fig. 7 indicate the direction of electron flow. A polyazulene battery yielded a maximal open-circuit voltage of ca. 2.3V and an optimal initial short-circuit current of 4 mA. These data are summarized in Table II for both polyazulene and polythiophene batteries. These preliminary results for polyazulene are taken from

Table II. Batteries from polyazulene and polythiophene

	Polyazulene	Polythiophene
Elemental composition	(AZ) $_{14}^+$ · BF $_4^-$	(TH) $_{14}^+$ · BF $_4^-$
Current density	0.4-2.2 mA/cm 2	0.02 mA/cm 2
Voltage	0.5-2.3V	0.5V

five such batteries, while those for polythiophene (monomer derived) are based upon a single battery test. Polythiophene batteries derived from the dimer may conceivably yield higher values since they can store more charge (six monomer units share one charge) than the monomer-derived films. The batteries tested so far could be recharged at constant current, e.g., at 1 mA, to yield similar values in the regenerated cells.

Our values are actually quite similar to the "all polymer" polyacetylene batteries of MacDiarmid *et al.* (18). However, unlike polyacetylene, which is known to be air sensitive, polyazulene batteries can be open to the air, at least short-term (days) tests revealed no apparent effect of air on the stability of the batteries. However, the long-term effect of oxygen on the re-chargeability of polyazulene batteries has not been investigated thus far. Figure 8 shows the voltage change during a constant current discharge of 0.15 mA for a polyazulene cell in 0.1M TEAFB acetonitrile. More work is in progress.¹

Electrocatalysis of the Cathodic Reduction of Carbon Dioxide on Platinized Titanium Dioxide Film Electrodes

Milena Koudelka, Alain Monnier, and Jan Augustynski*

Département de Chimie Minérale, Analytique et Appliquée, Université de Genève, 1211 Genève 4, Switzerland

ABSTRACT

Cyclic voltammetric measurements on the electrochemical reduction of CO₂ at platinized and nonplatinized TiO₂ film electrodes are reported. It is shown that carbon dioxide, dissolved in aqueous solution or present in a mixture with water vapor, undergoes strong, irreversible adsorption on the Pt-TiO₂ surface. The adsorption of CO₂, taking place at open circuit, results in the formation of electrochemically detectable species. The reduction of the adsorbed carbon dioxide at the Pt-TiO₂ electrode starts at even lower cathodic potentials than in the case of unsupported Pt electrode and produces two kinds of reduced species revealed by anodic peaks on the cyclic voltammograms. The existence of two electrochemically detectable reduced-CO₂ species is explained in terms of the surface diffusion of the reaction intermediates and/or products between adsorption sites at the metal, Pt, and at the oxide, TiO₂.

Among various oxide-supported noble metal catalysts, the platinum-titanium dioxide system has recently attracted particular attention because of its potential applications in the field of photocatalysis and/or gas-phase heterogeneous catalysis. Thus, a suspension of platinized TiO₂ in an acidic aqueous solution, irradiated with the UV light, has been shown (1) to induce the photodecomposition of water into hydrogen and oxygen. Another example of a photocatalytic reaction (which, contrary to the previous one, is characterized by a negative Gibbs free energy change) is the photodecomposition of acetic and other carboxylic acids into corresponding alkanes and carbon dioxide (2, 3). In these processes, platinum particles are believed to act as local cathodes for the formation of adsorbed hydrogen atoms and for the H₂ evolution which accompany various photoanodic reactions involving positive holes photogenerated at the surface of n-type TiO₂.

In the related field of water photolysis, Grätzel and co-workers (4, 5), using RuO₂ and Pt cosupported on colloidal TiO₂ particles as redox catalyst in the presence of Ru(bipy)₃²⁺ sensitizer, have succeeded in improving considerably the efficiency of water cleavage by visible light. The above results have been explained (5) in terms of adsorption of the sensitizer at the surface of TiO₂ particles as being a crucial step of the overall process.

In addition, various transition metal catalysts supported on TiO₂, including the Pt-TiO₂ system, have recently been investigated (6) with special regard to their activity for CO-H₂ Fischer-Tropsch synthesis.

Following a preliminary study in this laboratory (7) on the cathodic reduction of dissolved CO₂ at polycrystalline TiO₂ and RuO₂-TiO₂ film cathodes, we have undertaken a systematic characterization of different activated-TiO₂ electrodes. In this paper, the electrochemical characteristics of TiO₂ and platinized TiO₂ film electrodes are discussed in connection with the hydrogen evolution and carbon dioxide reduction reactions.

Experimental

TiO₂ and platinized TiO₂ film electrodes were prepared by a thermal decomposition method using cross sections (~0.3 cm²) of 99.8% titanium rods (Kobe Steel, Limited) as a support. The TiO₂ films were obtained by applying onto the previously etched Ti substrates, layer by layer, a solution of TiCl₄ (puriss. from Fluka) in a mixture of analytical-grade methanol and ethanol. Each layer of the solution was decomposed by heating in air at ~450°C. In the case of platinized electrodes, one or two final layers of an aqueous solution of H₂PtCl₆ (Fluka) were applied before submitting them,

for about 40 min, to a final thermal treatment in argon at ~550°C. Thus formed, TiO₂ films were 10-15 μm thick and consisted of anatase. The amount of platinum present on the surface of platinized TiO₂ samples was checked by means of x-ray induced photoelectron spectroscopy (XPS) (8). For different samples analyzed by XPS the platinum content in the outermost surface layer ranged from 10 to 13 atom percent (a/o) (given with respect to Ti(IV) from TiO₂, taken as 100 a/o). Since the mean escape depth for the photoelectrons with a kinetic energy close to 1200 eV is usually considered to reach 15-20 Å, the above result indicates that the coverage of the TiO₂ surface with Pt was in all cases distinctly less than a monolayer. This is additionally supported by the evidence, based on the observed decrease of the amount of Pt on the surface following the activation of the electrode at 550°C, that platinum diffuses to a significant extent into the TiO₂ substrate.

All solutions employed in electrochemical experiments were made up with analytical-grade chemicals and twice-distilled water. For most experiments, a calomel reference electrode in 0.1N KCl solution was used. Potentials on this scale are referred to as *E* (V vs. 0.1 NCE). Carbon dioxide or argon, both under 1 atm, were continuously bubbled through the solution; the bubbling was interrupted only for the duration of a cyclic voltammetry experiment. All measurements were effected at 40°C.

Results and Discussion

The choice of a suitable electrolyte for the study of CO₂ reduction at TiO₂ and Pt-TiO₂ electrodes was quite a complex question because of the known tendency of a number of ions (especially anions) to adsorb irreversibly on the surface of TiO₂ (9). Thus, for example, the nature of the second anion present in the solution has been shown (10) to strongly affect the cathodic reduction of Fe(CN)₆³⁻ ions at the TiO₂ film electrodes similar to those used in the present study. Among various nearly neutral solutions, chloride solutions appear to influence least the cathodic behavior of TiO₂. Therefore, after a series of preliminary cyclic voltammetry experiments, a 0.5M KCl solution was chosen as a supporting electrolyte. In addition, most of the electrochemical measurements were repeated using a 0.5M K₂SO₄ solution; no significant differences were observed.

Figure 1 shows typical cyclic voltammetry *i*-*E* profiles for Pt, Pt-TiO₂, and TiO₂ electrodes, recorded in an argon-saturated 0.5M KCl solution. For comparison purposes, similar experiments were also performed in a deaerated 0.5M KHCO₃ solution, which was chosen in order to minimize the possible influence of anion adsorption on the surface of platinum (11). They en-

able us to conclude that, if in the case of bright Pt the presence in the solution of Cl^- ions affects the amount of charge corresponding to H deposition, no such effect is perceptible for the Pt-TiO₂ electrode.

The hydrogen evolution at the bright platinum and Pt-TiO₂ electrodes started in the same (within 100 mV) potential region, -0.8 to -0.9V vs. 0.1 NCE, while it was shifted about 0.7V to more cathodic potentials in the case of the nonplatinized TiO₂ electrode. However, similar shapes of the *i*-E curves observed for the platinized and nonplatinized TiO₂ suggest that, in spite of a much larger hydrogen overvoltage exhibited by the latter electrode, the sequence of cathodic reactions at both kinds of surfaces is probably the same. In particular, the initial increase of the cathodic current, occurring at potentials preceding the hydrogen region, is likely to be consistent with a partial-surface-reduction of TiO₂

which must involve the proton transfer from the adsorbed molecule of water (7). At more cathodic potentials (i.e., at about -0.8V for Pt-TiO₂ and -1.6V vs. 0.1 NCE for TiO₂), the electrode surface is supposed to become covered with adsorbed hydrogen atoms, giving rise to an anodic current maximum on the reverse sweep. Cyclic voltammograms obtained in 0.5M KCl solution saturated with CO₂ (Fig. 2) showed a number of features differentiating them from the curves in Fig. 1. The most significant one was a distinct increase of the cathodic current at the Pt-TiO₂ electrode, occurring already at about -0.2V (Fig. 2a), i.e., at the potentials less negative than in the case of the bright Pt electrode

(Fig. 2b). On the reverse (anodic) sweep, up to three distinct peaks, corresponding, in order of increasing potentials, to the oxidation of hydrogen (peak A) and of two reduced forms (or reduction products) of CO₂ (peaks B, C) electrodeposited at the Pt-TiO₂ electrode, were observed. This constitutes an important difference with respect to the behavior of bright platinum for which a single peak, usually associated (12) with the oxidation of "reduced carbon dioxide", occurred on the anodic sweep (Fig. 2b).

When the potential of the Pt-TiO₂ electrode was repetitively cycled, extending each time the cathodic limit by an additional 0.1V while holding the anodic limit the same, the oxidation charge increased, and peaks C, B, and finally A appeared successively (Fig. 3a). The fact that peak C was already clearly visible when the cycle was limited cathodically at -0.5V is to be connected with a marked affinity for CO₂ exhibited by the hydrated Pt-TiO₂ surface. Experiments consisting in simply exposing a Pt-TiO₂ electrode¹ to 0.5M KCl solution saturated with CO₂ and transferring it, after thorough washing, to an Ar-saturated 0.5M KCl solution, have revealed only a small difference between the cyclic voltammetry *i*-E profiles obtained in the latter solution and those usually observed in solutions saturated with CO₂. A prolonged cycling of the potential between extended limits, corresponding, to the H₂ and O₂ evolution reactions, respectively, was

* Before being submitted to the adsorption experiments, freshly prepared Pt-TiO₂ and TiO₂ electrodes were repetitively cycled (within the utmost potential limits shown in Fig. 1b and 1c) in 0.5M KCl solution saturated with argon. About ten cycles usually sufficed for the electrodes to reach a reproducible voltammetric behavior.

Fig. 3. Cyclic voltammetry *i*-E profiles at $50 \text{ mV} \cdot \text{s}^{-1}$, corresponding to various cathodic limits. A, left: Pt-TiO₂. B, right: TiO₂ electrodes in CO₂-saturated (1 atm) 0.5M KCl at 40°C.

necessary in order to remove most of the chemisorbed CO₂ from the Pt-TiO₂ surface. No such behavior was observed in the case of nonplatinized TiO₂ film electrodes; furthermore, the corresponding cyclic voltammetry *i*-*E* profiles obtained in CO₂/0.5M KCl solution showed only two anodic peaks (Fig. 3b). This indicates that the Pt-TiO₂ film electrodes exhibit actually a quite specific activity for CO₂ reduction which cannot be simply explained, for example, in terms of enhanced surface conductivity, but is probably the result of a profound modification of the energetics of CO₂ adsorption.

In this connection, it seems interesting to mention recent results concerning the gas-phase adsorption of CO₂ on platinized TiO₂ powder, reported by Tanaka and White (13). According to these authors, the Pt-TiO₂ catalyst induces, at room temperature, a decomposition of carbon dioxide into chemisorbed oxygen atoms and carbon monoxide. The decomposition rate of CO₂ has been significantly higher on reduced Pt-TiO₂ samples than on the oxidized ones. In order to check whether the dissociative adsorption of CO₂ from aqueous KCl solution could be responsible for the presence of an additional anodic peak (peak B or peak C) observed on the reverse sweep in our cyclic voltammograms (Fig. 2a), a few experiments were also performed in a 0.5M KCl solution saturated with carbon monoxide. As appears from the latter measurements, the thermally formed Pt-TiO₂ electrodes behave with regard to the CO adsorption in quite a different manner than smooth or platinized platinum. In fact, cyclic voltammograms of Pt recorded in solutions saturated with CO usually exhibit a sharp peak during anodic sweep, placed at about 0.9V (RHE), assigned (14) to the oxidation of adsorbed carbon monoxide to carbon dioxide. In addition, as a consequence of a repulsive interaction between the coadsorbed hydrogen atoms and carbon monoxide molecules, the potential at which hydrogen starts to be evolved at platinum is substantially shifted in the negative direction with respect to that observed in the absence of CO from the solution. Both of these features, typical of the CO adsorption on

platinum, were absent from the cyclic voltammograms of the Pt-TiO₂ electrodes, the only indication of the presence of CO in the solution being a slight increase of the cathodic current in the region of potentials corresponding to the formation of H_{ad} atoms together with a broadening of the related anodic peak. These results do not allow, therefore, any definitive conclusion about the nature of the interaction (dissociative or not) between CO₂ and the hydrated Pt-TiO₂ surface. The existence of two distinct species, formed as a result of the cathodic reduction of CO₂ adsorbed on the Pt-TiO₂ surface, has been confirmed by the experiments carried out with a rotating disk Pt-TiO₂ electrode. As shown in Fig. 4, the rotation of the electrode leads to a disappearance from the *i*-*E* curve of peak B, while peak C, placed at more anodic potentials, remains practically unchanged (Fig. 4b). This suggests that one of the above species (that associated with peak B) undergoes an easy desorption into the solution, while the second one (associated with peak C) remains strongly adsorbed on the Pt-TiO₂ surface. A similar conclusion can be drawn from the changes in the shape of cyclic voltammograms as a function of the sweep rate. As shown in Fig. 5, an increase of the sweep rate from 20 to 50 mV · s⁻¹ produces an enhancement of peak B, and, in addition, a shoulder, placed nearly at the same potential as peak C, appears on the cathodic side of the voltammogram. For still higher sweep rates (100 and 200 mV · s⁻¹), peak C increases more rapidly than peak B, and the above-mentioned shoulder is slightly shifted in the direction of more cathodic potentials. Such behavior is consistent with the height of peak B's being controlled by the rate of diffusion of the related species from the surface of the electrode and the height of peak C increasing proportionally to ν , the sweep rate (rather than to $\nu^{1/2}$).

Conclusions

We have shown that the behavior of the Pt-TiO₂ film electrode with regard to the reduction of aqueous CO₂ differs markedly from those exhibited by both the unsupported Pt and the nonplatinized TiO₂. Two most

Fig. 4. Potentiodynamic *i*-*E* profiles at 50 mV · s⁻¹ for a stationary (continuous lines) Pt-TiO₂ and a rotating disk (at 1800 rpm) Pt-TiO₂ electrode in CO₂-saturated 0.5M KCl at 40°C. Cathodic limits: -0.9V for (a, left) and -0.6V for (b, right).

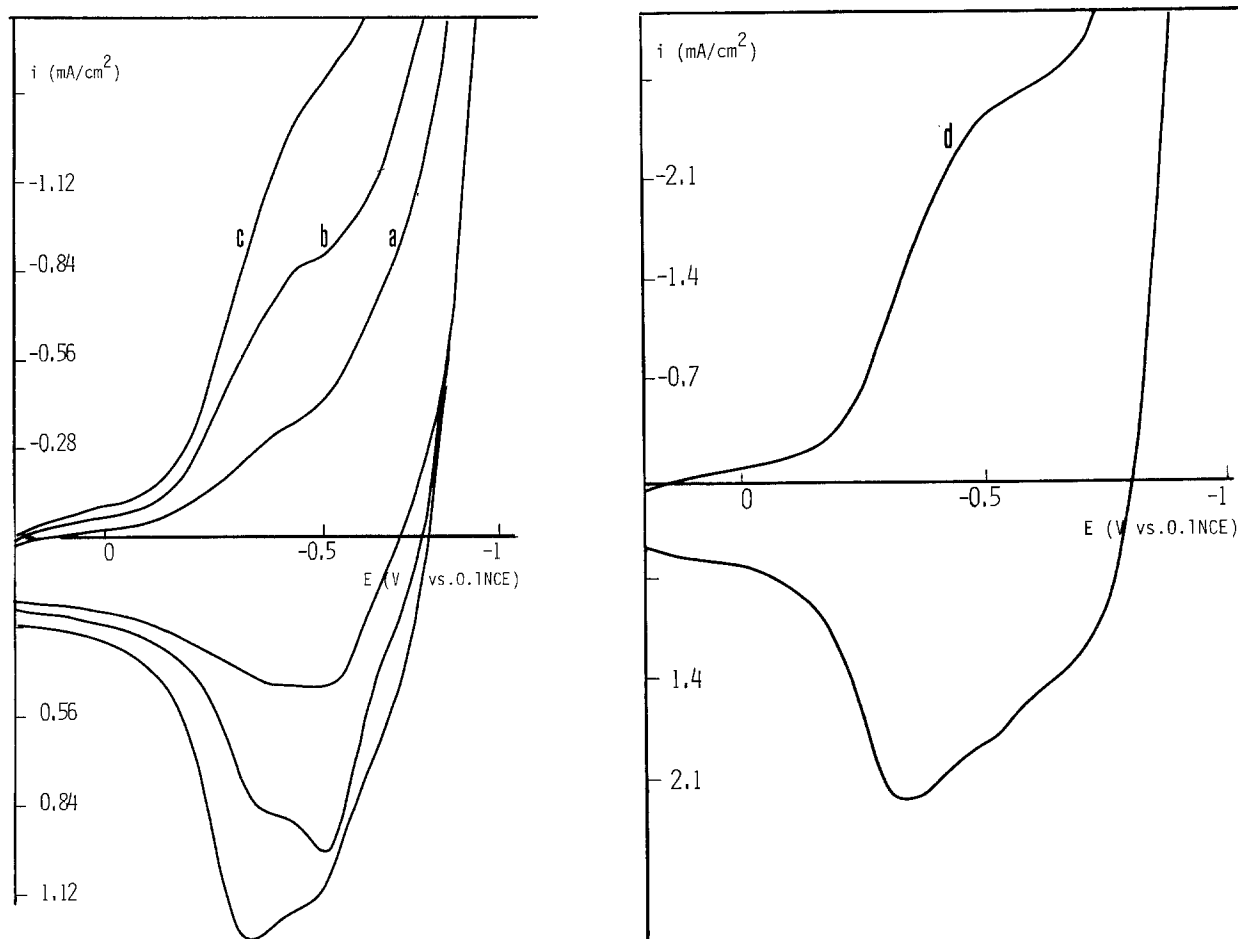

Fig. 5. Cyclic voltammetry i - E profiles, obtained at 20 (curve a), 50 (curve b), 100 (curve c) and 200 $\text{mV} \cdot \text{s}^{-1}$ (curve d) for Pt-TiO₂ in CO₂-saturated (1 atm) 0.5M KCl at 40°C.

significant features of this behavior are the strong, irreversible adsorption undergone by CO₂ at open circuit (i.e., at quite positive potentials, between 0.1 and 0.0V vs. 0.1 NCE or about 0.75–0.65V vs. RHE) and the existence of two distinct intermediates and/or products of the CO₂ reduction at the Pt-TiO₂ electrode. Both the Pt metal and the oxide TiO₂ are apparently needed to observe the chemisorption of CO₂ which takes place in the presence of H₂O adsorbed dissociatively on the oxide surface. It is to be noted, in this connection, that only exposure of the Pt-TiO₂ surface to a mixture of CO₂ and H₂O vapor, but not to dry CO₂, results in the formation of electrochemically detectable chemisorbed species. In the case of metallic (unsupported) Pt, the chemisorption of CO₂ is observed only at cathodic potentials preceding hydrogen evolution: in the presence of the H_{ad} atoms.

