Stoichiometry of Formation and Conductivity Response of Amorphous and Crystalline Complexes Formed Between Poly(ethylene oxide) and Ammonium Salts: $\text{PEO}_x \cdot \text{NH}_4\text{SCN}$ and $\text{PEO}_x \cdot \text{NH}_4\text{SO}_3\text{CF}_3$

ABSTRACT

Stoichiometries have been studied for the interaction between poly(ethylene oxide) and the ammonium salts NH_4SCN and $\text{NH}_4\text{SO}_3\text{CF}_3$ in the polymer to salt composition range 10:1 to 2:1. A single crystalline phase having the approximate composition 4:1 $\text{PEO} \cdot \text{NH}_4\text{SCN}$ was identified, and an approximate phase diagram was constructed. The $\text{PEO} \cdot \text{NH}_4\text{SO}_3\text{CF}_3$ system is more complex, and a phase diagram was not obtained; however, at least two compounds of 8:1 and 4:1 stoichiometry are indicated. Conductivity plots indicate that the metastable amorphous phase of the various materials has a conductivity approximately $10^3 \Omega^{-1} \text{cm}^{-1}$ higher than that of the crystalline phase at room temperature. The NH_4^+ ion rather than H^+ is implicated as a charge carrier. We were not successful in determining transference numbers for anions and cations.

Recently, solvent-free polymer electrolytes have attracted considerable attention because of their potential application in high energy density batteries and because of the many unanswered fundamental questions on ion transport in polymers (1-4). The temperature-dependent conductivity of amorphous polyether-salt complexes reveals curved plots of $\ln(\sigma T)$ vs. $1/T$, which are linear when the temperature variable $1/(T - T_0)$ is employed. This functional dependence of the ion transport has previously been observed for small molecule diffusion through polymers, and one possible interpretation is that cooperative polymer conformation fluctuations are responsible for the transport process. The empirical constant T_0 represents the temperature below which the polymer motions responsible for ion transport are frozen out, and therefore it is approximately equal to the glass transition tem-

perature, T_g . The $1/(T - T_0)$ dependence is reproduced by the configurational entropy model of Gibbs and co-workers, which gives Eq. [1] for the conductivity

$$\sigma = AT^{-1/2} \exp \{-K/T - T_0\} \quad [1]$$

where

$$K = T_0 \Delta \mu S_c^* / B k_B \quad [2]$$

A , T_0 , and B are constant, S_c^* is the minimum configurational entropy required for rearrangement, and k_B is the Boltzmann constant. The pre-exponential term, A , is proportional to the carrier concentration (5). The related Fulcher equation was applied to the amorphous solid electrolytes, alkali metal salts in poly(propylene oxide), by Armand and co-workers (6).

Most of the research to date has focused on lithium and sodium ion conductors, where the respective metals may be used as reversible electrodes (7-9). In the present work, ammonium ion has been chosen for

* Electrochemical Society Active Member.

study because little is known about the transport of proton containing species in polymer electrolytes. Also, the ammonium containing poly(ethylene oxide) (PEO) systems provide metastable amorphous phases, which are useful for testing theories on ion transport. This research has focused on the stoichiometry of interaction between NH_4SCN or $\text{NH}_4\text{SO}_3\text{CF}_3$ and PEO, and a comparison of ion transport in the crystalline and amorphous states of these polymer electrolytes.

The size of the NH_4^+ ion is interesting in its relationship to structural models for PEO-salt complexes which have been presented to date. The most convincing model indicates that cations Li^+ , Na^+ , or K^+ reside in a helical tunnel and are coordinated to oxygen atoms in a fashion very similar to cations in an 18-crown-6 complex (10), where the cavity size for each is essentially the same (diam $\sim 2.6\text{\AA}$ for PEO complex and for 18-crown-6). Until recently, x-ray crystal structures of many 18-crown-6 complexes of ammonium and rubidium salts have indicated that these cations, both with a radius of 1.48\AA , are too large to fit in the cavity, but sit on top of it. Recent structures of 18-crown-6 with ammonium ions indicate that this assertion is incorrect and instead the depth of penetration of the crown ether by an ammonium ion depends on the relative strength of interaction of the ion surrounding groups (11). Hydrogen bonding is an important interaction here.

Complexes of PEO with rubidium and cesium salts have been reported to be amorphous, unlike the crystalline complexes obtained when using the smaller alkali metal cations Na^+ and K^+ (10). An explanation for this behavior might be that since the cations do not fit inside the helical cavity, the structure is not regular and therefore not crystalline. Also, irregular crosslinking of the polyether backbone through interactions with cations may induce the amorphous structure. But RbI has been shown to form a crystalline complex with an eight-oxygen polyether capped by aromatic end groups; the polyether is wrapped around the cation in a helical fashion. This complex is originally obtained as an oil which slowly recrystallizes. Under similar conditions with NH_4SCN substituted for RbI as the complexing salt, crystals were not obtained (12).

The evidence indicates that size and hydrogen bonding ability play important roles in interactions of NH_4^+ with short chain polyethers and possibly with PEO. From the previous information, it would be difficult to predict the exact stoichiometry of interaction of ammonium salts with PEO. Anion differences, which would affect crystal packing, might also be expected to play an important role. For example, the complex $\text{PEO} \cdot \text{Na}[\text{B}(\text{C}_6\text{H}_5)_4]$ has a maximum ratio of ether oxygens to Na^+ of about 7:1 due to the bulky anion (13).

Experimental

Materials.—Poly(ethylene oxide) (PEO) with an average molecular weight 600,000 (Aldrich) was purified and dried as described previously (10). Reagent grade NH_4SCN was dried under vacuum at 100°C for 19h. $\text{NH}_4\text{SO}_3\text{CF}_3$ was prepared by neutralization of freshly distilled HSO_3CF_3 to pH 6 with ammonium hydroxide, recrystallization from THF/hexane, and drying under vacuum for 24h. $\text{ND}_4\text{SO}_3\text{CF}_3$ was prepared from $\text{NH}_4\text{SO}_3\text{CF}_3$ and D_2O . Due to the hygroscopic nature of these salts and purified PEO, all operations were carried out in a nitrogen atmosphere dry box or using standard Schlenk techniques. Anhydrous salts were checked for signs of water by IR prior to use. Reagent grade methanol (MCB) was dried by refluxing over iodine-activated magnesium for 1 day followed by distillation under a nitrogen atmosphere. Tungsten bronze, $(\text{NH}_4)_x\text{WO}_3$ ($x \approx 0.25$), was prepared by reduction of ammonium paratungstate in hydrogen at-

mosphere (300 torr) at $\sim 500^\circ\text{C}$ by the method of Dickens *et al.* (14).

The polymer electrolytes were prepared typically on a 0.5g scale by combining stoichiometric quantities of the polymer and salt and addition of 15 ml anhydrous methanol. The mixture was stirred until all solids dissolved. Dissolution indicates complexation, since PEO is not soluble in methanol. The solvent was removed by evaporation under vacuum and dried under high vacuum (10^{-3} torr) for 24h.

Differential scanning calorimetry (DSC).—Thermal analysis of PEO-ammonium salt electrolytes was carried out using a Perkin Elmer DSC-2 differential scanning calorimeter on a range of 1 mcals with a heating rate of 10 K/min unless otherwise noted. Endothermic transition temperatures were determined by the intersection of a line drawn through the leading edge of the fusion peak with an extrapolated base line. Samples were typically 1-4 mg and loaded under a nitrogen atmosphere in hermetically sealed aluminum pans. Peak shape and location depend somewhat on packing, geometry, and size of sample, which could not be well controlled since samples were either films or cut from chunks.

An iridium standard was used to calibrate the DSC-2 temperature scale and for heat of fusion calculations. After each scan, samples were quenched at 320 K/min down to 300 K. The samples were then rescanned using the original conditions. After recrystallization from the melt (time dependent on stoichiometry and salt) samples were scanned again.

Optical polarized microscopy.—Crystalline-amorphous state changes were observed using optical polarized microscopy. A Leitz Wetzlar polarizing microscope equipped with a Mettler FP52 hot stage was used to observe the disappearance of birefringence. Samples were prepared by hot pressing electrolyte material between a microscope slide and cover slip and sealing with epoxy in a nitrogen atmosphere.

X-ray diffraction measurements.—X-ray diffraction measurements were obtained with a Rigaku automated diffractometer and radiation analyzer using $\text{CuK}\alpha$ radiation. Symmetrical reflection was used on pressed pellets which were held in place and protected from atmospheric moisture by Scotch-brand transparent tape. A beryllium window was used for the sample side exposed to x-rays.

Conductivity measurements.—AC impedance measurements over the frequency range 20 Hz-500 kHz were made using a Hewlett Packard 4800A vector impedance meter. Polymer samples were pressed at 10,000 psi in a $\frac{1}{2}$ in. diam die (thickness 1-2 mm) and loaded in a sealed sample holder between either 0.2 mm-thick Pt disks or $(\text{NH}_4)_{0.25}\text{WO}_3$ electrodes which were $\frac{1}{2}$ in. diam pellets (~ 2 mm thick) pressed from finely ground powder. Variable temperature measurements between 25° and 100°C were carried out with the sample in a thermostated heating chamber controlled by a Bruker B-ST temperature control unit.

Results and Discussion

Polymer-salt phases.—The x-ray diffraction patterns of various stoichiometries of $\text{PEO} \cdot \text{NH}_4\text{SCN}$ mixtures are shown in Fig. 1. Comparison of the pattern of the 8:1 composition with that of pure PEO indicates the presence of uncomplexed crystalline PEO in addition to crystalline polymer salt complex. At high salt concentrations, 3:1 and 2:1 compositions, reflections arising from the presence of free salt are seen. The pattern for $\text{PEO}_{4.0}\text{NH}_4\text{SCN}$ does not contain reflections of either free salt or uncomplexed polymer. Differential scanning calorimetry experiments confirm the conclusion, drawn from the x-ray results, that a crystalline complex is formed between salt and polymer with the approximate stoichiometry of $\text{PEO}_{4.0}\text{NH}_4\text{SCN}$. The DSC

thermograms are shown in Fig 2. A single sharp endotherm at 68°C is found for $\text{PEO}_{4.0}\text{NH}_4\text{SCN}$. Optical microscopy experiments show that this endotherm corresponds to the melting of the crystalline complex. Decreasing the salt concentration successively to the 5:1 and 6:1 compositions gives a relative decrease in the magnitude of the 68°C endotherm and the appearance of an endotherm at $\sim 42^\circ\text{C}$. The latter can be assigned to the eutectic melting of a mixture of $\text{PEO}_{4.0}\text{NH}_4\text{SCN}$ and PEO. Optical microscopy also shows that this represents the transition from a crystalline to an amorphous phase. The phase diagram for the PEO- NH_4SCN system is shown in Fig. 3. The melting points of NH_4SCN and PEO 600,000 are 149° and 65°C , respectively. The complex $\text{PEO}_{4.0}\text{NH}_4\text{SCN}$ melts at 68°C , and the temperature of the eutectic melt is 42°C . The endotherm at $\sim 95^\circ\text{C}$ in the DSC thermogram of the 3:1 composition does not arise from the polymer-salt interaction, but is assigned on the basis

Fig. 2. Differential scanning calorimetric scans of the poly(ethylene oxide)-ammonium thiocyanate system. The ratio of polymer to salt is indicated. The heating rate was $10^\circ\text{C}/\text{min}$ in each scan.

Fig. 3. Approximate phase diagram for the PEO · NH_4SCN system. The 4:1 (PEO · NH_4SCN) complex, shown at 0.2 mol fraction of salt, may exist over a range of stoichiometry, but this was not readily established.

of optical microscopy to a phase transition in crystalline NH_4SCN (15).

In contrast to the data for 8:1 PEO · NH_4SCN , the x-ray diffraction pattern of 8:1 PEO · $\text{NH}_4\text{SO}_3\text{CF}_3$ does not contain reflections assignable to free PEO. The DSC thermogram for this complex (Fig. 5) shows a single endotherm at 41°C . The failure to detect un-

complexed PEO by x-ray powder diffraction suggests that the thermal event observed at 41°C is not a eutectic melting, as was found for the NH_4SCN case, but corresponds to the crystalline-amorphous phase transition of a polymer-salt complex. Increasing the salt concentration to the 4:1 composition gives a second higher temperature endotherm in the DSC traces at 60°C (Fig. 5). This is assigned to the crystalline melt of a second polymer salt complex phase corresponding roughly to 4:1 polymer to salt stoichiometry similar to that found in the PEO- NH_4SCN system. Although a single endotherm is seen in the DSC at a composition of 10:1, evidence for the presence of small amounts of PEO is seen in optical microscopy and x-ray diffraction. The diffraction pattern (Fig. 4) is essentially identical to that of 8:1 PEO · $\text{NH}_4\text{SO}_3\text{CF}_3$ with the exception of an additional reflection which corresponds to one of the two strong reflections found for PEO. Comparison of the x-ray diffraction patterns of the 8:1 and the 5:1 stoichiometries reveals a close similarity with additional strong reflections being

Fig. 4. X-ray diffraction patterns for $\text{NH}_4\text{SO}_3\text{CF}_3$ (upper trace), PEO (lower trace), and complexes formed between these constituents (center traces). The ratios of PEO to $\text{NH}_4\text{SO}_3\text{CF}_3$ are indicated.

Fig. 5. Differential scanning calorimetric thermograms of the PEO- $\text{NH}_4\text{SO}_3\text{CF}_3$ system. The ratio of polymer to salt are indicated. The heating rate was $10^\circ\text{C min}^{-1}$ in each scan.

found for the latter. This is consistent with the DSC results, which indicate that both of the crystalline complex phases are present at the 5:1 stoichiometry. Similarly, the diffraction pattern of the 3:1 stoichiometry is much different from that of the 8:1 supporting the DSC result, which shows that the low salt concentration complex phase is absent at the 3:1 stoichiometry. Interestingly, the 3:1 and 2:1 compositions do not appear, from the x-ray data, to contain free uncomplexed salt. This behavior contrasts with the NH_4SCN system, and thus the endotherm at 94°C seen in the DSC traces at high concentrations of $\text{NH}_4\text{SO}_3\text{CF}_4$ may possibly arise from a further polymer · salt complex phase.

The rates of crystallization of the polymer · salt phases are slow. Rescanning of the DSC samples, after quenching and equilibration at room temperature, gives thermograms in which the 41° and 60°C endotherms are absent. The rates of crystallization vary with polymer:salt stoichiometry and anion. For the $\text{NH}_4\text{SO}_3\text{CF}_3$ complexes, crystallization from the melt is complete after 24h; the low salt stoichiometry phase crystallizes more slowly. In the case of NH_4SCN , the rates are slower on the order of weeks for the 8:1 and 6:1 stoichiometries and a few days for 4:1. For $\text{PEO}_{3.0}\text{NH}_4\text{SO}_3\text{CF}_3$, the endotherm at $\sim 94^\circ\text{C}$ is seen on immediate rescanning, while the endotherm at 57°C is absent.

Conductivity measurements.—Measurements of the conductivity of the PEO ammonium ion complexes were carried out at temperatures between 25° and 100°C. Plots of $\ln(\sigma T)$ vs. $1/T$ for NH_4SCN and $\text{NH}_4\text{SO}_3\text{CF}_3$ complexes of various stoichiometries are shown in Fig. 6 and 7, respectively. Perhaps the most

striking features are the steep rises in conductivity over relatively small temperature intervals, which occur when the crystalline complexes are heated. For $\text{PEO}_{8.0}\text{NH}_4\text{SCN}$, this sharp rise occurs at about 45°C . Similarly, for the 5:1 complex there is a pronounced rise at $\sim 45^\circ\text{C}$ with a smaller inflection at $\sim 72^\circ\text{C}$, while for the 4:1 only a single sharp rise in conductivity is observed at $\sim 72^\circ\text{C}$. This latter transition has been observed previously for the 4:1 complex (16), but no conductivity was reported for the amorphous state. For the 3:1 stoichiometry, the inflection is slightly elevated to $\sim 80^\circ\text{C}$ due to the presence of excess salt. This behavior parallels the endothermic events seen in the DSC measurements which correspond to the crystalline to amorphous phase transitions. Conductivity plots of the $\text{PEO} \cdot \text{NH}_4\text{SO}_3\text{CF}_3$ complexes (Fig. 7) show the same features with sharp rises or inflections corresponding to features in the DSC traces (Fig. 5).

The slow recrystallization of the complexes from the amorphous melt facilitates the measurement of the conductivity in that phase below the crystalline melting temperature. Cooling to room temperature and remeasuring the conductivities between 25° and 100°C gives the curves in Fig. 6b and 7b. Notable is the large enhancement in conductivity in the amorphous phase over that in the crystalline material, about a factor of $10^3 \Omega^{-1} \text{cm}^{-1}$ at room temperature. Also, for the amorphous phase the curve is not strictly linear but is slightly bowed; thus the system does not exhibit true Arrhenius behavior. The transitions seen in the conductivity plots are reproducible after recrystallization.

Conductivity in PEO-salt complexes has been shown to be essentially ionic in nature (7). The relative mobilities of cation and anion, however, are of particular importance, especially in relation to the practical ap-

Fig. 6. Electrical conductivity, σ ($\Omega^{-1} \text{cm}^{-1}$), vs. temperature plotted as $\ln(\sigma T)$ vs. $1000/T$, for crystalline and amorphous phases of $\text{PEO} \cdot \text{NH}_4\text{SCN}$ at various ratios of polymer to salt: Δ , 8:1; \circ , 5:1; \times , 4:1; \square , 3:1. A, left: crystalline material. Measurements made starting at room temperature ($\sigma \sim 1 \times 10^{-8}$) and heating to 100°C ($\sigma \sim 2 \times 10^{-3}$). Dashed line indicates conductivities in the amorphous phase shown in B. B, right: amorphous material. After quenching the sample from 100°C to room temperature, conductivities were measured starting at room temperature ($\sigma \sim 1 \times 10^{-5}$) and heating to 100°C ($\sigma \sim 2 \times 10^{-3}$).

Fig. 7. Electrical conductivity, σ ($\Omega^{-1} \text{cm}^{-1}$), vs. temperature plotted as $\ln(\sigma T)$ vs. $1000/T$, for crystalline and amorphous phases of $\text{PEO} \cdot \text{NH}_4\text{SO}_3\text{CF}_3$ at various ratios of polymer to salt: Δ , 8:1; \circ , 5:1; \square , 3:1. A, left: crystalline material. Measurements made starting at 35°C ($\sigma \sim 5 \times 10^{-8}$) and heating to 100°C ($\sigma \sim 1 \times 10^{-3}$ for 8:1, $\sim 3 \times 10^{-4}$ for 3:1). Dashed line indicates conductivity in the amorphous phase shown in more detail in B. B, right: amorphous material. After quenching the sample from 100° to 35°C , conductivities were measured starting at 35°C and heating to 100°C . For the 8:1 electrolyte, σ increases from $\sim 2 \times 10^{-5}$ to $\sim 1 \times 10^{-3}$ and is about a factor of 2.5 less for the 3:1 electrolyte.

plications of polymer electrolytes in energy storage devices. Weston and Steele have shown that in 8:1 PEO · LiClO₄ complexes the transport number for the lithium ions is less than 0.5 (8), and Sorensen and Jacobsen have found a cation transport number of 0.54 in PEO_{4.5}LiSCN (9).

As indicated below, ionic motion in PEO · NH₄X probably does not involve proton transfer from NH₄⁺ to the polyether polymer backbone. The conductivity behavior of PEO_{4.0}ND₄SO₃CF₃ is essentially identical to that for the normal isotopic ammonium complex, and there is no increase in the slope of the Arrhenius plots due to an isotope effect. Therefore, a transport mechanism involving proton transfer seems unlikely.

An experiment was performed in which a polymer complex was doped with ammonia, because the presence of free NH₃ might provide a mechanism for proton transport. The polymer salt complex absorbs ammonia readily and swells and exhibits mechanical properties similar to those of an undoped polymer salt complex in the amorphous phase. No enhancement of conductivity was observed. The ammonia-doped polymer has roughly the same conductivity as the undoped material in the amorphous phase, again indicating that H⁺ conductivity does not occur. Finally, evidence for the mobility of NH₄⁺ was obtained using ion reversible and ion blocking electrodes. Figure 8 shows the ac complex admittance plots for 5:1 PEO · NH₄SO₃CF₃ in the frequency range 50 × 10⁴ to 20 Hz with Pt (blocking) and (NH₄)_{0.25}WO₃ (reversible) electrodes. The latter electrode material is reversible to NH₄⁺ ions and shows the "spur" typical of an arrangement where the double-layer capacitance at the electrode-electrolyte interface is removed by reversible transfer of NH₄⁺ ions. The ammonium ions are thus clearly

implicated as a mobile species in these polymer electrolytes. However, we were unsuccessful in determining the transport number with a polarization cell having ammonium tungsten bronze electrodes, so it is possible that the anion contributes substantially to the conductivity.

Conclusion

Although determining the stoichiometry of interaction has been an important segment of this work, the most significant aspect has been determining the conductivity behavior of these materials in their crystalline and metastable, amorphous states. In the amorphous state, conductivity enhancement at room temperature is roughly 10³ Ω⁻¹ cm⁻¹ greater than for the corresponding crystalline state of these electrolytes. This behavior strengthens the assumption that cooperative polymer conformation fluctuations are responsible, at least in part, for the transport process in these conductors. Such a large conductivity enhancement indicates that other amorphous solid electrolytes above their T_g's might be very promising as fast ionic conductors.

Other comparisons of crystalline vs. amorphous conductivity in the same electrolyte have been reported (8, 16). But in the PEO · LiClO₄ 8:1 comparison (8), the amorphous state was induced by the addition of water, so the true comparison of conductivities may be difficult to make, since water is known to increase conductivity. In another report (16), slightly higher conductivities due to annealing above the melting point of the electrolyte PEO · LiClO₄ 8:1 or PEO · LiSO₃CF₃ 8:1:1 are suggested to be due to slow recrystallization, but this conclusion is not confirmed by other means.

Fig. 8. Plot of the imaginary part vs. the real part of the admittance (Y) for PEO · NH₄SO₃CF₃ 5:1. a, left: with Pt electrodes at 43°C. b, right: with ammonium tungsten bronze electrodes at 45°C. The equivalent circuits corresponding to cases A and B are shown with circuit elements: bulk resistance, R ; geometric capacitance, C_{geom} ; double layer capacitance C_{dl} . Frequencies (20 Hz-500 kHz) are listed next to data points.

ABSTRACT

n- and p-type InSe single crystals have been grown by the Bridgman-Stockbarger method and characterized by their electronic transport properties. A photoelectrochemical study in aqueous media using the cleavage surface shows rectifying behavior in the dark, confirming diode behavior for both. InSe electrodes exhibit anodic and cathodic photocurrents. These photocurrents are related to a photoelectrochemical effect when a positive bias is applied to n-type InSe and when a negative bias is applied to p-type InSe, whereas the cathodic photocurrent for the n-type and the anodic photocurrent for the p-type are due to a photoconductive effect. Flatband potentials in acidic solution have been determined from the change of sign of the photocurrent and from Mott-Schottky plots of the capacitance (-0.6V vs. SCE for n-type and $+0.2\text{V}$ vs. SCE for p-type). The flatband potential is not pH dependent. Photocurrent spectra indicate a 1.2 eV bandgap. The behavior of InSe electrodes is explained in terms of the location of the valence and conduction bands on the electrochemical scale.

The photoelectrochemical properties of lamellar transition-metal dichalcogenides have recently received a great amount of attention as electrodes in photoelectrochemical cells. The group VIA (W and Mo) chalcogenides have been studied most often (1), as these materials have bandgap between 1.0 and 1.6 eV (2). Another layered-type semiconductor with an adequate bandgap (1.3 eV) for solar energy conversion is indium selenide (InSe); however, its photoelectrochemical properties are not well characterized. This material exhibits n- or p-type conductivity depending on the growth conditions (3-4). InSe belongs to the III-VI semiconductor group, which includes GaS, GaSe, and GaTe (2). Among these compounds, only the photoelectrochemical behavior of p-type GaSe electrodes has been studied (5). This material has a bandgap of 2 eV.

The lamellar structure of InSe is strongly anisotropic and shows covalently bonded units (Se-In-In-Se) held

together by van der Waals forces (Fig. 1). The cleavage plane, that is the van der Waals surface, is made of selenium atoms bonded together with covalent forces. With the Bridgman growth method, the rhombohedral γ -3 R polytype is formed (6). The optical properties and the band structure are fairly well known in the ordinary configuration $\vec{E} \perp \vec{C}$ (7-8), \vec{C} being the crystallographic direction perpendicular to the van der Waals surface, and \vec{E} being the electric vector of in-

cident light. The energy gap in InSe is "quasidirect," that is to say that the direct gap is at 1.3 eV, and the optical transition is only weakly allowed by spin-orbit coupling in the valence band. A parabolic exciton is bound to this gap ($n = 1$, $E = 1.257$ eV). The indirect gap, some 50 meV below the energy of the direct gap, is weak enough not to be observable in optical absorption. Two direct transitions at 2.4 and 2.78 eV are also permitted in this direction. In the solar spectrum region, the absorption coefficient values vary from 10^{-3} cm $^{-1}$ at the absorption edge to 10^{-4} cm $^{-1}$ at 2.5 eV. A remarkable photoconductivity behavior with the occurrence in InSe of negative photoconductivity and photomemory effects has led to the proposal of complex schemes of recombination centers (9). Photovoltaic properties have been studied on single crystals (9f-10).

InSe can be obtained as large crystals using the Bridgman technique, and this material can be used as a model for the photoelectrochemical behavior of lamellar materials, especially for studying the influence of structural effects on the performance in electrochemical cells. Crystals can easily be cleaved in planes

perpendicular to the c axis and only little lattice damage should result from surface preparation. Thus

the $\perp c$ face exhibits quite ideal properties for interfacial studies. As the first part of this study, we report the photoelectrochemical behavior of n- and p-type InSe samples in aqueous solution when the exposed

surface is parallel to the layers ($\perp c$ face).

Experimental

Crystal growth.—The InSe crystals were grown by the Bridgman-Stockbarger method from the high purity elements, 6N In and 5N Se, using an excess of In (11). The phase diagram of InSe indicates an incongruent melting of InSe (12), and $In_{1+x}Se$ compositions have been used in order to avoid the peritectic reaction. n-Type compounds have been obtained when chlorine or gallium were the doping agents, whereas for p-type compounds the doping agent was zinc (3).

Electrical characteristics.—The transport properties were determined from the resistivity and Hall voltage measurements of these crystals. Ohmic electrical contacts were made by ultrasonically soldering with pure indium metal for the n-type material and with conductive silver paint for the p-type crystals. The resistivity was measured using the four-probe direct current van der Pauw technique. The activation energy of the impurity levels was obtained from the variation of the resistivity with temperature from liquid nitrogen to room temperature. The number and sign of current carriers were determined by alternating current Hall measurements.

Experimental procedure.—The layer planes of the cleaved single crystal were used without pretreatment. Ohmic contacts to the back of the crystals were made as described above. The crystals were encapsulated in epoxy resin (EPOXI-PATCH) exposing only the layer planes to the electrolyte. Electrolytes were prepared from reagent-grade chemicals and distilled water. Photoelectrochemistry studies were done in 0.1M H_2SO_4 . In addition, 1M KCl and 0.1M NaOH electrolytes were used in order to find the effect of pH on the photoelectrochemical properties. I_3^-/I^- and $Fe^{2+}/$

Table II

Nature of the electrodes	Initial photovoltages values	
	0.1M H_2SO_4	0.1M NaOH
n-type sample 1	-330 mV	-230 mV
p-type sample 3	+280 mV	+230 mV

Fe^{3+} redox couples were also examined. The reference electrode was saturated calomel and the counterelectrode a platinum wire. Several procedures were used: dark current/voltage characteristics [$I(V)$], capacitance/voltage characteristics [$C(V)$], and photocurrent I_{ph} as a function of the electrode potential V and incident light wavelength. Since the optical range of interest was the near infrared and visible region of the spectrum, a simple Pyrex optical flat window was used. The capacitance of the semiconductor space-charge region was determined by measuring that part of a small (10 mV) ac signal at 1 kHz and 500 Hz, which was in quadrature with the initial reference phase. The exact value of the capacitance was obtained by comparing the observed signal with the values obtained for capacitors of known value. The detection of the in phase and quadrature signals was performed using an ADS-1 ATNE lock-in detector. The illumination of the electrodes was performed by a 70W tungsten-iodine lamp. The intensity of the white light focalized on the semiconductor was close to 100 mW/cm 2 . Either direct or chopped white light or monochromatic chopped light (Jobin Yvon H-20 Spectrometer) was used. The frequency of the chopper was approximately 100 Hz, and the modulated photocurrent was detected with the lock-in amplifier. The spectral distribution of the combination of the tungsten-iodine lamp and the monochromator was determined using a thermocouple detector (2M Dexter) in the infrared region and a calibrated silicon diode (P V 215-EGG) in the visible region.

Results

Transport properties.—The transport properties are reported in Table I for the three samples used as photoelectrodes. These values should be considered as average ones, because, due to the nonstoichiometric Bridgman growth method used, there is some discrepancy between the electrical results across the crystal ingot.

For the experimental value of the carrier density determined from the Hall voltage measurements, assuming a one-electron band model, the width of the depletion layer was estimated (last column of Table I). The formula used is $w = [2 \epsilon \epsilon_0 (V - V_B)/e N_0]^{1/2}$, where ϵ , the dielectric constant of InSe, is 9.74 (7d), and the band bending $V - V_B$ has been chosen to be 1V.

Photovoltages.—The initial photovoltage values obtained in 0.1M H_2SO_4 and in 0.1M NaOH are reported in Table II. After several voltammetric sweeps under light, these values decrease to less than 60 mV.

Voltammetric behavior in the dark.—In 0.1M H_2SO_4 in the dark, the interfaces of samples 1 (n-type) and 3 (p-type) are rectifying, i.e., they have a diode-like voltammogram (Fig. 2a and 2b). However, the character of a given interface is found to change with time after several voltammetric sweeps under light. A deterioration of the diode behavior in the dark is found.

Table I

Sample number	Type	Doping agent	Resistivity Ω cm $^{-1}$	Mobility cm $^2/V$ s	Carriers number/cm 3	Impurity level activation energy	Depletion layer $\mu V^{-1/2}$
1	n	100 ppm Cl $_2$	5	1000	$1.7 \cdot 10^{15}$	0.1 eV	0.8
2	n	10 ppm Ga	42	400	$1.0 \cdot 10^{15}$		1.0
3	p	500 ppm Zn	240	40	$6.8 \cdot 10^{14}$	0.27 eV	1.6

Fig. 2. I-V curves of three InSe samples in the presence of 0.1M H_2SO_4 . A, top: Sample 1. ----: in the dark. —: under direct white light (70W tungsten-iodine lamp). B, middle: Sample 3. ----: in the dark. —: under direct white light (70W tungsten-iodine lamp). C, bottom: sample 2. ----: in the dark. —: under direct white light (70W tungsten-iodine lamp).

For sample 2 (n-type), the initial current varies linearly with the applied potential and at $\pm 1V$ vs. SCE it is equal to $1 \mu A$ (Fig. 2c).

Voltammetric behavior under illumination in 0.1M H_2SO_4 .—The current voltage characteristics under white light for samples number 1, 3, and 2 are represented in Fig. 2a, 2b, and 2c. respectively. All samples show both anodic and cathodic photocurrents. For

sample 1 (n-type), the photocurrent changes sign at $-0.7V$ and at $\pm 1V$ from this value the intensity of the anodic photocurrent is twice the cathodic one. For sample 3 (p-type) at $\pm 1V$ from the change of sign of the photocurrent occurring at $+0.2V$, the cathodic photocurrent is ten times greater than the anodic one. Sample 2 shows a linear photocurrent curve of several $\mu A/cm^2$ and the current changes sign at $-0.2V$.

The shapes of the current-voltage curves change when the wavelength of the light varies. For sample 1, the cathodic photocurrent decreases when the wavelength decreases. For example, between 1040 and 990 nm it is two times larger than the anodic photocurrent (at $\pm 1V$ from the change of sign), while at 680 nm it becomes ten times weaker than the anodic photocurrent (Fig. 3a). The contrary is observed for the p-type sample 3, and the ratio of the cathodic to the anodic photocurrent equals 2 at 1000 nm and 12 at 640 nm (Fig. 3b). The variation of the photocurrent was measured as a function of the variation of the light wavelength. The semiconductor electrodes were polarized for all samples at $+1V$ and $-1V$ from the change of the sign of the photocurrent. The results are presented for samples 1, 3, and 2 in Fig. 4a, 4b, and 4c, respectively.

To observe the effect of pH on the current-voltage characteristics of InSe, new electrode samples were tested in contact with solution of 1M KCl and 0.1M NaOH. Photocurrent voltage characteristics show that there is no real change in the value of the intercept of the photocurrent curves with the potential axis when the pH changes. For the p-type InSe, the cath-

Curve 2: photoconductivity spectrum when a +1.2V is applied. C, left: n-type sample 2. Photoconductivity spectra when a +0.8V is applied (curve 1), and when a -1.2V is applied (curve 2).

Fig. 5 I-V curve of p-InSe (sample 3) under chopped white light (70W tungsten-iodine lamp) in solutions containing 0.1M H_2SO_4 (---), 0.1M KCl (-.-.-), and 0.1M NaOH (—).

odic photocurrent decreases from H_2SO_4 to KCl and to NaOH (Fig. 5) and for the n-type InSe the anodic photocurrent changes in a similar way. A strong hysteresis of the curves, depending on whether the values are obtained as the potential is increasing or decreasing, is observed in the presence of KCl or NaOH. Since previous experimenters had reported the stabilization of electrodes in aqueous solution by the addition of I_3^-/I^- , electrodes of InSe were placed in a solution of 1M KI dissolved in 0.5M H_2SO_4 . For both p- and n-type samples, no change was observed in the shape of the photocurrent, but only a large decrease of the intensity. The electrodes were no longer shiny and started to turn brown. The same result was observed in presence of $\text{Fe}^{2+}/\text{Fe}^{3+}$.

In the presence of 0.1M H_2SO_4 , InSe photoelectrodes were reasonably stable, but after an exposure of several hours under white light (70W tungsten lamp) the crystals were photocorroded and a thin red layer of selenium appeared which could easily be removed by adhesive tape.

Capacitance measurements.—Capacitance measurements were undertaken to determine the flatband potentials. New crystals were used so that the measurement could be performed on a surface which had not yet been corroded. Figures 6a and 6b show the plot of capacitance vs. potential and the curves of $1/C^2$ vs. V (Mott-Schottky plot) for sample 1 (n-type) and sample 3 (p-type), respectively. For both n- and p-type samples, we obtained linear Mott-Schottky plots over a potential range of 300-500 mV in 0.1M H_2SO_4 . From

the intercept, values of -0.6V for sample 1 (n-type) and $+0.2\text{V}$ vs. SCE for sample 3 (p-type) were estimated for the flatband potentials. It was not possible to calculate flatband potentials from a sample after substantial photocorrosion had occurred as the capacitance curves were no longer regular.

Discussion

The sign of the photopotentials and the shape of the dark current are in agreement with the transport properties determined for the n- or p-type electrodes. Contrarily, the current voltage characteristics under illumination do not clearly indicate the carrier type of the electrodes because all samples show both anodic and cathodic photocurrents. From the transport properties measurements, it appears that the majority carrier density is low for InSe and the hypothesis of a photoconductive effect responsible for the unexpected anodic and cathodic photocurrents could be invoked. This photoconductive effect corresponds to an increase in carriers or of their mobility by the absorption of light. The decrease of the intensity of these photocurrents under forward bias when the wavelength decreases (Fig. 3a and 3b) is an indication that they are due to an effect not at the junction but in the bulk, which is the case for the photoconductivity. To prove the existence of a large photoconductivity in InSe, we did the following experiment with a p-type crystal in contact with the air. Two electrical contacts were made with one on the front of the crystal at one end and the other contact on the back at the other end. A controlled bias between $+1\text{V}$ and -1V across the front and back contacts was applied. When the sample was illuminated by a small spot of light (1mm^2) not striking the electrical contact, a several microamperes photocurrent appeared, proportional to the applied voltage, and with direction changing with the sign of the bias. The curve obtained under this condition is similar to the curve number 2c obtained for sample 2 in contact with 0.1M H_2SO_4 , and the photocurrents are thus only photoconductive currents. When we did the same experiment lighting only the front contact, we got a large photocurrent under cathodic bias and a smaller one in the other direction under opposite bias. The curve obtained is similar to that shown in Fig. 2b for the p-type sample in contact with H_2SO_4 , the Schottky barrier being established by the metallic electrical contact. The anodic photocurrent for the n-type sample 1 and the cathodic photocurrent for the p-type sample 3 in contact with an electrolyte is consistent with the presence of the Schottky barrier at the semiconductor/electrolyte interface. From the diminution of the intensity of the cathodic photocur-

Fig. 6. Capacitance-voltage curve and Mott-Schottky plot ($1/C^2$ vs. V) for two samples in 0.1M H_2SO_4 . Frequency: 1 kHz. A, left: n-type sample 1. B, right: p-type sample 3.

rents obtained for the p-type sample 3 when the electrolyte changes from H_2SO_4 to KCl to NaOH , it is obvious that this cathodic photocurrent is due to the hydrogen evolution (Fig. 5). The anodic photocurrent for the n-type sample 1 may be due to a photocorrosion reaction; the intensity of the anodic photocurrent is higher in presence of H_2SO_4 than in presence of NaOH . From these results, we can deduce that the current curves under illumination *vs.* potential represented in Fig. 2a and 2b for samples 1 and 3 show the presence of two effects: photoelectrochemical and photoconductive. For sample 2 (n-type), there was no formation of a Schottky barrier, and only the photoconductivity was observed. The reasons for this are not clear. Figures 4a and 4b represent for n- and p-type materials the spectral response due to the photoelectrochemical process (curve 1) and the photoconductivity spectrum (curve 2). The spectral response determined in the region where the primary photocurrent is due to a photoelectrochemical reaction between the semiconductor and the solution is in good agreement with published optical absorption spectra (3, 7d). For the photocurrent spectra shown in curve 1, the $I_{\text{ph}} \sim (E_g - h\nu)^{n/2}$ law was not verified for either $n = 1$ or $n = 4$. From Fig. 4a curve 1 and 4b curve 1, we can see that the bandgap energy is around 1.2 eV; however, the small peak at 1.24 eV may be due to the exciton bonded to the direct transition at 1.35 eV (7d). The particular shape of the photoconductivity spectra shows again that the current decreases when the energy of the light increases (Fig. 4a, curve 2, 4b, curve 2, 4c) as expected due to the photoconductive effect (9f).

Flatband potentials from the Mott-Schottky plots and photocurrent curves are in agreement. They are estimated as -0.6V for the n-type and $+0.2\text{V}$ for the p-type. The resistivity measurements at low temperatures give the activation energy of the impurity levels—the difference between the Fermi level and the edge of the conduction band ($E_C - E_F$) for an n-type—as 0.1 eV. The difference between the Fermi level and the edge of the valence band ($E_V - E_F$) for the p-type (*i.e.*, the activation energy) equals 0.27 eV. From these results presented above and with the 1.2 eV value for the bandgap energy, the position of the bandedges for n- and p-type InSe can be estimated as -0.45V *vs.* NHE for the conduction band and as $+0.75\text{V}$ *vs.* NHE for the valence band. From these values reported in Fig. 7, it appears that InSe could be a good hydrogen evolving semiconductor photocathode if a suitable metal catalyst is plated at the surface. As a p-type lamellar semiconductor, InSe could be used to study photointercalation, the principle of which was described by Tributsch (13). The position of the bandedges authorizes one to predict that, among the cations that could be intercalated, copper (I) would be the most promising because the copper redox potential is situated between the band energy levels of InSe.

Conclusion

The photoelectrochemical behavior of the van der Waals surfaces of n- and p-type InSe have been studied in 0.1M H_2SO_4 . Under white light, voltammetric study shows the presence of photocurrents of two origins: photoelectrochemical reactions and photoconductivity. The behavior of InSe electrode has been characterized in terms of the location of the valence and conduction bands. These results permitted us to choose copper as a suitable cation to be used to demonstrate that the photoinduced intercalation is possible in a p-type layered compound (14). Since previous results from band structure calculation (8), optical data, and transport measurements (7a-7d, 15) show the existence of a large anisotropy in the physical properties of InSe between the direction of the van der Waals surfaces and the direction perpendicular to the layers, the photo-

Fig. 7. Schematic representation of the energetics at the n-type and p-type InSe electrode/solution interface.

effect should reflect this anisotropy. The results of these experiments will be reported subsequently.

I-V Behavior of the CdSe/Sulfide-Polysulfide and CdSe/Ferro-Ferricyanide Photoelectrochemical Systems

Joseph Reichman and Michael A. Russak

Grumman Aerospace Corporation, Research and Development Center, Bethpage, New York 11714

ABSTRACT

The initial results of a comparison study of the I-V behavior in the n-CdSe/sulfide-polysulfide and the n-CdSe/ferro-ferricyanide photoelectrochemical systems are reported. The greatly enhanced power conversion efficiency of the latter system (14.2% at 52 mW/cm², AM2) compared to the former (7.2%) is attributed to the greater band bending induced in the electrode by the more positive redox potential of the ferro-ferricyanide couple, as well as the enhanced minority carrier transfer kinetics due to a better match between the CdSe valence band and the energy level of the reduced redox species. Energy band diagrams of both systems are presented, and an analysis of monochromatic and dark I-V behavior discussed.

CdSe electrochemical photovoltaic systems have been under investigation for several years, with the CdSe-aqueous sulfide-polysulfide (SPS) electrolyte receiving the most attention (1-4). Some work has also been reported for the CdSe-ferro-ferricyanide (FFC) electrolyte (5-7). However, only recently have efficiencies higher than those found in SPS electrolyte and reasonable stabilities been reported for CdSe in aqueous alkaline FFC electrolyte (8). The key to achieving those improvements is coating the CdSe with a protective layer of Se (8) or a conducting polymer such as polypyrrole (9).

The purpose of this paper is to report results of a comparison study between the CdSe-aqueous SPS and FFC electrolytes. This study was initiated to investigate the origins of very significant differences in I-V behavior that we found in these cells, which resulted in an efficiency of 14.2% for the FFC electrolyte compared to 7.2% for the SPS electrolyte.

Experimental

The experiments reported here were done with an n-CdSe (1120) single-crystal (Cleveland Crystal Corporation) electrode which was back contacted using a copper wire and silver-filled epoxy on an evaporated indium (~5000Å thick) layer. The back and sides of the electrode were covered with insulating epoxy. The electrode was polished with 0.05 μm Al₂O₃, and then etched in 4:1 (volume) HCl:HNO₃. The exposed CdSe area was 0.18 cm². A sulfide-polysulfide electrolyte composition of 2.5M Na₂S, 1M S, 1M KOH, and a ferro-ferricyanide electrolyte composition of 0.5M K₄Fe(CN)₆, 0.5M Na₂Fe(CN)₆, 1M KOH were used for the photoelectrochemical measurements. Before being

tested in the FFC electrolyte, the electrode was anodized in 1M Na₂SO₄, as described by Frese (10, 11), to provide an Se layer of about 1500Å to inhibit photo-corrosion. Dried N₂ was bubbled through the electrolytes during the evaluations to minimize electrolyte oxidation and provide agitation. The white light source was a W-I ELH lamp mounted in a dichroic reflector, which provided a good AM2 spectral simulation (12). Monochromatic I-V curves were obtained using a 0.25m grating monochromator and a 1 kW xenon arc lamp. All light intensities were measured with a calibrated thermopile detector.

Results and Discussion

The I-V curves for the CdSe electrode in the SPS and FFC electrolytes are shown in Fig. 1. The incident light intensity was 52 mW/cm². The superior performance of the electrode in FFC is quite evident in this figure; in particular, the improved fill factor (FF) and increased open-circuit voltage (V_{oc}) are most notable. The short-circuit current densities (J_{sc}) differ only slightly in this case. In general, the J_{sc} for the FFC will depend on the concentration of the redox ions in solution, the thickness of the selenium layer (10, 12), and the optical path length of the incident radiation through the electrolyte. The significant increase in FF and V_{oc} is general, however, and has been observed for a number of single-crystal and thin film CdSe samples. The intensity dependence of the J_{sc} was also measured up to 200 mW/cm², and was found to be linear up to 52 mA/cm² for the SPS electrolyte and linear up to 18-20 mA/cm² for the FFC electrolyte at ~100 mW/cm². The saturation in the FFC electrolyte is probably due to the onset of the diffusion-limited current (12). The output of the CdSe/Se/FFC system was stable for several hours at white light intensities

Key words: energy conversion, semiconductor, electrolyte, junction.

Fig. 1. I-V traces of CdSe in (a) SPS and (b) FFC electrolytes at 52 mW/cm² light intensity.

between 50 and 100 mW/cm², after which a slow decrease in photocurrent was noted. There was no measurable decrease in output observed in the experiments done at 600 nm with intensities of ~1 mW/cm² from which the kinetic analysis was done.

To gain an understanding of the causes of the observed differences in V_{oc} and FF, additional measurements were made to determine some of the basic parameters of the two systems. The flatband potential (V_{FB}) was measured in each electrolyte by noting the potential at which the photogenerated current became zero using phase-sensitive detection and 150 mW/cm² chopped-light illumination.

Values of -1.62 and -0.96V were determined for SPS and FFC, respectively, and these are in agreement with those determined by extrapolation of Mott-Schottky plots for these electrolytes (8, 13). The ionized donor density of $1 \times 10^{17} \text{ cm}^{-3}$ derived from the C-V data agreed with the value obtained by Hall measurements. In addition, the equilibrium redox potentials of the electrolytes were measured on Pt using SCE as the reference and found to be -0.8 and +0.26V for the SPS and FFC, respectively.

Based on these measurements, potential diagrams for the two junctions were constructed. These are shown in Fig. 2. The flatband potential corresponds to the Fermi potential of the CdSe when the bands are flat. The conduction band edge potential was calculated from the measured donor density assuming a conduction-band density of states of 10^{19} . The valence band edge potential was determined using the bandgap energy of 1.7 eV. As indicated in Fig. 2, the equilibrium band bending of the FFC system is 1.22V, as compared to only 0.8V for SPS system. This makes the maximum attainable V_{oc} of the FFC system 0.42V greater than that of the SPS system. The measured open-circuit

Fig. 2. Potential diagrams for CdSe/SPS and CdSe/FFC junctions

voltage difference of 0.3V at 52 mW/cm² light intensity is somewhat less than this maximum attainable difference. The deviation is due to the increased dark current of the FFC system as will be shown. The greater band bending of the FFC system can also account in part for the improved fill factor.

Measurements of quantum efficiencies and dark currents as a function of potential were made to determine if the difference in band bending is the only cause for the change in performance characteristics. Figure 3 shows the quantum efficiency of the CdSe electrode in the two electrolytes as a function of band bending (i.e., 0.0V corresponds to the V_{FB} for each system). These data were obtained using chopped (25 Hz) 600 nm light and lock-in detection. 600 nm was selected because there is no electrolyte absorption in SPS or FFC and the transmission of the Se overlayer is >95% (11).

If the difference in the I-V characteristics shown in Fig. 1 were caused only by the difference in equilibrium band bending, then the quantum efficiency curves of Fig. 3 would superimpose. However, the FFC electrolyte system shows a higher quantum efficiency at smaller values of band bending than the SPS electrolyte. In this region of band bending, space-charge region recombinations become an important photocurrent limiting mechanism (13, 14). These results then indicate that for the FFC system charge transfer kinetics are faster than for SPS, and so reduce the minority carrier density in the space-charge region which reduces recombination losses.

Calculations of the monochromatic I-V data at 600 nm were made using a model that has space-charge region and bulk recombination as the photocurrent loss mechanisms (14) and has provided consistent results for the CdSe/SPS system (13). However, before the model was applied to the CdSe/FFC data, some additional measurements were done to insure that the CdSe/Se (corrosion layer)/FFC system was not a buried p-n junction/ohmic electrolyte interface similar to that reported for metal-filmed semiconductors (15). The CdSe electrode was etched and then anodized in 1M Na₂SO₄ to develop a Se corrosion layer of ~3000Å. The electrode was briefly run in the FFC electrolyte, after which it was washed thoroughly with deionized water and dried. The front face was then coated with an evaporated layer of In about 5000Å thick, which was carefully contacted with Ag epoxy to make an In/CdSe/Se/In structure. The I-V trace for this showed ohmic behavior, as seen in Fig. 4, indicating that the Se corrosion layer was not providing a buried junction. These findings are consistent with the

Fig. 3. Quantum yield as a function of band bending of CdSe electrode in the two redox electrolytes at 1.24 mW/cm², 600 nm incident radiation.

Fig. 4 I-V trace for In/CdSe/Se/In structure showing ohmic behavior.

kinetic analysis done by Frese establishing the good hole conduction of the Se corrosion layer (11).

Reasonably good fits to the I-V data were obtained with the model using minority carrier hole charge transfer velocities of 1000 and 400 cm/s for the FFC and SPS electrolytes, respectively. This was the only adjustable parameter considered. For an equal concentration of redox couples, this would make the rate constant of the FFC couple about five times faster than the SPS couple. This improvement in charge transfer of the FFC system is consistent with its one-electron charge transfer compared to more complex electron transfer for the SPS system. Additionally, the greater overlap of the FFC reduced ion energy states with the CdSe valence band states also would favor higher charge transfer rates (8).

To compare charge transfer rates for the majority carrier electrons in the FFC and SPS electrolytes, measurements were made of the dark currents as a function of potential. The results are presented in Fig. 5, where the dark current is given as a function of band bending using the obtained values of V_{FB} . As previously discussed for the photocurrent, if the charge transfer rates were equal, the two curves would superimpose. For the same amount of band bending, however, the FFC system shows considerably higher dark currents. In addition, the slope of the I-V curve for the FFC displays ideal diode behavior with a slope of 60 mV/decade at band bending greater than 0.3V. The SPS system, on the other hand, displays nonideal diode behavior over the entire potential range. The greater dark current in the FFC electrolyte is attributed to a greater charge transfer rate for majority carriers. As the band bending gets smaller, greater differences in the dark currents of the two systems are observed. This is due to the increasing nonideal behavior of the SPS electrolyte and is attributed to charging of surface states. This shifts the flatband potential to more negative values with increasing voltage. Changes in voltage appear across the Helmholtz region, as well as the space charge region, thereby making the change in current less sensitive to changes in voltage. This surface-state charging effect also appears in the FFC electrolyte; however, it occurs only at potentials closer to flatband.

Conclusions

The improved performance characteristics of CdSe electrodes in FFC electrolyte compared to SPS electrolyte are attributed not only to enhanced minority carrier charge transfer kinetics, but also to greater equilibrium band bending induced by the more positive

Fig. 5. Dark current as a function of band bending of CdSe electrode in the two redox electrolytes.

redox potential of the FFC. The increased dark current in the FFC electrolyte compared to the SPS electrolyte is due to enhanced charge transfer kinetics for majority carriers, and it acts to reduce the difference in the open-circuit voltage of the two systems that might be expected from differences in equilibrium band bending.

The Stability of Silane Layers on Titanium Dioxide Electrodes

R. Vithanage and H. O. Finklea*

Department of Chemistry, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061

ABSTRACT

Silane monolayers were synthesized on TiO₂ electrodes and examined for their stability during the photoelectrolysis of water at various pH's. X-ray photoelectron spectroscopy was used to monitor the silane layer; correction was required for the frequent presence of a contaminant layer after the electrochemical treatment. In general, silane layers suffered noticeable losses after ca. 3 C/cm² of charge was passed. Considerable improvements in stability could be obtained by cross-linking the silane layer during synthesis and by reacting the electrode a second time. The most stable silane layer was synthesized from SiCl₄ "capped" with Me₂SiCl₂.

Silanization is one of the most versatile methods of generating modified electrode surfaces (1). It is based on the reaction between a hydrolytically sensitive Si-X bond (X = Cl, OR, NHR) and a surface OH group (Eq. [1]). The latter function can be found on any wet oxide surface. The list of

successfully silanized electrode substrates includes metals (Au, Pt), quasimetals (highly doped SnO₂, In₂O₃), and semiconductors (Si, Ge, TiO₂, GaAs) (1-3).

With respect to semiconductor electrodes, two applications of silanization have been sought: inhibition of photoactivated corrosion (3a-3d, 4) and catalysis of electrochemical processes, e.g., hydrogen evolution (3d-3f, 3h, 1, 5). Two questions of interest with respect to silanized electrodes are (i) the effects of the silanization on the semiconductor electrode properties, and (ii) the durability of the silane layer. On the former question, the published evidence indicates that there is little, if any, effect on electron transfer properties, provided that the redox molecule either is bound close to the semiconductor surface or has access to the surface. The latter question is likewise important; a durable modified electrode is essential for any practical applications.

We wish to address the question of durability of nonelectroactive silane layers on semiconductor electrodes. To avoid complications due to the concomitant corrosion of the electrode, TiO₂ is chosen as a model substrate. A strenuous test for silane stability is the photoelectrochemical oxidation of water at the TiO₂ anode. Gas evolution tends to disrupt surface films. Likewise, very reactive intermediates (hydroxy radicals) are generated at the surface. Except for fairly acidic electrolytes (6), TiO₂ is stable during photoelectrolysis.

An earlier report (7) indicated that silane layers survived photoelectrolysis at intermediate pH's. We have extended our test to longer photoelectrolysis times and a wider pH range, and have found evidence for partial loss of the silane layer under these conditions. To increase the durability of the silane layer, attempts were made to internally cross-link the silane moieties.

The history of the silane layers was monitored by x-ray photoelectron spectroscopy (XPS).

Experimental

Electrode preparation.—Disk electrodes (6 mm diam) were cut from a single-crystal boule of rutile (Commercial Crystal Laboratories), exposing the (001) face. The disks were initially polished, doped in hydrogen (600°C), and etched in hot concentrated sulfuric acid (250°C), as previously described (8). Prior to silanization, the electrodes were steamed for 2-3h to ensure hydration. After their first use, the electrodes were hand polished using 5 μm alumina, etched, and steamed before each experiment.

* Electrochemical Society Active Member.

Silanization.—Using a procedure developed for silanizing TiO₂ powders (9), the TiO₂ electrodes were dried under vacuum at 150°C for 2h, and then exposed without cooling to a controlled pressure of silane vapor (liquid silane at 15°C). After 1h, excess vapor was pumped away.

A cross-linking reaction scheme was devised to improve silane layer stability. Following the silanization reaction, the electrodes were exposed to water vapor (liquid at 15°C) for 1h, pumped down for 20 min, and then heated (150°C) under vacuum for 2h.

A double cross-linking reaction refers to the silanization and cross-linking procedure being repeated a second time.

Electrochemistry.—Photocurrent generation was performed in four different electrolytes of varying pH: 0.5M H₂SO₄ (pH 0.5), H₃PO₄/KH₂PO₄ buffer, ionic strength 0.2M (pH 2.0), KH₂PO₄/Na₂HPO₄ buffer, ionic strength 0.2M (pH 6.0), and 0.1M NaHCO₃/0.1M Na₂CO₃ (pH 10.0). The TiO₂ electrode was irradiated with the water-filtered output of a 150W Xe arc lamp. At ca. 1V vs. SCE photocurrent densities of 0.7-2 mA/cm² were obtained. Photocurrent generation was terminated after approximately 1C of charge (3.5 C/cm²) had passed. No significant changes in the photocurrent level were observed during this test; photocurrent densities of silanized electrodes were comparable to that of clean electrodes. As noted previously (7), the photocurrent-voltage curves were not noticeably affected by any of the silanizations.

XPS.—All XPS spectra were recorded on a du Pont 650B spectrometer with a magnesium anode. Titanium, oxygen, carbon, and silicon were monitored before and after each photoelectrochemical experiment. Peak areas of the Ti(2p_{3/2}) and Si(2p) peaks were calculated by triangular approximation. Peak energies are referred to C(1s) at 285.0 eV.

Results

TiO₂ is readily modified by a variety of silanes. Successful silanizations yield characteristic changes in the XPS spectra (7): (i) the Ti(2p) peaks are reduced in intensity, (ii) the O(1s) spectrum changes from a single peak at 530 eV to a doublet, the second peak being at 532 eV, and (iii) the Si(2s) and Si(2p) peaks appear above background signal. An estimation of average thickness for the silane layer can be obtained from the comparison of the Ti peak intensity to that of a blank electrode (see below) (10, 11). In general, the synthetic procedure yields silane layer thicknesses consistent with one or two monolayers. Occasionally low silanization yields, i.e., very small Si peaks, are observed. Such instances we attribute to poorly hydroxylated surfaces (9). As a consequence, electrodes are steamed over a beaker of boiling water to promote maximum hydration of the surface. However, uncontrolled polymer formation is undesirable. The synthetic procedure is designed to maintain strictly anhydrous conditions to prevent the silane from reacting

with any species other than the surface O-H groups. Such precautions usually work, but in a few experiments polymer coatings did form (strong Si peak, no visible Ti peak), most notably with SiCl_4 .

The diagnostic criteria for silane stability is based on the Si and Ti peaks. While the higher binding energy peak in the O(1s) spectrum is characteristic of silanized electrodes, organic contamination of the electrodes produces a similar peak. In order to avoid large uncertainties introduced by day-to-day variations in the spectrometer sensitivity, the Si(2p) peak area is normalized by the Ti(2p_{3/2}) peak area for each sample. The Si-to-Ti peak ratio is monitored as a function of electrochemical treatment. Qualitatively, a stable silane layer should exhibit no change in the ratio after photocurrent generation. Loss of the silane layer should cause the Si peak to decrease, the Ti peak to increase, and the Si-to-Ti peak ratio to decrease sharply. These criteria were used to establish that the silane layers are stable to soaking in the four electrolytes for 12h (but they are rapidly stripped in 1M NaOH).

However, both the Si and Ti peak areas often decrease after the electrochemical treatment, and the C(1s) peak increases. Such an effect can be explained by the deposition of a contaminant layer (probably organic) upon the electrode surface. The coating reduces peak intensities of all underlying elements due to inelastic scattering of the photoelectrons. A possible source of the contamination is the epoxy (Shell Epon 828 + du Pont PACM-20) used to insulate the TiO_2 disk edges. The presence of the coating prevents the simple interpretation of silane stability given above.

Electrode contamination should in fact cause an increase in the Si-to-Ti peak ratio for a stable silane layer. This prediction is based on the exponential decrease of photoelectron intensity with the thickness of the scattering layer (10)

$$I_{\text{coated}}/I_{\text{clean}} = \exp(-d/\lambda) \quad [2]$$

In Eq. [2], d is the thickness of the coating and λ is the characteristic scattering length of the substrate photoelectron. The appropriate values for λ are estimated to be 1.7 nm for the Ti(2p_{3/2}) photoelectrons and 2.2 nm for the Si(2p) photoelectrons (10). Applying Eq. [2] to the Si-to-Ti peak ratio, one obtains

$$\frac{I_{\text{Si}}}{I_{\text{Ti}}}(\text{coated}) = \frac{\exp(-d/\lambda_{\text{Si}})}{\exp(-d/\lambda_{\text{Ti}})} \frac{I_{\text{Si}}}{I_{\text{Ti}}}(\text{uncoated}) \quad [3]$$

where d is now the thickness of the organic coating overlying both the silane and the TiO_2 . When the values for λ_{Si} and λ_{Ti} are substituted into Eq. [3], one gets

$$\frac{I_{\text{Si}}}{I_{\text{Ti}}}(\text{coated}) = \exp(+d/7.5 \text{ nm}) \frac{I_{\text{Si}}}{I_{\text{Ti}}}(\text{uncoated}) \quad [4]$$

Consequently, the Si-to-Ti peak ratio appears larger as a result of the organic contaminant layer. Equation [4] also predicts that the Si-to-Ti peak ratio should be less sensitive to the thickness of the contaminant layer than either the Si or Ti peaks.

With this in mind, we present our results in the form of stacked bar graphs, shown as a function of pH. One TiO_2 electrode was used at each pH. The upper bar graphs illustrate the Ti(2p_{3/2}) peak area; loss of Ti peak intensity after photocurrent generation indicates contamination of the electrode. The lower bar graphs are the Si-to-Ti ratios. For reference, a monolayer of silane corresponds to a Si-to-Ti peak ratio of 0.05-0.10. Figures 1, 2, and 3 contain the results for the single "normal" silanization, the cross-linking reaction, and the double cross-linking reaction, respectively.

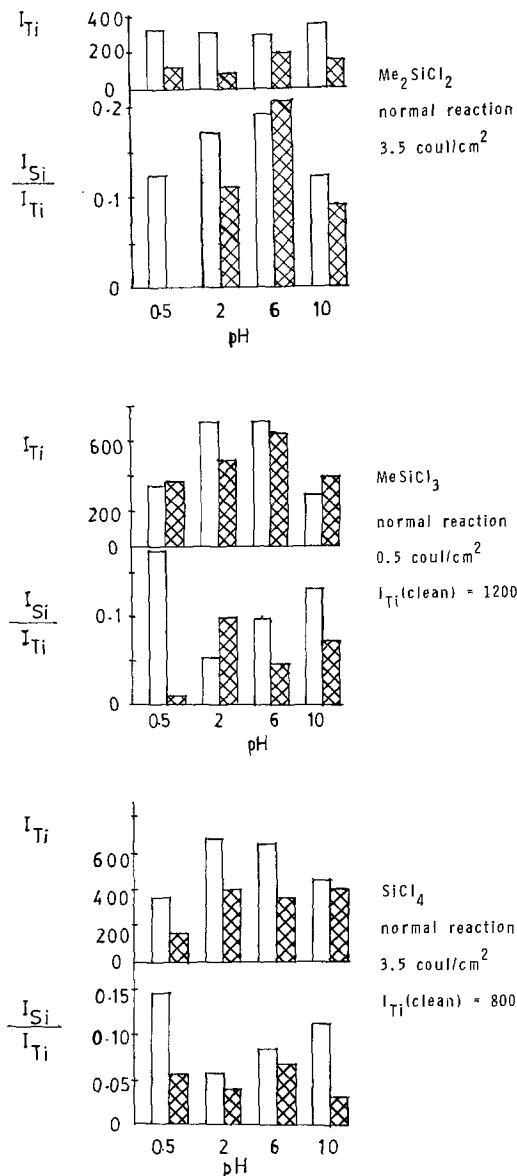

Fig. 1. Normal reaction conditions (see text). Open bars: after silanization. Cross-hatched bars: after photocurrent generation. A, top: Me_2SiCl_2 . B, middle: MeSiCl_3 . C, bottom: SiCl_4 .

Discussion

In earlier papers, we reported that silane layers on TiO_2 electrodes survived photocurrent generation in water (7) and in acetonitrile (12). Both the photocurrent density and the total coulombs of charge passed were over a factor of ten lower than in the present work. Consequently, we attribute the loss of silane

Fig. 2. Cross-linked once. $\text{MeSi}(\text{OMe})_3$. Same convention as in Fig. 1.

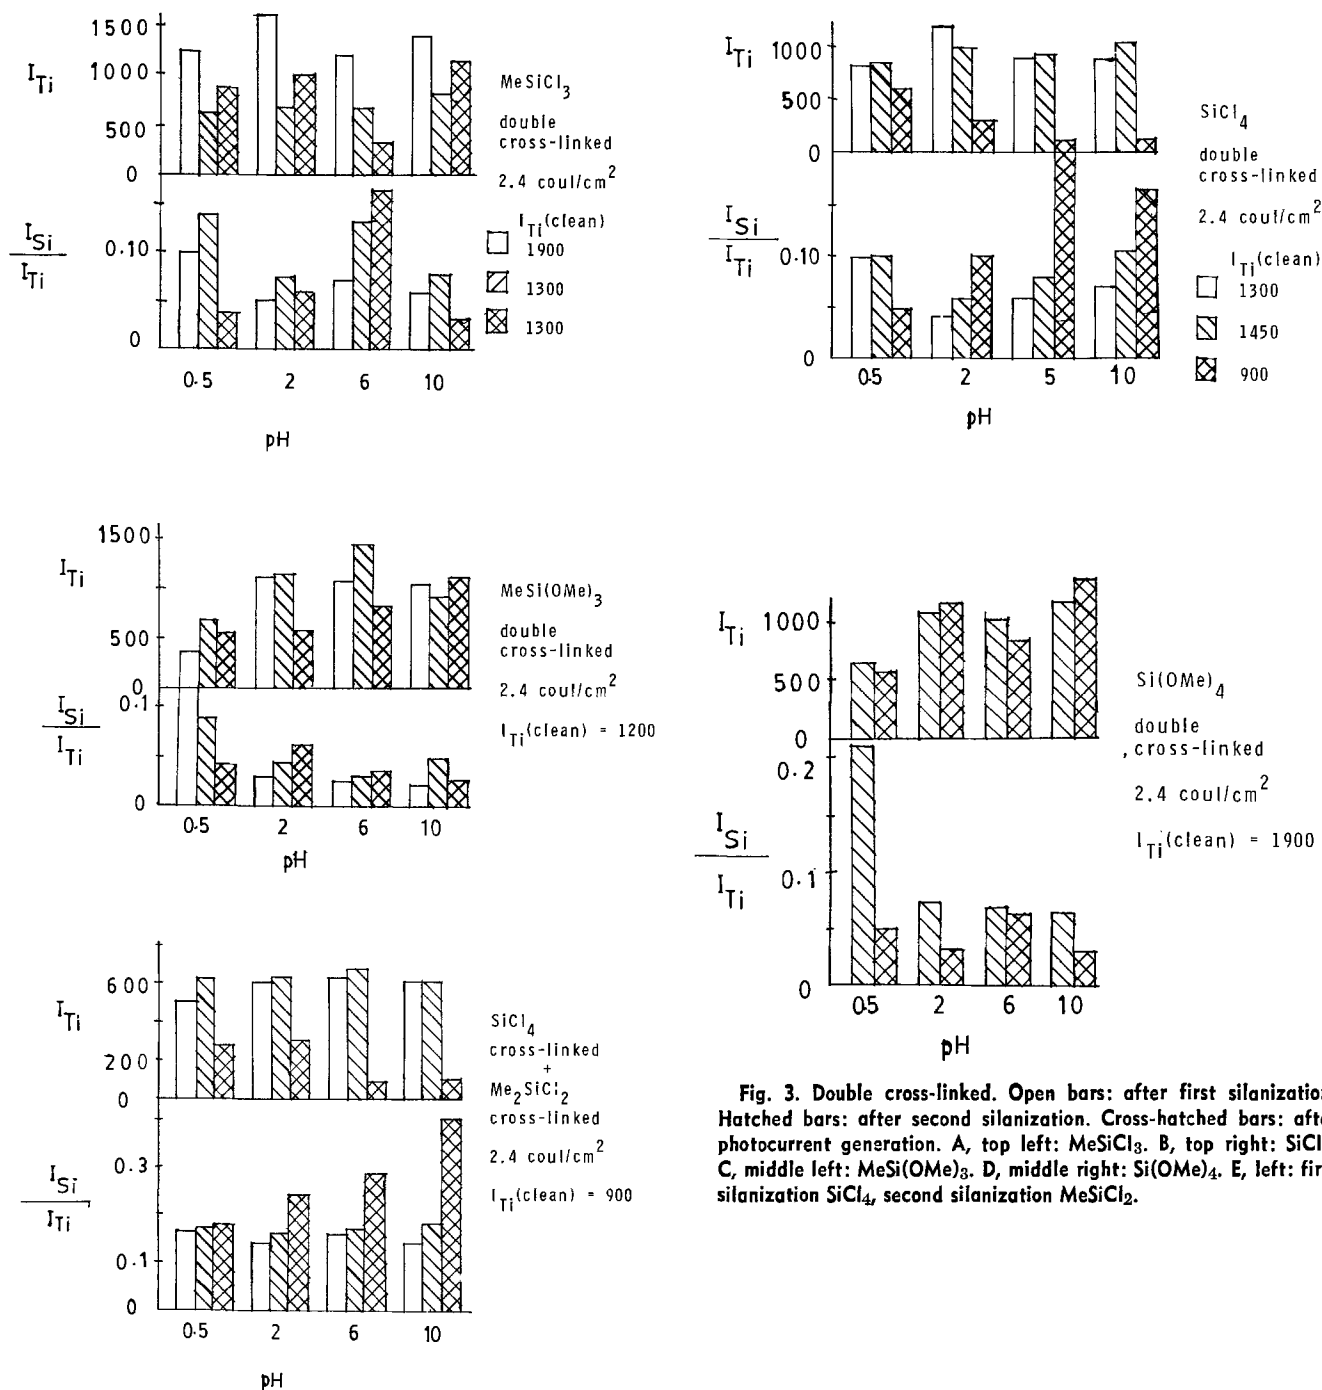

Fig. 3. Double cross-linked. Open bars: after first silanization. Hatched bars: after second silanization. Cross-hatched bars: after photocurrent generation. A, top left: MeSiCl₃. layers shown here to the more severe test conditions. Figure 1 illustrates the point for Me₂SiCl₂, MeSiCl₃, and SiCl₄. In nearly every case, the Si-to-Ti ratio decreases concurrently with a decrease in the Ti peak area. The loss is particularly noticeable in 0.5M H₂SO₄ (pH 0.5). Given the prediction that the Si-to-Ti ratio should increase when electrode coating is observed, it is apparent that a sizable fraction of silane has been removed. Not shown are the data for a monofunctional silane, hexamethyldisilazane. Complete loss of silicon results from the photocurrent generation for that silane.

The cross-linking reaction was devised as a means of improving the silane layer stability. The proposed reaction sequence is shown in Fig. 4. A trifunctional (or tetrafunctional) silane is reacted with surface O-H groups, as in the "normal" reaction. With the assumption that an average of two bonds are formed between the silicon and the surface (9, 11), one or more unreacted Si-X (X = Cl, OMe) bonds exist on each silane. Added water vapor converts these bonds to silanols. In the final step, the silanols are condensed to form a lateral linkage between silicons. The expecta-

tion of greater stability is based on the lateral cross-links. Silane loss most likely proceeds via hydrolysis of the M-O-Si linkage. If this connection is severed, then lateral cross-links would prevent the silicon atom from leaving the surface. Eventually the broken linkage may "heal," *i.e.*, recondense.

These expectations are supported by the data (Fig. 2). MeSi(OMe)₃ generates surface layers that appear stable at pH 6 and 10. The apparent loss at pH 2 may be anomalous (in fact, results for individual electrodes must be treated with caution; the overall pattern of a given experiment is more reliable).

As a further effort for extra stability, we proceeded to the double cross-linking scheme. The objective of the second silanization is to block any holes existing in the first silane layer and to tie up any free surface OH groups. Another objective is to construct a second silane layer on top of the first one. This is predicated on the knowledge that free silanols exist after the cross-linking reaction with tetrafunctional silanes (9).

The results are summarized in Fig. 3. The Ti peak areas and Si-to-Ti peak ratios are shown after each silanization step (Fig. 3d excepted) as well as after

Fig. 4. The cross-linking reaction scheme

the electrochemical treatment. It is evident that the silane coverage increases following the second silanization; however, the net increase is small. When Ti peak areas are normalized for variations in the spectrometer sensitivity (given by the area of a "clean" Ti peak), no significant change in the Ti peak areas is visible. Likewise, the Si-to-Ti peak ratios show slight increases. We interpret this result as indicating (i) that there are few "holes" in the first silane layer, i.e., monolayer saturation is achieved in the course of the reaction (9), and (ii) that in the case of the tetrafunctional silanes, the density of free silanols on the modified surface is considerably lower than that of the original surface.

Surface layer stability varies from silane to silane in a nonsystematic fashion. MeSiCl_3 (Fig. 3a) exhibits noticeable loss of silane except at pH 6. $\text{Si}(\text{OMe})_4$ (Fig. 3d) presents the same pattern: a decrease in the Si-to-Ti peak ratios along with a slight gain in the Ti peak ratios. However, SiCl_4 (Fig. 3b) and $\text{MeSi}(\text{OMe})_3$ (Fig. 3c) show the pattern expected for a stable silane layer coated with a contaminant layer: loss of Ti signal, gain of Si-to-Ti peak ratios. In all of these experiments, loss of the silane layer is most evident at pH 0.5. Silane loss is probably associated with TiO_2 corrosion. Whether the silane layer inhibits corrosion is not apparent from these experiments.

A final experimental variation reveals a promising direction for stable surface layers (Fig. 3e). When TiO_2 electrodes are first modified with SiCl_4 and then Me_2SiCl_2 (both cross-linked), the surface layer thus formed exhibits the best stability observed so far, even at pH 0.5. It is possible that the bonded dimethylsilyl moieties impart a hydrophobic character to the surface layer. We suggest that hydrophobicity may be another key to surface layer stability on electrodes.

With the assumption of silane layer stability, Eq. [2] and [4] can be used to estimate the thickness of the contaminant layer for the data in Fig. 3e. From the diminution of Ti peak areas with respect to that of a clean electrode, coating thicknesses of 1.2, 3.6, and 3.0 nm are calculated at pH 2, 6, and 10, respectively. Based on increases in the Si-to-Ti peak ratio, the corresponding numbers are 3.1, 3.8, and 5.8 nm. The agreement is only approximate. The larger values obtained using the Si-to-Ti ratios suggest that the 7.4 nm coefficient in Eq. [4] may be too large, which in turn would indicate a greater difference in the scattering lengths of Ti and Si photoelectrons than the theoretical values suggest. For example, a scattering

length of 2.7 nm for Si(2p) photoelectrons would change the coefficient of Eq. [4] to 4.6 nm, and would give values of 1.9, 2.4, and 3.6 nm for the coating thicknesses. Another problem is the hidden assumption that silane and contaminant layers are uniform in thickness across the electrode surface. This assumption seems unlikely in view of the facile water oxidation at the TiO_2 anode. Access of reagents to the electrode and products from the electrode appears to be unhindered. Also, rearrangements of the silane morphology may be occurring. For these reasons, we have not presented quantitative estimations of silane layer thickness before and after photoelectrolysis for most of the data.

A comparison of Fig. 2 with Fig. 3c highlights a major problem with surface syntheses. For the same silane [$\text{MeSi}(\text{OMe})_3$] and nominally the same synthesis procedure, a considerable difference (factor of two) is seen in the Si-to-Ti peak ratio on newly silanized electrodes. A similar wide variation in coverage is implied by the different Si-to-Ti peak ratios obtained with all the different silanes and for a given silane on the four electrodes. The factors affecting silane coverage are still poorly understood. However, the changes observed in the Si-to-Ti ratio for a single electrode are more certain. Repetitive measurements of that ratio on a single electrode over a 2 week period show a standard deviation of only 18% about the mean (seven measurements) and no systematic trend, despite a considerable change in spectrometer sensitivity.

Conclusions

The stability of thin silane layers on TiO_2 during the photoelectrolysis of water can be markedly improved by cross-linking the silane layers during synthesis, and also perhaps by adding a hydrophobic "capping" layer. Very long-term stability is not known; even the most stable silane layers may eventually degrade. When possible, pH extremes should be avoided. The silane layers do not affect the photoelectrolysis current density.

The Role of the Lower Metal Oxide/Higher Metal Oxide Couple in Oxygen Evolution Reactions

P. Rasiyah* and A. C. C. Tseung*

Department of Chemistry, The City University, London EC1V OHB, England

ABSTRACT

The minimum potential for the evolution of oxygen on six oxides (RuO₂Li_{0.1}Ni_{0.9}O, Li_{0.3}Co_{2.7}O₄, IrO₂, PbO₂, and PtO₂) in 5N KOH has been studied by potentiostatic steady-state and galvanostatic charging experiments. The results show that there is an excellent correlation between the minimum potential for oxygen evolution on the first three oxides and their lower oxide/higher oxide couples (RuO₂/RuO₄ = 1.387V; Ni₂O₃/NiO₂ = 1.43V; Co₂O₃/CoO₂ = 1.447V) listed in Pourbaix diagrams. For IrO₂, there was good agreement between the lower oxide/higher oxide couple (IrO₂/IrO₃ = 1.35V) determined in this work by galvanostatic charging. Galvanostatic charging on PbO₂ and PtO₂ indicates that oxygen evolution takes place at 1.76 and 1.71V, respectively. However, these two values do not correlate with their lower oxide/higher oxide couple values. It is therefore suggested that oxygen evolution on such oxides proceeds via the OH⁻/HO₂⁻ couple (1.77V), where the reaction intermediates are physisorbed. We also discuss the stability of the lower and higher oxides of the six metals considered from the point of view of the crystal field concept.

Although oxygen evolution has been studied on numerous metals and oxides and many mechanisms have been put forward to explain the oxygen evolution reactions on these substrates, no satisfactory explanation has yet been given for the different voltage values on different substrates at a particular current density. It is of great fundamental interest to determine the factors responsible for the differences. Up to now few investigations (1-3) have been directed at ascertaining these factors.

Ruetschi and Delahay (1) carried out a theoretical investigation and concluded that different overvoltages on metals arise because of the difference in the magnitude of the M—OH bond energies. They assumed the rate-determining step to be the initial discharge of the OH⁻ ion. The M—OH bond energies were estimated in three ways and then plotted against the values of the overpotential for oxygen evolution at 1 A/cm² in 1N KOH at room temperature. The slope of the plot was taken to indicate the difference in overvoltages and the heats of activation and was accounted for by the changes in the M—OH energy that occur from metal to metal. The authors did not choose to plot all the bond energy values, since some of them showed marked departures from the correlation. Co metal showed the lowest overpotential and the highest M—OH bond energy.

Tseung and Jasem (2), in a recent investigation of oxygen evolution on semiconducting oxides, emphasized the role of the metal/metal oxide couple or the lower metal oxide/higher metal oxide couple in determining the minimum potential required for oxygen evolution, together with other essential factors such as electrical resistivity, electrode microstructure, and corrosion properties. Based on these criteria, they suggest that NiCo₂O₄ is of interest as an oxygen evolution electrocatalyst. Teflon-bonded NiCo₂O₄ gave an oxygen evolution current density of 1 A/cm² at 1.6V vs. the dynamic hydrogen electrode (DHE) at 70°C in 5N KOH.

The work carried out by Vijh (4), although not directly pertaining to oxygen evolution, warrants mention. He found an empirical correlation between the

two quantities, the metal/metal oxide standard electrode potential and the electronic conductivity, which have been postulated to govern oxygen evolution. Vijh also correlated the bandgap of the oxides to the metal/metal oxide standard electrode potential, thus linking the two solid-state properties to the electrode potential.

Hickling and Hill (3) carried out oxygen evolution measurements on ten different metal anodes in alkaline solution over a current density range of 10⁻⁵ to 1 A/cm², in 1N KOH at 20°C. They also studied the variation of the oxygen overvoltage on the different metals with time. Table I gives the oxygen evolution potential obtained by Hickling and Hill on ten metals at a current density of 1 A/cm² in 1N KOH. Also included in Table I are the lower oxide/higher oxide couples of the ten metals. These values were obtained from literature (5), except for lead, whose value was obtained by galvanostatic charging (Fig. 1). Figure 1 gives the plot of oxygen evolution potential obtained by Hickling and Hill on ten metals at a current density of 1 A/cm² vs. the lower oxide/higher oxide couple, showing a very good correlation. The metal Cd was not included in the correlation since its lower oxide/higher oxide couple was not available in literature. The results presented in Table I suggest that the oxygen evolution

potential at high current densities (e.g., 1 A/cm²) on metals is governed by the lower oxide/higher oxide couple of the metal.

This paper describes the oxygen evolution studies carried out on six oxides to ascertain the role of the lower oxide/higher oxide couple in relation to the oxygen evolution performance.

Choice of Oxides

An oxide should possess two important properties to be considered for this study: corrosion resistance and fairly low electrical resistivity. Six oxides were chosen for this study: PtO₂, Li_{0.1}Ni_{0.9}O, Li_{0.3}Co_{2.7}O₄, IrO₂, PbO₂, and RuO₂. Although the corrosion resistance of the latter three oxides is doubtful, initial polarization studies carried out proved that these oxides have adequate corrosion resistance for the purpose of this study.

Materials and Methods

IrO₂ and PtO₂ were prepared by thermal treatment of IrCl₃ and H₂PtCl₆ · H₂O, respectively. Li_{0.1}Ni_{0.9}O and Li_{0.3}Co_{2.7}O₄ were prepared by freeze drying. These two oxides were doped with Li⁺ to lower their electrical resistivity. RuO₂ and PbO₂ were obtained commercially. The room temperature, compressed, powder resistivities of the six oxide powders were measured using a Teflon die. The Brunauer, Emmett, and Teller (BET) specific surface areas of the six oxides were also measured. Table II gives the electrical resistivities and the BET specific areas of the six powders.

Electrode preparation.—Since this investigation involves a comparative study of six oxides, it is necessary to normalize the oxide loading of the electrodes. Furthermore, the electrode preparation has to be carried out under uniform conditions. The electrocatalyst loadings of each of the six oxide electrodes were controlled as far as possible to contain approximately 1 m² of BET specific surface area of oxide per cm² of electrode. The oxide loading was kept at such high values so that oxygen evolution potentials would be the lowest possible for all six electrodes and a comparative study would be possible. Initial exploratory work based on different oxide loading confirmed the validity of this approach. For example, a preanodized FEP- (fluorinated ethylene propylene) bonded Li-doped Co₃O₄ electrode

of electrocatalyst loading 27.8 mg/cm² gave an oxygen evolution performance of 1.562V vs. the DHE in 5N KOH at a current density of 5 mA/cm². Changing the electrocatalyst loading from 27.8 mg/cm² to 32.1 mg/cm² gave approximately the same oxygen evolution potential under similar conditions. Similar observations were made for PtO₂. Preanodized PtO₂ electrodes consisting of 44 and 63 mg of PtO₂ per cm² gave oxygen evolution potentials of 1.771 and 1.774V for a current density of 5 mA/cm² under similar conditions. Furthermore, for each oxide, initial optimization studies were carried out by preparing electrodes containing different FEP-to-oxide ratio and then subjecting them to oxygen evolution studies.

Electrochemical evaluation.—All electrodes were preanodized to obtain a stable electrocatalytic surface and to reduce the oxygen bubble size. Electrodes of different oxides required different preanodization conditions. A three-compartment glass cell was used for all electrochemical measurements. A DHE was used as the reference electrode. When calibrated against a reversible hydrogen electrode in 5N KOH at 25°C, the potential of the DHE was found to be -18 mV. The interrupter technique was used to measure the ohmic drop between the Luggin capillary and the working electrode.

Anodic charging curves were used to determine the couple that determines the potential at which oxygen evolution begins in 5N KOH at 25°C. The curves for the oxides of Ir, Pb, and Pt were obtained by passing a small anodic current on cathodized electrodes (10 mA/cm² for 5h) which were previously anodized. The charging curves on the oxides of Ru, Ni, and Co were carried out on freshly prepared electrodes.

Results and Discussion

The charging curve on reduced IrO₂ (Fig. 2) shows two peaks at potentials less than 0.5V. This region has been related to adsorption of atomic hydrogen (6, 7) on Ir. At higher potentials, there are two points of inflection, at 0.84 and 0.94V, and a peak at 1.35V. The points of inflection at potentials 0.84 and 0.94V could be related to Ir/IrO and Ir/IrO₂ couples, which have values (8) of 0.81 and 0.93V, respectively. Since the ratio of the charges between the potential range 0.84-0.94V and 0.94-1.35V is approximately 1:1, it could be concluded that Ir ion attains an oxidation state of six, i.e., forms IrO₃ before evolving oxygen. Thus, for IrO₂, the lower oxide/higher oxide couple that governs oxygen evolution is IrO₂/IrO₃, which has the value of 1.35V. The charging curves on the oxides of Ru, Ni, and Co (not given) suggested that the potentials of couples that govern oxygen evolution are 1.39, 1.44, and 1.47V, respectively. These values are in good agreement with the lower oxide/higher oxide couple values of 1.387 (RuO₂/RuO₄), 1.434 (Ni₂O₃/NiO₂), and 1.447V (Co₂O₃/CoO₂) reported by Pourbaix (5). The study of oxygen evolution on PbO₂ and PtO₂ is interesting in that in the case of the former the cation is of oxidation state four, which is the highest that is possible for Pb. In the latter case, the next highest oxidation state is six determined by the couple PtO₂/PtO₃ of value 2.0V. Charging curves on reduced PbO₂ and PtO₂ (Fig. 3 and 4) show peaks at potentials of 1.76 and 1.71V, respectively, before oxygen evolution takes place. These two values cannot be assigned to a higher oxidation state in either case. However, the values are very close to the potential of the OH⁻/HO₂⁻ of 1.77V, thus, having the possibility of oxygen evolution taking place via the formation of the peroxide intermediate. If this is the case, these two oxides behave as an inert surface on which the reaction intermediates are physisorbed (ps), as opposed to the active surfaces where chemisorbed intermediates are formed on the other four oxides. A mechanism with (HO₂⁻)_{ps} intermediate could be

The $(\text{HO}_2^-)_{\text{ps}}$ could evolve oxygen by a further multi-step process.

Figures 5-9 give the V - $\log i$ plots for oxygen evolution on preanodized FEP-bonded RuO_2 , IrO_2 , PtO_2 , Li-doped NiO , Li-doped Co_3O_4 , and PbO_2 electrodes, at 25°C in $5N$ KOH . Table III gives the oxygen evolution potentials for a current density of 1 mA/cm^2 , the couples that are expected to govern oxygen evolution, and the potential values of these couples. The oxygen evolution potential corresponding to a current density of 1 mA/cm^2 was taken to be the minimum potential

for oxygen evolution, since the current potential characteristics at current densities of 1 mA/cm^2 and less deviated from the oxygen evolution Tafel slope for most of the oxides considered. The currents at regions where the oxygen evolution Tafel slope deviates is attributed to the anodic reactions leading to oxidation state changes before the highest oxidation state oxide is formed.

Figure 10 gives the plot of the oxygen evolution potentials for a current density of 1 mA/cm^2 on the six oxides and the respective couples that govern oxygen evolution showing a good correlation. According to this correlation, it could be inferred that the oxides of Ir, Ru, Ni, and Co evolve oxygen only after their surface cations undergo oxidation state transitions and attain the respective potentials of the lower oxide/higher

Fig. 4. Anodic charging curve on reduced PtO_2 at 25°C in 5N KOH.

oxide couple. However, the results suggest that PtO_2 and PbO_2 evolve oxygen at potentials very close to the $\text{OH}^-/\text{HO}_2^-$ couple, without undergoing any formal oxidation state changes.

Table IV gives the lattice type, the cation oxidation number, the cation environment, and the electron dis-

tribution in the d orbitals of the cation in the oxides at rest and in the highest oxidation state oxide. Since oxygen evolution is a surface process, it is assumed that the higher oxidation state cation that is formed is in the same environment within the rigid host lattice. All cations except the Co^{2+} cations of the Li-doped Co_3O_4 are in octahedral environment. It is assumed that the cations in the octahedral environment of the lattice have sufficient high field to induce the low spin electronic arrangement. If transitions to higher oxidation states involves removal of electrons from destabilized d orbitals, i.e., from e_g orbitals in octahedral environment (o) and t_{2g} orbitals in tetrahedral environment (t), then the higher oxidation state is stabilized. An example of this is the $\text{Co}^{2+}(\text{t}) \rightarrow \text{Co}^{3+}(\text{t}) \rightarrow \text{Co}^{4+}(\text{t})$ oxidation state transitions in Li-doped

Co_3O_4 bringing about $e_g^4 t_{2g}^3 \rightarrow e_g^4 t_{2g}^2 \rightarrow e_g^4 t_{2g}^1$ electron transitions, respectively. The corresponding energy transition could be given as $-12Dq' + 2P \rightarrow -16Dq'' + 2P \rightarrow -20Dq''' + 2P$, where $10Dq$ is the magnitude of the crystal field splitting and P is the pairing energy. However, since an increase in oxidation state of a cation in a fixed environment increases the value of the $10Dq$ (9), assuming the value of P to be constant, it could be stated that $10Dq''' > 10Dq'' > 10Dq'$. Thus, an increase in oxidation state of a cation in a fixed environment brings about a further stability by increasing the magnitude of the crystal field splitting. From the above arguments, $\text{Ni}^{2+}(\text{o}) \rightarrow \text{Ni}^{4+}(\text{o})$ will be energetically feasible, and $\text{Ru}^{4+}(\text{o}) \rightarrow \text{Ru}^{8+}(\text{o})$ forms the stable rare gas configuration of Kr. In the case of IrO_2 , where $\text{Ir}^{4+}(\text{o}) \rightarrow \text{Ir}^{6+}(\text{o})$ transition is postulated, the loss of

crystal field stability by the removal of two electrons from the t_{2g} orbitals in forming Ir^{6+} can be outweighed by the gain in stability due to loss of pairing and an increase in crystal field splitting energy due to the higher oxidation state transition. The stability of Co^{4+} formed by the $\text{Co}^{3+}(\text{o}) \rightarrow \text{Co}^{4+}(\text{o})$ in Li-doped Co_3O_4 could be justified by an argument similar to that put forward for IrO_2 . This discussion shows that the higher oxidation state surface species that are formed on the four oxides under consideration, although chemically unstable and structurally highly strained, are brought about by oxidation state transitions that are energetically feasible.

Pb ion in PbO_2 has an outer electronic arrangement of $5d^{10}$ and therefore oxidation states greater than four are very unlikely for it and have not been reported in general literature. As for PtO_2 , where the Pt^{4+} has an electronic configuration which in the octahedral environment of $t_{2g}^6 e_g^0$ could also be considered to be stable. It could be argued that such a postulation is in contradiction to the previously proposed activity of $\text{Co}^{3+}(\text{o})$, which is of the same electron configuration. However, it must be borne in mind that $\text{Co}^{3+} \rightarrow \text{Co}^{4+}$ transition requires (10) an energy equivalent of only approximately 0.3V, whereas PtO_2 has to be raised from its potential at rest to 2.0V to elevate the oxidation state of Pt from +4 to the next possible state of +6. Therefore, due to the restriction of oxidation state transition in PtO_2 and PbO_2 , oxygen evolution could take place on them by an alternative process.

The exchange current densities for oxygen evolution were evaluated from the polarization data of the six oxides. The exchange current densities are pseudo-values and are based on unit geometric area of the electrode. The pseudoexchange current density of any one oxide will vary, depending on the oxide loading of the electrode. However, since the loading of all six oxide electrodes were normalized, a comparative study of the pseudoexchange current densities is facilitated. Table V gives the pseudoexchange current densities and the Tafel slopes for oxygen evolution on the six oxides. A plot of the negative log of the pseudoex-

PbO ₂	3.5	0.121

change current densities and the couple governing the minimum potential of oxygen evolution for the six oxides (Fig. 11) does not show any correlation, suggesting that the oxygen evolution rate on the oxides is not totally dependent on the magnitude of the lower oxide/higher oxide couple. Figure 12 gives the plot of the negative log of the pseudoexchange current density vs. the ratio of the lower oxide/higher oxide couple and the Tafel slope for the six oxides and shows good correlation. Therefore, although the minimum potential of oxygen evolution on oxides is determined by the lower oxide/higher oxide couple, the rate of oxygen evolution is also dependent on the Tafel slope. Therefore, the factors that determine the magnitude of the Tafel slope, such as the type and nature of the sites, extent of site coverage, etc., are also important in determining the rate of oxygen evolution.

The trend shown in Fig. 12 can be explained as follows: the Tafel line intercept, which is the overpotential η at unit current density is given $\eta = -b \log i_0$, where b is the Tafel slope and i_0 is the pseudoexchange current density. From Fig. 10, η is proportional to value of the couple governing oxygen evolution, E . Thus E is proportional to $-b \log i_0$, and hence $E/b \propto -\log i_0$.

Conclusions

This study shows that the behavior of oxides towards oxygen evolution can be divided into two groups. In one group, the oxides evolve oxygen by undergoing an increase in the cationic oxidation state before evolving oxygen. The intermediates formed during this process are of the chemisorbed type. Oxygen evolution takes place on these oxides at fairly low overpotentials, very close to the potential of the lower oxide/higher oxide couple. Oxides of Ir, Ru, Ni, and Co belong to this group. The other group of oxides evolve oxygen at fairly high overpotentials close to the potential of the OH⁻/HO₂⁻ couple of 1.77V. This group consists of either oxides that are of stable electronic configuration at rest, e.g., PbO₂ where Pb⁴⁺

Fig. 12. Relationship of the pseudoexchange current density for oxygen evolution of six oxides at 25°C in 5N KOH and the respective ratio of the couple governing evolution (E') and the Tafel slope (b).

is a d¹⁰ ion and on which further oxidation state transitions are not very possible, or oxides that undergo oxidation state transitions at very high potentials, e.g., PtO₂ having a PtO₂/PtO₃ couple of 2.0V. This study suggests that oxygen evolution on this group of oxides takes place by the formation of physisorbed HO₂⁻ as intermediate.

Electrochemical Properties of $\text{WO}_3 \cdot x(\text{H}_2\text{O})$

II. The Influence of Crystallization as Hydration

Nobuyuki Yoshiike and Shigeo Kondo

Matsushita Electric Industrial Company, Limited, Central Research Laboratory, Moriguchi, Osaka, 570 Japan

ABSTRACT

Electrochemical properties of WO_3 films prepared by vacuum evaporation and stored in high humidity atmosphere have been studied in organic electrolytes. Structures of the film have been analyzed by electron diffraction analysis and x-rays. It has been found that the evaporated amorphous WO_3 film is crystallized to form $\text{WO}_3 \cdot \text{H}_2\text{O}$ crystal and furthermore $\text{H}_2\text{WO}_4 \cdot \text{H}_2\text{O}$ from surface layer to bulk layer in high humidity air. Hydrated $\text{WO}_3 \cdot x(\text{H}_2\text{O})$ crystal layer may act as a high resistant layer on the electrochemical reaction, so that the hydrated layer, remarkably, loses the electrochromic activity.

WO_3 is one of the most useful materials for electrochromic displays (ECD) (1-6). At present, a reasonable model for coloration is explained by Faughnan *et al.* (3), whereby the double injection of electrons and protons into the film forms tungsten bronzes. The bronze has a stable memory effect and can be switched back into the original colorless state by reversing the current. Recent studies (7-13) have confirmed that water in the film plays an important role in the coloration and bleaching mechanism. Hurditch (7) has studied the dependence of the coloration phenomenon on the water content in the film. He suggested $\text{WO}_3 \cdot \text{aq}$ as intermediate between a fractionally hydrated form of tungsten oxide and a polytungstic acid. Zeller and Beyeller (8) concluded that the crystal water not only provides a high ionic conductivity which is conditional for a fast electrochromic reaction, but also stabilizes electrocatalytically active surface sites. Reichman and Bard (9) reported that the kinetic behavior of the electrochromic process is attributable to differences in porosity and water content of the film.

The states of water in the WO_3 film may be classified into three groups: physisorbed water, chemisorbed water as hydroxylated, or hydrated water having a crystal structure. The authors (14) have recently confirmed the influence of free water as physisorption and chemisorbed water as hydroxylation and/or hydrolysis on the electrochemical properties of evaporated WO_3 films. In particular, we have suggested that the water adsorbed in the film during the evaporation and from ambient air after the ventilation of the vacuum chamber not only provides a fast electrochromic reaction at first, but reacts gradually with WO_3 by hydroxylation and/or hydrolysis to shift the potential of the cathodic reaction to negative side, and then the hydroxylated film loses the electrochromic coloration density at the same applied potential.

Tungstates (15) may generally be obtained by precipitating tungstate solutions with mineral acids. Paola *et al.* (16) reported the electrochromism in anodically formed tungsten oxide films. They prepared tungstates and measured cyclic voltammetry of the films in H_2SO_4 aqueous electrolytes, and they suggested a new coloration mechanism. Reichman *et al.* (9) also reported the behavior of WO_3 anodic films.

In this paper, we report the formation of tungstate crystals from evaporated amorphous WO_3 films stored in high humidity air and the electrochemical properties of the tungstate films in propylene carbonate electrolytes.

Experimental

Preparation of WO_3 films.— WO_3 films were deposited by an electron beam evaporation method. WO_3 targets (99.99%) were supplied by Furuuchi Kagaku Company, Limited. The deposition rate was 4-5 Å/s, the deposition angle was varied within 40° with a planetary rotation, and the substrate temperature was usu-

Key words: electrochromism, display, hydration, tungsten oxide.

ally maintained at 80°C after keeping at 110°C for 5 min. The total gas pressure in the chamber during the evaporation process was controlled by N_2 gas introduction to be $4-5 \times 10^{-5}$ torr. Deposited WO_3 films were confirmed by electron diffraction analysis to be typically amorphous. Packing density of the film calculated from film thickness, and its weight was 5.38 g/cm³, and the reflection index evacuated from the interference patterns of visible absorption and film thickness was 1.85.

The substrates were In_2O_3 -coated glass (20 Ω/cm²) used for electrochemical measurements and electron diffraction analysis, glass plates for x-ray diffraction analysis, and Al films for electron diffraction analysis.

For the purpose of investigating the influence of humidity on the evaporated films, the films were stored in humidity-controlled air at different conditions with a thermostat (Nagano Kagakukikai, Model NEW LH-20).

Analysis of WO_3 films.—Electron diffraction analyses of the films were carried out with an electron microscope (Nihon Denshi, Model JEM-200CX); the accelerated voltage was 80 kV. The incident beam angle was 5°-6°, and electron diffraction patterns were formed by reflection from surface of WO_3 films.

Direct x-ray diffraction patterns of the films (16,000 Å thick) on glass plates were obtained by using a Philips Model APD-10 goniometer. Cu_α radiation (voltage: 50 kV, current: 40A) was used. The scanning speed was 2° 2θ/min. The d spacings were compared with the ASTM index values and reference papers.

Transmission electron microscope photographs of the film were taken with a positive replica method using the microscope described above.

Electrochemical measurements.—The electrochemical measurements, especially cyclic voltammetry measurements, were performed with a potentiostat (Hokuto Denko, Model HA-301), which was supplied with voltage from a function generator (same company, Model HB-104). The WO_3 film thickness and area were 3000Å and 0.3 cm², respectively. The counter-electrode was a Pt plate, and the reference electrode was a saturated calomel electrode (SCE). The electrolytes were propylene carbonate (PC) solutions containing 0.3M LiClO_4 and 0.03M LiBF_4 . PC (first grade, Wako Junyaku) was freshly distilled under vacuum, LiClO_4 (purity 99%, Mitsuwa Kagaku), and LiBF_4 (purity 93%, Morita Kagaku) were used. Ar gas was bubbled for more than 5 min before measurements. H_2O content in the electrolytes was checked in each case by an Aquacounter (Hiranuma Seisakusho, Model AQ-3B), and these concentrations were typically 0.03-0.05M.

Results and Discussions

Structures of WO_3 films.—Electron diffraction measurements formed by reflection from surface were taken with WO_3 films on Al film substrates stored in

Fig. 1. Electron diffraction patterns of WO_3 films ($16,000\text{\AA}$ thick on Al) stored in different conditions after the storage in air at 25°C and 50% RH for 72h. A: on treatment. B: 40°C and 95% RH for 1h. C: 80°C and 95% RH for 1h. D: 100°C for 1h at 1×10^{-6} torr after treatment B.

different conditions are shown in Fig. 1. The film stored in air at 25°C and 50% RH for 72h was amorphous; the film stored in air at 40°C and 95% RH for 1h had a crystal structure pattern, and the film stored at 80°C and 95% RH for 1h remained amorphous. This will be interpreted as dehydration of the film at high temperatures (i.e., 80°C). An endothermic peak was observed on amorphous WO_3 with differential thermal analysis at around 90°C (19). Once the film was crystallized, no differences in the reflection patterns could be observed even after treatment in a vacuum chamber at 100°C and 1×10^{-6} torr for 1h (Fig. 1d). A surface reflection pattern was also observed with the WO_3 film on In_2O_3 -coated glass stored in air at 40°C and 95% RH for 1h, but it was not as well defined as the film on Al films. The reflection pattern did not appear with the film stored in air at 25°C and 50% RH for long periods (more than 4000h). Hence, the crystallization does not occur under the conditions of <50% RH and < 25°C .

The d spacings with the definite patterns were estimated by using a reference of Au diffraction pattern, and are tabulated in Table I with $\text{WO}_3 \cdot \text{H}_2\text{O}$ values of the ASTM (no. 18-1418) and Glemser (17). Table I shows that the reflection pattern of the film stored in high humidity air can be assigned to $\text{WO}_3 \cdot \text{H}_2\text{O}$ crystal. Needless to say, the d spacings were different from those of the substrate compounds: Al, Al_2O_3 , $\text{Al}(\text{OH})_3$, and/or In_2O_3 . The d spacing of the strongest peak with ASTM values ($d = 3.49\text{\AA}$) was not observed. This may be explained by the crystallization of film with a preferred orientation, because, besides many rings, clear spots were also observed.

X-ray diffraction analyses of the WO_3 films on glass plates which were stored in air at 40°C and 95% RH are shown in Fig. 2. The diffraction pattern was observed with the film after the storage for 24h, but not with the film after 2h. However, a definite electron reflection pattern was observed with the same film stored for 2h. The penetration depth with electron probe is much less than with x-ray, and then surface layer and bulk layer is examined with electron reflection patterns and x-ray diffractions, respectively (20). Therefore, the crystallization may proceed from surface layer to bulk layer.

2.290	9	2.304	10	030
1.720	2	1.729	6	040

The d spacings of x-ray analyses were compared with $\text{H}_2\text{WO}_4 \cdot \text{H}_2\text{O}$ values of the ASTM (no. 18-1420) and are tabulated in Table II. The peaks at $d = 6.857$,

Fig. 2. X-ray diffraction patterns of WO_3 films ($16,000\text{\AA}$ thick on glass plate) stored in air at 40°C and 95% RH for different time. A: 2h. B: 24h.

3.437, 2.290, and 1.720 Å can be assigned closely to the d spacings of the $\{0k0\}$ planes of $\text{H}_2\text{WO}_4 \cdot \text{H}_2\text{O}$, and the intensity ratios agree exactly among themselves. These results may be attributed to the presence of monoclinic $\text{H}_2\text{WO}_4 \cdot \text{H}_2\text{O}$ which crystallized with a preferred orientation of the $\{010\}$ planer parallel to the substrate. The peak at 5.335 Å may be attributed to the presence of a small amount of $\text{WO}_3 \cdot \text{H}_2\text{O}$.

Electron reflection patterns of the film (1.6 μm thick) on In_2O_3 -coated glass stored in air at 40°C and 95% RH for 24h was observed and assigned to $\text{H}_2\text{WO}_4 \cdot \text{H}_2\text{O}$ crystal, but its patterns were not as clear as those on Al. Hence the orientation of crystallization may depend on the surface state of substrates.

Consequently, under the condition of high humidity, it was predicted that a recombination as hydration of the film with dissociation of W-O-W bonding occurs, and the $\text{WO}_3 \cdot \text{H}_2\text{O}$, and furthermore the $\text{H}_2\text{WO}_4 \cdot \text{H}_2\text{O}$, are formed as follows

Transmission electron microscope examinations of WO_3 films by a positive replica method shows that the porous surface layer of amorphous film was changed to a dense and glassy layer by crystallization, as shown in Fig. 3.

Electrochemical properties.—Cyclic voltammograms of the WO_3 films which were stored in different conditions for 1h (after the storage of as-deposited film in air at 25°C and 50% RH for 72h) are shown in Fig. 4. In Fig. 4, the potential cycling started at +1000 mV vs. SCE and returned to -400 mV with a 200 mV/s scan rate. The cathodic current which started at +250 mV

Fig. 3. Transmission electron microscope photographs with a positive replica method of WO_3 films stored in different conditions. A: 25°C and 50% RH for 72h. B: 40°C and 95% RH for 24h after the treatment of A.

Fig. 4. Cyclic voltammograms at 0.2 V/s scan rate in PC electrolytes of WO_3 films stored in air at different temperatures and 95% RH for 1h after storage in air at 25°C and 50% RH for 72h. Curve 1: no treatment. Curve 2: 25°C. Curve 3: 30°C. Curve 4: 40°C. Curve 5: 60°C. Curve 6: 80°C.

is associated with the coloration reaction of the film, and the anodic current is associated with the bleaching reaction. Figure 4 shows that, in spite of the rarity of change of the starting potential of the cathodic reactions, the cathodic current decreased with the storage in high humidity atmosphere and the peak potential of the anodic current shifted to positive side with the storage. That is, both the cathodic and anodic reactions become slower with the storage, and these changes are assigned to a deterioration of electrochromic activity. The extent of the deterioration was distinguished with the storage at 40°C and 95% RH, and it was smaller with the storage at temperatures higher than 40°C.

Cyclic voltammograms of the films which were stored in air at different relative humidities at 40°C for 1h are shown in Fig. 5. The electrochromic activity of the films decreased with increasing humidity of the atmosphere.

In order to make the detailed behavior of hydrated WO_3 more clear, cyclic voltammograms of freshly prepared films were measured connected in series to various different resistances. These are shown in Fig. 6. Figure 6 shows that the potential of the cathodic reaction does not change, but rather that the cathodic current decreases and the anodic current peak shifts to the positive side with the resistivity of the resistances. This behavior is similar to the cyclic voltammograms of the film having a crystal surface layer (see Fig. 4, curve 4). Therefore, hydrated crystal surface layers may act as a resistant layer against electrochemical reaction. That is, the layer may contribute to the depression of diffusion of proton and/or electron mobility. This effect of crystal surface layer can also be supported with the results of the TEM photograph (Fig. 3) showing the crystal surface to be more dense than the amorphous film.

Consequently, the crystallization will be remarkably different from both the effect of physisorbed water improving the electrochemical reaction and the effect of chemisorbed water shifting the cathodic reaction to negative potentials. In order to prepare ECD's having constant electrochromic properties, the exposure of the WO_3 film to even slightly high humidity atmospheres (i.e., 60% RH) at around room tempera-

Fig. 5. Cyclic voltammograms at 0.2 V/s scan rate in PC electrolytes of WO_3 films stored in air at 40°C and different humidities for 1h after storage in air at 25°C and 50% RH for 72h. Curve 1: no treatment. Curve 2: 60% RH. Curve 3: 80% RH. Curve 4: 90% RH. Curve 5: 95% RH.

ture to 80°C during storage and assembly must be avoided.

Conclusion

Evaporated amorphous WO_3 can be crystallized to form $\text{WO}_3 \cdot \text{H}_2\text{O}$ crystals and $\text{H}_2\text{WO}_4 \cdot \text{H}_2\text{O}$ crystal from surface layer to bulk layers after storage in high humidity air for relatively short time. The hydrated crystal layer may act as a high resistance layer on the electrochemical reaction so that the electrochromic activity of the film is remarkably deteriorated.

Activation of Glassy Carbon Electrodes by Dispersed Metal Oxide Particles

I. Ascorbic Acid Oxidation

Shaojun Dong and Theodore Kuwana*

Department of Chemistry, The Ohio State University, Columbus, Ohio 43210

ABSTRACT

Various metal oxides (MOx) were dispersed onto a glassy carbon (GC) surface for the purpose of catalyzing the oxidation of ascorbic acid (AH₂). Of the 37 different metal oxides examined, more than 20 showed varying degrees of rate enhancement (henceforth referred to as activation) for AH₂ oxidation. The highest degree of activation was exhibited by those MOx's whose oxidation state of the metal was +3 or higher, such as zirconium oxide, ceric oxide, cobaltic oxide, chromic oxide, stannic oxide, and the previously reported alumina. The double layer capacitance was also observed to increase with MOx/GC's compared to the bare GC electrode. This increase suggested that the surface area of the GC electrodes increased due to the dispersion of MOx. The pH dependence of the AH₂ activation at MOx/GC was considerably different from that at a bare GC electrode and suggested that the enhancement mechanism may involve an acceleration of a proton-transfer step via AH₂ interaction with the MOx/GC surface. A model of the physical structure of the MOx/GC surface is proposed to account for the carbon surface activation.

We recently reported (1, 2) that α -alumina dispersed on glassy carbon surfaces (henceforth referred to as α -Al₂O₃/GC) enhanced the rate of the electrode reaction with ascorbic acid (AH₂), 1,2-dihydroxybenzene (1,2-H₂Q, commonly called catechol), 1,4-dihydroxybenzene (1,4-H₂Q, commonly called hydroquinone), and oxalic acid (H₂Ox). The rate enhancement (henceforth referred to as activation) resulted in the lowering of the overpotential by 200-300 mV with the α -Al₂O₃/GC compared to highly polished, bare GC electrode. Catechol and hydroquinone, the two compounds with product reversibility, exhibited electrochemically reversible cyclic voltammograms at α -Al₂O₃/GC. Adsorption of the electroactive species onto the α -alumina particles also was observed. It was suggested that activation possibly involved an acceleration in the rate of proton transfer by the alumina.

To further assess the nature of the MOx activation, various MOx's, differing in elemental composition and oxidation states, were dispersed onto GC surfaces. The electroactive species used for assessing the extent of activation was ascorbic acid, whose electrochemical behavior is quite sensitive to the surface state of the glassy carbon surface (3, 4). The catalysis of AH₂ through surface modifications, i.e., via immobilization of redox mediators (3, 5, 6), polymeric films (7, 8), spontaneous adsorption (9), and metal adatoms (10, 11) has been reported.

As reported herein, a total of 37 different MOx's were mechanically dispersed onto GC surfaces and examined by cyclic voltammetry (CV). It was surprising to find that more than 20 oxides exhibited some degree of rate enhancement as evidenced by either the anodic peak potential, E_{pa} , shifting to less positive values and/or the peak current, i_{pa} , increasing in comparison to a bare GC electrode. The higher valent, harder refractory oxides, such as ZrO₂, CeO₂, Cr₂O₃, and the previously reported α -Al₂O₃, appeared to give the most pronounced effect to AH₂ oxidation.

In our earlier work with 1 μ m α -Al₂O₃ dispersed on GC, an increase in the double layer capacitance was observed, indicating an increase in the surface area. Also, catechol, hydroquinone, and ascorbic acid were reported to adsorb on this electrode. The extent to which these two factors may be important in the observed activation are discussed. The characteristics of AH₂ oxidation at MOx/GC electrodes are determined using the electrochemical methods of CV, chrono-

amperometry, and chronocoulometry, in addition to experiments performed using electrodes in rotating disk and thin-layer cell configurations.

Experimental

Chemicals.—L-ascorbic acid (Baker Analyzed Reagent Grade) was used as received. All of the metal oxides were from SPEX Industries, Incorporated. Twice distilled water was used for the preparation of solutions. The supporting electrolyte was 0.1M phosphate buffer at pH 2.0 (0.1M ortho-phosphoric acid with 0.1M sodium phosphate added for pH adjustment).

Electrode preparation.—A Kel-F shrouded GC disk (Bioanalytical Systems, Incorporated, West Lafayette, Indiana) with a geometric area of 0.071 cm² and a Tokai glassy carbon, GC-20, (Tokai Carbon, Limited, Tokyo) with a geometric area of 0.43 cm² were used as working electrodes. The surfaces of the GC's were polished successively with emery paper and alumina (Buehler, Limited, Chicago, Illinois, 1.0, 0.3, and 0.05 μ m) on an optical flat (Harrick Scientific Corporation, Ossining, New York) until a mirror-like finish was obtained on the surface. Final polishing was done on a polishing cloth (Buehler). Residual polishing material was removed from surfaces by sonication of the electrodes in a water bath for 30 min during which the water (twice distilled) was changed frequently. An electrode prepared by this procedure will be considered as a "bare" GC (henceforth referred to as GC₀). The metal oxides were dispersed onto the surface by rotating the GC under light hand pressure with a small amount of the desired MOx in slurry form on an optical flat. The MOx/GC surfaces were rinsed with doubly distilled water several times prior to immersion in the test solution. Electrodes were prepared and used immediately for each run.

Equipment and instrumentation.—Cyclic voltammograms were obtained with a BAS (Bioanalytical Systems, Incorporated, West Lafayette, Indiana) cyclic voltammeter Model CV-1B-120 connected to a three-electrode cell. A silver/silver chloride (saturated KCl) electrode served as the reference, and all potentials in the text will be reported with respect to this reference. A Houston (Houston Instrument Company, Austin, Texas) Model 2000 X-Y recorder served to record data. Chronoamperometric and chronocoulometric experiments were conducted with a home-built potentiostat with output capabilities of 150 mA and a rise time of less than 50 μ s. Input pulse signals to the potentiostat were provided by a PAR (Princeton Applied Re-

* Electrochemical Society Active Member.

Key words: metal oxides, particles, ascorbic acid, glassy carbon, electrochemistry.

search Corporation, Princeton, New Jersey) Model 175 waveform generator.

Rotating disk electrochemical experiments were performed with a Pine Instruments (Pine Instruments Company, Greenville, Pennsylvania) Model RDE-3 potentiostat and a Model ASR-165 analytical rotator. The rotating disk electrode (RDE) consisted of a glassy carbon disk shrouded by Teflon with a geometric electrode area of 0.49 cm^2 .

Scanning electron microscopy (SEM) photomicrographs of MO_x/GC surfaces were acquired on a Cambridge Stereoscan Model S4-10 (EG&G Ortec, Oak Ridge, Tennessee) with elemental analysis determined by energy dispersive x-ray (EDX) analysis with an ORTEC 6200 Multichannel Analyzer. Particle size distribution was determined by a computer imaging system (Videoplan by Carl Zeiss, Incorporated, Germany) using enlarged SEM photographs. The distribution function of the particle diameters was determined, as well as the average and the standard deviation of the diameters. The smallest particle diameter that could be imaged with the present system was 5 nm.

Results

Scope of MO_x activation.—Considerable variation of the potential at which AH_2 was oxidized was observed depending on the pretreatment procedure for preparing the GC electrode. With the procedure described in the experimental section, the cyclic voltammograms were found to be quite reproducible from run to run. Typical voltammograms of AH_2 oxidation at a GC_0 in phosphate buffer (pH 2.0) are shown in Fig. 1 (dashed lines). The average E_{pa} value of the broad i-E waves was 0.49V ($\sigma = 0.06\text{V}$ for 60 values), which is close to the previously reported (2) value of $+0.454 \pm 0.05\text{V}$ in $0.05\text{M H}_2\text{SO}_4$. A reverse wave was not observed for AH_2 because of the rapid hydrolysis of the oxidized product to dehydroascorbic acid. Examples of AH_2 oxidation at MO_x/GC are shown in Fig. 1; the solid curves labeled a, b, and c correspond to cyclic voltammograms at CeO_2 , ZrO_2 , and Cr_2O_3 , respectively, dispersed onto GC surfaces in phosphate buffer at pH 2. The effect of these oxides on AH_2 oxidation is considerable, i.e., the CV i-E waves became narrower with the i_{pa} enhanced and the E_{pa} values shifted to less positive potentials by 200–300 mV in comparison to the E_{pa} at GC_0 .

To explore the activation with respect to the elemental and valence composition of MO_x 's, 37 different metal oxides as particles were dispersed onto GC surfaces. The results for AH_2 oxidation (phosphate buffer, pH 2.0) with several of these oxides are tabulated in Table I. More than 20 oxides exhibited some degree of "catalysis," with the more effective activators appearing to be correlated with the higher valent oxides. For example, SnO_2 and PbO_2 exhibited activation, while the lower valent, SnO and PbO , did not. However, care must be exercised in interpreting such results because many oxides may be partially solubilized and/or undergo varying extents of hydration or hydrolysis in the acidic aqueous media. Ascorbic acid is also known to form complexes with certain metal ions (12, 13), although complexation may be minimal in acidic solutions.

Because of the large number of MO_x 's exhibiting activation properties, it was important to disperse particles with known chemical inertness and see whether activation occurred. Zak (2) had previously indicated that garnet/GC and KRS-5/GC did not activate AH_2 oxidation. However, the most inert material for use as a test particle appeared to be synthetic diamond commonly used as metallographic polishing compounds. Such diamond "dust" is often suspended in organic dispersing agent to prevent particle agglomeration. In order to remove the dispersing agent, the diamond particles (Buehler diamond, $1 \mu\text{m}$) were

Fig. 1. Cyclic voltammograms of 1 mM ascorbic acid in phosphate buffer at pH 2.0 at GC_0 (dotted line) and at MO_x/GC electrodes (solid line). a: CeO_2/GC . b: ZrO_2/GC . c: $\text{Cr}_2\text{O}_3/\text{GC}$. first washed with acetone in a Soxhlet extractor, filtered and dried, and then washed thoroughly with twice-distilled water. The particles were heated and stored in a vacuum oven at 500°C . They were dispersed onto a GC surface by the usual mechanical abrasion method. The cyclic voltammograms of ascorbic acid, catechol, and hydroquinone at a diamond/GC were essentially unchanged from those at a GC_0 electrode. Thus, this apparent lack of activation by diamond was consistent with its known chemical inertness.

Earlier, it was speculated that the MO_x may accelerate the rate of the proton transfer step since the compounds, such as AH_2 , $1,2\text{-H}_2\text{Q}$, and $1,4\text{-H}_2\text{Q}$, have a common feature of involving protons in the overall reaction. It is therefore interesting to examine the behavior of ferrocyanide/ferricyanide, which undergoes an outersphere, one-electron redox reaction without the participation of any protons. Trace d in Fig. 1 (dotted curve) is a typical i-E wave for ferro-/ferricyanide at a GC_0 electrode. The separation of the cathodic and anodic peak potentials was usually the order of 100–150 mV at glassy carbon and considerably more than the 60 mV characteristics of a reversible electrode reaction. The voltammograms for ferro-/ferricyanide at MO_x/GC 's such as CeO_2 and ZrO_2 remain essentially identical to those at GC_0 , if one corrects for the larger,

background charging current. Thus, the ferro-/ferricyanide redox reaction is not markedly affected by the presence of MOx. The scope with respect to compound types is currently being examined to ascertain whether involvement of a proton in the rate-determining step of the redox reaction is a prerequisite to MOx activation.

The presence of MOx on the GC surface was confirmed by elemental analysis using EDX, and the particle dispersion/distribution was determined by SEM. Figure 2 shows SEM photomicrographs of CeO₂, ZrO₂, Co₂O₃ as representative samples of MOx/GC's. The particle size and its distribution were evaluated by particle imaging from enlargements of these SEM photomicrographs. The size distributions for these oxides are given in Fig. 3. The total surface area occupied by MOx ranged from 10% for CeO₂ to 19% for Co₂O₃. In our previous α -Al₂O₃ work, coverages ranged from 20% to 30%. The extent of activation can become coverage dependent if the coverage is too low. However, a detailed study of the coverage dependence has been deferred until a method of fractionating the particles and dispersing them reproducibly is devised. It will then be possible to assess the relationship between the size and coverage to the effectiveness of activation.

Adsorption.—Since the MOx particles are on the average much larger than the width of the diffuse double layer, it is difficult to envision a mechanism of activation. In our earlier work (1, 2) with α -Al₂O₃/GC, surface adsorption by AH₂, catechol, and hydroquinone was evidenced by the shape of the CV i -E

waves, particularly at low concentrations of the electroactive species, where the adsorptive wave predominated. Adsorption was also indicated by the non-zero intercept on the charge axis of the extrapolated plots of Q vs. $t^{1/2}$ from chronocoulometry. Thus, the question arose whether surface adsorption was a prerequisite to activation.

At MOx's such as CeO_2 , ZrO_2 , ThO_2 , and Cr_2O_3 , the plots of the i_p vs. $v^{1/2}$ from CV data for AH_2 were linear and extrapolated to the zero current intercept when corrected for background. Similarly, adsorption of AH_2 on these same electrodes appeared to be absent as evaluated by chronocoulometry. However, varying amounts of adsorption were observed by both CV and chronocoulometry on Co_2O_3 and $\alpha\text{-Al}_2\text{O}_3/\text{GC}$'s. Such variation made it difficult to make quantitative statements with respect to adsorption.

With catechol and hydroquinone, where electrochemical product reversibility is observed, the successive "dump-fill" thin-layer method introduced by Soriaga and Hubbard (14, 15) worked extremely well to examine the question of adsorption. In this method, the electrochemical charge required to exhaustively electrolyze material in a thin-layer cell for the first solution filling, Q_1 , is compared to the second, Q_2 , filling. If a quantity of species in terms of charge, Q_{ads} , is adsorbed and electroactive, then

$$Q_1 = Q_{\text{ads}} + (Q_{\text{soln}})_1 + Q_b$$

where $(Q_{\text{soln}})_1$ is the electroactive species remaining in the solution phase of the thin-layer cell, and Q_b is the background charge. Of course, Q_1 can be calculated and in this case should correspond to Q_T , the total amount of electroactive species introduced into the thin-layer cell by the first filling. If the adsorbed species remains on the electrode surface during the second filling, the charge Q_2 will be

$$Q_2 = Q_1 + Q_{\text{ads}} + Q_b$$

and, hence, the difference between Q_2 and Q_1 provides a means of determining Q_{ads} . This case is illustrated by the plot of Q_1 (triangles) and Q_2 values (open circles) for catechol at ZrO_2/GC as a function of catechol concentration (phosphate buffer, pH 2.0) in Fig. 4. It appears that saturation coverage of the ZrO_2/GC surface is attained at catechol concentrations of 0.1M or higher. Values of Q_1 coincide with those of Q_T (repre-

Fig. 4. The charge, Q , in microcoulomb for the first (triangles) and second (open circles) fillings of the thin-layer cell with known concentrations of catechol in phosphate buffer (pH 2.0) at a ZrO_2/GC electrode. The solid line is drawn for the charge calculated from the known concentration of catechol and thin layer volume of $9.35 \mu\text{l}$. The charges, Q_1 and Q_2 , were determined by integrating the area under the voltammetric, current-potential curve obtained at a scan rate of 2 mV/s .

sented by the solid line), which is calculated from the concentration and the thin-layer volume, and assuming a two-electron redox reaction for catechol. The cell volume was determined using known concentrations of ferrocyanide. One can conclude from the coincidence of Q_1 and Q_T that the adsorbed catechol remains electroactive in the potential region of the CV scan. Similar adsorption results have been obtained for catechol and hydroquinone at $\alpha\text{-Al}_2\text{O}_3/\text{GC}$ (1, 2).

For AH_2 , the cyclic voltammograms in the thin-layer cell at CeO_2/GC are illustrated in Fig. 5, traces a (first filling) and b (second filling). Activation at this electrode is clearly seen by comparing the voltammograms of traces a and b with that of trace c, which is at a bare GC electrode. An increase in the background charging current is also evident by comparing traces d(1) and d(2) of Fig. 5. Although the voltammogram for the second filling (trace b) is broader in shape than for the first filling (trace a), the charges, Q_1 and Q_2 , were identical when corrected for Q_b . Similar results were obtained for AH_2 at ZrO_2/GC and the values of Q_1 and Q_2 were identical over a ten-fold concentration range and coincided with Q_T (assuming $n = 2$). Thus, the conclusion can be drawn that, if any AH_2 was adsorbed, it was electroactive in the potential range of the CV scan. However, it is not possible in the case of AH_2 to delineate whether adsorption occurred because the parent AH_2 cannot be electrochemically regenerated.

In the case of AH_2 at $\alpha\text{-Al}_2\text{O}_3/\text{GC}$, considerable variation occurred from experiment to experiment, and Q_1 was often less than Q_T , which initially was taken to mean that the adsorbed AH_2 was not electroactive. However, it was found that if the cell was vacuum degassed prior to filling with deoxygenated solutions of AH_2 , Q_1 was equal to Q_T . Apparently, AH_2 is catalytically oxidized by oxygen in the presence of the

Fig. 5. Current-potential (i - E) curves for the oxidation of 0.75 mM ascorbic acid in phosphate buffer (pH 2.0) at CeO_2/GC for (a) first filling and (b) second filling. Curve (c) is the i - E curve at GC_0 . Curves labeled d(1) and d(2) are background i - E curves at GC_0 and CeO_2/GC , respectively, in phosphate buffer without ascorbic acid. Volume of thin-layer cell was $9.35 \mu\text{l}$, and the scan rate was 2 mV/s .

α -Al₂O₃/GC surface. The rate and stoichiometry of this catalysis has not been quantitated. Further studies on this interesting question of AH₂ adsorption and oxygen catalysis with MOx/GC electrodes will be examined with a newly constructed optical thin-layer cell in which the optical pathlength and the electrode surface area to solution volume are relatively large (16).

Electrode area.—At MOx/GC electrodes, the “double layer” charging current is increased, as is evident from the larger background envelope of the cyclic voltammograms or the background charge during chronocoulometric experiments. This charge is three to four times greater than that at GC₀. Although oxides such as CeO₂, ZrO₂, and α -Al₂O₃ are supposedly insulators, the double-layer charge suggests that there could be a considerable increase in the area of the conductor surface.

The question is whether or not this increase in the area is real. If it is, what is the source? A partial clue to answer this question comes from the observation that the slopes of the i_p vs. $v^{1/2}$ plots for AH₂ oxidation from CV experiments were always slightly larger for the MOx/GC than for the GC₀. Chronoamperometric, chronocoulometric, chronopotentiometric, and rotating disk experiments were conducted to pursue this question of electrode area. If these experiments are conducted under diffusion-controlled conditions, any surface roughness will affect the observed current only at short times; i.e., when the diffusion-layer thickness is comparable to the surface roughness. SEM photomicrographs did not indicate any surface cracks, crevices, or other defects greater in dimension than the maximum 1 μ m particle size (e.g., α -alumina). This meant that the measured geometric area of the electrode should govern the current under diffusional mass-transfer conditions, certainly at times greater than 1s (17, 18). The current functions for these three methods, as normalized to those obtained at GC₀, are tabulated in Table II. In addition to AH₂, data are included for ferricyanide reduction and ferrocyanide oxidation. To check possible differences due to the commercial source of GC and the means by which the electrode is affixed to the cell, Tokai GC-20 and BAS GC electrodes were used. The geometric area of the GC-20 was 0.43

Table II. Normalized current functions of ferricyanide, ferrocyanide, and ascorbic acid at MOx/GC electrode with different methods

Compound (conc)	Normalized current function*

* Normalized current function at MOx/GC to GC₀ electrode.
^b Data for a BAS GC electrode, geometric area = 0.071 cm².
^c Data enclosed in parentheses for a Tokai glassy carbon (GC-20 grade), geometric area = 0.43 cm².
^d Data enclosed in square brackets for a rotating glassy carbon electrode (Pine Instrument), geometric area 0.49 cm²; rotation rate 100-3600 rpm.

cm² (area defined by the size of the sealing gasket), whereas the BAS electrode had an area of 0.071 cm². Without exception, the normalized current functions for the electroactive species were larger at the MOx/GC than at GC₀. The statistical averages of the normalized current functions, including the RDE results, are 1.10 with a standard deviation of 0.06 at CeO₂/GC, and 1.14 with a standard deviation of 0.07 at ZrO₂. The increase in the current function with MOx/GC electrodes in comparison to GC₀ appears real. Chronoamperometric and chronopotentiometric data were taken over a time period of 1-20s. Any effect of the surface roughness to the *i*-t or *E*-t transients should have been negligible at these times. The situation at the RDE is different, since there is convective-diffusional mass transport. The convective solution flow near the interface of MOx/GC may have been altered with respect to GC₀.

pH studies.—The pH dependence of the E_{pa} and i_{pa} was studied by CV to see the effect of MOx/GC vs. GC₀ to the AH₂ oxidative mechanism. At GC₀, the i_{pa} was independent of pH, whereas at CeO₂/GC, for example, the i_{pa} decreased with increasing pH until ca. pH 6, at which the i_{pa} became independent of pH. i_{pa} and E_{pa} are plotted in Fig. 6 for CeO₂/GC and GC₀. The E_{pa} vs. pH varied with a slope of 52 mV/pH in the acidic region at GC₀ until ca. pH 4, where the E_{pa} became independent of pH. The 52 mV/pH slope is in agreement with a value reported by Sternson (19) at a carbon paste electrode. For CeO₂/GC, the E_{pa} varied with a slope of ca. 42 mV/pH between pH 2 and 5.5 and then continued to decrease in an irregular fashion as pH increased until ca. pH 8. At this pH, the E_{pa} appeared to become independent of pH. The “breaks” in the *E* vs. pH plot in the pH 6-8 region for CeO₂/GC may reflect the pK_a of this surface where the metal oxide is acting as a weak acid. Similar results have been obtained for AH₂ at ZrO₂ at ZrO₂/GC.

The normalized current functions as determined by chronoamperometry, chronocoulometry, and RDE at two different pH values, 2.0 and 8.0, for AH₂ are summarized in Table III. Assuming that these currents are controlled by the mass-transfer rate of AH₂, the difference in the normalized values reflect a difference in the diffusion coefficient(s) of AH₂ at these two pH's. Gerhardt and Adams (20) have reported a *D* value of 0.53₂ (± 0.026) $\times 10^{-5}$ cm²/s at pH 7.4, as determined by the flow injection method. This *D* value is for the ascorbate ion [pK_a is 4.0-4.2 (21-22) for AH₂]. The neutral AH₂ is expected to have a higher *D* value than

Fig. 6. The anodic peak potentials (circles) and the peak currents (triangles) are plotted for GC₀ (dotted line) and CeO₂/GC (solid line) for 1 mM ascorbic acid oxidation as a function of pH. The peak currents have been background corrected. Buffer was 0.1M phosphate and pH adjusted using 1M NaOH. The data were taken from linear sweep voltammetric *i*-*E* curves. Scan rate was 100 mV/s.

Table III. Current functions of ascorbic acid at MOx/GC and GC₀ taken at pH 2.0 and 8.0

Method (reagent, conc)	Electrode	Current function		
		pH 2	pH 8	ratio (pH 2/pH 8)

				avg 1.10 $\sigma = 0.08$

for ascorbate. The average ratio of the normalized current function at pH 2 with respect to pH 8 was 1.10 with a standard deviation of 0.08. Since $(D_{\text{pH}2})^{1/2}/(D_{\text{pH}8})^{1/2}$ is directly proportional to this ratio, a $D_{\text{pH}2}$ value of 0.64×10^{-5} cm²/s is calculated. This $D_{\text{pH}2}$ is an estimated value that needs to be verified by an independent method.