In addition to its capability to dissociate water, the role of the TiO₂ support in the cathodic reduction of CO₂ can be to provide acceptor sites for the reduced species formed on the adjacent metal sites. For instance, Solymosi *et al.* (15), in their infrared study of the surface interaction between H₂ and CO₂ (in gas phase) over a TiO₂-supported rhodium catalyst, found that the formed formate ions are preferentially adsorbed on the TiO₂ support. Thus, the likely existence of two kinds of adsorption sites on the Pt-TiO₂ surface and the possibility of the desorption of the reaction products via the TiO₂ support would explain the presence of multiple anodic peaks on the reverse sweep of cyclic voltammograms in Fig. 2a and 3a.

Luminescence Probe Studies of Nafion Polyelectrolytes

N. E. Prieto and C. R. Martin*

Department of Chemistry, Texas A&M University, College Station, Texas 77843

ABSTRACT

Results of luminescence probe studies of solutions of the polyelectrolytes obtained upon dissolving Nafion are reported. The primary objective of this work was to study the nature of the interactions between these anionic polyelectrolytes and their counterions. Both 1100 and 1200 equivalent weight Nafion were studied; solutions of these Nafions were prepared using a procedure developed in this laboratory. These luminescence probe studies have shown that strong binding to the Nafion polyelectrolytes occurs when both hydrophobic and electrostatic interactions are possible. Hence, Nafion preferentially binds hydrophobic cations such as $\text{Ru}(\text{bpy})_3^{2+}$ (bpy = 2,2'-bipyridine), methylviologen, and auramine O over simple inorganic cations such as H^+ , Na^+ , and Mg^{2+} . The implications of this unusual ion exchange selectivity to transport properties of Nafion films and membranes are discussed.

Perfluorinated ionomers (1) have been used in a variety of electrochemical applications, including use in chlor-alkali cells (2, 3), water electrolyzers (4), zinc-bromine cells (5), hydrogen-halogen cells (6), hydrogen-oxygen fuel cells (7), and as agents for the preparation of chemically modified electrodes (8). These ionomers also have a number of nonelectrochemical uses (9, 10). Because of their remarkable versatility, much current research effort is being devoted to studying the morphological and chemical properties of these ionomers (1). We have recently described a procedure for dissolving perfluorinated ionomer membranes (11). This allows, for the first time, for a study of the intrinsic chemical properties of the poly(perfluorosulfonate) (PFS) molecule itself. Such studies should allow for a more thorough understanding of the chemical features, and perhaps of the morphological features, of ionomer membranes. We report at this time results of various luminescence probe studies of the polyelectrolytes obtained by dissolving the 1100 and 1200 equivalent weight versions of du Pont's Nafion (1). The primary objective of this work is to study the interactions between these anionic polyelectrolytes and their counterions.

Experimental

Materials.—Samples of 1100 and 1200 equivalent weight Nafion were kindly donated by E. I. du Pont de Nemours and Company. These were dissolved using the procedure of Martin *et al.* (11), which uses 50:50 ethanol-water as the solvent. The alcohol was removed from these solutions, immediately before use, by heating. The Na^+ form of the polyelectrolytes (Na-PFS's) were obtained by adding carefully measured quantities of NaOH to the polymer solutions. $\text{Ru}(\text{bpy})_3\text{Cl}_2 \cdot 6\text{H}_2\text{O}$ (bpy = 2,2'-bipyridine) (G. F. Smith), 1,1'-dimethyl-4,4'-bipyridinium dichloride hydrate (methylviologen) (Aldrich), and 1,1'-diheptyl-4,4'-bipyridinium dibromide (heptylviologen) (Aldrich) were used without further purification. Tris(2,4-pentanedione)cobalt(III), $\text{Co}(\text{acac})_3$, (Alfa) was recrystallized from benzene, washed with diethyl ether, and dried at 60°C (12). Auramine O [4,4'-(imidocarbonyl)bis(N,N'-dimethylaniline) monohydrochloride] (the cation is abbreviated AO^+ (Sigma) was recrystallized from NaCl (13). 11-(3-hexyl-1-indolyl)undecyltrimethylammonium bromide [the cation is abbreviated (6-In-11⁺) (14)] was donated by N. J. Turro. All other reagents were ACS reagent grade and were used without further purification. Triply distilled water was used throughout this work. The 1100 and 1200 equivalent weight versions of Nafion gave essentially identical results. Only the 1100 data are reported.

Emission intensity and absorbance measurements.—Emission spectra were obtained using a Spex Fluorolog

2 spectrofluorometer. $\text{Ru}(\text{bpy})_3^{2+}$, AO^+ , and 6-In-11⁺ were excited at 455, 435, and 290 nm, respectively. Emission intensity was monitored at 600 nm for the $\text{Ru}(\text{bpy})_3^{2+}$ quenching studies. Absorption spectra were taken using a Beckman Model 26 photometer.

The solutions for the luminescence intensity measurements were prepared by adding aliquots of stock solutions of the polymer (1% weight volume [w/v]) to $\text{Ru}(\text{bpy})_3^{2+}$ ($2 \times 10^{-5}\text{M}$), AO^+ ($5 \times 10^{-5}\text{M}$), or 6-In-11⁺ ($2 \times 10^{-5}\text{M}$) solutions in quartz cuvettes. Hamilton microliter syringes were used. The cuvette solution was mixed thoroughly after each addition of polymer solution, and intensities were corrected for dilution. The addition of salt solution or quencher to a PFS/ $\text{Ru}(\text{bpy})_3^{2+}$ or PFS/ AO^+ solution followed a similar procedure.

Lifetime measurements.— $\text{Ru}(\text{bpy})_3^{2+}$ lifetime measurements were done at the Center for Fast Kinetics Research at the University of Texas at Austin. Lifetimes for $\text{Ru}(\text{bpy})_3^{2+}$ in pure water, in a solution 0.01% in H-PFS (proton form of the polyelectrolyte) and in a solution of 0.01% Na-PFS were obtained [all solutions were $2 \times 10^{-5}\text{M}$ in $\text{Ru}(\text{bpy})_3^{2+}$]. Solutions were degassed with prepurified nitrogen. A Quantrel YG 481 Nd:YAG Q-switched dye laser (535 nm, ca. 10 ns pulse) was used as the excitation source. Luminescence emission was monitored at 650 nm with an RCA R928 photomultiplier tube and processed with a Biomation (Gould) multichannel analyzer and a PDP-11/70 minicomputer. Metal screens were used to attenuate the incident laser intensity.

Results and Discussion

The luminescence probe studies.—As noted above, the primary objective of this work is to study the nature of the interactions between the Nafion polyelectrolytes and their counterions. Clearly, an electrostatic interaction (15a) will be present, but because hydrophobic interactions (15b) have been implicated in various studies of Nafion membranes (8, 16, 17), it was of interest to see if evidence for such interactions could be observed in solutions of the polyelectrolytes. Luminescence probe studies have been shown to be quite effective at characterizing polyion-counterion interactions in other polyelectrolyte systems (18-24). Two types of luminescence probe experiments were used here. The first involved studies of the effect of addition of the PFS's on the luminescence emission intensities of various cationic probes in aqueous solution. Three structurally diverse probes, 6-In-11⁺ (14, 22, 23), $\text{Ru}(\text{bpy})_3^{2+}$, and AO^+ (24) were chosen for these studies. 6-In-11⁺ was chosen because the effect of solvent polarity on its emission characteristics are dramatic and well characterized (14, 22, 23), and because it has been used to study polyion-counterion interactions in poly(styrene-sulfonate) (PSS) (23). $\text{Ru}(\text{bpy})_3^{2+}$ was chosen because Lee and Meisel have

* Electrochemical Society Active Member.

suggested that hydrophobic interactions between this ion and the fluorocarbon chain material occur in 1200 equivalent weight Nafion membranes (16). AO^+ was chosen because it has proved to be ideally suited for studying polymer-probe interactions (24).

The second set of luminescence probe experiments involved studies of the effect of the PFS's on the rates of quenching of $\text{Ru}(\text{bpy})_3^{2+*}$ by various electron transfer quenching agents. $\text{Ru}(\text{bpy})_3^{2+}$ was chosen for these studies because it strongly binds to the PFS's (*vide infra*) and because its luminescence in aqueous solution has been well characterized (25).

Luminescence intensity studies.—Figure 1 shows the effect of addition of an aqueous solution of Na-PFS (1 w/v) on the emission spectra of 6-In-11⁺. A pronounced blueshift in the position of the emission spectrum is observed (wavelength of maximum emission intensity, λ_{max} , in water is 374 nm, λ_{max} in Nafion solution is 356 nm). A blueshift in the emission of a probe (relative to water) is often indicative of a more hydrophobic environment for the probe (26). [The photochemical mechanism for such a shift is discussed by Brand and Gohlke (26).] The observed blueshift, then, suggests that Nafion is engaging in hydrophobic interactions with 6-In-11⁺. In this type of luminescence probe study, however, it is desirable to compare the emission of the probe from the unknown environment with its emission spectrum from some well-characterized environment. It is known that PSS can engage in strong hydrophobic interactions with its counterions (18, 23). Turro and Okubo observed a pronounced blueshift in the emission of 6-In-11⁺ from aqueous solutions of PSS, which they attributed to hydrophobic binding of this probe by PSS (23). The similarity in the responses of this probe to the unknown (Nafion) and standard (PSS) environments adds further evidence for hydrophobic interactions between 6-In-11⁺ and Nafion.

In addition to the shift in λ_{max} , a decrease in emission intensity, with the initial additions of Na-PFS, is observed (Fig. 1b), followed by a gradual increase in intensity with further additions (Fig. 1c). Similar results were obtained by Turro and Okubo in their investigations of Na-PSS (23). They suggest that quenching by trace impurities present in the polymer solution may account for the initial decrease in emission intensity (23).

Further evidence for a strong hydrophobic component to the interaction between 6-In-11⁺ and PFS is obtained from studies of 6-In-11⁺ absorption spectra. As shown in Fig. 2, the absorbance at 290

Fig. 1. Effect of addition of Na-PFS on fluorescence spectra for 6-In-11⁺ ($2 \times 10^{-5} \text{M}$). A: no Nafion added. B: after addition of Na-PFS solution, 3.79×10^{-8} mols of $-\text{SO}_3^-$ sites added. C: after addition of more Na-PFS solution, 5.05×10^{-7} mols of $-\text{SO}_3^-$ sites added.

Fig. 2. Excitation spectra of 6-In-11⁺ ($2 \times 10^{-5} \text{M}$, monitored at 374 nm). A: no Nafion added. B: after addition of Na-PFS solution, 7.26×10^{-8} mols of $-\text{SO}_3^-$ sites added. C: after addition of more Na-PFS solution, 1.99×10^{-7} mols of $-\text{SO}_3^-$ sites added.

nm increases as Na-PFS is added to a solution of 6-In-11⁺. Turro has shown that the absorbance for this probe increases as the polarity of the environment around the probe decreases (22, 23); furthermore, a similar increase in absorbance was observed with PSS (23). Figure 2 shows excitation spectra obtained with the fluorometer, but true absorbance spectra (obtained with the spectrophotometer) gave identical results. Finally, it is important to note that while the data shown in Fig. 1 and 2 refer specifically to the Na⁺ form of PFS, essentially identical results were obtained with the proton form. These studies clearly show that 6-In-11⁺ engages in strong hydrophobic interactions with the PFS's.

Figure 3 shows the effect of concentration of Na-PFS (expressed as the molarity of $-\text{SO}_3^-$ sites) on the intensity of emission by $\text{Ru}(\text{bpy})_3^{2+*}$. Emission intensity is expressed as the ratio I/I^0 , where I^0 is the intensity in pure water, and I is the intensity after addition of an increment of the Na-PFS solution (21). Emission intensity increases with increasing concentration of PFS until a stoichiometrically equivalent amount of $-\text{SO}_3^-$ sites have been added to the solution (i.e., until $2 \times [-\text{SO}_3^-] = [\text{Ru}(\text{bpy})_3^{2+}]$). This increase in intensity is not due to some polymer-induced change in bulk concentration of the $\text{Ru}(\text{bpy})_3^{2+}$, because the absorption spectrum (corrected for dilution) is unaffected by the presence of PFS, nor is it due merely to a change in the shape of the emission

Fig. 3. Dependence of $\text{Ru}(\text{bpy})_3^{2+*}$ luminescence emission intensity on concentration of Na-PFS. $[\text{Ru}(\text{bpy})_3^{2+}] = 2 \times 10^{-5} \text{M}$. $\lambda_{\text{EX}} = 455 \text{ nm}$, $\lambda_{\text{EM}} = 610 \text{ nm}$.

band, because an analogous plot of the areas under the emission bands gives an identical curve. When greater than stoichiometric amounts of PFS are added, a leveling in emission intensity is observed (Fig. 3).

The leveling of the emission intensity at the stoichiometric equivalence point implicates a role for electrostatic interactions in the observed increase in emission intensity. However, if a hydrophilic, divalent metal ion (e.g., Mg^{2+}) is added to a $Ru(bpy)_3^{2+}$ /PFS solution, a huge excess of the hydrophilic ion is required to return I/I° back to 1 (Fig. 4, the ratio (mols Mg^{2+} /mols $Ru(bpy)_3^{2+}$) to make $I/I^\circ = 1$ is ca. 1000). If the increase in emission intensity (Fig. 3) resulted from purely electrostatic interactions, the ability of Mg^{2+} to replace $Ru(bpy)_3^{2+}$ as the counterion of the polyelectrolyte would not be so severely retarded, that is, one might expect the ratio (mols Mg^{2+} /mols $Ru(bpy)_3^{2+}$) required to make I/I° ca. 1 to be close to unity. Given the hydrophobic nature of $Ru(bpy)_3^{2+}$, the results in Fig. 4 indicate that there is also a strong hydrophobic interaction between this counterion and the PFS's. The binding of $Ru(bpy)_3^{2+}$ to the PFS's is via a concerted hydrophobic/electrostatic interaction.

When $Ru(bpy)_3^{2+}$ is used as a luminescence probe of hydrophilic polyions, where only electrostatic interactions are extant, emission intensity does not change with the concentration of the polyion (27). This suggests that the increase in emission intensity in Fig. 3 is caused by the hydrophobic part of the interaction. Kurimura *et al.* saw a similar increase in emission intensity when PSS was added to a $Ru(bpy)_3^{2+}$ solution and also concluded that this increase was due to hydrophobic interactions (21). A consideration of the effect of water on the nonradiative rate constant provides a possible explanation for the observed increases in $Ru(bpy)_3^{2+}$ emission intensity. As recently noted by Casper and Meyer (28), water is particularly effective at promoting nonradiative decay in $Ru(bpy)_3^{2+}$. It seems likely, then, that any interaction which shields $Ru(bpy)_3^{2+}$ from water will increase its quantum yield [the radiative rate constant is relatively insensitive to solvent (28)]. Since it is the incompatibility of water and the hydrophobic solute which promotes hydrophobic bonding (15b), it is reasonable to assume that when bound to PFS, $Ru(bpy)_3^{2+}$ minimizes

Fig. 4. Effect of addition of $MgSO_4$ on emission intensity of $Ru(bpy)_3^{2+}$ from a $Ru(bpy)_3^{2+}$ /Na-PFS solution. 2×10^{-8} mols $Ru(bpy)_3^{2+}$, 6×10^{-8} mols Nafion $-SO_3^-$ sites (see Fig. 3).

its contact with water. Therefore, a quantum yield increase would be expected.

The final luminescence probe used was AO^+ . In nonviscous solvents, electronic excitation energy in AO^+ is dissipated as heat via rotation of its phenyl rings (24). For this reason, AO^+ does not fluoresce in water (Fig. 5) or other nonviscous solvents (24). Binding of AO^+ to polyanions hinders phenyl ring rotation, and fluorescence can be observed (24). Figure 5 shows that Na-PFS can induce fluorescence in AO^+ . As was the case with $Ru(bpy)_3^{2+}$, fluorescence intensity is proportional to $[-SO_3^-]$ until a stoichiometrically equivalent quantity of polymer is added. Furthermore, huge excesses (ca. 1000-fold) of Na^+ are required to return the emission intensity to background levels, indicating that AO^+ also binds via a concerted hydrophobic/electrostatic interaction.

Quenching studies.—It is well known that quenching reactions between an electronically excited cation and a cationic quencher are accelerated in the presence of a polyanion (19, 27, 29). This acceleration is due to the concentration of the cations in the domain around

Fig. 5. Fluorescence spectra of AO^+ as a function of concentration of Na-PFS ($[AO^+] = 5 \times 10^{-5} M$, $\lambda_{EX} = 435$ nm). 1: no Na-PFS. 2: 9×10^{-9} mols of $-SO_3^-$ sites. 3: 1.8×10^{-8} mols $-SO_3^-$ sites. 4: 2.7×10^{-8} mols $-SO_3^-$ sites. 5: 3.6×10^{-8} mols $-SO_3^-$ sites.

the polyion chains (*i.e.*, the local concentrations of both emitter and quencher are higher than the bulk concentrations) (19, 27, 29). It was of interest to see if acceleration of quenching reactions between cationic quenchers and $\text{Ru}(\text{bpy})_3^{2+}$ could be observed in the presence of the PFS's. Furthermore, given the strongly hydrophobic nature of the PFS's (*vide supra*), it was of particular interest to see if a contribution from hydrophobic interactions (18) could be discerned in any acceleration observed.

Quenching rate constants were determined using the emission intensity form of the Stern-Volmer equation (30). Typical Stern-Volmer plots are shown in Fig. 6. We have obtained apparent quenching rate constants from such plots for hydrophilic cation, hydrophobic cation, and neutral quenchers in the presence of both Na-PFS and H-PFS's (Table I). Measured $\text{Ru}(\text{bpy})_3^{2+}$ lifetimes of 640 ± 10 ns (Na-PFS) and 590 ± 10 ns (H-PFS) were used for calculation of these rate constants. They are called apparent quenching rate constants because they have been calculated assuming the bulk quencher concentrations. To obtain real quenching rate constants, the values shown in Table I would have to be normalized, as described by Meisel *et al.* (19). Since it is the magnitude of the rate constant enhancement which is of interest here, normalization was not attempted.

Table I shows that quenching rate constants are enhanced for all of the cationic quenchers. The amount of enhancement can be described quantitatively by the enhancement factor (α), which is the ratio of the apparent rate constant in the presence of the polymer to the rate constant observed in pure water. Enhancement factors (Table II) for the hydrophobic cations (methylviologen and heptylviologen) are seven to ten times larger than the enhancement factors for the hydrophilic cations. As in the previous set of experiments, these data show that hydrophobic interactions can play an important role in the binding of counterions to the PFS's. Again, however, the importance of the electrostatic component of the interaction is demonstrated because quenching by neutral $\text{Co}(\text{acac})_3$ is not changed appreciably by the presence of the polyanion.

As was indicated by the data obtained in the intensity studies, a concerted hydrophobic/electrostatic interaction is required to produce strong binding.

Conclusions

This work has shown that strong binding to the Nafion polyelectrolytes occurs when both electrostatic and hydrophobic interactions are possible. This helps to explain why a Nafion film on an electrode surface retains hydrophobic counterions (*e.g.*, $\text{Ru}(\text{bpy})_3^{2+}$, MV^{2+}) (8) when the film is immersed in a solution containing high (*e.g.*, 0.1M) salt concentrations and none of the hydrophobic ion. Nafion shows very different selectivity than the polyelectrolytes investigated by Anson (31), which apparently bind only via electrostatic interactions. We are currently investigating ion exchange selectivity in cationic analogs of Nafion to see if hydrophobically driven ion exchange is a general phenomenon.

This work raises important points concerning the transport properties of Nafion. The permeability of a material to a solute species is proportional to the product of the partition constant and the diffusion coefficient for that species in the material. In most of the electrochemical applications of Nafion, high permeability to cations is desired. Because of the affinity of the polymer for hydrophobic cations (*i.e.*, high partition constant), these ions could show higher permeabilities than smaller alkali metal ions, if the membrane is in contact with a solution containing both types of cations. Finally, these data corroborate results obtained previously in this laboratory, which showed that rates of ionic diffusion through Nafion films can be affected by hydrophobic interactions (32).

Acknowledgments

This work was supported in part by the Office of Naval Research and the Robert A. Welch Foundation. The authors would like to thank M. A. J. Rodgers and S. Atherton of the Center for Fast Kinetics Research, University of Texas at Austin, for assisting with the lifetime measurements and for valuable discussions.

Manuscript submitted March 11, 1983; revised manuscript received Oct. 26, 1983. This was Paper 566 presented at the San Francisco, California, Meeting of the Society, May 8-13, 1983.

The Office of Naval Research assisted in meeting the publication costs of this article.

The Effect of Reactive Gases on Oxygen Sensor Responses

J. I. Federer

Oak Ridge National Laboratory, Metals and Ceramics Division, Oak Ridge, Tennessee 37830

ABSTRACT

Ceramic electrolyte oxygen sensors consisting of stabilized zirconia with platinum electrodes were compared in flowing gases in a laboratory apparatus. The oxygen partial pressures indicated by these sensors in reactive gases were substantially different. Gases containing CO produced a greater difference than gases containing H₂. The responses of these sensors were attributed to their relative catalytic behavior.

Commercially available oxygen measuring devices include those based on ceramic electrolytes, paramagnetism, and electrometry. An important use of oxygen sensors is measurement of oxygen concentrations in the combustion environments of industrial furnaces and automobile exhausts. In these applications, the sensors measure the oxygen concentration and, if coupled with auxiliary instrumentation, control the air/fuel ratio being burned. A potential application for oxygen sensors is in fluidized bed combustors (FBC's) burning coal. The need for an oxygen sensor was demonstrated during corrosion testing of candidate steam-tube materials in a test bed. Severe oxidation-sulfidation corrosion of type 316 stainless steel occurred in one location of the bed, but the same alloy corroded little at similar temperatures in other locations (1, 2). This behavior suggested that the corrosiveness of the environment varied significantly within the bed. Corrosion of stainless steels by an oxidation-sulfidation mechanism is governed by the thermodynamic stability

Key words: ceramics, electrolyte, cell, catalysis.

of the oxides and sulfides of the elements involved (3, 4). Fluctuations in oxygen and sulfur concentrations that result in combinations of low oxygen and high sulfur might increase corrosion. An oxygen measuring system (OMS) was needed, therefore, to study and control corrosion behavior in fluidized beds. Several movable devices might systematically reveal oxygen concentrations within the bed, thereby aiding interpretation of corrosion results. Subsequently, stationary devices at strategic locations could monitor and control oxygen concentrations at levels consistent with efficient combustion and acceptable corrosion.

Commercially available oxygen sensors were investigated to determine the type most suitable for FBC use. This investigation focused on the mode of operation, temperature capability, and measuring range of ceramic electrolyte, paramagnetic, and electrometric devices. Paramagnetic devices use the paramagnetic property of oxygen (most other gases are diamagnetic) to produce a flow of oxygen, a constituent of a gas mixture, over a thermistor in contact with the gas.

Current flow in the thermistor is proportional to the oxygen content of the gas. In electrometric devices, oxygen in a gas is reduced to hydroxyl ions at the cathode of an electrochemical cell. Migration of the ions to the anode under the influence of an imposed voltage constitutes an electric current, which is proportional to the oxygen content of the gas. This investigation revealed that paramagnetic and electrometric devices can measure oxygen concentrations in samples only at approximately ambient temperature. Since the typical operating temperature of an FBC is 875°C, samples would have to be extracted and cooled for measurement. Possible problems with extracted samples include clogging of sampling lines with particulate matter and change in composition of the gas sample caused by shift in equilibria during cooling or by mixing. These potential problems and limited measuring range eliminated paramagnetic and electrometric devices in favor of those based on ceramic electrolytes. The latter have several apparent advantages over the other types: high temperature capability, which allows *in situ* measurements; wider measuring range; and faster response to changes in oxygen concentrations. Possible problems with ceramic electrolyte sensors include breakage by thermal shock or impact by bed material, corrosion and erosion, and sluggish response due to deposition of bed materials. Although these problems might be minimized by design or mode of operation, the serious nature of another problem identified during laboratory testing requires understanding for maximum usefulness of these devices in FBC's. This problem concerns the difficulty of measuring oxygen concentrations in reactive gas mixtures using commercially available ceramic electrolyte probes. This paper concerns the large differences in response that were obtained during comparison of commercially available oxygen probes in a laboratory apparatus.

Oxygen Probes Evaluated

Two Corning *in situ* probes (Model 8081) were tested. Their construction is similar to that shown in Fig. 1. The alumina protection tube was 22.2 mm od by 0.6m long. The two probes were similar except for a porous ceramic layer over the sensor of one probe. Layers of this type protect the sensor against erosion. Two Bosch automobile exhaust sensors, modified as shown in Fig. 2, were also tested. The original housing and electri-

cal lead (neither shown in Fig. 2) were replaced with two stainless steel tubes and a Teflon insulator. An extracted-sample (off-line) oxygen sensor served as a reference sensor. All sensors had stabilized zirconia ceramic electrolytes with platinum electrodes.

The zirconia is typically in the form of a closed-end tube (Fig. 1). The closed end is coated inside and outside with a thin porous layer of platinum. The platinum coatings form the electrodes of a solid-state electrochemical cell, and platinum wires attached to the electrodes permit the cell voltage to be measured. In the normal mode of operation, a gas of known oxygen concentration (usually air) is in contact with the inner surface (cathode) of the sensor, and the outer surface is in contact with a gas of lower oxygen content to be measured. At the cathode, where the oxygen concentration is high, oxygen molecules dissociate and acquire electrons to become ions as shown

At the anode, where the oxygen concentration is low relative to the cathode, the reverse reactions occur. The net result is an open-circuit cell voltage, which is related to the unknown oxygen concentration through the Nernst equation

$$E = (RT/nF) \ln(p_{\text{O}_2})_r / (p_{\text{O}_2})_x$$

where n is the number of gram equivalents per mol (here four, from the oxygen ionization reaction), F is Faraday, or 96,500 coulombs per gram equivalent, R is the gas constant, or 8.314 J/(mol · K), T is the absolute temperature in degrees kelvin, $(p_{\text{O}_2})_r$ is the reference oxygen partial pressure,¹ and $(p_{\text{O}_2})_x$ is the partial pressure to be determined. The cell voltage depends directly on T and inversely on $\ln(p_{\text{O}_2})_x$. As will be shown, apparent values of $(p_{\text{O}_2})_x$ in dynamic reactive gases can vary between the actual value and the thermodynamic equilibrium value. The platinum coating on the sensor tends to catalyze reactions in reactive gases. The indicated $(p_{\text{O}_2})_x$ in a dynamic system of flowing reactive gases, therefore, represents a local approach to equilibrium at the surface of the sensor.

¹ Throughout this paper p_{O_2} represents the partial pressure of molecular oxygen.

Fig. 2. Modified Bosch oxygen sensor

Apparatus

The apparatus for comparing the Corning and Bosch probes is shown schematically in Fig. 3. Gas mixtures with selected oxygen contents were metered into the two lines leading to the oxygen probe furnace. The gases were first heated by contact with extended surfaces in the preheat furnace and then passed through insulated tubing into the probe furnace. Although the time required to respond to sudden changes in oxygen concentration was also measured in this apparatus (5), only the results of comparing probes under steady-state flow conditions will be described here. During these comparisons, gas of the desired p_{O_2} followed the crossover path indicated in Fig. 3. The two Corning probes were placed in the apparatus, as depicted in Fig. 3. Two Bosch probes were similarly located in a subsequent experiment.

An extracted-sample oxygen sensor manufactured by Applied Electrochemistry, Incorporated, (AEI) served as the reference sensor. The AEI instrument was also used to display the output from the probes being tested. Unlike instruments provided with most commercially available oxygen probes, which typically display oxygen content ranging from 0 to 25% with a minimum resolution of 0.01%, the AEI instrument displays the cell output in millivolts (0-1000 mV), oxygen content in percent (1×10^{-6} to 100%), and $\log p_{O_2}$ [atm] (0 to -20).

Comparison tests required gas mixtures containing different concentrations of oxygen. Mixtures were prepared from air, Ar, Ar-80% CO, Ar-0.5% CO, CO, Ar-4% H₂, and CO₂. The AEI system was calibrated with air, argon (for which the oxygen content was determined independently), and CO₂-CO mixtures, for which the oxygen content was calculated from the expression for the equilibrium constant K of the reaction

$$K = p_{CO_2}/p_{CO}p_{O_2}^{1/2} \text{ or } p_{O_2} = (p_{CO_2}/Kp_{CO})^2$$

where p_{CO_2} , p_{CO} , and p_{O_2} are the partial pressures of CO₂, CO, and O₂, respectively. The p_{O_2} of air, the p_{O_2} of argon determined by mass spectrometric analysis, and the calculated p_{O_2} of Ar-CO-CO₂ mixtures at equilibrium at 750°C are shown in Fig. 4, a plot of p_{O_2} values measured by the reference sensor against calculated or analytically determined p_{O_2} values. No data are shown between about 1 Pa and 2 pPa because the required small flow rates of CO could not be accurately measured. Nevertheless, agreement appears to be satisfactory over 19 orders of magnitude.

With the knowledge that the reference oxygen sensor accurately measured p_{O_2} , mixtures of various p_{O_2} could be prepared by simply mixing gases until the desired p_{O_2} was indicated by the reference sensor, that is, without accurately metering the gas components. The accuracy

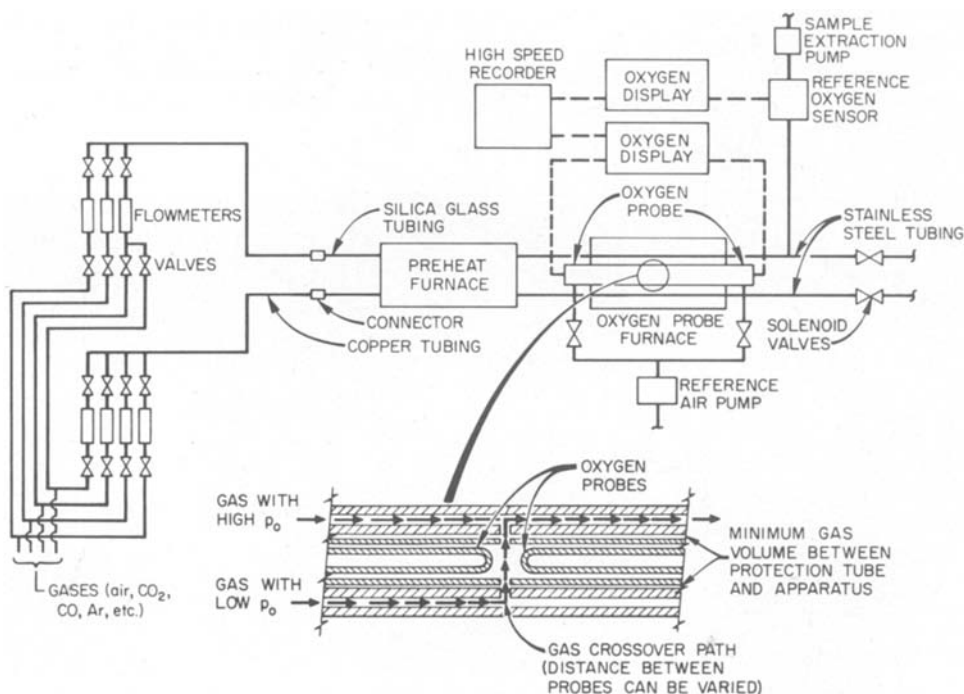

Fig. 3. Apparatus for testing the performance of oxygen probes.

Fig. 4. Calculated p_0 values vs. values measured with the reference oxygen sensor.

of the device was checked periodically, however, with mixtures of known compositions.

Results

The Corning probes were compared with the reference sensor at 750°C by use of steady flows of gases of different p_0 . The results are shown in Fig. 5, wherein p_0 indicated by the reference is plotted against that indicated by the Corning probes. Because the values depended on gas flow rate and exposure time, the data in Fig. 5 represent steady values after 3-6h of steady flow. During these tests, the probe with the porous ceramic layer required much longer times to attain a steady p_0 , apparently because the porous layer restricted access of gas to the sensor. Nevertheless, both probes eventually reached substantial agreement with the reference sensor.

The Bosch probes are compared with the reference sensor at 750°C in Fig. 6, wherein the cell voltage of the Bosch probes is plotted against the reference from 0 to about 800 mV (21 kPa-0.31 nPa). The dashed line in Fig. 6 indicates the desired agreement between the Bosch and reference sensor, and the data points show the actual agreement. At the higher oxygen concen-

Fig. 5. Comparison of Corning probes with reference sensor

Fig. 6. Comparison of Bosch probes with reference sensor

trations, represented by cell voltages of 0-200 mV, the agreement is satisfactory, but at higher cell voltages (lower oxygen concentrations) agreement is poor. The points for the Bosch sensors at cell voltages greater than about 200 mV could be represented by straight lines intersecting the reference sensor axis at about 225 mV (Bosch 2) or 350 mV (Bosch 1). The shift away from the line of perfect agreement occurred when the gas mixtures contained substantial amounts of CO.

The Bosch and reference sensors are both ceramic electrolyte cells consisting of stabilized zirconia closed-end tubes coated inside and outside with platinum. A possibly important difference between the cells, however, is an additional coating of metal oxide on the outer platinum coating of the Bosch cell. A cross section of the Bosch sensor in Fig. 7 shows the platinum and metal oxide coatings on the zirconia. The porous platinum coating is about 3 μm thick, and the oxide coating (also porous) varies from 35 to 100 μm in thickness. X-ray diffraction revealed that the oxide is a spinel or a mixture of spinels. X-ray fluorescence revealed the presence of Al, Fe, Mg, Ti, V, Cr, Mn, and Ni. This doubly coated outside surface is in contact with the atmosphere being measured, and the other surface (inside) is always in contact with air, the reference gas for both sensors. A possible explanation for the difference in behavior between the two sensors is the presence of this extra coating. Although the platinum coating on the reference sensor can catalyze the oxidation of CO to CO₂, which reduces p_0 at the sensor surface, the metal oxide coating on the Bosch sensor

Fig. 7. Coatings on the outer surface of the Bosch sensor

partially prevents catalysis by the platinum. Consequently, when both sensors are in contact with a reactive gas mixture such as CO₂-CO, the reference sensor indicates a lower p_0 because of a more complete reaction at the sensor surface. The Bosch sensor, being less catalytically active, measures p_0 nearer to the actual (unreacted) value in the gas mixture.

Additional comparisons were obtained with mixtures of air with Ar-4% H₂ and with Ar-0.5% CO. The concentration of either H₂ or CO was gradually increased in the mixtures, as shown in Table I, to cause p_0 to decrease by formation of H₂O or CO₂, respectively. The resulting p_0 was calculated from the final gas composition, assuming that all H₂ or CO had reacted with oxygen to form H₂O or CO₂. Table I shows that p_0 indicated by the Bosch and reference sensors, in agreement with calculated values, gradually decreased as available oxygen was consumed. When the gas reached compositions that allowed all available oxygen to be converted to either H₂O or CO₂, the reference sensor indicated lower p_0 values by many orders of magnitude. The indicated values approached thermodynamic equilibrium values that can be calculated from the final gas composition and the equilibrium constants. Lack of better agreement between calculated values and those indicated by the reference sensor can be explained in part by an estimated accuracy of only $\pm 10\%$ in initial gas flow rate. Also, flow rates may have been too high to allow attainment of equilibrium at the surface of the sensor.

The Bosch sensor also indicated much lower p_0 values when all available oxygen was consumed; however, in a manner similar to that in Fig. 6, the Bosch sensor indicated higher p_0 than did the reference. The indicated difference in p_0 between the Bosch and reference sensors was about a factor of 10⁴ for gases containing excess hydrogen and about 10¹³ for gases containing excess CO. These results show not only that the Bosch and reference sensors have different catalytic behavior, but that the Bosch sensor is more catalytic to gases containing excess H₂ than it is to gases containing excess CO.

Discussion

The results of this work revealed that the design of ceramic electrolyte sensors significantly affects performance. Although consisting basically of stabilized

zirconia with platinum electrodes, the Corning and Bosch sensors performed differently. The two Corning sensors agreed with the reference oxygen sensor over a wide range of p_0 values. When contacted with a reactive gas mixture (CO₂-CO), the platinum catalyzed the oxidation of CO resulting in p_0 values predicted by thermodynamic equilibrium between CO and CO₂. Manifestation of the same effect was observed during measurements in an FBC when a large concentration of CO was present in the combustion environment (6). In this latter case, a gas chromatograph and a paramagnetic device indicated p_0 values approximately 12 orders of magnitude higher than did a ceramic electrolyte sensor. The anomaly was attributed to the catalytic behavior of the ceramic electrolyte sensor.