Discussion and Conclusion

Several metal oxides, such as CeO₂, ZrO₂, Co₂O₃, and α -Al₂O₃, dispersed onto a GC surface enhanced the rate of AH₂ oxidation. A tentative model is therefore proposed to explain this enhancement by the MOx particles. In this model, a thin porous layer of carbon and MOx particles, intimately intermixed, adheres to the base GC. The MOx particles protrude from this layer and can be partially covered with carbon. This porous particle mixture with conductive carbon explains why the double layer capacitance increases. The increase in the faradaic current functions, as measured by cyclic voltammetry, chronoamperometry, and chronopotentiometry, can be explained if the assumption is made that there is an additional current component from electroactive material penetrating into the porous layer and MOx particles; the latter depends on the crystallinity and the pore sizes. This model is analogous to a thin polymeric-coated electrode where the polymer is swollen by the solvent, thereby allowing ions and/or electroactive species to penetrate. A major difference of the porous carbon-MOx layer is that electronic conduction via the carbon can occur to the outer periphery of the layer.

In this model, more than one diffusional term controls the mass-transfer, i.e., the usual solution diffusion term, D , and the diffusion inside the porous layer and particle, D_i . Because of the tortuosity of the path inside these latter materials, the magnitude of D_i is much less than that of the solution. Thus, the faradaic current function is enhanced due to the additional current from any electroactive species "adsorbed" in the porous layer and the particles, the time function of this current depending on the value of D_i . The increase in the area, as reflected by the capacitive current, is now rationalized by the presence of this conductive, porous layer.

This proposed model of the MOx/GC surface needs to be further tested by diffusion-kinetic studies at rotating disk electrodes and with ac impedance. Rotating electrodes are ideal probes and have been applied advantageously to similar situations at polymer-coated electrodes (23). However, ac impedance is a powerful method to extract electrical parameters, such as resistive and capacitive terms, and to probe surface

porosity. A long optical-pathlength, thin-layer cell is also under development to help quantitate surface adsorption phenomena (16).

The scope of compound types that can be activated by MOx/GC's is also under study. Preliminary results are consistent with the contention that the involvement of protons in the overall redox process is a prerequisite to the observed-rate enhancement. However, proton involvement alone does not insure activation. For example, the electrochemistry of several aromatic and aliphatic aldehydes were unaffected by α -alumina (24). Thus, the structural features important to activation are currently not understood.

Wightman and co-workers (4) have recently observed an enhanced electrochemical reversibility for ascorbate and ferricyanide at heat-treated (520°-540°C for 2-24h) glassy carbon. Such heat-treatment is undoubtedly removing adsorbed impurities, changing surface topography and functionalities, and increasing the surface area. In this respect, the role of the MOx may be to activate the carbon by creating a fresh carbon surface from the mechanical abrasion process and then maintaining activity by preferentially adsorbing impurities from the solution that would otherwise adsorb on the active sites of the carbon. Quantitating the possible multieffects of dispersed MOx and correlating them to explain the enhancement of charge-transfer rates will be a challenging problem.

Stability of Undoped and Oxidized Polyacetylene

R. Huq* and G. C. Farrington*

Department of Materials Science and Engineering, University of Pennsylvania, Philadelphia, Pennsylvania 19104

ABSTRACT

The stability of polyacetylene has been examined by thermogravimetric analysis and measuring the change in its electronic conductivity upon heating in various atmospheres. Samples included unreacted polyacetylene as well as films that had been oxidized chemically, with bromine and iodine, and electrochemically, with AsF_6^- as the anion. Fresh polyacetylene and samples which have been oxidized to the conducting state react rapidly with oxygen in a gaseous atmosphere, especially in the presence of moisture. At room temperature, the reaction with oxygen is largely irreversible, and presumably interrupts the conjugated double bond network of the polymer. The resulting material is not readily oxidized or reduced to an electronically conducting state.

Polyacetylene (Fig. 1) is a simple conjugated organic polymer with quite unusual electrical and electrochemical properties. Films of polycrystalline polyacetylene, which has the general formula, $(\text{CH})_x$, can be easily synthesized by the catalytic polymerization of acetylene. Typical films are composed of fibers of polyacetylene and have extremely high surface areas, generally 40-60 m^2/g .

The extraordinary properties of polyacetylene are observed when it is oxidized or reduced. When polycrystalline polyacetylene films are exposed to various oxidants, such as iodine or bromine, it reacts to form compounds of the type, $(\text{CHX}_y)_x$ (typically, $y < 0.10$). Upon exposure to reducing agents, such as n-butyl lithium, compounds of the type $(\text{Li}_y\text{CH})_x$ result (typically, $y < 0.3$) (1-7). From the viewpoint of electrochemistry, the most intriguing aspect of polyacetylene chemistry is that these reactions can be carried out electrochemically in nonaqueous electrolytes containing appropriate dissolved anions and cations.

If the conditions are gentle, these chemical or electrochemical oxidation/reduction reactions do not attack the conjugated polymer chains, and the reactions are reversible. However, if the reaction conditions are more severe, irreversible attack and interruption of the conjugated polymer network takes place. The reversible reactions are functionally similar to the oxidation reactions of transition metal dichalcogenides, such as TiS_2 . As a result, the oxidized and reduced polyacetylenes have been suggested for use as electrodes in nonaqueous batteries (8).

Extensive studies of the electrical properties of the polyacetylenes have been reported (9-17). However, relatively little work describing the stability of these materials has appeared. Notable exceptions are the contributions of Rolland *et al.* (18) and Yen *et al.* (19). The goals of our research have been to examine those aspects of the stability of fresh and reacted polyacetylene which influence its potential electrochemical applications. We have carried out a systematic study of the stability of fresh and oxidized polyacetylene by monitoring the change in electronic resistivity of samples in contact with argon, oxygen, and air from 20° to 100°C. Thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) measurements were also carried out.

Experimental Details

The polyacetylene used in this work was supplied by Professor A. MacDiarmid and co-workers in the Department of Chemistry of the University of Pennsylvania. The films were typically about 0.01 cm thick and highly fibrous, with a density of ca. 0.4 g/cm^3 . The films were not subjected to further chemical analysis.

Conductivity was measured in a specially designed glass cell with electrical feed throughs so that experiments could be carried out in various atmospheres. Samples were sandwiched between two Pt mesh electrodes. The electrodes were connected to a computer-controlled Solarton 1170 complex impedance analyzer which was used to measure conductivity. The tempera-

* Electrochemical Society Active Member.

ture of the cell was determined and regulated by a thermocouple located about 5 mm from the sample.

All samples were handled and stored under argon or in vacuum. Cell loading was carried out in an argon-atmosphere dry box (Vacuum Atmospheres).

Oxidized samples were prepared either in the conductivity cell, by exposing fresh polyacetylene to small partial pressures of iodine or bromine, or electrochemically. For the *in situ* reactions, a bulb containing the halogen was attached to the cell, and its temperature adjusted to maintain a known vapor pressure of halogen. The onset of oxidation was signalled by a dramatic increase in the electronic conductivity of the sample. Electrochemical oxidation was carried out in a separate electrochemical cell in a propylene carbonate electrolyte containing 1.0M LiAsF₆. The propylene carbonate used to prepare the electrolyte was obtained from Burdick and Jackson; the electrolyte salt from U.S. Steel, Agri-Chemical Division (electrochemical grade). Before use, the electrolyte was percolated through a column of neutral activated alumina (Fisher-Brockman, activity 1). The electrolyte was then pre-electrolyzed between two lithium electrodes. The film was oxidized at a controlled potential of 3.8V vs. Li/Li⁺. The level of oxidation [value of γ in (CHX _{γ})_x] was in the range of 0.02-0.03.

TGA measurements were carried out with a du Pont 951 Thermogravimetric Analyzer and 910 Differential Scanning Calorimeter. Samples weighing 1-2 mg were heated at 5°C/min over the temperature range of 22°-200°C in nitrogen.

Results

Stability of fresh polyacetylene.—The resistivity of samples of unoxidized polyacetylene was about 10¹⁰ Ω-cm, which indicated that the material was quite pure and mainly in the *cis* form (20). The effects of exposing films to argon (99.999%), oxygen (99.996%), and moist air, in that order, for short times (3-5h) are shown in Fig. 2. Between gases, the samples were exposed to a vacuum of about 10⁻⁵ torr for 24h. The vacuum partially reversed the conductivity changes that were observed.

Figure 3 shows the influence of temperature upon the resistivity of films exposed to argon and oxygen. During heating in argon from 25° to 100°C, the conductivity of the material increased with an average activation energy of 0.49 eV (11 kcal/mol) (Fig. 4). Our results agree well with those of Rolland and co-workers (21), who have reported a value of 0.50 eV for fresh, *cis* polyacetylene and 0.30 eV for the *trans* form.

In oxygen, the resistivity initially decreased and then increased dramatically around 65°C, as the material became brittle and was transformed from golden-gray to yellowish-brown. The initial decrease

Fig. 4. Arrhenius plot for resistivity of (CH)_x in Ar

in resistivity was small in comparison to the dramatic decrease in resistivity, from 10¹⁰ (Ω-cm) to 10² (Ω-cm), which takes place when a fresh film is exposed to 0.5 torr iodine. We saw no evidence that the overall oxidation reaction was reversible. We found that the oxidation proceeded more rapidly in moist air, and could be observed even at room temperature. Yen *et al.* (19) and Pochan (22) have reported similar results.

These results indicate that, at moderate temperatures, polyacetylene films react readily with oxygen, and more rapidly in the presence of moisture. At lower temperatures the reaction may initially be reversible, but at higher temperatures or longer times it is largely irreversible. The process ultimately destroys the usefulness of polyacetylene as an electrochemical electrode. However, we must note that, under the conditions used in these experiments, oxygen served both as the oxidizing agent and the dopant. Our results do not indicate whether polyacetylene films are stable when exposed to oxygen in an electrolyte which contains another anion which may act as an alternate dopant.

Stability of oxidized films.—The temperature dependence of the resistivity of polyacetylene films which have been oxidized to the conducting state either chemically, by bromine and iodine, or electrochemically, with AsF₆⁻ as the anion, was studied from 25°-100°C (Fig. 5, 6, 7) in argon. The resistivities of films oxidized with bromine or iodine increase at relatively low temperatures. For example, the resistivity of a

Fig. 5. Influence of temperature on the resistivity of $(\text{CHBr}_y)_x$ in Ar.

film of composition approximately $(\text{CHI}_{0.01})_x$ was reasonably stable from 25° to 55°C. Above 60°C, it slowly rose many orders of magnitude. Figure 8 dramatically illustrates the progressive increase in resistivity observed for an iodine-oxidized film at various temperatures.

In samples oxidized with bromine, the resistivity increase commenced at lower temperatures, around 45°C. Films which had been electrochemically oxidized with AsF_6^- as the anion were stable to considerably higher temperatures, somewhat above 65°C. Rolland

Fig. 8. Influence of heating and cooling cycles on the resistivity of $(\text{CHI}_y)_x$ in Ar.

et al. (18) have found that films oxidized with SbF_5 are stable to about 80°C, whereas films reacted with $\text{CF}_3\text{SO}_3\text{H}$ begin to degrade slightly above 25°C.

It could be argued that the increases in resistivity observed as the temperature was increased were simply the result of the reversible loss of halogen from the films or the homogenization of the oxidant within the bulk fibrils. To test these ideas, we oxidized a sample of polyacetylene in 0.5 torr iodine vapor at 25°C. Its initial resistivity was $2.8 \times 10^2 \Omega\text{-cm}$. After heating to 100°C and cooling to room temperature over 15h in an argon atmosphere (Fig. 6), its resistivity increased to $5.5 \times 10^4 \Omega\text{-cm}$. When the sample was re-exposed to 0.5 torr iodine at room temperature, its resistivity decreased, but only to $1.7 \times 10^3 \Omega\text{-cm}$, a level about eight times its initial value before heating. Subsequent cycles of heating, cooling, and re-exposure to iodine produced a progressive increase in the room temperature resistivity of the sample (Fig. 8). These experiments do not eliminate the possibility that homogenization or halogen loss contribute to the resistivity increases observed. However, our observations indicate that irreversible reaction contributes significantly to the resistivity changes.

In contrast, a sample which had been electrochemically oxidized with AsF_6^- as the guest anion was much more stable (Fig. 7) during heating. With the dopants we investigated, the stability of reversibly oxidized polyacetylene was least with Br^- and greatest with AsF_6^- . Corresponding anion effects were seen in the TGA and DSC results discussed below.

Thermal analysis measurements.—TGA and DSC measurements which complement the conductivity studies were also carried out. Figures 9 and 10 show the resistivity, TGA, and DSC behavior of films oxidized with iodine and bromine, respectively. These experiments were carried out in a nitrogen atmosphere. Ito *et al.* (23) have previously reported that unoxidized polyacetylene does not thermally decompose in nitrogen until above 300°C. They found that unoxidized polyacetylene, whether *cis* or *trans* at the beginning, turned brown without losing weight when heated in vacuum at about 325°C for 5 min. Weight loss was observed to begin around 420°C. They suggested that phenyl groups are first formed at the lower temperature, which then decompose to yield a weight loss at the higher temperature.

With films oxidized with bromine or iodine, we found that weight loss began around 90°C (bromine) and 120°C (iodine). At 160°C, the total weight loss reached 21% for the material oxidized with bromine and 15% for that oxidized with iodine.

Fig. 9. Resistivity, TGA, and DSC (5°C/min) results for $(\text{CHI}_y)_x$.

DSC analysis over the range of 25°–180°C revealed only one exothermic peak for either the bromine- or iodine-oxidized samples. The peak position varied from 80°C (bromine) to 140°C (iodine) (Fig. 9 and 10). The heat of reaction observed for the decomposition of the iodine-oxidized material was 124 mcal/mg. Pron (24) has also observed the removal of iodine from polyacetylene above 100°C and has concluded that the process is irreversible and occurs by the evolution of HI and a small amount of I_2 .

The TGA and DSC results are completely consistent with the resistivity measurements. However, in all cases we have found that changes in resistivity are the most sensitive and early indications of changes in the sample chemistry.

Conclusions

Oxygen reacts readily with fresh polyacetylene, apparently faster in the presence of moisture. Although the initial stages of oxidation may be reversible, the process is eventually irreversible and presumably involves the interruption of the conjugated double-bond network essential for electronic conductivity in the material. We must point out that, under our experimental conditions, oxygen was both the oxidant and the source of the doping ion. Our results do not demonstrate that oxygen would irreversibly react with polyacetylene if another dopant ion, such as I^- in a solvent, were in contact with the material during exposure to oxygen. In fact, MacDiarmid *et al.* (25) have reported that polyacetylene is stable in an aqueous electrolyte containing either HBF_4 or HF in contact with bubbling oxygen gas. The difference between these conditions and ours is that, in the aqueous electrolyte, oxygen serves only as a source of energy to oxidize the polymer. Further attack of the polymer chain is apparently prevented by the introduction of BF_4^- or F^- , which are stable doping ions.

Polyacetylene films which have been oxidized to the conducting state with bromine or iodine decompose between 45° and 55°C. Films which contain AsF_6^- as

Fig. 10. Resistivity, TGA, and DSC (5°C/min) results for $(\text{CHBr}_y)_x$.

the dopant ion are more stable. The decomposition decreases the electronic conductivity of polyacetylene and ultimately destroys its usefulness as an electrode.

Our results underscore the point that polyacetylene films must be handled in extremely dry and oxygen-free atmospheres, at least when they are not in contact with an electrolyte containing stable dopant anions. Polyacetylene is not a material that forgives casual handling. It is unreasonable to expect reproducible electrochemical results using samples of polyacetylene whose origins are uncertain.

ABSTRACT

The oxygen reduction reaction was investigated at platinum electrodes in phosphoric acid in the concentration range 0.7M (6.6%) to 17.5M (95%) at 25°C using the rotating ring-disk electrode technique. As a complement, cyclic voltammograms on platinum and potentials of zero charge of mercury were obtained as a function of phosphoric acid concentration. The mechanism of the oxygen electrode reaction is discussed in terms of the direct four-electron transfer reduction to water and the formation of hydrogen peroxide as an intermediate in a parallel two-electron transfer reaction. The rate constants of the intermediate reaction steps were calculated from the ring-disk data for various potentials and electrolyte concentrations. The characteristics of the reaction were found to be markedly dependent on the concentration of phosphoric acid. These results are interpreted in terms of changes in oxygen solubility, proton activity, and double layer characteristics when passing over from a water to a phosphoric acid solvent structure.

Concentrated phosphoric acid is presently used as the electrolyte in advanced fuel cells. The factor limiting the efficiency of this fuel cell system is the overpotential for oxygen reduction reaction in the concentrated acid medium. In fact, this reaction is approximately two orders of magnitude slower in concentrated H₃PO₄ than in aqueous solutions of strong acids, such as trifluoromethanesulfonic acid (1, 2).

Previous studies on the reduction of oxygen on platinum in concentrated H₃PO₄ focused on examining the Tafel behavior over a wide temperature range (3-5). The conclusions can be summarized as follows. (i) Three Tafel regions can be observed. Above 0.8V (vs. RHE), a 60 mV Tafel slope is obtained. This slope changes to 120 mV in the region of potentials between 0.8 and 0.6V. Below 0.5V, very high Tafel slopes (over 200 mV) are observed. The mechanism of the reaction in the third region is not completely understood. (ii) Tafel slopes in the intermediate range (120 mV) are independent of temperature, contrary to predictions from electrode kinetic theory. Appleby (5) suggested that this phenomenon could be associated with a change in the double layer structure with tem-

perature. But the question is far from settled. Yeager *et al.* (6) suggested that this phenomenon is due to a compensating effect of the entropic and enthalpic terms in the rate expression. (iii) Rotating ring-disk investigations (7, 8) have shown that the reduction of oxygen in concentrated phosphoric acid follows two parallel paths: a direct four-electron reduction to water and a couple of two-electron transfer reduction reactions to water with hydrogen peroxide as the intermediate. (iv) The rate of the reaction is first order with respect to the oxygen partial pressure (4). (v) The reaction order with respect to proton activity is 3/2 in the low current density region (60 mV Tafel slope) and 1 in the high current density region (120 mV Tafel slope).

The structure and properties of concentrated H₃PO₄ are not well understood, but these certainly are expected to play a role in the slow reduction of oxygen at platinum. Recently, the authors examined the structure of the mercury/concentrated H₃PO₄ interface (9) and concluded that the double layer in concentrated H₃PO₄ is thicker than in aqueous media. Thus, it seems reasonable to assume that a transition with respect to both the interfacial and bulk properties will occur when passing over from a water to a phosphoric acid solvent structure. For this reason, the present study was undertaken to elucidate the effect of the struc-

ture of H_3PO_4 solutions, ranging in concentration from 7 to 95%, on the kinetics of oxygen reduction at platinum electrodes.

Experimental

The equipment, preparation of the electrode, and the experimental procedure for the rotating ring-disk experiment have already been described (10). The same setup was used for the cyclic voltammetric experiments. Phosphoric acid (85%, electronic grade, J. T. Baker) was treated with 10% hydrogen peroxide (90%, stabilizer free, FMC) and heated to 50°–70°C for 1h. The solution was concentrated to 85% by evaporation at 160°C in Teflon vessels. This solution was diluted with double-distilled water that was previously treated with alkaline permanganate. Further evaporation of the 85% stock solution was done to obtain the 95% concentration. Before use, solutions were pre-electrolyzed for 24h with platinum electrodes to eliminate electroactive impurities.

All potentials were measured against a dynamic hydrogen electrode (DHE). The values were converted to a reversible hydrogen electrode (RHE) scale by measuring, for each solution, the potential difference between the DHE and a floating-type fuel cell hydrogen electrode.

Results and Discussion

Cyclic voltammetry.—Figure 1 shows the cyclic voltammograms on Pt, obtained as a function of H_3PO_4 concentration. No difference was observed for a stationary or a rotating electrode, which is indicative of the absence of impurities in the electrolyte. According to this figure, it is apparent that for concentrations of H_3PO_4 up to about 4M there is no effect on the characteristics of the voltammogram. On the other hand, for higher concentrations, it is observed that the potential of oxide formation commencement progressively shifts to more positive values. Also, the total charges for oxide formation and reduction decrease for these increasing acid concentrations. These findings can be associated with a strong adsorption of phosphate species on the electrode that interferes with the oxide formation. However, the effect may be partly due to a decrease in the activity of water as the concentration of H_3PO_4 increases (11).

Mass-transfer-corrected Tafel behavior.—The mass-transfer-corrected Tafel behavior for oxygen reduction on platinum for different H_3PO_4 concentrations is shown in Fig. 2. The plots correspond to the equation

$$E = \frac{2.3RT}{\alpha_c F} \log i_0 - \frac{2.3RT}{\alpha_c F} \log \frac{i_{d1} i_d}{i_{d1} - i_d} \quad [1]$$

where α_c is the transfer coefficient, i_0 the exchange current density, i_d the disk current density, and i_{d1} the limiting disk current density. The Tafel plots presented in Fig. 2 are independent of rotation speed. In the region from 0.6 to 0.8V, Tafel slopes are about 120 mV. This result is similar to that obtained by others (3-7, 11) in acid media. Thus, it seems reasonable to conclude that the overall reduction of oxygen is controlled by the first charge transfer step under Langmuir adsorption conditions. Below 0.5V, higher Tafel slopes (> 200 mV/decade) are observed and the current seems to reach a limiting value. Because these limiting currents are not due to mass transfer, a change in the reaction mechanism must be taking place. This change probably involves a chemical rate-determining step, which may be the dissociative adsorption of the oxygen molecule. This point was not investigated further because the potential region lies outside the range of interest for fuel cells.

Mechanistic aspects of electroreduction of oxygen.—Recently, theoretical aspects of the reduction of oxygen on rotating ring-disk platinum electrodes have been considered (10). In this work, it was concluded

that the mechanism proposed by Damjanovic *et al.* (12) is the most appropriate. The reaction scheme is as follows

where a indicates an adsorbed state and b is the bulk of the solution. Two equations for calculating the reaction rate constants k_1 , k_2 , and k_3 are (10)

$$\frac{I_{d1}}{I_{d1} - I_d} = 1 + \frac{k_1 + k_2}{0.62 D_{\text{O}_2}^{2/3} \nu^{-1/6}} \omega^{-1/2} \quad [3]$$

$$\frac{I_d}{I_r} = \frac{1}{N} \left(1 + 2 \frac{k_1}{k_2} + \frac{2(k_1/k_2 + 1)k_3}{0.62 N D_{\text{H}_2\text{O}_2}^{2/3} \nu^{-1/6}} \right) \omega^{-1/2} \quad [4]$$

where I_d and I_r are the disk and ring currents, respectively; I_{d1} is the limiting current on the disk electrode; N is the collection efficiency; ω is the rotational speed; ν is the kinematic viscosity of the electrolyte; and D_{O_2} and $D_{\text{H}_2\text{O}_2}$ are the diffusion coefficients of oxygen and hydrogen peroxide, respectively. Accordingly, plots of $I_{d1}/(I_{d1} - I_d)$ vs. $\omega^{-1/2}$ and I_d/I_r vs. $\omega^{-1/2}$ should yield two straight lines, and the rate constants can be calculated from the intercepts and the slopes of these straight lines. In this way, the values of k_1 , k_2 , and k_3 , as functions of electrode potential for oxygen reduction on Pt, were evaluated from the ring-disk data for various phosphoric acid concentrations (Fig. 3-6).

In all cases, it was found that the ratio k_1/k_2 is greater than 10, which means that most of the oxygen reduces to water directly through the four-electron transfer reaction. Because $k_1 \gg k_2$, the relationship between i and k_1 can be written approximately as

$$i \cong 4FA k_1 c_{\text{O}_2} = 4FA k_1' c_{\text{O}_2} a_{\text{H}^+} \exp \left(- \frac{\alpha_c F}{RT} E \right) \quad [5]$$

Therefore, k_1 should have the same dependence on phosphoric acid concentration as i/c_{O_2} at any potential. This can be seen in Fig. 7 where k_1 , i , and i/c_{O_2} for a potential of 0.7V are plotted as a function of H_3PO_4 concentration. Clearly, k_1 and i/c_{O_2} have the same concentration dependence.

From Fig. 3, 4, and 5, it is apparent that for H_3PO_4 concentrations up to 8M, k_2 has the same potential dependence as k_1 . This means that the rate-determining step is probably the same for both reactions. At higher concentrations, k_2 is surprisingly independent of potential, which means that the rate of the reaction is chemically controlled (chemical step prior to electron transfer step). In this case, the rate of the reaction may be determined by the adsorption of the O_2 molecule, which must be oriented preferentially at the interface in order to lead to H_2O_2 formation. This can be inhibited by a predominance of phosphate species at the interface, which is supported by the fact that the constant value of k_2 shows a marked decrease with the increase in H_3PO_4 concentration.

The behavior of k_3 is similar to that of k_2 (cf. Fig. 5 and 6); k_3 increases with the overpotential in the low overpotential regime and is more or less independent of potential when E becomes more negative than 0.5V vs. RHE. Increased phosphoric acid concentration results in decreased k_3 . It can be shown that the significant decrease in k_2 and k_3 with increasing H_3PO_4 concentration leads to an increase in the faradaic efficiency for the reduction of oxygen to water. This is

Fig. 1. Cyclic voltammograms on Pt at a scan rate of 50 mV/s in H_3PO_4 over the concentration range 6.6-95 w/o (weight percent) at 25°C.

Fig. 2. Mass-transfer-corrected Tafel behavior for oxygen reduction on Pt in H_3PO_4 over the concentration range 6.6-95 w/o at 25°C. Tafel behavior is independent of electrode rotating speed in the 400-3600 rpm region.

important because it means that at the high concentrations used in fuel cells the amount of formation of H_2O_2 is negligible and the faradaic efficiency is close to unity.

Effect of anion adsorption on the rate of oxygen reduction.—The decrease in the oxygen reduction rate with increasing H_3PO_4 concentrations can be attributed to several factors. These include the oxygen solubility, proton activity, and changes in double layer structure. In the region of potential considered, the rate of oxygen reduction in acid media as shown by Eq. [3] is first order with respect to the oxygen concentration and the proton activity (4, 13). Experimental evidence

(14) has indicated that both oxygen solubility and proton activity decrease with increasing H_3PO_4 concentration; one would, therefore, expect a lower oxygen reduction current in concentrated H_3PO_4 solutions.

However, the most significant factor in determining the rate of oxygen reduction may be due to the change in the double layer structure at the electrode/electrolyte interface with H_3PO_4 concentration. A recent study (9) has shown that the double layer thickness is greater at a mercury electrode/concentrated H_3PO_4 interface than at a mercury electrode/aqueous electrolyte interface. Thus, the distance for electron tunneling can be expected to be greater at the electrode/phosphoric

acid interface than at the electrode/aqueous electrolyte interface. At the same time, the presence of phosphate species on the electrode surface could interfere with the adsorption of reactants and/or intermediates. To

Fig. 7. Dependences of i , i/c_{O_2} , and k_1 for oxygen reduction at Pt on H_3PO_4 concentration at 25°C.

provide further evidence of strong anion adsorption, a separate experiment using a streaming electrode technique (15) was made to determine the effect of phosphoric acid concentration on the potential of zero charge on a mercury electrode. Figure 8 shows the plot of the potential of zero charge (E_z) as a function of H_3PO_4 concentration. A large change of E_z toward more negative values was observed as the concentration of H_3PO_4 increased, which is evidence for increasing adsorption of phosphate species at the interface. The change of E_z with H_3PO_4 concentration is linear, which means that the properties of the double layer undergo a gradual change. It can be expected that the extent of adsorption of the phosphate ion on platinum is at least as much as that on mercury. The presence of phosphate ions on the electrode surface blocks the ac-

Fig. 8. Dependence of the potential of zero charge on mercury on H_3PO_4 concentration at 25°C.

tive sites for the charge-transfer reaction and causes a decrease in the oxygen reduction current.

The plots of i/c_{O_2} vs. H_3PO_4 concentration (Fig. 7) indicate that the rate of the reaction has a minimum at a certain H_3PO_4 concentration. This behavior has sometimes been observed for electrode reactions in mixed solvents (16). The phenomenon can be attributed to differential solvation between the electrode and the reacting species. Thus, if the latter is preferentially solvated with water molecules while the electrode is covered by phosphate species, a lower rate of reaction should then be expected. On the other hand, if the electrode and the reactant share the same solvating species, as would be the case in dilute or very concentrated phosphoric acid electrolytes, then the activated complex may be nearer the electrode surface and higher rates should be expected.

Conclusions

The results of the cyclic voltammetric and rotating ring-disk electrode experiments make it possible to reach the following conclusions on the effects of phosphoric acid concentration on oxide formation and oxygen reduction kinetics at platinum.

1. At concentrations below 4M, phosphoric acid has hardly any effect on the cyclic voltammograms. Above 4M, there is a progressive shift of the potential for commencement of oxide formation in the positive direction. Strong anion adsorption is indicated.

2. In the potential range 0.8-0.6V, the slope of the mass-transfer-corrected Tafel plots is nearly equal to 120 mV/decade and is practically independent of concentration. Below 0.6V, the slope becomes quite high (≈ 200 mV/decade), and then the current densities tend to a limiting value, which decreases with increasing acid concentration.

3. The mechanism proposed by Damjanovic *et al.*, that is, the four-electron transfer reduction in which the first electron transfer step is rate determining, appears most appropriate at potentials above 0.6V. The limiting current densities are probably due to a rate-determining dissociative adsorption of oxygen.

4. The rate constants for the two (k_2)- and four (k_1)-electron transfer reduction reactions have the same potential dependence. The ratio k_1/k_2 is greater than

10, which again supports the second conclusion. At concentrations above 8M, k_2 is independent of potential, probably because of the need for a preferential orientation of oxygen leading to the formation of H_2O_2 .

5. The decrease in reaction rates at higher concentrations can be attributed to four causes: lower oxygen solubility, lower proton activity, increased specific adsorption of anions, and a thicker double layer. Complementary experiments that yielded the concentration dependence of the potential of zero charge on mercury support the view that specific adsorption of anions is quite strong.

6. Minima in the plots of i/c_{O_2} and of k_1 vs. concentration at a fixed potential illustrate the effects of differential solvation between electrode and reaction species on oxygen reduction kinetics. Similar phenomena have been observed for other reactions in mixed solvents.

Semiconductor Electrodes

LIV. Effect of Redox Couple, Doping Level, and Metal Type on the Electrochemical and Photoelectrochemical Behavior of Silicide-Coated n-Type Silicon Photoelectrodes

Fu-Ren F. Fan, Theresa Varco Shea, and Allen J. Bard*

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The surface potentials of silicide-coated n-type silicon photoelectrodes as functions of the potential of solution redox couples and the bias potential show that the Fermi level of these photoelectrodes is strongly pinned at the silicide/Si interface. The built-in potential barrier is consistent with the constancy in the photovoltage observed in solutions containing various reversible couples with redox potentials spanning a range larger than the bandgap of silicon. The performance of these photoelectrodes depends strongly on the metal, the charge transfer kinetics at the silicide/solution interface, and the doping density of silicon substrate.

One approach to stabilizing small bandgap semiconductors against photocorrosion in photoelectrochemical (PEC) cells involves the utilization of a thin noble metal overlayer (1). We have recently demonstrated that noble metal silicide-coated n-Si electrodes and suitably modified forms (e.g., with RuO_2) can photogenerate highly oxidizing species, such as chlorine and oxygen, with durable photoelectrochemical performance in aqueous solutions (2). In the previous work, we proposed that the photovoltage arises at the Si/silicide junction, based on preliminary studies with a few redox species in solution, and suggested several factors which contribute to the high stability and good performance of these photoelectrodes. However, fundamental investigations of the interfacial energetics and the effect of the charge transfer kinetics at the silicide/solution interface on the PEC performance were not

reported. In this paper, we examine the surface potential of these photoelectrodes as functions of the potential of solution redox couples and the bias potential. We also demonstrate that the performance of these silicide-coated n-Si electrodes depends strongly upon the metal, the charge transfer kinetics at the (silicide/solution) interface, and the doping level of silicon substrate. Additionally, we confirm that constant photopotentials are observed on these electrodes for solution couples with redox potentials spanning a range from -0.67 to $+1.1V$ vs. SCE, which is larger than the bandgap of silicon.

Experimental

Silicon substrates for silicide growth were n-Si(100) ($0.02-2.5 \Omega\text{-cm}$) single crystals donated by Texas Instruments and n-Si ($\sim 1 \Omega\text{-cm}$) polycrystals donated by Dr. R. Noufi. Silicides were prepared by procedures reported previously (2). The detailed procedures for

* Electrochemical Society Active Member.

Key words: semiconductor, photoelectrochemistry, silicides.

preparing the ohmic contacts and mounting and sealing the electrodes were also similar to those previously reported (3). The exposed area of the photoelectrodes ranged from 0.1-0.3 cm². The light source, if not otherwise mentioned, was a tungsten-halogen lamp fitted with a 13 cm-thick water filter with an intensity of 65 mW/cm². The voltammetric experiments were performed with the same apparatus and by procedures previously described. Reagent grade chemicals were used without further purification. All solutions were prepared from triply distilled water. All experiments were carried out with the solution under a nitrogen atmosphere. The electrode arrangement used in the measurement of surface potential is illustrated in Fig. 1. For electrodes used in surface potential measurements, a thicker Pt overlayer was deposited on the silicide layer to lower the sheet resistance to <100Ω. A silver contact was made to a portion of silicide overlayer. This Ag layer was sealed, as was the back ohmic contact, with insulating silicone rubber. Strong rectifying behavior in the current-voltage curve was observed between these two contacts indicating the absence of shorts between the two metal layers.

Results and Discussion

Surface potential of Pt-silicide-coated n-Si electrode.—The surface potential (between PtSi and SCE), V_s , of n-Si(Pt) electrode at open circuit was the same as the redox potential of the solution, V° , as measured by an independent Pt electrode (see Fig. 2); this demonstrates that the silicide layer was in equilibrium with the solution redox couples.

In a solution containing supporting electrolyte (0.5M Na₂SO₄, pH 5) only, no appreciable background current was observed at a Pt electrode over the potential range -0.6 to 0.6V vs. SCE and V_s , as shown in curve a of Fig. 3, was essentially equal to the applied potential

Fig. 1. The setup and the electrode configuration used in the measurement of surface potential of n-Si(Pt) electrode. V is the high impedance voltmeter consisting of a FET operational amplifier (Type NE 536T) in a voltage follower made with an input impedance $> 10^8\Omega$.

Fig. 2. Surface potential (V_s) and rest potential (V_{InGa}) of n-Si(Pt) electrode vs. potential of redox couples (V°) in 1M KCl. a: Fe-EDTA⁻²⁻. b: Fe(CN)₆^{3-/4-}. c: I⁻/I₃⁻. d: Fe^{2+/3+}. e: Fe(o-phenanthroline)₃^{2+/3+}.

Fig. 3. Surface potential of n-Si(Pt) vs. applied potential in 0.5M Na₂SO₄ (curve a) and in 0.5M Na₂SO₄, 0.5M K₄Fe(CN)₆, and 0.5M K₃Fe(CN)₆ (curve b).

V_a (where V_a is the potential between the ohmic contact to Si and SCE). Since V_s represents the change of the potential drop between PtSi and solution, the results imply that the applied voltage is almost completely absorbed by changes of potential across the Helmholtz double layer (if the potential drop across the diffuse double layer and at the ohmic contact is neglected). (see Scheme I).

When equimolar (0.5M) amounts of Fe(CN)₆³⁻ and Fe(CN)₆⁴⁻ were added to the solution, the rest potential of the n-Si(Pt) electrodes was 0.25V vs. SCE, which is equal to formal potential, V° , of the Fe(CN)₆^{3-/4-} couple. In the dark, a small anodic current was observed when an anodic potential scan (Fig. 4, curve c) was applied to the n-Si(Pt) electrode

Scheme 1. A, top: in terms of interfacial energetics, neglecting the potential drop across the diffuse double layer and at the ohmic contact. $\Delta V_L = \Delta V_H = V_a - \frac{E_{\text{redox}}}{e}$; band-bending unchanged. B, bottom: in terms of distribution of V_a (vs. reference electrode) in the system. Dotted line: no external bias. Solid line: with external bias.

through the InGa ohmic contact. The potential scan generates a peak current at about -0.38V vs. SCE at a scan rate of 100 mV/s due to mass transport limitations (Fig. 4c). The voltammetric curve of PtSi was obtained by applying a potential scan through the front Ag contact to the PtSi. As shown in curve a of Fig. 4, both anodic and cathodic currents were mass-transfer limited.

The current-voltage curve of the n-Si/PtSi diode (current flow and voltage, V_D , between InGa to Si and Ag contact to PtSi) is shown in curve b of Fig. 4. In the reverse bias (anodic bias) direction, the current was essentially the same as that in curve c and was much smaller than the anodic current (shown on curve a of Fig. 4) taking place on PtSi. In the forward bias direction, before mass-transfer limitation took over, the diode current was smaller than the cathodic current (shown on curve a of Fig. 4) on PtSi and was nearly equal to the real current flow through the n-Si(Pt) electrode (shown on curve c of Fig. 4).

The system can thus be modeled as the Si-PtSi diode in series with the PtSi/solution interface. At a given current, V_a is given by the sum of V_D and V_s plus any internal iR drops. As shown in curve b of Fig. 3, in the presence of equimolar $\text{Fe}(\text{CN})_6^{3-}$ and $\text{Fe}(\text{CN})_6^{4-}$, V_s was essentially fixed at V_o' of the $\text{Fe}(\text{CN})_6^{3-/4-}$ couple when V_a was positive of V_o' . When V_a was negative of the potential at which mass-transfer limitation or the electron-transfer kinetics on PtSi becomes important, the change of V_s was equal to the change of V_a . If we assume that the potential drop across the diffuse double layer and at the ohmic contact is negligible, we can calculate the distribution of the applied voltage into the change of band bending, ΔV_b , (which is equivalent to the drop across the diode, V_D), and the change of potential drop across Helmholtz double layer, ΔV_H ; this is plotted in Fig. 5. As shown in this figure, $\Delta V_H \cong 0.0\text{V}$ when V_a is positive of V_o' , indicating that the applied voltage is mainly absorbed inside the semiconductor.

Fig. 4. a: voltammetric curve on PtSi (through Ag contact). b: current-voltage curve of the n-Si/PtSi diode. c: voltammetric curve on n-Si/PtSi (through InGa contact). Scan rate: 100 mV/s and in $0.5\text{M Na}_2\text{SO}_4$, $0.5\text{M K}_3\text{Fe}(\text{CN})_6$, and $0.5\text{M K}_4\text{Fe}(\text{CN})_6$. pH 5. Exposed PtSi electrode area $< 0.1\text{ cm}^2$.

When V_a is negative of V_o' , the applied voltage distributes both in ΔV_H and ΔV_b (Scheme II); ΔV_b approaches a maximum at a potential near the potential at which the peak current through the system was observed. Then ΔV_H increases and ΔV_b decreases steadily because of mass-transfer limitations to the current.

Interfacial energetics.—We have carried out cyclic voltammetry for a variety of redox couples with V_{redox}

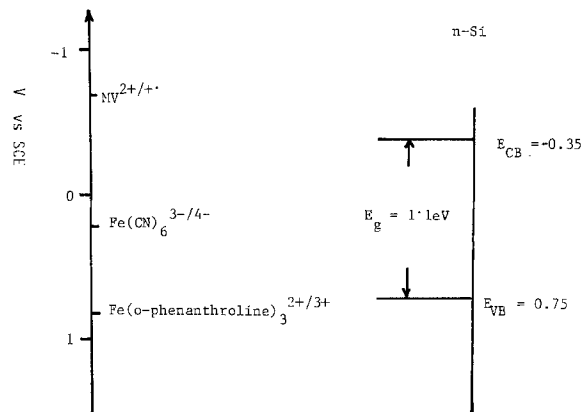

Fig. 5. The change of band-bending, ΔV_b , and the change of potential drop across Helmholtz double layer, ΔV_H , as functions of the applied potential, V_a . Scan rate: 100 mV/s and in $0.5\text{M Na}_2\text{SO}_4$, $0.5\text{M K}_3\text{Fe}(\text{CN})_6$, and $0.5\text{M K}_4\text{Fe}(\text{CN})_6$. pH 5.

Scheme II. A, top: in terms of interfacial energetics. $\Delta V_1 = \Delta V_H + (V_b' - V_b)$ $V_a = V_s + (V_b' - V_b)$; band-bending unchanged. B, bottom: in terms of distribution of V_a (vs. reference electrode) in the system.

values spanning a range that is wider than the bandgap of silicon in aqueous solution (see Scheme III). Those redox couples all show one-electron reversible cyclic voltammograms on a Pt electrode (Fig. 6), so that possible complications caused by different interfacial charge transfer kinetics at the silicide/solution interface are not important. As shown in Fig. 6, in the dark, MV^{2+} is reduced at an n-Si(Ir) electrode with a cathodic peak potential (V_{pc}) of $-0.9V$ vs. SCE. No anodic peak corresponding to the reoxidation of MV^+ was observed in the dark, because of the lack of holes in n-Si and the unfavorable energetics for electron injection from solution species. Under illumination with

Scheme III

65 mW/cm^2 , MV^{2+} is reduced at more negative potential with V_{pc} at $-1.07V$ and reoxidized with V_{pa} at $-1.01V$ vs. SCE due to the photogeneration of holes. With $V_{oc} = |V_{pa}[n\text{-Si(Ir)}] - V_{pa}(\text{Pt})|$ (4, 5), this represents $V_{oc} = 0.4V$ for $MV^{2+/+}$. Similar results were obtained for $\text{Fe}(\text{CN})_6^{3-/4-}$ and $\text{Fe}(\text{o-phenanthroline})_3^{2+/3+}$. This constancy of V_{oc} for various one-electron reversible redox couples with potentials beyond the bandedges of silicon is consistent with our previous results over a more restricted range (2) and suggests that the electrolyte solution species do not interact with silicon substrate. Rather, the interaction is with the silicide overlayer and the interfacial energetics is dominated by this interaction. Apparently, the interfacial energetics depend strongly upon the coverage of silicide on silicon substrate. Electron spectroscopic (AES and XPS) analyses (2, 8) show that most of the silicide layer we prepared were richer in silicon than in metal. Even under those conditions, n-Si(M) electrodes behave as if the surface of Si electrode were wholly covered by a uniform metal layer. The effect of variation of the thickness of the metal overlayer, the annealing conditions, and coverage of silicides or metals on the interfacial energetics is currently under investigation.

Effect of charge transfer kinetics.—The charge transfer kinetics at the electrode/solution interface might

Fig. 6. Cyclic voltammograms of three reversible couples at scan rate of 100 mV/s on Pt (A) and on n-Si(Ir) (B) in the dark (broken lines) and under illumination with 65 mW/cm^2 (solid curves). Curve a: $MV^{2+/+}$. Curve b: $\text{Fe}(\text{CN})_6^{3-/4-}$. Curve c: $\text{Fe}(\text{o-phenanthroline})_3^{2+/3+}$.

affect the potential at which processes occur, as well as the voltammetric behavior of the photoelectrode and the observed photopotentials (6, 7). This was investigated in the following several experiments. The charge transfer kinetics of the Fe(II)/Fe(III) couple was changed by variation of the concentration of chloride ion, $[Cl^-]$. As shown in Fig. 7a, an increase in the concentration of Cl^- increased the rate of Fe(II)/Fe(III) redox reaction at Pt electrode. ΔV_p ($\Delta V_p = V_{pa} - V_{pc}$) decreased from 330 mV at $[Cl^-] = 0.0M$ to 60 mV when $[Cl^-] = 6M$, where the reaction approached reversible behavior, without a significant shift in the midpoint potential. The ratio of the anodic peak current (i_{pa}) vs. the cathodic peak current (i_{pc}) approaches unity when $[Cl^-]$ is increased (9). A similar trend was observed with an n-Si(Ir) electrode under illumination with 80 mW/cm² (see Fig. 7b), although the peak potentials were shifted towards more negative values by about 0.4V, as compared with those on Pt (corresponding to the photovoltage observed on those electrodes). This similarity of behavior suggests that the rate-limiting process under illumination is the kinetics of charge transfer at the Si(M)/solution interface.

Effect of dopant concentration in the silicon substrate and type metal (M) overlayer on the voltammetric behavior of n-Si(M) electrode.—The deposition of a metal onto a semiconductor will usually result in the formation of an ohmic contact or a Schottky barrier, depending on the relative work functions of semiconductor and metal, the surface treatment of semiconductor before deposition, and the interfacial chemistry that occurs upon deposition or during annealing (10). By keeping the conditions for etching, metal deposition, and postannealing constant and varying the doping density of silicon substrate, we found very different voltammetric behavior in the dark and

under illumination (see Fig. 8). The dark oxidation current increased and the reduction current decreased systematically with decreased resistivity of the silicon wafers, suggesting that samples with a higher resistivity form better rectifying junctions with silicide. Corresponding to this behavior, a better photoeffect was observed on samples with higher resistivity. The photoelectron spectroscopic results (8) suggested that metal diffuses a few hundred angstroms into the silicon substrate. The incorporated transition metal could facilitate electron transfer and recombination in the space-charge layer. This effect will be more prominent when the width of the space-charge layer becomes narrower due to higher doping density. The incorporated transition metal in the space-charge layer might also form effective recombination centers that scavenge photo-generated holes and thus degrade the photoeffect. This is consistent with the results shown in Fig. 8.

The effect of the nature of the metal on the voltammetric behavior is summarized in Fig. 9. Several interesting conclusions result from these studies. First, the work function of metals listed in Fig. 9 covers a range of at least 0.8V (11); however, V_{oc} of these silicide-coated n-Si electrodes only covers about 0.25V. This insensitivity of V_{oc} with respect to the work function of metal is basically consistent with the results observed in solid-state devices (12). Secondly, the higher the rectifying ratio (R_r) is (the absolute ratio of the dark reduction current vs. the dark oxidation current at equal potential difference with respect to the rest potential), the better the photoeffect is. Both Pt and Ir show very high R_r values and have high V_{oc} and short-circuit photocurrents (i_{sc}), whereas Ru shows poor R_r , V_{oc} , and i_{sc} . The factors contributing to the poor photoeffect on n-Si(Ru) electrodes are not clear and require further investigation.

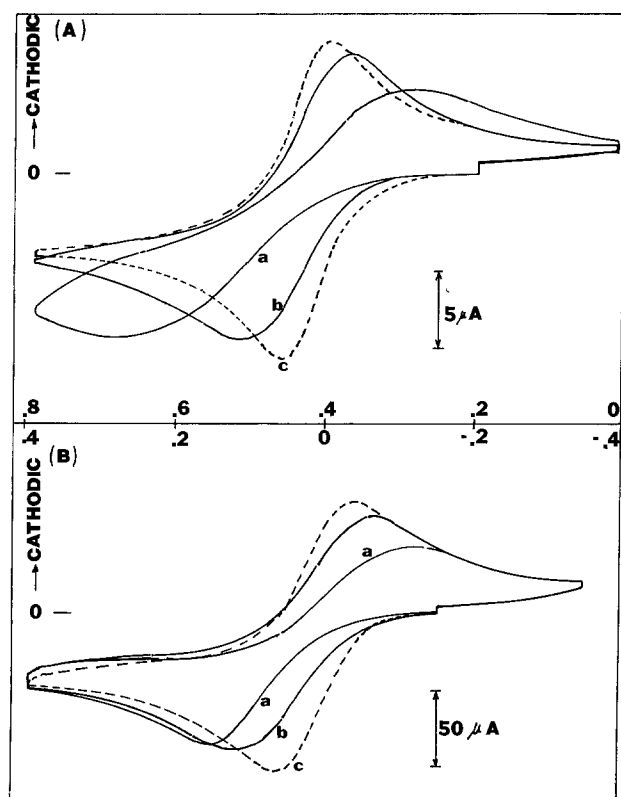

Fig. 7. Cl^- concentration dependence of cyclic voltammograms of Fe^{2+} at scan rate of 100 mV/s on Pt (A) and on n-Si(Ir) (B) under illumination with 80 mW/cm². In conclusion, the measurement of the surface potential of n-Si electrodes coated with a thin layer of noble metal silicide reveals that changes in the applied potential on these electrodes are mainly absorbed across Helmholtz double layer either in the dark or under illumination. A constancy of open-circuit photovoltage was observed on these electrodes for reversible redox couples which span a potential range larger than the bandgap. These EC and PEC characteristics simulate those found when Fermi-level pinning occurs (13). The interfacial charge transfer kinetics at the silicide/solution interface also plays an important role in the EC and PEC performance, as does the doping density of silicon substrate and the type of metal overlayer.

Acknowledgments

We thank Dr. R. Gerald Keil for his suggestion on the electroplating of ruthenium and Professor Mark S.

Wrighton for his suggestion on the experiment about the constancy of photovoltage with respect to reversible redox couples. The assistance of Professor Gregory A. Hope and Dr. M. Schmerling, as well as the comments and suggestions of Dr. Ronald Wilson, are gratefully acknowledged. Redox Conduction: Its Use in Electronic Devices

P. G. Pickup and Royce W. Murray

Kenan Laboratories of Chemistry, University of North Carolina, Chapel Hill, North Carolina 27514

ABSTRACT

A sandwich electrode composed of a film of the electroactive polymer $[Os(bpy)_2(vpy)_2]^{P+}$, sandwiched between a Pt disk electrode and a porous Au film, becomes conductive when the Pt and Au potentials are properly poised in relation to the potential at which the Os(III/II) mixed valent state becomes generated. The potential control is normally judged in relation to a reference electrode. The reference electrode can be shorted to, or made common with, the Au electrode, so that two-terminal potential control circuitry can be employed to cause or not cause redox conduction through the sandwich. Such arrangements are used to illustrate principles for using the sandwich electrode as a two-terminal device that acts in a manner similar to a Zener diode, and as a triode-like three-terminal device in which the current between two terminals is controlled by the potential applied at the third.

That electrochemical charge can be transported through films of redox polymer saturated with electrolyte solution and coated on electrodes has been recognized since 1978 (1). Such films can contain the equiv-

Key words: osmium, polymer modified electrode, electron diffusion, diode, triode.

alent of thousands of monomolecular layers of electroactive sites yet be rapidly oxidized and reduced by the electrode (2). For a pyrazoline polymer, where the electroactive sites were affixed to the polymer lattice, Kaufman *et al.* (3) proposed that charge transport can occur by electron self-exchange reactions between oxi-

dized and reduced pyrazoline sites. When a concentration gradient of oxidized and reduced sites exists, such reactions lead to a net electron current which follows Fick's diffusion law as shown both experimentally (4) for several redox polymers and theoretically (5), and is characterized by a diffusion coefficient (D_{ct}). Diffusion laws also apply when the electroactive site is a counterion of a polyionic film (6), but competitive physical diffusion of the redox site must then be considered (7). In both cases, starting from a fully reduced or oxidized polymer, electron transport (e.g., "redox conduction current") must be accompanied by a net oxidation or reduction of some of the electroactive sites of the polymer, and so is turned on by underlying electrode potentials near the formal potential of the electroactive species in the polymer.

Normally, redox conduction in electroactive polymer films is observed using an electrode contacting the film on one side and an electrolyte solution on the other. To exploit certain of the properties of redox conduction, however, it is of advantage to contact the second side of the polymer film with a structure which can serve as electron donor or acceptor. We have done this with a second electroactive polymer film in the case of bilayer electrodes (8), and most recently in a sandwich electrode (9), with a second electrode (a Au film) which is porous to the contacting electrolyte/solvent bath (Fig. 1). This paper addresses the application of the sandwich electrode to make a simple electronic device which can be used as a two-terminal rectifying device, similar in some respects to a Zener diode, or as a three-terminal device in which the current between two terminals is controlled by the potential applied at the third. The polymer film employed is made by electropolymerization of the vinyl-substituted complex (8, 10) $[\text{Os}(\text{bpy})_2(\text{vpy})_2]^{2+}$ onto a Pt electrode. We should emphasize that the purpose of the study is to demonstrate the concept of making a device based on redox conduction and electrochemical principles.

Figure 1 shows the concentration gradient for Os(III) redox sites in a film of poly- $[\text{Os}(\text{bpy})_2(\text{vpy})_2]^{2+}$ in a sandwich electrode in which the potentials of the two electrodes are controlled so that the left-hand (Pt) electrode acts as electron acceptor and the right-hand electrode (porous Au) acts as electron donor. The

Fig. 1. Sandwich electrode showing schematic representation of the proposed mechanism of redox conduction and a concentration profile for the situation when Au is significantly negative of E° and Pt significantly positive of E° .

current passing through the film shown in Fig. 1 depends upon the concentration gradients of oxidized or reduced Os sites in the film, which are determined by the potentials applied to the two electrodes. In our previous experiments (9), the potentials of the two electrodes were controlled relative to some reference electrode placed in the contacting solution. An analytical expression for the steady-state current as a function of the potentials of the two electrodes (E_{Pt} and E_{Au}) relative to the reference electrode is readily derived, and is formally analogous to the equation for twin-electrode thin layer electrochemistry (10)

$$i = \left[\frac{nFAD_{ct}C_T^2}{\Gamma_T} \right] \left[\frac{1}{1 + \exp[gf(E^\circ - E_{Pt})]} \right] \left[\frac{1}{1 + \exp[gf(E^\circ - E_{Au})]} \right] \quad [1]$$

where C_T and E° are concentration and formal potential of polymer redox sites, Γ_T is surface coverage of redox polymer in mol/cm², f is nF/RT , and g is a constant to correct for the nonideality of the polymer film (9b).

It is useful to consider a three-dimensional plot of Eq. [1] as shown in Fig. 2. Each line on the grid surface in this plot represents current as a function of E_{Pt} at constant E_{Au} or vice versa. Each line then corresponds to a constant oxidized-polymer concentration on one side of the film and thus a concentration gradient and hence current proportioned by the concentration of oxidized polymer on the other side. Take, for example, the trace at $(E_{Au} - E^\circ) = 0$ (whose ends are marked with stars \star), in which there is always a 50% oxidized layer of polymer at the Au electrode. When $E_{Pt} - E^\circ$ is significantly negative (e.g., $-0.2V$), there is no oxidized polymer at the Pt, and so the concentration gradient will be half maximum and a current of $nFAD_{ct}C_T^2/2\Gamma_T$ will flow from Au to Pt. At $(E_{Pt} = E_{Au})$, the concentration gradient and current are zero. At more positive $E_{Pt} - E^\circ$, a limiting current $nFAD_{ct}C_T^2/2\Gamma_T$ flows from Pt to Au as the polymer at the Pt electrode becomes virtually 100% oxidized.

The preceding example presumes control of both Pt and Au electrode potentials relative to a reference electrode potential, which is a three- or four-electrode experiment as used previously (9). Under this circumstance, the current for a given $E_{Pt} - E_{Au}$ potential difference could be found readily from Fig. 2. If now instead one considers not controlling either electrode's

Fig. 2. Three dimensional plot of current at the Pt electrode vs. the Pt electrode potential (E_{Pt}) and the Au electrode potential (E_{Au}) for a Pt/polymer/Au sandwich electrode according to Eq. [1] ($g = 0.8$). The grid extends to $\pm 0.26V$ for the two potential axes, and the current axis is in arbitrary units. Also shown are the loci of the triode-type experiments of Fig. 8 ($-\bullet-\bullet-$).

potential relative to a reference electrode, but just the potential difference $E_{Pt} - E_{Au}$ between them, as would be the case in a two-electrode cell, we see that a given difference between E_{Au} and E_{Pt} no longer defines a unique point on the current-potential surface of Fig. 2. In fact, a range of different currents through the film are possible for any given absolute value of $E_{Pt} - E_{Au}$. Thus, true two-electrode potential control presents a fundamental difficulty. On the other hand, to exploit the sandwich arrangement shown in Fig. 1 in an electronic device, it is desirable to simplify the potential control requirements for the device by using only a two-electrode cell, i.e., controlling only the potential difference between the two electrodes. This paper describes how this can be done while maintaining a usable reference to the current-potential pattern of Fig. 2.

Experimental

The construction of the sandwich electrode has been described elsewhere (9). The electrode assembly consists of six independent Pt disk microelectrodes (tips of wires) sealed in a single Teflon [or glass (9b)] shroud. Five electrodes are coated with 0.1-1.0 μm polymer by reductive electropolymerization of the $[\text{Os}(\text{bpy})_2(\text{vpy})_2]^{2+}$ monomer complex. The whole face of the electrode assembly is then coated with ca. 0.1 μm vapor-deposited gold. The sixth Pt disk serves as a direct electrical contact to the gold film.

The problem of shorts between the gold and the Pt disk described in earlier papers (9a) has now been largely overcome. The multi-electrode assembly allows five sandwich electrodes to be constructed simultaneously, at least one of these is typically not shorted at all, and the others can usually be successfully conditioned (9a) to remove initial shorts.

All experiments were performed in 0.1M $\text{Et}_4\text{NClO}_4/\text{acetonitrile}$. The solutions were normally degassed with N_2 . A conventional, locally built potentiostat and a triangle wave generator were used to apply a variable potential difference across the polymer film and to measure the current through the film. Two-electrode control was effected by connecting both the reference and auxiliary electrode terminals of the potentiostat to the gold film and connecting the working electrode terminal to one of the polymer-coated Pt microelectrodes. The potentiostat is thus used merely as a current follower and can be replaced by an ammeter or some other current measuring device or circuit. A PAR Model 175 Universal Programmer was used when voltage pulses were required, and a second triangle wave generator when two independent potential differences were required. The Ag/AgCl electrode was prepared by (11) depositing AgCl at 0.4 A/cm^2 for 30 min from 0.1M HCl .

Results and Discussion

To determine the current/voltage characteristics of a Pt/poly- $[\text{Os}(\text{bpy})_2(\text{vpy})_2]^{2+}/\text{Au}$ sandwich device in 0.1M $\text{Et}_4\text{NClO}_4/\text{CH}_3\text{CN}$, the potential difference between the Pt and Au electrodes ($\Delta E = E_{Pt} - E_{Au}$) was varied linearly with time, starting from zero with no reference electrode in the cell. A scan speed of 20 mV/s, which would give an almost steady-state response in four-electrode experiments, was used. However, a steady-state (or even near steady-state) response was not obtained at first in this two-electrode experiment. Redox conduction currents were observed, but the potential difference range over which they occurred continually changed with time so that repetitive scans were not reproducible. The direction and rate of the change varied from one experiment to the next. After some time of scanning, the current/voltage pattern did tend to stabilize and become more nearly reproducible, but again the time required for stabilization and the final ΔE potential difference range giving

redox conduction varied from one experiment to the next.

The above behavior can be rationalized with reference to Fig. 2. Since neither the Pt nor Au electrode potentials are independently controlled, but only the potential difference between the two is controlled, a position on the three-dimensional surface of Fig. 2 is not specified. Also, the potentials of the two electrodes (relative to the reference electrode scale), and hence the current, can be influenced by the reactions of impurities such as Au ions from gold oxidation during conditioning, O_2 , or H_2O . One simplifying factor is the very large surface area of the Au electrode relative to that of the Pt, so that a large charge is required to change its potential. [SEM shows the gold film to be made up of small particles. It is porous and exhibits a large charging current (9a).] Thus, as ΔE is varied, so that the polymer film becomes mixed valent and redox conduction occurs, the potential of the Au electrode typically changes by only ca. 50 mV. However, the Au electrode potential does tend to drift with time.

A conceptual solution to this problem would be to charge the polymer to its 50/50 mixed valent state at the start of the experiment. Then both Pt and Au should initially be at E° for the polymer (0.78V vs. Ag/AgCl), and any applied potential difference $E_{Pt} - E_{Au}$ should just cause a redistribution of oxidized and reduced sites. Hence, redox conduction currents should be centered at $\Delta E = 0$. However, even if initially charged, the polymer does not in fact remain for long in the 50/50 mixed valent state, and the potentials of the two electrodes still drift with time. A change to more positive ΔE is probably due to reduction of Au(I) ions from gold dissolution; the more usual change is a lowering of ΔE , presumably due to oxidation of solvent impurities by Os(III) in the film.

Reference electrodes.—The drifting potential problem described above was solved by connecting a reference (or pseudoreference) electrode directly to the Au electrode. In this way, the Au electrode is kept at the reference electrode potential, and its potential does not change as the potential difference between it and the Pt electrode is changed, yet the simplicity of two-electrode potential control is preserved. The reference electrode used has in principle to reversibly pass a charge equal to that required to oxidize half of the redox polymer film (to generate a mixed valent film) without significantly changing its potential. This limits the number of reference electrodes that can be used, but still there are many that are suitable. By using different reference electrodes, it is possible, furthermore, to systematically vary the potential difference at which the sandwich electrode becomes conducting.

Ag/AgCl.— Ag/AgCl proved to be a suitable reference electrode in the experimental arrangement shown in Fig. 3, either with or without chloride added to the reference electrode compartment. Plots of redox conduction current vs. ΔE for this arrangement are shown in Fig. 4a for positive ΔE (where E_{Pt} is more positive than E_{Au}). The potential difference ΔE was scanned continually at 20 mV/s between 0.5 and 1.0V; the first and twentieth cyclical potential scans are shown. The redox conduction wave for the Os(III/II) couple is reasonably reproducible. The only changes over 20 scans are a slight increase in the limiting current (from 7.5 to 8.4 mA/cm^2) and a very slight change in wave-shape. The increase in i_{lim} is of unknown origin, but is also observed in four-electrode redox conduction measurements using this polymer (9b). The slight hysteresis in the forward and reverse waves of Fig. 4a, also observed in four-electrode redox conduction measurements (9b), is of unknown origin, but does diminish at lower scan rates. The current is half of its limiting value at 0.78V ($\Delta E_{1/2}$), which is E° for this polymer vs. Ag/AgCl . The i_{lim} and ($\Delta E_{1/2}$) values obtained

Fig. 3. Schematic representation of the sandwich electrode diode-type device, showing the potentiostat connection for measurement of i vs. ΔE characteristic. Five Pt electrodes are coated with polymer, and one is left bare to serve as a contact to the gold film. Gold is deposited over both electrodes and Teflon shroud in a continuous film. Only one polymer-coated electrode is used at a time; the others do not effect the behavior of the device.

in this experiment are the same as those obtained by using the same electrode in a four-electrode redox conduction experiment.

Figure 4b shows the result for scanning to negative values of ΔE (i.e., E_{Au} more positive than E_{Pt}) for the same electrode used for Fig. 4a. Two waves, with $\Delta E_{1/2} = -1.27$ and -1.48 V, respectively, are observed, which are caused by the Os(II/I) and Os(I/0) mixed valent states ($E^{o'} = -1.27$ and -1.48 V vs. Ag/AgCl). The currents are much higher ($i_{lim} = 0.4$ A/cm²) (9b), but gradually decay during consecutive scans. The decay is probably due to irreversible damage caused to the highly reducing polymer by trace O₂. There is also a hysteresis between the forward and reverse scans which is also observed in four-electrode redox con-

Fig. 4. Current vs. voltage characteristic of the sandwich-electrode device shown in Fig. 3, for a 6.5×10^{-8} mol/cm² poly-[Os(bpy)₂(vpy)₂]²⁺ film with Ag/AgCl reference. Stars mark the formal potentials (vs. Ag/AgCl) of Os(III/II), Os(II/I), and Os(I/0) from left to right, respectively, in the polymer film. Panel A: First (—) and twentieth (---) scans at 20 mV/s. Panel B: First (—) scan and limiting currents (---) of second and third scans at 20 mV/s.

duction experiments, as is the instability. The hysteresis is less at 5 mV/s.

The current/voltage characteristics in Fig. 4a and 4b are typical for the arrangement of Fig. 3. No observable current (at the current sensitivities used) is seen between +0.5 and -1.0V, and so this region is not shown. At potential differences $\Delta E > +1.0$ V, the limiting current remains constant at its limiting value until solvent oxidation commences at between +1.5 and +2.0V (depending upon the solvent dryness and purity). Then the current increases and damage to the sandwich, ultimately shorting, occurs. At potential differences more negative than -2.0V, solvent reduction occurs and destruction of the sandwich is very rapid.

Thus the sandwich shown in Fig. 3 behaves like a Zener diode device with both positive and negative breakdown voltages. These breakdown voltages (ca. +0.7 and -1.2V in this case) are of different magnitude and the conductivity and current vs. ΔE profiles are different. In both cases, an approximately exponential change in current with ΔE is followed by a leveling off to give a limiting current independent of ΔE . As an "electronic conductivity" ($i/\Delta E$) increases to a maximum and then decreases linearly. ("Electronic conductivity" means the effective electronic conductivity if it is imagined that the current is driven by a potential rather than concentration gradient.)