The Bosch sensors indicated much higher p_0 than the reference when exposed to reactive gas mixtures in which the equilibrium oxygen concentration is very low. In this case, the reference sensor indicated p_0 values near to calculated equilibrium values. At the same time, the Bosch sensor indicated p_0 values 4 and 13 orders of magnitude higher than the reference for gas mixtures containing H₂ and CO, respectively. The catalytic behavior of the Bosch sensor evidently is quite different from that of the reference and Corning sensors. A possible explanation for the difference in catalytic behavior is the nature of the ceramic layers. Whereas the porous ceramic layer on the Corning sensor was fabricated separately and then placed in contact with the sensor, the oxide layer on the Bosch sensor was evidently applied as a coating by flame spraying or by a similar method. Although the coating on the Bosch sensor was quite porous (see Fig. 7), the method of application may have produced intimate contact between the oxide and platinum layers, thereby greatly reducing the surface area and associated catalytic effect of the platinum layer. Haaland (7) searched for noncatalytic electrodes for measuring nonequilibrium oxygen concentrations associated with combustibles (CH₄, C₃H₈, CO, and H₂). He found that platinum electrodes were catalytic in mixtures of oxygen and each of the combustibles. Silver and gold catalyzed CO, even though both were only slightly catalytic to CH₄. Platinum electrodes poisoned with lead were the least catalytic to nonequilibrium gas mixtures of the electrodes investigated.

^a Plus inlet N₂ and argon and any remaining H₂ or CO after all O₂ is consumed. ^b Calculated from final gas composition assuming that all H₂ and CO react with O₂ (if available) to produce H₂O and CO₂, respectively. ^c Gas composition that allows all O₂ to be converted to H₂O or CO₂. ^d Calculated from final gas composition and equilibrium constants at 750°C: 5.75 E+09 for H₂-O₂-H₂O and 7.25 E+09 for CO-O₂-CO₂.

If all gases within the FBC atmosphere were at equilibrium, the catalytic behavior of the sensor would not be important, and the sensor would accurately display p_{O_2} . Intuitively, equilibrium would not be expected in an FBC because of complex reaction kinetics associated with numerous gaseous species and because of imperfect mixing of air, powdered coal and limestone, and reaction products. The previously mentioned discrepancy between a ceramic electrolyte, paramagnetic sensor, and gas chromatograph indicate a state of nonequilibrium (6). Thus, in reactive gas mixtures, the response of a ceramic electrolyte sensor will depend to some extent on its catalytic behavior. In an FBC, the sensor would probably be influenced by several factors, including the actual p_{O_2} of the gas, gas composition, gas flow rate, catalytic behavior, and deposits on the sensor. The sensor probably would become coated with a material consisting mostly of $CaSO_4$, unless protected by a filter. If the sensor initially had a bare platinum electrode, the coating might decrease the catalytic behavior in a manner similar to the oxide coating on the Bosch sensor.

In spite of the data presented herein showing different behavior by ceramic electrolyte sensors, and discussion of reasons why these devices will not accurately measure p_{O_2} in reactive gases, they might still be useful diagnostic tools in FBC's. Rocazella *et al.* demonstrated the ability of a Bosch probe to differentiate combustion products resulting from stoichiometric and air-rich mixtures (8). Furthermore, they showed that corrosion characteristics in several alloys correlated well with p_{O_2} values indicated by the probe.

A Potentiodynamic Study of Metals Affecting Precious Metal Recovery from Alkaline Cyanide Solutions

D. W. Kirk* and F. R. Foulkes*

Department of Chemical Engineering and Applied Chemistry, University of Toronto, Toronto, Ontario, M5S 1A4, Canada

ABSTRACT

A potentiodynamic study was carried out to determine the effects of various ions on the electrorecovery of precious metals from an industrial cyanide leaching solution. Synthetic solutions were prepared and studied to determine the effects of Cu, Ni, and Pb individually and in combination on the recovery of gold and silver. Lead, known to be electrochemically active, was studied at a low concentration (1 ppm), whereas copper and nickel were studied at high concentrations (250 ppm), corresponding to levels found in an industrial solution. Both copper and lead were found to enhance silver and gold reduction reactions in the potential sweep measurements. Separation of the two reactions was also improved. In addition, these two metals inhibited the onset of hydrogen evolution. Nickel had the opposite effect. Separation and initiation of the gold and silver plating peaks was inhibited, and the hydrogen evolution reaction was depolarized. The influence of nickel predominated over the effects of copper and lead. The data, obtained from synthetic electrolyte solutions, were compared with those obtained from the industrial leach solution.

The purpose of this study was to investigate the effects of interactions between various metals dissolved in an aqueous alkaline cyanide solution. The results of this work will be used to help explain the behavior of industrial leach solutions in electrowinning operations. The particular industrial solution considered in this case was an alkaline cyanide electrolyte used for precious metal recovery from a gold bearing ore from Pamour Mines, Porcupine, Ontario. As a result of the leaching operation, a number of metals were dissolved. Gold and silver, together with a substantial amount of copper, were recovered by precipitation with zinc. Although gold and silver recovery by electrolysis could be an attractive alternative because of the possibility of selective metal re-

covery, the effect of the interaction of the various metals in solution on the electrowinning operation is not known.

Studies using porous flow through reactors for metal electrorecovery have shown that both industrial and multicomponent synthetic electrolytes yield much poorer metal recovery and current efficiency than the corresponding single-component electrolytes (1-5). The difficulties with multicomponent electrolytes result in part from polarization and depolarization effects, codeposition, underpotential deposition, and catalytic effects. Even trace amounts of some metals can cause substantial changes in plating rates. McIntyre and Peck (6) showed that trace amounts of Hg, Tl, Pb, and Bi could greatly enhance gold plating rates in alkaline phosphate electrolytes. The metals were reported to remain in the electric double layer and act as catalysts

* Electrochemical Society Active Member.

Key words: electrodeposition, voltammetry, precious metals, alkaline cyanide.

for the plating reaction. In the case of multicomponent solutions, there is little evidence whether all, or only certain plating reduction reactions, would be accelerated.

The behavior of metal ions also is affected by the electrolyte. Cyanide complexes with metals to form stable anions. Gold, for example, is found almost exclusively as $\text{Au}(\text{CN})_2^-$. Electromigration forces acting near the electrode surface in cyanide solutions are therefore different than those in chloride solutions. In chloride solutions, more negative electrode potentials increase the electromigration force towards the electrode, whereas in cyanide solutions, more negative potentials increase the repulsion of the complexed metal from the electrode. The reduction potential of some metals is affected by cyanide electrolytes and metals such as copper and nickel can form a variety of complexes so that the plating behavior of a complex mixture of metals is not easily predictable.

Before a study of precious metal electrowinning was carried out, linear potential sweep profiles of various metals singly and in combination were measured. The metals studied were those found in significant concentrations in the industrial leach solution or those thought to have catalytic properties (Au, Ag, Cu, Ni, Pb). In order to have the results applicable to porous bed work, a porous graphite felt was used in the linear sweep voltammetry work.

Experimental

The electrochemical cell used for linear sweep voltammetry (LSV) measurements consisted of a 50 ml Pyrex glass cell sealed using a rubber stopper with ports for electrodes and gas sparging. The working electrode consisted of porous graphite felt (Carborundum Corporation, Niagara Falls, New York) $0.6 \times 0.6 \times 1.9$ cm with a specific surface area¹ of 3.45×10^3 cm^{-1} and porosity 0.88. Contact was made by means of a Pt wire (0.08 cm diam) imbedded 1.6 cm into the felt and sealed in a glass tube to isolate it from the solution. The electrode appears to partially utilize both internal and external surface area, since metal deposits were found throughout the electrode. A total resistance of the carbon felt of $7 \times 10^{-3} \Omega$ was calculated from a measured specific conductivity of $5.0 \times 10^3 \text{S}$. The electrode was soaked for 24h in KOH solution and then well rinsed in double-distilled water before use.

A saturated calomel reference electrode² was housed in a Luggin capillary with the capillary tip 2 mm from the graphite surface. The counterelectrode was a platinum disk (1 cm diam) set 2 cm from the working electrode. Tank nitrogen gas was bubbled through the solutions for 5 min before each run using a glass frit for good gas dispersion. During a run, nitrogen gas was passed over the solutions to maintain a low dissolved-oxygen content.

The industrial leach solution was supplied courtesy of Pamour Mines, Porcupine, Ontario. The synthetic electrolytes were prepared from analytical-grade KOH and KCN and double-distilled water. Gold solutions were obtained by dissolving gold powder (99.9%) in alkaline cyanide; solutions of other metals (Cu, Ag, Ni, Pb) were prepared from their nitrate salts. pH and cyanide determinations were obtained using an Orion Digital pH meter Model 401 with glass pH and cyanide specific electrodes, respectively.

A PAR potentiostat Model 371, programmer Model 175, and coulometer Model 379, and a Houston Instruments Omnigraphic 2000 XY recorder were used for the LSV and reactor measurements. A sweep rate of $10 \text{ mV} \cdot \text{s}^{-1}$ was used. A rotating disk electrode (Astra Scientific International, Incorporated) was also used. The glassy carbon electrode for the rotating disk had a diameter of 2 mm.

¹ Manufacturer's data based on total volume.

² All potentials are reported vs. the SHE.

A porous flow-through electrochemical reactor was used to compare actual metal recoveries at various potentials with potential sweep measurements. The cell shown in Fig. 1 was constructed of Pyrex and contained a platinum current feeder and anode. The cathode bed, consisting of the porous graphite felt previously described, was 3.1 cm diam and 2.3 cm deep. A saturated calomel reference electrode, housed in a Luggin capillary with the tip 2 mm from the bed, was placed upstream of the carbon fiber electrode. This arrangement restricted the maximum bed potential to prevent hydrogen evolution.

The electrolyte flow rate was controlled by gravity feed and was monitored at the cell outlet. A flow rate of $15 \text{ ml} \cdot \text{min}^{-1}$ was used, and no channeling was observed at this rate. Gold, silver, and copper were determined by neutron activation analysis, and nickel was determined by polarography.

Results and Discussion

Effect of oxygen.—A steady-state linear potential sweep of a 0.025M KOH solution is shown in Fig. 2a. Curve a is the potential profile of the solution after purging the solution with nitrogen for 5 min. There is evidence of two small cathodic peaks at -0.22 and -0.8V . Curve b is the potential profile of the first scan after the solution had been oxygenated for 5 min. The two peaks are much more prominent in curve b and were thought to belong to the reduction of residual oxygen. The first peak at -0.2V in the deoxygenated solution and -0.34V in the oxygenated solution most likely corresponds to the reaction (7, 8)

The shift in the start of the peak from about -0.075 to $+0.13 \text{V}$ would correspond to a 2.9×10^3 change in oxygen concentration. Gordienko and Antropov (9) found the first peak at -0.24V on Fe electrodes and identified it as HO_2^- formation. The second peak has been noted by a number of workers (11-13) and identified as the reduction of the $\text{O}_{2\text{-ads}}$ species or direct O_2 reduction.

Reactions involving either two or four electron pathways have been suggested in the literature (9, 10, 14, 16-18) to account for the reaction.

Effect of cyanide.—In Fig. 2b, steady-state potentiodynamic profiles are shown for cyanide and cyanate

additions to the alkaline electrolyte. At 0.01M KCN, little change is noted in the cathodic portion of the sweep. The anodic portion of the sweep shows an oxidation reaction which begins at less positive potentials (0.49V) than in the cyanide-free solution (Fig. 2a, curve a). The reaction normally proposed for cyanide oxidation is that via (19)

This reaction has a reversible potential of $\approx -0.99\text{V}$ for 0.01M KCN + 0.025M KOH + $\approx 10^{-6}\text{M}$ CNO⁻ and would therefore have an unusually large overpotential. Another possibility is that the cyanide depolarizes the oxygen evolution reaction. The rate-determining step for oxygen evolution without cyanide present is

with a transfer coefficient (α_A) of 0.5 (31). One reaction that could depolarize the reaction is

Oxidation of cyanide would then take place by chemical reaction with oxygen or peroxide via

or

The ratio of CN⁻ oxidized to oxygen used still would be 2:1, and the apparent ratio of Faradays of electrons per mol of CN⁻ oxidized would be 2:1, as reported in the literature (20). In Table I, the experimentally measured numbers of faradays per mol of CN⁻ oxidized are presented at various potentials. Since no

* 95% confidence limits.

Each value represents the average of four measurements taken in a sequence of 15 min periods in solutions without deoxygenation. From a 50 ml solution of 0.01M KCN + 0.025M KOH, 2 ml were removed every 15 min. After addition of 1 ml of 10M KOH, the sample was diluted to 50 ml and the CN⁻ concentration recorded.

one-electron reactions could be found to account for the oxidation, the low values of n (i.e., ≤ 2) apparently indicate that some oxidation may be caused by residual oxygen. In order to accommodate the cyanide-specific ion electrode, these measurements had been carried out in an open cell without deoxygenation. If the data are corrected for oxygen solubility ($8.5 \text{ mg} \cdot \text{dm}^{-3}$ at 22°C) (32) assuming that $8.5 \text{ mg} \cdot \text{dm}^{-3} \text{ O}_2$ is available for the decomposition of cyanide in each measurement, then the values of n become 1.40 ± 0.5 , 2.38 ± 0.2 , 1.97 ± 0.8 , and 2.35 ± 0.5 for the potentials 0.542, 0.742, 0.942 and, 1.142V vs. SHE, respectively. These values indicate that the number of faradays per mol of cyanide oxidized by electrolysis is two, as should be expected.

An increase in the cyanide concentration to 0.1M (Fig. 2b, curve b) causes the oxidation reaction to initiate at less positive potentials, as would be predicted from reaction [2]. The increase in cyanide concentration causes the cathodic portion of the sweep to shift $\approx 150 \text{ mV}$ more positive. Depolarization of the hydrogen evolution reaction or reduction of the cyanate ion formed from the previous oxidation cycle could cause this shift. Addition of cyanate (0.1M) to the electrolyte (Fig. 2b, curve c) does show a more pronounced reduction reaction starting at about -0.9V . The reversible potential for reaction [2] in 0.1M $\text{CN}^- + 0.1\text{M CNO}^- + 0.025\text{M OH}^-$ is -0.875V .

The cyanate addition causes the suppression of the oxidation reaction to more positive potentials, which is consistent with the predicted behavior if reaction [2] is operative.

It can be seen that the exponential current rise at the end of the cathodic scans is apparently terminated with the start of a plateau. This feature is apparently the result of gas bubble formation in the porous bed and subsequent blockage of electrode surface area. Depletion of the reactants within the porous bed could also contribute to this behavior.

Effect of gold.—Potential scans for an alkaline cyanide electrolyte (0.1M KCN + 0.025M KOH) with the addition of gold cyanide are shown in Fig. 3a. At a gold concentration of 17.5 ppm (curve a), there is a small shoulder on the curve at about -1.2V . With a more concentrated solution (175 ppm Au), a peak develops. The reversible potentials for the gold plating reaction [7] are -0.796 and -0.737V for 17.5 ppm and 175 ppm Au, respectively (19)

A series of oxidation reactions can be seen in the anodic portions of the scans, indicating the dissolution of gold plated during the cathodic scans. The nature of the dissolution reactions has been discussed elsewhere (21-26). With the addition of 1.0 ppm Pb to the solution (Fig. 3a, curve c), there is a shift in the gold plating reaction to less negative potentials. A large oxidation peak at -0.35V is seen in the scan. This peak is at a potential at which gold dissolution has been found (21, 25, 26). The magnitude of the oxidation peak is greater than the reduction peak, so that additional plating also must occur at potentials more negative than the reduction peak. A potential scan with only Pb (1 ppm) present in the alkaline cyanide solution (0.1M KCN + 0.025M KOH) is shown in Fig. 3b. No major peaks are noted, but in the anodic scan there are two small oxidation peaks, presumably from lead dissolution. Some of the complex behavior of the gold oxidation peak seen in Fig. 3a, curve c is apparently due to the lead oxidation reactions, since evidence of the two lead peaks can be seen in the large oxidation peak (Fig. 3a, curve c).

The reversible potential for lead ion reduction (1 ppm) in uncomplexed form is about -0.3V . Therefore,

the inhibition of the hydrogen evolution reaction is probably the result of plated lead which has a large hydrogen overvoltage. In contrast, the overpotential for cyanide oxidation or oxygen evolution seen in Fig. 3b is slightly reduced with the presence of Pb.

The effect of Pb additions on gold plating in alkaline phosphate solutions has been studied by McIntyre and Peck (6), who reported that Pb and other metals (Hg, Tl, and Bi) caused depolarization of the gold plating reaction by acting as a catalyst in the electrical double layer at the cathode surface. Of these metals with catalytic activity, only Pb was found in the industrial leach solution. An analysis of the industrial solution is given in Appendix 1.

Effect of silver.—Potential scans in alkaline cyanide solution (0.1M KCN + 0.025M KOH), with the addition of Ag, are shown in Fig. 3c. Curve a is the potential scan with a 2.3 ppm Ag content. The plating reaction is not readily distinguished from the background reduction reactions (Fig. 2b, curve b). However, the anodic scan shows the presence of two small oxidation reactions at -0.45 and -0.3V , presumably from the dissolution of Ag plated during the cathodic scan. A tenfold increase in the Ag concentration to 23 ppm (Fig. 3c, curve b) results in the appearance of a distinct reduction peak at -1.05V . Since the silver cyanide reduction reaction has a reversible potential of -0.409V for $\text{CN}^- = 0.1\text{M}$ and $\text{Ag}^+ = 23 \text{ ppm}$, there is a substantial overpotential for the reaction

With the appearance of a silver reduction peak for the larger silver concentration, an increase in the two oxidation peaks would be expected. This is observed in Fig. 3c, curve b. The two peaks merge, forming a larger peak with a maximum at -0.32V .

The addition of 1 ppm Pb to the electrolyte (Fig. 3c, curve c) results in a substantial drop in the overpotential for silver deposition. The plating reaction now begins at about -0.75V . A much larger peak also can be seen in the anodic scan, indicating that more silver is plated in the cathodic scan. It is interesting to note that the silver oxidation reaction also is depolarized by the lead addition and begins at more negative potentials (-0.55V) than the apparent reversible potential (-0.409V). This is probably the consequence of the depletion of the $\text{Ag}(\text{CN})^-$ species during the cathodic scan. There is evidence of a lead oxidation peak (Fig. 3b) in the silver oxidation peak (Fig. 3c, curve c).

Effect of copper.—Copper is found in the industrial leach solution. The possible reduction reactions are

From equilibrium data, $\text{Cu}(\text{CN})_2^-$ should predominate.