Polyvinyl-ferrocene.—A polyvinyl-ferrocene- (PVF) coated Pt electrode has been shown to be a good reference electrode (12). This polymer reference is attractive for these experiments because it can be deposited in a large amount, relative to the quantity of poly-[Os(bpy)₂(vpy)₂]²⁺, directly upon the Au film, thereby simplifying the device, and when charged to its 1:1 Fe(III/II) state, the PVF^{0/1+} film should poise the gold film at a constant potential. Note that this arrangement (Fig. 5) is a bilayer electrode (8), with a conductor whose potential can be controlled, interposed between two polymer films.

PVF was first tested as a separate reference electrode in the arrangement of Fig. 3. Several drops of a toluene solution of a polyvinyl-ferrocene-siloxane copolymer (PVF-MPS) (Ref. 13, copolymer 4) were sequentially evaporated on a coiled Pt wire, and the polymer film then cross-linked by exposure to moist HCl vapor. Approximately 10⁻⁸ mol of ferrocene sites were present on the electrode. The Os polymer film used contained approximately 10⁻¹¹ mol of redox sites. This Pt/PVF-MPS reference electrode replaced the Ag/AgCl electrode in the arrangement shown in Fig. 3. It was not oxidized before the experiment. Scanning $\Delta E = 0$ to 1V (i.e., E_{Pt} more positive than E_{Au}) at 100 mV/s gave the i vs. ΔE response shown in Fig. 6. The first and tenth scans are shown, in which the positive and negative sweeps for the first scan show significant hysteresis, and the redox conduction wave moves to

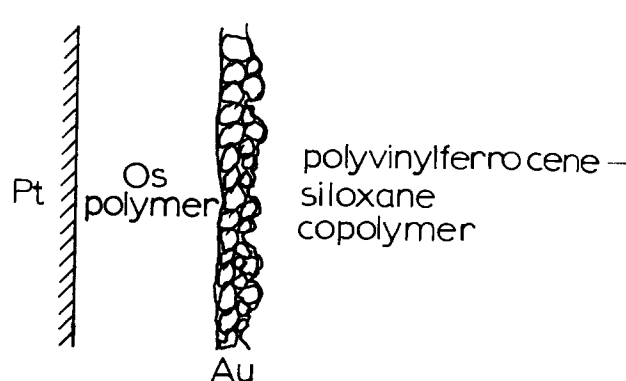

Fig. 5. Schematic representation of a sandwich-electrode diode with a self-contained PVF-MPS polymer reference to keep the gold film at a fixed potential.

Fig. 6. Current vs. voltage characteristic for the device shown in Fig. 3 with a 2.6×10^{-8} mol/cm² poly-[Os(bpy)₂(vpy)₂]⁺² film and a Pt/PVF-MPS polymer reference electrode. First (—) and tenth (---) scans at 100 mV/s.

somewhat more negative ΔE on subsequent scans. By the tenth scan, the hysteresis is small and there is little change between consecutive scans.

This behavior can be rationalized by considering the oxidation state of the PVF-MPS film. Initially the PVF-MPS film is mainly in the Fe(II) oxidation state, and so its rest potential and that of the Au electrode which it contacts is somewhat more negative, about 0.08V, than E° for PVF-MPS, which is +0.45V vs. Ag/AgCl (13). The E° for the Os(III/II) reaction is +0.78V vs. Ag/AgCl (9), and, accordingly, on the first potential sweep the half-wave potential $\Delta E_{1/2}$ of the Os(III/II) reaction occurring on the Pt electrode is at +0.41V (+0.78 - 0.45 + 0.08). On the subsequent negative scan of the Pt electrode potential vs. that of Au and of the PVF-MPS film, we find that $\Delta E_{1/2}$ occurs at 0.38V vs. SSCE. Thus, in some way the PVF-MPS film has become, on the average, more oxidized during the voltammogram, so that its and the Au electrode potential are more positive. This trend of the PVF-MPS film becoming more oxidized continues, but slows to a very small rate of change as the PVF-MPS gradually becomes more oxidized. Table I contains $\Delta E_{1/2}$ values for the sandwich electrode after a number of different experiments. After long periods of use, the $\Delta E_{1/2}$ sometimes drops below the ideal $\Delta E_{1/2} = +0.33$ V that a 1:1 PVF-MPS mixed valent state should yield, but the difference (90 mV) is not great, and this does not always occur, as illustrated by Table I. When allowed to rest, the $\Delta E_{1/2}$ does become poised at a value near the ideal +0.33V.

Measurements over a ΔE range of +2.0 to -2.0V were also made with the Pt/PVF-MPS reference electrode arrangement of Fig. 3. The results were similar to those obtained with an Ag/AgCl reference electrode (Fig. 4), except that the redox conduction of all three waves occurred at potentials ca. 0.45V more negative,

Table I. $\Delta E_{1/2}$ for both positive and negative scans for the device shown in Fig. 3 with a Pt/PVF-MPS reference electrode.

Scan rate = 100 mV/s.

Operation in chronological order	$\Delta E_{1/2}$ positive, V	$\Delta E_{1/2}$ negative, V
Initial	0.41	0.38
Tenth scan	0.35	0.34
Fifteenth scan	0.34	0.33
After some potential-step experiments	0.30	0.29
After Pt/PVFS had not been used for 30 min	0.36	0.35
After 40 min continual scanning	0.26	0.24
After Pt/PVFS had not been used for 20h	0.36	0.35
After 30 min continual scanning	0.34	0.31

which merely reflects the difference between the potentials of the Ag/AgCl and Pt/PVF-MPS reference electrodes.

An improvement, in terms of practicality, in this device is attained by depositing the PVF-MPS polymer directly onto the gold electrode (Fig. 5). A few drops of the PVF-MPS toluene solution were allowed to evaporate to dryness on the gold-coated sandwich electrode, and the polymer was cross-linked with moist HCl. This electrode assembly gave the same type of current vs. ΔE response, as shown in Fig. 6. Initially, $\Delta E_{1/2}$ was 0.44V, but after a few scans it had dropped to 0.34V, and it soon stabilized at 0.31V. This arrangement is both compact and genuinely "two electrode." The positive and negative "diode" breakdown voltages are clearly determined by the potential of the PVF-MPS, as they were with the Ag/AgCl reference in the previous example.

A triode-type device.—We have shown above that the two-terminal sandwich electrode arrangements of Fig. 3 and of Fig. 5 act in a similar manner to a diode. The diode conductivity (the limiting currents of Fig. 4 and 6) depends on the magnitude and polarity of the applied, two-terminal potential ΔE .

It is possible to apply a second potential difference to produce a device which acts in a similar manner to a triode, as shown in Fig. 7. One potential (ΔE_1) is applied between the Pt and Au electrodes as before, and a second potential difference (ΔE_2), with a common terminal to ΔE_1 , is applied between the Au and Ag/AgCl electrodes. In the circuit in Fig. 7, the current flowing between the Au and Pt electrodes is now also controlled by the potential difference between the Au and Ag/AgCl electrodes, as is demonstrated by the voltammograms shown in Fig. 8. In the traces shown, the potential difference applied across the Os polymer film (ΔE_1), was held constant at 50 mV (curve A), 100 mV (curve B), 300 mV (curve C), or 500 mV

Fig. 7. Circuit for demonstration of the triode-type device. WE, RE, and AE are the three terminals of the potentiostat, which measure current. ΔE_1 and ΔE_2 are supplied by independent triangle wave generators.

Fig. 8. Current vs. ΔE_2 for the device shown in Fig. 7 at fixed values for ΔE_1 of 50 mV (A), 100 mV (B), 300 mV (C), and 500 mV (D). ΔE_2 was varied linearly at 1 mV/s. 9.1×10^{-8} mol/cm² poly[Os(bpy)₂(vpy)₂]²⁺.

(curve D), while the potential difference between the Au and Ag/AgCl electrodes (ΔE_2) was scanned at 1 mV/s (using a triangle wave generator connected between the Ag/AgCl electrode and the gold electrode contact).

The traces of Fig. 8 can be understood with reference to Fig. 2. The locus of the scans used in Fig. 8 are plotted on Fig. 2 and labeled in the same way (i.e., curve A in Fig. 2 corresponds to $\Delta E_1 = 50$ mV, curve A of Fig. 8). Consider curves A of Fig. 2 and 8. When $\Delta E_2 = 0.0$ V, then $E_{Au} = 0.0$ V (vs. Ag/AgCl), and $E_{Pt} = +0.05$ V (is ΔE_1). Since $E^\circ = 0.78$ V vs. Ag/AgCl for Os(III/II), the polymer is completely reduced, there are no concentration gradients within the film, and no current flows. As ΔE_2 increases and E_{Au} and E_{Pt} both approach E° , both electrodes become capable of driving the Os(II) \rightarrow Os(III) reaction. However, there will always be more oxidized polymer at the Pt electrode than at the Au electrode, because $\Delta E_1 = +0.05$ V, and so electrons will flow from Pt to Au. The difference in [Os(III)] concentration at the two electrodes, and hence the current, will be greatest when $(E_{Pt} - E^\circ) = (E^\circ - E_{Au})$, since at E° the Nernstian plot (Fig. 2) has the largest gradient. As ΔE_2 becomes yet larger, the current decreases to zero as both E_{Pt} and E_{Au} become significantly greater than E° and the polymer film is completely oxidized.

Last, consider curves D of Fig. 2 and 8. When $\Delta E_1 = 500$ mV, following the reasoning for curves A, there exists a range of ΔE_2 values between 0.35 and 0.65 V, for which the film is almost completely oxidized at the Pt electrode and almost completely reduced at the Au electrode. Thus, over this entire region the limiting current of the polymer film continues to flow from Pt to Au.

Response time for the diode-type device.—The rate at which the current passing through the diode-type devices discussed here changes from near-zero to the limiting current, or vice versa, as ΔE passes the breakdown potential, depends on how quickly the osmium polymer can be charged to its mixed valent state. Thus, the diode response time is influenced by the polymer film thickness and the concentration of redox sites, since these determine the total quantity of Os sites in the polymer, and by the rate at which electron diffusion occurs through the polymer as measured by the parameter D_{ct} .

Figure 9 shows the result of repeatedly stepping the potential difference ΔE applied to the sandwich-cell arrangement of Fig. 3, with a Ag/AgCl reference electrode, between 0.0 and +1V at 5s intervals. This stepping program crosses the breakdown potential, as seen with reference to Fig. 6. For each potential step, there is a current spike of ca. ± 0.1 A/cm² (measured by an

Fig. 9. Current vs. time plot for the device shown in Fig. 3 with a 4.7×10^{-8} mol/cm² poly[Os(bpy)₂(vpy)₂]²⁺ film and an Ag/AgCl reference electrode. The potential difference ΔE across the film was repeatedly stepped from 0.0 to +1V and back (*) at 5s intervals.

oscilloscope) which rapidly decays to either zero or i_{lim} , depending upon the applied potential difference. The rate at which this current decay occurs and the device achieves a stable response should be described by the finite diffusion current-time relation (4d)

$$i = \left[\frac{nFAD_{ct}^{1/2}C_T}{(\pi t)^{1/2}} \right] \left[\sum_{k=0}^{\infty} (-1)^k \left[\exp \left[\frac{-k^2 d^2}{D_{ct} t} \right] - \exp \left[\frac{-(k+1)^2 d^2}{D_{ct} t} \right] \right] \right]$$

This equation allows estimate of the time required to oxidize or reduce, say 99% of the polymer. For the electrode used for Fig. 9, $D_{ct} = 1.6 \times 10^{-9}$ cm²/s as evaluated from the limiting current. Taking $C_T = 1.5 \times 10^{-3}$ mol/cm³ and $d = 3.1 \times 10^{-5}$ cm from Γ_T/C_T , we estimate that the polymer film should be 99% charged in ca. 1s. This is approximately what is experimentally observed (Fig. 9).

(★ D_{ct} was initially 5.0×10^{-9} cm²/s for this electrode, which is in agreement with results reported elsewhere (9). However, prior to the experiment of Fig. 9, this electrode had been used extensively in the somewhat unstable Os(I) and Os(0) states, which caused D_{ct} to gradually decrease to 1.6×10^{-9} cm²/s.)

An undegraded poly-[Os(bpy)₂(vpy)₂]²⁺ film has a D_{ct} of 5×10^{-9} cm²/s. If a sandwich device could be constructed from this polymer with a film thickness as low as 500Å, then by the above analysis, it could be charged to 99% in just 10 ms. This is a reasonable switching time for a diode device in many circumstances, particularly for electrochromic applications which also rely upon electrochemical reactions (14).

Stability.—The stability of the sandwich electrode devices discussed in this paper has been quite variable. Some individual electrodes in the multimicroelectrode assembly are stable for hours of continual use, while others exhibit behavior interpretable as a short between the Pt and Au electrodes after just one scan through the Os(III/II) redox conduction wave. The Os(III/II) redox activity, observed cyclic voltammetrically with a film on a Pt electrode, is also stable for many hours. We believe that the sandwich-electrode assembly is inherently stable and that instability where observed is due to nonoptimum construction methods. In particular, other work in this laboratory (11) has shown that use of glass rather than Teflon for the shroud, and very particular polishing procedures, promotes a much lower incidence of shorting effects. It appears that the shorting often occurs on the edge of the Pt microdisks. Additionally, we have identified a number of conditions which promote instability during use of the electrode: (i) reduction of the polymer to Os(I) or Os(0) causes (eventually) irreversible damage to the polymer and often pro-

duces shorting. (ii) If the potential of the Pt electrode is made too positive (e.g., +2V vs. SSCE), then shorting occurs. (iii) If the electrode assembly is allowed to dry and then is reused, shorting occurs.

We describe our most stable electrode assembly as an illustration of stability that has been achieved. This electrode, which initially demonstrated a limiting current of 38 mA/cm², was used as a diode-type device in the manner of Fig. 3 for ca. 1h scanning ΔE between 0.0 and +1V at 20 or 100 mV/s, then as a triode-type device at scan rates from 1-100 mV/s for ca. 1h, stored under acetonitrile unused for 1h, and then as a triode-type device for a further 2.5h at a scan rate of 1 mV/s. There then followed 23h of nonuse, ca. 1h of use as a diode-type device, 20h of nonuse, and finally measurements of redox conduction of the Os(I) and Os(0) states, during which it shorted. During this sequence of experiments, i_{lim} for Os(III/II) redox conduction increased from 38 to 45 mA/cm² during the first 40 min of use, and then gradually decreased to 35 mA/cm² just before the electrode's fatality.

Since in practical use these devices would be subject to voltage pulses, rather than linear voltage changes, we investigated their stability when subject to 0.0 to +1V voltage pulses with pulse widths between 5s and 0.1 ms. No evidence for decreased stability was observed.

Electrocatalytic Rate Enhancement of Propylene Epoxidation on Porous Silver Electrodes Using a Zirconia Oxygen Pump

M. Stoukides and C. G. Vayenas*¹

Department of Chemical Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

Propylene epoxidation and deep oxidation on porous silver electrodes was studied galvanostatically in the solid electrolyte cell C₃H₆, C₃H₆O, CO₂, H₂O, O₂, Ag|ZrO₂(8% Y₂O₃)|Ag, O₂. It was found that when O²⁻ ions are pumped electrochemically to the silver catalyst electrode, the rates of propylene epoxidation and oxidation to CO₂ increase significantly with simultaneous enhancement of the selectivity to propylene oxide. The opposite effect is observed upon reversal of the pumping voltage. The enhancement in the rate of epoxidation and deep oxidation can exceed the rate of O²⁻ pumping by two orders of magnitude. The magnitude of the catalytic rate enhancement depends on the imposed current, anodic gas composition, and catalyst electrode surface area, and is proportional to the pumping voltage. This new phenomenon is similar to that observed with ethylene oxidation and appears to be due to formation of a catalytically active surface silver oxide at the anode.

Stabilized zirconia solid electrolyte cells have been used in recent years as oxygen gauges (1), as fuel cells with H₂, CO, CH₄ (2), and NH₃ (3, 4) as the fuel, as a means of measuring the oxygen activity on working metal catalysts (5, 6), as oxygen pumps to dissociate oxygen containing compounds, such as H₂O (7) and NO (8, 9), and to enhance the rate of certain catalytic reactions such as CO hydrogenation (10).

It was found recently that stabilized zirconia oxygen ion pumps can also be used to influence the product

selectivity of certain catalytic reactions; a porous polycrystalline silver film was used simultaneously as one of the electrodes of a stabilized zirconia oxygen concentration cell and as a catalyst for ethylene oxidation (11, 12). With ethylene and O₂ present at the anode and the cell open-circuited, the silver film acts as a regular catalyst for ethylene epoxidation (i.e., ethylene oxide formation) and deep oxidation (i.e., formation of CO₂). However, it was found that the product selectivity and yield change considerably when external voltages are applied to the cell and O²⁻ ions are pumped to or from the working catalyst. It was found that the selectivity to ethylene oxide (mols ethylene oxide produced/mols ethylene re-

acted) can increase or decrease by more than 20% and that the ethylene oxide yield (mols ethylene oxide produced/mols ethylene fed to the reactor) can increase or decrease by more than a factor of two. These phenomena were attributed to the formation of a catalytically active surface silver oxide (11, 12).

In the present communication, we report on similar phenomena observed with propylene oxidation on porous silver electrodes in stabilized zirconia cells. It is shown that the catalytic activity and selectivity of silver for propylene oxidation can be modified considerably by electrochemical oxygen pumping. The results are consistent with the surface silver oxide model proposed for ethylene oxidation (12).

Experimental

A schematic diagram of the apparatus used in the investigation is shown in Fig. 1. It consists of a gas feed system, a stabilized zirconia reactor cell, and a gas analysis system.

The reactor cell shown in Fig. 2 consists of a 1/2 in. id 8 mol percent (m/o) Y_2O_3 stabilized ZrO_2 tube closed flat on the one end, obtained from Zircoa Corning Glass. The reactor volume was 30 cm³. A porous silver catalyst electrode film was deposited on the flat bottom of the zirconia tube by coating with a thin layer of Ag suspension in butyl acetate, followed by drying and calcining at 400°C. Auger electron spec-

Fig. 2. Schematic diagram of the cell reactor

toscopic analysis showed that the resulting Ag films are fairly clean, with only trace impurities of Na and S (6). A similar Ag film was deposited on the outside bottom wall of the zirconia tube, which was exposed to ambient air.

Several stabilized zirconia reactor cells were used in the course of the present investigation. The electrolyte thickness of each cell was roughly between 150 and 300 μ m. The cells differed in the surface area of the silver catalyst electrode. These areas were determined by measuring the reactive oxygen uptake of the catalyst Q (mols O_2) upon titration with ethylene, as described in detail elsewhere (6). The surface areas of the catalyst electrodes used in the present investigation are given in Table I.

After an induction period which lasted approximately 48h for each new catalyst, the catalyst electrode open-circuit activities and selectivities remained constant ($\pm 2\%$) for several weeks (12). All the data reported here, including surface areas, were obtained after the termination of the induction period.

The reactants were certified standards of propylene diluted in N_2 and Matheson zero-grade air. They could be further diluted in N_2 , in order to maintain the partial pressure of ethylene or oxygen constant during the experiments. Reactants and products were analyzed by on-line gas chromatography. A Porapak Q column was used to separate air, propylene, carbon dioxide, and propylene oxide; a molecular sieve 5A column was used to separate oxygen and nitrogen. The concentration of CO_2 in the reactant effluent stream was also monitored continuously by means of a Beckman 864 Infrared Analyzer.

Constant current or voltage across the cell was applied by means of a AMEL 549 potentiostat-galvanostat. The voltage drop across the cell was monitored with a J. Fluke 891 A differential voltmeter. Current was measured by a J. Fluke 8040 A multimeter. Further experimental details are given in Ref. (11, 12).

Results

Close agreement was observed ($\pm 1\%$) between measured and theoretical EMF values when O_2 , N_2 , or He mixtures of known P_{O_2} were fed through the zirconia cell reactor. This verified the pure ionic conductivity of the solid electrolyte. When propylene-oxygen mixtures are fed through the reactor, the open-circuit EMF E , which reflects the oxygen activity a_{O_2} on the catalyst (5, 6) according to

$$E = (RT/4F) \ln [a_{O_2}/(0.21)] \quad [1]$$

takes values between -10 and -100 mV, indicating that $a_{O_2} < P_{O_2}$, because the intrinsic rate of oxygen adsorption is comparable to the rate of the surface oxidation steps (13).

The effect of oxygen pumping.—The effect of electrochemical oxygen pumping on the rates of propylene epoxidation r_1 and deep oxidation r_2 is shown in Fig. 3. At time $t < 0$ the circuit is open and the silver catalyst electrode acts as a regular catalyst for propylene epoxidation (i.e., conversion to propylene oxide) and deep oxidation (i.e., conversion to CO_2). Since temperature ($395^\circ \pm 1^\circ C$) and gas feed composition ($P_{Pr} \sim 2.8 \cdot 10^{-3}$ bar, $P_{O_2} \sim 0.15$ bar) are maintained constant, the catalyst electrode is at a steady state characterized by $r_{10} = 0.050 \cdot 10^{-7}$ mol/s and $r_{20} = 2.53 \cdot 10^{-7}$ mol/s.

Table I. Catalyst electrode surface areas

RC2	$1.5 \cdot 10^{-7}$
RC3	$7.6 \cdot 10^{-7}$
RC4	$1 \cdot 10^{-7}$
RC5	$10 \cdot 10^{-7}$

Fig. 3. Transient effect of oxygen pumping during propylene oxidation.

At time $t = 0$, a constant current of $+200 \mu\text{A}$ is applied to the cell. Oxygen ions are pumped to the catalyst. This causes a transient increase in both reaction rates. Figure 3 shows that the relative increase in r_1 is higher than the corresponding relative increase in r_2 ; and thus, the selectivity to propylene oxide increases. The system reaches a new steady state after approximately 30 min. At $t = 50$ min, the circuit is opened and the catalyst returns to its initial steady state, indicating the reversibility of the phenomenon. At $t = 100$ min, a constant current of $-100 \mu\text{A}$ is applied across the cell, so that O^{2-} are pumped from the catalyst. As a result, both rates decrease and so does the selectivity to propylene oxide. Figure 3 shows that when the circuit is opened again, both rates return to their original steady-state values r_{10} and r_{20} .

The rate of oxygen transport through the electrolyte $G_{\text{O}^{2-}}$ can be calculated from the value of the imposed current i ($G_{\text{O}^{2-}} = i/2F$ gramatom oxygen/s). The increase in the rate of oxygen consumption due to the

increase in the rate of epoxidation and deep oxidation during reaction was found to exceed $G_{\text{O}^{2-}}$ by a factor as high as 150. This shows that the catalytic properties of the silver catalyst electrode are changing substantially during oxygen pumping.

Effect of current and pumping voltage.—Figures 4 and 5 show the effect of imposed current on the final steady-state increase in the rates of propylene epoxidation and deep oxidation for two reactor cells which differed in catalyst area. In both cases, temperature and gas phase composition were kept constant throughout the experiments. It can be seen that both rates increase with increasing current up to 250–300 μA , above which they remain practically constant. The effect is qualitatively the same for both rates; however, the relative increase in the rate of epoxidation r_1 is much larger than that in r_2 ; thus, selectivity to propylene oxide increases. It can also be seen from Fig. 4 and 5 that the relative increases in r_1 and r_2 are higher for

Fig. 4. Steady-state effect of current on the rate of propylene epoxidation.

Fig. 5. Steady-state effect of current on the rate of propylene oxidation to CO_2 .

reactor cell RC2 than for RC1. This is due to the higher catalyst electrode surface area of RC1 as shown in Table I and discussed below.

Figure 6 shows a typical cell voltage response to a galvanostatic step increase in current. At $t < 0$, the circuit is open and the cell voltage equals the open-circuit EMF E given by the Nernst equation [1]. At $t = 0$, a constant current of $200 \mu\text{A}$ is imposed across the reactor cell. The initial sharp rise in V at $t = 0$ corresponds to the ohmic drop iR_c , where R_c is the ohmic resistance of the solid electrolyte and the electrodes. The subsequent gradual increase ΔV to a final asymptotic value corresponds to formation of surface

Fig. 6. Galvanostatic transient voltage response

intermediates on the catalyst electrode. A similar voltage behavior was observed during the electrocatalytic oxidation of ethylene (12). One can define the pumping voltage ΔV from

$$\Delta V = V - E - iR_c \quad [2]$$

As shown in Fig. 7, the pumping voltage response during a galvanostatic transient parallels the reaction rate response. Within the accuracy of the measurements, both transients are characterized by the same

Fig. 7. Galvanostatic transient response of deep oxidation rate and cell overvoltage.

Fig. 8. Effect of pumping voltage, gaseous composition, and catalyst electrode surface area on the rates of propylene epoxidation ($i = 1$, \circ) and deep oxidation ($i = 2$, \bullet).

relaxation time constant τ_0 , defined as the time required for ΔV or Δr_1 and Δr_2 to reach 63% of their final asymptotic values ΔV_{\max} , $\Delta r_{1, \max}$, and $\Delta r_{2, \max}$, respectively. Furthermore, as shown in Fig. 8 and Table II for a given reactor cell and for given temperature and gaseous composition, the steady-state increase in reaction rates $(\Delta r_i)_{\max}$ is roughly proportional to the steady-state pumping voltage $(\Delta V)_{\max}$, i.e.

$$(\Delta r_i)_{\max} = \beta_i (\Delta V)_{\max} \quad [3]$$

The proportionality constants β_i strongly depend on gaseous composition and catalyst electrode surface area, as discussed below.

Effect of surface area and gaseous composition.—Table II contains steady-state data obtained from five different reactors RC1, RC2, RC3, RC4, and RC5. Comparing runs 7 and 9, which were obtained with almost identical pumping voltage, temperature, and gaseous composition, it can be seen that the relative increase in the reaction rates $(\Delta r_i/r_{i0})$ is inversely proportional to the catalyst electrode surface area. Similar conclusions can be reached by comparing runs 2 and 8, which were obtained with almost the same gaseous composition, temperature, and current and comparable pumping voltage. The same behavior has been observed during ethylene oxidation on silver (11, 12).

Similar to ethylene oxidation, the relative increase in the rates of epoxidation and deep oxidation at constant catalyst electrode surface area, temperature, and imposed current is roughly proportional to P_{O_2}/P_{Pr} . This can be seen from runs 7 and 8 of Table II.

Figure 8 contains all the steady-state data of Table II, obtained with five different reactors, and shows that, similarly to ethylene electro-oxidation (12), all the data can be adequately described by one single expression

$$\frac{\Delta r_i}{r_{i0}} \cdot Q \cdot \frac{P_{Pr}}{P_{O_2}} = \alpha_i \Delta V \quad [4]$$

where α_1 , α_2 ($i = 1, 2$) are constants with a ratio $\alpha_1/\alpha_2 = 2.5 \pm 0.5$. Equation [4] contains as a limiting case Eq. [3], which is valid for constant gaseous composition.

In view of the fact that over the range of experimental conditions of the present investigation, r_{i0} are first order in propylene and zero order in oxygen (13), it follows from Eq. [4] that

$$\Delta r_i = K_{i0} \cdot \alpha_i \cdot \Delta V \cdot P_{O_2} \quad [5]$$

where K_{i0} are the intrinsic rate constants for propylene epoxidation ($i = 1$) and deep oxidation ($i = 2$), respectively.

Discussion

The observed phenomena show clearly that the properties of the silver catalyst electrode change significantly during electrochemical oxygen pumping. The increase in the rates of propylene epoxidation and deep oxidation can exceed the rate of oxygen transport through the electrolyte by two orders of magnitude. The selectivity also changes considerably. It can be easily shown that the electrolyte temperature

cannot rise locally more than 2 K at most, due to i^2R_c heat generated during oxygen pumping. This was also shown by measuring the temperature of the electrolyte at a distance of 1 mm from the two electrodes and observing no measurable temperature rise during pumping. The absence of local catalyst heating due to oxygen pumping is also demonstrated by the fact that upon reversing the direction of pumping, both r_1 and r_2 decrease (Fig. 3).

Internal and external gas phase diffusional limitations at the porous silver catalyst electrode have been shown to be totally negligible under the conditions of these experiments (6, 13). Therefore, it can be safely concluded that it is the intrinsic properties of the silver catalyst which change during electrochemical oxygen pumping.

When oxygen is pumped to the catalyst, the oxygen activity of the catalyst electrode increases dramatically. Thus, it becomes possible to at least partly oxidize the silver catalyst electrode. In previous communications related to ethylene electro-oxidation, it has been shown that the phenomenon involves surface rather than bulk oxidation of the silver crystallites (11, 12). The experimentally observed relaxation time constants of the present investigation show conclusively that this is also the case during propylene oxidation: the polycrystalline Ag films used could typically adsorb $6 \cdot 10^{-7}$ mol O_2 (Table I). Typical currents employed in the present study during the galvanostatic transients were of order 100 μA , corresponding to $2.6 \cdot 10^{-10}$ mol O_2/s transported through the electrolyte. Thus, the time required to fully cover the silver surface with surface oxide is of order 36 min in good agreement with the experimental relaxation times (Fig. 3, 6, 7). Bulk oxidation of the silver catalyst would require approximately $2 \cdot 10^{-4}$ mol O_2 . With $i = 100 \mu A$, this would correspond to relaxation time constants of about 50h. It therefore follows that the observed phenomenon is related to surface oxidation of the silver crystallites.

The observation that the transient rate changes parallel the transient overvoltage behavior (Fig. 7) strongly suggests that the increase or decrease in the rates is caused by a corresponding increase or decrease in the surface concentration of an adsorbed oxygen species or surface silver oxide. This is further corroborated by the striking similarity in the effect of oxygen pumping during ethylene (11, 12) and propylene oxidation on silver catalyst electrodes.

There is previous evidence in the literature for the existence of surface silver oxides, including the work of Seo and Sato (14) who observed a continuous exoelectron emission from silver catalysts during ethylene epoxidation, which was proportional to the rate of epoxidation. They explained their results in terms of formation of surface silver oxide Ag_2O with molecular oxygen ion O_2^- adsorbed on it. This proposed picture seems to be in excellent agreement with the present results, i.e., with

$$\Delta r_1 = K_{i0} \cdot \alpha_1 \cdot (\Delta V) P_{O_2} \quad [5]$$

if the change in the amount of surface silver oxide is proportional to ΔV and the coverage of molecular oxygen adsorbed on the oxide is proportional to P_{O_2} , or at least if the rates of epoxidation and combustion on the silver oxide are first order in oxygen.

Quantitative kinetics.—In previous communications (11, 12), we have denoted the surface oxygen species formed during oxygen pumping by AgO_2^* and its surface concentration by c (mol/cm²). The relationship between Δc and the pumping voltage ΔV can be established by the following analysis. Neglecting the double layer capacitance of the electrode-electrolyte interface, one can split the constant current i imposed during a galvanostatic transient in two parts (15)

$$i = C_{ad} \frac{d(\Delta V)}{dt} + i_{CTR} \quad [6]$$

where i_{CTR} is the current corresponding to the charge transfer reactions, i.e.

and C_{ad} is the adsorption pseudocapacitance of the oxide, which by definition equals (15)

$$C_{ad} = \frac{dq}{dV} = \lambda_0 AF \frac{d(Sc)}{d(\Delta V)} \quad [7]$$

where S is the surface area of the catalyst electrode, q is the charge stored in the oxide, A is the electrolyte surface area, and λ_0 a constant. λ_0 depends on the gas-electrode-electrolyte interline "area" per unit electrolyte area and depends solely on the catalyst porosity. Since all the electrodes used in the present investigation were prepared by the same calcination procedure, it is reasonable to assume they all had similar porosities and thus, similar values of λ_0 .

The experimental observations can be explained quantitatively by making the following assumptions. (i) The oxide pseudocapacitance C_{ad} is constant, in which case, Eq. [7] becomes

$$\Delta(Sc) = \frac{C_{ad}}{\lambda_0 AF} \Delta V \quad [8]$$

(ii) The changes Δr_i in the rates of propylene epoxidation r_1 and deep oxidation r_2 are proportional to the change in the mols of AgO_2^* . Both rates are first order in oxygen.

$$\Delta r_1 = K_1 \cdot P_{O_2} \cdot \Delta(Sc) \quad [9]$$

From Eq. [8] and [9], one obtains

$$\Delta r_1 = K_1 \frac{C_{ad}}{\lambda_0 AF} (\Delta V) P_{O_2} \quad [10]$$

which coincides with the experimental Eq. [5] and with

$$\alpha_1 = \frac{K_1}{K_{i0}} \cdot \frac{C_{ad}}{\lambda_0 AF} \quad [11]$$

It should be noted that according to Eq. [10], Δr_1 and Δr_2 do not depend on the electrode surface area. Finally, to explain the dependence of $\Delta r_1/r_{i0}$ on ΔV and gas phase composition, one can assume that the oxide forms on Ag sites which are inactive for reaction and take into account that at temperatures above 350°C and under open-circuit conditions both r_{i0} and r_{20} are first order in propylene and zero order in oxygen (13)

$$r_{i0} = K_{i0} \cdot Q \cdot P_{Pr} \quad [12]$$

This last equation is not inconsistent with the hypothesis that the rates on AgO_2^* are first order in oxygen, to the extent that the surface concentration of AgO_2^* is small under open-circuit conditions.

Combining Eq. [10]-[12], one obtains the experimental Eq. [4]. Equation [4] shows that for given gaseous composition and pumping voltage, the relative increase in the rates of epoxidation and deep oxidation are inversely proportional to the surface area Q of the catalyst electrode. This is because the intrinsic rates r_{i0} are proportional to Q , while the rate enhancement Δr_1 caused by oxide formation does not depend on Q .

In summary, the effect of oxygen pumping during propylene oxidation on silver is qualitatively identical with the effect during ethylene oxidation (11, 12). This corroborates the proposition that the rate enhancement is caused in both cases by surface oxidation of

the silver catalyst electrode. The use of *in situ* surface science techniques should prove very useful for the elucidation of the exact nature of this surface oxide. Although the exact form of the surface silver oxide is not yet known, the proposed macroscopic model can adequately explain all the experimental observations.

We note that, although zirconia oxygen pumps have been known to dramatically enhance the rate of certain reactions, such as NO decomposition (8) and CO hydrogenation (10), ethylene and propylene oxidation on silver are the first known reactions where oxygen pumping has been shown to cause a change in product selectivity.

Technical Notes

Calorimetric Determination of the Heat Generation Rate of Sodium-Sulfur Cells during Discharge and Charge

Reinhard Knoedler*

Brown, Boveri & Cie AG, Central Research Laboratory, Heidelberg, Germany

High temperature sodium-sulfur batteries (beta-batteries) are being developed for electric vehicle propulsion and load leveling applications. As with all battery systems, heat is dissipated during operation due to irreversible polarization losses. It is important to know the rate of this heat generation as precisely as possible, because these data are vital for the design of the cooling equipment. Measurements of this kind were performed already for the high temperature LiAl/FeS system (1, 2). It turned out that, because of the chemistry of this system, there is an almost constant rate of heat dissipation during discharge. In contrast, Na/S-cells are expected to show a more complex behavior because during discharge sodium polysulfides of different composition (Na_2S_x with $x = 3-5$) are generated electrochemically which contribute to the heat generation rate by their entropy change.

In principle, heat rates can be determined either by the adiabatic or the isothermal method. In adiabatic measurements, a cell is operated in a furnace with good heat insulation (vacuum-foil) and low heat capacity. From the temperature gradient and the heat capacity, the heat generation rate can be calculated (3). This method is applicable only for currents of greater than 10-15A, dependent on the cell resistance. Another characteristic of this method is that the cells can be operated only discontinuously. This is because the measuring time is only a few minutes and the states of discharge have therefore to be changed in a

stepwise manner. This is in contrast to the isothermal arrangement (calorimeter), as will be described in the following, where measurements can be carried out only at currents smaller than about 15A and continuous operation is required. Thus, isothermal measurements will complete the data on the thermal properties of Na/S-cells.

Isothermal measurements are generally performed by directly determining the heat flux from the cell at constant temperature (1). The advantage over adiabatic measurements is the considerably higher accuracy. This is due partly to the fact that the value of the heat capacity of the cell, which is not well known, is not needed to obtain the data. In addition, it is experimentally easier to establish good isothermal conditions than good adiabatic conditions (because even a vacuum-multifoil insulation has its losses). As mentioned above, isothermal measurements are useful, especially when relatively long discharge/charge times are to be used and continuous operation is required.

Experimental Arrangement

In contrast to prismatic LiAl/FeS cells (2), where good thermal contact can be obtained rather simply by pressing the cell between flat plates, that process is more difficult with cylindrical Na/S cells. Therefore, each Na/S cell has to be fitted individually into a cylindrical shaped calorimeter in order to provide a good thermal contact. Figure 1 shows the principal features of the calorimeter, which was designed and built for the measurements described below.

* Electrochemical Society Active Member.

Fig. 1. Schematic for the calorimeter for the determination of heat-generation rates of cylindrical Na/S cells.

The cell is contained inside a furnace consisting of two concentric heaters, H1 and H2. Both are made of two aluminum half-cylinders each. After fixing the heating wire on the outside of one half-cylinder, the other is heat-shrunk unto it, thus giving minimal heat-transfer resistance. Between H1 and H2, a 2.5 mm air gap is provided, which allows the maintenance of a constant temperature gradient. At the top and the bottom of the cell, thermal insulation and additional heaters are placed. This ensures that almost all the heat generated during discharge leaves through the cell wall and thus can be determined. All lead wires

which are coming from the cell (current, voltage, 3 Pt-100 resistance thermometers) are contacted thermally to H2 in order to prevent heat losses. Measurements of vertical temperature distribution showed that ΔT is well below 1°C . This indicates that indeed the heat loss through the wire leads is negligible.

The cells which were tested were taken from a standard series (4). They were about 23 cm long and 3.6 cm in diam. Their capacity was about 44 Ah, and their dc resistance at the beginning of discharge about 15 m Ω . During discharge this value increased a few milliohms. All measurements were carried out at 340°C .

Principle of Operation

With the arrangement described above, the heat flux from the cell during discharge or charge can be measured directly. This is done by maintaining a constant temperature gradient ΔT between H1 and H2, thus fixing the heat flux between H1 and H2 to a constant value, independent of the heat-generation rate \dot{Q}_z of the cell. Therefore, if \dot{Q}_1 is the power output of the heater H1

$$\dot{Q}_1 + \dot{Q}_z = \text{const} = \dot{Q}_{10} \quad [1]$$

\dot{Q}_{10} denotes the power output of H1 when the cell is not being operated. The heat-generation rate of the cell can then be obtained by recording the difference between the power output of H1 with and without cell operation

$$\dot{Q}_z = \dot{Q}_{10} - \dot{Q}_1 \quad [2]$$

At discharge currents of $\approx 15\text{A}$, maximum values of \dot{Q}_z of about 15 W have to be expected. Therefore, \dot{Q}_{10} must be a little higher than this value in order to be able to satisfy Eq. [2]. However, the value should not be too high, because this would decrease the accuracy. For the same reason, the temperature difference ΔT should be as low as possible, say about 10°C . As a consequence, the air gap (2.5 mm) between H1 and H2 was designed to yield a value of the coefficient of the heat transfer of about $1.5\text{ W}/^\circ\text{C}$. Experimentally, a value of $1.1\text{ W}/^\circ\text{C}$, which is near the designed one, was obtained.

Measurements were usually carried out at $\Delta T = 8^\circ\text{C}$ – 15°C , depending on the discharge/charge current. After temperature equilibrium was established, the cell was discharged or charged continuously. Due to the heat generated by the cell, the controller of heater

Fig. 2. Measurement of the heat-generation rate of a dummy cell. Power output of dummy increased stepwise.

Fig. 3. Heat generation rate of a Na/S cell during discharge with different currents.

H1 adjusts the heating power to a lower value in order to keep ΔT constant. The difference in heating power is, according to Eq. [2], directly the heat-generation rate of the cell. The controller of heater H1 allows the temperature difference to rise several tenths of a degree during the discharge cycle. This small error was corrected by adding 1.1W per $^{\circ}\text{C}$ to the measured \dot{Q}_z value. The accuracy of the measurements was estimated to be $\pm 0.1\text{W}$.

Before testing Na/S cells, a dummy cell with a similar heat capacity and of a similar size was operated in the calorimeter in order to test the general performance. Figure 2 shows the behavior of this dummy cell when its heating power is increased in several steps up to 15.3W. It can be seen that the measured values are in good agreement with those preset at the dummy. The time needed for establishing equilibrium turned out to be about 10 min. This is why it is not possible to discharge the cell in less than about 3-4h, which

means currents of 11-15A. If higher currents are applied, the calorimeter is too slow to follow rapid changes in the heat-generation rate, which indeed are being observed in Na/S cells (see, e.g., Fig. 3).

Results

In Fig. 3, the heat-generation rate of a cell during discharge is shown for different operating currents. The OCV, which is also included in the figure, indicates the transition between the two-phase and the one-phase region as it could be derived from the cell voltage at low discharge currents. The OCV reaches a value of 1.78V at about 40 Ah state of discharge. This voltage corresponds to a composition of Na_2S_3 . According to the phase diagram (5), discharging beyond this value at 340°C is possible until a composition of about $\text{Na}_2\text{S}_{2.7}$ is reached. In the present case, this means a state of discharge of about 45 Ah (i.e., 90% utilization). Beyond this value, the cell is "overdis-

Fig. 4. Heat generation rate of a Na/S cell during charge with different currents.

Fig. 5. Heat generation rate divided by operating current vs. operating current for different states of discharge (0.0 Ah = fully charged, 44 Ah = fully discharged).

charged," which is accompanied by formation of solid Na_2S_2 . Figure 3 shows that in the two-phase region there is a continuous increase in the heat-generation rate. In the middle part of the one-phase region, there is a plateaulike shallow minimum. Near the end of discharge, a sharp rise takes place, and (most pronounced for the smaller currents) a discontinuity is observed at a state of discharge where formation of solid Na_2S_2 can be expected. It should be pointed out that the transition from the two-phase to the one-phase region which can be seen in the OCV does not coincide with the corresponding transition in the heat-generation rate.

Figure 4 shows the heat-generation rate during charging with two different currents. Due to entropy effects, the cell takes up heat from the environment when in the far discharged state. Corresponding to the discharging behavior, a shallow minimum is observed in the one-phase region. Near the fully charged state, the heat-generation rate increases strongly because of the increase in cell resistance. As expected, the values

are considerably smaller than during discharge with the same currents.

Discussion

The heat generation rate \dot{Q} in electrochemical cells can be expressed as (3)

$$\dot{Q} = I \left(\eta \mp T \frac{dE}{dT} \right) \quad [3]$$

where I is the current, η the polarization, and $T \frac{dE}{dT}$ the entropy term. T is the absolute temperature and dE/dT the temperature dependence of the open-circuit voltage. The minus sign is to be applied for discharge, the plus sign for charge. If only resistance polarization is taken into account, then $\eta = IR_z$ where R_z is the dc resistance of the cell. Equation [3] can then be transformed to

$$\frac{\dot{Q}}{I} = IR_z \mp T \frac{dE}{dT} \quad [4]$$

Figure 5 shows a plot of \dot{Q}/I vs. I for different states

Fig. 6. Resistance of a Na/S cell as a function of the state of discharge.

Fig. 7. Entropy term as a function of the state of discharge for different modes of operation.

of discharge and shows that Eq. [4] is indeed valid. From the Y-axis intercept at $I = 0$, the entropy term can be obtained, and from the slope of the straight lines the cell resistance. In Fig. 6 the cell resistance obtained in this manner is plotted together with the dc resistance (at currents beyond 11A) from direct electric measurements. It can be seen that a maximum occurs at the transition between the two-phase and the one-phase region and that at the end of discharge the resistance rises. The two curves are in good agreement within measuring accuracy. A plot of the entropy term, as extracted from Fig. 5, using Eq. [4] is shown in Fig. 7. There is a maximum at the end of discharge, followed by a minimum and a steep increase. The entropy term as obtained from the charge experiments can be seen to be clearly different from that. This suggests that, especially in the one-phase region, equilibrium was not reached.

In contrast to this, the entropy measured during a stepwise (several-hours wait) operation manner (3) showed no difference between charging and discharging. In this case, the maximum occurred in an earlier state of discharge, namely, in the transition region between the one-phase and the two-phase region, and its magnitude is higher than in the continuous mode. All these facts show a considerable dependence on the mode of operation, and this has to be taken into account when thermal management is being considered.

With the data obtained from the measurements described above, it is possible to obtain the overall thermal energy Q_e which is dissipated during a complete cell discharge or charge. Figure 8 shows the result of an integration of the heat-generation rate as it is shown in Fig. 3 and 4 up to 44 Ah. Q_e can also be calculated

Fig. 8. Overall thermal energy dissipated during a full charge or discharge as function of the current.

culated by

$$Q_e = \int_0^t \dot{Q} dt = C \left(I \int_0^1 R_z dD \mp T \int_0^1 \frac{dE}{dT} dD \right) \quad [5]$$

where D is the state of discharge, going from 0 to 1, and C the capacity of the cell (44 Ah). Therefore, from the slope of the straight lines in Fig. 8, the average resistance can be obtained and from the Y-axis intercept the average entropy term. According to this, even at currents approaching zero, a finite value of the thermal energy of about 4 Wh will be dissipated independent of the cell resistance. In Fig. 8, the data for two cell types with different resistances are plotted. Extrapolation of both lines yield the same Y-axis intercept. In the charging mode there is heat dissipation only with currents greater than 5A; below this value heat is taken up from the environment.

Conclusion

Data have been presented which are necessary for thermal management purposes, especially the design of cooling equipment. It has been shown that the heat-generation rate during discharge depends on the mode of operation. When discharged stepwise, a shallow maximum in the heat-generation rate occurs at the

transition from the one-phase to the two-phase region. In the case of a continuous discharge, this maximum is being shifted to the one-phase region. This behavior shows that the equilibration in Na/S cells takes considerable time, especially in the one-phase region. This must be taken into account in thermal management considerations.

Effect of Surface Modification on Subbandgap Response of n-InP Photoelectrodes

D. N. Bose, Y. Ramprakash, and S. Basu

Materials Science Centre, Indian Institute of Technology, Kharagpur, India

Subbandgap response has been shown by Butler to be a sensitive indicator of the nature of the surfaces of GaP and SrTiO₃ photoelectrodes (1, 2). In particular, mechanical damage and cathodic aging were found to enhance the subbandgap response. In this paper, we demonstrate that surface modification of InP by Ru ions diminishes subbandgap response due to removal of surface states from the bandgap, as postulated by Parkinson, Heller, and Miller (3) for the case of n-GaAs. Heat-treatment of InP and anodic dissolution both lead to enhanced subbandgap response. These results are correlated with the increase in flat-band potential due to Ru modification as demonstrated from C-V characteristics, and also with significant changes in the nature of the transient response.

Experimental

n-InP samples were single crystals obtained from Metals Research, England, Sn-doped with $n = 4.7 \times 10^{18} \text{ cm}^{-3}$ and of (111) orientation. Ohmic contacts were made by alloying In-Sn dots at 400°C for 1 min in a hydrogen atmosphere. Surfaces were subsequently etched in concentrated HCl for 15s, whereby a black matte surface was obtained. Specimens were then immersed in the appropriate redox system, i.e., 0.04M Te²⁻/Te₂²⁻ or [Fe(CN)₆]^{4-/3-} for 30 min. After washing, they were immersed in a solution of 0.01M RuCl₃ and 0.1M HNO₃ for 1h to accomplish surface modification. This was followed by gentle washing in triple-distilled water.

The electrochemical cell was a two-electrode system with Pt as a counterelectrode and was illuminated by a 1.5 kW tungsten-halogen lamp adjusted to produce AM1 illumination at the photoelectrode. High purity

argon was bubbled through the redox solutions initially and during experiments in the Te²⁻/Te₂²⁻ redox. Detailed spectral response of the photoelectrodes with and without Ru modification was first studied between 0.4 and 1.2 μm using a Jarrell-Ash monochromator. The steady-state currents were measured using a Keithley 160B multimeter. Subsequently, the subbandgap response was studied using single-crystal InP ($n = 4.7 \times 10^{18} \text{ cm}^{-3}$, 0.055 cm thick) or Si ($n = 9.24 \times 10^{13} \text{ cm}^{-3}$, 0.029 cm thick) as filters with a tungsten-halogen source. The light beam was chopped by a PAR 125A light chopper at 84 Hz and the current output measured across a 10 kΩ load resistance which was fed to a PAR Model 5101 lock-in amplifier. The detection sensitivity was ±0.1 μV. The InP and Si filters acted as optical windows with high energy cutoff at 1.29 and 1.08 eV, respectively, as estimated from their absorption spectra.

Results and Discussion

Figure 1 shows the photocurrent response obtained using a monochromatic beam on n-InP specimens under identical conditions with and without Ru modification in Te²⁻/Te₂²⁻ redox electrolyte. It is evident that the subbandgap response is diminished in both magnitude and spectral extent by the modification. Similar results were also obtained on n-InP crystals grown by gradient-freeze technique in our laboratory.

Subsequent experiments were carried out alternately with white light followed by the use of an InP or Si filter. The ratio of the response provided a method for rapid evaluation of surface properties. Table I indicates that the subbandgap response decreased on Ru modification and that the ratio remained unchanged when this

Fig. 1. Spectral response of n-InP in $\text{Te}_2^-/\text{Te}_2^{2-}$ redox, (a) without, and (b) with Ru modification.

electrode was kept in the dark for 24h and thereafter illuminated for 5h. The decrease in response with full AM1 illumination was due to change in color of the redox couple and not to photodissolution. The effect of 0.1M HNO_3 nitric acid without RuCl_3 was negligible, as was confirmed by control experiments.

It was found that Ru modification also increased V_{FB} (from 0.125 to 0.23V), as determined from the C-V characteristics. Similar results were obtained with n-type gradient-freeze-grown InP ($n = 3.2 \times 10^{17} \text{ cm}^{-3}$), in which V_{FB} increased from 0.24 to 0.44V on Ru modification (4).

Experiments with $[\text{Fe}(\text{CN})_6]^{4-/\text{3-}}$ redox showed that the subbandgap response was larger by almost two orders of magnitude, indicating the creation of surface states within the bandgap. The AM1 response was also higher due to more efficient hole transfer. Ru treatment again diminished the subbandgap response. Due to anodic dissolution with this redox after 5h of illumination, the ratio of subbandgap to white-light response increased by a factor of three.

The drastic effect of heat-treatment on InP given in Table II shows that heating for a short time at 500°C in argon atmosphere has a harmful effect on the surface properties due to outdiffusion of phosphorous. Such heat-treatments are commonly encountered in ohmic-contact formation. Our method gives a quick quanti-

tative estimate of surface deterioration by examining the subbandgap response in $\text{Te}_2^-/\text{Te}_2^{2-}$.

Finally, transient response experiments were carried out (Fig. 2) on unmodified and modified surfaces in $\text{Te}_2^-/\text{Te}_2^{2-}$ redox. These responses were significantly different, the decrease in response after the initial increase on illumination demonstrating the presence of localized states within the bandgap in unmodified surfaces. These centers can be considered to be electron traps, as explained by Dahlberg and Orr (5).

Conclusions

Subbandgap response involves the excitation of carriers from states within the bandgap either in the bulk or at the surface to either band. The variation of photovoltaic response with surface treatment shows the latter is the case. Direct excitation from surface states to either band is known to have a low probability, and hence a two-step process involving excitation in the bulk, followed by charge transfer to surface states within the bandgap, and finally hole transfer to the redox level is envisaged. The subbandgap response demonstrates the decrease in surface-state density due to Ru ion treatment and increases due to dissolution in $[\text{Fe}(\text{CN})_6]^{4-/\text{3-}}$ redox or heat-treatment. The broad similarity of the behavior with InP and Si filters indicates that the surface states extend 0.2-0.3 eV within the bandedges but with decreasing density away from the edges.

The increase in V_{FB} with Ru modification is an indication that Fermi-level pinning due to surface states is removed, while the change in transient response shows

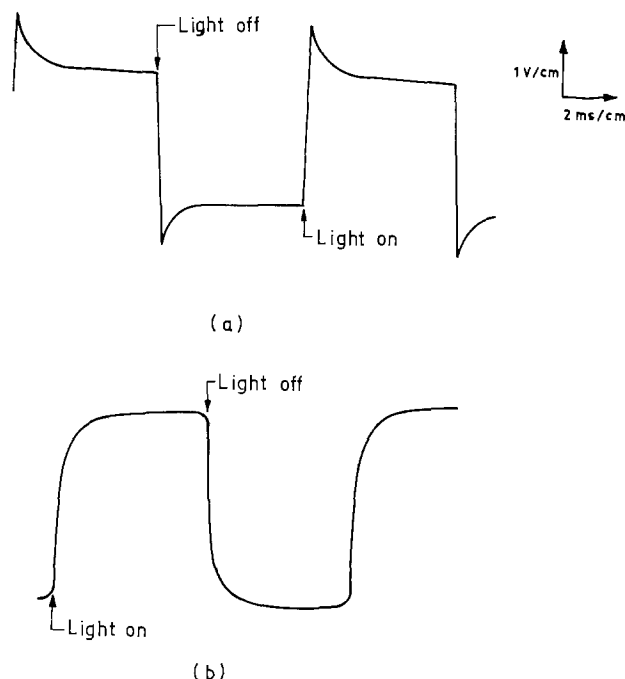

Fig. 2. Transient photovoltaic response (a) without, and (b) with Ru modification.

that Ru modification renders these states inactive in carrier trapping at the surface.

The Microstructures and Growth Rates of FeS on Pure and Not-So-Pure Iron

R. A. McKee and R. E. Druschel

Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830

ABSTRACT

The sulfidation rates of iron to $Fe_{1-x}S$ have been measured for three batches of nominally pure iron, and rather significant differences in microstructures and growth rates have been observed. The measurements were made at 700°C over the sulfur pressure range of 1-10³ Pa as part of a study of the general aspects of the microstructures and growth rates of this highly nonstoichiometric sulfide of iron. Apparently due to rather small differences in silicon content, 0-40 ppm, the scale microstructure, scale adhesion, and growth rate vary significantly. Silicon that is dissolved as small Fe_3SiO_4 particles in the iron accumulates at the scale/metal interface during the sulfidation reaction causing a layered growth. The overall reaction rate is reduced at the lowest pressures, but remains unchanged at higher pressures.

In many of the sulfidation studies of iron (1-4), comments about the microstructural development of FeS have included descriptions of a layered growth scale. This layered scale consists of an inner layer of equiaxed grains overgrown by an outer layer of columnar grains. However, in recent work (5) of our own we found that it is possible to form a single layer, columnar growing, sulfide scale on iron. We show, in what follows, that these different characteristics of the scale microstructure are due to specimen purity, and that relatively minor levels of silicon in the iron apparently cause the layer growth that has been the commonly reported microstructure for FeS on iron. Moreover, we can report that, while significant changes do occur in the growth rates, there is no apparent influence on the a- to c-direction growth change with pressure. Of the three batches of nominally pure iron studied, all exhibit the a to c transformation at the same pressure.

Experimental

All measurements were made at 700°C and in pure sulfur vapor. The experimental technique has been documented carefully in a previous publication (5), and no detailed discussion of it will be presented here. However, since we wish to discuss both qualitative and quantitative differences in iron sulfidation rates and microstructures, we ran our experiments in the exact manner that was previously reported (5) except that we used all three batches of material as specimens simultaneously mounted in the apparatus. In this study, as before, we used a multispecimen technique to determine reaction rate constants, *i.e.*, each point on a reaction rate curve was obtained from a separate specimen run for a specific time. This has resulted in an unequaled reproducibility in reaction rate data.

The materials we used were purchased as "Marz grade" iron from Materials Research Corporation (MRC). Three different batches were purchased, and our analyses are reported in Table I. As is clear from a study of Table I, batch A iron is the purest and batch C is the least pure; in fact, batch C could even be called a dilute alloy. Although batch C is much less pure than batch A or B, there is no measurable difference be-

tween the growth rate and microstructure of FeS formed on batches B and C, but a real distinction does exist between batch A and batch B or C.

Results and Discussion

We have investigated the rate of reaction for several batches of "pure" iron, and Fig. 1 and Table II give comparisons between rate data we have obtained as well as data by others. As cited previously (5), the pressure range covered in our data spans the a- to c-direction change that occurs for scale growth in this material. The change in rate that occurs at approximately $p_{s_2} = 10$ Pa is due to an apparently faster rate of diffusion in the c-direction than in the a-direction of FeS. At sulfur pressures below 10 Pa, the

Fig. 1. Reaction rate data for FeS forming on iron at 700°C

major growth direction of the scale is along the a-direction normal to the iron surface, and above 10 Pa a reorientational effect occurs giving only c-direction growth. This happens for all of the materials we used and, therefore, seems to be only dependent on pressure. Similarly, the data obtained illustrate parabolic growth kinetics; Fig. 2 shows data plotted as (thickness of FeS)² vs. time, and for the range of scale thicknesses studied (as great as 240 μm), no departure from parabolic kinetics is observed.

The basic finding that we wish to present and discuss is that sulfide scales formed on nominally pure iron vary significantly in microstructures and growth rates as a result of apparently minor variations in silicon content in the iron. Figures 3 and 4 show examples of the microstructures of FeS formed on iron at 700°C and 1 Pa sulfur pressure (the reaction was

SULFIDATION OF IRON "ALLOY" IN SULFUR VAPOR - 700°C

Fig. 2. Scale growth kinetics for FeS forming on batch B or C iron at 700°C. Parabolic kinetics is illustrated; the maximum scale thickness is 240 μm . Each point represents a separate experiment on a different specimen.

Fig. 3. FeS scale on batch A iron, growth at 700°C, $p_{S_2} = 1$ Pa, reaction time 10 min. The upper portion of the figure shows the scale in cross section in polarized light and bright field illumination, and the lower portion shows an SEM image of the scale at a 45° angle to the surface with a portion of the scale popped off, revealing the metal underlayer.

carried out in pure sulfur vapor). Figure 3 is the result for batch A material, and Fig. 4 is for batches B and C (analyses of these materials are given in Table I).

The lowest silicon content material, batch A, exhibits sulfidation characteristics that have been fully described recently (5), but for comparison here, we see columnar growth with compact single-layer crack-free grains as opposed to the layered structure for the scale formed on batch B, the higher silicon content material. The micrographs in Fig. 3 and 4 are polarized light, bright field, and SEM (scanning electron microscopy) images showing the metal and sulfide phases. The SEM pictures were taken by first popping off a scale segment, then mounting and polishing the specimens for the bright field and polarized light microscopy.

The features to note in Fig. 3 and 4 are the grain sizes of the columnar segments of the scales, the scale/metal interfaces, and the multilayered scale in Fig. 4. In both figures, the outer columnar grains have ap-

Fig. 4. FeS scale on batch B iron, growth at 700°C, $p_{S_2} = 1$ Pa, reaction time 10 min. proximately the same diameter, and the orientational relation for their growth is identical. That is, the grains are highly oriented and grow with their major axis being the a-direction for the hexagonal, pyrrhotite, FeS phase (5). This a-direction is normal to the metal surface, and the individual grains are rotated randomly about this axis. It is at the scale/metal interface that the real distinction in these materials is made. The scale/metal interface is represented as a clean separation of the two phases in Fig. 3 for batch A material; the scale completely detaches on cooling. However, the scale does not separate completely from the metal phase for batch B material, shown in Fig. 4. The innermost layer of the sulfide remains attached, and gross scale separation that does occur on cooling is at a boundary between the layered equiaxed grains of the sulfide itself. Finally, the multilayer aspect of scale growth for batch B or C material is illustrated further in Fig. 5. Figure 5 is a higher magnification of the scale segment that has cracked off, inverted, and is visible in Fig. 4. This scale segment shows that pores have formed between the layers, but it also illustrates that the layers were in intimate contact at temperature, *i.e.*, fractured surfaces are visible at the

Fig. 5. Scale segment illustrating details of the layered microstructure.

separated layers. We will discuss this feature of the microstructure in more detail later.

In older literature (6), it has been illustrated that commercially pure iron contains fine dispersions (1-2 μm diam), and it was suggested that these particles are oxides and sulfides of Fe or Mn and contain silicon as silicates. If the particles are stable in the iron at a particular reaction temperature, then they could accumulate at the scale/metal interface and potentially influence the microstructure and growth rate of the iron sulfide. We have studied the metal microstructure of the three batches of material that we used in our experiments; they all contain spherical-shaped particles. Bright field photomicrographs show the particles in batch A to be black or opaque while the particles in batches B and C appear to be glassy. Electron microprobe analysis indicates that batch A particles are the monoxide of iron, FeO, but batch B and C particles are the orthosilicate of iron, Fe_2SiO_4 . An examination of what happens when the FeO or Fe_2SiO_4 particles are encountered by the growing sulfide phase is instructive in considering the microstructural development of FeS on iron.

The iron and precipitate particles are primary and secondary contributions to scale growth in our experiments. The primary sulfidation reaction is

and this process occurs by the outward migration of iron ions through the sulfide scale with the sulfide growth actually occurring at the scale/gas interface. The particles, when encountered by the growing Fe-FeS front, are secondary contributions to the scale growth, but the mechanism for their contribution is not so clear. Figure 6 illustrates the metal/scale interface for batch A and B iron; A in the lower and B in the upper micrograph. The spherical-shaped precipitates are shown in the metal phase in both micrographs, but they remain distinguishable and have collected at the Fe/FeS interface in only batch A iron; the black area in both micrographs is mounting material. The silicate particles in batch B iron are not distinguishable in optical light at the interface, but their decomposition at the interface can be detected using x-ray imaging methods. Figure 7 shows back-scattered electron and Si-K α x-ray images of the interface of batch B iron. The silicate particles are visible in the iron, but although a particle can be seen

Fig. 6. The metal scale interfaces for batch A and B iron; A in the lower and B in the upper micrograph.

Fig. 7. Back-scattered electron and Si-K α x-ray images of the interface of batch B iron.

at the interface, a decomposition process has occurred leaving the silica to spread along the interface. Moreover, a map of the oxygen K α line shows a similar distribution of oxygen.

The mechanism for decomposition of either an FeO particle or Fe₂SiO₄ particle is essentially the same: sulfur in the environment reacts with the particle to decompose it. However, the decomposition product of the silicate particle is the most interesting. The ortho-silicate will decompose according to

From examinations of the microstructure, the silica spreads along the interface between the Fe and FeS phases (see Fig. 7), and pore formation in the inner equiaxed layers (see Fig. 2 and 3) is likely due to the accumulation of SO₂ in the scale. This SO₂ accumulation and a dissociative migration through the scale could be analogous to the process of carbon in nickel forming CO₂ in the scale during nickel oxidation (7).

With the experiments that we have done thus far, anything past these observations is certainly speculation. However, it seems clear that the silicate particles do decompose leaving silica to spread along the interface. The decomposition is very likely according to Eq. [2]. A final point in this section relating to this secondary contribution to scale growth (decomposition of the silicate particles) is that it is possible that

the layered scale occurs because of a change in mechanism of growth in the vicinity of a particle at the scale/metal interface. The FeS that is formed according to Eq. [1] forms at the scale/gas interface, but the resultant FeS that forms when the particle decomposes, according to Eq. [2] producing SiO₂, SO₂, and FeS, may be at the scale/metal interface giving rise to the equiaxed inner layers. Further experiments have been planned and are in progress to determine the mechanism for particle decomposition and how it relates to the observed scale microstructure.

Conclusion

We have shown that the commonly reported microstructure for FeS formation on iron is a direct result of silicon contamination of the iron. This silicon effect is to reduce the reaction rate and alter the microstructure from ideal columnar crack-free scale growth to a layered microstructure. An additional effect that has been observed, but only qualitatively, is that silicon improves the adherence properties of FeS scale on iron by leaving an inner layer of the scale firmly attached to the metal substrate.

Ellipsometry Measurements as Direct Evidence of the Drude Model for Polycrystalline Electrochromic WO₃ Films

David H. Mendelsohn¹ and Ronald B. Goldner*

Department of Electrical Engineering, Tufts University, Medford, Massachusetts 02155

ABSTRACT

The optical constants of polycrystalline electrochromic (EC) tungsten trioxide (WO₃) films, prepared by rf sputtering, were measured by ellipsometry at three wavelengths: 940, 633, and 546 nm. For each wavelength, the optical constants were measured at various states of coloration. It is shown that these measurements provide direct evidence for the validity of the free-electron Drude model (i.e., the reflectivity modulation that is observed in polycrystalline EC films of WO₃ is primarily determined by the density and scattering of the free electrons).

Electrochromic (EC) materials are substances for which the optical properties can be reversibly altered with the passage of an electrical current. It is widely accepted that this involves the injection or extraction of electrons and charge compensating ions (1). Most of the EC research to date has been focused on amorphous materials for display applications. The injected electrons in amorphous EC materials predominantly occupy localized states, and this leads to a modulation of the optical absorptivity.

We have been investigating the possibility of using EC materials for controlling solar and thermal infrared energy transfer through windows as a means of decreasing heating and cooling loads in buildings. Consequently, we are interested in obtaining a modulated reflectivity $R(\lambda)$ (λ = wavelength) characteristic. This translates into the requirement that the injected electrons occupy predominantly delocalized (conduction-band) states; and, therefore, the EC material should exhibit a metallic [Drude (2, 3)] behavior. Such a requirement suggests that a crystalline or polycrystalline state is desirable. Previous work by Schirmer *et al.* (4) supports this view. They performed experiments on recrystallized WO₃ films that had been thermally evaporated. The films were amorphous in the as-deposited state and were recrystallized by a thermal anneal. Their recrystallized films, when deeply colored, exhibited a near-infrared reflectivity close to

35% at 2.5 μm wavelength. They were able to fit their results with a Drude free-electron model using an energy-dependent scattering time, $\tau(E)$.