At a copper concentration of 600 ppm, the reversible potentials for reactions [9], [10], and [11] are -0.430 , -1.11 , and -1.16V , respectively. In order to check the coordination number for the copper in the cyanide complex, copper nitrate solution was added to a 0.01M KCN solution and the remaining free cyanide determined. The results indicated that 3.9 ± 0.2 mols of cyanide were lost per mol of copper added. This would suggest that the $\text{Cu}(\text{CN})_4^{-3}$ predominates. However, the mechanism for copper cyanide formation given by Miller (27) is

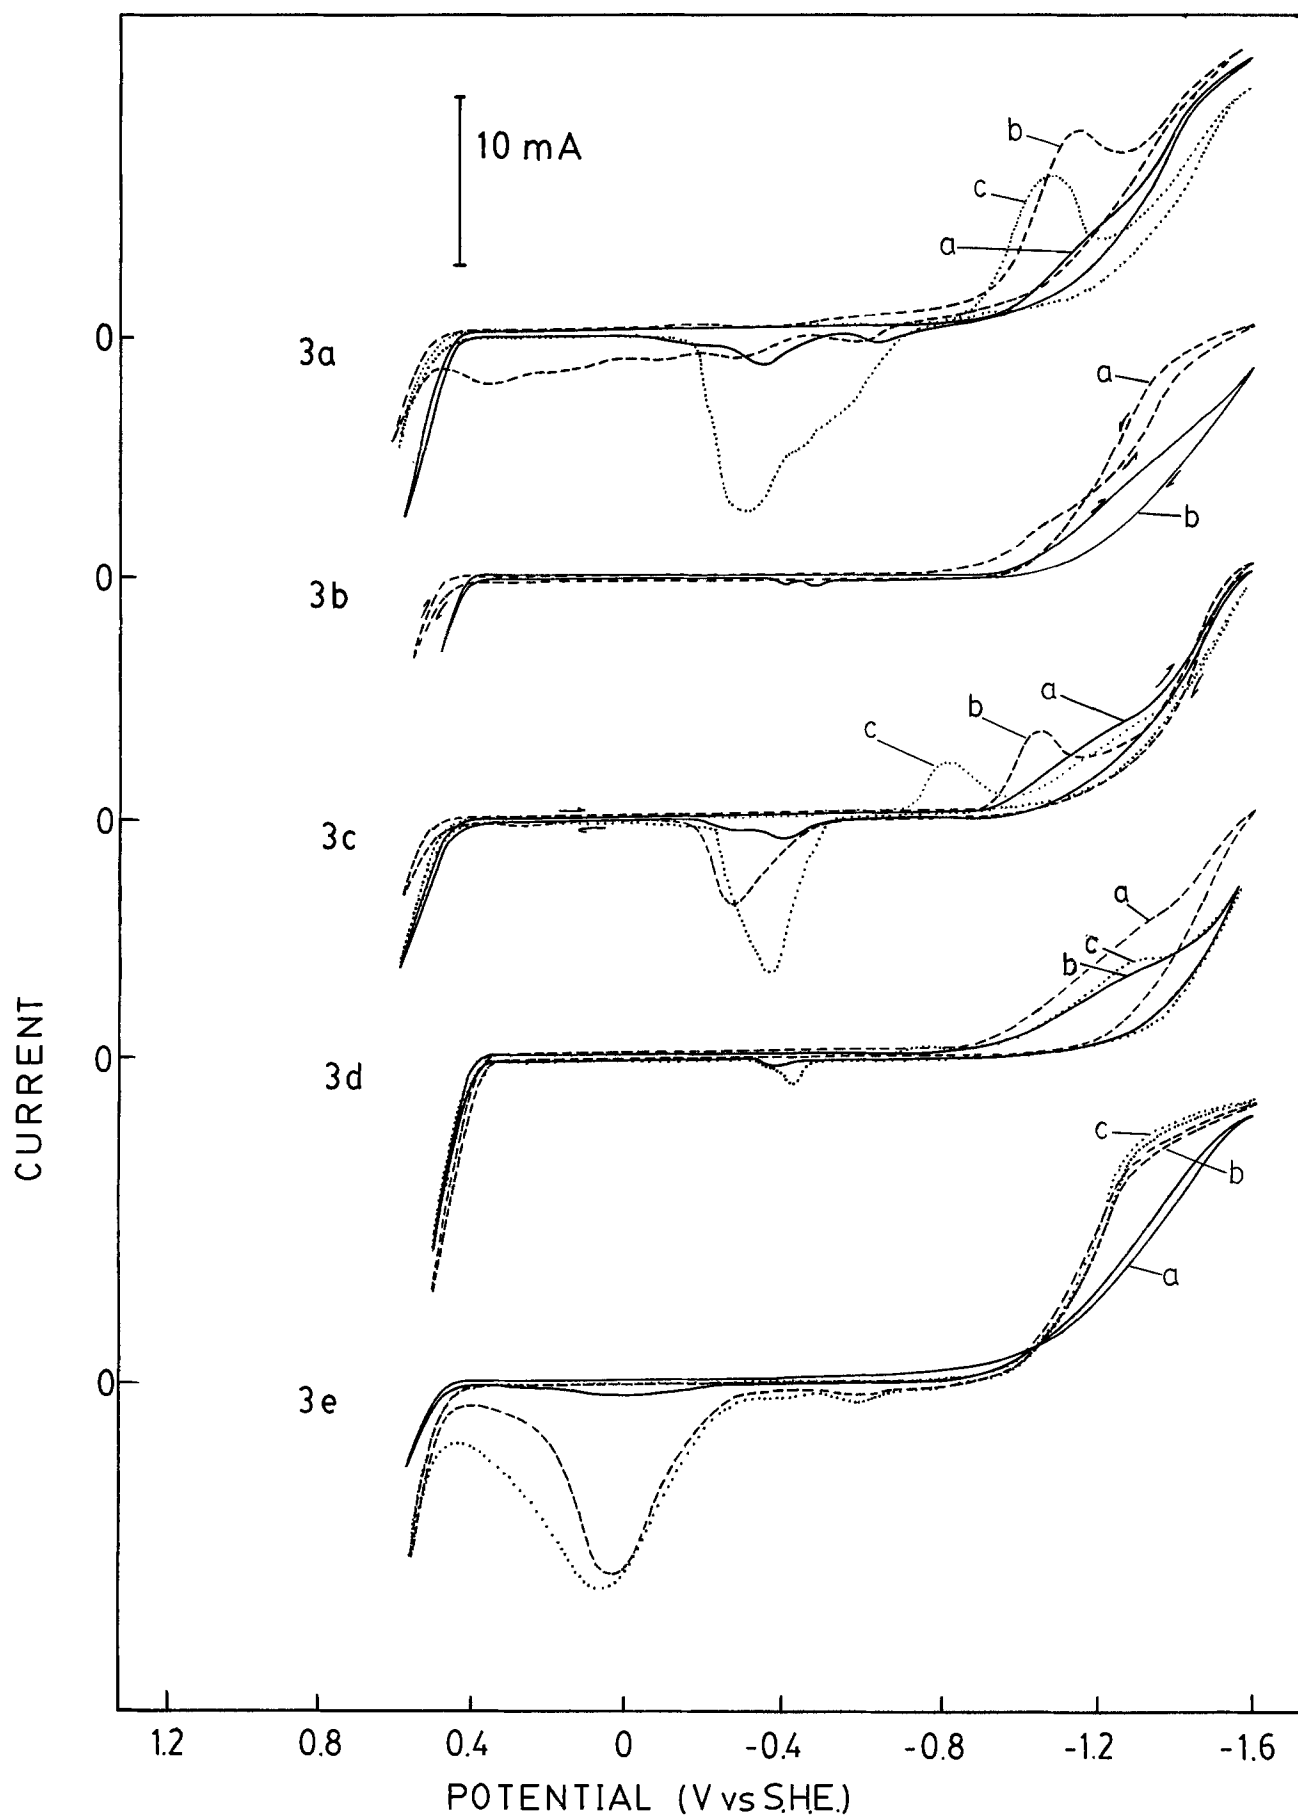

Fig. 3. Steady-state potential sweep profiles of a 0.025M KOH + 0.1M KCN solution at 22°C. Sweep rate: $10 \text{ mV} \cdot \text{s}^{-1}$. 3a: effect of gold. a: 17.5 ppm Au. b: 175 ppm Au. c: 175 ppm Au + 1 ppm Pb. 3b: effect of lead. a: no Pb. b: 1 ppm Pb. 3c: effect of silver. a: 2.3 ppm Ag. b: 23 ppm Ag. c: 23 ppm Ag + 1 ppm Pb. 3d: effect of copper. a: 300 ppm Cu. b: 600 ppm Cu. c: 600 ppm Cu + 1 ppm Pb. 3e: effect of nickel. a: 250 ppm Ni. b: 500 ppm Ni. c: 500 ppm Ni + 1 ppm Pb.

From this reaction sequence, 2.5 mols of free cyanide would be lost per mol of copper added. Since a value of 3.9 was determined, some of the copper must be in a higher oxidation state than $\text{Cu}(\text{CN})_2^-$. Penneman and Jones reported (28) that the principal complex in alkaline cyanide is $\text{Cu}(\text{CN})_3^{2-}$.

Figure 3d, curve a shows the steady-state potential sweep profile for copper containing alkaline cyanide electrolyte (0.025M KOH + 0.1M KCN + 300 ppm Cu). Comparison with Fig. 2a, curve b with the absence of copper reveals that the shoulder observed at -1.4V is smaller with the 300 ppm Cu addition. No oxidation peak is apparent in the anodic scan with the copper present. Both features indicate that copper does not plate under these conditions. In the anodic portion of the scan there is a noticeable depolarization of the anodic oxidation reaction. The reaction begins at about +0.25V, compared with +0.4V with no copper present (Fig. 2a, curve b).

With a copper concentration of 600 ppm (Fig. 3d, curve b), the current in the cathodic portion of the sweep is lowered to a greater extent than with 300 ppm Cu. In this case, however, there is evidence of an oxidation peak at -0.45V, indicating that some plating may have taken place. Only a slight further decrease in the anodic depolarization can be seen with the larger Cu concentration. From these measurements it can be seen that copper inhibits the hydrogen evolution reaction and accelerates the anodic oxidation of cyanide and oxygen evolution. The addition of 1 ppm of Pb to the electrolyte (Fig. 3d, curve c) results in the appearance of a small peak in the cathodic scan at -1.38V. The corresponding anodic scan has an oxidation peak at -0.5V, which overlaps the peak found without the lead addition (-0.45V). With only lead present (Fig. 3b) there is also an oxidation peak at -0.5V, although this smaller than with the copper present. It is not clear to what extent the oxidation peak is due to copper or lead oxidation.

Effect of nickel.—Nickel also is found in the industrial leach solution at a concentration of 250 ppm. A steady-state potential sweep profile is shown in Fig. 3a, curve a for a solution 0.025M KOH + 0.1M KCN + 250 ppm Ni. The Ni addition does not change the current measured at either end of the anodic or cathodic sweeps from the solution without Ni present (Fig. 2a, curve b). However, with nickel present, there is less hysteresis shown at the cathodic end, and there is a small, broad oxidation peak at about 0.0V. This peak is enhanced when the nickel concentration is increased to 500 ppm (curve b). In addition, this peak was observed to be caused by a reduction reaction beginning at about -1.2V. (The cathodic scan limit was terminated at successively less negative potentials until the oxidation peak could no longer be detected.)

If the nickel is assumed to be complexed as $\text{Ni}(\text{CN})_4^{2-}$, then the reversible reduction potential can be calculated from thermodynamic data (30)

For the conditions 0.1M KCN + $8.516 \times 10^{-3}\text{M}$ $\text{Ni}(\text{CN})_4^{2-}$ (600 ppm Ni) $E = -1.07\text{V}$. Therefore, the oxidation peak found at -0.05V could be the oxidation of nickel plated in the previous cathodic scan.

Alternatively, nickel can form an oxidation/reduction couple involving nickel cyanide complexes (19)

The addition of 1 ppm of Pb to the solution (Fig. 3e, curve c) results in only a slight increase in the nickel oxidation peak at -0.05V.

Effect of metal combinations.—A steady-state potential sweep profile is shown in Fig. 4a for a solution 0.025M KOH + 0.1M KCN with 17.5 ppm Au + 2.3 ppm Ag (curve a). Only a single plating peak is observed at about -1.15V, but two overlapping oxidation peaks are at -0.25 and -0.30V. Comparison with the profiles with Au and Ag present individually (Fig. 3a, curve a and Fig. 3c, curve a) reveals that only a few changes occur. The complex nature of the oxidation peak at potentials $\geq -0.4\text{V}$ is enhanced with both Au and Ag present, and the gold oxidation peak at -0.67V (Fig. 3a, curve a) is not observed. These effects could be the result of the sensitivity of the dissolution reactions to changes in surface structure with both Au and Ag plated.

With the addition of 1 ppm Pb to the solution (Fig. 4a, curve b), two reduction peaks now can be found at -0.82 and -1.0V, and the hydrogen evolution reaction is inhibited. The gold and silver plating reactions apparently are independently depolarized and enhanced by the presence of Pb. The first peak at -0.82V corresponds to the silver plating peak in Fig. 3c, curve c, and the second peak at -1.0V corresponds to the gold plating peak in Fig. 3a, curve c. Only a single oxidation peak is found with Pb present.

The effect of copper (300 ppm) on the steady-state potential sweep profile with both silver and gold present in the solution is shown in Fig. 4b, curve a. When compared with Fig. 4a, curve a, this profile reveals that copper also causes the silver and gold plating reactions to be separated and shifted to less negative (less cathodic) potentials. Copper also suppresses the onset of the hydrogen evolution reaction; a shoulder at -1.3V can be seen. The inhibiting effect of copper on the hydrogen evolution reaction was not expected, since without gold and silver present little effect was found (Fig. 3d, curve a). McIntyre and Peck (26) reported that in alkaline phosphate solutions copper did not depolarize gold plating. In contrast, in the alkaline cyanide solution in this study, copper did depolarize both the gold and silver plating reactions. In the anodic scan there is evidence of greater metal plating from the large complex anodic peak at -0.32V. In addition to the gold and silver oxidation, this peak also may contain a contribution from a copper oxidation reaction (Fig. 3c, curve b).

The effect of Ni addition to the steady-state potential sweep profile of the solution with Au, Ag, and Cu present is shown in Fig. 4b, curve b. In this case, some of the depolarizing effect of copper is lost. A single plating peak is seen at -0.88V, and the corresponding oxidation peak at $\sim -0.42\text{V}$ is reduced in magnitude. In addition, the hydrogen evolution reaction is depolarized. In the anodic scan there is an additional oxidation peak at $\sim 0.0\text{V}$, which is found when only nickel is present (Fig. 3e, curve a).

With the addition of 1 ppm of Pb to the combination of Ag + Au + Cu + Ni (Fig. 4c, curve b), the depolarizing effects of Pb on gold and silver plating no longer appear to be present. The hydrogen evolution reactions are only marginally inhibited with nickel present in the solution. There is no evidence that the amount of Au and Ag plated increases with lead addition, as it did in the solution without Ni present (Fig. 4a, curve b).

Thus it appears that the presence of nickel has the most detrimental effect on the recovery of gold and silver of any of the metals studied. There does not appear to be any separation of the gold and silver plating reactions, and the hydrogen evolution reaction is depolarized, increasing the likelihood of low current efficiency. Copper addition, on the other hand, appears to

Fig. 4. Steady-state potential sweep profile of a 0.025M KOH + 0.1M KCN solution at 22°C. Sweep rate: $10 \text{ mV} \cdot \text{s}^{-1}$. 4a: effect of gold and silver. a: 17.5 ppm Au + 2.3 ppm Ag. b: 17.5 ppm Au + 2.3 ppm Ag + 1 ppm Pb. 4b: effect of gold and silver with copper and nickel. a: 17.5 ppm Au + 2.3 ppm Au + 300 ppm Cu. b: solution a + 250 ppm Ni. 4c: effect of metal combinations with and without lead. a: 17.5 ppm Au + 2.3 ppm Ag + 300 ppm Cu + 250 ppm Ni. b: solution a + 1 ppm Pb.

allow separation of the gold and silver plating peaks while inhibiting the hydrogen evolution reaction. The copper effects are masked by the presence of nickel. Lead has been shown to depolarize gold and silver plating reactions in alkaline cyanide as well as inhibit hydrogen evolution. Lead also enhances the separation of gold and silver plating peaks in potential scan measurements. The presence of nickel, however, eliminates the catalytic effects of lead.

Industrial solutions.—A steady-state potential sweep profile for an industrial leach solution is shown in Fig. 5. The solution composition is given in Appendix 1. The profile shows a single reduction peak at about -0.95V , which is most likely a mixed gold and silver plating reaction. The reaction begins at more negative

potentials than in the synthetic solution (Fig. 4c, curve b), and hydrogen evolution begins at less negative potentials. Thus, separation difficulties or poor current efficiencies might be expected for gold and silver recovery with potentials more negative than -1.0V . An anodic peak is seen at about -0.38V , and is characteristic of the gold and silver dissolution reaction found in the synthetic solutions. Another oxidation reaction is found beginning at about 0.0V . This corresponds to the nickel oxidation reaction observed in Fig. 3c starting at potentials near 0.0V . The reaction is irreversible, since no corresponding reduction peak could be found. A rotating glassy carbon disk electrode (2 mm diam) was also used to test the industrial leach solution. A single reduction wave was found beginning at -0.72

Fig. 5. Steady-state potential sweep profile of an industrial leach solution at 22°C. Sweep rate: $10 \text{ mV} \cdot \text{s}^{-1}$. Composition given in Appendix 1, cyanide concentration adjusted to 0.1M.

and leveling off at -0.86 V for a sweep rate of $10 \text{ mV} \cdot \text{s}^{-1}$.

At a sweep rate of $20 \text{ mV} \cdot \text{s}^{-1}$ and a rotation speed of 1000 rpm, the first sweep potential profiles were recorded with successive increments of gold (11 ppm units). The current measured at -0.76 V in the rotating disk measurements (corresponding to the plateau seen in Fig. 5) increased linearly with gold concentration.

The same procedure was followed with silver doping of the industrial leach solution with 10 ppm Ag increments. A shoulder, which was slightly better resolved at slower sweep rates ($5 \text{ mV} \cdot \text{s}^{-1}$), was found at -0.66 V in the potential sweep measurements. Although the currents at -0.66 V increased linearly with silver concentration, there was no well-defined limiting current region.

With copper additions of 200 ppm increments to the leach solution, the currents at potentials $\leq -1.36 \text{ V}$ increased with copper concentration, but there was no evidence of a peak or shoulder for copper plating. However, in the anodic scans, an oxidation peak was found at $+0.22 \text{ V}$, which increased with copper concentration.

The rotating disk measurements have better mass-transfer rates and more uniform potentials at the working electrode surface than do the graphite felt electrodes, so that the peak potentials tend to be closer to the reversible values. Thus, the plating peak found using the industrial leach solution is at -0.95 V for the porous carbon electrode and -0.86 V for the rotating disk electrode. Measurements using porous flow-through electrodes should correspond more closely to measurements using the porous carbon electrode.

Experiments also were conducted to determine the composition and extent of recovery at various potentials. These measurements were undertaken as a preliminary investigation of the behavior of the use of a porous flow-through reactor for metal recovery. Although the conditions for metal recovery were different than the conditions used in potential sweep measurements, the reactor used the graphite felt as a porous flow-through cathode. Diffusional limitations did not appear to be a significant factor in the work. A de-

scription of the reactor has been given in the experimental section.