In another paper (5), we shall report the results of reflectivity measurements on polycrystalline WO₃ films prepared by rf sputtering (for which the 2.5 μm wavelength reflectance of the films in a deeply colored state was found to exceed 60%). We likewise have been able to obtain a Drude fit to the reflectivity data. Ellipsometric studies were made on the same samples to provide a direct test for the validity of the Drude model by measuring the coloration-induced variations in the optical constants, n (refractive index) and k (extinction coefficient) at three wavelengths. In this paper, we wish to report the results of those studies and, in particular, that not only did the results agree with the reflectivity measurements, but, of greater importance, they provided direct proof of the validity of the free-electron Drude model.

Experimental

Polycrystalline samples of WO₃ were prepared by rf sputtering onto a substrate held at $325^\circ \pm 10^\circ\text{C}$ in an atmosphere of 10% oxygen and 90% argon at 40 mtorr² (6). The crystallinity was determined by x-ray diffraction measurements (5). The substrate was tin-doped indium oxide (ITO)-coated glass.³

² The samples were prepared by Dr. Tim Rose, EIC Laboratories, Newton, Massachusetts.

³ The ITO-coated glass (5 Ω/\square Nesatron) was purchased from PPG Industries, Pittsburgh, Pennsylvania.

* Electrochemical Society Active Member.

¹ Present address: Eikonix Corporation, Bedford, Massachusetts 01730.

Measurements were taken to determine the characteristics of the ITO and glass. A prism-coupled optical waveguide (PCOW) apparatus, similar to that used by Tanaka and Ohtuska (8), was used in its "substrate mode" to determine that the glass (n, k) = (1.5225, 0.00) at 633 nm wavelength, estimated to be nondispersive. Note that the notation used here is (n, k) where n is the real part of the complex refractive index \underline{N} and k is the "extinction coefficient," such that $\underline{N} = (n - ik) = n(1 - iK)$; K is the "attenuation index" (7). PCOW measurements were coupled with ellipsometry measurements to determine the parameters of the chemically reduced ITO layer: (n, k, d) = (1.16, 0.10, 0.548 μm) at 940 nm wavelength. At 633 nm wavelength, (n, k, d) = (1.82, 0.01, 0.548 μm). The ITO parameters at 546 nm wavelength were estimated to be the same as those at 633 nm. The ellipsometric measurements were made at 546, 633, and 940 nm. Estimates of uncertainty for the ITO figures are ($\delta n, \delta k, \delta d$) = ($\pm 0.05, \pm 0.02, \pm 0.030 \mu\text{m}$). The step height of monitor sample of WO_3 was $0.560 \pm 0.050 \mu\text{m}$ as measured on a Sloan profilometer. PCOW and ellipsometry measurements agreed with this value, but could not reduce the uncertainty; the film thickness of the WO_3 was a principal source of error in this experiment.

A bath of (approximately) 1N H_2SO_4 with 10% glycerol (by volume) was used as the ion source/electron insulator for coloration and bleaching of the WO_3 layer. A counterelectrode of graphite completed the cell. The *in situ* optical density and reflectivity of the sample were monitored as functions of injected charge, measured by a crude charge integration circuit connected to the cell excitation circuit. Approximately 110 mC/cm² of injected charge were needed to achieve the maximum coloration shown in this data. As the charge was injected in steps and relaxation towards a bleached state occurred between steps, the sum of the injected charges was considerably larger (approximately 270 mC/cm²) than the charge needed to color a sample directly from its bleached state. If

fading (probably oxidation) had not occurred, less injected charge would have been needed to achieve the measured coloration states. After each color or bleach step was completed in the acid bath, the sample was rinsed in deionized water, dried with an argon jet, and measured. The sample was returned to the acid bath at the end of each set of measurements, and the process was continued until the sample had been run through a color/bleach cycle of sequential steps.

The ellipsometer used was a modified Rudolf Research reflection ellipsometer with a fixed incident angle of 70 degrees. The modifications included the addition of two light sources and a number of apertures, and the application of a silicon detector with a lock-in amplifier for detection of the infrared (940 nm) source. The wavelengths provided were 546 nm (line-filtered Hg lamp source), 633 nm (3.5 mW He-Ne laser), and 940 nm (infrared LED, RCA 1010A). The procedure involved adjusting the polarizer and analyzer for beam extinction with a fixed compensator azimuth of 45 degrees. The compensator, a muscovite mica retarder, was calculated for retardations of 90.0 degrees at 546 nm, 77.7 degrees at 633 nm, and 52.3 degrees at 940 nm. The refractive indexes of the retarder were estimated to be nondispersive and the transmission coefficient of 1.000 was estimated as constant.

The polarizer (P) and analyzer (A) azimuths were recorded for each color/bleach cycle. The P and A values were entered into a modified version of the McCrackin ellipsometry program (available as part of the National Bureau of Standards Technical Note 479) (7). The program was used to obtain delta and psi pairs (the polar coordinates of the complex total reflection of the optical system), from which (n, k) pairs were obtained. In all cases, (n, k) were assumed to be constant throughout the film thickness.

Results and Discussion

The results of this analysis appear in Fig. 1. Three curves are shown to represent the three wavelengths

Fig. 1. Optical constants of rf sputtered electrochromic WO_3 films (polycrystalline, 0.56 μm thick) in various coloration states. a: 940 nm wavelength. b: 633 nm wavelength. c: 546 nm wavelength. A, B = bleached states. E, F, K = intermediate coloration states. G, H = deeply colored states.

used. Each curve begins at its lower-right extreme (k near 0) in its bleached state and moves toward the upper left as the sample is colored. A few data points are shown on each curve to illustrate the effect of experimental uncertainties. Note that the uncertainties of the (n, k) values are greatest in the bleached state. These uncertainties are mainly due to the uncertainty of the WO₃ film thickness. When k is low for a film, there are many possible ellipsometric solutions which may be within the bounds of the top-film thickness uncertainty. As the extinction coefficient k becomes larger, the reflectivity is increasingly characterized by the film properties near the surface. Considerable absorption can cause the ellipsometric solutions to become almost independent of top-film thickness and underlying layer parameters. This explains the reduced uncertainties for the colored film data. Finally, as n becomes very low and k high, the uncertainties in azimuth readings become more significant. This last point explains the increasing uncertainty of the 940 nm data points in the film's most colored states.

One can use the McCrackin ellipsometry software (7) to obtain theoretical reflection intensities for each (n, k) at normal incidence. Such calculations were made so that ellipsometry data could be compared to data obtained from the reflection spectrophotometer. The correlation was good; the data matched to within measurement error in all cases but one point.

The reflection spectrophotometer readings showed that the reflectivity of the WO₃/ITO/glass sandwich was as high as 62% ($\pm 5\%$) at 2.50 μm wavelength (5, 8). Due to the relatively high extinction coefficient in the highly colored state, the reflectivity of the 0.56 μm WO₃ film was virtually independent of the reflectivity of the underlying layers.

The results of the ellipsometry measurements when plotted as k vs. n provide direct qualitative evidence that the reflectivity modulation associated with the charge injection or extraction in polycrystalline WO₃ is caused primarily by a modulation of the free-electron density. Consider the behavior of the optical constants, n and k , in the vicinity of a plasma resonance for a hypothetical free-electron Drude solid with an initial plasma energy, $E_p = 1.0$ eV (Fig. 2). Note that for an observation photon energy above 1.2 eV, n decreases with coloration (with increasing plasma energy or free-electron density), but k increases, i.e., at a fixed photon energy, there is a distinct inverse relationship between n and k which can only be explained by a free-electron model. Furthermore, the amount of decrease in n reaches a maximum and then reduces as the observation energy increases. The amount of increase in k , however, continuously reduces with increasing observation energy. These qualitative Drude model predictions agree with the results of Fig. 1. In Fig. 1, we observe that n decreases and k increases with coloration, and the largest change in

Fig. 2. Illustration of dispersion of optical constants n (refractive index) and k (extinction coefficient) of a hypothetical free-electron Drude solid with two different plasma energies. "Bleached" state plasma energy = 1 eV. "Colored" state plasma energy = 3 eV. Scattering loss energy = 1 eV. The (Drude) equations used were: $\epsilon_1 = 1 - E_p^2/(E^2 + E_\gamma^2)$; $\epsilon_2 = (E_\gamma/E) (E_p^2/[E^2 + E_\gamma^2])$; $n^2 = 1/2 [(\epsilon_1^2 + \epsilon_2^2)^{1/2} + \epsilon_1]$; $k^2 = 1/2 [(\epsilon_1^2 + \epsilon_2^2)^{1/2} - \epsilon_1]$; where E_p = plasma energy, E_γ = scattering loss energy, and E = photon energy.

k occurs at 940 nm with smaller changes at shorter wavelengths. Note that the coloration endpoints show n smallest for the colored sample at 633 nm, with the minimum n values somewhat higher at 940 and 546 nm wavelengths. This observation matches the expected behavior of n in the colored state, based on observations of the "n_{colored}" curve in Fig. 2. (The largest change in n also seems to occur at 633 nm, with smaller changes at 940 and 546 nm. This point is also in agreement with expected results, but is not experimentally well demonstrated because the optical constant uncertainties are very large in the bleached state.)

It should be noted that by using only the free-electron Drude model one cannot account completely for the 546 and 633 nm data of Fig. 1. At 546 nm, the extinction coefficient, k, exhibits a peak at an intermediate coloration state. We tentatively associate this with an absorption arising from increased filling of bound-electron states by some of the injected electrons. This bound carrier absorption saturates at an intermediate coloration state. (The bound states are completely filled.) Subsequently, as more electrons are injected, there is a decrease in bound-state absorption. This arises from an increase in the filling of conduction-band states, i.e., the conduction-band filling leads to fewer initial bound state-to-final conduction band state transitions analogous to the Burstein-Moss effect (9). The slight convexity of the 633 nm data is very likely also caused by bound-electron states. Further research is needed to quantify the relative roles of the bound- and free-electron states; but the data clearly demonstrate the dominating influence of the free electrons on the optical constants of polycrystalline WO₃, especially in the near infrared.

Conclusions

The results of the spectroscopic ellipsometry measurements of the optical constants of polycrystalline WO₃ in various states of coloration are in good agreement with independent reflectivity measurements (which have been found to be well described by a Drude model fit), and provide direct confirmation of the validity of a free-electron Drude model. This clearly demonstrates that the reflectivity modulation observed in polycrystalline WO₃ (and probably in other crystalline electrochromic materials) is associated with a high degree of

modulation of the free-carrier density. It suggests, furthermore, that to develop practical controlled radiant-energy transfer devices using EC materials, the sources of the free-electron carrier scattering in the EC materials must be identified and reduced. We are currently addressing these problems.

Acknowledgments

Some of the polycrystalline WO₃ samples used in this research were kindly provided by Dr. David Rauh and Dr. Tim Rose of EIC Laboratories, Newton, Massachusetts. Tufts University students James Alexander, William Henderson, and David Fitzpatrick aided in the preparation of experimental apparatus and associated software. The authors would also like to gratefully acknowledge the enthusiastic support and encouragement of David Pellish (Department of Energy) and Carl Lampert (University of California, Berkeley, California). Analysis of Chemical Vapor Deposition of Boron

Maria Michaelidis*¹ and Richard Pollard**

Department of Chemical Engineering, University of Houston, Houston, Texas 77004

ABSTRACT

A one-dimensional model has been developed which describes the interactions among hydrodynamics, multicomponent heat and mass transfer, and reaction kinetics for chemical vapor deposition of boron from boron trichloride using an impinging jet apparatus. The analysis includes variable physical properties and finite interfacial velocity and has provision for simultaneous homogeneous and heterogeneous reactions. Comparison of theoretical predictions with experimental data suggests that decomposition of BHCl₂ on the surface can control the deposition rate. The model also indicates that homogeneous production of BHCl₂ has a significant effect on the process.

Boron is a hard, light, refractory element that exhibits semiconducting behavior and high corrosion resistance. Consequently, there are many potential applications for boron in electronic components, refrac-

tory coatings, and composite materials. The most common manufacturing technique involves chemical vapor deposition (CVD) from a boron halide in a reducing atmosphere. Typically, a cool reactant stream is passed over a hot, solid surface on which boron is deposited.

Experimental studies of CVD of boron have used either heated filaments (1-4) or the impinging jet apparatus (5-7). In the jet system, the reactant gas mix-

Key words: boron deposition, impinging jet, modeling.

ture is passed through a nozzle placed at right angles to the heated substrate surface. The gas flows normally to the center of the substrate and then flows away radially in all directions. An analysis (7) of this apparatus identifies regions of importance for mass-transfer and surface kinetics. However, the model assumes equilibrium in the gas phase, and it is not able to account fully for the dependence of the boron deposition rate on process parameters such as substrate temperature and inlet gas composition. Specific kinetic expressions have been proposed for reduction of BCl_3 in hydrogen (2, 3), but transport phenomena were not included in these models and, therefore, their predictive capabilities are questionable.

In this paper, a general approach to the analysis of CVD of boron from BCl_3 is presented. The axisymmetric stagnation point flow configuration is modeled because experimental data are available (5-7) and because the hydrodynamics and mass-transfer characteristics of this system are relatively well understood (8-12). In particular, the region near the stagnation point is uniformly accessible from a mass-transfer standpoint (10) so that a one-dimensional model may be used. The analysis presented here considers multi-component heat and mass transfer, coupled with laminar fluid flow, and simultaneous homogeneous and heterogeneous reactions with finite reaction rates. Variable physical properties are included, as well as a finite interfacial velocity at the reaction surface. With the model, it is possible to explain experimental observations and to identify rate-controlling factors for CVD of boron.

Transport Phenomena

Momentum, heat, and mass transfer for an impinging jet are modeled subject to the following restrictions: (i) steady-state operation, (ii) laminar flow of Newtonian fluid, (iii) no viscous dissipation of energy, (iv) radiation and natural convection neglected, (v) constant total pressure across diffusion layer, (vi) negligible thermal diffusion, and (vii) ideal gas mixture. With these restrictions, the equations of motion and continuity of the fluid become

$$\rho \mathbf{v} \cdot \nabla \mathbf{v} + \nabla \cdot \underline{\underline{\tau}} = 0 \quad [1]$$

$$\nabla \cdot (\rho \mathbf{v}) = 0 \quad [2]$$

where

$$\underline{\underline{\tau}} = -\mu [\nabla \mathbf{v} + (\nabla \mathbf{v})^T] + \frac{2}{3} \mu I \nabla \cdot \mathbf{v} \quad [3]$$

Equations [1]-[3] are simplified further by assuming that the hydrodynamics obtained experimentally can be approximated by the classical axisymmetric stagnation point flow pattern (8). For this ideal case, the velocity component normal to the surface, the gas composition, and the transport properties are independent of radial position. [This is consistent with the observation (7) that the boron deposition rate is uniform close to the stagnation point.]

The transformation of von Kármán (13) suggests that, with cylindrical coordinates, the velocity components can be expressed as

$$v_r = arF(\zeta), \quad v_\theta = 0, \quad v_z = -2\sqrt{av_\infty} H(\zeta) \quad [4]$$

where

$$\zeta = z\sqrt{a/v_\infty} \quad [5]$$

The hydrodynamic parameter a can be correlated with the average nozzle exit velocity and the system geometry (10). For nonuniform, laminar flow at the exit of the circular nozzle used in the experiments (7), a theoretical relationship for a may be used (10, 14)

$$a = \frac{4w}{\pi d^3 \rho} \left(2.464 - 1.0629 \frac{L}{d} + 1.5794 \frac{L^2}{d^2} \right) \quad [6]$$

where $0.05 \leq L/d \leq 0.5$.

Substitution of Eq. [4] into Eq. [1]-[3] gives

$$F - \frac{dH}{d\zeta} = H \frac{d \ln \rho}{d\zeta} \quad [7]$$

$$F^2 - 2H \frac{dF}{d\zeta} = \frac{\rho_\infty}{\rho} \frac{d}{d\zeta} \left(\frac{\mu}{\mu_\infty} \frac{dF}{d\zeta} \right) + 1 \quad [8]$$

It should be noted that a third hydrodynamic equation is not needed because the angular velocity component is zero. The magnitude of the normal velocity component at the surface is related to the mass-transfer rate by the definition for the mass average velocity

$$\underline{v} = \frac{1}{\rho} \sum_i M_i \underline{N}_i \quad [9]$$

where \underline{N}_i is the molar flux of species i . Equation [9] is used in conjunction with the relationship between the fluxes \underline{N}_i and the reaction kinetics (see below) as a boundary condition for Eq. [7]. The boundary conditions for Eq. [8] are

$$F = 0 \quad \text{at} \quad \zeta = 0 \quad [10]$$

$$F = 1 \quad \text{at} \quad \zeta = \infty$$

The fluid density ρ , used in the equations above, is directly related to total gas concentration by

$$\rho = \bar{M}c \quad [11]$$

where $\bar{M} = \sum_i x_i M_i$. The concentration is, in turn, related to pressure with the ideal gas law

$$p = cRT \quad [12]$$

The thermal energy equation can be expressed in dimensionless form as (15)

$$\begin{aligned} -2 \frac{\tilde{C}_p}{\tilde{C}_{p_\infty}} H \frac{dT}{d\zeta} &= \frac{T}{Pr_\infty T_\infty} \left[\frac{k}{k_\infty} \frac{d^2 T}{d\zeta^2} + \frac{dT}{d\zeta} \frac{d(k/k_\infty)}{d\zeta} \right] \\ &+ \frac{sT}{T_\infty} \frac{dT}{d\zeta} + UT \quad [13] \end{aligned}$$

where

$$\left. \begin{aligned} \tilde{C}_p &= \sum_i x_i \tilde{C}_{p_i} \\ Pr_\infty &= \frac{\mu_\infty \tilde{C}_{p_\infty}}{k_\infty \bar{M}_\infty} \\ s &= - \frac{\sum_i J_i \tilde{C}_{p_i}}{\tilde{C}_{p_\infty}} \\ U &= - \frac{\sum_i \tilde{H}_i^* R_i}{T_\infty \tilde{C}_{p_\infty}} \\ J_i &= \underline{J}_i / c_\infty \sqrt{v_\infty a} \\ R_i &= R_i / c_\infty a \end{aligned} \right\} \quad [14]$$

The temperatures of the surface and the bulk fluid are specified as boundary conditions for Eq. [13].

The dimensionless multicomponent diffusion equation is (15, 16)

$$\nabla x_i = \sum_{k \neq i} \frac{x_i J_k - x_k J_i}{D_{ik}} \quad [15]$$

where D_{ik} is a dimensionless transport property for binary interactions, defined as $D_{ik} = c D_{ik}/c_{x\nu_x}$. For a mixture of n species, there are $(n-1)$ independent force balances in the form of Eq. [15], and there are $\frac{1}{2}n(n-1)$ independent transport properties because D_{ii} is not defined and, by Newton's third law of motion, $D_{ik} = D_{ki}$. The mole fractions in Eq. [15] are related by

$$\sum_i x_i = 1 \quad [16]$$

A steady-state material balance in the gas phase is

$$\nabla \cdot \underline{N}_i = R_i \quad [17]$$

where R_i is the net homogeneous rate of production of species i and

$$\underline{N}_i = \underline{J}_i + c_i v \quad [18]$$

In dimensionless form, Eq. [17] becomes

$$\frac{d^2 x_i}{d\zeta^2} = \sum_{k \neq i} \left[\frac{x_i R_k - x_k R_i}{D_{ik}} + \frac{2cH}{c_x D_{ik}} \left(x_i \frac{dx_k}{d\zeta} - x_k \frac{dx_i}{d\zeta} \right) + J_k \frac{d}{d\zeta} \left(\frac{x_i}{D_{ik}} \right) - J_i \frac{d}{d\zeta} \left(\frac{x_k}{D_{ik}} \right) \right] \quad [19]$$

for the one-dimensional problem considered here. There are $n-1$ independent force balances with the form of Eq. [19] which can be used, together with the relationship between the fluxes

$$\sum_i M_i J_i = 0 \quad [20]$$

to describe mass transfer in a multicomponent system.

At the surface, $n-1$ Stefan-Maxwell relations, Eq. [15], are combined with Eq. [16] to give the boundary conditions for the composition. Far from the surface, equilibrium compositions at the bulk fluid temperature are specified as boundary conditions.

Chemical Reactions

The equations derived above, which describe the transfer of heat, mass, and momentum for axisymmetric stagnation point flow, can be used to predict the behavior of systems with an arbitrary number of homogeneous and heterogeneous reactions. For CVD of boron from a mixture of boron trichloride and hydrogen, thermodynamic studies (7) indicate that, over the temperature range of interest, five principal species are present in the gas phase: H_2 , HCl , BCl_3 , $BHCl_2$, and BCl . Several mechanisms have been proposed for the formation of boron from BCl_3 (2, 3, 5). Here, it is assumed that BCl_3 can be reduced either homogeneously or heterogeneously by the following reversible reactions

At the surface, the deposition reaction

can also take place.

The net rate of each reaction is regarded as the difference between the rates of forward and backward reactions and can be represented as

$$r_i = [k_{if} \pi x_i^{\nu_{i1}} - k_{ib} \pi x_i^{-\nu_{i1}}] \theta_v^{\nu_i} \quad [24]$$

$$\nu_{i1} > 0 \quad \nu_{i2} < 0$$

The coefficient θ_v represents the interaction between gas phase molecules and the surface; it can be taken as unity for homogeneous reactions. For heterogeneous processes, it is assumed implicitly in Eq. [24] that

dynamic equilibrium is established between the rates of adsorption and desorption. Consequently, θ_v may be regarded as the fraction of active surface sites that is available for adsorption of reactants. It can be related to compositions in the gas phase immediately adjacent to the surface by an expression of the form (17)

$$\theta_v = \frac{1}{1 + \sum_i K_{s,i} x_i^{q_i}} \quad [25]$$

where $K_{s,i}$ is an effective equilibrium constant for adsorption/desorption of species i . The values for exponents n in Eq. [24] and q_i in Eq. [25] are dependent on the specific model chosen for the surface processes.

In Eq. [24], k_{if} and k_{ib} are rate constants for forward and backward reactions, respectively. The exponent ν_{i1} is the stoichiometric coefficient for species i in reaction 1. It is positive for reactants and negative for products, and may be obtained from Eq. [21]-[23], which are assumed to be elementary reaction steps. The temperature dependence of the rate constants in Eq. [24] is assumed to be given by

$$k_{ib} = A_1 e^{-E_1/T} \quad [26]$$

where E_1 can be regarded as an activation energy for reaction 1.

In the model, the kinetic behavior can be described by the following set of independent parameters (15): E_a , $\theta_1 = k_{2b}/k_{1b}$, $\theta_2 = k_{3b}/k_{1b}$, $\theta_3 = k'_{2b}/k'_{1b}$, $\theta_4 = k^2_{1b} e^{E_a/T_s} / c_{x\nu_x} k'_{1b}$, $\theta_5 = e^{-E_a/T_s} c_x a / k'_{2b}$, $K_{s,i}$, q_i , and n . The term E_a represents an activation energy for the deposition process. Different activation energies could be chosen for each reaction, but it is assumed that the temperature dependence of the deposition rate will be dictated by the activation energy for the rate-limiting step. The dimensionless parameters θ_1 and θ_2 describe the relative rates of the heterogeneous reactions, and θ_3 is a ratio of rate constants for the homogeneous reactions. The parameter θ_4 represents the relative rates of the homogeneous and heterogeneous reactions. θ_5 specifies the rate of homogeneous production of BCl , as described by Eq. [22], compared to the mass-transfer rate, as characterized by the hydrodynamic constant a . The quantities $K_{s,i}$, q_i , and n are associated with the details of the adsorption and desorption process at the reaction surface. In some cases (see below), it is possible to incorporate these quantities into the definition for θ_4 .

The forward and backward rate constants are related by an equilibrium constant $K_1 = k_{if}/k_{ib}$, which can be defined in terms of equilibrium reactant and product compositions using Eq. [24]

$$K_1 = \prod_i x_i^{\nu_{i1}} \quad [27]$$

In general, K_1 is related to a pressure-independent equilibrium constant K_{pl} by

$$K_{pl} = p^m K_1 \quad [28]$$

In Eq. [27], the activity of any solid phase is taken to be unity, and, in Eq. [28], m represents the net number of molecules produced by reaction 1. The temperature dependence of K_{pl} is predicted from standard heats of reaction $\Delta H(T)$, with

$$\left[\frac{\partial \ln K_{pl}}{\partial (1/T)} \right]_p = -\Delta H(T)/R \quad [29]$$

and from free energy data at 25°C (18), to give expressions of the form

$$\ln K_{pl} = \alpha_1 + \beta_1/T + \gamma_1 \ln T + \delta_1 T + \epsilon_1 T^2 \quad [30]$$

The coefficients α_1 , β_1 , γ_1 , δ_1 , ϵ_1 used for the reactions are summarized in Table I.

Table I. Equilibrium constants for boron deposition reactions: coefficients for Eq. [30]

Reaction	Eq.	α	$10^4 \beta$	γ	$10^8 \delta$	$10^6 \epsilon$
I	[21]	+17.51	-0.81	-2.08	+0.94	-0.07
II	[22]	-0.11	-3.52	+2.61	-2.69	+0.35
III	[23]	-1.76	+2.78	-1.39	+1.38	-0.13

In the gas phase, the net rate of production of species i is given as

$$R_i = - \sum_j \nu_{ij} r_j \quad [31]$$

At the surface, a similar summation for the heterogeneous reactions represents the molar flux \bar{N}_i from the surface relative to the interface. The variables \bar{N}_i and R_i link the rates of the individual reactions to the equations that describe heat, mass, and momentum transfer for the impinging jet.

Interactions among the governing differential equations are caused directly by the inclusion of a finite interfacial velocity (see Eq. [9]) and variable physical properties in the analysis. Relationships for the temperature and composition dependences of physical parameters needed in the model are summarized in the Appendix.

For CVD of boron, with five species (H_2 , HCl , BCl_3 , $BHCl_2$, and BCl) in the gas phase, the steady-state behavior is described by Eq. [7], [8], [11]-[13], [16], and four Eq. [19] for variables F , H , c , p , T , and x_i . In addition, Eq. [20] and four Eq. [15] are used for the fluxes j_i . These fluxes are eliminated within the computer program by numerical inversion of Eq. [15] and [20]. The governing coupled algebraic equations and nonlinear, ordinary differential equations, subject to the specified boundary conditions, are solved numerically by a finite difference technique accurate to $O(h^2)$ (16, 19, 20). Parameters that must be specified in the model include surface and bulk temperatures, inlet gas composition, hydrodynamic parameter a (related to jet mass flow rate by Eq. [6]), and operating pressure.

Results and Discussion

Initially, simulations were obtained without inclusion of adsorption/desorption effects in the analysis (i.e., $\theta_v = 1$ in Eq. [24]). Figure 1 compares the experimental temperature dependence of dimensionless boron deposition rate with theoretical predictions, for three sets of model parameters (see Table II). The top curve is the locus of maximum deposition rates calculated with the mathematical model. It can be regarded as a combined thermodynamic-mass transfer limit since, for this curve, the reactions are locally at equilibrium but the finite mass-transfer rate through the diffusion layer limits the fraction of the bulk fluid that can reach the surface. The actual deposition rate is smaller than the thermodynamic-mass transfer limit as a result of finite chemical reaction rates, particularly at low substrate temperatures.

The curves in Fig. 1 represent extreme cases, with kinetic parameters chosen to give the "best fit" with different rate-limiting reactions. It can be seen that, with $\theta_v = 1$, the model predictions do not give a satisfactory match with the experimental data. Neverthe-

Table II. Values of kinetic parameters for Fig. 1

Curve Rate-limiting reaction (at surface)	I	II	III

Experimental data (●): $x_{BCl_3} = 0.4$, $L/d = 0.375$; (■) $a = 310 \text{ s}^{-1}$, (●) $a = 626 \text{ s}^{-1}$. Full curves: theoretical predictions for $a = 626 \text{ s}^{-1}$ with different kinetic parameters (see Table II). Dashed curves: theoretical predictions for $a = 310 \text{ s}^{-1}$ with different kinetic parameters. Uppermost curve (— · — ·): thermodynamic-mass transfer limit.

less, they can be used to provide insight into the physical phenomena involved in the process. When heterogeneous decomposition of $BHCl_2$ controls (curves II), the theoretical deposition rate is very sensitive to surface temperature. This is because the equilibrium constant for reaction II is a strong function of temperature (see Table I). For curves I and III, the slopes in Fig. 1 are close to observed results, but, as with curves II, the dependence of S on mass flow rate is unacceptable.

The model has also been used to consider reactions in the gas phase. These homogeneous reactions provide pathways that are in parallel with the surface reactions. If reaction I is rate-limiting, and if it occurs predominantly in the gas phase, the mass-transfer dependence of S in Fig. 1 becomes more acceptable, but the slopes for the curves are too small. Increases in activation energy E_a fail to raise the slopes significantly because their magnitudes are dictated by variations in local compositions with temperature. If reaction II occurs primarily in the gas phase, boron deposition rates are predicted to be at least an order of magnitude smaller than those observed experimentally. The extent of homogeneous reaction II is very small because decomposition can only occur in the narrow high temperature region close to the substrate. Further from the surface (lower gas temperatures), the equilibrium constant is small and this favors the back reaction.

Combinations of kinetic parameters that gave more than one reaction far from equilibrium were also considered, but no significant improvements were obtained. In all cases, it was observed that reaction II tends to dominate the process, especially at low surface temperatures. Furthermore, none of the simulations considered above were able to predict the correct changes in deposition rate with inlet gas composition.

The influence of inlet gas composition on S is presented in Fig. 2, for a specific jet mass flow rate. The

Fig. 2. Dependence of dimensionless boron deposition rate on inlet gas composition. Experimental data (7): $\blacktriangle \sim a = 102 \text{ s}^{-1}$ at $x^0_{\text{BCl}_3} = 0.4$. Full curve: theoretical prediction with kinetic parameters $\theta_1 = 2.3 \times 10^5$, $\theta_2 = 80.0$, $\theta_3 = 8.0 \times 10^4$, $\theta_4 = 4.6 \times 10^{-11}$ at $x^0_{\text{BCl}_3} = 0.4$ (see Eq. [34]), $\theta_5 = 9.0 \times 10^{-8}$ at $x^0_{\text{BCl}_3} = 0.4$, $E'_a = 2.7 \times 10^4 \text{ K}$, $E_a = 3.0 \times 10^3 \text{ K}$. Uppermost curve (— · — · —): thermodynamic-mass transfer limit. $T_s = 1373 \text{ K}$, $T_\infty = 298 \text{ K}$, $p_\infty = 1.013 \times 10^5 \text{ N/m}^2$.

dependence of the thermodynamic-mass transfer limit on $x^0_{\text{BCl}_3}$ results from composition changes near the substrate surface and from changes in the variables ν_∞ and a that are included in the definition of the dimensionless rate of boron production. The deviation of the actual deposition rate from the limiting value is almost independent of composition; both curves show a maximum at $x^0_{\text{BCl}_3} \approx 0.5$.

The close correspondence between theoretical predictions and experimental results is a consequence of the specific values for the kinetic parameters chosen for the model. In particular, the shape of the curve is controlled by the values for n , $K_{s,i}$ and q_i in Eq. [24] and [25]. The results in Fig. 2 are for

$$\theta_v^n = \frac{1}{K_{s,\text{BCl}_3} \sqrt{x_{\text{BCl}_3}}} \quad [32]$$

where

$$K_{s,\text{BCl}_3} = A_s e^{-E_s/T_s} \quad [33]$$

From a physical standpoint, Eq. [32] could imply that BCl_3 is the dominant adsorbed species and that dissociation occurs on adsorption (17).

With this simplified expression for θ_v , it is convenient to redefine the dimensionless kinetic parameter θ_4 to include K_{s,BCl_3}

$$\theta_4 = \frac{k_{21b}^2 e^{-E'_a/T_s}}{c_{\infty} \nu_\infty k'_{1b} K_{s,\text{BCl}_3}^2} \quad [34]$$

where $E'_a = 2E_s - E_a$. In this way, the relevant kinetic parameters for CVD of boron are θ_1 to θ_5 , E_a , and E'_a with $n_{\text{BCl}_3} = \frac{1}{2}$ and $q_i = 0$ otherwise. It should be noted that, by inclusion of θ_v in accordance with Eq. [32], the composition dependence of each heterogeneous reaction rate has been altered and E'_a can now have either a positive or a negative value.

Other relationships for θ_v have been tested. If adsorption of any other species is used in Eq. [32], or if θ_v is taken as unity, the maximum in Fig. 2 is predicted at $x^0_{\text{BCl}_3} > 0.5$. Also, the maximum becomes sharper and moves to smaller compositions as the product n_{BCl_3} is raised. It is conceivable that a satisfactory match could also be obtained with a higher value for

n_{BCl_3} together with additional composition terms in the expression for θ_v (Eq. [25]). However, this would necessitate introduction of extra kinetic parameters, and it is not clear that greater insight into the system behavior would be obtained.

A maximum in deposition rate with inlet gas composition has also been observed in other CVD systems. For silicon deposition from SiCl_4 , an etching reaction between SiCl_4 and silicon has been proposed as an explanation for the effect (21). The analogous reaction for CVD of boron would be

Inclusion of this heterogeneous reaction in the model raises the rate of reaction III (Eq. [23]), but the net deposition rate does not give the maximum observed experimentally.

Figure 3 shows the effect of substrate temperature on boron deposition rate at three mass flow rates. The temperature dependence of the thermodynamic-mass transfer limit corresponds to changes in the binary diffusion coefficients (see Fig. 7). The slope for the actual deposition rates is approximately $1.2 \times 10^4 \text{ K}$. This can be regarded as an apparent activation energy for boron deposition. However, it is emphasized that this value is a combination of E'_a , composition changes, and the temperature dependence of the equilibrium constant for the rate-determining reaction.

With the kinetic parameters that provide a match between experiment and theory, heterogeneous decomposition of BHCl_2 is not in equilibrium, and the rate of this step can control the boron deposition rate, i.e., the ratio of backward to forward reaction rates can be smaller for this step than for the other reactions. However, increases in surface temperature or reductions in mass flow rate tend to reduce the importance of reaction II. Under these circumstances, decomposition of BCl_3 to BHCl_2 (reaction I) becomes more significant. Reaction I occurs both homogeneously

Fig. 3. Dependence of dimensionless boron deposition rate on substrate temperature. Experimental data (7): $\blacktriangle \sim a = 417 \text{ s}^{-1}$, also see Fig. 1. Full curves: theoretical predictions with kinetic parameters as in Fig. 2, unless stated otherwise. Uppermost curve (— · — · —): thermodynamic-mass transfer limit. $x^0_{\text{BCl}_3} = 0.4$, $p_\infty = 1.013 \times 10^5 \text{ N/m}^2$, $T_\infty = 298 \text{ K}$.

and heterogeneously, but most conversion occurs in the gas phase. The extent of the homogeneous pathway determines the dependence of S on mass flow rate, *i.e.*, on θ_5 . (With reaction I in equilibrium, the homogeneous reaction would have a negligible effect on the deposition rate. Consequently, it would be impossible to match theory and experiment at more than one mass flow rate.)

With the value for θ_3 specified in Fig. 2 and 3, homogeneous reaction II is essentially in equilibrium. However, as with the $\theta_v = 1$ results (see above), only a small fraction of the BHC_2 can decompose in the gas phase, and therefore this pathway is unimportant. With $\theta_2 = 80.0$, reaction III is also close to equilibrium. If the kinetic parameters were changed to make reaction III the rate-limiting step, the slopes of the curves in Fig. 3 at low mass flow rates would be too small.

The experimental values of S at 1473 K are slightly higher than the theoretical predictions (see Fig. 3). This might be attributed to natural convection which, for the reactor configuration considered here (7), would tend to raise the actual deposition rates above the results predicted on the basis of forced convection alone. In general, the contribution of natural convection becomes larger as the magnitude of the ratio Gr/Re^2 increases (7, 15). This ratio is largest at high surface temperatures and low jet mass flow rates.

In addition to predicting deposition rates, the model also provides information on changes in compositions, velocities, and physical properties across the diffusion layer. Typical composition profiles are presented in Fig. 4. A maximum in BCl composition is consistent with the fast rate of reaction III. With higher surface temperatures, reaction rates at the surface are increased, and, hence, a small maximum for x_{BHC_2} may be predicted.

An approximate estimate of the diffusion layer thickness can be obtained from the composition profiles, even though some species reach their bulk compositions closer to the surface than others. For the example in Fig. 4, an approximate thickness is 0.2 cm, which is

Fig. 4. Composition profiles in diffusion layer adjacent to reaction surface. Parameter values as in Fig. 3, with $\theta_5 = 3.6 \times 10^{-7}$ and $T_s = 1373$ K.

smaller than values for CVD of silicon (15) but larger than values for electrolyte solutions.

For the operating conditions used in Fig. 4, the variations of some physical properties are shown in Fig. 5. The density changes by a factor of 5.5 across the diffusion layer in direct association with changes in T and \bar{M} . Viscosity and thermal conductivity both vary by factors of about 4. These changes distort the velocity profiles from the constant property results (see Fig. 6). With larger values for T_s , variations in μ and ρ are less marked, and the constant physical property solution is approached. Even though the local velocities are influenced by the bulk temperature, the choice for T_s in the model has a negligible effect on the deposition rate. This is primarily because the extent of the gas-phase reactions declines sharply as one moves away from the reaction surface.

Conclusions

A model has been developed which describes the interactions among hydrodynamics, multicomponent heat and mass transport, and reaction kinetics for the impinging jet system. The analysis includes variable physical properties, finite interfacial velocity, and simultaneous homogeneous and heterogeneous reactions.

This model has been used to study CVD of boron from BCl_3 in hydrogen. The effects of inlet gas composition, jet mass flow rate, and surface temperature have been investigated, and several features of the process have been elucidated.

1. With five gas-phase species and a set of seven independent kinetic parameters, the predicted dependence of boron deposition rate on inlet gas composition, jet mass flow rate, and surface temperature matches experimental results.

2. The model indicates that the relative importance of the reactions for CVD of boron is dependent on the operating conditions. Heterogeneous decomposition of BHCl_2 tends to be rate determining, although production of BHCl_2 becomes more important at low mass flow rates and high surface temperatures. The homogeneous pathway for BHCl_2 decomposition is unimportant, whereas the extent of production of BHCl_2 in the gas phase is significant and dictates the effect of mass flow rate on the rate of boron deposition.

3. Inclusion of adsorption/desorption effects, with BCl_3 as the dominant adsorbed species, is able to account for the dependence of deposition rate on inlet gas composition.

4. Physical properties, such as density and viscosity, vary by factors of between 4 and 6, across the diffusion layer and this distorts the fluid flow profiles. The diffusion layer thickness is in the range 1-10 mm.

APPENDIX

Physical Properties

Viscosity.—The temperature dependence of the viscosity of each species in the gas phase is predicted from the Chapman-Enskog kinetic theory (22)

$$\mu_i = \frac{2.6693 \times 10^{-5} \sqrt{M_i T}}{\sigma_i^2 \Omega_{\mu_i}} \quad [\text{A-1}]$$

The parameter σ_i is the collision diameter (18, 23), and Ω_{μ_i} is a dimensionless function which depends on kT/ϵ_i , where ϵ_i is a characteristic energy of interaction between molecules and k is Boltzmann's constant. For each species, Eq. [A-1] is rewritten in the simplified form

$$\mu_i = \delta_{ii} T^{\psi_{ii}} \quad [\text{A-2}]$$

and values for δ_{ii} and ψ_{ii} are given in Table A-I. The viscosity of the gas mixture is calculated with the Wilke correlation (24)

Table A-I. Values for parameters in Eq. [A-2] and [A-7]

Species, i	μ_i ($\text{N} \cdot \text{s}/\text{m}^2$)		k_i ($\text{W}/\text{m} \cdot \text{K}$)	
	$10^7 \delta_{ii}$	ψ_{ii}	δ_{ii}	ψ_{ii}
H_2	2.14	0.66	2.61×10^{-8}	0.74
HCl	1.24	0.85	7.74×10^{-8}	0.95
BCl_3	0.98	0.84	3.51×10^{-5}	0.98
BHCl_2	0.89	0.93	1.12×10^{-5}	0.93
BCl	0.37	0.98	2.27×10^{-5}	1.07

Fig. A-1. Temperature dependence of binary diffusion coefficients

$$\mu_{\text{mix}} = \sum_{i=1}^n \left(x_i \mu_i / \sum_{j=1}^n x_j \phi_{ij} \right) \quad [\text{A-3}]$$

where

$$\phi_{ij} = [1 + (\mu_i/\mu_j)^{1/2} (M_j/M_i)^{1/4}]^2 / [8 + 8M_i/M_j]^{1/2}$$

Diffusivity.—Diffusion coefficients for binary interactions are estimated from (22)

$$\frac{cD_{ij}}{\sqrt{T}} = \frac{2.2646 \times 10^{-5} \left(\frac{1}{M_i} + \frac{1}{M_j} \right)^{1/2}}{\sigma_{ij}^2 \Omega_{D_{ij}}} \quad [\text{A-4}]$$

where σ_{ij} is a mean collision diameter which is taken as $(\sigma_i + \sigma_j)/2$. The dimensionless quantity $\Omega_{D_{ij}}$ is analogous to Ω_{μ_i} used for the viscosity calculations, but the characteristic of the intermolecular potential field should now represent both species i and j , and is assumed to be given by $\epsilon_{ij} = \sqrt{\epsilon_i \epsilon_j}$. Figure A-1 shows the temperature dependence of diffusion coefficients obtained from Eq. [A-4]. In the analysis, a simplified form

$$cD_{ij} = B_{ij} T^{l_{ij}} \quad [\text{A-5}]$$

is chosen with parameters which best fit the curves in Fig. A-1 over the temperature range of interest (see Table A-II).

Specific heat.—The temperature dependence of the heat capacity (18, 25) of each species is obtained from

$$\tilde{C}_{pi} = \alpha_i + \beta_i T + \gamma_i T^2 \quad [\text{A-6}]$$

where the coefficients are summarized in Table A-III.

Thermal conductivity.—An approximate relationship

$$k_i = \delta_{2i} T^{\psi_{2i}} \quad [A-7]$$

is used to describe data (18) for the temperature dependence of k_i (see Table A-I). The thermal conductivity of the mixture is given by an expression analogous to Eq. [A-3]

$$k_{mix} = \sum_{i=1}^n \left(x_i k_i \left/ \sum_{j=1}^n x_j \phi_{ij} \right. \right) \quad [A-8]$$

LIST OF SYMBOLS

a	hydrodynamic constant (s^{-1})
A_1	pre-exponential factor for backward rate constant
A_s	pre-exponential factor for adsorption/desorption equilibrium constant (see Eq. [33])
c	total concentration (mol/cm^3)
c_i	concentration of species i (mol/cm^3)
\tilde{C}_p	molar heat capacity of mixture ($\text{J}/\text{mol} \cdot \text{K}$)
\tilde{C}_{pi}	molar heat capacity of species i ($\text{J}/\text{mol} \cdot \text{K}$)
d	nozzle diam (cm)
D_{ik}	diffusion coefficient for binary interactions (cm^2/s)
D_{ik}	dimensionless diffusion coefficient for binary interactions
E_a	kinetic parameter representing activation energy of rate-limiting step (K)
E'_a	$= 2E_s - E_a$, modified E_a (K)
E_s	activation energy for K_{s,BCl_3} in Eq. [33] (K)
E_1	activation energy for reaction 1 (K)
F	dimensionless radial velocity defined in Eq. [4]
Gr	Grashof number
h	mesh size (m)
H	dimensionless axial velocity defined by Eq. [4]
\tilde{H}_i^*	molar enthalpy of ideal gas (J/mol)
\underline{I}	unit matrix
\underline{J}_i	$= N_i - c_i v$, flux of species i relative to mass average velocity ($\text{mol}/\text{m}^2 \cdot \text{s}$)
J_1	dimensionless J_1
k	Boltzmann constant ($1.3806 \times 10^{-23} \text{ J}/\text{K}$)
k_i	thermal conductivity of species i ($\text{W}/\text{m} \cdot \text{K}$)
k_{if}	forward rate constant for reaction 1
k_{ib}	backward rate constant for reaction 1
k'_{ib}	backward rate constant for homogeneous reaction 1
K_1	equilibrium constant for reaction 1
K_{p1}	equilibrium constant defined by Eq. [28]
$K_{s,1}$	equilibrium constant for adsorption/desorption of species i
L	distance between end of nozzle and substrate surface (cm)
m	exponent in Eq. [28]
M_i	molecular weight of species i
\bar{M}	average molecular weight
n	exponent in Eq. [24]
\underline{N}_i	flux of species i ($\text{mol}/\text{m}^2 \cdot \text{s}$)
p	gas pressure (N/m^2)
Pr	Prandtl number
q_i	exponent in Eq. [25]
r	radial coordinate (m)
r_1	rate of reaction 1
R	universal gas constant ($8.3143 \text{ J}/\text{mol} \cdot \text{K}$)
Re	Reynolds number
R_i	rate of homogeneous production of species i ($\text{mol}/\text{m}^3 \cdot \text{s}$)
\tilde{R}_i	dimensionless R_i
s	dimensionless parameter defined by Eq. [14]
S	dimensionless boron deposition rate
T	temperature (K)

U	dimensionless parameter defined by Eq. [14]
\underline{v}	mass average velocity (m/s)
v_r	radial velocity (m/s)
v_θ	angular velocity (m/s)
v_z	axial velocity (m/s)
w	jet mass flow rate (g/s)
x^{oBCl_3}	inlet mole fraction of BCl ₃
x_i	mole fraction of species i
z	axial distance from disk surface (m)

Greek Symbols

ϵ_{ij}	maximum energy of attraction between molecules i and j (J)
ζ	dimensionless axial distance coordinate defined by Eq. [5]
θ_k	dimensionless kinetic parameter ($k = 1$ to 5)
θ_v	parameter defined by Eq. [24]
μ	fluid viscosity ($\text{kg}/\text{m} \cdot \text{s}$)
ν_{il}	stoichiometric coefficient for species i in reaction l
ν_∞	bulk kinematic viscosity (m^2/s)
ρ	fluid density (kg/m^3)
σ	collision diam for Lennard-Jones potential (m)
$\underline{\tau}$	viscous stress tensor (N/m^2)

Superscripts

A Flexible Multilayer Resist System Using Low Temperature Plasma-Deposited Silicon Nitride

B. R. Soller,^{*,1} C. R. Snider,^{*,2} and R. F. Shuman¹

Sperry Research Center, Sudbury, Massachusetts 01776

ABSTRACT

A three-layer resist system which uses positive photoresists for planarizing and imaging and an intermediate layer of plasma-deposited silicon nitride is described. The planarizing layer is 2 μm -thick Shipley AZ[®] 2430. The silicon nitride transfer layer is deposited at low temperature over hard-baked AZ 2430. Photon or electron imaging is done in a thin layer of resist spun on top of the transfer layer. The silicon nitride deposition process is described, and the properties of the resulting film are detailed. The planarizing photoresist is patterned by oxygen reactive ion etching. The vertical etch rate and the degree of isotropy are measured as a function of rf power and oxygen pressure. Controllable and reproducible undercut is achieved with this multilayer resist system. The resist profile is demonstrated to be suitable for lift-off applications or anisotropic etching of the substrate.

Multilayer resists have been employed by many to accomplish high resolution pattern transfer (1-6). The multilayer resists described here consist of three layers (Fig. 1). The bottom layer, the one covering the substrate, is a thick polymer layer which is used to planarize the topography of the substrate. A second layer, the transfer layer, separates the planarization layer from the imaging layer. The transfer layer keeps the imaging resist from mixing with the planarizing material, which may also be a photoresist. A thin imaging resist is then spun on top of the transfer layer. Because the resist is thin and flat, it is possible to achieve high resolution patterns even over complex topography. The imaging resist is exposed and developed and then used as a mask for etching the transfer layer. The etched transfer layer is subsequently used as a mask for reactive ion etching (RIE) of the planarizing layer. The transfer layer is usually an inorganic material which forms a nonerodible mask for oxygen RIE.

One advantage of multilayer resists is their flexibility. Because the planarizing resist is plasma or reactive ion etched, the sidewall profile can be accurately and reproducibly controlled. The thick resist may be vertically etched so the multilayer resist can be used as an etch mask for anisotropic etching of the substrate. The multilayer resist is a better mask for substrate etching than single-layer resist because the transfer layer, rather than an organic resist, is exposed to the plasma. A properly chosen transfer-layer material will stand up to plasma etching better than photoresist. Multilayer resists can also be processed so that the planarizing resist is undercut beneath the transfer layer. This profile is ideal for lift-off applications. The metal thickness is controlled by the thickness of the planarizing resist, making lift-off of thick metals possible. The pattern resolution is controlled independently by imaging in the thin top resist.

Additional flexibility is gained by being able to image in any type of resist. Photo-, E-beam, or x-ray resists can be used as the imaging resist without regard to future harsh processing steps. The resist is used only for lithography and as a mask for etching 1000Å of the transfer material. The imaging resist is usually re-

moved during reactive ion etching of the planarization layer. The multilayer resist system described here is being used in the application of same-level mixed lithography (7). In this application the resist is both optically and E-beam exposed. As a consequence, it is necessary to be able to optically align through the resist. For this reason, a transparent material is necessary for the transfer layer. Silicon nitride was chosen as the transfer material.

Silicon nitride is compatible with both silicon and GaAs technologies. It is currently used in both technologies as a final passivation layer because it serves as an excellent barrier to alkali diffusion. It also has application as an interlevel dielectric in multilayer metallization. Because it has such widespread use in the industry, processing with silicon nitride is routine, and its properties are well characterized. Silicon nitride can be plasma deposited at low temperatures uniformly across a wafer. It is also easily etched in fluorocarbon plasmas. This ease in handling makes silicon nitride a good choice for the transfer-layer material.

This paper will describe a multilayer resist system composed of plasma-deposited silicon nitride and positive photoresists. The processing steps will be described and the applications will be demonstrated.

Experiments

The multilayer resist (Fig. 1) was applied on 3 in. silicon wafers. The planarization layer was typically 1.7-2.0 μm of AZ[®] 2430,³ which was baked at 200°C for 30

³ AZ is a registered trademark of American Hoechst Corporation, Somerville, New Jersey, for their photoresist products.

min in a convection oven. The silicon nitride transfer layer was applied on top of the hard-baked resist. Thickness of this layer was generally $0.1 \mu\text{m}$.

The silicon nitride was plasma deposited in a modified Technics Planar Etch II reactor, as shown schematically in Fig. 2. The two electrodes, 20.3 cm in diam, were separated by 3.0 cm. Samples were uniformly spaced on the heated platen. The reactant gases entered the chamber through an annular plate, passed a diffusion ring, and flowed radially inward over the samples. The reaction by-products were exhausted through the center hole of the heated deposition plate.

Pressure and gas flow into the reactor were controlled independently. Reactant gases were controlled by a three-gas flow/ratio mass flow controller. This system provided closed-loop flow control and the capability of slaving any two of the gases to a third. Individual gas flows, as well as total-flow rate, were accurately maintained within the chamber. The desired process pressure was controlled independently by using a throttle valve and controller on the exhaust port. Depositions were made at a substrate temperature of 125°C . The platen was heated by a resistance heater sandwiched between the two aluminum plates comprising the platen. Temperature monitoring and control were accomplished by a thermocouple positioned between the plates.

The production of silicon nitride (Si_3N_4) was achieved by coreaction of nitrogen (N_2), ammonia (NH_3), and silane (SiH_4). Silane was introduced in an argon carrier gas, where the SiH_4/Ar ratio was 10/90. Ammonia was added because it is more easily dissociated than nitrogen. The larger concentration of free nitrogen atoms in the plasma resulted in silicon nitride films, which are less silicon rich than the films deposited from N_2/SiH_4 plasmas. The use of ammonia resulted in material having a more uniform index of refraction and thickness.

Under typical deposition conditions, input gas-flow rate ratios were $\text{N}_2/\text{NH}_3/\text{SiH}_4$ equal to 37/4.5/33.5 sccm. A total chamber pressure of 700 mtorr was maintained with the throttle valve. The plasma was sustained with 50W rf power applied to the top electrode from a 30 kHz generator. Under these conditions the deposition rate was $120 \text{ \AA}/\text{min}$.

The properties of the silicon nitride film were characterized using a Rudolph AutoEl ellipsometer. The silicon nitride film was deposited directly on silicon substrates to determine the index of refraction and film thickness. The film thickness uniformity over a 3 in. wafer was determined by using the ellipsometer to

measure thickness at nine points on a wafer. The etch rate in Transene-buffered HF was measured by determining the film thickness before and after a timed etch. Etching in buffered HF was done for several different times, and the etch rates were calculated. The etch rate of the silicon nitride film in a CF_4/O_2 plasma could not be calculated in this way because the plasma changes the reflecting properties of the silicon nitride.

The imaging resist layer was spun on the silicon nitride transfer layer over HMDS adhesion promoter. Generally, $0.5 \mu\text{m}$ -thick AZ 2415 or Microposit 3000-18 was used for pattern definition. These resists could be either optically or E-beam exposed. After the pattern was developed in the imaging resist, it was used as a mask to etch the silicon nitride.

The silicon nitride was etched in a second Technics planar system. The etch gas was 97.5% CF_4 and 2.5% O_2 . The pressure was determined by the gas flow and maintained at 400 mtorr. The wafer was placed on a 20.3 cm grounded electrode, and etching was completed in 48s using 50W applied power. The wafers were given a 9s dip in Transene buffered HF before nitride etching. Following the nitride etch, the wafers were baked at 100°C for 1h.

Reactive ion etching of the planarization layer was done with 13.56 MHz rf power applied to the bottom electrode of a Plasma Therm PK 1241 reactor. The electrode was 25.4 cm in diam, and the chamber volume was 13.5 liters. The applied power was varied between 50 and 450W, while the gas pressure and flow rate were held constant.

The etch gas used was MOS purity oxygen from Matheson. The flow of gas into the chamber was controlled by mass flowmeters. The pressure was held constant by an automatic venetian-blind valve controlled by a capacitance manometer. Pressures between 5 and 100 mtorr were studied. All etching was done with both electrodes maintained at 40°C .

In order to determine the etch rate, the samples were etched for varying time periods such that none of the etches completely removed the resist. Measurements were made from SEM photos of the etch depth and the amount of undercut. Etch rates were calculated from these data. The average etch rate and the standard deviation from the mean are reported. The amount of resist undercut, as measured at the resist-nitride interface, divided by the etch depth for the same time period is defined as the degree of isotropy. The degree of isotropy is a quantitative measure of the resist profile.

Silicon Nitride

The silicon nitride film that was plasma deposited in the system described above had an index of refraction of 1.81 ± 0.02 . This should be compared to the index of refraction of stoichiometric Si_3N_4 , which is 1.98. The lower index of the film deposited in our system suggests that it is nitrogen-rich material. This material can be deposited with a thickness uniformity of better than 5% over the surface of the wafer and less than 3.5% between three 3 in. wafers in the same run. The material which is deposited is more chemically reactive than either thermally deposited silicon nitride or plasma-deposited nitride, which is deposited at a higher temperature. The material being described etches in Transene-buffered HF at $700 \text{ \AA}/\text{min}$. For comparison, plasma nitride deposited at 250°C etches at $500 \text{ \AA}/\text{min}$; the etch rate of material deposited at 325°C is $300 \text{ \AA}/\text{min}$; 750°C thermal nitride etches at $100 \text{ \AA}/\text{min}$ in BHF. In a CF_4/O_2 plasma which is 2.5% O_2 , the etch rate of the 125°C plasma nitride is $1400 \text{ \AA}/\text{min}$. The etch is nearly isotropic, but since only 1000 \AA of nitride is being defined, the pattern dimensions can be preserved by stopping the etch just as the endpoint is reached.

Prior to silicon nitride deposition, the planarizing resist was hard-baked in a convection oven where the

Fig. 2. Schematic drawing of planar reactor for the plasma deposition of silicon nitride. Material is deposited at 125°C by coreaction of N_2 , NH_3 , and SiH_4 with flows 37, 4.5, and 33.4 sccm, respectively, and a total pressure of 400 mtorr. The power is 50W.

minimum bake conditions were 200°C for 30 min. Baking at a temperature lower than 200°C resulted in a wrinkled photoresist layer with a textured silicon nitride layer on top of it. This is illustrated in Fig. 3. During plasma deposition of silicon nitride, the surface of the AZ 2430 planarizing resist was heated to temperatures greater than 125°C. At these temperatures, cellosolve acetate is volatilized from AZ resists and nitrogen gas is also released from decomposition of the photoactive compound (8). If the planarizing resist is not prebaked, these gases will be released during the silicon nitride deposition resulting in a wrinkling of both films. Shaw *et al.* (8) determined that for AZ 1350J photoresist, samples had to be heated to 160°C to remove all volatile components. For AZ 2430, samples must be heated to 200°C to prevent wrinkling.

Under some conditions, the silicon nitride film became completely resistant to a CF_4/O_2 plasma etch. It is believed that the silicon nitride surface becomes oxidized after it is deposited. This oxynitride surface layer can be removed in Transene-buffered HF. It was found that a 9s dip in buffered HF is the minimum time required to completely eliminate this unwanted film. After 9s the "oxide" layer was removed and almost all 1000Å of the silicon nitride film remained. The source of this oxide contamination is still being investigated.

After the CF_4/O_2 plasma etch of the nitride transfer layer, the wafer was baked at 100°C in a convection oven for 1h. The baking step was performed to prevent the nitride erosion seen in Fig. 4, which is a scanning electron micrograph of the multilayer resist after the planarization layer has been etched using the silicon nitride layer as a mask. This nitride erosion results in images substantially smaller than those originally defined in imaging resist, as well as ragged edges on those features. It is believed that the erosion is caused by the presence of fluorine in the plasma at the beginning of the oxygen RIE step. This fluorine may be trapped on the surface of the imaging resist during the CF_4/O_2 plasma etch of the nitride. Microprobe analysis has indicated the presence of fluorine

Fig. 3. SEM plots of silicon nitride transfer layer which was deposited on AZ 2430 which was not hard baked. Temperature increase during the deposition process causes both the resist and the nitride film to wrinkle.

Fig. 4. Multilayer resist after nitride layer and planarization layer are etched. Ragged edges are caused by unwanted fluoride etching of the silicon nitride. The fluorine contamination can be removed by baking the wafer after the nitride etch.

in this layer, while Dobkin and Cantos (9) also found evidence for this in their work. Oxygen RIE removes the top imaging resist as well as the bottom planarizing resist, an interaction which releases the trapped fluorine to react with the silicon nitride transfer layer. The fluorine is only present at the beginning of the O_2 etch, because it is only released from the surface of the imaging resist.

The problem arises when the imaging resist does not have a square profile. Poor resist profiles are dome shaped, being thinner near the edges of the feature than in the middle. If the edges of the imaging resist are removed very early in the oxygen etch, the silicon nitride will be exposed to reactive fluorine. This is probably the cause of the nitride erosion. One solution to the problem would be to have resist profiles which do not have sloping walls, since this would assure that all fluorine is removed from the surface of the photoresist and pumped away before any silicon nitride is uncovered. An empirical solution to the problem has been to bake the sample before the oxygen RIE step is done. It is believed that the baking releases the fluorine from the surface of the photoresist; however, we have been unable to confirm this with a microprobe experiment because the fluorine signals are very small.

Reactive Ion Etching and Profile Control

Once the features were defined in the silicon nitride layer, it was used as a mask for etching the thick planarizing resist. This resist was etched in a low pressure oxygen plasma. The wafers were placed on the powered electrode so that they received high ion bombardment. Figure 5 shows the measured degree of isotropy as a function of chamber pressure and rf power. The degree of isotropy is a quantitative way to describe the profile of the etched resist and silicon nitride mask, and is defined as the lateral etch rate divided by the vertical etch rate. Figure 5 shows that power has very little effect on changing the degree of isotropy. Large variations in the degree of isotropy do occur when the pressure is varied. Completely anisotropic etching occurs only at pressures below 5 mtorr and powers greater than 150W. The dependence

Fig. 5. Degree of isotropy of hard-baked AZ 2430 after oxygen RIE. The ratio of lateral to vertical etch rate is shown as a function of rf power for several system pressures.

of the degree of isotropy on oxygen pressure and rf power will be discussed further in another paper (10).

The vertical etch rate of the planarizing resist is plotted against power for constant pressure values in Fig. 6. Except for the data taken at 100 mtorr, the etch rate increases linearly with power input. At 100 mtorr, the etch rate increases with power, but not linearly. As the rf power input into the system increases over the range studied, the electrons in the plasma acquire a higher average energy. As the electron energy increases, the number of ionizing collisions increases (11). Ionization of the oxygen molecules produces positive ions, which are accelerated vertically toward the wafer by the sheath potential. Increasing the rf power increases both the number of positive ions and the sheath potential so that the vertical etch rate is seen to increase with the power.

The effect of varying the system pressure on the etch rate is more complicated. At low pressures (less than ~ 100 mtorr), the etch rate increases with increasing pressure because the number of reactive species increases with the increasing number of electron-molecule collisions. (There are more O₂ molecules available for collisions at higher pressures.) As the number of molecules increase with increasing pressure, the time between electron-molecule collisions decreases. This shortened time results in lower average electron energy because the electric field has less time to accelerate the electron before it collides (12). The lower average electron energy results in fewer

Fig. 6. Etch rates for hard-baked AZ 2430 in an oxygen plasma. The etch rates are given as a function of rf power for several system pressures.

collisions energetic enough to ionize the molecular oxygen. At pressures greater than ~ 100 mtorr, the number of ionizing collisions starts to decrease as the pressure is increased, as seen in Fig. 6.

Reactive ion-etch parameters can be chosen based on the information in Fig. 5 and 6. Gas pressure and rf power determine the degree of isotropy obtained in the planarizing resist profile. The etch rate data are used to determine the etch time to endpoint. Figure 7 shows the multilayer resist which has been defined anisotropically. The imaging resist layer is removed during the oxygen RIE so the SEM photograph only shows the etched transfer and planarization layers. The imaging resist, Microposit 3000-18, was exposed with electrons. By using electron beam lithography, features as small as $0.3 \mu\text{m}$ have been processed with this multilayer scheme. Etching beyond endpoint produces a film on the sidewalls of the planarizing resist on silicon substrates. It is believed that these films are similar to those described by Kinsbron (13). On silicon substrates, the sidewall film is probably some silicon-oxygen compound and is easily removed in buffered HF.

Figure 8 shows the multilayer resist processed with an undercut so it can be used for lift-off definition of metals. The degree of isotropy is 0.25, and $0.4 \mu\text{m}$ of a metal alloy has been deposited over the multilayer resist. The degree of isotropy is reproducible within the error bars shown in Fig. 5. This reproducibility leads to well-controlled lift-off profiles. The thick planarization layer makes it possible to define very tall features. The silicon nitride transfer layer has supported as much as a $1.5 \mu\text{m}$ layer of Ti/Au alloy without any signs of strain. After the metal has been deposited over the multilayer resist, the planarizing resist must be dissolved to carry away the excess metal. Resists baked at 200°C are not soluble in acetone, the usual lift-off solvent. A commercial epoxy remover, Uresolve Plus (Dynaloy, Incorporated), is suitable for removing the hard-baked resist in the final lift-off step. Uresolve Plus is strongly alkaline and is not suitable for lift-off directly on GaAs. Other, less caustic solvents are being sought for this application.

Fig. 7. Anisotropically etched AZ 2430 with a Si₃N₄ mask. The imaging resist which was removed in the oxygen RIE step was patterned using E-beam lithography.

Fig. 8. Multilayer resist processed with an undercut suitable for lift-off metal deposition. $0.4 \mu\text{m}$ of Ti/Au is deposited on the resist structure.

Summary

A very flexible multilayer resist system has been developed using positive resists and plasma-deposited silicon nitride. The low temperature plasma nitride can be uniformly deposited over the surface of the wafer, resulting in a three-layer system which is completely transparent, making optical alignment possible. The imaging resist can be either optically or E-beam exposed, and no charging occurs during the E-beam exposure.

Reactive ion etching of the planarizing resist produces controllable profiles. The profile can be varied from vertical wall to any degree of isotropy desired for a lift-off application. Characterization of the etch rate and degree of isotropy as a function of pressure and power has led to predictable and reproducible resist profiles.

Effective Segregation Coefficient of Boron in Silicon Ingots Grown by the Czochralski and Bridgman Techniques

P. S. Ravishankar,* L. P. Hunt,* and R. W. Francis*

Exxon Research and Engineering Company, Solar Electric Conversion Unit, Linden, New Jersey 07036

ABSTRACT

Hall measurements and four-point probe resistivity measurements were used to determine the concentration profile of boron in doped semiconductor silicon ingots grown by Czochralski and Bridgman techniques. The concentration profiles were fitted to the normal segregation equation and the effective segregation coefficient, k_{eff} , was calculated. The average value of k_{eff} for boron was 0.786 ± 0.036 in Czochralski single crystals and 0.803 ± 0.036 in Bridgman polycrystals.

Silicon made by carbothermic reduction of silica in an arc furnace is becoming increasingly important as a source of low cost silicon for solar cells (1-3). The arc furnace-derived silicon normally contains both boron and phosphorus doping impurities which are difficult to assay reliably by chemical analysis. Multiple recrystallization of the arc furnace silicon and Hall measurements on the crystals thus obtained has been suggested as an accurate method of determining boron and phosphorus concentration in arc furnace silicon

(4). The method, however, requires an accurate knowledge of segregation coefficients for these impurities. This information is also necessary to estimate the extent of purification achievable by crystal growth.

An equilibrium distribution coefficient is based strictly on thermodynamic considerations. It is normally calculated from a phase diagram as the ratio of the slope of solidus to liquidus. However, in practice, this value of the distribution coefficient can be approached only at slow growth rates and for solidification from well stirred melts. Therefore, it is customary

to define an effective segregation coefficient, k_{eff} , as

$$k_{\text{eff}} = x_s/x_1 \quad [1]$$

where x_s and x_1 are the concentrations (atom fraction) of an impurity in the solid at the solid/liquid interface and the bulk melt, respectively. Unlike the equilibrium coefficient, the value of k_{eff} is dependent on the actual crystal growth conditions such as growth rate, amount of stirring in the melt, etc. Therefore, this value will, in general, be different for different methods of crystal growth.

A survey of the literature for k_{eff} of boron can be somewhat disquieting. For the Czochralski technique, reported values vary from 0.7 to 0.85 (5-7). An even wider range is found for float-zone recrystallized material. Even though 0.8, with only one significant digit, is the traditionally accepted segregation coefficient for boron, it is not certain whether this is an effective or an equilibrium value, k_{eq} .

In this paper, a procedure is reported for the experimental determination of the effective segregation coefficient of boron in specific Czochralski and Bridgman crystal growth systems. The normal segregation equation

$$x_s = x_0 k_{\text{eff}} (1 - g)^{k_{\text{eff}} - 1} \quad [2]$$

is rearranged in logarithmic form as

$$\ln (x_s/x_0) = \ln k_{\text{eff}} + (k_{\text{eff}} - 1) \ln (1 - g) \quad [3]$$

where x_0 is the initial impurity concentration in the melt. A log-log plot of Eq. [3] results in a straight line, and k_{eff} can be calculated from both the slope and the intercept.

Description of Experiments

The Czochralski crystals were grown in a HAMCO CG-2000 Czochralski crystal grower. Crystals of <111> orientation were pulled from a 20 cm diam quartz crucible containing 6 kg of semiconductor grade silicon doped with boron to $\sim 0.3 \Omega\text{-cm}$. The crucible and seed were counter rotated at 15 and 8 rpm, respectively. The operation was carried out in argon at 14 torr. The ingots were grown at constant growth rates of 5 and 10 cm/h. The ingot diameters were not constant, but averaged either 5 or 7.5 cm. Slices were cut at several (about 5) locations along the ingot. Accurate weights for the appropriate crystal sections were measured in order to permit determination of the values of fraction solidified, g , for a given slice. The concentration of boron in the crystal, x_s , was determined by Hall measurements made on the individual slices. Using Eq. [3], a plot of $\ln (x_s/x_0)$ vs. $\ln (1 - g)$ was made. The slope and intercept for the straight line were obtained by a least squares fit.

The Bridgman crystals were grown by a directional solidification of semiconductor silicon doped to $\sim 0.3 \Omega\text{/cm}$. The freezing rates for these crystals ranged from 1 to 2 cm/h. A vertical section of the resulting polycrystalline ingot was etched in NaOH. Several four-point probe measurements were made at various positions (about 10) along the vertical axis. An average resistivity of several (about 4) readings at each location was converted to concentration using the equation suggested by Thurber *et al.* (8). The interface shape for different growth conditions was estimated from experiments where this parameter was

measured independently. From the interface shape, the value of the fraction solidified was calculated geometrically. The g vs. x_s data were treated as described for Czochralski crystals.

Discussion of Results

Single-crystal silicon.—Table I shows k_{eff} calculated from the slope and intercept for Czochralski crystals grown under different conditions. The square of the correlation coefficient R^2 is also shown in the table. Its value close to unity demonstrates a good linear fit to the data. The difference between the value of k_{eff} as estimated from the slope and the intercept is expressed as a percentage error in Table I. Since the intercept value requires a knowledge of x_0 and the slope value is independent of x_0 , the value from the slope should be more reliable. The small variation in k_{eff} from slope can be attributed to errors in the measurement of g . The value from the intercept is within 10% of the slope value. This error probably represents the accuracy with which a few milligrams of boron can be weighed for use as the dopant. In Table II, the mean value of k_{eff} from the slope is given for the crystals grown at the same growth rate and also for all four crystals combined. Within experimental error, the mean k_{eff} seems to be independent of growth rate. Therefore, it can be concluded that k_{eff} is 0.786 ± 0.036 for this particular Czochralski process and equipment.

Though calculation of k_{eq} requires knowledge of the phase diagram, it is possible to estimate this value from k_{eff} . For example, the BPS model (9, 10) relates k_{eff} to k_{eq} , by the equation

$$k_{\text{eff}} = \frac{k_{\text{eq}}}{k_{\text{eq}} + (1 - k_{\text{eq}}) \exp \{-V\delta/D\}} \quad [4]$$

According to Eq. [4], k_{eff} should increase as $(V\delta/D)$ increases. The results given in Table II show that, if anything, the mean k_{eff} decreases slightly as V is increased. This is the basis for the conclusion that the variation of k_{eff} with V is not significant.

Rearranging Eq. [4],

$$\ln [(1 - k_{\text{eff}})/k_{\text{eff}}] = \ln [(1 - k_{\text{eq}})/k_{\text{eq}}] - (V\delta/D) \quad [5]$$

If sufficient data were available at each growth rate, a plot of Eq. [5] should give a straight line of slope (δ/D) and intercept $(\ln [(1 - k_{\text{eq}})/k_{\text{eq}}])$ from which k_{eq} can be calculated. Since sufficient data were not available, this procedure was not carried out. However, it can be concluded that the measured k_{eff} is probably very close to k_{eq} .

Polycrystalline silicon.—The data for polycrystalline silicon is shown in Table III. In some cases, k_{eff} calculated from the intercept deviates by as much as

EB-104	0.975	0.822	0.683	16.9

Mean k_{eff} from slope = $0.803 \pm 0.036^*$.

* 95% confidence limits.

27.5% from the slope value. As discussed before, this error may be caused by the error in x_0 . It is important to note that the k_{eff} from the slope, which is independent of x_0 , has much less scatter. The mean k_{eff} from the slope for all five of the ingots is 0.803 ± 0.036 . The significance of the difference between this value and the value obtained for Czochralski growth depends on the confidence one wishes to place in the data. However, the higher value of k_{eff} for Bridgman growth is consistent with the fact that there is much less stirring in Bridgman growth than in Czochralski growth.

Conclusions

1. The effective segregation coefficient, k_{eff} , for Czochralski growth is 0.786 ± 0.036 .
2. For the range of growth rates used, k_{eff} is independent of growth rate within experimental error. This suggests that the measured k_{eff} is probably very close to the equilibrium value, k_{eq} .
3. k_{eff} in polycrystalline silicon grown by the Bridgman method is 0.803 ± 0.036 .

ABSTRACT

A significant influence of thermal nitridation on the electrical characteristics of nitroxide films was found in this study. Nitridation at temperatures lower than 1000°C results in a great negative shift of flatband voltage V_{FB} . However, the value of V_{FB} continuously decreases with the increasing of nitridation time at nitridation above 1000°C. After annealing of nitroxide films in N₂ gas at 1000°C for 30 min, a decrease of V_{FB} , compared with the same nitridation conditions, was observed. From quasi-static C-V measurements, it shows that not only interface fixed charge Q_{ss} but also surface-state density N_{ss} are reduced in the decreasing of V_{FB} after annealing the films in N₂ gas. This effect is more prominent for nitridation at lower temperatures; however, there still exists some degree of reduction in V_{FB} for nitridation at higher temperature and longer time. The negative bias-temperature instability, sometimes called "slow trapping," is revealed by accelerated aging with negative gate bias at elevated temperatures. It is found that the instability problem is more severe for samples which are nitrided at lower temperatures but N₂ annealing can reduce the negative bias-temperature instability. After N₂ annealing, nitroxide films prepared with nitridation above 1150°C provide good properties for MOS devices.

Currently, thermally grown SiO₂ film is used as a gate insulator in MOSLSI's. According to the scaling method (1), a reliable thin insulator is required for VLSI applications. However, due to several serious problems of thin SiO₂ films, including low resistivity to the diffusion of impurities (2, 3), high field instabilities (4-7), and hot electron effects (8-9), we can expect that the quality of SiO₂ films becomes inadequate for VLSI devices when the thickness of the gate oxide is getting thinner.

Thermal nitridation of SiO₂ is considered to be the best candidate to replace SiO₂ as the gate insulator in films less than 300Å thick since this material has demonstrated excellent masking characteristics against diffusion of impurities, remarkable improvement in dielectric breakdown voltages, larger dielectric constant, and good stability of MOS structure (10-12).

In this study, relatively thick nitroxide films (around 650Å), instead of thinner nitroxide films, were chosen because we could eliminate the poor quality factor caused from unreliable thin oxide films. This paper shows that the interfacial characteristics of MOS structure can be improved by applying N₂ annealing on nitrided oxide films.

Experimental

Electrical measurements were made on MOS structures. In this experiment, n-type, (100) oriented silicon wafers, with resistivities ranging from 4 to 7 Ω-cm, were used. These wafers were cleaned in a hot solution of H₂SO₄ + H₂O₂ and rinsed in deionized water. Oxide films with thicknesses of around 650Å were thermally grown on the wafers in the ambient of wet oxygen gas. The oxidized wafers were proceeded to thermal nitridation in ultrapure ammonia gas. The nitridation temperature and time were varied from 900° to 1200°C and from 30 min to 3h, respectively. After this process, the wafers were divided into two groups. There was a group with no additional processing, the others were annealed in nitrogen gas at 1000°C for 30 min. 1 μm in thickness of aluminum was deposited on the wafers, and a metal pad of 100 mil² was then patterned using the conventional lithography and etching techniques. After metallization, the wafers were sintered at 450°C in forming gas for 30 min.

The value of flatband voltage V_{FB} was calculated on C-V curves. Bias-stress tests using an applied volt-

age of -20V were made on MOS capacitors at 300°C for 3 min to reveal the negative bias-temperature instability. A quasi-static C-V technique was used to determine the interface fixed charge Q_{ss} and surface-state density N_{ss} .

Results

For samples without N₂ annealing, the changes of flatband voltages V_{FB} with respect to nitridation temperature and time are shown in Fig. 1. Nitridation at temperatures lower than 1000°C results in a great

Fig. 1. The changes of flatband voltages V_{FB} with respect to different nitridation temperature and time for samples without N₂ annealing.

Table I. Q_{SS} and midgap N_{SS} vs. nitridation time for samples that were nitrided at 950°C and received N_2 or no N_2 annealing

	NO N_2 annealing				N_2 annealing			
	30 min	60 min	90 min	180 min	30 min	60 min	90 min	180 min
Q_{SS} (cm^{-2})	6.6×10^{11}	5.07×10^{11}	4.92×10^{11}	2.2×10^{11}	5×10^{11}	3.18×10^{11}	2.14×10^{11}	1.04×10^{11}
N_{SS} ($cm^{-2}ev^{-1}$)	7.82×10^{10}	4.68×10^{11}	5.08×10^{11}	5.55×10^{11}	5.78×10^{10}	4.4×10^{11}	4.55×10^{11}	4.96×10^{11}

negative shift of V_{FB} . However, as temperature increases above 1000°C and nitridation time exceeds 90 min, the V_{FB} value rapidly decreases. Figure 2 shows the changes of V_{FB} for samples that were N_2 annealed, the curves have similar tendency of variation to Fig. 1, but V_{FB} is smaller compared with the same nitridation conditions. As temperature increases above 1100°C and reaction for 180 min, the samples have nearly the same value of V_{FB} .

For samples that were N_2 annealed, the decrease of V_{FB} corresponds to the reduction of N_{SS} and Q_{SS} . This can be clearly seen in the representative data shown in Table I. These data are obtained from samples which were nitrided at 950°C by using quasi-static C-V technique.

Table II shows data of midgap N_{SS} and Q_{SS} for samples which were nitrided at 1150°C and had been annealed in N_2 gas. Both Q_{SS} and midgap N_{SS} can be reduced to the order of 10^{10} for a nitridation time longer than 90 min.

Upon negative bias-temperature aging, the slow trapping is revealed in the shift of the high frequency C-V curve to a more negative direction. The magnitude of flatband voltage difference ΔV_{FB} reflects the degree of instability. The dependence of ΔV_{FB} on nitridation temperatures with reaction time varied from 30 to 180 min and is shown in Fig. 3. ΔV_{FB} increases with the

increasing of nitridation time for temperatures lower than 1150°C and nearly saturates at higher temperatures of 1150° and 1200°C. However, samples that were N_2 annealed consistently achieve lower ΔV_{FB} values.

Fig. 3. The dependence of flatband voltage of different ΔV_{FB} on various nitridation temperatures and time for samples with and without N_2 annealing.

Discussion

As seen in Fig. 1, with the increase of nitridation time the negative shift of V_{FB} increases significantly at 900°C and decreases explicitly at elevated temperatures above 1000°C. This phenomenon might be interpreted as the following mechanism. At first, the hydrogen gas produced during ammonia nitridation processing dissolves into the SiO₂ skeleton. Then, the dissolved hydrogen molecules react with the surrounding Si-O bondings, forming the dangling bonds. Both N_{ss} and Q_{ss} , therefore, increase significantly and cause the V_{FB} shift phenomenon (2). The V_{FB} shift consequently is strongly related to the solubility of hydrogen gas in a SiO₂ layer. Since the hydrogen molecule is very small in molecular diameter and has nonpolar characteristics, the solubility of hydrogen in SiO₂ may be assumed to be similar to its solubility in aqueous solution (13). That is, the hydrogen solubility in a SiO₂ layer may decrease with the increase of temperature and be negligibly small at elevated temperatures above 1000°C compared with that at 900°C. Consequently, the dangling bond formation at temperatures above 1000°C is not explicitly seen.

The slow trapping instability can be a major threat to reliability of p-channel MOSFET. The mechanism of slow trapping has not been established. However, the effect is greater when initial Q_{ss} or N_{ss} is large (14, 15). In the case of Table I, N_{ss} exhibits the reverse. Comparing Fig. 3 with Table I, we can conclude that the increase of ΔV_{FB} is due to the increase of N_{ss} .

After N₂ annealing, the atomic bonds at the interface of silicon and nitroxide can be rearranged (16). Both N_{ss} and Q_{ss} are reduced to a certain amount, therefore, V_{FB} and ΔV_{FB} also decrease. This effect is clearly shown in Fig. 2 and Fig. 3.

Conclusion

The electrical characteristics of the nitroxide films were studied. The negative direction shift of V_{FB} due to the deterioration of hydrogen gas can be alleviated by N₂ annealing. Such an anneal also reduces the negative bias-temperature instability.

N₂ anneal is recommended for nitroxide films which are prepared with nitridation above 1150°C to achieve stable device operational characteristics.

ABSTRACT

This work focuses on the quality of epitaxial silicon deposited when the total thickness grown is in the range of 0.5-0.9 μm from the initial physical interface. Shallow junctions were fabricated to evaluate device potential of the thin films. Defect levels were evaluated. The ability to reproduce doping profiles was also evaluated. The studies have shown that the epitaxial silicon deposited to 0.5 μm thickness is suitable for device fabrication.

This study has focused on evaluation of the quality of the epitaxial silicon deposited to thicknesses in the 0.5 μm range. The concerns with regard to the silicon quality this close to a physical interface included: (i) whether doping profiles could be reproduced and thicknesses controlled, (ii) whether defect levels arising from the interface would have an effect on devices, and (iii) whether the silicon obtained would be suitable for device fabrication.

* Electrochemical Society Active Member.

Experimental

The concentration profiles in this study were obtained by spreading resistance measurement technique. Figures containing spreading resistance data show either the raw data of spreading resistance in ohms vs. depth in microns, or data converted to log of the dopant concentration vs. depth from the surface. The spreading resistance data was obtained on samples beveled to angles of 20 min. An Automatic Spreading Resistance Probe (Solid State Measurements, Incorpo-

rated) was employed. Error corrections were made using methods developed by Hu (1). In addition to the spreading resistance data, SIMS data were taken on a number of films for comparison and cross checking (Fig. 5 and 6 show examples of such comparisons). Figure 1 shows a diagrammatic representation of concentration profiles as shown in later figures and discussed below. The physically thin epitaxial films were deposited to a total thickness of 0.5–0.9 μm from the initial growth interface. Sharp transitions (0.06–0.15 μm) from the arsenic n^+ buried layer at a concentration of 1×10^{19} atoms/cm³ in the silicon substrate to a 2×10^{16} atoms/cm³ level were obtainable using the High-Lo Epi process described elsewhere (2–5), which employs a $\text{SiCl}_4\text{-H}_2$ system at atmospheric pressure. Films were deposited at 1050°C in an AMT 1200 epitaxial reactor with different process variations for the epitaxial depositions, as described below. Referring to the schematic concentration profile of Fig. 1, for purposes of discussion, "flat zone" is defined as the distance from the surface to a concentration of 1×10^{17} atoms/cm³ in the epitaxial layer. "Transition region" is the depth required to go from a concentration of 1×10^{17} atoms/cm³ to the subcollector concentration value of 1×10^{19} atoms/cm³.

Occurrence of defects in the films, such as oxidation stacking faults, epitaxial stacking faults, and hillocks, were evaluated using wet chemical decoration techniques similar to those described in previous work (6, 7). Wright etching (8) times were kept to below 1 min because of the thinness of the films. In addition to Wright etch decoration, anodic etch was used to monitor the electrically active defect sites. Etch current characteristics *vs.* time were examined for films in the 0.5–3.0 μm range. For the anodic etching, the epitaxial film surfaces were exposed to a dilute HF solution (used as the electrolyte), while a positive voltage was applied to the substrate wafer. A platinum wire in the solution acted as the cathode. Conditions used for the anodic etching were varied. In general, an HF concentration of 5% was employed. An applied voltage of 2–3V was generally used for the thin films and 10V for the films greater than 1 μm ; 10–60s were typical times employed for the anodic exposure. After Wright etch and anodic etch, microscopic examination of the etched sites was made.

To evaluate the device potential, shallow junctions were formed in the uniformly doped regions. Junctions

were formed in the lightly doped n-type films by diffusion using CVD boron-doped polycrystalline silicon films as a diffusion source. Diffusion was at a temperature of 900°C for 30 min. Breakdown voltages and diode leakage measurements were made on the junctions formed.

Results and Discussion

Concentration profiles.—To develop a sharp concentration profile in the thin films, a preliminary evaluation of autodoping relative to input-dopant concentration was carried out. A series of epitaxial films were deposited wherein all variables were held constant except deposition time (see Table I, runs 1, 2, 3, and 5). These films were deposited on arsenic-doped substrates ($\sim 10^{19}$ atoms/cm³). The process sequence used for these runs included a 17 min prebake and thermal equilibration to 1150°C to produce surface outgassing and to minimize autodoping. This was followed by deposition at 1050°C for the times shown in Table I. A postbake of 1 min followed each deposition time before ramp down. Spreading resistance curves for runs 1, 2, 3, and 5 in this series are plotted in Fig. 2 and show a decreasing sharpness in profile with increasing deposition time at constant doping input. Run 4 in Fig. 2 (curve 4) was grown with no doping introduced to test effectiveness of the dopant input concentration being employed. The fact that this run did not produce a surface concentration or profile significantly different than the other runs indicated that the input concentration of 32 cm³/min of 50 ppm arsine in H_2 was insufficient to affect the film profile and indicated that the profiles obtained were entirely due to autodoping from the substrate. For comparison, curve 6 has been included in Fig. 2. This film was deposited for 22 min with all conditions similar to the 32 cm³ dopant input series except that the dopant was increased to 48 cm³/min. This increased dopant input leads to the sharpness observed in the profile and indicates that intentional doping predominates over autodoping. The importance of determining the proper doping level following prebake to achieve abrupt transitions in thin epitaxial films is thus demonstrated in these experiments.

The effect of varying time at this higher doping input is shown in Fig. 3. The film profiles in this figure were obtained using the same growth conditions as in Table I, except that deposition times of 22, 17, and 14 min were used for curves 7, 8, and 9, respectively. It will be noted that the abrupt profile is retained with the higher doping level with decreasing time even as the films become thinner. The flat zones and transition regions for the curves are given in Table II. Table III summarizes key refinements used to develop the sharp transitions in the films. A High-Lo- (2-5) type process sequence was used. This included a high tem-

14	0.57	0.079	1	8

characteristics desired, having a flat zone of 0.495 μm and a transition region of 0.087 μm. More detailed features of this particular profile are given in Fig. 5. Figure 6 shows SIMS data for this same film. The concentration of the flat zone, as well as the general overall profile, is slightly higher than the value obtained by spreading resistance; however, the transition region and measured depths are similar. This run had an 1150°C prebake for 15 min. A somewhat thinner film was achieved in run 12 with a doped epi deposition time cut to 6 min. The flat-zone and transition regions are retained, indicating that this process can perhaps be extended to even thinner epi.

Runs 13 and 14 were experiments where total deposition time was held constant while the doped and undoped epi thicknesses were varied. Run 13 had a 3 min undoped region and a 6 min doped region, and

Fig. 5. Spreading resistance As concentration profile in a 0.65 μm thick epitaxial film.

Fig. 6. SIMS As concentration profile in 0.65 μm thick epitaxial film.

14 had a 1 min undoped region and an 8 min doped region. These variations had little effect on the transition region but did change the flat-zone thickness. There seems to be little advantage to making these thickness changes, though further study may be warranted. It would appear more desirable to pursue reducing the temperature of the epi growth in order to improve the sharpness in the transition region.

Reproducibility of the process in duplicating doping profiles was evaluated for a more typically used film deposited on ion-implanted blanket subcollectors doped to $\sim 10^{19}$ atoms/cm³. The results are summarized in Table IV.

Defects.—Defects in the films, such as oxidation stacking faults, epitaxial stacking faults, and hillocks, were examined using wet chemical decoration. Overall defect levels ($\sim 10^2/\text{cm}^2$) were found to be no higher than levels for thicker films (1–2 μm). In addition to Wright etch decoration, anodic etch was used to monitor the electrically active defects in the films. Etch current characteristics *vs.* time were examined for films in the 0.5–3.0 μm range. Current profiles during the anodic etching is a function of epitaxial film doping and thickness as well as defect levels. Films of higher quality (low defect counts) on similarly conductive (n^+) substrates required longer etch times to show a rapid current rise characteristic in the etch curves at punch through to the conductive substrate. The epitaxial stacking faults were more commonly

revealed with the anodic etching treatments. A number of the thin films were oxidized so that the oxide/silicon interface formed was within 0.2, 0.4, and 0.6 μm of the physical epitaxial interface. The oxide was then stripped. Some of the wafers were subjected to Wright etch, and others were to anodic etching. No oxidation stacking faults were observed except in a few instances at the outer edges of wafers. For the anodically treated samples, the etch curve characteristics for the films (representing different distances from the interface) indicate that fewer defects are present as one approaches the epitaxial physical interface. From these observations, it appears that defects arising from the interface are not a limitation in growing thinner films. The anodic etching was done on limited portions of the films. However, extensive sampling of diodes (described below) formed on the thin films was made, and the uniform diode properties overall would indicate electrically active defect levels were sufficiently low such as not to effect the individual devices.

Fig. 9. Typical leakage current distribution for diodes

Diode characterization.—To evaluate the device potential, shallow junctions were formed in the uniformly doped regions, and electrical measurements were made. A histogram of the breakdown voltages is shown in Fig. 7. Forward and reverse diode characteristics are given in Fig. 8. Breakdown voltages of junctions were consistent with film thicknesses and doping concentrations. Leakage measurements on diodes having 40,000 μm^2 areas were in the order of 10^{-11} A. Figure 9 is a histogram of leakage measurements and shows the

epitaxial films to be of excellent quality. Recently, high performance transistor structures have been fabricated and reported for these thin films (0.8-0.9 μm) (9-11).

Optical Etch-Rate Monitoring: Computer Simulation of Reflectance

P. A. Heimann* and R. J. Schutz*

AT&T Bell Laboratories, Murray Hill, New Jersey 07974

ABSTRACT

We report on a numerical simulation of the signal from a laser etch-rate monitor which utilizes changes in the optical reflectance of a layered structure while the top layer is being etched. The simulation can be applied to structures having several layers. For a strongly absorbing layer such as aluminum ($k = 7.1$), the reflectance is constant until the layer has been etched completely. For a moderately absorbing layer such as a transition-metal silicide (k between 1.5 and 2.5), light can be transmitted through the film and can be reflected from the underlying layers when the silicide has been etched down to a few hundred angstroms thick. The only required parameters are the wavelength of the light, and, for each layer, the indexes of refraction and absorption, the initial thickness, and the etch rate. It can also be applied to cases where portions of the film area are being etched at different rates, such as when part of the film is covered with photoresist. The simulation is applied to several etch processes, including silicide-polysilicon gate and metallization etches. Good agreement is found between experimental and calculated data.

The technique of etch-rate monitoring and endpoint detection by optical reflectance is becoming more widely used (1-3). Advantages of this technique include the simplicity of the apparatus, the insensitivity of the reflectance to changes of the etching gases, process parameters or etch rate, and the fact that it can provide a continuous monitor of the etch rate. In order to make full use of this technique, a detailed simulation of the reflectance vs. etching time is desirable.

When monochromatic radiation is reflected from a layered structure whose transparent (or semi-transparent) top layer is being etched, the intensity of the reflected radiation oscillates. This periodic change in intensity is due to the interference of waves reflected from the outer and interior surfaces of the structure. The signal is relatively easy to explain for a single layer on an opaque substrate. For a multilayered structure, subtle changes in signal,

Electrochemical Society Active Member.

which are meaningful but difficult to interpret intuitively, often occur. Therefore, a computer program has been written to calculate the reflectance of up to four layers plus a substrate and to include the interference from adjacent areas with different structures and etch rates. The program runs on a Honeywell 6000 computer and provides graphic as well as numerical output.

Theory

The theory of multilayer reflectance is described in many books on optics, and will not be repeated here, except for a brief description of the matrix method (4,5) for calculating reflectance. The effect of each layer j (see Fig. 1a) upon the incident light is described by a 2×2 complex matrix C_j

$$C_j = \begin{bmatrix} \exp(i\delta_{j-1}) & \tau_j \exp(i\delta_{j-1}) \\ \tau_j \exp(-i\delta_{j-1}) & \exp(-i\delta_{j-1}) \end{bmatrix} \quad [1]$$

Fig. 1. a: Parameters for calculation of multilayer reflectance. b: Reflectance from more than one type of structure on a wafer. Dashed line shows extra layer of vacuum for multiple-area calculations.

with

$$\bar{r}_j = \frac{\eta_{j-1} - \eta_j}{\eta_{j-1} + \eta_j} \quad [2]$$

$$\eta_j = n_j + ik_j \quad [3]$$

$$\delta_j = 2\pi d_j \eta_j / \lambda \quad [4]$$

Here n_j is the index of refraction of layer j , k_j is its absorption per vacuum wavelength λ , and d_j is the layer thickness. The absorption k_j is related to the attenuation of light through the layer by

$$I/I_0 = \exp(-4\pi k_j d_j / \lambda) \quad [5]$$

where I and I_0 are the transmitted and incident light intensities, respectively.

The matrix C_i is found by setting δ_0 arbitrarily equal to zero, since the phase shift in the external (vacuum) region does not affect the measured reflectance. Matrices for each layer are then multiplied together in the same order as the corresponding layers (top to bottom) yielding a product matrix \bar{C} . The complex reflection coefficient \bar{r} is defined as the ratio of two elements of \bar{C}

$$\bar{r} = \frac{\bar{C}_{21}}{\bar{C}_{11}} \quad [6]$$

and the measured reflectance R is given by

$$R = |\bar{r}|^2 \quad [7]$$

Using this method, some interesting predictions can be made. For example, it is easy to show that the reflectance is a periodic function of the thickness of the top layer (if it is not strongly absorbing), with one period corresponding to a thickness change Δd given by

$$\Delta d = \lambda/2n \quad [8]$$

Therefore, the optical etch-rate monitor signal repeats itself after etching about 2150\AA ($6328\text{\AA} \div 1.47 \div 2$) of silicon dioxide or about 800\AA ($6328\text{\AA} \div 3.90 \div 2$) of polycrystalline silicon (polysilicon), when using a He-Ne laser

source. This is the periodicity which is widely used for optical etch-rate monitoring, since the etch rate is simply the thickness corresponding to one period, divided by the etch time required to make one complete period. It can also be shown that the variation of reflectance with film thickness approximates a sinusoid when the index of refraction is close to 1.0, and becomes less symmetrical as the index gets larger.

Another result is that, when the thickness of any transparent layer ($k_j = 0$) is an integral multiple of the wavelength of the light in the material, i.e.

$$d_j = N(\lambda/n_j), N = 1, 2, 3 \dots \quad [9]$$

then from Eq. [3] and [4] the term $\exp(i\delta_j)$ has the same value as for zero thickness, and it can be shown that the total reflectivity of the structure is the same as it would be if that layer were absent. This is true not only for the top layer, but also for layers deeper in the structure. One can also show that if the thickness is given by

$$d_j = (N + 1/2)\lambda/n_j \quad [10]$$

then the complex reflection coefficient \bar{r} is the negative of the zero-thickness case, but the observed reflectance R is the same. Therefore, a general rule is that a layer which is an integral number of half-wavelengths thick will have the same optical effect as no layer at all. For example, if the oxide in a polysilicon/oxide/silicon structure is one wavelength thick, then the structure looks like polysilicon/silicon. Since heavily doped polysilicon and lightly doped silicon have nearly the same indexes of refraction, the reflectance is practically independent of polysilicon thickness and cannot be used to monitor polysilicon etching. This undesirable effect has been observed experimentally [6].

A third interesting result, from the standpoint of practical application, is the total reflectance when two different areas on the wafer are etching at different rates. This is the case when part of the wafer surface is covered by a low-etch-rate resist and the remaining area is to be etched at a higher rate. For each area, the reflected light has an amplitude and phase which depends upon the film structure of that area, and the light beams reflected from different areas will interfere with each other (see Fig. 1b). The overall effect of these two types of interference (among light reflected from different layers within an area and among light reflected from different areas) can be calculated by adding the complex reflection coefficients \bar{r}_m corresponding to each area, and then taking the squared amplitude of that sum. This model does not include diffraction at the step edges, but the contribution from this effect is expected to be small if the areas are large compared to λ . The interference of the light reflected from different areas will be treated in detail in a subsequent paper (7).

One method of maintaining the proper phase relationship among the various \bar{r}_m 's is to include the space above all the areas (except the highest) as an additional layer, with the index of refraction for vacuum ($n = 1, k = 0$) and with a thickness such that all areas have the same total thickness (see broken line in Fig. 1b). It can be shown that another method, which does not require this additional vacuum layer, is to redefine δ_{m0} for each area m as

$$\delta_{m0} = -\frac{2\pi}{\lambda} \sum_j d_{mj} \quad [11]$$

where the summation is over all layers except the substrate. This latter scheme is easier to incorporate into a computer calculation. If each area m covers a fraction f_m of the total area, then the overall complex reflection coefficient is

$$\bar{r} = \sum_m f_m \bar{r}_m \quad [12]$$

and the reflectance R is found from Eq. [7].

Examples

In this section, we present the results of simulations of optical etch-rate monitor (OERM) signals for various structures, and compare them to experimental results, where available. All of the curves are based upon the 6328\AA red light from a He-Ne laser. Discrepancies be-

tween calculation and experiment can be caused by uncertainty in the values for indexes of refraction and by slowly varying additive signals due to light emitted by the etching gases.

Polysilicon etching.—The standard polysilicon gate technology requires an etch of polysilicon on field oxide. Figure 2 shows the calculated OERM signals for etching 3200Å of polysilicon on top of field oxides of two different thicknesses. Again, the total thickness being etched can be found by counting cycles of the OERM curve. The small signal for the 4305Å oxide is caused by its integral wavelength thickness and demonstrates the effect described earlier (see Eq. [9] and [10]). Figure 3 shows the signal strength (difference between minimum and maximum reflectivity) vs. oxide thickness. One can see that this effect is detrimental only over narrow ranges of oxide thicknesses, and those thickness ranges can be avoided during device fabrication without placing severe constraints upon device design.

In both Fig. 2a and 2b, the endpoint of the polysilicon etch occurs when the reflectance is close to the minimum value observed during the etch. In fact, the reflectance at this endpoint is always less than halfway between the maximum and minimum reflectance values (see Table I). This fact can be incorporated into automated endpoint detection schemes (8).

Silicide-polysilicon etching.—The simulation is also useful for modeling the etching of an optically absorbing

layer. For a strongly absorbing layer such as aluminum ($k = 7.1$) (9), the reflectance is constant until the layer has been etched completely. For a moderately absorbing layer such as a transition-metal silicide (k between 1.5 and 2.5) (10), light can be transmitted through the film and can be reflected from the underlying layers when the silicide has been etched down to a few hundred angstroms thick. Figure 4 shows calculated OERM signals from etching an aluminum/polysilicon/oxide/silicon structure (a) and a silicide/polysilicon/oxide/silicon structure (b). For the first case, the aluminum is nearly opaque, so the OERM signal is flat during most of the aluminum etch, and it changes only when the metal has been nearly etched away. In this case, the endpoint can be estimated (to within about 100Å) as the point where the signal starts to change. For the second case, the signal starts to change while the silicide is several hundred angstroms thick, and such an estimate would yield a significant error. Figure 5 shows how the structure of the silicide-etch OERM curve

Fig. 4. Calculated OERM signal for structures of aluminum/polysilicon/oxide/silicon (a) and silicide/polysilicon/oxide/silicon (b). In both cases, the top layer is 2000Å thick and etches at 1000 Å/min, the polysilicon is 3404Å thick and etches at 500Å/min, and the oxide is 3229Å thick. Arrows indicate transition from metal or silicide etching to polysilicon etching.

SILICIDE/POLYSILICON ON FIELD OXIDE

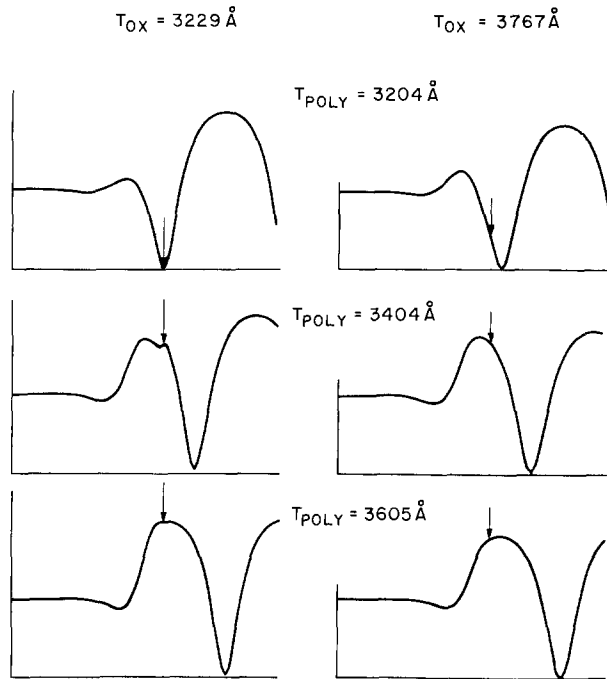

Fig. 5. Calculated OERM signal for a silicide/polysilicon/oxide structure, for various values of polysilicon thickness (T_{POLY}) and oxide thickness (T_{OX}). Arrows indicate transition from silicide etching to polysilicon etching.

is affected by the thickness of the underlying polysilicon and oxide layers. In order to see the OERM curve to determine transition from silicide to polysilicon etching, one needs an accurate knowledge of these thicknesses (note the effects of a change of only 200Å in polysilicon thickness) and one needs to use a model, such as the one described here, to calculate the curve shape expected for those thicknesses. Figure 6 shows an experimentally observed signal from the initial portion of this etch with nominal thicknesses of 3000Å polysilicon and 3500Å oxide. There is fair agreement with the calculated curve in Fig. 5 for 3204Å polysilicon and 3767Å oxide. The slight discrepancy between the calculated and experimental curves is due to uncertainty of the exact thicknesses of the polysilicon and oxide layers, and to a possible change in silicide surface texture during etching. No arrow has been placed in Fig. 6. Had the polysilicon thickness been measured prior to silicide deposition, the OERM curve could have been modeled using this simulation and the location of endpoint on the OERM curve could have been predicted.

Fig. 6. Experimental OERM signal for silicide/polysilicon/oxide/silicon structure, for the complete silicide etch and the initial portion of the polysilicon etch. Nominal thicknesses are 3000Å polysilicon and 3500 Å oxide.

Multiple areas.—There are cases in which the light beam might be directed onto a region of the wafer containing two different types of layered structures, one of which is covered with photoresist. In some cases, this region could be a structure specialized for optical etch-rate monitoring, such as a diffraction grating (11). In other cases, this region could be the actual device area, which would eliminate the need to devote a large area (about 1-2 mm²) for use as a reflector in etch-rate monitoring. The latter case would be useful if, for instance, such an area would be difficult for an operator to locate, or if it would require an additional mask in a step-and-repeat camera.

As an example of this multiple-area simulation, Fig. 7 shows the calculated OERM signal for 2.0 μm of a metal which has half of its area covered by a resist of index 1.60. The case where there is no resist erosion is shown in Fig. 7a, and the case where the resist etch rate is one-fifth of the metal etch rate is shown in Fig. 7b. One can see that when resist erosion occurs, the OERM signal is quite complicated, since neither the amplitude nor the period remain constant. The average period is shorter here, since a 2 μm etch depth corresponds to 6.3 cycles in the zero-erosion case and to 7.1 cycles in the 1:5 etch-rate-ratio case. If the termination point of the etch process is determined by counting OERM cycles, and if resist erosion is not taken into account, then the etch will be terminated before the desired depth has been reached. This is in agreement with the experimental results of Sternheim *et al.* (3), who found that the optical etch rate monitor yielded a step (in silicon) which, when measured with a stylus instrument, was lower than expected from counting periods of the optical signal. If the resist erosion rate is known, even if only approximately, this simulation can predict the actual number of OERM cycles which will occur during the etch to the desired depth.

Conclusions

The simulation described above is currently in use for calculating multilayer, multiarea reflectance during etching. When combined with analytical calculations and ex-

Fig. 7. Calculation of OERM signals obtained from a metal with half of its area covered by resist. Metal etch rate is 1000 Å/min. a: No resist erosion. b: Resist erodes at one-fifth of metal etch rate.

perimental results, it is proving useful for understanding optical etch-rate monitor signals, and for developing new schemes to improve the usefulness of this technique.

Retardation of Boron Diffusion in Silicon

Chol Kim*

Faculty of Science and Technology, Sophia University, Tokyo 102, Japan

ABSTRACT

Boron diffusion profiles incline steeply near diffusion fronts, since the diffusivity decreases from the intrinsic value with decreasing the local boron concentration. The retardation of boron diffusion occurs only when the surface concentration is lower than the intrinsic carrier density at the diffusion temperature.

Various researchers have carried out boron diffusion in silicon, which has surface concentration less than the intrinsic carrier density at the diffusion temperature. The boron diffusion sources employed were B_2O_3 (1), elemental boron (2), and boron-doped oxide (3). In the papers, boron diffusivity was calculated from the boron surface concentration and the diffusion depth, assuming that, in the intrinsic diffusion condition, the boron diffusivity is not dependent on the local concentration and that the boron profile could be described by the complementary error function (erfc). However, the boron diffusivity reported by Ghoshtagore, who employed doped epitaxial silicon layer as the boron source, is much smaller than the intrinsic value (4). In practical boron diffusion, it has often been observed that the actual diffusion depth is much shallower than the value predicted by the erfc or by the Gaussian function with an intrinsic diffusivity.

Recently, it was found that, when boron-excess BN film, deposited on a silicon surface and encapsulated with Si_3N_4 film, was used as a boron diffusion source, the boron surface concentration could be controlled over the range of 2×10^{18} to $2 \times 10^{20} \text{ cm}^{-3}$ according to the deposition temperature of the BN film under proper gaseous flow conditions and held constant during the heat-treatment for boron diffusion (5). This makes it possible to employ the Boltzmann-Matano analysis on the boron diffusion profiles over a wide range of surface concentration, in terms of the diffusivity viewed as a function of the local boron concentration.

Experimental

Mirror finished silicon wafers, having a phosphorus concentration of $2.4 \times 10^{15} \text{ cm}^{-3}$ and (100) orientation, were used as a substrate. On the wafers, the 30 nm layer of boron-excess BN was deposited in the temperature range 440°-830°C under the gaseous flow conditions 50 cm^3/min of 1% B_2H_6 in N_2 , 70 cm^3/min of NH_3 , and 2000 cm^3/min of nitrogen carrier gas. The 30 nm layer of Si_3N_4 was successively formed on the BN surface at 720°C with 20 cm^3/min of 5% SiH_4 in N_2 , 70 cm^3/min of NH_3 , and 2000 cm^3/min of nitrogen carrier gas. The experimental apparatus has been described in a previous paper (6). Boron diffusion into silicon from the BN film was carried out by

heat-treatment in nitrogen atmosphere in the temperature range of 1050°-1200°C for the diffusion time of 15-300 min.

Lee (7) performed a comparison of an incremental sheet resistance profile to analyzed spreading resistance profile of a shallow phosphorus diffusion. Except near the surface, the results were in good agreement. In this study, this spreading resistance technique was employed mainly to obtain the boron diffusion profiles, and the incremental sheet resistance method was also used to determine the surface concentration and the profiles near the surface. The diffusion depth was determined not only by the spreading resistance technique, but also by the spherical drilling and staining technique. The difference between the values of diffusion depth determined by the two methods was within the range of $\pm 5\%$ for all samples tested in this investigation.

Fig. 2. Normalized profiles. The original data are shown in Fig. 1

Results

The boron diffusion profiles with the surface concentration of $6 \times 10^{18} \text{ cm}^{-3}$, which is lower than the intrinsic carrier density n_i of $2.0 \times 10^{19} \text{ cm}^{-3}$ at the diffusion temperature of 1200°C , are shown in Fig. 1. During the diffusion heat-treatment, the boron surface concentration C_s was constantly kept at $6.5 \times 10^{18} \text{ cm}^{-3}$, and the diffusion depth increased from 1.65 to $4.30 \mu\text{m}$ in proportion to the square root of diffusion time.

Figure 2 is a replot of the profile data shown in Fig. 1, in which the distance from the surface is normalized to the square root of diffusion time, and the boron concentration is also normalized to the surface concentration. The solid line in the figure corresponds to the erfc curve, assuming the intrinsic diffusivity D_i to be $1.4 \times 10^{-12} \text{ cm}^2/\text{s}$. The normalized boron profiles fit the erfc curve only for the normalized concentration more than 0.1, but they differ near the diffusion front, where the profiles inclined steeply above the solid line. The resulting depth of the diffusion front is only 55-60% of the one expected from the erfc curve which assumes the intrinsic diffusivity D_i .

Because the diffusion profiles are coincident when plotted as shown in Fig. 2, the Boltzmann-Matano technique is applicable to calculate the diffusivity D . The boron diffusivity D as a function of the local boron concentration is shown in Fig. 3. For a local concentration higher than $1 \times 10^{18} \text{ cm}^{-3}$, the diffusivity D was constant at the intrinsic value of $1.4 \times 10^{-12} \text{ cm}^2/\text{s}$. However, for any con-

Fig. 3. Boron diffusivity vs. local boron concentration.

Fig. 4. Boron diffusivity at the diffusion front vs. boron surface concentration.

centration lower than $1 \times 10^{18} \text{ cm}^{-3}$, the diffusivity D decreased with decreasing local boron concentration. For a boron concentration of $1 \times 10^{16} \text{ cm}^{-3}$, the diffusivity is about $2.5 \times 10^{-13} \text{ cm}^2/\text{s}$, that is, $1/4$ of the intrinsic value. As a figure for the retardation of the boron diffusion, we define the diffusivity D_f at the local concentration of $1 \times 10^{16} \text{ cm}^{-3}$.

The boron diffusion with the surface concentration in the range of 2×10^{18} to $2 \times 10^{20} \text{ cm}^{-3}$ was carried out at 1200°C . The diffusion time was chosen so that the resulting diffusion depth would be in the $1.5\text{-}6.0 \mu\text{m}$ range to obtain detailed profile data near the diffusion front where the boron concentration decreased steeply. In all cases, the Boltzmann-Matano analysis was performed, and the diffusivity D was calculated as a function of the local boron concentration. The results are summarized in Fig. 4, in terms of the diffusivity D_f vs. the boron surface concentration C_s . For boron diffusion with the surface concentration higher than the intrinsic carrier density n_i of $2.0 \times 10^{19} \text{ cm}^{-3}$, the diffusivity D_f at the diffusion front agrees with the intrinsic diffusivity D_i shown as a dashed line in the figure. The retardation of boron diffusion at the diffusion front was not observed. For a low surface concentration less than $2 \times 10^{19} \text{ cm}^{-3}$, the diffusivity D_f at the diffusion front was smaller than the intrinsic value.

To confirm the retardation of boron diffusion at lower temperature than 1200°C , boron diffusion was carried out at 1050° , 1100° , and 1150°C . As shown in Fig. 5, the diffusivity D_f at the diffusion front was always smaller than the intrinsic diffusivity D_i for the surface concentration of less than 10^{19} cm^{-3} , even though the diffusivity D_f was coincident with the intrinsic value for the higher surface concentration. The retardation of boron diffusion occurs only when the surface concentration is less than the in-

Fig. 5. Boron diffusivity at the diffusion front vs. the reciprocal of diffusion temperature.

intrinsic carrier density n_i at diffusion temperatures in the 1050°-1200°C range. Figure 5 also shows that, under the intrinsic condition, the diffusivity D_f depends not only on the diffusion temperature, but on the surface concentration of diffused layer.

ABSTRACT

We report on studies of the transport and incorporation of chlorine in SiO₂ during the oxidation of silicon in O₂/HCl mixtures at 1000° and 1100°C using Auger sputter profiling (ASP) and secondary ion mass spectrometry (SIMS). The experimental results obtained were analyzed using general particle-transport considerations including both diffusion and drift components. Data obtained from the SIMS profiles of the chlorine concentration in SiO₂ indicate that chlorine transport is aided by an electrochemical field in the oxide, although this field is undoubtedly not electrical in nature. Data obtained from the ASP profiles show that the Si-SiO₂ interface acts as a sink for chlorine. By fitting the transport relations to the data obtained, an accurate model for chlorine transport is derived.

In recent years, there has been much interest in the effect of chlorine additions to the oxidizing ambient during silicon oxidation (1-42). Chlorine in the grown oxides neutralizes positive alkali ions in the oxide (21), provides better reproducibility in breakdown voltages (11), reduces stacking faults (16), and directly affects the oxidation kinetics (23). In addition, because of the electrochemical similarities between oxygen and chlorine, studies of chlorine incorporation may provide additional insight into the mechanisms of oxide growth.

In this paper, we describe the results of Auger sputter profiling (ASP) and secondary ion mass spectrometry (SIMS) studies of silicon dioxide grown in O₂/HCl ambients. Our ASP and SIMS studies on O₂/HCl-grown oxides may be summarized as follows: (i) high levels of chlorine reside on the oxide side at the SiO₂/Si interface in a region less than 30Å wide. (ii) The total interface chlorine increases

with growth temperature for a fixed oxide thickness. (iii) The total interface chlorine for a fixed temperature increases monotonically with oxide thickness. We believe the evolution of the chlorine distribution can be described in terms of field-driven transport of a chlorine species to the SiO₂/Si interface region where it is incorporated, possibly, in various Si-Cl-O-H complexes. With the arrival of sufficient chlorine a new phase is nucleated, and ultimately SiCl₄ compounds are formed which cause blisters at the interface.

We introduce a simple kinetic model which is consistent with these results to predict the amount of interface chlorine for a given oxidation process, and present data showing the total interface chlorine as a function of oxide-growth temperature and thickness. We will present a brief summary of the conclusions of several studies regarding the distribution of chlorine in HCl-grown oxides and compare these results with our own recent work.

Experimental

To gain an understanding of the effects of various process conditions on chlorine distribution and transport, we examined several sets of sample structures. All oxide thicknesses were determined by ellipsometric measurements. One such set consisted of (100)- and (111)-oriented n-type silicon oxidized in O₂/5% HCl at 1000° and 1100°C. A second sample series consisted of silicon oxidized in dry O₂ at 1100°C to a thickness of 1060Å. This second set was then annealed in Ar/5% HCl at 1100°C for various times. Examination of these sample sets allowed us to evaluate the chlorine transport and incorporation processes with and without the presence of a simultaneous oxidation process. Two additional sample sets consisted of silicon wafers, which underwent complementary sequential growth processes. One sample was oxidized in O₂/5% HCl to 500Å, and this was followed by oxidation in dry O₂ to a total thickness of 1000Å. The other sample was oxidized first in dry O₂ to 500Å and then in O₂/5% HCl to a total thickness of 1000Å. These samples were compared in an effort to determine the stability of chlorine distribution during silicon oxidation in the absence of a chlorine source in the ambient. This also provided an indication of the ability of chlorine to permeate an initial dry O₂ oxide layer. We also examined oxides grown in O₂ with no HCl as controls.

All samples were examined using Auger sputter profiling. To calibrate sensitivity factors, standards of both Si and SiO₂ were investigated using implants of ³⁵Cl⁺ at 50 keV for a total dose of $3.0 \times 10^{15} \text{ cm}^{-2}$. Auger sputter profiling was performed using a Varian high-resolution Auger electron spectrometer. The primary Auger electron beam was operated at 10 μA, 4.5 keV, rastered over an area 600 μm on a side. This gave an electron-beam flux of 3 mA cm⁻² and a power flux of 13.5 W cm⁻². Sputter profiling was performed with Ne⁺ at 1.0 keV with a current density of 36 μA/cm². The sputtering rate was determined to be 27 Å min⁻¹ by comparison with ellipsometric measurements. All experiments were carried out using a liquid nitrogen cryoshroud to minimize background contamination of samples. For these conditions, the Auger depth resolution is better than 30Å (43), and the chlorine detection limit is approximately $1 \times 10^{19} \text{ cm}^{-3}$ in a profiling mode. Secondary ion mass spectrometry (SIMS) analysis was also performed on a representative selection of these samples.¹ The samples were analyzed using O₂⁺ ions at 8 keV.

We have used both Auger sputter profiling and SIMS because the two techniques offer complementary capabilities: Auger provides superior depth resolution (primarily through lower ion energies for sputtering), and SIMS offers superior sensitivity. It is difficult to make statements about absolute concentrations with either technique, however, without resorting to sample standards. The investigation of the implanted standards, however, provided us with a means of determining absolute concentrations in the SIMS experiments to the accuracy afforded by the implant standards. In previous studies of chlorine in SiO₂ using Auger sputter profiling, distortions of the profile due to electron irradiation have been observed. In this study, the conditions described above were chosen so that these effects were not significant. Both ASP and SIMS show some variations in signal sensitivity over a series of experimental runs. In our work, we consistently scaled SIMS data to the Auger data, since our Auger data base for each sample was considerably larger. The resulting concentrations quoted here are good to within 20%, not including errors due to the implant standards. Note that this is a systematic error introduced during the calibration process. Measurements of relative concentration from sample to sample can be expected to yield a precision better than ±20%.

A typical O₂/HCl-grown SiO₂ ASP profile is shown in Fig. 1. The sample is a lightly doped, n-type (100) silicon crystal thermally oxidized at 1100°C to a thickness of 910Å in an ambient containing O₂/5% HCl. In the figure, the peak to peak heights of the differentiated electron energy distribution for several Auger transition energies are shown. The silicon signal shown is due to the 92 eV Si-LVV transition, which is present only in unoxidized elemental silicon; this signal (along with the oxygen) serves as a marker to locate the interface.

¹SIMS analysis performed by C. A. Evans and Associates.

Fig. 1. ASP profile of SiO₂ grown in O₂/5% HCl at 1100°C. This figure records the peak to peak height of the differentiated Auger electron energy distribution curve, for experimental conditions described in the text. The three curves show the depth distribution of oxygen (511 eV), silicon (92 eV), and chlorine 181 eV). The chlorine peak represents a concentration of $1.8 \times 10^{21} \text{ cm}^{-3}$ at a FWHM of 50Å.

The chlorine-interface peak appears in the oxide approximately 10Å from position where the oxygen signal is down by 50% (we define this point as the interface position). The chlorine-peak concentration and FWHM (full width at half maximum) for this sample are $1.8 \times 10^{21} \text{ cm}^{-3}$ and 50Å, respectively. The 50Å FWHM contrasts sharply with the peak widths of from 100-200Å in previous studies (12, 32), and we have, in fact, measured chlorine distributions with FWHM as narrow as 30Å, which is still due in large part to experimental broadening effects. Chlorine levels in the bulk oxide are below our detection limit of $1 \times 10^{19} \text{ cm}^{-3}$ for these operating conditions (chosen to minimize electron-beam effects). We also note a small, gradual rise in chlorine concentration in the SiO₂, which becomes detectable approximately 200Å from the interface. It is also clear that the chlorine levels fall off very quickly in the silicon substrate.

Figure 2 provides an illustration of the complementary features of ASP and SIMS, and shows SIMS and ASP profiles of an n-type, (100) Si sample grown in O₂/5% HCl at 1000°C to 2060Å; the upper panel is on a linear scale, the lower on a semilog scale. The solid curve is the Auger profile showing the very sharply peaked distribution of the interface chlorine. Superimposed on this is the dashed SIMS profile of the same sample. The two curves represent the same total amount of chlorine. Clearly, the ASP technique as used in these experiments has superior depth resolution due to knock-on broadening (43) and ion enhanced diffusion effects for the ion energies employed. SIMS, however, has a superior sensitivity. This is clear from the lower panel, which records on a log scale the bulk oxide chlorine distribution for the same sample. We cannot detect these low chlorine levels with the Auger technique, due to the low electron-beam fluxes necessary to minimize electron-beam effects. The small rise in the chlorine distribution seen with ASP in Fig. 1, however, does seem to be indicative of the clear monotonic increase in chlorine evident in Fig. 2.

At this point, we will address the effects of the electron and ion beams used in these experiments. Previous work by Chou *et al.* (44) shows that the Auger primary electron-beam-activated chlorine in the oxide allowing it to move and caused the chlorine at the surface to desorb. We have profiled SiO₂/Si structures implanted with chlorine and, from these studies, determined to what extent the electron primary beam and ion beam distort the chlorine distribu-

Fig. 2. Chlorine distribution as a function of depth for SiO₂ grown in O₂/5% HCl at 1100°C. Top: linear plot, where solid curve is Auger sputter profile. The profile cuts off at the sensitivity limit for this run. The broken curve is the SIMS profile for the same sample. Note that the total integrated chlorine is approximately the same for the two curves, as expected. Bottom: Log plot of the same SIMS data.

tion (45). The electron beam, consistent with previous work, does enhance chlorine mobility, presumably through the generation of defects in the oxide. The amount of chlorine transport induced by the electron-beam scales with the total charge injected into the sample by the electron beam. One effect is to deplete the chlorine present at the interface. In Fig. 3, we show the total interface chlorine as measured with electron beam fluxes of 3 mA cm⁻² and 100 mA cm⁻², respectively. For our measurements of interface chlorine, we used a flux of 3 mA cm⁻², which was turned on within 100 Å of the SiO₂/Si interface. Thus, we operated within the boxed region in the figure. We conclude that our ASP profiles provide an accurate measure of the interface chlorine distribution.

The ion beam can also be expected to effect the chlorine distribution in our ASP and SIMS profiling experiments. The dominant effect of an ion beam on a particle distribution is to generate a random walk process analogous to a thermal diffusion process (43). Calculations of these effects for the ASP and SIMS profiles described here lead to broadening effects of 20 Å for the ASP results and 150 Å for the SIMS results.

Figure 4 provides further support for the assertion that the ion beam distorts the original distribution only through broadening. We show a SIMS profile of chlorine implanted in SiO₂. Also shown for comparison is the nominal chlorine implant distribution as calculated from implant parameters

Fig. 3. Total interface chlorine for an oxide grown in O₂/5% HCl at 1100°C as a function of electron-beam-exposure time. Curves are shown for beam fluxes of 3 mA cm⁻² and 100 mA cm⁻². Boxed region denotes flux level and exposure time used in data collection.

Fig. 4. SIMS profile (solid) of chlorine implanted in SiO₂. ³⁵Cl⁺ was implanted at 50 keV into a 980 Å layer SiO₂ to yield 3.0 × 10¹⁵ cm⁻². The calculated distribution is shown for comparison (dashed).

(46). The SIMS ion beam has broadened the implant distribution in an rms fashion where the broadening is 160 Å.

Theoretical Considerations of Chlorine Transport Through SiO₂

We will briefly present a single-particle transport model for chlorine incorporation in growing SiO₂, and, to establish a working picture, we present a schematic diagram of the SiO₂/Si structure in Fig. 5. The surface and interface denote regions which probably differ significantly in structure and chemistry from the bulk-oxide region, and give rise to the chemical potential sinks there. As used here, we will take the surface to consist of essentially one or two monolayers (ΔX_s), and, as we have seen, the interface region (ΔX_i) is 30 Å or less wide and possibly only a few monolayers thick. We assume that each region is homogeneous with well-defined structural properties. Also shown in Fig. 5 is a schematic diagram of the electrochemical field acting on the chlorine which we have derived from our experimental results. We will say more about the electrochemical field in the discussion section. The key features are chemical potential sinks at the surface and interface which model interfacial-segregation mechanisms, a high chemical potential in the Si, as little Cl dissolves in the Si itself, and a gradient in the electrochemical potential due to a "field" whose origin at this time is uncertain. In discussing the transport properties, we will also assume that the surface

Fig. 5. A, top: Schematic illustration of the SiO_2/Si structure during particle transport. The surface, bulk, and interface regions are each characterized by distinct structural properties. Particle accumulation in the surface and interface is denoted by $Q(\text{cm}^{-2})$. Also shown are the various flux terms. The important concentration levels are C_G (gas phase concentration), $C_{EQ}(0)$ equilibrium concentration in SiO_2 at $x = 0$, C_0 (actual concentration in SiO_2 at $x = 0$), C_1 (concentration in SiO_2 at $x = x_0$), and C_{Si} (concentration in silicon substrate at $x = x_0 + x$). J has been taken as constant through the oxide due to the use of the steady-state approximation. Also, $J_{out} \ll J$ for the conditions of our experiments. B, bottom: Illustration of the potential of the chlorine due to the electrochemical fields acting during oxidation.

and interface regions are so narrow that the concentration is a constant throughout these regions.

Transport in the bulk-oxide region can be described by the equation

$$J(x, t) = -D(x) \frac{\partial C}{\partial x}(x, t) + \mu(x)F(x, t)C(x, t) \quad [3]$$

where D is the diffusion coefficient, μ is the mobility, and F is a general field. The driving force due to F comprises numerous effects, including electric fields, stress fields, chemical bonding, defects, and activity gradients (47-49). As used in this context, it is undoubtedly not due to an electric field, as we will show later.

In addition to Eq. [3], we have the equation of continuity for the case of no recombination or generation giving

$$\begin{aligned} \frac{\partial C}{\partial t} &= -\frac{\partial J}{\partial x} \\ &= -\frac{\partial}{\partial x} \left[-D \frac{\partial C}{\partial x} + \mu FC \right] \end{aligned} \quad [4]$$

To simplify the above equations, we would like to work in the steady-state domain. The necessary condition for steady state is given by Fromhold (47) as

$$t \gg \tau \quad [5]$$

where

$$\frac{1}{\tau} = \frac{D}{4} \left(\frac{F}{k_B T} \right)^2 + \frac{\pi^2 D}{x_0^2} \quad [6]$$

and t is the time required to grow an oxide layer of thickness x_0 . If Eq. [5] is satisfied, all of the time dependent terms in the expansion for $C(x, t)$ are negligible. Physically, steady state implies that the chlorine species is sufficiently dilute and mobile so that it can rapidly respond to any perturbation which causes a deviation from the steady-state condition. Later, we will show that the chlorine transport through the bulk oxide is close to steady state so that this assumption is valid.

In steady state, Eq. [3] becomes

$$J(t) = -D \frac{\partial C}{\partial x} + \mu F(x, t)C(x, t) \quad [7]$$

where J is now constant with position and varying in time, and we have taken D and μ as constant for simplicity. Equation [7] is the general transport equation in steady state. The general solution to Eq. [7] for any time t is then given (using an integrating factor) by

$$C(x, t) = \frac{C(0, t) - J(t) \int_0^x \frac{1}{D} \left[\exp \left(\frac{-1}{k_B T} \int_0^y F(z, t) dz \right) \right] dy}{\exp \left[\frac{-1}{k_B T} \int_0^x F(z, t) dz \right]} \quad [8]$$

where F is the generalized force field of Eq. [3], and $J(t)$ and $C(x, t)$ are related by the boundary conditions [47].

A simple case which appears adequate to describe our results is obtained if F is not a function of x . This gives a linear potential gradient, as shown in Fig. 5. In this case, Eq. [8] can be integrated to give

$$C(x, t) = \frac{C(0, t) - J(t)k_B T / DF(t) \{1 - e^{-F(t)x/k_B T}\}}{e^{-F(t)x/k_B T}} \quad [9]$$

For $F(t) = 0$, this reduces to the familiar diffusion profile in steady state

$$C(x, t) = C(0, t) - \frac{J(t)x}{D} \quad [10]$$

A definite solution for $C(x, t)$ and $J(t)$ from Eq. [9] can be obtained from the boundary condition at the Si-SiO₂ interface. Here again we will apply a simple model that seems adequate to describe our results: namely, that $J(t) = kC(x_0, t)$. This represents a first-order process for chlorine in the SiO₂ to be "trapped" by the Si-SiO₂ interface, since (see Fig. 5) $J_{out} \ll J$. This gives

$$J(x_0) = \frac{C(0, x_0)\mu\phi/(1 - e^{-\phi/k_B T})}{x_0 + \mu\phi e^{-\phi/k_B T}/k(1 - e^{-\phi/k_B T})} = \frac{P}{x_0 + \lambda} \quad [11]$$

and

$$\begin{aligned} C(x, x_0) &= \frac{x_0 J(x_0)}{\mu\phi} \\ &+ e^{\phi x/k_B T x_0} \left\{ C(0, x_0) - \frac{J(x_0)x_0}{\mu\phi} \right\} \end{aligned} \quad [12]$$

where $D/k_B T$ has been replaced by a mobility μ , and F has been replaced by ϕ/x_0 , where ϕ is the electrochemical potential drop across the oxide (as shown in Fig. 5), and the time variable t has been replaced by oxide thickness x_0 . P and λ , as defined in Eq. [11], will be used in subsequent descriptions for simplicity.

The interface chlorine can be calculated by integrating the flux over time. For the case of thermal growth of SiO₂, we can relate oxide thickness and time by (41)

$$x_0 = \sqrt{B} \left(t + \tau + \frac{A^2}{4} \right)^{1/2} - \frac{A}{2} \quad [13]$$

and

$$\frac{dx_0}{dt} = \frac{B}{2x_0 + A} \quad [14]$$

B , A , and τ are constants characteristic of a given oxidation. These equations lead to an expression for interface chlorine Q as a function of x_0

$$Q(x_0) = Q_0 + \frac{P}{B/A} \left[\frac{x_0 - x_1}{A/2} + \left(1 - \frac{\lambda}{A/2} \right) \ln \left(\frac{x_0 + \lambda}{x_1 + \lambda} \right) \right] \quad [15]$$

x_1 is the thickness at which $Q(x_1) = Q_0$. It will be chosen as that value of oxide thickness after an initial period of rapid growth not described by the Deal-Grove growth law [typically $x_1 \approx 200 \text{ \AA}$ (41)]. This expression allows us to calculate the interface chlorine for a given oxide thickness.

Results

In this section, we will present the results of our studies, and we will follow this with a detailed discussion. We begin by looking at samples grown in O₂/HCl. As noted above, Fig. 1 exhibits the features common to all oxides examined in this study. These data were from an oxide grown in O₂/5% HCl at 1100°C. All samples were characterized by bulk oxide chlorine levels below our ASP detection limit of $1 \times 10^{19} \text{ cm}^{-3}$. The position of the peak in chlorine concentration occurs on the oxide side of the interface about 10 Å away from the oxygen signal 50% point. Although this actual value is probably not significant, it does give evidence that the chlorine lies on the "SiO₂ side" of the interface. The chlorine peaks have FWHM of 30-50 Å. Note that these widths are upper limits to the actual distributions. Keeping in mind the effects of electron escape depth and the broadening mechanisms in the ASP process, the actual peak widths would be better described as 30 Å or less, and the interface chlorine could conceivably occupy only a few monolayers in the interface region.