The percentage of copper, gold, nickel, and silver recovered from the industrial leach solution is shown as a function of cathode potential in Fig. 6. It is clear from Fig. 6 that silver is efficiently recovered at potentials $\leq -0.66 \text{ V}$. The reduction peak found for silver in the potential scans is the result of silver deposition. The single reduction peak in the potential sweep measurements for the industrial leach solution indicates that the gold and silver reduction reactions were not well separated. This behavior is supported by the results of Fig. 6. Although not efficiently recovered, gold is partially removed from the electrolyte at -0.66 V .

Fig. 6. Percent metal recovery from industrial leach solutions at various potentials. Flow rate: $15 \text{ ml} \cdot \text{min}^{-1}$, $T = 22.5^\circ \pm 1.5^\circ \text{C}$.

Some copper (14.5%) was also removed, although there is little evidence for copper ion reduction at potentials $\leq -1.36\text{V}$ in the potential scan measurements.

There are two possibilities for the unexpected copper recovery. One is that the metals codeposit and that the earlier evidence for copper deposition was hidden in the silver and gold peaks. It is known that copper contamination in gold plating baths results in codeposition Andreeva *et al.* (33) showed that with copper present in gold cyanide solutions, the gold overpotential increases and at the same time the copper overpotential decreases. Zur and Ariel (34) reported that the presence of copper in acid chloride solutions caused a lowering of gold recovery efficiency from 90% to $\leq 60\%$ with their porous electrode reactor. In our work, both gold and silver were recovered efficiently over a large potential region, but the recovered metal contained a large copper content. The mass ratio of Cu: Au in the industrial electrolyte is so great (10:1) that codeposition might be expected. The other possibility is that chemical adsorption might account for some of the recovery. Although the effect of chemical adsorption was reduced by allowing the solution to flow through the reactor for a minimum of 5 min before the experiment was commenced, and by operating the reactor at steady state for 30 min, chemical adsorption cannot be ruled out because of the large surface area of the porous electrode. Chemical adsorption might be expected to cause a fairly uniform utilization of the porous bed. However, this was not observed, since the metal distribution in the bed indicated that only the entrance region of the bed had a significant copper content. From Fig. 6, it can be seen that the copper recovery was at best 39.6% and showed only a small increase with potential. The cause of the large variation of percent recovery of copper has not been determined. The gold recovery is high at potentials $\leq -0.86\text{V}$. Thus, the gold reduction peak found in the potential sweep experiments corresponds to a gold plating reaction. The presence of nickel has a pronounced effect on synthetic solutions containing copper, silver, and gold. Although no reduction peak was found in the potential sweep work, an oxidation peak resulting from the prior reduction of nickel at potentials more negative than -1.2V was found. From Fig. 6, it can be seen that even at the most negative potentials (-1.59V) no nickel plating was found. Thus, it would appear that the nickel oxidation peak at -0.05V in the potential sweep work was not from deposited nickel; most likely it was from a reduced nickel cyanide species. It is not clear whether the effect of nickel in polarizing the gold and silver plating reactions and depolarizing the hydrogen evolution reaction is due to monolayer deposition or modification of the double layer. (The analysis for nickel was not sufficiently sensitive to detect monolayer deposition.) However, bulk deposition of nickel can be ruled out.

It was found that potential variation within the bed did not cause the codeposition of copper and gold with silver. The upstream position of the reference electrode caused the largest electrode/solution potential difference to occur in the upstream portion of the bed where 90% of the metal deposition took place. A decreasing potential difference was found with bed depth, so that the potentials shown in Fig. 6 represent the greatest driving force available for plating.

Conclusions

1. Linear scan voltammetry measurements show that metal ion interactions play a significant role in the behavior of alkaline cyanide solutions.

2. Lead in low concentrations (1 ppm) acts as a depolarizer for both silver and gold plating in alkaline cyanide. Lead also inhibits hydrogen evolution. The catalytic action of lead is not effective with nickel in the solution (250 ppm).

3. Copper (300 ppm) can act as a depolarizer for both silver and gold plating reactions in alkaline cyanide solutions. Hydrogen evolution is inhibited by copper if gold and silver are also present in the solution. The copper catalytic activity is inhibited by the presence of nickel (250 ppm).

4. Nickel (250 ppm) inhibits both silver and gold plating and depolarizes the hydrogen evolution reaction in alkaline cyanide solutions.

5. Gold and silver can be efficiently recovered from the industrial leach solution even in the presence of nickel. However, copper also codeposits.

Gas Permeation in SPE Method

I. Oxygen Permeation Through Nafion and NEOSEPTA

Z. Ogumi,* Z. Takehara,* and S. Yoshizawa*

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Kyoto, Japan

ABSTRACT

The permeation of oxygen at atmospheric pressure through Nafion® 120 and NEOSEPTA® ACH-45T ion-exchange membranes was investigated by an electrochemical monitoring technique, which utilizes SPE composite electrodes prepared by an electroless plating method. The oxygen diffusion coefficients were almost the same ($\sim 10^{-7} \text{cm}^2 \cdot \text{s}^{-1}$) for each material, but the oxygen solubility was much higher in Nafion than in NEOSEPTA. The oxygen solubility in NEOSEPTA could be explained in terms of dissolution in the aqueous component of the membrane, but the oxygen solubility in Nafion was too high for such an explanation, and was postulated to involve the role of the polytetrafluoroethylene backbone.

Recently, electrolyzers employing solid polymer electrolyte (SPE) have undergone extensive investigation for applications such as water electrolysis (1), brine electrolysis (2), and electro-organic synthesis (3-5). With these SPE methods, the permeation of electrochemically reactive species through the SPE material results in decreases in current efficiency and unwanted side reactions. This has been observed, for example, in electro-organic syntheses using "both-sides" SPE methods (5), in which anodic and cathodic reactions take place on electrodes deposited on both sides of the SPE membrane. Permeation by electrically neutral gases is easier than by ionic species bearing the same charge as the fixed ion of the SPE material because of the smaller size and absence of appreciable electrostatic repulsion in the case of the former. The permeation of diffusant depends strongly on the properties of the ion exchange membrane and on the conditions encountered.

Recent solid-polymer electrolyte fuel cells have received considerable interest as electrochemically regenerative energy storage systems (6). As encountered in electrolyzers, gas permeation through the solid-polymer materials (usually ion-exchange membranes) decreases efficiency of fuel cells.

Because of its high chemical and thermal stability, a perfluorinated sulfonic acid membrane such as Nafion® usually is employed in a solid-polymer electrolyte fuel cell. Perfluorinated ion-exchange membranes also are desirable for use with SPE electrolyzers, although conventional ion-exchange membranes based on a styrene-divinylbenzene copolymer may be applicable to some systems (3).

Nafion is based on a polytetrafluoroethylene backbone with pendant side chains of the form

The structure of Nafion has attracted the interest of many workers and has been the subject of considerable investigation (7). Using low angle x-ray measurements, Yeo and Eisenberg (8, 9) have inferred an ionic cluster model with a Bragg distance of 51Å. This model recently has been improved by Yeager and Steck (10). As mentioned above, permeation through Nafion is important both in fuel cells and in SPE electrolyzers. It is also of interest from the viewpoint of elucidating the peculiar structure of Nafion (7). In this regard, the permeation parameters of hydrogen (11), chlorine (11), and bromine (11, 12) have been investigated. In the present work, the diffusion coefficients and the solubilities of oxygen through Nafion 120 and NEOSEPTA® ACH-45T have been investigated by electrochemical monitoring of diffusion transients using SPE composite electrodes prepared by an electroless plating method (3). The values for the two different membranes are compared and discussed with reference to reported permeation parameter data.

Experimental

Membrane.—Nafion 120, a cation exchange membrane, and NEOSEPTA ACH-45T, an anion exchange membrane, were chosen for this study. These membranes have exchange capacities of 0.83 meq/g and 1.3-2.0 meq/g and thickness of 0.025 cm (unreinforced) and 0.014-0.020 cm (reinforced), respectively. The former is widely used as a chemically and thermally stable membrane with a perfluorosulfonic group and is the product of E. I. du Pont de Nemours and Company (Wilmington, Delaware), and the latter is a typical hydrocarbon anion exchange membrane with a quater-

* Electrochemical Society Active Member.

Key words: gas, diffusion, ion exchange, membrane.

nary ammonium group and the product of Tokuyama Soda Company (Yamaguchi, Japan).

The Nafion 120 membranes were pretreated by soaking in boiling water in the Na^+ form for 30 min. The NEOSEPTA membranes, supplied in the Cl^- form, were converted to the NO_3^- or OH^- form by immersion for more than 12h in 1M NaNO_3 or 0.5M NaOH .

Chemicals.—All chemicals except hydrazine were of reagent grade. Hydrazine was of chemical pure grade. All chemicals were used without further purification. Solutions were prepared with distilled water. Nitrogen was of 99.99% purity and oxygen of 99.6% purity.

Deposition of Pt or Ag on the membranes.—Platinum was deposited on one or both sides of the Nafion using an electroless plating method described previously from chloroplatinic acid solution using hydrazine as a reductant (3). In this method, the reductant diffuses through the membrane, which is set to separate a deposition cell into two compartments of a metal ion solution and of a reductant solution. The reductant diffusing through the membrane reduces the metal ion on the surface of the membrane facing the metal ion solution. NEOSEPTA in the NO_3^- or OH^- form was deposited with Ag by the same method, but on only one side. These prepared SPE composite electrodes are referred to as Pt-Nafion and Ag-NEOSEPTA, respectively.

Electrolysis cell.—The SPE composite electrode was mounted in the cell described schematically in Fig. 1. This cell was separated by the composite into two compartments. The right-hand compartment facing the deposited metal on the composite was filled with 0.5M K_2SO_4 , whereas the left-hand compartment contained prehumidified gas. The electrodes were connected to a potentiostat (Hokuto Denko Model HA-301). The electrode potential was measured against a Ag/AgCl (3.3M KCl) reference electrode positioned in a Luggin capillary. For linear potential sweep voltammetry, a function generator (Hokuto Denko Model HB-104) was connected to the potentiostat, and nitrogen was bubbled through the right-hand compartment throughout the experiment. The temperature of the solution in the right-hand compartment was kept constant by circulating the solution between the cell and the stock tank, which was located in a thermostated bath. The gas temperature was kept constant by flowing the gas through a long copper tube immersed in the constant temperature bath.

Permeation measurements.—The permeation of oxygen through the membrane was monitored using the electrochemical technique used by Yeo *et al.* (11) to

measure the permeation of hydrogen and halogens through Nafion and by Nanis *et al.* (13) and Yoshizawa *et al.* (14) to measure hydrogen permeation through iron.

When oxygen was introduced into the left-hand compartment of the cell in Fig. 1, which was previously filled with nitrogen, oxygen permeated the membrane separating the two compartments. The oxygen permeation rate was monitored electrochemically by the SPE composite electrode bonded to the side of the membrane away from the gas compartment. This was achieved by setting the potential of the bonded electrode at a value at which the incoming oxygen was reduced under mass-transfer-limited conditions. All measurements were carried out at atmospheric pressure.

Results

E-i relationships.—Figure 2 shows the results from a set of linear potential sweep experiments on Pt-Nafion. Curve a was obtained using 100% nitrogen and curve b using 100% oxygen. Despite the very slow sweep rate of $5 \text{ mV} \cdot \text{s}^{-1}$, at $-0.1 \text{ V vs. Ag}/\text{AgCl}$, a small current peak is observed that corresponds to the reduction of the oxygen permeating through the membrane. A comparison of curve b with curve a shows that oxygen is reduced under mass-transfer limiting conditions below $-0.05 \text{ V vs. Ag}/\text{AgCl}$. The mass transfer is here controlled by the diffusion through the membrane. Similar E-i curves were obtained using Ag-NEOSEPTA.

Although the actual mechanism of oxygen reduction on SPE composite electrodes is a complex problem, it has been assumed that the overall reduction on Pt-Nafion and on Ag-NEOSEPTA takes place according to the four-electron reduction process. It is reasonable to assume that oxygen ultimately is reduced to water on Pt and Ag electrodes on SPE composites since the metals are deposited in a manner similar to that of Pt blacks (3) and are known to be very active catalysts for the decomposition of any peroxides that might be formed as intermediates (15). This will be discussed in more detail in a subsequent paper (16). In all the experiments of the present work, therefore, the potential of the SPE composite electrode was set at $-0.25 \text{ V vs. Ag}/\text{AgCl}$ in order to reduce oxygen under diffusion limiting conditions. The steady-state reduction current was assumed to be proportional to the oxygen content of the gas in the left-hand compartment of the cell.

Oxygen permeation results.—The oxygen permeation transients observed as reduction currents reflect diffusion under a well-defined set of initial and boundary conditions. These conditions can be described in terms of the variation with time (t) of the oxygen concentration (c) at any distance (x) from the left-hand side

Fig. 1. Schematic diagram of an electrolysis cell fitted with a one-side SPE composite. a: SPE composite. b: working electrode on SPE composite. c: counterelectrode. d: Ag/AgCl reference electrode. e: gas compartment. f: 0.5M K_2SO_4 .

Fig. 2. E-i curves on Pt-Nafion. Sweep rate: $5 \text{ mV} \cdot \text{s}^{-1}$. Curve a: nitrogen. Curve b: oxygen in the gas compartment, 0.5M K_2SO_4 in the right compartment.

of the membrane, which has a thickness (l). Assuming the stepwise introduction of oxygen into the left-hand compartment at time $t = 0$ and that the dissolved oxygen concentration at the input side of the membrane instantaneously achieves and maintains the constant value (c_0), then

$$c = c_0; x = 0; t \geq 0 \quad [1]$$

Since oxygen arriving at the right-hand side (*i.e.*, at the electrode on the SPE composite) is reduced quantitatively to water, then

$$c = 0; x = l; t \geq 0 \quad [2]$$

Prior to the introduction of oxygen, the membrane contacts 100% pure nitrogen gas and nitrogen-saturated 0.5M K_2SO_4 , so that the initial condition is

$$c = 0; 0 < x < l; t = 0 \quad [3]$$

Fick's second law (Eq. [4]) is applicable and can be solved under the conditions set by Eq. [1]-[3] by the use of Laplace and Fourier transformations

$$\frac{\partial c}{\partial t} = D \frac{\partial^2 c}{\partial x^2} \quad [4]$$

The oxygen diffusion flux (J) is described by Fick's first law

$$J = -D \frac{\partial c}{\partial x} \quad [5]$$

Solving the above equations yields the flux (J_t) at $x = l$ and time t in terms of the dimensionless form (J_t/J_∞) *vs.* τ , the reduced dimensionless time

$$J_t/J_\infty = (2/\sqrt{\pi\tau}) \cdot \exp(-1/4\tau) \quad [6]$$

where

$$\tau = Dt/l^2 \quad [7]$$

D is the diffusion coefficient, and J_∞ is the steady-state flux at $t \rightarrow \infty$. The numerically obtained theoretical curve of (J_t/J_∞) *vs.* τ is plotted as the solid line in Fig. 3.

Under steady-state diffusion conditions, a linear concentration gradient is established through the membrane and the flux can be expressed in terms of the steady-state current density i_∞

$$i_\infty = \frac{nFDc_0}{l} \quad [8]$$

where n assumed to be 4, is the number of mols of electrons consumed per mol of oxygen reduced at the monitoring electrode on the SPE. A plot of J_t/J_∞ ($=i_t/i_\infty$) against time (t) should fit with the theoretical curve of Fig. 3. The selection arbitrarily of one point from the curve leads directly to the value of D through Eq. [7]. For example, $J_t/J_\infty = i_t/i_\infty = 1/2$ corresponds to $\tau = 0.138$ from Eq. [6] or from the theoretical curve of Fig. 3. Using Eq. [7]

$$D = 0.138 \cdot l^2/t_{1/2} \quad [9]$$

where $t_{1/2}$ is the time at which (i_t/i_∞) becomes 1/2 on the experimentally obtained plot of (i_t/i_∞) *vs.* t . The closeness of the fit of the experimental transient curve with the theoretical curve is a measure of the extent to which the diffusional behavior of the system agrees with the postulated model. The fit also tests the experimental results. As an example, the broken "build-up" curve in Fig. 3 shows one set of experimental results obtained for the transient permeation behavior of oxygen through Pt-Nafion at 25°C.

The steady-state permeation rate (i_∞) can be directly measured, and c_0 can be calculated from Eq. [8] using the D value obtained from the transient measurement.

An analogous theoretical analysis can be made for the stepwise change of the gas composition in the left-hand compartment from oxygen to nitrogen. Since in this case the current decreases with time, the curve is called a "decay" curve (as opposed to the previous case, in which the curve resulting from the introduction of oxygen was termed a "buildup" curve). The theoretical decay curve also was calculated and is shown in Fig. 3. The experimental results show good agreement with both the buildup and decay curves. The current was corrected for the inevitable residual current ($\sim 10 \mu A$) shown in Fig. 2, which was measured before and after all experiments and stayed small and almost constant during each measurement.

Table I summarizes the results of permeation measurements on Pt-Nafion and Ag-NEOSEPTA. It can be seen that the oxygen diffusion coefficients are almost identical in both membranes. The oxygen solubility, however, is remarkably higher in Pt-Nafion than in Ag-NEOSEPTA. Figure 4 shows the Arrhenius plot for the oxygen diffusion coefficient in Pt-Nafion when the right-hand compartment contained 0.5M K_2SO_4 solution and the left-hand compartment contained prehumidified oxygen gas. Analysis of the re-

Table I. Permeation parameter of oxygen through Nafion and NEOSEPTA ACH-45T

Membrane	Temp °C	$J_{\infty} \times 10^6$ A · cm ⁻²	$t_{1/2}$ s	$D \times 10^7$ cm ² · s ⁻¹	$c_0 \times 10^8$ M
Nafion	20	26.7	355	2.4	7.20
	30	28.6	295	2.9	6.50
	40	36.7	193	4.4	5.30
	50	46.8	197	5.2	5.90
NEOSEPTA	25	4.7	131	2.4	0.77

sults shows that

$$D = 3.1 \times 10^{-3} \exp(-5500 \pm 120/RT) \text{ cm}^2 \cdot \text{s}^{-1} \quad [10]$$

where $R = 1.987 \text{ cal} \cdot \text{mol}^{-1} \cdot \text{deg}^{-1}$ and T is absolute temperature. The diffusion coefficient was found to be dependent on the sample number and pretreatment history of the Nafion, which will be discussed in detail in a subsequent paper; the oxygen solubility was almost independent of the sample and pretreatment.

Discussion

E-i relationships.—Even at the very slow sweep rate of $5 \text{ mV} \cdot \text{s}^{-1}$, a small peak was observed in the oxygen voltammogram in Fig. 2. This reflects the very small diffusion coefficient of $10^{-7} \text{ cm}^2 \cdot \text{s}^{-1}$ (discussed below) and the formation of a stable diffusion layer that must be inside the membrane. At faster sweep rates, very large double layer charging currents were observed that can be ascribed to very large active surface areas of the SPE composite electrodes. Ag-NEOSEPTA was stable for more than 50h during the permeation measurements. Since stable peroxides would very readily attack NEOSEPTA ACH-45T membranes, this supports the assumption that peroxides are not formed as intermediates during the oxygen reduction, or, if formed, are rapidly decomposed. This confirms that oxygen is totally reduced on the electrode to water by the four-electron process.