To determine the effects of growth time and temperature on chlorine incorporation, we will use the total chlorine concentration per cm² under the peak as a measure of total interface chlorine. This removes any uncertainty due to profiling broadening factors. Figure 6 shows the total integrated chlorine Q at the interface of the O₂/HCl oxides investigated as a function of growth temperature and oxide thickness for the conditions investigated. Error bars are the standard deviations calculated from several runs for each sample. There is a monotonic increase of interface chlorine with oxide thickness for a fixed-growth temperature. There is also some variation between (100) and (111) sample substrates. From these data, we can see no clear evidence of any saturation in the chlorine concentration over this range of oxide thickness. It appears that the SiO₂/Si interface is a good sink for chlorine up to at least $2 \times 10^{15} \text{ cm}^{-2}$. In fact, from other studies (35), it appears that the chlorine concentration will increase to the point that SiCl_x compounds are formed, resulting in blisters at the interface, although we have no evidence for this effect for these conditions.

Fig. 6. Total integrated chlorine at the SiO₂/Si interface as a function of oxide growth temperature and thickness for (100) and (111) orientations. Error bars denote standard deviation for several runs. Note the vertical scales of 10^{15} cm^{-2} for 1100°C and 10^{14} cm^{-2} for 1000°C. The straight lines are least square fits to the data points and have been terminated at $x = x_1$ for the samples investigated.

The bulk-oxide chlorine levels were below our ASP detection limit. Because superior signal sensitivity was required and depth resolution is not critical in the bulk oxide, we employed SIMS to examine the chlorine concentration in our O₂/HCl oxides. Figure 7 records on log scales the chlorine distributions of three selected samples as measured by SIMS. The samples were oxidized in O₂/HCl with variations

Fig. 7. Log plots of chlorine SIMS profiles. We take the crosshatched areas to be chlorine in the bulk oxide; the remainder is segregated at the surface or interfaces. A, top: SiO₂ grown in O₂/5% HCl at 1000°C. B, middle: SiO₂ grown in O₂/5% HCl at 1100°C. C, bottom: SiO₂ grown in O₂/10% HCl at 1100°C.

in time, temperature, and HCl pressure, as described in the caption.

The results obtained by SIMS for the interfacial-chlorine concentrations were within $\pm 30\%$ of the average values obtained from the Auger studies on the same samples. Part of this error is due to the difference in width of the Auger and SIMS profiles.

In addition, these profiles show a peak in chlorine concentration at the oxide surface as well as the distribution through the bulk SiO_2 . The general features for all the samples investigated were similar. The bulk concentration profile, which we take as the crosshatched area in the figure, is very different from the linearly decreasing profile expected from a simple diffusion process. Instead, the chlorine concentration increases monotonically from its near-surface value to a much higher value near the interface. This profile can, however, be adequately described by the model presented in the previous section, as we will see below.

We have also examined oxides which underwent sequential growth, first in dry O_2 and then in O_2/HCl , and compared these with oxides with the growth sequence reversed. This allowed us to determine the stability of interface chlorine during a dry O_2 oxidation and the ability of chlorine to permeate a dry oxide and accumulate at the SiO_2/Si interface.

The sequential growth samples consisted of p-type (100) Si oxidized at 1100°C in dry O_2 and $\text{O}_2/5\%$ HCl. The dry- O_2 step was the first oxidation step for one set and the second oxidation step for the other set. In each case, the $\text{O}_2/5\%$ HCl and dry- O_2 oxidation steps were performed to yield approximately 500\AA of oxide growth for each step and total oxide thicknesses of approximately 1000\AA . In Fig. 8, we show the incorporation of total interface chlorine as a function of time for the sequentially grown oxides. For comparison, we show the standard O_2/HCl oxide as the solid curve. The broken curve is for an initial O_2 oxidation followed by an O_2/HCl oxidation. For this case, the incorporation proceeds rapidly, the slope of the curve being the same as for the nonsequential O_2/HCl oxidation. Samples grown first in O_2/HCl and then in dry O_2 (dashed dotted curve) show decay of interface chlorine as oxidation proceeds, consistent with diffusion of Cl back through the oxide and into the gas phase.

To determine the stability of interface chlorine when oxidation is not occurring, we have also examined samples grown in $\text{O}_2/5\%$ HCl and then annealed in Ar at 1100°C for

Fig. 8. Total interface chlorine as a function of processing time at 1100°C with 5% HCl. The solid curve is a standard oxidation; the broken curve corresponds to an initial oxidation in dry O_2 to $\sim 500\text{\AA}$ followed by the O_2/HCl oxidation; the dashed-dotted curve corresponds to an O_2/HCl oxidation to $\sim 500\text{\AA}$ thickness followed by an O_2 oxidation. Included are arrows 500\AA oxide thickness increments.

1h. We saw no evidence for depletion of interface chlorine in this case, indicating that oxidation is enhancing reincorporation of Cl from the interface into the SiO_2 or the Cl mobility or both. However, van der Meulen *et al.* (13) have reported depletion of the interface of chlorine by annealing at a higher temperature of 1200°C .

To isolate the importance of the oxidation process on chlorine transport and incorporation, we also examined n-type (100) Si oxidized in dry O_2 at 1100°C to produce oxides 1060\AA thick. These were then annealed for various times in Ar/5% HCl at 1100°C . In Fig. 9, we show the total interface chlorine as a function of time for the samples which were first oxidized in dry O_2 and then annealed in Ar/5% HCl. For comparison, we show the chlorine-incorporation rate for the O_2/HCl and O_2/HCl oxides from the previous figure. We can see that the chlorine-incorporation rate is significantly lower when oxidation is not occurring, even though the interface is stationary, again indicating the effect of the oxidation process on chlorine transport.

Discussion

In this section, we will discuss possible mechanisms occurring during the incorporation of chlorine at the SiO_2/Si interface. Before proceeding, however, it is worthwhile to review briefly some of the earlier studies of chlorine in SiO_2 and to compare and contrast these with our own findings.

Early studies of chlorine distributions in SiO_2 were performed by Kriegler *et al.* (12) and van der Meulen *et al.* (13). Using nuclear backscattering, they found that chlorine present in oxides grown in O_2/HCl mixtures accumulated at high levels in a region roughly $100\text{-}200\text{\AA}$ wide at the SiO_2/Si interface. Total interface chlorine levels ranged from less than $0.06 \times 10^{15} \text{ cm}^{-2}$ for 900°C oxides to $1.7 \times 10^{15} \text{ cm}^{-2}$ for 1150°C oxides. They found the levels of chlorine increased with oxidation temperature and ambient HCl partial pressure. The authors report a depth resolution of 200\AA , which indicates some difficulty in carefully characterizing the chlorine peaks, however.

More recently, Deal *et al.* (33) performed studies similar to those of van der Meulen *et al.* using SIMS, which should be more sensitive than nuclear backscattering to chlorine. They found the same behavior of chlorine segregation to the SiO_2/Si near interface region. They reported that chlorine incorporation increased with oxidation temperature, oxide thickness, and ambient HCl partial pressure. They also noted a somewhat greater level of chlorine for (111) silicon than for (100) silicon at 1100°C . Their SIMS data yielded total chlorine concentrations comparable with the data of van der Meulen *et al.* and a typical FWHM of 150\AA .

Fig. 9. Total interface chlorine as a function of processing time at 1100°C with 5% HCl. Sequential processes are as indicated. Solid curves begin at the transition points for the sequential processes. Included are arrows 500\AA oxide thickness increments.

Frenzel and Balk (38) have presented SIMS and Auger data on oxides grown in TCE/O₂ and CCl₄/O₂. They postulated the existence of a laterally inhomogeneous chlorine-rich region at the SiO₂/Si interface which measured 200Å or less in width. They also argue for the presence of an SiO_x transition region at the interface which is roughly 300Å wide. Similar SIMS data by Tsong *et al.* (39) shows chlorine pileup with a 200Å FWHM.

The Frenzel-Balk argument for lateral inhomogeneities in the chlorine distribution relies upon the presence of a chlorine SIMS signal extending into the silicon substrate. They attribute this to nonuniform oxide sputtering rates due to an irregular lateral distribution of chlorine. Chlorine levels in the silicon substrate in our studies, however, prove to be less than our detection limit of $1 \times 10^{19} \text{ cm}^{-3}$, so the argument for lateral inhomogeneities put forth in their paper is not compelling. However, recent work by Monkowski *et al.* (32) shows electron microscopy evidence for an inhomogeneous chlorine phase near the SiO₂/Si interface. Our work suggests that the extent in depth of this new phase is less than 30Å. Finally, the excess silicon observed by Frenzel and Balk in a broad SiO_x phase contains approximately $3 \times 10^{16} \text{ cm}^{-2}$ excess silicon atoms, nearly 20 times the total amount of measured chlorine. It seems probable that the enhancement in the Si Auger signal in the oxide observed in their work is due to an artifact in the ASP experiment.

In our work, we have found levels of interface chlorine in good agreement with results of other groups. In contrast to these earlier studies, however, we have seen that this interface chlorine is distributed over a region less than 30Å wide, and we therefore associate this chlorine directly with the SiO₂/Si interface. The presence of a chemical potential sink for chlorine at the Si-SiO₂ interface, therefore, appears clearly established.

For the chlorine to reach the interface and remain there during oxidation, it must be transported rapidly compared to the interface velocity, and, in addition, the interfacial chlorine must also move with the growing interface. Rapid transport implies that the chlorine distribution quite rapidly reaches steady state. Additional evidence for this comes from our sequential growth studies (Fig. 8). The rate of chlorine incorporation for the O₂/O₂/HCl oxidation (broken curve) rapidly reaches that of the O₂/HCl oxidation, indicating that the velocity of the chlorine is large compared with the Si/SiO₂ interface velocity.

In addition, the rate of chlorine incorporation at the interface is slower for a sequential process with an O₂ oxidation followed by an Ar/HCl anneal. This indicates that the chlorine-transport process is affected by the oxidation process itself. This may come either through a reaction between the HCl and O₂ as

or be due to an effect of the oxidation process on the structure or electrochemical properties of the oxide.

The chlorine profiles obtained through the bulk of the SiO₂ are not linear, indicating that the transport process is not just a simple diffusion mechanism for the chlorine present. A simple model which does describe this profile, as well as the other features of chlorine incorporation, is based on the presence of an electrochemical field driving chlorine transport, as shown in Fig. 5. Within this model, the chlorine distribution in the SiO₂ would be given by Eq. [12], which can be rewritten as

$$C(x, x_0) = C_1(x_0) + e^{\phi x/k_B T} C_2(x_0) \quad [17]$$

The dashed regions of Fig. 7 take this form. The fit of these curves to the profiles with the exception of the surface and interface peaks is excellent, as can be seen from the figures.

The microscopic mechanisms for the effects discussed above is unclear. The interfacial segregation of chlorine is undoubtedly due to lowering of the interfacial free energy due to chemical bonding effects, strain considerations, etc. Work by Monkowski *et al.* indicates that the higher chlorine concentrations SiO_xCl_y compounds form at the interface; the segregated interface chlorine may be a precursor to the formation of these compounds.

The nature of the mechanism responsible for the chlorine distribution in the bulk, which can be described by a constant field acting on the chlorine, is also not clear at all. Possible field sources are stress, activity gradient (due to variations in the number of available chlorine sites in the oxide or interactions with hydrogen present), and electrical fields, among others. The electrical-field mechanism is unlikely, however, since high levels of space charge would be necessary to compensate for the large chlorine concentrations observed; these, in turn, would cause the chlorine-concentration profile to deviate from what is predicted by Eq. [12].

Modeling of Chlorine Transport and Incorporation

In this section, we will use the general transport equations derived above to analytically model chlorine transport through SiO₂. In modeling this process, we will start with Eq. [11], which relates the chlorine flux to oxide thickness. We also have a relationship for the interface-chlorine concentration Q from Eq. [15]. For modeling purposes, it is easier to look at the rate of chlorine incorporation per unit oxide thickness

$$\frac{dQ(x_0)}{dx_0} = \frac{2P}{B} \cdot \frac{x_0 + A/2}{x_0 + \lambda} \quad [18]$$

Looking back at Fig. 6, we see that $Q(x_0)$ is close to a straight line, so that $\lambda \sim A/2$ (unless $A/2, \lambda \gg x_0$ which is not the case for these thicknesses). Values for P for the 100 samples, along with other relevant parameters for the linear fits of Eq. [18] to Fig. 6, are shown in Table I.

For a simple diffusion model, we would expect similar values for P to be obtained for both the 100 and 111 samples, since B does not vary from 100 to 111 orientations. However, P contains the field term which may vary from 100 to 111, and, in addition, A varies from 100 to 111, and we might also expect a variation in λ . In any case, the slopes are within a factor of two of each other (much closer for the 1100°C samples) which is in reasonable agreement if these factors are taken into consideration.

Parameters from the fit of Eq. [17] to the data of Fig. 6 are shown in Table II. Of particular interest is the value of the diffusion coefficient. The values given are considerably smaller than what would be expected from the diffusion of other molecules that diffuse interstitially. This may indicate that the chlorine-transport process involves exchange with the SiO₂ lattice which would lead to the smaller diffusion coefficients. It may also be due to the inclusion in the profiles of chlorine that has exchanged with the lattice and is no longer free to diffuse. Since the product of the diffusion coefficient and the concentration always appears in transport equations, a larger value of the concentration leads to a smaller value of the diffusion coefficient.

Irrespective of the mechanisms involved, we can use the parameters of Tables I and II to calculate the chlorine con-

Table I. Summary of transport parameters for chlorine in SiO₂ samples oxidized in O₂/5% HCl

	O ₂ /5% HCl (100) 1000°C	O ₂ /5% HCl (100) 1100°C
x_1	139Å	171Å

Electron-Electron Interactions in Finely Focused Beams of Low Energy Electrons

T. R. Groves

Hewlett Packard Laboratory, Palo Alto, California 94304

ABSTRACT

Although low current beams of low energy electrons can be finely focused through the use of retarding field focusing optics, it had been suggested that the reduced axial spacing of the low energy electrons could lead to serious defocusing because of electron-electron interactions. However, the Monte Carlo simulation of such electron-electron interactions in the region between final lens and target plane shows that there are no appreciable differences in energy spread and spot diameter with beam currents up to 5 μ A transported through aperture sizes greater than 0.01 mm in radius at energies of 10 keV, 1 keV, and 100 eV. Preliminary experimental results indicate that current density of 250 A/cm² of 1 keV electrons can be obtained by using hairpin tungsten filaments.

Low energy (< 5 keV), low current (<< 1 μ A) electron beams can be finely focused by immersing the target plane in a retarding electrostatic field (Fig. 1) because the spherical and chromatic aberration coefficients C_s and C_c of the total focusing system (i.e., magnetic lens plus retarding field) are greatly reduced (1). At higher currents ($\geq 1 \mu$ A), as

needed in E-beam lithographic systems, the electron-electron interactions can become a limiting factor for the minimum probe diameter obtainable. This is true in conventional higher (≥ 10 keV) energy electron-beam systems (2); in retarding field systems where electrons are slowed down in the region between the final lens and the target

Fig. 1. Final lens region of an electron probe system. In conventional mode, $V_2 = V_1$; in retarding field mode, $V_2 < V_1$.

plane, the electron-electron interactions may set an even lower limit. We report here the results of the Monte Carlo simulation of electron-electron interactions in conventional and retarding field systems. There appears to be little increased effect, and the experimental results are consistent with the conditions specified.

Monte Carlo Simulation

A version of the program described by Groves *et al.* (3) was modified to account for the retarding field and for image charges induced by the target plane.

Initialization.—The simulation starts with a sample of 100 electrons distributed within the aperture area at the exit of the final magnetic lens (Fig. 2). Each electron is assigned a set of randomly generated radial coordinates (x_i, y_i), and zero initial energy spread is assumed. All the electrons are directed toward an ideal geometrical point with an initial energy of 10 keV. In the conventional case, this ideal point is at the focus on the target plane; in the retarding field case, it lies beyond the target plane so that the retarding electrostatic field brings about a focus at the target plane for each beam current, final landing energy, and aperture size. Every electron is also given a time t_i which is determined by the beam current I , i.e., $0 < t_i < 100 \cdot e/I$. The final step of the initialization is to advance all the electrons' positions by

$$\begin{aligned} x_i &= x_i + \dot{x}_i \cdot t_i \\ y_i &= y_i + \dot{y}_i \cdot t_i \\ z_i &= z_i + \dot{z}_i \cdot t_i + at_i^2/2 \end{aligned}$$

Their velocities are modified (if necessary) by

$$z_i = z_i + at_i$$

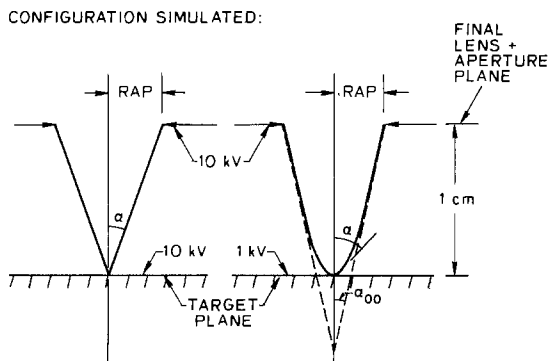

Fig. 2. Conventional and retarding field configurations simulated

where $a = 0$ for conventional case, $a = e(V_2 - V_1)/m_e$ for retarding field case, V_1 is the initial starting voltage, and V_2 is the final target plane voltage.

Stepping.—First, the time of flight between the final lens plane and the target plane is divided into 100 steps of equal time T

$$T = \frac{l/100}{\sqrt{\dot{x}_i^2 + \dot{y}_i^2 + \dot{z}_i^2}}$$

where l is the distance between aperture and target (1 cm in our model). At each step, the Coulomb force and the Lorentz force between all electron pairs are calculated. Then the positions and the velocities of the electrons are updated accordingly. This process goes on until the last electron has reached the target plane. When an electron arrives at the target plane, its position and velocity are recorded. From these recorded data, the spot diameter d , energy spread ΔE , and axial defocusing ΔZ (for conventional cases) are calculated. The spot diameter is determined such that 80% of the total current is included. In conventional cases, the minimum spot may occur at a different axial position from the focus because of electron-electron interactions. The program looks for the minimum spot diameter and its corresponding axial position by extrapolating from the positions and velocities recorded at the target plane. The energy spread is the standard deviation from the mean final energy at the target plane for both configurations.

Results

A fixed-beam current of $5 \mu A$ for different aperture sizes in the conventional arrangement was used to simulate different values of space charge parameter σ (4). As the aperture radius is decreased, the interactions become stronger; this is evident from the increase both in the energy spread and spot diameter of the electron beam. Furthermore, the axial defocusing, zero at negligible interactions, reaches a maximum and then becomes negative as the electron-electron interactions are increased; this is in agreement with the classical space-charge theory (4). Shown in Table I are the two cases of retarding field configurations with final landing energies of 1 keV and 100 eV, respectively. When the aperture radius is 0.1 mm or larger, the energy spread and spot diameter appear to be quite close to their conventional 10 keV counterparts. For very small apertures, however, the electron-electron interactions increase considerably.

Experimental Measurement

A scanning electron microscope (SEM) was modified to investigate the relation between beam diameter and beam current in conventional and in retarding field configurations. The arrangement is shown in Fig. 3. A flat aluminum slab was used as the target plane with a 1000 mesh/in. Ni grid mounted over the 2 mm diam hole. Conventionally, the aluminum target is grounded and the cathode is at -10 kV; in retarding field mode, the target is connected to -9 kV.

Table I. Values of energy spread (ΔE) and minimum beam diameter (d) for the conventional and retarding field configurations for a beam current of $5 \mu A$

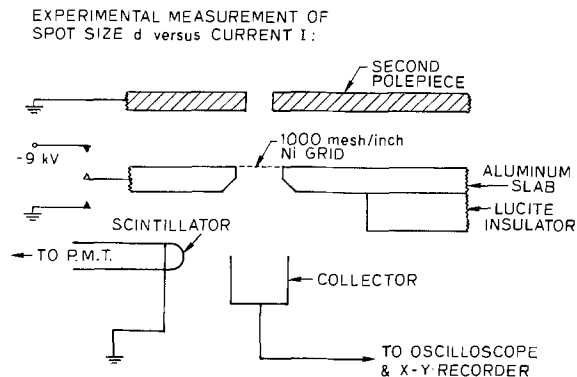

Fig. 3. Experimental arrangement for measuring beam diameter and beam current.

Underneath the mesh grid, a Faraday cup is used to collect the transmitted electrons. As the beam is scanned across the mesh, the signal rise time gives the measurement of the spot diameter and the beam current is measured. Some results are shown in Table II. Because of limitations of the SEM, contributions to the spot diameter arise mainly from the aberrations for large values of RAP, the Gaussian diameter of the source at small values of RAP, and electron-electron interactions in regions other than that between the final lens and target.

Discussion

Dayan *et al.* (5) suggested that a sample size of 100 is inadequate for currents above $10 \mu\text{A}$ at 20 kV because then the sample length becomes as short as the stepping interval. We have restricted the maximum current to $5 \mu\text{A}$ to minimize such an error. As a check on the error, three simulations were carried out with 200 electrons. The discrepancy in values of energy spread and spot diameter between 200- and 100-electrons simulation is about 10%. Furthermore, using a different set of randomly generated numbers, the variation in the results is within 5%. Further credibility to the validity of the Monte Carlo simulation results from the agreement of values of Δz at low values of σ (*i.e.*, serious interactions) with those determined from the classical treatment of the axial defocusing in conventional cases. For example, the maximum axial defocusing occurs at $\text{RAP} = 6 \times 10^{-4} \text{ cm}$ where $\sigma = 2.4$. This is the same value of σ which gives the maximum axial defocus according to Klemperer and Barnett (4).

It is not immediately obvious why the electron-electron interactions are not more serious in the retarding field case. One possible explanation is that the retardation is accompanied by an increase in convergence angle, thus reducing the interactive impulses. The experimental results are consistent with the main conclusion that the extra space-charge effects in the retarding field region has only

Table II

Aperture Radius	Current	Spot Diam	
RAP (cm)	I (μA)	d (μm)	
3×10^{-2}	5.0	2.3	Conventional $V_1 = 10 \text{ kV}$ $V_2 = 10 \text{ kV}$
3×10^{-2}	2.5	1.1	
3×10^{-2}	1.0	1.0	Retarding Field $V_1 = 10 \text{ kV}$ $V_2 = 1 \text{ kV}$
3×10^{-2}	5.0	2.6	
3×10^{-2}	2.5	1.2	
3×10^{-2}	1.0	1.1	

minor overall effect as predicted by Monte Carlo calculation.

Conclusion

1. There is no significant difference in energy spread and spot diameter for the conventional ($V_1 = V_2 = 10 \text{ kV}$) and retarding field ($V_1 = 10 \text{ kV}$, $V_2 = 1 \text{ kV}$ and 100V) configurations for currents up to $5 \mu\text{A}$ for the geometry shown. Hence the advantages of the previously reported low aberrations of the retarding field configuration are not offset by the electron-electron interactions in the final lens and the target plane region.

2. The Monte Carlo space-charge program predicts axial defocusing of high perveance beams in accordance with classical space-charge theory.

3. Experimentally, a current density of 250 A/cm^2 with 1 keV electrons at target plane is obtainable using tungsten hairpin filaments.

ABSTRACT

The effect of film thickness on the electrical properties of boron-doped LPCVD polysilicon films with doping concentration ranging from 1×10^{17} to 1×10^{19} cm^{-3} has been characterized from 1.2 μm down to 0.1 μm . The resistivity increases exponentially as the film thickness decreases, rather than remaining constant, and the rate of increase is a strong function of doping concentration. After a quantitative study on the physical mechanisms which can affect the resistivity as film thickness decreases, the carrier trapping effect due to grain-size variation at different film thicknesses is shown to be the dominant factor. A trapping model without assuming the depletion approximation can explain well the experimental data and enhances understanding of the resistivity behavior as the polysilicon film thickness decreases.

Polycrystalline-silicon (polysilicon) material is composed of aggregates of single crystal grains with a grain boundary between adjacent grains. The grain boundary is a transitional region between different orientations of neighboring crystallites. Polysilicon films have been widely used in integrated circuits such as silicon gates, interconnections, passivation or isolation layers, diffusion sources, resistors, monolithic distributed RC filters, diodes, active devices, and redundancy programming elements. Its increasing range of applications ensures the importance of this material in the coming era of VLSI.

Since the demand for better performance and higher packing density of VLSI circuits requires the device size to be scaled not only in the horizontal but also in the vertical direction, the thickness of polysilicon films used in most integrated-circuit applications has been scaled from several micrometers (1, 2) down to tenth of a micrometer (3). In addition, the film deposition generally has changed from atmospheric-pressure chemical vapor deposition (APCVD) (1, 2) to low-pressure chemical vapor deposition (LPCVD) (4) for better film quality and higher throughput. As a result, understanding of the thickness scaling effect on the electrical properties of LPCVD polysilicon films in the submicrometer range is important for device design in VLSI circuits.

Kamins (1) studied the thickness dependence of Hall mobility and resistivity in APCVD polysilicon films, which had thickness ranging from 3 to 24 μm and were doped by diffusion with concentrations ranging from 10^{18} to 10^{19} cm^{-3} . Resistivity of these polysilicon films decreases with increasing film thickness. Kamins showed that this decrease in resistivity is due mainly to the increase of mobility. Because an APCVD polysilicon film with thickness larger than several micrometers is composed of a few layers of grains stacked in the thickness direction, the measured mobility is actually an average mobility over the film thickness. The mobility near the top surface is larger in a thicker film because the grain size becomes larger. Mei *et al.* (5) studied the resistivities of APCVD polysilicon films which had thickness down to 0.25 μm and were doped by phosphorus ion implantation with a concentration of 1.2×10^{19} cm^{-3} . The resistivity also decreases with increasing film thickness. It was reasoned that this resistivity increase is due mainly to dopant segregation to the interface between polysilicon film and its underlying oxide layer. Recently, Colinge *et al.* (6) proposed a theoretical equation [Eq. (5) in (6)] for the mobility in polysilicon films, which considers the ef-

fect of film thickness by including the polysilicon/oxide interface scattering mechanism. They used 1.95 μm as the mean free path of electrons in silicon, which implies that if a polysilicon film thickness is reduced to the range of 1.95 μm , the effect due to collisions of electrons to the polysilicon/oxide interface can become a dominant factor to cause the resistivity increase.

The above review shows that the effect of film thickness on the electrical properties of LPCVD polysilicon films at different doping concentrations has not been fully understood and that, in fact, different viewpoints exist on the dominant mechanism for the resistivity changes as the film thickness decreases. In this work, therefore, we first characterized the electrical properties of boron-doped LPCVD polysilicon films which had thickness ranging from 1.2 down to 0.1 μm and doping concentration ranging from 1×10^{17} to 1×10^{19} cm^{-3} . It will be shown that as the film thickness decreases, the resistivity increases exponentially, rather than remaining constant as in conventional resistor materials, and the rate of increase is a strong function of doping concentration. There are several possible physical mechanisms to cause this increase, such as polysilicon/oxide interface scattering, dopant segregation to the grain boundaries, dopant leaching or loss, dopant segregation to the polysilicon/oxide interface, and changes of the number of carriers trapped into grain boundaries because of grain-size variations. A detailed quantitative analysis will show that the dominant mechanism causing the resistivity increase is the carrier trapping effect due to grain-size reduction.

Experimental Results

Sample preparation and measurements.—Undoped polysilicon films 0.1–1.2 μm thick were deposited onto 0.80 μm thick SiO_2 layers thermally grown on silicon wafers. The deposition was done in an LPCVD reactor at 620°C by H_2 ambient pyrolysis of silane with a deposition rate of 80 Å/min. The implanted boron doses were selected to give calculated doping concentrations at three different levels: 1×10^{17} , 2×10^{18} , and 1×10^{19} cm^{-3} . The calculations assumed a uniform dopant profile and no dopant loss. The implantation energies were selected to yield a maximum implantation dose near the center of the polysilicon films. After the devices were patterned by plasma etching, a 0.80 μm -thick CVD oxide layer was deposited at 430°C. Contact windows were opened, and the wafers were divided into two groups. One group had the contact windows implanted heavily with boron to give p^+

contacts; the other group did not have this implantation. All the wafers were then annealed at 900°C for 420 min in N₂ to remove the implantation damage and to ensure uniform dopant distribution. A 1.0 μm-thick aluminum layer was deposited and defined over the contact areas. The contacts were alloyed at 450°C for 20 min in N₂. The devices included different shapes of resistors, van der Pauw structures (8), and cross-bridge structures (8).

The thickness of polysilicon film was measured by an α-step profiler. The grain structure and grain size were studied using transmission electron microscopy (TEM) techniques. Figure 1 shows the typical cross-sectional TEM micrographs. It was found that all the grain structures of undoped and doped samples were conical, and no significant recrystallization was observed, in contrast to the reported grain growth in phosphorus-doped samples in Ref. (9). From thin to thick polysilicon films, the surface roughness becomes worse, and the grain size at the top of the surface, which corresponds approximately to the distance between the hillocks (9), increases. A quantitative measurement of the grain size was performed using top-viewed TEM micrographs shown in Fig. 2. Two methods were used, and the results agreed well. One method was to measure the area of a certain region and to count the number of grains within that area. The average grain size L is calculated from the following equation

$$L = (\text{area}/\text{number of grains})^{0.5}/m \quad [1]$$

where m is the micrograph magnification factor. The other method (10) was to draw a line and to count the number of grains across the line. The average grain size is

$$L = (\text{line length}/\text{number of grains})/m \quad [2]$$

The measured grain size decreases as the film thickness decreases (Fig. 3).

By using the secondary ion mass spectroscopy (SIMS) technique (11), dopant profiles were proven uniform, and no significant dopant loss was observed. The SIMS analysis was done with a 12 keV O₂⁺ beam raster scanned and gated to accept 20% of the central portion. Charging problems were minimized by using the electron flood gun and integration of the secondary ion energy distribution. We used a 50 keV boron implantation with dose of 5×10^{14} cm⁻² as a standard. The measured doping concentrations were within 20% of the projected values. Figure 4 shows typical SIMS profiles of samples which have projected doping levels of 2×10^{18} cm⁻³ and thickness of either 0.2 or 1.0 μm.

Electrical measurements included the I-V characteristics, resistivity, and Hall voltages. Resistivity was always measured over the linear I-V range with small applied bias. Sheet resistances for some high-value resistors were difficult to obtain from the Hall setup and were calculated, therefore, from measured resistance and device geometry.

Results.—The measured sheet resistance vs. film thickness at room temperature is shown in Fig. 5a for a doping

Fig. 1. Cross-sectional TEM micrographs. A, top: $t = 1950 \text{ \AA}$, $N = 1 \times 10^{17} \text{ cm}^{-3}$. B, bottom: $t = 9800 \text{ \AA}$, $N = 2 \times 10^{18} \text{ cm}^{-3}$. t = film thickness, N = doping concentration.

concentration of $1 \times 10^{17} \text{ cm}^{-3}$, and in Fig. 5b for $2 \times 10^{18} \text{ cm}^{-3}$. The contacts between aluminum and polysilicon in samples without p⁺ contact dopants are ohmic at small applied voltage. Inclusion of the p⁺ contact dopants does not significantly affect the sheet resistance. Figure 5a and 5b shows that when the film thickness decreases, the sheet resistance increases exponentially. The thickness dependence of the resistance is considerably larger at a doping concentration of $2 \times 10^{18} \text{ cm}^{-3}$ than at $1 \times 10^{17} \text{ cm}^{-3}$. The resistivity, which can be calculated by multiplying the sheet resistance by the film thickness, is also

Fig. 2. Top view TEM micrographs of the samples in Fig. 1

Fig. 3. Measured average grain size vs. film thickness

shown in Fig. 5a and 5b as a function of film thickness. A rapid increase of the resistivity with decreasing film thickness occurs, especially at thickness less than $0.8 \mu\text{m}$. This behavior is different from ohmic resistors of other materials, the resistivity of which is generally independent of thickness.

Theoretical Interpretation

Two theories have been proposed to model the transport properties of doped-polysilicon films. The first is a dopant-segregation model, where the grain boundary serves as a sink to cause preferential segregation of

Fig. 4. Measured dopant profiles vs. film thickness

dopant atoms that become inactive at the boundary (12, 13). This model, however, cannot explain the mobility minimum at a critical doping concentration, the temperature dependence of the resistivity, and the hyperbolic-sine I-V behavior of polysilicon resistors at high electric field. The second theory is a carrier trapping model (1, 2, 7, 14-16), where the trapping states inside the grain boundary, due to defects and incomplete atomic bondings, can trap free carriers from the ionized dopants. This process not only reduces the number of free carriers, but also creates a potential barrier surrounding the grain boundary, which impedes the motion of carriers from one crystallite to another. This model better explains the sharp changes of resistivity with doping concentration, the mobility minimum, the temperature dependence of resistivity, and the hyperbolic-sine I-V behavior at high

Fig. 5. Measured sheet resistance and resistivity vs. film thickness at room temperature. A, above: $N = 1 \times 10^{17} \text{ cm}^{-3}$. B, right: $N = 2 \times 10^{18} \text{ cm}^{-3}$.

electric field. Even if the dopants do segregate, the trapping model can still be applied, based on an active dopant concentration that can be obtained by subtracting the inactive dopant concentration from the actual doping concentration (15, 17).

For thin-film polysilicon resistors, several physical mechanisms may cause the observed resistivity increase when film thickness decreases. The effect of these mechanisms will be considered individually below.

Scatterings at horizontal grain boundaries and polysilicon/oxide interface.—TEM results on LPCVD films show that the grain structures in all samples having different film thicknesses are conical. In such conical structures, grain boundaries rarely occur in the direction parallel to the polysilicon/oxide interface, in contrast to the randomly stacked grain structures usually observed in APCVD polysilicon films. If the structure had many stacked layers of such horizontal grain boundaries, the resistances of the samples with p⁺ contact dopants could not be the same as those without the contact dopants because the grain boundary is a high resistance region. However, it is found that the resistances of samples with p⁺ contact dopants are approximately equal to those without p⁺ contact dopants. This demonstrates that, even though horizontal grain boundaries may exist occasionally, they do not seriously disturb the current flow, and the possibility of carriers colliding with the horizontal grain boundaries is low. Since the mean free path of carriers in the intrinsic silicon is approximately 200Å,¹ which is much smaller than the thinnest film thickness in our samples, the carriers should have had several collisions before scattering at the polysilicon/oxide interface. As a result, the scattering effects due to both polysilicon/oxide interface and horizontal grain-boundaries should not be the dominant factor responsible for the resistivity increase (18) in LPCVD polysilicon films with thickness down to 0.1 μm. Another piece of indirect evidence to support the conclusion is that when the oxide layer above polysilicon film is removed, the measured resistance does not change too much from the resistance of samples with the top oxide layer present, and the rate of resistivity increase as the films become thinner is almost the same. In addition, that different rates of the resistivity increase at different doping concentrations is difficult to explain based on scattering effect.

Dopant segregation to grain boundaries.—Although the amount of dopant segregation to grain boundaries can be a function of film thickness, Mandurah *et al.* (19) showed that no significant segregation effect occurs in boron-doped polysilicon films. In our boron-doped samples, the grain-boundary segregation should not be the dominant factor for the resistivity increase.

Dopant leaching or loss.—After implantation and before annealing, the samples were coated with a thin layer of low temperature deposited oxide to protect their surfaces from furnace ambient and to prevent loss of dopants during the high temperature process. The SIMS results (Fig. 4) proved that the actual doping concentration in the polysilicon film is close to the projected value within 20% variation, and no significant loss was found even in the thinnest samples.

Segregation to polysilicon/oxide interface.—From the SIMS results as shown in Fig. 4, no significant pileup of the dopants was found at the polysilicon/oxide interface in the samples with doping concentration up to 2×10^{18} cm⁻³. It should be noted that an electron flood gun for charge compensation was employed. While not shown in Fig. 4, the silicon signal remained constant when sputtering through the Si/SiO₂ interface. It has been shown (20) that at normal incidence O₂⁺ bombardment, silicon is completely oxidized to SiO₂. At a doping level of 1×10^{19} cm⁻³, a small pileup of the dopants has been observed; however, its amount is not so significant as to affect the absolute doping level in the film. This effect can become important at higher doping concentration.

¹ The mean free path λ is $v_{th}(m^* \mu / q)$, where v_{th} is thermal velocity of the carriers, $v_{th} = (3kT/m^*)^{0.5}$, and μ is mobility. In intrinsic silicon, $\lambda \approx 237\text{\AA}$ for holes and $\approx 204\text{\AA}$ for electrons at room temperature. In a doped silicon crystallite, λ is even smaller. For example, $\lambda \approx 130\text{\AA}$ at a doping concentration of around 10^{20} cm⁻³.

Carrier trapping.—Before a quantitative calculation of the carrier trapping effect on the resistivity change due to reduction of film thickness, general features of the carrier trapping model are briefly reviewed here. Several assumptions were made in the previous trapping models (2, 15) to simplify the calculation. The polysilicon film is assumed to be composed of identical crystallites having a grain size L , and the grain boundary is assumed to contain Q_T cm⁻² of traps located at an energy level of e_T with respect to the intrinsic Fermi level at the grain boundary (Fig. 6). The traps are assumed to be initially neutral and become charged by trapping carriers. When dopants are added into polysilicon films, some of the mobile carriers around the grain boundary are trapped by the trapping states in the grain boundary, resulting in a depletion region. Using these assumptions, an abrupt depletion approximation was used to calculate the energy band in the crystallites. For a given grain size, since the effective trapping states in the grain boundary are finite, there exist two possible conditions, depending on the doping level. If the doping concentration is high, the crystallite can only be partially depleted and a neutral region remains (Fig. 6b). If the doping level is decreased to a critical doping concentration N^* , the crystallite is totally depleted (Fig. 6c). Because the crystallite becomes totally depleted, the number of free carriers remaining in the crystallite drastically decreases, thus causing a sharp resistivity increase. As the doping level further decreases, the crystallites remain in the condition of total depletion, and resistivity increases at a rather gradual rate. This explains why the resistivity vs. doping concentration curve of polysilicon films has a sharp change in slope near the critical doping level N^* . Similarly, at a given doping concentration, there exists a critical grain size L^* below which the grains are totally depleted. For a grain size around the value of L^* , as the grain goes from partial to total depletion, the resistivity change due to grain size variation is drastic.

As mentioned above, TEM results showed that when polysilicon film thickness is reduced, the grain size decreases. The effect of such grain-size change on the resistivity of polysilicon films will be examined based on the carrier trapping model below.

The previous trapping models (2, 14, 15) using the depletion approximation can clearly describe the transport

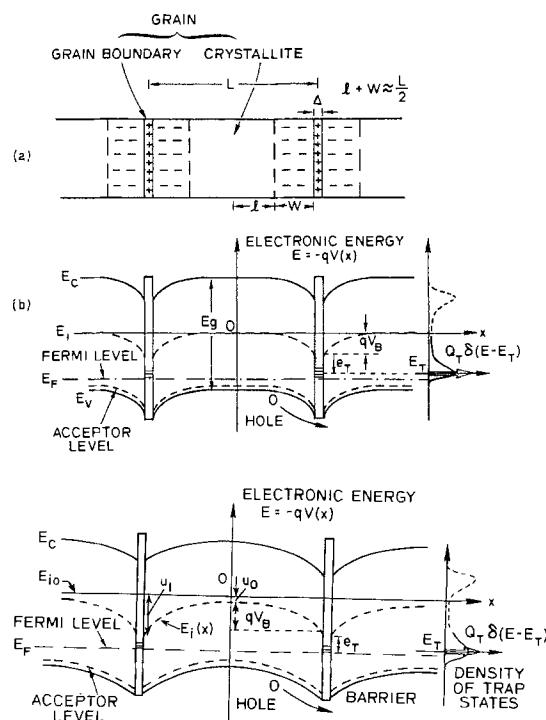

Fig. 6. The polysilicon trapping model. a: One-dimensional grain structure. b: Energy-band diagram of partially depleted grains for p-type dopants. c: Energy-band diagram of totally depleted grains for p-type dopants.

properties of polysilicon films. However, the depletion approximation causes abrupt changes in the resistivity with respect to grain-size variations near the transition between the partial depletion and the total depletion condition (21).² These abrupt changes can be smoothed by using a more accurate solution of Poisson's equation without assuming the depletion approximation (21). Recently, an exact solution for polysilicon resistivity was derived, which can avoid such abrupt changes and is valid over a wide range of doping concentrations, temperatures, and grain sizes (22). In this work, because samples are not very heavily doped and data were measured at room temperature, the exact Fermi-Dirac statistics of free-carrier distribution can be approximated by Boltzmann statistics, thus relaxing our exact analysis (22) to similar equations derived by Board and Darwish (21), except that a more precise formulation of the Fermi level in the bulk silicon E_{i0} as zero energy and assuming the electron (hole) energy positive (negative) for upward and negative (positive) for downward direction (Fig. 6), the Fermi level is

$$E_F = kT \ln \left\{ \frac{1}{4} \exp(E_A/kT) \left[\sqrt{1 + 8(N_A/n_i) \exp(-E_A/kT)} - 1 \right] \right\} \quad [3]$$

where N_A is the doping concentration, n_i is the intrinsic carrier concentration, and impurity level E_A , is (15)

$$E_A = \left(\frac{1}{2} E_g - 0.08 + 4.3 \times 10^{-8} N_A^{1/3} \right) + E_i(0) \quad [4]$$

By solving Poisson's equation and using suitable boundary conditions (21), the relationship of intrinsic Fermi level at grain boundary $E_i(L/2)$ with respect to the intrinsic Fermi level at the center of grain $E_i(0)$ can be calculated from

$$\left(\frac{Q_T^+}{2L_D q N_A} \right)^2 = (u_1 - u_0) + \beta(e^{u_1} - e^{u_0}) + (e^{-u_1} - e^{-u_0}) \quad [5]$$

where $L_D = (2kT\epsilon/q^2 N_A)^{0.5}$, $\beta = kT/q$, u_1 and u_0 are defined as $E_i(L/2)/kT$ and $E_i(0)/kT$, respectively, and the ionized trap density in the grain boundary Q_T^+ is related to the number of metallurgical traps Q_T as follows (2, 15)

$$Q_T^+ = \frac{Q_T}{1 + 2 \exp[u_1 + (e_T - E_F)/kT]} \quad [6]$$

where e_T is the trapping-state energy level with respect to the intrinsic Fermi level at the grain boundary. The corresponding grain size L is given by

$$L = L_D \int_{u_0}^{u_1} [(u - u_0) + \beta(e^u - e^{u_0}) + (e^{-u} - e^{-u_0})]^{-1/2} du \quad [7]$$

By varying u_0 , therefore, the corresponding u_1 and L can be calculated using Eq. [5] and [7].³ The resistivity is then obtained from (15)

$$\rho = \frac{(2\pi m^* kT)^{1/2}}{L q^2 p(0)} \exp(qV_B/kT) \quad [8]$$

where $qV_B = kT(u_1 - u_0)$ and $p(0) = N_A \exp(-u_0)$. For simplicity, crystallite bulk resistivity is not included.

To compare theory to the experimental results, it is necessary to determine m^* , permittivity ϵ , n_i , E_g , L , Q_T , and e_T . The values of single-crystal silicon were used for the first five parameters (15) and L was measured from TEM micrographs (Fig. 3). Q_T and e_T were obtained experimentally from the ρ vs. $1/kT$ curves of polysilicon resistors by using similar procedures described in Ref. (15). The method is valid because the samples used for parameter extraction have doping concentrations away from N^* , and thus the depletion approximation is valid.

² This can be interpreted in terms of film thickness as follows: at a given doping concentration, when film thickness changes such that its grain size is close to L^* , the abrupt depletion approximation becomes invalid.

³ The contents of Eq. [5], [6], and [7] are different from their corresponding expressions in Ref. (21) by including the necessary corrections.

Fig. 7. Measured and theoretical resistivity vs. average grain size of different thickness films.

Also, since Q_T could be precisely determined, the value of e_T was adjusted within a reasonable degree to produce the best results of the ρ vs. L curves. Figure 7 shows the measured resistivities of different thickness films vs. the measured average grain sizes. The theoretical curves agree well with the experimental data and explain the drastic increase of resistivity with decreasing film thickness. Because decrease of film thickness causes reduction of grain size, when the grain size reaches around 210Å at doping concentration of $2 \times 10^{18} \text{ cm}^{-3}$, most of the grains go from partial depletion into total depletion, and the number of free carriers available for conduction drastically decreases, thus causing a sharp increase of resistivity. In contrast, at doping concentration of $2 \times 10^{17} \text{ cm}^{-3}$ for the range of film thickness studied in this work, most of the grains have been totally depleted, and therefore, the changes of resistivity are not so drastic as in those samples with doping concentration of $2 \times 10^{18} \text{ cm}^{-3}$. As a result, the carrier trapping effect due to grain-size variation at different film thicknesses is a dominant factor for the resistivity increase in boron-doped LPCVD polysilicon films as the film thickness decreases ($\geq 1000\text{Å}$).

Conclusions

The effect of film thickness on the electrical properties of boron-doped LPCVD polysilicon films has been studied down to film thickness of $0.1 \mu\text{m}$. It has been found that the resistivity increases exponentially as the film thickness decreases, rather than remaining constant, and the increasing rate is a strong function of doping concentration. After a quantitative study of the physical mechanisms which may affect the resistivity as film thickness decreases, the carrier trapping effect due to grain-size variation at different film thicknesses was shown to be the dominant factor. A trapping model without assuming the depletion approximation can explain the experimental observations well and enhances understanding of the resistivity behavior as polysilicon film thickness decreases. It also shows that when the polysilicon films are employed in VLSI circuits, the sensitivity of the resistivity to the film thickness must be considered in the device design (23).

Polycrystalline Silicon Recrystallization by Combined CW Laser and Furnace Heating

J. Shappir* and R. Adar

School of Applied Science and Technology, The Hebrew University of Jerusalem, Jerusalem, Israel

ABSTRACT

A modified CW argon laser-induced lateral recrystallization of polycrystalline silicon is described. Holding the sample in a furnace at elevated temperature of about 1000°C resulted in significantly reduced thermal gradients and stresses. A wider range of power is allowed for proper recrystallization both on oxide and substrate areas simultaneously. Preferred thermal profiles enabled larger lateral epitaxy of ~50 μm per single scan. The higher substrate temperature resulted also in wider melted areas and high scan rates of 80 cm/s enabling much shorter processing time.

In recent years, intensive effort has been made in different techniques to obtain large area silicon on insulator (SOI) as an alternative substrate for integrated circuits. Besides the obvious advantages of reduced junction capacitance, no device coupling, and no contact spiking, it can eventually lead to three-dimensional integration of electronic devices (1, 2). Gat *et al.* observed (3) that the recrystallization of polysilicon layers on an insulating substrate by a CW laser beam results in grains having dimensions up to $2 \times 25 \mu\text{m}^2$.

In order to fabricate larger-area SOI structures without grain boundaries and with complete control of the crystallographic orientation, seeded lateral epitaxy technique has recently been studied (4, 5). In this technique, a region where the polysilicon is in direct contact with the silicon substrate serves as a seed for lateral crystal growth to the area where the polysilicon is over an insulating layer.

With standard isoplanar technology, lateral epitaxy of 20-30 μm was obtained. Modified coplanar structure with no step between the polysilicon on silicon (PS) and polysilicon on oxide (PO) or the utilization of thin underlying insulators (< 1500Å) resulted in further increase of the lateral epitaxy to 70-80 μm (5, 6).

In the standard laser recrystallization configurations, the silicon wafer is attached to a metal chuck that can be heated up to 700°C (6) and the laser beam raises the layer temperature to above its melting point of 1415°C. Such an arrangement suffers from two major drawbacks: (i) It is difficult to find optimal recrystallization conditions for both the PS and PO areas due to the difference in the vertical heat conduction in the two regions, and (ii) the high lateral thermal gradients are bound to reduce the crystalline quality of the recrystallized layer.

To overcome these two problems, the approach of this work was to raise the substrate temperature to about 1000°C by placing it in a diffusion furnace and use lower laser power to raise locally the polysilicon temperature to its melting point. In this setup, the wafer loses most heat by blackbody radiation rather than by thermal conductance to the metal chuck.

In the following, certain results of this combined laser and furnace recrystallization technique are reported.

Experimental

The experimental setup consisted of the laser, the optics, the scanners, and the furnace, where the wafer was held during the recrystallization process. The laser was a Coherent 18W Ar ion laser, operated in the multiline mode with wavelengths near 0.5 μm. The optical system consisted of two lenses in a beam expanding structure that served both as beam expander and focusing element to obtain an 80 μm diam spot size, at a focal distance of 700 mm. The beam was scanned across the wafer by means of two galvanometer-driven mirrors. The silicon wafer was vacuum held by an adjustable quartz tube which entered the furnace from its back side. The system also included a conventional metal vacuum chuck for comparison purposes. The experimental setup is illustrated schematically in Fig. 1.

The 0.5 μm-thick polycrystalline silicon layer was deposited on a standard isoplanar structure, obtained by local oxidation of the p-type <100> silicon substrate to 0.7 and 1.1 μm oxide thicknesses. As a stabilizing capping layer, use was made of CVD-deposited Si₃N₄ or thermally grown SiO₂ layers of various thicknesses. After the recrystallization step, the capping layers were removed and Secco etch (7) was used to reveal the grain boundaries.

Results

Effects of recrystallization at elevated substrate temperatures.—The main advantage of the recrystalliza-

*Electrochemical Society Active Member.

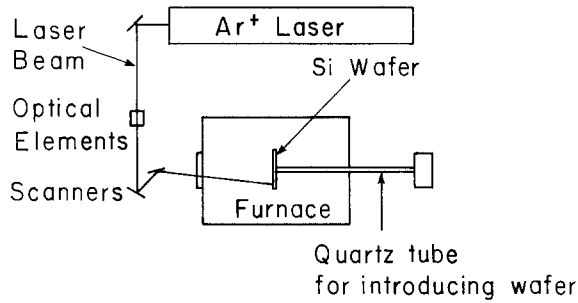

Fig. 1. The experimental setup

tion process at high substrate temperatures is in having a wider window of allowed laser power for good recrystallization both on the PO and PS regions. This can be seen in Fig. 2, where recrystallization was performed with substrate temperatures of 1000°C, 700°C, and 400°C using oxide capping. At low substrate temperature, catastrophic results were observed in the PO regions, while no recrystallization took place in PS regions. As the substrate temperature increased, the difference between the two regions was reduced. At 1000°C, similar results were obtained both in PO and PS regions.

The experimental conditions in Fig. 2d are identical to those of Fig. 2c, with the exception that the wafer was held by the metal chuck at 400°C. It is concluded that the wafer temperature is one of the dominant factors affecting the quality of recrystallization; the way the wafer is held has little influence.

The furnace temperature has also a profound effect on the width of the molten zone of a single laser scan with fixed velocity and power, as shown in Fig. 3.

The thermal gradients and their effect on the lateral epitaxial regrowth.—As was established in previous works (5, 8, 9), the direction of the grains' growth in the recrystallization process is identical to the thermal gradients in the trailing edge of the laser-induced molten zone.

The temperature profile is determined by the laser beam shape, its scan rate, and the thermal conductivity of the sample. Figures 4a and 4b represent typical recrystallization structures in PO regions for low power and scanning velocity and high power and velocity, respectively. The isothermals and the momentary solidification front can be easily traced starting at the top side of the scan and advancing to the bottom side, always at a right angle to the grain boundaries. The resulting profiles are also shown in Fig. 4.

Fig. 2. Recrystallization at furnace temperature of: (a) 1000° (b) 700°, and (c) 400°C. In (d), the wafer is attached to a metal chuck at 400°C. Oxide thickness in PO regions is 1.1 μm. The PO is the center region.

Fig. 3. The dependence of the single-scan molten zone width in the PS regions on the furnace temperature with laser power as a parameter. Scan velocity was 8 cm/s.

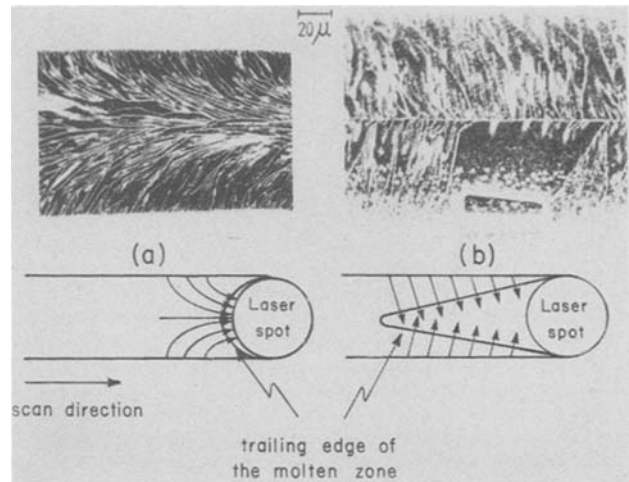

Fig. 4. The structure of the grain boundaries and the momentary solidification front in (a) low power and velocity recrystallization ($P = 4W$, $v = 8$ cm/s) and (b) high power and velocity conditions ($P = 12W$, $v = 80$ cm/s.)

For a given silicon on insulator structure, the substrate temperature and the absorbed heat density determine the cooling time of the layer from its maximal temperature to below the melting point. This cooling time multiplied by the scanning velocity equals the characteristic length of the molten zone behind the moving laser beam.

When this length is smaller than the beam radius, as in Fig. 4a, the profile of the trailing edge of the molten zone is similar to the beam shape, *i.e.*, circular for Gaussian beam. In the case when this length is much larger than the beam dimension, the trailing molten zone no longer follows the beam shape, as seen in Fig. 4b, and the thermal gradients are directed almost perpendicular to the scan direction.

A moving solidification front with a small radius of curvature is known to induce a higher density of defects and dislocations as compared to a flat front (5). This is reflected in the size of the epitaxial lateral distance. The gradient structure in Fig. 4b represents almost flat solidified front, while in Fig. 4a, this front is significantly more curved. The results consistently show more than 50 μm lateral single crystal in the high scan power and rate (Fig. 4b), as compared to less than 25 μm in the slow scanning conditions (Fig. 5). The central horizontal line in Fig. 4b is where the crystals growing from both sides do meet.

In the case of the high scanning velocities of 50-80 cm/s, the molten silicon area is so large that the situation is close, in a sense, to the situation of pulsed-laser recrystal-

Fig. 5. The lateral epitaxial distance is limited by defect formation to less than $25 \mu\text{m}$ when the gradients are curved, and can be increased to more than $50 \mu\text{m}$ when the solidification front is almost flat (Fig. 4b).

lization. Under such conditions, the thermal gradients are strongly dependent on the layer configuration, *i.e.*, the layout of the PS and PO regions. The vertical thermal conduction is significantly higher in the PS than in PO regions, and thus the PS region is first to solidify, and the recrystallization propagates in all directions away from the PS into the PO region, as shown in Fig. 6.

Thermal effects in the PO-PS border.—Although it is not clear yet what are the exact mechanisms which restrict the lateral epitaxial distance (5, 10), it is agreed upon that moving from the PS into the PO region is a critical step which can introduce high defect density (11, 12). This is demonstrated in Fig. 2a and 7, where a discontinuity in the thermal profile near the interface between the PS and PO region is observed. Figure 8 represents schematically the changes in the maximal temperature along the scan axis shown in Fig. 7. These variations were repeatedly observed in different scanning conditions. In the PS side (regions b and f in Fig. 8), a decrease in the scan width is observed. This implies lower temperatures in these areas, as compared to regions farther away from the PO regions (a and g). This is explained by extra heat flow in the lateral direction to underneath the PO region where the substrate is relatively colder because of the insulating oxide layer. This phenomenon is slightly stronger where the beam passes from the PO to the PS (region f), probably because the lateral conduction of heat opposite the scanning direction is always more efficient. As a consequence of the heat flow from the PS regions, the temperature gradients across the oxide is smaller near the PO edge (regions c and e), and thus a lower cooling efficiency towards the substrate exists there. This, in turn,

Fig. 6. The lateral epitaxial distance from PS islands in rapid scan and moderate power is less dependent on the scan direction and propagates up to $10 \mu\text{m}$ in the "reversed direction."

Fig. 7. Variation in the laser effect near the PS-PO interfaces. The PO is the center region.

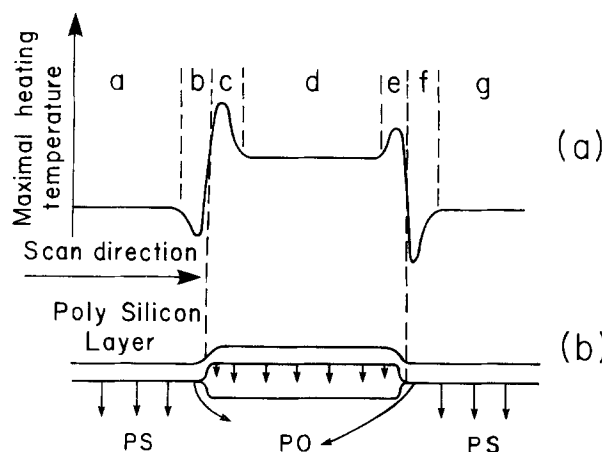

Fig. 8. The variation of the maximal temperature along the scan axis a), can be explained by heat flow to underneath the oxide layer, as shown by the arrows in (b).

leads to higher temperature of the layer which eventually broadens the melted-region width (Fig. 7) and may even cause a local damage in the recrystallized layer just as it starts to propagate into the PO region (Fig. 2a). These findings do not contradict the conclusions of Ohkura *et al.* (13), who claim that in regions b and f the temperature is higher than in regions a and g, since, as shown in Fig. 8, extremely close to the region c the temperature of region b might be still higher than in region a.

Discussion

It was shown that carrying out the lateral, laser-induced, recrystallization at elevated substrate temperatures around 1000°C reduces the thermal stresses significantly, as compared to $400^\circ\text{--}500^\circ\text{C}$ conventional hot-chuck systems. Holding the wafer during this process in a heated furnace implies that the Si wafer loses the absorbed laser power by blackbody radiation.

By means of high velocities and laser power, made possible by the high temperature conditions, certain control over thermal gradients was possible with a fixed-beam shape. An almost flat solidifying front was achieved, resulting in as far as $50 \mu\text{m}$ lateral epitaxy in a single scan. The higher scan rate and the obtained wider molten zone imply also much shorter processing time, as compared to the conventional approach.

Under such recrystallization conditions, lateral seeded epitaxy is observed also when the laser beam moves from the PO to the PS region. The mechanism of the lateral recrystallization in this case is believed to be the same as the "bridging epitaxy" observed in pulsed-laser annealing (14, 15). The lateral bridging obtained is $7\text{--}10 \mu\text{m}$ as compared to only $1.2\text{--}2.5 \mu\text{m}$ previously reported. This im-

proved result is again associated with the high temperature conditions. Another significant advantage of the high substrate temperature is the increase in the laser power window of proper recrystallization both on PS and PO areas.

Finally, it was pointed out that an undesired increase in the thermal discontinuity exists near the oxide edge. This was attributed to lateral heat flow to underneath the oxide. Minimal step in the polysilicon layer structure by silicon etching before the local oxidation step (5) can probably decrease this phenomenon.

In conclusion, it was shown that performing the CW laser-induced lateral recrystallization at elevated substrate temperature can have an important advantage in overcoming some of the technological problems connected with thermal stresses. The high temperature conditions enable also higher area coverage velocities and might lead to larger and better quality epitaxial silicon on insulator structures.

Cleaning of Si and GaAs Crystal Surfaces by Ion Bombardment in the 50-1500 eV Range

Influence of Bombarding Energy and Sample Temperature on Damage and Incorporation

ABSTRACT

Silicon and gallium arsenide single crystals were cleaned in high vacuum by very low energy ion bombardment. High currents (up to 1 mA/cm²) were produced by a triplasmatron source down to energies of 50 eV. *In situ* Auger analyses showed that Si and GaAs clean surfaces are obtained at room temperature for bombarding energies as low as 70 and 50 eV, respectively. The incorporation of bombarding ions and the bombardment-induced disorder were studied *ex situ* by Rutherford backscattering and channeling. For silicon, the incorporation (Ar or Xe) increases linearly with bombarding energy while the Auger signal saturates above 200 eV. This result indicates that at high energies, ions are incorporated at greater depths than the sampling depth of the Auger technique. For GaAs, ion incorporation takes place only above 200 eV. The bombardment-induced disorder increases with the bombarding energy. Above 200 eV, a strong correlation was observed between incorporation and disorder, demonstrating that the latter was stabilized by the incorporated ions. However, at very low energies, a significant disorder remains (10¹⁶ and 5 × 10¹⁵ atom/cm², for Si and GaAs, respectively) for a very small concentration of incorporated ions, indicating the presence of "intrinsic disorder" related to the sputtering mechanism. No influence of the beam current on bombardment-induced incorporation or disorder was detected. For silicon, at very low bombarding energies, the disorder increases with the sample temperature during bombardment, with a noticeable effect already observed at 100°C. This is due to bombardment-enhanced diffusion of the ions and associated damage stabilization. At higher bombarding energies, no temperature dependence was observed because the range of bombarding ions was greater than the diffusion length.

In the preparation of semiconductor devices, the nature of surfaces has been a long standing concern. It is well known today that high quality devices are obtained only from clean and undamaged surfaces. For instance, the production of low resistance ohmic contacts or of high quality and reproducible Schottky diode characteristics (1) is directly related to obtaining such surfaces. But the ease in achieving such a perfect surface depends, of course, on its chemical reactivity, which is very high for

* Electrochemical Society Active Member.

Key words: semiconductor, surfaces, crystallography, sputtering.

most semiconductors. Consequently, the presence of undesirable surface impurities is hard to avoid.

Of all the possible methods of semiconductor surface preparation, chemical etching is most generally used. During or just after this chemical treatment, an inhomogeneous oxide layer is formed. In addition to oxygen, the major impurity was found to be carbon. Other trace elements such as Cl, Br, N, and S may be observed. This latter contamination depends on the etching solution used to remove the native oxide. Many studies have been carried out, on silicon or gallium arsenide, germanium, gallium phosphide, and indium phosphide (2, 3).

An obvious way to be free of the atmospheric native oxide is to proceed under vacuum conditions. One method to achieve a clean well-ordered surface consists of heating the substrate in UHV at a temperature high enough to evaporate the surface oxide, i.e., 1200°C for silicon (4), 550°C for gallium arsenide (5), 800°C for germanium, and 500°C for indium phosphide (3). Thermal desorption can be achieved through the use of a heated filament, by electron beam heating the back side, or by pulsed or continuous laser irradiation (6). Problems such as diffusion of impurities to and from the bulk or departure from stoichiometry in the case of compound semiconductors set limits to this method.

Another approach widely used today is physical sputtering and subsequent annealing. It consists of inert gas ion bombardment followed by heating at a temperature lower than that required for thermal decomposition of the oxide to expel the retained bombarding species and remove the damage induced in the surface region (7). Most studies center around residual ion damage and primary ion retention before and/or after annealing as a function of ion energy, sample temperature during sputtering, and current density. As shown by Sachse *et al.* (8) for Ar bombardment of Si {111}, the behavior of lattice damage and argon trapping as a function of annealing temperature is strongly dependent on the bombarding ion energy. The required annealing temperature was shown to increase with the sputtering ion energy in the range 0.5-2.5 keV. In the same way, Yamada *et al.* (9) pointed out that annealing of Si {100} is achieved at 720°C when the Ar ion energy is less than 1.5 keV. Moreover, Ne and Kr bombardment necessitate lower annealing temperatures than Ar. For 150 eV Ar ion energy from a RF triode arrangement, Koch *et al.* (10) find that an annealing treatment at 600°C for 20 min is sufficient to remove the ion damage for Si. Bean *et al.* (11) have investigated the effect of varying the sample temperature from 25° to 800°C during sputtering of {100} and {111} silicon surfaces with 1 keV Ar⁺ ions. They have studied Ar retention with the help of both AES (Auger electron spectroscopy) and ⁴He⁺ RBS (Rutherford backscattering spectrometry). For as-bombarded samples, the Ar Auger signal decreases when the temperature during sputtering is increased. At the same time RHEED (reflection high energy electron diffraction) patterns show an increasing degree of surface order. However, when AES and RHEED show a fully ordered and Ar-free topmost surface region resulting from 800°C sputtering, ⁴He⁺ RBS and channeling give evidence of disorder and Ar capture. The argon content increases from 1.4×10^{14} to 1.5×10^{15} atoms/cm² when the temperature during sputtering goes from 150° to 800°C. Ar atoms extend approximately 500Å into the bulk for the latter temperature.