Oxygen permeation.—The good agreement of the experimental curves with the theoretical curves over the complete range of values confirms that the permeation obeys the postulated ideal diffusion behavior and that the deposition of metals on the membrane does not disturb the ideal diffusional conditions.

Table II summarizes some diffusion coefficients and solubilities of oxygen and a number of other species in

Fig. 4. Arrhenius plot for oxygen diffusion coefficient through Pt-Nafion in $0.5M \text{ K}_2\text{SO}_4$.

	9.5M NaOH	60	—	—	—

several media that are relevant to Nafion and NEOSEPTA ACH-45T. The oxygen diffusion coefficients shown in Table I for Pt-Nafion and Ag-NEOSEPTA, which are almost equal in value, are reasonable when compared with the values in Table II for chlorine (11) and bromine (12) through Nafion, although the values are two orders of magnitude smaller than the corresponding values in water (17).

The activation energy for the diffusion of oxygen through Nafion has been determined to be about $5500 \text{ cal} \cdot \text{mol}^{-1}$ (see Fig. 4). This value appears reasonable in view of the values of $5170 \text{ cal} \cdot \text{mol}^{-1}$ for hydrogen through Nafion and $5560 \text{ cal} \cdot \text{mol}^{-1}$ for chlorine through Nafion determined by Yeo and McBreen (11).

The relatively low oxygen solubility in Ag-NEOSEPTA is easily explained by the dissolution of the gas in the aqueous portion of the membrane when the volume of the hydrocarbon backbone and the high concentration of the electrolyte in the membrane are taken into consideration. However, the oxygen solubility in Pt-Nafion was found to be much higher than in Ag-NEOSEPTA. The structure of Nafion is much different from NEOSEPTA, a usual hydrocarbon ion exchange membrane. In their model, Yeager and Steck divided Nafion into three regions, a hydrophobic PTFE backbone region, a hydrophilic aqueous region, and an intermediate region (10). They concluded the aqueous region as almost the same as an aqueous solution of high concentration. Adopting their model, we see that this high solubility cannot be borne by the aqueous part of the Nafion on account of the very low solubility of oxygen in water or in aqueous solution (17). Additionally, changing cation from K^+ to Na^+ scarcely caused the change of the solubility. As indicated in Table II, oxygen is, however, highly soluble in some hydrophobic solvent, e.g., benzene or fluorinated solvents (18). The solubilities and permeabilities of several gases through polytetrafluoroethylene (PTFE) have been investigated using gold and platinum metallized thin PTFE membranes (19, 20). The data for oxygen are included in Table II. Yeo *et al.* (11) and Will (12) seem to have considered that the diffusants dissolve in the aqueous portion of Nafion. Although this explanation is sufficient to explain the solubilities of chlorine and bromine in Nafion, the solubilities of hydrogen, determined by Yeo *et al.* and of oxygen, from the present work, are too high to be explained on this basis. The high solubilities indicate a specific interaction between the PTFE backbone of Nafion and the hydrogen and oxygen, thus resulting in some special influence of the PTFE backbone on the gas permeation characteristics of Nafion. The influence of the PTFE backbone should appear in both hydrophobic and intermediate regions of Nafion in the model by Yeager and Yeo. The details of these effects are being investigated.

Summary

The permeation of oxygen through Nafion 120, a cation-exchange membrane of the perfluorinated sul-

ionic acid type, and through NEOSEPTA ACH-45T, an anion-exchange membrane of styrene-divinylbenzene copolymer, was investigated by an electrochemical monitoring technique using SPE composite electrodes. While the oxygen diffusion coefficients of both membranes were quite similar, the oxygen solubility was much higher in Nafion than in NEOSEPTA. The higher value in Nafion cannot be explained in terms of dissolution of the gas in the aqueous part of the membrane. Instead, specific interaction between oxygen and hydrophobic backbone in Nafion is inferred.

Acknowledgments

Special thanks are due to Professor F. Foulkes, visiting professor from the University of Toronto, for his helpful discussions. The authors also wish to thank E. I. du Pont de Nemours and Company and the Tokuyama Soda Company for providing membrane samples.

Kolbe Electrolysis of Mixtures of Aliphatic Organic Acids

P. F. Levy, J. E. Sanderson, and L. K. Cheng

Dynatech R/D Company, Cambridge, Massachusetts 02139

ABSTRACT

Kolbe electrolysis of mixtures of n-butanoic with n-hexanoic acid and propanoic with n-hexanoic acid have been performed in aqueous solution at a smooth platinum anode. Typically, hexane production by the oxidation of butanoic acid, or butane production from propanoic acid, in aqueous solution is not observed to exceed a few percent. In the current work, significant increases of these products were observed. In addition, a substantial fraction of the remaining C₃ or C₄ acids reacted were converted to mixed alkane dimers with hexanoic acid. These results are interpreted by a model in which n-hexanoic acid and its various oxidation products form a lipophilic layer at the anode surface which provides an environment where further oxidation to carbonium ions is disfavored. This model has been suggested previously to explain pressure effects on Kolbe electrolysis (1). This observation supports the feasibility of producing mixed linear alkanes for use as fuels and chemicals from mixed organic acids which may be produced by anaerobic fermentation of organic matter.

The Kolbe reaction, decarboxylation and dimerization of aliphatic carboxylic acids, has been observed to occur at smooth platinum anodes (2, 3) following the stoichiometry

Hofer and Moest (4) described the electrolytic oxidation of organic acids to produce alcohols

a reaction which is prevalent at carbon anodes (5). Production of side products has been observed to accompany alcohol and dimer formation. The primary side product is usually olefin

where R' and R'' are either hydrogen or organic radicals. Other side products include esters, nondimerized alkanes, and cyclopropane derivatives (3, 6). Oxygen can also be produced when the reactant is carried out in aqueous solution, particularly at low current densities.

The production of dimeric alkane (Kolbe) product predominates when the reaction is carried out at smooth platinum anodes with acetic and fatty acids containing at least six carbon atoms. Reported yields of Kolbe product from propanoic acid are only a few percent and n-butanoic only slightly higher (5, 7). This paper reports increased yields of dimer product from propanoic and n-butanoic acids in mixtures with n-hexanoic acid. A model is suggested to explain these results. Effects seen due to changing current density, temperature, liquid flow rate, and reactant concentration are consistent with the suggested model.

Experimental

The details of the experimental electrolysis system used in this study are described in a previous paper (1). Briefly, the system shown in Fig. 1 consists of a flow-through electrolytic cell (ECO, Incorporated) modified and reinforced to allow it to be operated at elevated pressure, a 1 liter liquid reservoir, pump, power supply, and condenser. Product gas collection

Fig. 1. Diagram of integrated electrolysis system.

is accomplished by liquid displacement. The anode is a platinum foil sheet and cathode is stainless steel. The electrodes are separated by a pressed fiber gasket giving an electrode spacing of approximately 0.15 mm. The exposed internal surface area of the electrodes is either 36.0 or 7.33 cm².

All products (gaseous, water immiscible, and water soluble) are separated and quantified by gas chromatography. All reagents were reagent-grade materials obtained from major supply houses and were used without purification. In all experiments, 0.5M sodium sulfate was used as a supporting electrolyte. The pH of the solution was adjusted to 7.0 with sodium hydroxide at the start of each experiment.

Results

Experiments were run in which mixtures of various concentrations of butanoic and hexanoic or propanoic and hexanoic acids were reacted, temperature was varied in the reaction of butanoic or pentanoic acid, and flow rate, concentration, or current density was varied in the reaction of pentanoic acid.

In the tabulation of the results of these experiments, the product distributions are reported as percent of organic acid reactant converted to each product based on the total amount of that organic acid reacted in the experiment. In each experiment reported, hydrogen is recovered accounting for the total current supplied. Material balances indicated in the results show the percentage of anode product recovered compared to the total current supplied.

Mixtures of butanoic and hexanoic acids were electrolytically oxidized on a platinum anode. The initial pH in all these experiments was 7.0 and the final pH was 9.0 (± 0.3). The yield of butanoic acid products

is shown in Table I. The yield of coupled products formed entirely or partially from 0.7M butanoic acid (n-hexane and n-octane) increases as the initial concentration of hexanoic acid increases, up to 0.35M, as seen in Fig. 2. The ratio of butanoic to hexanoic acid reacted in these experiments is observed to decrease as hexanoic acid concentration is increased (Fig. 3). This ratio can be normalized as indicated in the figure, and the normalized ratio of acids reacted is approximately 1/3 (butanoic/hexanoic) at all hexanoic acid concentrations above 0.35M. In the same set of experiments, the formation of coupled products from hexanoic acid (n-octane and n-decane) in the presence of 0.7M butanoic acid follows a similar pattern to that observed for butanoic acid when examined as a function of hexanoic acid concentration (Fig. 4).

An analogous increase in the formation of coupled products (butane and heptane) from propanoic acid was seen when hexanoic acid was added to the electrolysis solution (Table II). In these experiments the normalized ratio of propanoic/hexanoic acid reacted is 1/6.25.

The effects of temperature, current density, concentration, and liquid flow rate were observed in electrolysis solutions containing a single reacting organic acid (butanoic or pentanoic). The results in general are consistent with other studies of these variables (6). Table III shows an increase in alcohol formation at increased temperature. Table IV shows a decrease in dimer formation with decreasing flow rate (Runs 158, 164, and 166). At a relatively low flow rate, an increase in organic acid concentration restores dimer formation to that seen at high flow rates (Runs 166, 167, and 168). An effect on the product distribution is observed for current densities below 0.27 A/cm² (Fig.

5). As the current density decreases, products requiring a two-electron oxidation are favored. At current densities below 0.13 A/cm^2 a significant increase in production of O_2 from water is observed.

Discussion and Conclusions

Conditions favoring production of coupled products from propanoic, butanoic, and pentanoic acids have been reported. These conditions include the presence of hexanoic acid, current densities above 0.27 A/cm^2 , low temperature, high liquid flow rate, and high reacting organic acid concentrations. Earlier work demonstrated increased yields of coupled products at elevated reactor pressures (1).

The hypothesis suggested in our earlier paper (1), that coupled product yield is increased by improving the integrity of a lipophilic layer at the electrode surface, is further supported by the experimental results presented in this paper. The influence of hexanoic acid on the products formed from butanoic acid is interpreted to be caused by the formation of a lipophilic layer comprised of hexanoic acid, its electrolysis prod-

Fig. 3. Ratio of butanoic to hexanoic acid reacted as a function of hexanoic acid concentration in the mixture.

ucts, and intermediates. The existence of this layer is most strongly supported by the ratio of butanoic/hexanoic acid reacted in the mixed acid experiments. The normalized ratio of 1/3 (Fig. 3) suggests a higher partition coefficient for hexanoic acid than butanoic acid into the lipophilic layer. Observation of a lower normalized ratio between propanoic and hexanoic acids is consistent with the relative partition coefficients of these acids between aqueous and organic solvents.

If it is the influence of the lipophilic layer that primarily controls the product distribution rather than properties of the reacting acids themselves, then the formation of coupled products in the mixed acid runs should be governed by a mass action statistical distribution. The formation of coupled products from two reacting organic acids can be represented by the general equation

Fig. 4. Yield of dimeric alkane products from hexanoic acid in mixtures with butanoic acid.

If " r " is defined as the ratio of the organic acids reacted (a/b), then the statistical distribution of coupled products formed is

$$R_1 - R_1 = r^2$$

$$R_1 - R_2 = 2r \quad [5]$$

and

$$R_2 - R_2 = 1$$

This interpretation is applied to results from the mixed acid experiments in Table V. Expected product distributions are calculated from the ratio of butanoic to

Fig. 5. Yield of products from pentanoic acid as a function of current density.

hexanoic acid reacted and compared with experimentally observed product distributions. In the presence of greater than 0.3M hexanoic acid, reasonably good agreement is seen between the expected and observed distribution of coupled products. Over a thirty-six fold range of observed ratios, all calculated values agree to within better than a factor of two. Variations from the expected and observed distribution may be due to factors not considered by this simple model such as differences in diffusivity and competing reactions leading to formation of other products.

The extent to which the ratios of dimeric products to cross-coupled products can be explained by a simple statistical model argues against electrochemical control of the product distribution. Perhaps a more powerful argument may be made based on the effect of the mere presence of hexanoic acid, and presumably other

longer chain fatty acids, on the degree of coupling of the short chain acids, which have generally been observed to give very low yields of coupled product. The clearest illustration of the effect may be seen by comparing the results of Runs 147 and 151 listed in Table II. In these experiments, the addition of 1.0M hexanoic acid to the electrolyte solution resulted in an increase in the conversion of propanoic acid to butane from a negligible amount to approximately one-third of the acid reacted, probably the highest butane yield ever observed in aqueous Kolbe electrolysis. One could argue that any increased yields of the cross-coupled products could be a result of the electrochemical behavior of the longer chain acid, but it is difficult to explain the increased yields of short chain dimer by anything but a physical effect of the longer chain acid and its electrolysis products.

Results from the experiments which varied temperature, current density, flow rate, and concentration may be interpreted as being supportive of the hypothesis of control of product distribution by a lipophilic layer. As the integrity of the layer is disrupted by increased temperature (volatilization of olefin products), local depletion of reacting organic acid (seen at low flow rate and low bulk concentration), or lowered current density allowing infiltration of water, the formation of dimeric (noncarbonium ion) products is decreased. This explanation is consistent with the effect of reactor pressure on the product distribution reported previously (1).

The ability to improve alkane (coupled product) yields for C₃ to C₅ acids in Kolbe electrolysis has potential practical applications in conversion of dilute

aqueous solutions of organic acids to hydrocarbons. Particularly in the conversion of mixed organic acids obtained from the fermentation of polysaccharides, substantial yields of coupled alkane products can be obtained from C₃ to C₆ acids, providing a sufficient concentration (0.35M) of hexanoic acid is maintained or, as previously shown (1), if the reaction is carried out under pressure.

Voltammetric and XPS Analysis of Metal-Complexed Polytyramine Films : Geometry-Dependent Electron Transfer Therein

Minh-Chau Pham, Pierre-Camille Lacaze, and Jacques-Emile Dubois

Institut de Topologie et de Dynamique des Systèmes de l'Université Paris VII, associé au CNRS, 75005 Paris, France

ABSTRACT

Electrodes coated with redox polymers are prepared by coordinating various metal ions with ligands from polytyramine films. The nature of the cation determines the geometry of the metal-polymer complex and hence the voltammetric behavior of the coatings. Electron transfer between adjacent pairs of redox centers inside the film can occur with a four-coordinate structure, but not with a penta- or hexacoordinate structure.

Various methods have been used to bind transition metal complexes to ligand containing polymers (1-8). Recent studies in this field deal with the variations in the electrochemical responses of electrodes coated with metal-complexed films (9-12).

Our previous study on the preparation and analysis of polyquinolinol films coordinated with Cu(II) or Co(II) ions indicates that the electrical and electrochemical properties of these electroactive electrodes depend on the geometry of these metal-complexed films (12). We report herein the XPS and voltammetric analysis of metal complexed films formed by coordinating Cu(II), Co(II), Fe(II), Zn(II), or Mn(II) ions with ligands from polytyramine films. Like our results for metal complexed polyquinolinol films (12), our results on metal-complexed polytyramine films indicate that their electrochemical behavior, as well as the electron transfer mechanism therein, depends on the nature of the cation which determines the complex geometry.

Experimental

Only commercial reagents were used. The tyramine was from Aldrich. All of the chlorides (CuCl₂, 2H₂O;

CoCl₂, 6H₂O; ZnCl₂, MnCl₂, 4H₂O; FeCl₂, 4H₂O) were from Prolabo (R. P. Normapur); CH₃COOH and CF₃COONa from Aldrich; and LiClO₄ from Fluka. The methanol was a Baker analyzed reagent. The de-ionized water was distilled twice in a quartz apparatus.

Electrochemical experiments were performed with a PAR 173 potentiostat connected to a PAR 175 programmer. The electrodes were bulk or thin layer Pt, deposited on glass plates by sputtering.

Film identification by x-ray photoelectron spectroscopy (XPS) was conducted on a Vacuum Generators Escalab MKI instrument using unmonochromated MgK_α x-rays.

Multiple reflection IR spectra were recorded on a Model 9 Wilks Scientific Corporation device mounted on a Nicolet 60 SX spectrometer.

Results

Polytyramine film formation.—The preparation and characterization of polytyramine films with a thickness of ca. 50 nm formed by electrochemical oxidation on platinum or iron electrodes is described in a previous

study on polyphenylene oxide films with amino group substituents (13).

For the present study, different thicknesses of these polytyramine films were prepared by electrochemically oxidizing tyramine (0.1M) in 0.3M NaOH-MeOH and subjecting the electrode to different potential sweep cycles at 50 mV s⁻¹. A thickness of ca. 50 nm was obtained after ten successive sweep cycles between 0.0 and 2.0V (SCE); a thickness of ca. 120 nm was obtained by two sweep cycles between 0.0 and 3.0V (SCE) followed by eight sweep cycles between 0.0 and 2.0V (SCE); a thickness of 150 nm was obtained by four sweep cycles between 0.0 and 3.0V (SCE) followed by eight sweep cycles between 0.0 and 2.0V (SCE).

The multiple-reflection IR spectrum of the polytyramine film (Fig. 1) displays an absorption band at 1255 cm⁻¹ ascribable to the C—O—C polyoxide groups. There are two other characteristic bands at 3364 and 3268 cm⁻¹ attributed to the —NH₂ group (N—H stretching), and another band at 1080 cm⁻¹ attributed to the C—N bond (C—N stretching). These vibrations are also observed with the tyramine monomer (in KBr pellet) at 3334, 3282, and 1042 cm⁻¹ (14).

XPS analysis confirms that the films of different thicknesses are indeed polymer films (Fig. 2a).

Calculating the intensity of the XPS signals emitted by the various elements while taking into account the sensitivity of each gives C₈O_{2.2}N_{1.09} as the approximate formula for the polytyramine film. The same type of calculation for a simple tyramine film obtained by evaporating a methanol solution with tyramine onto a Pt electrode gives C₈O_{0.96}N_{0.9} as the formula for tyramine. The oxygen index of ca. 2.2 in the polytyramine film might be accounted for by a side reaction occurring during the electrochemical polymerization. With tyramine, which is a *para*-substituted phenol, coupling of the phenate radicals can occur at the *ortho* position of the phenol group (15); during anodic coupling of the phenol, a nucleophilic agent such as CH₃O⁻ can attack the quinol-ether polymer intermediate (I) at the *meta* position (see Scheme). This interpretation resembles that advanced by Mengoli *et al.* (16) for the grafting of amine moieties onto polyphenylene oxide during the electropolymerization

of phenol in the presence of amines. Such a side-reaction mechanism indicates that C₈O_{2.2}N_{1.09} might be the formula for polytyramine.

Metal complexed polytyramine film formation.—Cu(II) ions can be coordinated with ligands from a polytyramine film by immersing the film for 15 min in a boiling 5 × 10⁻¹M aqueous medium of CuCl₂. The polytyramine-Cu(II) film is then rinsed ultrasonically in distilled water and is air-dried.

For complexation with Co(II), Fe(II), Mn(II), or Zn(II) ions, an organic medium is required. After dissolving 10⁻¹M MCl₂ [M is Fe(II), Zn(II), Co(II), or Mn(II)] in DMF and bringing this solution to boiling point, a polytyramine film immersed therein for 15 min forms a complex with the metal ions M. After complexation, the treated sample is first rinsed in DMF by ultrasonic stirring to eliminate MCl₂ traces; it is then again rinsed ultrasonically in methanol to eliminate DMF traces. Thereafter, it is air-dried before use in experiments.

XPS analysis of a polytyramine-Co(II) complex.—XPS analysis of a polytyramine film before and after the treatment with CoCl₂ indicates that the treatment indeed results in the formation of a complex between cobalt ions and ligands of the polytyramine film.

Six samples of polytyramine films of various thickness treated with CoCl₂, 6H₂O were analyzed by XPS (Fig. 2b). Averaged binding energies, averaged com-

Fig. 1. IR spectrum of the polytyramine film obtained on Pt.

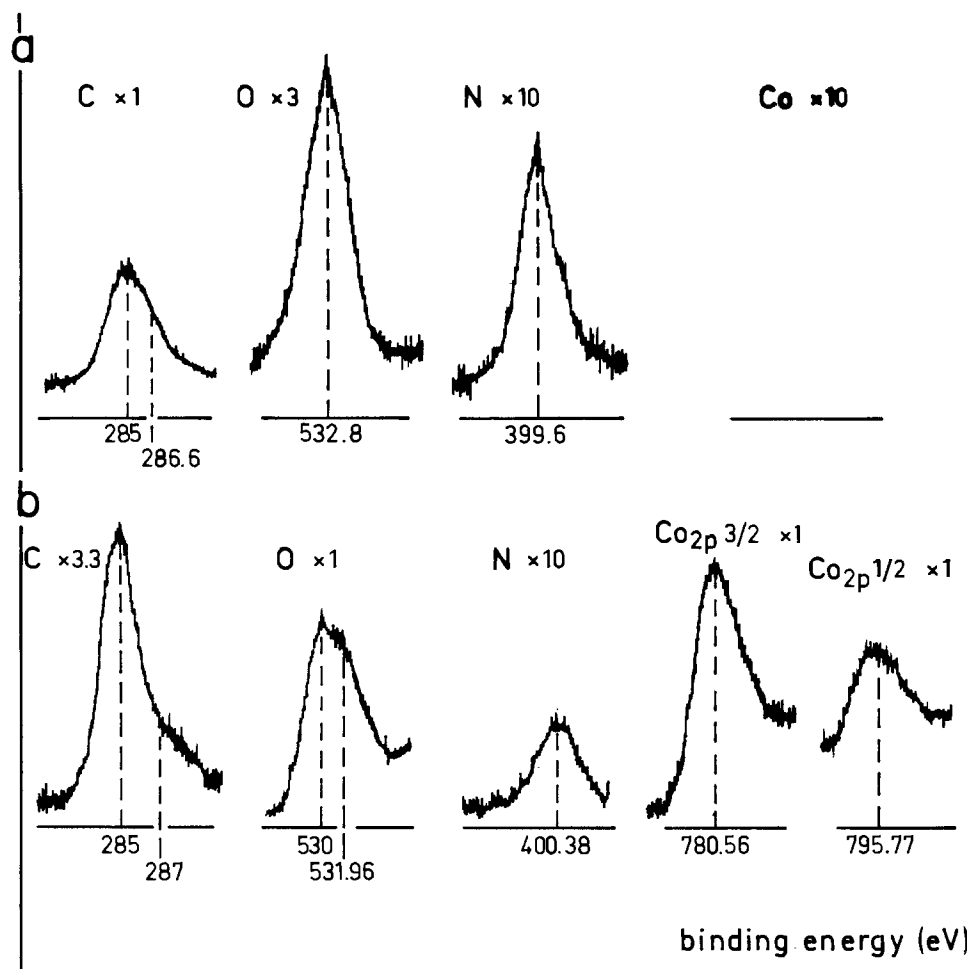

Fig. 2. XPS spectra of (a) a polytyramine film, and (b) a polytyramine-Co(II) film.

plexed film formulas, and bond types are given in Table I (17, 18).

A comparison of the spectra of a polytyramine film (Fig. 2a) with the spectra of a polytyramine-Co(II) (Fig. 2b) shows that in the N_{1s} spectrum, the nitrogen binding energy increases from 399.6 eV in the untreated sample to 400.38 eV in the treated sample (thereby indicating that the partial charge from the N atoms increases, in accordance with actual coordination between Co(II) ions and N). The treated film also displays two O_{1s} signals (one at 530.57 eV that might arise from interaction between H_2O molecules and Co(II) ions, and one at 531.96 eV ascribable to C—O—C bonds in interaction with Co(II) ions, plus a $Co_{2p_{3/2}}$ and a $Co_{2p_{1/2}}$ signal (at 780.56 and 795.77 eV).

Quantitative analysis of the six samples gives $C_3O_{3.58 \pm 0.82}N_{1.12 \pm 0.03}Co_{0.88 \pm 0.33}$ as the average formula of the polytyramine-Co(II) complex. The rather large standard deviations for the oxygen and cobalt in this

formula might be due to incomplete metalation between the polymer ligands and the Co(II) ions.

Plotting the oxygen index vs. the cobalt index using six data points gives an approximate straight line with a slope of ca. 2 and an ordinate origin of 2. This indicates the presence of ca. two additional oxygen atoms (aside from the two oxygen ligands in the untreated polytyramine film) per cobalt ion when complexation occurs.

XPS analysis of a polytyramine-Cu(II) complex.—Results of XPS analysis of a polytyramine film before and after complexation with $CuCl_2 \cdot 2H_2O$ are given in Table II.

The XPS spectra of a polytyramine-Cu(II) complex are given in Fig. 3. Like for the previously studied polyquinolinol films, before and after complexation with Cu(II) ions (12b), the increase in the N_{1s} binding energy of the complexed film is indicative of coordina-

Fig. 3. XPS spectra of a polytyramine-Cu(II) film.

tion between the Cu(II) ions and nitrogen ligands. The complexed film emits a Cu(II)_{2p_{3/2}} signal at 934.4 eV (19, 20). Unlike the polyquinolinol- and polytyramine-Co(II) complexes, the polytyramine-Cu(II) spectra display only one O_{1s} signal, thereby indicating that oxygenated ligands in the polytyramine-Cu(II) film come from the polytyramine; this is confirmed by quantitative analysis which gives C₈O_{2.3±0.3}N_{0.86±0.03}Cu_{0.01±0.01} as the formula for this complex. The oxygen index in this formula is about the same as in the formula of an untreated polytyramine film: C₈O_{2.2}N_{1.09}. This likeness indicates that, unlike what occurs with polyquinolinol- and polytyramine-Co(II) complexes, no oxygenated ligands from the salt participate in polytyramine-Cu(II) complexation.

XPS analysis of polytyramine-Fe(II), -Mn(II), and -Zn(II) complexes.—Results of XPS analysis of a polytyramine film after complexation with FeCl₂, 4H₂O, or MnCl₂, 4H₂O, or ZnCl₂, 4H₂O, are summarized in Table III.

Electrochemical responses of electrodes coated with metal-complexed polytyramine films.—Polytyramine-Cu(II) films were studied by cyclic voltammetry in an aqueous medium with 0.2M LiClO₄-HClO₄ or 0.2M CF₃COONa-CF₃COOH. A "forming" period similar to

that observed previously with poly(2-methyl-8-quinolinol)-Cu(II) complexes (12b) is observed, i.e., the peak current increases during the first potential scan cycles and then stabilizes. This phenomenon lasts much longer at pH 4 than at pH 2 (Fig. 4). In LiClO₄-HClO₄-H₂O (pH 2), at a scan rate of 200 mV s⁻¹, there is an oxidation and a reduction peak for the polytyramine-Cu(II)/polytyramine-Cu(I) couple at + 0.54 and + 0.4V (SCE), respectively.

Electrochemical data obtained by cyclic voltammetry for various polytyramine-Cu(II) films in various electrolytic media are given in Table IV.

The pH of the supporting electrolytes clearly affects the electroactivity of Cu(II) sites. Voltammograms recorded at pH 2 and 1 are more symmetrical and have shorter peak potential separations than voltammograms at pH 4. The above-reported XPS results showing inhomogeneous and incomplete complexation between Cu(II) ions and the polymer ligands of the film could mean that the remaining number of uncomplexed NH₂ groups which can be protonated increases as the pH becomes lower, thereby increasing the swelling and the flexibility of the polymer chain and lending it a more open texture. This in turn would facilitate counterion entry into the films and could thereby account for the significant pH-dependent difference in the forming periods and in the shapes of the voltam-

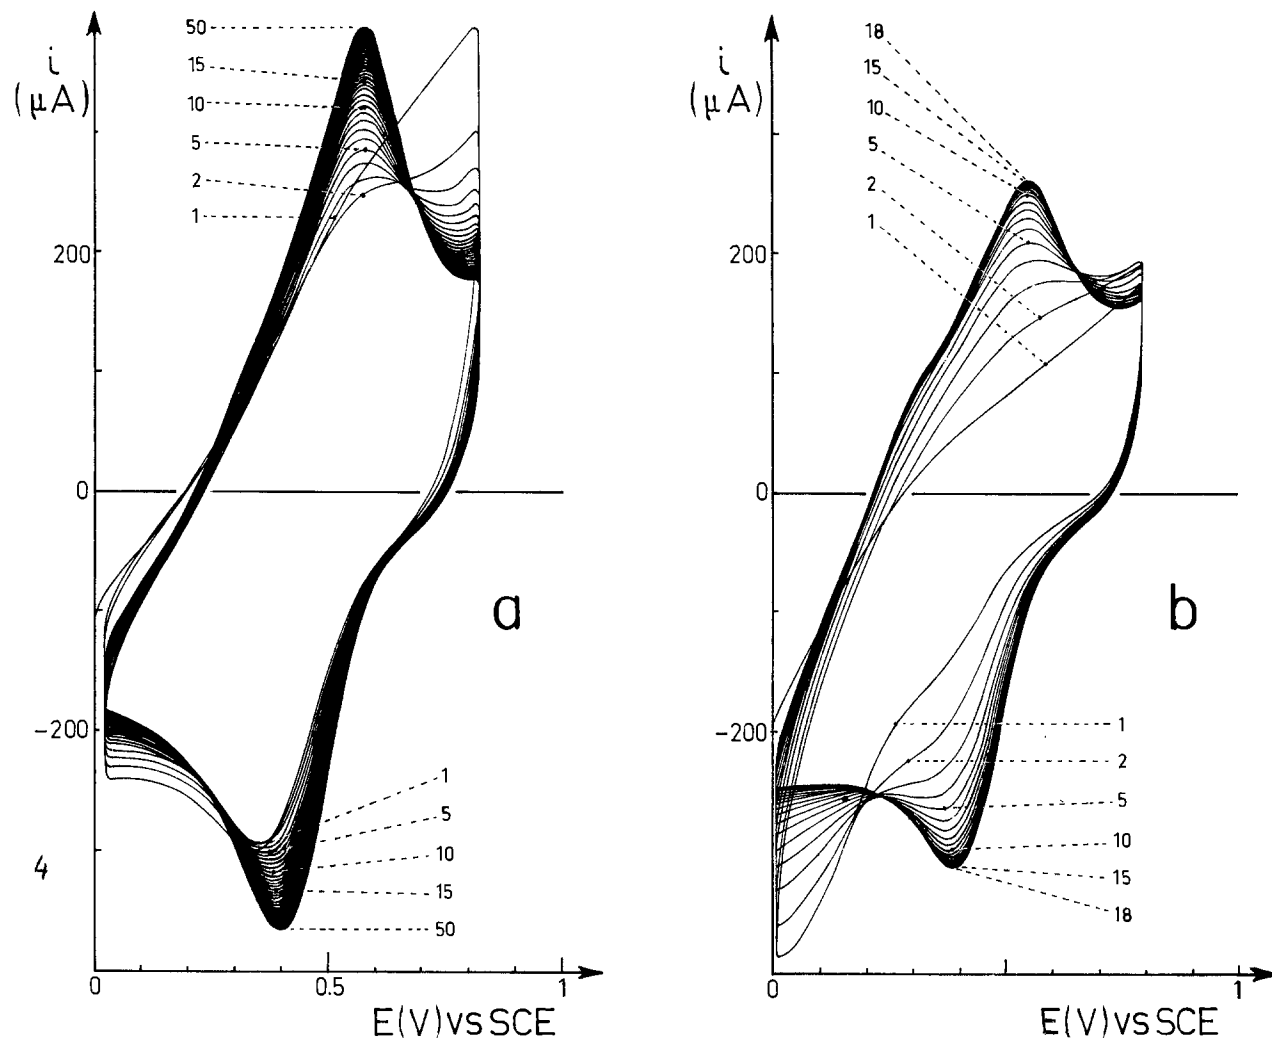

Fig. 4. Voltammograms recorded at 100 mV s^{-1} with a Pt electrode coated with a polytyramine-Cu(II) film during successive sweeps (the sweep number is given for each curve). A: $\text{LiClO}_4\text{-HClO}_4$ (pH 4) medium. B: $\text{LiClO}_4\text{-HClO}_4$ (pH 2) medium.

mograms for polytyramine-Cu(II) films. Anson *et al.* have also noticed that pH levels affect the electrochemical responses of electroactive polymer-coated electrodes (9).

The electrolyte-dependent variation in the voltammetric responses of the polytyramine-Cu(II) films bolsters this interpretation. The voltammograms of these same polytyramine-Cu(II) films display much greater peak potential separations in a CF_3COONa

electrolyte than in a NaClO_4 electrolyte at the same pH. Up to 200 mV s^{-1} , peak current intensities increase linearly with the scan rate; they increase less rapidly at faster scan rates.

Overall results indicate that with polytyramine-Cu(II) films the rate of the redox reaction of the films is controlled by the electrochemical charge diffusion rate through the film. Integration of the voltammogram gives $6.4 \times 10^{-9} \text{ mol cm}^{-2}$ as the concentration of

electroactive sites in the complex; *i.e.*, the equivalent of *ca.* six layers participate in the redox process.

The same type of electroactivity is observed with polytyramine films treated with 5×10^{-1} or $10^{-1}M$ $CuCl_2$ solutions. However, when a polytyramine film

is treated with a $5 \times 10^{-2}M$ $CuCl_2$ solution, there is almost no cyclic voltammetry response, even though a weak $Cu(II)$ signal is detected by XPS. This might be explained by a smaller density of $Cu(II)$ ions within the film, which would mean that the electroactive

sites are not close together enough for electron hopping transfer to be able to occur.

As the voltammogram of a thin polytyramine film (50 nm) treated with a $5 \times 10^{-1} M$ $CuCl_2$ solution (electrode 6, Table IV) also displays low peak currents, the current observed for a thick film can be considered to represent the integration of electroactive sites throughout the film thickness.

Polytyramine-Co(II) films on a Pt electrode subjected to cyclic voltammetry in 0.1M NaOH-H₂O display an electrochemical behavior totally unlike that of polytyramine-Cu(II) films. A perfectly reversible redox system is detected from the start, and no "forming" is observed; *i.e.*, as of the first potential scan between 0.0 and 0.4V (SCE), the polytyramine-Co(II)/polytyramine-Co(III) couple is observed at 0.10V (SCE) with ΔE_p equal to zero, and the peak current varies linearly with the sweep speed (Fig. 5). A concentration of cationic sites of only *ca.* 7×10^{-11} mol cm⁻² (the equivalent of a tenth of the layer at the metal-film interface) participates in the redox process. It is noteworthy that the voltammograms of two Pt electrodes coated with polytyramine-Co(II) films of unequal thickness (50 and 120 nm) are identical ($\Delta E_p = 0$) and have the same peak current intensity. The redox couple is very stable, as attested to by the fact that the peak current intensity remains unchanged even after hundreds of scan cycles between 0.0 and 0.4V (SCE) at 100 mV s⁻¹.

Polytyramine-Fe(II) films on a Pt electrode subjected to cyclic voltammetry in an aqueous medium containing 0.1M KCl-0.1M HCl behave like polytyramine-Co(II) films. The voltammogram displays reversible redox peaks at 0.47V (SCE) without a preliminary forming period, and the low concentration of electroactive sites is about the same as in polytyramine-Co(II) films (Fig. 6). The low concentration of electroactive sites and the good reversibility of the redox couple indicate that only cationic sites in the vicinity of the metal-film interface participate in the redox process. This would mean that the complex structure does not lend itself to electron hopping transfer within the film. It is more likely that the polytyramine-Fe(II) film is a penta- or hexacoordinate structure (as in the case of the cobalt-complexed polymer films), rather than a four-coordinate structure (as are the copper complexed polymer films).

It should be noted that, unlike copper or cobalt redox couples, the iron redox couple is not very stable. Peak current intensity diminishes after *ca.* 50 potential scan cycles.

Polytyramine-Mn(II) or polytyramine-Zn(II) films subjected to cyclic voltammetry elicit no response whatsoever, regardless of the medium.

Conclusion

Ligands from polytyramine films form complexes with Cu(II) or Co(II) ions less readily and less quickly than ligands from previously studied (12b) polyquinolinol films. However, the difference between the electrochemical responses of copper- and cobalt-complexed polytyramine films resembles the difference between the electrochemical responses of copper- and cobalt-complexed polyquinolinol films (12b).

This difference between copper and cobalt films might be explained by the fact that, in redox polymer films, communication between electroactive metals involves physical diffusion of the metal ions (from ligand site to ligand site) (21, 22) and/or electron self-exchange (2a, 2b, 22-24). In both oxidation states, copper would be more labile, whereas Co(III) would not physically diffuse through the coating to the electrode surface. Because the concentration of redox sites in the polymer cannot be measured, there is no way to measure the diffusion constant to distinguish contributions from the two mechanisms, electron hopping

and molecular diffusion. However, in the study at hand, electron hopping seems to be the prevalent charge-transport mechanism. The four-coordinate structure of the copper complexes would enhance electron hopping transfer between electroactive sites, whereas the penta- or hexacoordinate structure of cobalt-complexed films would enable only the cationic sites at the metal-film interface to participate in the redox process.

Cobalt complex redox couples are perfectly reversible with either polymer (in both cases $\Delta E_p = 0$); only a fifth of the polyquinolinol-Co(II) film layer or a tenth of the polytyramine-Co(II) layer is electroactive. In contrast, polymer films with copper-complex redox couples have high ΔE_p values; *ca.* 12 layers of a poly(2-methyl-8-quinolinol)-Cu(II) film or six layers of a polytyramine-Cu(II) film take part in the redox process. These high values demonstrate that most of the cationic sites throughout the copper-complexed polymers are indeed involved in the redox process.

Voltammetry results for an iron-complexed film resemble those for a cobalt-complexed film. This behavior is typical of a penta- or hexacoordinate complex.