Many studies have also been carried out on the effects of ion sputtering on GaAs. The retention of primary ions and near surface stoichiometry have only been probed by AES (12-15). Reference (15) gives an exhaustive compilation of Auger data, in which the Ga over As peak to peak height ratios were used "in order to determine changes in the surface composition more accurately." The results show the formation of an As depleted near surface region for high current density *J* and low temperature *T* and a GaAs stoichiometric surface for low *J* and high *T*. Lower current densities and higher temperatures are required to obtain a stoichiometric surface when the ion energy is increased. Competition between thermal annealing and bombardment damage processes is involved to account for the order-disorder transition of the GaAs surface region (the 20Å probed by AES). These results seem to indicate different trends than those obtained by Bean (11) on the temperature effect of sputtering induced damage for Si. As stated before, the disorder and the implanted primary ions diffuse into the bulk when the temperature is increased and cannot be seen by AES. An important result of the preceding studies (12-15) is that, even at bombarding energies as low as 250 eV, the surface is not Ar-free at room temperature.

From this brief review we can conclude that the preparation of a well-ordered impurity-free surface requires a careful choice of the parameters involved. The aim is to minimize the defects and implanted ions introduced dur-

ing bombardment in order to avoid a too high temperature annealing treatment.

In the present work, we report results on surface cleaning of {100} Si and GaAs crystals by ion bombardment under high vacuum conditions. The near surface composition was checked both by Auger analysis in order to get information on the few topmost surface layers and by nuclear microanalysis to calibrate the Auger results and study deeper layers (on the 100-1000Å range). The surface disorder was studied by channeling. As shown by the literature mentioned above, damage and impurity incorporation usually decrease at low bombarding energy. However, the sputtering efficiency also decreases so that higher current densities are required to achieve proper cleaning in a reasonable time. In this work, we use a triplasmatron source which can produce very high current densities down to energies below 100 eV. We have performed a systematic study of the influence of ion species, ion energy, and ion current density on the damage, and the ion implantation induced by bombardment. Moreover, we determined the lowest energy limit for surface cleaning (for our experimental conditions). We have also studied the effect of substrate heating during bombardment as a function of ion energy. Due to the mobility of point defects and to extended defects nucleation probabilities, the damage induced, even at low ion energy, is expected to vary strongly with the bombardment temperature. The same holds for impurity incorporation which may be related to the mobility of impurity-defect associations. Our results give clear evidence for such dependencies.

Experimental

Apparatus and procedure.—The ultrahigh vacuum stainless steel experimental setup in which the cleaning procedure was carried out is shown in Fig. 1. It is divided into four separable chambers: a sample introduction lock with fast pumping capability, an *in situ* surface analysis chamber with a cylindrical mirror analyzer (CMA) Auger electron spectrometer to monitor the chemical cleanliness of the surface, and an interaction chamber located at the end of the ion gun which consists of a plasma source and a transport chamber. The analysis chamber had a base pressure of $8 \cdot 10^{-10}$ torr obtained with ion pumping. The interaction chamber was pumped to $5 \cdot 10^{-8}$ torr by a turbomolecular pump, then pumped down to less than 10^{-8} torr using a cryopump. A quadrupole mass analyzer was used to monitor residual gas analysis at each stage of the experiments.

The ion source used was of the triplasmatron type which was described elsewhere (16-18). Briefly, it consisted of a miniature duoplasmatron source used as a hot cathode for the auxiliary discharge which took place in the expansion cup located behind the anode of the duoplasmatron. In order to reach a high efficiency, the expansion cup was positively biased with respect to the anode. This source had the advantage that there was no back-diffusion towards the main discharge. Thus, the source parameters and operating conditions were reproducible since the filament was not affected and had a long lifetime. With help of a toroidal magnetic field, the charged and neutral species were separated from the expanding plasma. Neutrals and photons could be used or analyzed in the axis of the plasma source even though this was not undertaken for the present study. Ions and electrons were carried along the strength lines of the magnetic field and separated according to their charge sign when biasing the target. For the cleaning experiments, nonreactive gases were solely employed. The pressure in the interaction chamber was varied from 10^{-5} to 10^{-4} torr depending on the sample current called for: 20-1000 $\mu\text{A}/\text{cm}^2$. This current density can be reached for a bias voltage in the range 50-1500V. The circular section of the ion beam has an intensity distribution peaked at the center with a FWHM (full width at half maximum) of about 20 mm. Mass analysis of the ion beam showed that for Ar bombardment, less than 0.1% of the ionized species were unwanted ions: H₂O⁺, N₂⁺, CO₂⁺, O₂⁺, and the percentage of multi-ionized species did not exceed 0.5%. Energy analysis showed that the energy distribution was centered at

Fig. 1. Schematic representation of the experimental setup showing the triplasmatron source consisting of the duoplasmatron (1) and the expansion cup (2), induction coils (3) giving rise to the toroidal magnetic field in the transport chamber (4). The neutral species path (5) and the charged species-substrate interaction chamber (6) are also shown. The introduction lock chamber (7) with sample holders storage capabilities (8) and the analysis chamber with CMA Auger electrons analyzer (11), and a place reserved for LEED apparatus (12) complete the setup. the bias voltage with a FWHM of 50 eV for Ar^+ and 35 eV for Kr^+ or Xe^+ .

In this study, the samples were {100} oriented p-type Si ($\sim 10^{17}$ - 10^{19} cm^{-3}) doped with B and {100} oriented n-type GaAs ($\sim 10^{18} \text{ cm}^{-3}$) doped with Si. After mechanochemical polishing, they were degreased in trichlorethylene, acetone, and methanol before being etched in HF or HCl solutions for Si or GaAs in order to remove the inhomogeneous oxide layer. Each cleaning stage was conducted in an ultrasonic bath. After being rinsed and dried, the samples were mounted with indium on a molybdenum platform smaller than the sample ($1 \times 1 \text{ cm}^2$) in order to avoid sputter deposition of the substrate holder onto the sample. The holder could be heated with halogen lamps up to 600°C . The temperature was monitored by a Chromel-Alumel thermocouple clamped in the molybdenum. The sample temperature was somewhat underestimated, however, no distinction between the sample and sample-holder temperature will be made in the text.

To check the surface cleanliness, the ion bombardment was stopped and the sample holder transferred into the analysis chamber. The Auger measurements proceeded under normal incidence conditions with an incident electron beam energy of 2 or 3 keV and $2 \mu\text{A}$ beam current provided from a 3 kV electron gun coaxial to the CMA. The beam diameter at the sample surface was about 0.3 mm. The modulation was 3V rms for all the peaks. The sweep rate was 0.1 V/s. The uncertainty in reading the peak position was estimated at $\pm 0.2 \text{ eV}$ for Si, C, and Ar and $\pm 0.3 \text{ eV}$ for O, As, and Ga.

In order to determine the surface disorder and the primary ion implantation, channeling combined with nuclear reaction analysis experiments was performed. For this purpose, the cleaned samples were removed from the "low energy ion" experimental setup and then analyzed with MeV beams obtained from the 2 MeV Van de Graaff accelerator of the Groupe de Physique des Solides de l'ENS. Rutherford backscattering in channeling geometry with $^4\text{He}^+$ ions was used to determine both the extent of lattice disorder and the primary ion concentration. The samples were mounted on a goniometer described previously (19). The energy distribution of the backscattered ions was measured using a 25 mm^2 silicon surface barrier detector with an overall energy resolution of approximately 12 keV FWHM. The detector was mounted on an arm which could be rotated around the chamber central

axis over a range corresponding to scattering angles between 90° and 170° , using an external control. For nuclear reaction analysis, the surface barrier detector was equipped with a Mylar absorber in order to stop the backscattered particles and analyze the nuclear reaction products. The goniometer was equipped with an XY table. Four samples could be placed on the sample holder. This allows one to simultaneously mount crystals and standard references for backscattering and nuclear reaction absolute calibration.

Data analysis.—Auger results.—Auger analyses were performed studying the two Ga and As peaks, and the Ar, Si, O, and C peaks. These peaks were readily identified from the literature. From Auger spectra, quantitative information on the change of the surface stoichiometry can be deduced only if the following conditions were satisfied: (i) the chemical composition of the surface does not change from one sputtering experiment to the other; (ii) the concentration of the elements studied remains constant all over the Auger electron escape depth; (iii) the Auger emission cross sections for all elements and transitions studied are known. Because of these limitations we used AES only as a highly qualitative and sensitive analytical tool to check the surface contamination. In some cases, ratios of peak heights (Ar/Si or As/Ga) were used in order to estimate changes in surface stoichiometry due to bombarding ion incorporation or to preferential sputtering.

Study by channeling of the heavy ion bombardment-induced damage.—The RBS spectra obtained from single crystals when the beam is aligned with a low index crystallographic axis (channeling geometry) exhibit a surface peak and a substrate background which is only a few percent of the one obtained in a "random" geometry. The surface peak, which corresponds to an overall number of atoms/ cm^2 (N_s) is due: (i) to ions backscattered from the very first atomic layers of the crystal (N_0), and (ii) to ions backscattered from atoms displaced from crystallographic sites near the top of the crystal (N_d). The first contribution which can be estimated accurately from Monte Carlo simulations on a perfect crystal (20) is dependent on the incident beam energy. For a given substrate, we have measured the surface peaks at various energies between 500 keV and 1.8 MeV and subtracted the predicted contribution N_0 for each energy. The quantity $N_s - N_0$ was found to be independent of incident beam en-

ergy. This proves that N_c is well estimated and hence that $N_d = N_s - N_c$ does represent the number of atoms displaced from crystallographic sites. In order to obtain the best estimate of N_d we have both to minimize N_c and the substrate background. Since N_c increases with beam energy, most experiments on silicon crystals were performed with low energy beams (500 keV $^4\text{He}^+$). In order to reduce the background/peak ratio, the experiments on silicon were performed by detecting the particles backscattered at grazing angles ($\theta_{\text{lab}} = 110^\circ$ or 120°). This geometry enhances the counting for the surface peak (greater cross section) and lowers the background since the energy loss of the backscattered ions is enhanced. The background was subtracted by drawing a straight line between the minimum background level behind the peak and the top of the surface peak. This procedure was shown to be valid in Ref. (20) by Monte Carlo simulations.

In the case of GaAs, the situation is more complex due to the presence of two elements with a small mass difference. If only the overall amount Ga + As is needed, the experiment can be performed as for Si, at 500 keV and grazing emergence. On the contrary, if the ratio of $[\text{Ga}]/[\text{As}]$ is to be determined, the experiment has to be performed at high energy (≈ 1800 keV) and large θ_{lab} (165°) in order to improve the mass separation.

Typical spectra for Si and GaAs are shown in Fig. 2-4. We also show in the insert the result of the background subtraction performed using an on-line computer.

The absolute amount of Si or GaAs corresponding to the surface peak was obtained by comparison with standards (Ta deposits on light substrates) known with a precision better than 3% (21). The oxygen concentration was obtained by nuclear reaction analysis using the $^{16}\text{O}(d, p)^{17}\text{O}^*$ reaction at 830 keV in a channeling geometry, in order to minimize the counts due to nuclear reactions with the Si background atoms. Using ^{16}O standards (22), we measured a few 10^{15} ^{16}O atom/cm 2 on a Si crystal with a precision better than 3%.

Once the contribution of N_c was subtracted from the surface peak, the number of displaced cations N_d and of oxygen atoms could be compared. It was known in the case of {100} Si (20) that even for chemically polished samples, an excess of displaced Si with respect to the oxide stoichiometry SiO_2 is found. This excess, which can be attributed to reordering of the first atomic planes of the Si crystal, is of about $2-3 \times 10^{15}$ atom/cm 2 . In the case of GaAs, we found that, for a chemically polished sample, the GaAs excess with respect to the oxide stoichiometry $\text{Ga}_2\text{O}_3 + \text{As}_2\text{O}_3$ was less than 1×10^{15} atom/cm 2 . For samples cleaned by low energy ion bombardment, if the Si or GaAs excess with respect to the oxide stoichiometry was not greater than for a chemically polished sample, the total number of displaced atoms measured in a channeling experiment was only indicative of the upper limit of the disorder induced by the bombardment as (i) the latter had removed all the oxides as checked by the *in situ* Auger measurement and (ii) at least the overall disordered layer had been oxidized during the transfer to the channeling chamber. If, on the contrary, the displaced atom excess with respect to the oxide stoichiometry was significantly higher than the excess found for a chemically polished sample, then the number of displaced atoms measured in the channeling experiment represented exactly the total amount of bombardment-induced disorder: all the disordered layer was not oxidized during the transfer.

Results and Interpretation

Room temperature bombardment.—Silicon.—All the results presented here were obtained on {100} silicon. Measurements on {111} Si were in good agreement with the {100} case.

The cleanliness of the samples was checked *in situ* by Auger analysis which also showed us evidence of bombarding Ar implantation. We found that silicon could be cleaned, within AES sensitivity limits, for bombarding energies down to 70 eV. In our experimental conditions, a full cleaning could not be obtained with 50 eV ions after

Fig. 2. [100] aligned RBS spectra on chemically polished (▲) and 100 eV Ar^+ -bombarded (●) Si samples. The surface peaks after background subtraction are shown in insert. The chemically polished sample is more oxidized but has less interface disorder than the Ar^+ -bombarded sample, yielding to an overall similar surface peak. The Ar bombardment was performed at room temperature with a 1 mA/cm 2 beam during 30 min.

Fig. 3. [100] aligned RBS spectra on chemically polished (\bullet) and 100 eV Ar^+ -bombarded ($+$) GaAs samples. The experimental conditions (E and θ_{lab}) are chosen in order to minimize the background and to obtain the overall contribution of Ga and As atoms in a single surface peak (which is also shown in insert after background subtraction). The Ar^+ bombardment was performed at room temperature with a 1 mA/cm^2 beam during 15 min.

Fig. 4. [100] aligned spectra on the same GaAs samples as in Fig. 3. The experimental conditions (E and θ_{lab}) are chosen to obtain separate surface peaks for As and Ga (these peaks are also shown in insert after background subtraction) and reach the As/Ga ratio for displaced atoms.

hours of bombardment with a beam current density of 1 mA/cm². This could have been due to recontamination from the vacuum.

Influence of Bombardment Energy

Figure 5 compares the variation of the AES Ar signal normalized to the Si signal, and the Ar incorporation measured by RBS as a function of Ar bombarding energy. While the AES signal exhibits a maximum around 200 eV, the Ar incorporation increases linearly with bombarding energy. These results demonstrate that above 200 eV, most of the Ar ions penetrate in the crystal at depths greater than the escape depth of the Auger electrons, *i.e.*, about 10 Å for Ar in Si. The incorporation was measured for the minimum bombarding dose leading to full cleaning; the slope corresponds to $\sim 1.7 \times 10^{14}$ Ar · cm⁻²/100 eV. For instance, at 70 eV, 1.3×10^{14} Ar · cm⁻² were incorporated. For samples bombarded with Xe ions, the RBS analysis also shows a linear increase in the Xe concentration as a function of ion bombarding energy. However, the slope is smaller than for Ar: 0.6×10^{14} Xe · cm⁻²/100 eV (see Fig. 5).

The bombardment-induced disorder was measured by channeling experiments as described previously. The oxygen content due to sample oxidation during transfer to the channeling chamber was always found around $5\text{--}6 \times 10^{15}$ atom · cm⁻². In all cases, the number of displaced Si atoms was significantly greater than the oxidized silicon, assuming the SiO₂ stoichiometry. The Si excess with respect to SiO₂ was always greater than the one observed on a chemically polished sample which was measured to be about 2.5×10^{15} atom · cm⁻² and was in good agreement with Ref. (20). Consequently, we can assume that, in our experiments, the overall displaced Si atoms, oxidized or not, represent precisely the disorder induced by the bombardment. This disorder (N_d) is represented as a function of bombarding energy in Fig. 6. These results correspond of Ne, Ar, and Xe bombardments. In all cases, a strong dependence on bombarding energy was observed. For all the ions, the disorder increased linearly with ion energy

Fig. 5. Comparison of the Ar and Xe incorporation in Si, as a function of bombarding energy, measured in RBS experiments, with the Ar/Si ratio obtained from Auger spectra: room temperature bombardments at 1 mA/cm².

Fig. 6. Overall bombardment-induced disorder in Si with Ne, Ar, and Xe ions, as a function of bombarding energy. Room temperature bombardments at 1 mA/cm². The point corresponding to the chemically polished samples (■) represents the disorder after subtraction of the oxide (SiO₂) contribution.

in the range 200–1500 eV. However, the slope increased significantly for Ne ions. This may well have been due to the fact that, at a given energy, light ions have a greater range and can hence induce disorder over greater depths. Below 200 eV, the damage decreased more rapidly with decreasing energy. It reaches about $8 \cdot 10^{15}$ atom · cm⁻² for Ar at 100 eV. The value corresponding to the disorder at the silicon-silicon dioxide interface for a classically chemically polished sample is also reported in Fig. 6.

From the above results, it appears clear that when the bombarding energy is increased, both the disorder and the ion incorporation increase. Unfortunately, it was not possible to check the Ne incorporation either by Auger or RBS experiments. We have reported in Fig. 7 the ratio of disorder to incorporated atoms as a function of bombarding energy. This ratio is quasi constant above 500 eV, indicating that the disorder may well be stabilized by the incorporated ions. However, at lower energies, the ratio increases markedly indicating the presence of some "intrinsic" disorder not directly connected to bombarding ion incorporation. As a matter of fact, the presence of such a disorder is closely related to the mechanisms of very low energy sputtering. The fact that atoms can be expelled with some efficiency in this energy domain implies some assumptions about the dissipation of the very locally deposited energy. A simple collisional description appears insufficient and "nonlinear" effects must be considered, leading to enhanced sputtering and related disorder formation.

It is of interest to compare our results to those obtained by Yamada *et al.* (9). These authors have also studied in the case of {100} Si the influence of bombarding energy and ion species. The two main differences are: (i) the energy domain explored (1.5 to 4 keV in their case) and (ii) the bombardment dose. Since these authors have carried out an UHV thermal cleaning followed by the adsorption of an oxygen monolayer which had to be sputtered, only 300 μC doses were needed. In our case, we had to remove

Fig. 7. Ratio of the number of displaced Si atoms to the incorporated bombarding ions (Ar or Xe) as a function of bombarding energy. Room temperature bombardments at 1 mA/cm^2 .

a native oxide with carbon contamination, and so in the same energy range (about 1.5 keV) the doses needed were 50 times higher. Of course, much higher doses were needed for lower bombardment energies. For instance, at 100 eV under 1 mA/cm^2 current density, the dose used in our experiment was about $1.5 \times 10^6 \mu\text{C}$, i.e., nearly four orders of magnitude above the dose used by Yamada *et al.* For bombardment at 4 keV, Yamada *et al.* found a strong increase of the disorder with the ion mass that saturates for masses heavier than 40. This is in contrast with our results below 1 keV, where Ne induces more disorder than heavier ions. For Ar bombardment Yamada *et al.* find, as in our experiment, a linear increase of disorder with bombarding energy. However, the slope of the curve (about 5×10^{15} displaced atoms per keV) is three times smaller than ours. This difference is certainly due to the very low dose used by Yamada *et al.* with respect to this work. It is interesting to notice that, at the same bombarding energy (1.5 keV Ar^+), the disorder induced in our case is about three times greater than in Ref. (9), for a bombarding dose fifty times higher. This result indicates that the damage saturates with bombarding dose. Yamada *et al.* have certainly not reached this steady state while we very likely have. A recent RBS study (24) of 4 keV Ar ion bombardment damage of semiconducting materials supports this statement. This is also confirmed by the fact that we induce, for 100 eV bombardment, a disorder 1.5 smaller than Yamada *et al.* at 1.5 keV, with a bombarding dose about $5 \cdot 10^3$ higher.

Influence of the Beam Current

Ar and Xe bombardments have been undertaken at 100 eV for various current densities between 20 and $1000 \mu\text{A/cm}^2$. At all current densities the bombardments were carried out up to full cleaning. The beam dose required to obtain this result was found to be current density independent, in all cases around 1.5 Cb. Moreover, the disorder induced and the bombarding ion incorporation were also found to be independent of the beam current density.

Gallium arsenide.—The samples were sputtered in the same way as Si.

Auger Results

The minimum energy at which a cleaning can be achieved was found, in our experimental conditions, to be 50 eV with Ar ions, i.e., somewhat smaller than for the silicon case (70 eV). The *in situ* Auger analysis after cleaning reveals that no argon incorporation is detectable below 200 eV bombardment energy (Fig. 8). This is in contrast to the silicon case where argon was detected at all bombardment energies. At energies higher than 200 eV, argon is detected. The Ar/Ga ratio is nearly constant between 300 and 600 eV and decreases for higher bombardment energies. This probably indicates that Ar penetrates to depths greater than the path length of Auger electrons. As Ga and As are heavier than Ar, the Ar incorporation was not measurable by RBS. The Auger spectra also give information about the near surface stoichiometry of the clean samples. This is illustrated in Fig. 9 where the ratio of the Ga and As peaks corresponding to the LMM high energy transitions is reported as a function of bombarding energy. This ratio increases significantly when the bombarding energy increases from 50 to 600 eV and then saturates at a value around 1.85 which is in good agreement with the measured value of Ref. (15).

These results demonstrate that, for low energy bombardment, the very near surface stoichiometry changes with bombarding energy, indicating a preferential sputtering of As. The saturation of the ratio shows that above 600 eV the composition in the depth domain sensed by the Auger technique becomes independent of bombardment energy, which does not exclude stoichiometry modifications at greater depths. It appears from Fig. 9 that low energy Xe bombardments lead to similar results to that of Ar. Moreover, for the two energies for which Xe bombardment were performed (100 and 200 eV), RBS spectra did not show Xe incorporation.

Fig. 9. Ga/As ratio obtained from Auger spectra as a function of bombarding energy (Ar and Xe ions). Room temperature bombardment at 1 mA/cm^2 .

Channeling Results

For all the bombarding energies used, the displaced Ga and As atoms (N_d) measured by surface analysis exceed the number of cations bonded to oxygen atoms, assuming $\text{Ga}_2\text{O}_3\text{-As}_2\text{O}_3$ stoichiometry for the native oxide. The minimum value of this excess, obtained for 50 eV bombardment energy, was about $2.5 \times 10^{15} \text{ atom} \cdot \text{cm}^{-2}$ while for a chemically polished sample, the excess is always smaller than $10^{15} \text{ atom} \cdot \text{cm}^{-2}$. We must hence assume, as for the silicon case, that all the atoms displaced by the bombardment have not been oxidized and that the quantity N_d represents the bombardment-induced disorder. This quantity is reported in Fig. 10 as a function of bombarding energy. Again, a quasi-linear dependence is observed. At 50 eV bombardment, the disorder corresponds to $5 \cdot 10^{15} \text{ atom} \cdot \text{cm}^{-2}$ while it is equal to $22 \times 10^{15} \text{ atom} \cdot \text{cm}^{-2}$ at 1500 eV . The slope is nearly two times smaller than for silicon. This may be due to the fact that the range of bombarding ions being smaller in GaAs than in Si for a given incoming ion, results in ion-induced disorder extending over a smaller range. Disorder is also observed at low energies where no ion incorporation was found.

Channeling experiments were performed with 1.8 MeV $^4\text{He}^+$ beams to distinguish between the displaced gallium and arsenic atoms (Fig. 4). We found in all cases that the ratio $N_{\text{Ga}}/N_{\text{As}}$ has a value between 1 and 1.1. Since the surface peaks represent from 5 to $22 \times 10^{15} \text{ atom} \cdot \text{cm}^{-2}$ depending on the bombarding energy, these results prove that the gallium excess with respect to the GaAs stoichiometry is not greater than about $10^{15} \text{ atom} \cdot \text{cm}^{-2}$. This result, when compared with the very strong departure from stoichiometry seen by Auger analysis, demonstrates that this departure concerns only the very shallow surface region sensed by the Auger technique. As the disorder, in particular at high bombarding energies, extends towards much greater depths, it appears that the correlation between overall disorder and departure from stoichiometry is poor.

Effect of the sample temperature during bombardment.—Silicon samples were heated in the range between

Fig. 10. Overall bombardment-induced disorder in GaAs with Ar and Xe ions as a function of bombarding energy. Room temperature bombardments at 1 mA/cm^2 . The point corresponding to the chemically polished sample (■) represents the disorder after subtraction of the oxide ($\text{Ga}_2\text{O}_3 - \text{As}_2\text{O}_3$).

27° and 550°C during argon bombardment. At 500°C , the effect of bombarding energy between 100 and 1500 eV was also studied. The *in situ* Auger analysis reveals a constantly decreasing normalized Ar signal from 27° to 400°C and no Ar peak above this temperature for a 100 eV bombarding energy (Fig. 11). On the contrary, the RBS analyses of the samples show that, for all bombarding energies, the ion incorporation is independent of the sample temperature during bombardment and is equal to the one found at room temperature. For instance, argon incorporation for 100 eV ion energy is reported in Fig. 11 as a function of the sample temperature. The comparison of Auger and RBS results clearly demonstrates that as soon as the sample is heated above 400°C the incorporated argon ions penetrate to depths greater than the Auger electron path length ($\sim 10 \text{ \AA}$) and do not desorb. These results, obtained for 100 eV bombarding energy are similar to those observed by Bean *et al.* (11) when sputtering with 1 keV ions.

The channeling analysis and oxygen content determination give us the following results: (i) The sample oxidation during the transfer to the channeling chamber is independent of the sample temperature during cleaning (oxygen content is always about $6 \cdot 10^{15} \text{ atom} \cdot \text{cm}^{-2}$). (ii) The number of displaced silicon atoms deduced from the channeling surface peak analysis is much greater than the oxidized silicon atoms and represents, therefore, the bombardment-induced damage. (iii) The temperature dependence of the damage varies with the bombarding energy. At low bombarding energies (100 eV) a very strong increase in the damage is observed when increasing the substrate temperature. As illustrated in Fig. 11, the increase in damage is about $10^{16} \text{ atoms} \cdot \text{cm}^{-2}$ between room temperature and 100°C . A trend towards damage saturation is observed at higher temperatures. Our interpretation of this result is the following. Damage is stabilized by low argon concentration all over the depths where argon diffuses. This diffusion is associated with the mobility of

Fig. 11. Temperature dependence for Si samples bombarded with 100 eV Ar^+ and heated during bombardment of: the Ar/Si ratio from Auger spectra (■); the Ar incorporation measured by RBS (▲); and the overall bombardment-induced disorder (●).

the "intrinsic" bombardment-induced damage. It is interesting to note that this process takes place at 100°C. Our interpretation is supported by the study of the damage evolution with bombardment energy, at temperatures higher than room temperature. For instance, in Fig. 12 the variation in the damage, ΔN_{Si} , between 27° and 500°C as a function of bombarding energy is very high at low bombarding energy (19×10^{15} atom \cdot cm⁻² at 100 eV) and decreases rapidly with bombarding energy: at 1500 eV, $\Delta N_{Si} = 0$. This behavior indicates that argon-assisted diffusion takes place over great depths with respect to the perturbed layer corresponding to 100 eV room temperature bombardment, but smaller or of the order of the perturbed layer corresponding to room temperature bombardment at 1500 eV. This is consistent with the value of the damage measured at 100 eV and 500°C. This value (25×10^{15} atom \cdot cm⁻²) is much higher than the one found for 100 eV bombardment at room temperature (7×10^{15} atom \cdot cm⁻²), but significantly smaller than the damage measured for 1500 eV at room temperature (43×10^{15} atom \cdot cm⁻²). Roughly, we can estimate that the argon diffuses during bombardment on heated samples over lengths of the order of 50Å. If this value is great with respect to the implanted argon range (case of 100 eV bombardment), the damage is increased by sample heating. On the contrary, if this value is small with respect to the argon range (case of 1500 eV bombardment) the damage is independent of sample temperature.

We have verified that the effects described above are related to bombardment-enhanced argon diffusion and not to simple thermal diffusion. This is proven by the fact that if room temperature bombarded samples are post annealed up to 500°C, no variation of the bombardment-induced damage or of the argon incorporation is observed.

For higher post annealing temperatures, a full recovery is observed. For instance, when a sample cleaned by 100 eV Ar bombardment at room temperature is post annealed at 550°C, no argon incorporation is found in RBS experiments and the surface peak analysis in channeling shows that the excess between N_d and the oxidized silicon (assuming SiO_2) is equal to the one found for a chem-

Fig. 12. Difference between the overall bombardment-induced disorders for 500°C and room temperature bombardments with Ar^+ ions (1 mA/cm^2), as a function of bombarding energy.

ically polished sample, i.e., about 2×10^{15} /cm². It must be pointed out that if the bombarding energy is increased, the post annealing temperature required for full recovery is higher [(720°C for bombarding energies around 1 keV as indicated in Ref. (9)]. Since impurity segregation towards the surface may take place above 600°C, it appears that the low temperature needed for recovery when low energy bombardment occurs should be favorable for surface electrical properties in device preparation.

We have also studied the influence of temperature during ion bombardment on GaAs. The experiments were performed at 100° and 200°C for 100 eV argon bombardment energy. No marked temperature dependence was observed for damage. This must be related to the fact that at 100 eV no argon incorporation was detected in GaAs, and, hence, the mechanisms described for the silicon case do not hold.

Summary

We have demonstrated that Si and GaAs crystals can be cleaned at room temperature by very low energy ion bombardment (below 100 eV), using a high intensity source. The bombardment-induced disorder, which does not depend markedly on the beam current, is significantly higher for low ion masses. However, the main effect is the very strong bombarding energy dependence of the disorder and of the bombarding ion incorporation. These two quantities are strongly correlated. When heating the sample during very low energy bombardment, the incorporated ions penetrate deeper into the sample and stabilize more damage. However, even though at very low energies the incorporation is small, some bombardment-induced damage is still present even for room temperature bombardment. This damage is, of course, very low as compared to that observed for standard bombarding conditions around 1 keV. For instance, near 100 eV, the maximum damage corresponds to 10^{16} and 5×10^{15} atom/cm² for Si and GaAs, respectively. Full surface recovery is only achieved by post annealing around 550°C for 20 min

for a Si sample cleaned by 100 eV Ar ions at room temperature. This treatment also removes the incorporated bombarding ions.

An ^{18}O Study of the Oxidation Mechanism of Silicon in Dry Oxygen

F. Rochet, B. Agius,* and S. Rigo

Groupe de Physique des Solides de l'École Normale Supérieure, Université Paris 7, 75251 Paris Cedex 05, France

ABSTRACT

The mechanism of thermal oxidation of silicon in dry oxygen was studied using ^{18}O as a tracer. SiO_2 layers first grown in natural oxygen were grown further in ^{18}O -enriched oxygen ($^{18}\text{O}_2$) up to thicknesses ranging from 5 to 26 nm at 930°C . ^{18}O profiling was carried out using the nuclear reaction microanalysis. Fixed ^{18}O is found near the Si/ SiO_2 interface (^{18}O FNI) and near the external surface of the oxide (^{18}O FNES). In this work we studied: (i) the possible origins of ^{18}O fixation near the external surface of the oxide (^{18}O FNES) and (ii) the possible growth mechanisms of films of thicknesses ranging from 260 to 5 nm. It was shown that ^{18}O FNES does not seem to be due to some interfering phenomena (network oxygen exchange with water vapor traces or effects connected with the experimental procedure) and is not due to a growth mechanism by Si transport. A step-by-step motion of network oxygen atoms seems to be the more likely to explain ^{18}O FNES. The amount of ^{18}O FNES becomes more important as the original thickness of the film becomes smaller. Even for thicknesses under 20 nm we always found large amounts of ^{18}O fixed near the Si/ SiO_2 interface, which corresponds to growth by oxygen species migrating through the oxide network and without measurable interaction with it (very likely O_2 molecules for thick oxide samples). However for ~ 5 nm thickness films, the amounts of ^{18}O FNES can reach 50% and 80% of the total amount of ^{18}O at O_2 pressures equal to 10 torr and 10^{-1} torr, respectively.

In their well-known model, Deal and Grove (1) put forward two basic assumptions: (i) silica has an open structure allowing interstitial dissolution of atoms or molecules, and (ii) the oxidant is assumed to be molecular. This leads to linear kinetics followed by parabolic growth when diffusion across silica film becomes rate limiting, the corresponding constants being $k_L = kC^*/N_i$ and $k_p = 2D_{\text{eff}}C^*/N_i$, respectively, where C^* is the oxidant solubility, N_i the number of network oxygen atoms per volume unit, k the reaction rate at Si/ SiO_2 interface, and D_{eff} the effective diffusion coefficient. According to Mott (2), one must consider the solubility in "normal" interstitial sites where percolation paths can be opened, so that deep sites do not have any contribution to growth. Revesz and Schaeffer (3) wrote a paper devoted to the same subject using structural considerations. In the case of water vapor oxidation, the kinetics match well with the theory of Deal and Grove, but for dry oxygen oxidation this theory only applies for thicknesses greater than 20-30 nm. Using ^{18}O as a tracer, Rosencher *et al.* (4) have studied the oxygen transport across the film during thermal oxidation. SiO_2

layers first grown in natural oxygen (130-300 nm) were further grown in highly ^{18}O -enriched oxygen for 8.5h at 930°C . The resulting SiO_2 films consisted of two ^{18}O -rich zones, one containing about 7% of the ^{18}O near the SiO_2 surface, and another containing 93% near the Si/ SiO_2 interface, while the bulk ^{18}O concentration was very low (under 0.3%). This shows that for these thicknesses the oxide grows mainly by an interstitial transport of oxygen without reaction with the network, which favors a model based on the transport of molecular oxygen as proposed by Deal and Grove (1). The presence of a small amount of ^{18}O at the external surface, if not due to an interfering phenomenon, might indicate that the existence of another oxygen transport mechanism cannot be entirely rejected.

Kinetics studies for various oxygen pressures p_{O_2} show that: (i) k_p is proportional to p_{O_2} , thus favoring a molecular oxygen transport, and (ii) k_L is found to be proportional to p_{O_2} (1), $p_{\text{O}_2}^{0.6}$ (5, 6), $p_{\text{O}_2}^m$ with m varying from 0.59 to 0.83, as the temperature is varied from 700° to 1000°C for SiO_2 films grown on (111) substrates and with m varying from 0.54 to 0.66 in the temperature range 850° - 1000°C for oxide films grown on (100) substrates (7). The pressure dependence of k_L was interpreted by O_2 reacting with silicon, which leads after calculation to a p_{O_2} law (1), by a

* Electrochemical Society Active Member.

Key words: semiconductors, glass, growth, nuclear reactions.

reaction at the Si/SiO₂ interface involving the presence of both atomic and molecular oxygen, which leads to a $p_{O_2}^m$ law with m lying between 0.5 and 1 (7). Blanc (8, 9) proposed a similar mechanism where the reaction of oxygen atoms predominates. This leads to a $p_{O_2}^{0.5}$ law. Concerning high pressure oxidation (p_{O_2} lying between 1 and 20 atm), Lie *et al.* (10) have recently shown that if k_p is still proportional to p_{O_2} , k_L is proportional to $p_{O_2}^{0.7}$, in the temperature range of 800°-1000°C. Their analysis is based entirely on the Deal-Grove model; they point out that such a pressure dependence of k_L would imply a complex interface reaction mechanism or a contribution due to gas phase transport at the SiO₂/gas interface above 1 atm. Various values can be found for k_p and k_L in the literature. Activation energies are extracted: for k_p and k_L , respectively, Deal and Grove (1) found them equal to 1.2 and 1.8 eV in the temperature range 900°-1200°C, while Irene and Van der Meulen (11) found them equal to 2.2 and 1.5 eV in the temperature range 780°-980°C. More recently, Irene and Dong (12) found in the high temperature range (980°-1150°C) activation energies near to those found in Ref. (1); moreover, they showed that k_p and k_L do not follow an Arrhenius law. Irene (13) has shown that the curvature of the Arrhenius plots of k_L values is consistent with the parallel paths mechanism proposed by Ghez and Van der Meulen (7). One must keep in mind that the typical values of activation energies corresponding to O₂ diffusion, Si-Si, and O-O single bonding are 1.2, 1.8, and 1.5 eV, respectively.

One must also notice that few people (5, 14-16) started oxidation from a well-controlled surface free from native oxide and used during the process an oxygen ambient free from impurities that might have produced water vapor. As a matter of fact, the natural oxide layer remaining at the silicon surface before oxidation may create a source of contamination for the thermal oxide and water traces in the ambient greatly modify the kinetics. A 20% increase in overall rate with only 25 ppm of water vapor in the ambient was reported by Irene *et al.* (17). Hopper *et al.* (5), who worked in clean conditions, try to account for their kinetics assuming that growth is the sum of two mechanisms being both present, corresponding to two linear parabolic reactions, one prevailing at small thicknesses, the other at large ones, with one of the mechanism involving charged species. So they based their assumption on Jorgensen's work (18). Jorgensen succeeded in accelerating or retarding thermal growth because he had an electric current flowed through the oxide; he, therefore, concluded the presence of charged species. This latter work has been criticized by Raleigh (19), who explained Jorgensen's results by stating that an electrolysis due to electrons can induce the transport of charged species different from those involved in "classical" thermal oxidation. Mills and Kroger (20) proposed a transport mechanism involving interstitial O²⁻ as responsible for ionic conduction. This has been discussed by Mott (21), who puts forward the fact that the reaction $O_2 + 4e \rightleftharpoons 2 O^{2-}$ leads to a reaction rate proportional to $p_{O_2}^{0.5}$. Jorgensen considers it proportional to p_{O_2} (22). So, if the transport of oxygen species is generally proposed to explain the oxidation of silicon, Mott (21) examines the existence of silicon vacancies, this being supported by energetic considerations. For film thicknesses above 130 nm, the experiments of Rosencher *et al.* show that it cannot be the major phenomenon responsible for growth (4).

Kinetics for very thin films (thicknesses <20 nm) are generally obtained under low pressure and at low temperature conditions. Thus any comparison with thick oxide kinetics is difficult. Especially one must notice that oxidation rate of (111)-oriented silicon at low pressure is smaller than that of (100)-oriented silicon, contrary to what happens at high pressure ($p_{O_2} > 1$ atm) (23). As well, oxidations are often performed in O₂-inert gas mixtures at atmospheric pressure (6, 24); thus, the amount of water vapor relative to O₂ partial pressure may be not well defined and not so negligible. Considering all the experimental results, it is difficult now to conclude about the type of kinetics laws. Experimental results have been fitted by linear-parabolic (5, 25, 27) or inverse-logarithmic laws (6, 24, 26), although Irene thinks that the linear type is prevailing (27); he explains those rather linear kinetics

by the fact that pores could exist, so that O₂ could run through these pores and have rapid access to Si/SiO₂ interface. Using transmission electron microscopy (TEM), Gibson *et al.* (28) concluded in favor of the existence of micropores. Nevertheless, Revesz (29-30) assumed the existence of channels responsible for an extended transition region of the two regimes of oxidation. As the oxide film thickens, these channels become distorted and the oxidation rate decreases and becomes linear parabolic. Let us emphasize that for Revesz, the channels are intrinsic structural features of noncrystalline SiO₂ and not gross morphological defects. Hopper *et al.* (5) observed that the growth rate varies more rapidly in the thin thickness range (<20 nm) than in the larger one (>30 nm). Fargeix *et al.* (31) interpret the results of Hopper *et al.* considering that "the diffusion through the first hundred angstroms of the oxide layer (near the Si/SiO₂ interface) is slowed down." Previously, the existence of an "interface blocking layer with different transport properties than the bulk oxide" was proposed by Tiller (32).

For very thin films (1.5-6 nm) at 400°C, Fehlner asserts he obtained growth kinetics of inverse-logarithmic type (26) due, as a consequence, to a mechanism involving charged species known as the Cabrera-Mott mechanism (33). In this model, transport is controlled by a high electric field, the potential drop at the film boundaries remaining constant. Kamigaki and Itoh (6) have obtained kinetics which are consistent with such a mechanism in the 950°-1100°C domain and for a partial pressure equal to 10⁻³ atm. Derrien and Commandré (16) worked under ultrahigh vacuum conditions in the range of thicknesses 0-3 nm under low pressure oxygen ambient (from 10⁻⁴ to 10⁻² torr) with temperatures lying between 750° and 1050°C. Evaluating oxide thicknesses by Auger electron spectroscopy, they interpret the kinetics they obtain by a phenomenological model based on charged oxygen diffusion through the oxide layer under the presence of a surface electric field.

The aim of this paper is to present a study of the mechanisms of silicon thermal oxidation in dry oxygen, using ¹⁸O as a tracer.

Experimental Procedures

Thermal Treatments

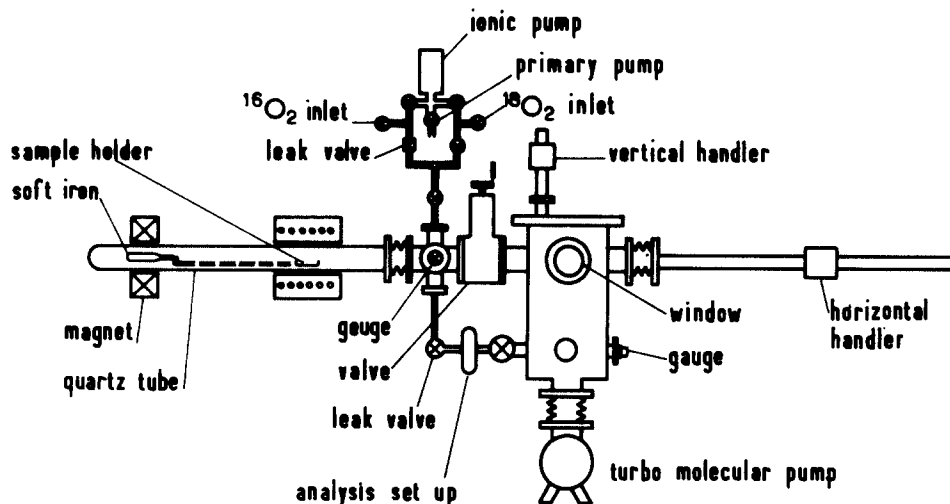

¹⁸O₂ oxidation.—Two kinds of thermal oxidation have been carried out.

Thick (>20 nm) oxide samples.—These samples were supplied by Laboratoire d'Electronique et de Technologie de l'Informatique of Grenoble. (100) oriented silicon wafers of resistivity 4-5 Ω cm were oxidized in a flow of dry natural oxygen to obtain oxide thicknesses between 50 and 260 nm, at atmospheric pressure and at temperatures ranging from 1000° to 1200°C. The 20 nm-thick oxides were grown in a natural O₂/N₂ mixture at 950°C.

Thin (<20 nm) oxide samples.—Oxide films were grown on (100)-oriented silicon wafers (resistivity 4-5 Ω cm), in dry natural oxygen in an ultrahigh vacuum technology (UHVT) furnace (Fig. 1) at 10 torr, 930°C for various durations. After cleaning, the Si substrates were annealed at 150°C under vacuum (10⁻⁹ torr). Then, they were pushed into the hot zone of the quartz tube and treated *in vacuo* (<10⁻⁸ torr) for about 1 min at 930°C. This is sufficient to eliminate the major part of water vapor adsorbed on the sample holders, but no examination of the surface cleanliness was available. This operation was necessary to stay in the realms of 3 ppm for water vapor traces during further oxidation treatments. The procedures for ¹⁸O₂ gas introduction and water vapor control, as well as the measured water traces contents, are identical to those of ¹⁸O₂ gas introduction described below. After growth in ¹⁸O₂, these samples were re-stored in the UHV chamber.

¹⁸O₂ oxidation.—All the ¹⁸O₂ treatments were performed at 930°C in the UHVT furnace (¹⁸O labeling guaranteed above 99%) by expanding ¹⁸O₂ in the 5 liter quartz tube. The ¹⁸O₂ gas previously passed through zeolites (degassed *in vacuo* at 200°C for 48h, which reduced the traces content of water. H₂¹⁸O partial pressure was measured by mass spectrometry using the classical trapping/desorption method in a quartz tube located before the spectrometer head. This was done in order to extract the signal

Fig. 1. Schematic drawing of the UHVT furnace used for thermal treatment in dry $^{18}\text{O}_2$ and $^{16}\text{O}_2$ gas.

corresponding to the water content of the oxidizing ambient from the background due to the continuous formation of water by hydrogenated species reacting with O_2 in the spectrometer head (34). H_2^{18}O partial pressure was never found above 3 ppm of the total pressure. In each experiment, the ^{18}O labeling of the gas was also measured by mass spectrometry.

Samples grown in $^{16}\text{O}_2$ outside the UHVT furnace.—As these samples were grown in $^{16}\text{O}_2$ ambient in a gas flow furnace different from our UHVT furnace, they are exposed to air between two thermal treatments. Thus, before any $^{18}\text{O}_2$ treatment they are introduced in the quartz tube hot zone *in vacuo* (10^{-8} torr) for about 1 min in order to eliminate water vapor adsorbed on the samples holders. One must also add that, if the $^{18}\text{O}_2$ treatments are performed at 930°C , the previous $^{16}\text{O}_2$ growth treatments were carried out at higher temperatures ($1000^\circ\text{--}1200^\circ\text{C}$). One cannot eliminate some "memory effect" on kinetics, as pointed out by Hamasaki (35), who investigated the oxidation kinetics of silicon using two-step oxidation at two different temperatures. He found that "in an initial stage of second oxidation the growth rate of the oxide is different from the oxide's equilibrium growth rate," and that "the difference in these growth rates is due to the difference in the linear growth rate of these two stages." However, we do not think that it might interfere greatly on location of the heavy isotope found near the external surface and near the Si/oxide interface. This is supported by results obtained with *in situ* addition of $^{18}\text{O}_2$ gas in an ambient as described further in the text.

Samples grown or regrown in $^{16}\text{O}_2$ in the UHVT furnace.—These samples (generally thin oxide samples) were introduced again in the hot zone without being exposed to air, which minimized pollutions and/or interfering phenomena due to such an exposure. As a consequence, no ^{16}O content measurement was available before ^{18}O treatments. In some cases, during the thermal treatment we added $^{18}\text{O}_2$ to the $^{16}\text{O}_2$ atmosphere, as the sample was left in the hot zone; this avoided thermal shock but introduced some decrease and evolution of the ^{18}O isotope concentration.

Data Analysis

^{16}O and ^{18}O amounts measurement.—The nuclear reactions $^{16}\text{O}(d,p)^{17}\text{O}^*$ and $^{18}\text{O}(p,\alpha)^{15}\text{N}$ induced by deuteron or proton beams from a 2 MeV Van De Graaff accelerator were used to measure the number of ^{16}O (N_{16}) and ^{18}O (N_{18}) atoms/cm² in the oxide layers (36). Absolute values of N_{16} and N_{18} were determined by comparison to standard references known to within $\pm 3\%$ (37), their relative precision was better than $\pm 1\%$. It is worthy to notice that the sensitivity of the $^{18}\text{O}(p,\alpha)^{15}\text{N}$ reaction is limited to $\sim 8 \cdot 10^{19}$ oxygen atoms/cm³ or $2 \cdot 10^{15}$ oxygen atoms/cm² by the natural abundance of the heavy isotope.

Equivalent ^{16}O and ^{18}O oxide thicknesses were calculated assuming an oxide density equal to that of SiO_2 , i.e., to $2 \cdot 21 (10^{15}$ oxygen atoms/cm²) corresponds to 0.226 nm). For oxide thicknesses lower than 20 nm, such equivalent

thickness was sometimes calculated, but one must keep in mind that departures from SiO_2 stoichiometry might occur (38).

^{18}O concentration-depth profiles.—The ^{18}O concentration depth profiles could be deduced from two different techniques: (i) analysis of the excitation curves of the $^{16}\text{O}(p,\alpha)^{15}\text{N}$ reaction near the 2 keV-wide 629 keV resonance (39), or (ii) step-by-step dissolution combined with nuclear microanalysis.

In the latter procedure, each studied wafer was cut into several pieces, one being kept without being chemically etched, the others being immersed in dilute HF (3% volume in H_2O) for various times. On each piece, the amounts of ^{16}O and ^{18}O were obtained from the nuclear reactions. Such a procedure was necessary when knowing that the particles beam can induce structural modifications (and as a consequence, spatial variations of the dissolution rate) in the impact zone. Thus a thickness nonhomogeneity from one part of sample to the other will be a source of error that must be taken into account. In comparison with the resonant reaction method, the step-by-step dissolution method gives a better depth resolution, and in some cases a better knowledge of local concentration; however, this method is more sensitive to thickness nonhomogeneities.

Results and Interpretation

Study of Oxygen Transport by Chemical Dissolution

The results of ^{16}O and ^{18}O content measurements (N_{16} and N_{18} , respectively) in the oxide *vs.* the different steps of dissolution are shown in Fig. 2 as a function of the total amount of oxygen N_{16} and N_{18} . This oxide was grown up to 47 nm in a dry natural oxygen flow at atmospheric pressure. This was followed by a further growth in $^{18}\text{O}_2$ in the UHVT furnace at 100 torr up to 86.3 nm. We can see after the first step of dissolution a first decrease of the ^{18}O content followed by a plateau. This sheer step is related to the ^{18}O fixed near the external surface of the oxide (^{18}O FNES), whereas the plateau corresponds to a very low ^{18}O -labeled oxide. After this plateau, there appears a linear decrease of the ^{18}O content of the oxide which is related to the dissolution of the layer corresponding to the ^{18}O fixed near the Si/oxide interface (^{18}O). As can be seen, the ^{18}O FNI concentration is nearly constant, and the ^{18}O FNES amount can be estimated to about 7% of the total ^{18}O amount. All these results are in good agreement with a previous work using resonance techniques (4). The ^{16}O results are complementary to ^{18}O observations; the first decrease of N_{16} corresponds to the dissolution of the interfacial layer, while the horizontal line corresponds to the dissolution of ^{18}O FNI. The N_{16} variation in this last case is less than $1 \cdot 10^{15}$ atoms/cm², when the amount of oxygen decreases about $100 \cdot 10^{15}$ atoms/cm². This means that the maximum value of ^{16}O isotopic concentration is equal to 1% at most. Thus, the corresponding ^{18}O labeling must be larger than 99%, i.e., equal to that of the gas (99.5%) within 0.5%; therefore, the heavy isotope found near the Si/SiO₂

Fig. 2. N_o^{18} (o) and N_o^{16} (□) (in atoms/cm²) obtained after different steps of dissolution as a function of the total amount of oxygen ($N_o^{18} + N_o^{16}$) for an oxide grown to 47 nm in $^{16}\text{O}_2$ and then up to 86.3 nm in $^{18}\text{O}_2$.

interface went through the pre-existing oxide matrix without any measurable interaction with it. Furthermore, the transition between ^{18}O and ^{16}O zone is so abrupt that a possible isotopic mixing due to some network oxygen self-diffusion (see Fig. 5) is not measurable in the range of accuracy of our techniques. Finally, the height of the ^{16}O plateau may correspond to oxygenated species adsorbed on the surface after dissolution and/or to the background of the ^{28}Si (d, p), ^{29}Si reaction. Concerning ^{18}O FNES, this may be due to (i) isotopic exchange between oxygen of the network and water vapor traces, (ii) to some oxide growth by silicon transport, or (iii) to fixation of oxygen due to step-by-step effective motion of network oxygen atoms and an external surface allowing exchange. Let us notice that there is always the possibility of interfering phenomena induced by exposure to air between $^{16}\text{O}_2/^{18}\text{O}_2$ treatments or by the presence of the native oxide at the surface and finally by the treatment under high vacuum at high temperature.

Nature and Origin of ^{18}O Fixed near the External Surface

Effects connected with the experimental procedure.—Between $^{16}\text{O}_2$ growth and $^{18}\text{O}_2$ further growth, the oxide was exposed to the room atmosphere and then treated under vacuum. Could this process be the cause of ^{18}O FNES? To answer this question, we carried out the following experiments.

Sample A (Table I) was oxidized in $^{16}\text{O}_2$ for 18.1 h at 930°C under 8.5 torr up to about 14 nm, and then, instead

of withdrawing it from the furnace, $^{18}\text{O}_2$ gas was introduced up to a total oxygen pressure of 29 torr for 3.5 h at the same temperature. From the ratio of pressures, we deduced the ^{18}O isotopic concentration to be 60%, which was in agreement with mass spectrometer measurements. Results confirm the existence of ^{18}O FNES corresponding to about 16% of the total amount of ^{18}O . Let us notice that for this thinner oxide film the ^{18}O content is larger than those previously obtained: 16% for about 14 nm ^{16}O equivalent thickness instead of 7% for 47 nm. This effect will be studied later. From this experiment we can conclude that the appearance of ^{18}O FNES is not due to an interfering phenomenon related to exposure to air and/or to high temperature vacuum treatments. However, we start from a sample very likely covered with a native oxide, and considering that this oxide might remain at the external surface when growth takes place by a Deal-Grove type mechanism, we can wonder if this native oxide may have the particular property of exchanging its oxygen atoms with those of the $^{18}\text{O}_2$ gas. In order to clarify this situation, a second experiment was carried out.

Sample B (Table I) was grown in an $^{16}\text{O}_2$ flow up to 190 nm and then dissolved down to 140 nm to be sure that the possibly remaining native oxide was removed. Then, this sample was submitted to a further growth in $^{16}\text{O}_2$ for 1.5 h at 930°C under 8 torr, and then $^{18}\text{O}_2$ gas was introduced up to a total pressure of 33 torr for 1.1 h at the same temperature. As can be seen, the presence of the ^{18}O FNES is confirmed: about 30% of the total amount (this result was checked by resonance technique).

Study of the possible mechanisms for the ^{18}O fixation near the external surface.—**Silicon transport.**—We have carried out the following experiments on two films of different original ^{16}O thicknesses (about 50 nm for sample C and 20 nm for sample D). They were subjected to an $^{18}\text{O}_2$ growth under 100 torr for 19 and 1.1 h, respectively. Each sample was cut into two parts. One part was kept as a test sample, the other was treated again in $^{16}\text{O}_2$ (for samples C and D, under 100 torr for 19 and 1.1 h, respectively). The results are summarized in Table II. We can easily see that for sample C the amount of ^{18}O FNES (i.e., N_s^{18}) is reduced by nearly a half, while for the thinner sample (sample D), the decrease is larger (this decrease which is a function of the original thickness will be discussed further). Thus isotopic exchange of oxygen occurs. If the fixation of the heavy isotope near the external surface was due to silicon transport, then the regrowth in an $^{16}\text{O}_2$ ambient would not diminish the surface ^{18}O amount. The Si $^{18}\text{O}_2$ would be unaltered but buried under a layer of Si $^{16}\text{O}_2$. This experiment cannot be used to distinguish between an exchange phenomenon due to water vapor traces and an exchange phenomenon due to a step-by-step effective motion of network oxygen atoms.

Exchange between water vapor traces and network oxygen atoms at the external surface.—In Table III, we calculate the equivalent water vapor pressure which would be necessary to obtain the whole ^{18}O FNES amount if the fixation of oxygen near the surface was entirely due to exchange with vapor traces. This calculation is performed by assuming that: (i) the ^{18}O mobile carrier is the H_2^{18}O

Table I. Measurements of ^{16}O and ^{18}O amounts obtained for two different oxide films (samples A and B) after different steps of dissolution. X_o^{18} is the equivalent ^{18}O oxide thickness. The samples were left in the hot zone when $^{18}\text{O}_2$ gas was added to $^{16}\text{O}_2$ (no thermal shock)

molecule, and its equilibrium concentration is proportional to the pressure $P_{\text{H}_2\text{O}}$, ^{18}O , (ii) the ^{18}O labeling of the H_2O traces is equal to 100%, and (iii) the reaction of the water molecules with the SiO_2 network is so fast that the ^{18}O isotopic equilibrium is reached.

Using the mathematical developments presented by Rigo *et al.* (40), we have calculated the equivalent minimum values of water vapor pressure. The corresponding exchanged amount is given by the equation

$$X = \frac{2}{\sqrt{\pi}} Cg^{18} \sqrt{D^*t}$$

where D^* is the effective diffusion coefficient, t the treatment duration, and Cg^{18} the isotopic concentration of water vapor traces. This expression is valid at this temperature for pressures in the 10 torr range. If at very low pressures (in the 10^{-4} torr range) D^* is still proportional to $p_{\text{H}_2\text{O}}$, we can obtain the equivalent water vapor pressure. Let us notice that measurements by mass spectrometer of H_2^{18}O yield values under 3 ppm of the total pressure. If for the thicker oxide samples (thickness ≥ 50 nm) such a hypothesis cannot be rejected, for the thinner oxide films, ^{18}O FNES is not due to an exchange between vapor traces and silicon oxide unless the mechanism assumed above is not valid any longer. As shown below, it would be difficult to explain the observed phenomena by water vapor traces.

Step-by-step effective motion of network oxygen atoms.—If the ^{18}O fixation near the external surface is not due to water vapor traces, we can consider that this exchange phenomenon, as evidenced by the decrease of the ^{18}O FNES amount after treatment in $^{16}\text{O}_2$ (Table II), is related to a step-by-step effective motion of network oxygen atoms. The particular role of the external surface is therefore emphasized: (i) some O_2 molecules are allowed to react at the surface, and then the dissociated species can migrate into the oxide, for example, by a vacancy type or by an interstitial type mechanism, and (ii) this surface allows network oxygen atoms to exchange with those of the O_2 gas. As a matter of fact, the oxygen species migrating through the pre-existing matrix in order to

react at the Si/oxide interface, within our method resolution, apparently do not interact with the network. Consequently, the external surface must exhibit some particular defect configuration that must be seldom encountered in the bulk.

Thickness effect on the respective amounts of ^{16}O fixed either near the surface or near Si/oxide interface.—**Thickness greater than 50 nm.**—Four samples of various original thicknesses X_o^{16} , named E_1 , F_1 , G_1 , and H_1 , were simultaneously treated at 930°C, 100 torr of $^{16}\text{O}_2$ for 8h. Another batch, consisting of samples E'_1 and G'_1 , was subsequently treated under the same conditions in order to control the reproducibility of the experiments. Finally, a third batch, consisting of samples (F_2 and H_2), was treated for 4h. The goal of simultaneous treatments was to avoid irreproducibilities from one treatment to another. The ^{16}O amounts before and after $^{18}\text{O}_2$ treatments and the incorporated ^{18}O amounts are reported in Table IV. Also in Table IV, we represent the equivalent thicknesses X_s^{18} (^{18}O FNES amounts) and X_i^{18} (^{18}O FNI amounts), which were obtained from fits of experimental excitation curves of the nuclear resonant reaction $^{18}\text{O}(p, \alpha)^{15}\text{N}$ with calculated curves assuming an ^{18}O concentration profile. Figures 3 and 4 represent such excitation curves for the samples H_1 and E_1 , respectively. Sample H_1 was tilted at $\theta = 68^\circ$ to separate the surface peak from the interface peak. The corresponding value X_s^{18} is equal to 1.57 nm. This value has been used in a test profile for sample E_1 (Fig. 4, where the dashed line represents the corresponding excitation curve). It appears that this curve cannot fit the experimental one. The surface peak is too great, and thus it is so for X_s^{18} . The profile that allows a good fit of the experimental curve is represented in the inset. It is seen that the corresponding value of X_s^{18} is equal to 0.9 nm, which is a smaller value than for the thinner sample H_1 . This shows that the variations of X_s^{18} observed by this method are relevant. From Table IV, one can notice a significant increase of X_s^{18} when X_o^{16} diminishes. The comparison between samples (E_1 , G_1) and (E'_1 , G'_1) identical treatment duration but nonsimultaneous experiments) shows that X_s^{18} increases with decreasing X_o^{16} in the same way. Samples (F_2 , H_2) treated during 4h show the same behavior and can give some evaluation of the kinetics of X_s^{18} . Between the fourth and eighth treatment hour ($\Delta t = 4\text{h}$), X_s^{18} roughly increases by 35% and by 57% for samples of original thickness $X_o^{16} \approx 178$ nm and $X_o^{16} \approx 47$ nm, respectively. Thus, the surface ^{18}O fixation rate is not linear. Since no appreciable increase of exchanged ^{18}O amounts was observed with decreasing oxide thickness in the case of labeled water vapor treatments (13 torr) (34), the present thickness effect is not indicative of an exchange with water vapor traces unless the phenomenon of exchange between water vapor traces and silica is not the same at very low pressures. The respective parts of ^{18}O FNES and ^{18}O FNI amounts are thus dependent on the original thickness of the oxides in the range 50-260 nm; a similar

Table III. Equivalent water pressure calculated for various oxide thicknesses

* Samples simultaneously grown in $^{16}\text{O}_2$. No re-exposure to air between two thermal treatments and thus no ^{16}O content measurement available.

study was carried out for thinner samples down to about ~5 nm.

Fig. 3. ^{18}O concentration profile measurement by the nuclear resonance method for sample H₁ of original thickness $X_o^{16} = 47.2$ nm treated in $^{18}\text{O}_2$ at 930°C, 100 torr for 8h. The sample was tilted at $\theta = 68^\circ$. The solid line is the best fit calculated for the profile represented in inset.

Thickness under 50 nm.—The results are reported in Table V. Two groups of samples were treated. First, sample J₁, J₂, and J₃, grown at 950°C in an $^{16}\text{O}_2/\text{N}_2$ mixture up to a thickness of about 19 nm, were subsequently submitted to an $^{18}\text{O}_2$ treatment at 930°C for about 1h, under a pressure of 100 torr. These samples were exposed to air between two thermal treatments. Although we approach the thickness domain where kinetics do not seem to follow the Deal-Grove model (1) any longer, we can notice that ^{18}O is still mainly found near the Si/oxide interface but the ^{18}O FNES amount now is around 20% of the total ^{18}O amount.

Second, samples K, L₁, L₂, L₃, M, and N, grown in the UHVT furnace in dry natural oxygen at 930°C, 9 torr, for various times (30-120 min), were subsequently treated in $^{18}\text{O}_2$, with no re-exposure to air, at 930°C for 1h and various pressures (0.1-9 torr) up to total thicknesses of about 5 nm. In this range of thicknesses, temperature and pressure where Kamigaki and Itoh (6) utilized the Mott-Cabrera model in order to fit the kinetics they found, we always found the heavy isotope located near the Si/oxide interface and near the external surface, but the ^{18}O FNES amounts are around 50% of the whole ^{18}O content when samples are still treated in $^{18}\text{O}_2$ at 9 torr. This ratio increases when the $^{18}\text{O}_2$ treatments are carried out under lower pressures, and can reach 80% of the whole ^{18}O amount at $p_{^{18}\text{O}_2} = 0.1$ torr. It appears that N_i^{18} follows a $p_{^{18}\text{O}_2}^{0.62}$ law, and N_s^{18} seems to follow a log $p_{^{18}\text{O}_2}$ law (N_s^{18} and N_i^{18} corresponding to the ^{18}O FNES and ^{18}O FNI amounts, respectively).

Discussion

As it can be noticed, there is no discontinuity in behavior for oxide films of thicknesses ranging from 260 to ~5 nm, both concerning the location of the heavy isotope and the increase of ^{18}O FNES amounts with decreasing original thickness X_o^{16} .

Fixation near the external surface

This thickness effect on ^{18}O FNES amounts could be interpreted in various ways

Fig. 4. ^{18}O concentration profile measurement by the nuclear resonance method for sample E_1 , of original thickness $X_{0,16} = 257$ nm treated in $^{18}\text{O}_2$ at 930°C for 8h. The solid line is the best fit calculated for the profile represented in inset. The ^{18}O FNES amount determined for sample H_1 was introduced in a trial profile whose theoretical excitation curve is represented by the broken line.

Fig. 5 Mixing effect on the $^{16}\text{O}/^{18}\text{O}$ boundary of a step-by-step effective motion of network oxygen atoms concurrent of an interstitial motion of molecular oxygen for an oxide film grown in $^{18}\text{O}_2$ and then in $^{18}\text{O}_2$.

1. The effect could be a structural change during growth, as observed for very thin films by Agius *et al.* (41). This was previously postulated by Revesz and Schaeffer (3).

2. The effect could be an enhancement of the concentration of oxide defects in connection with the film growth rate. The step-by-step motion of network oxygen atoms could be interpreted by some vacancy or interstitialcy-type mechanism. During oxide growth, defects in excess could be created at the silicon-oxide interface or at the external surface, respectively. Let us emphasize that one observes an injection of interstitial silicon atoms from the SiO_2/Si interface into the silicon substrate (42, 43). This was interpreted by Lin *et al.* (42) as an incomplete oxidation of Si by O_2 creating extra interstitial Si atoms both in the oxide and the Si substrate. The completion of the oxidation is performed through a further oxidation of these interstitial Si in the oxide. As no evidence of a migration of Si atoms was obtained through our labeling experiments, it seems to us that oxygen vacancy type defects generated at the Si/SiO_2 interface could be a reasonable explanation. Moreover, as one observes that the generation of interstitial Si into the Si substrate varies with the oxide growth rate (42, 43), one could imagine that the concentration of network defects in the oxide could be also related to the oxide-growth rate. In the case of network oxygen diffusion by network defects, the effective self-diffusion coefficient of network oxygen atoms is proportional to the concentration of oxide-network defects. Thus, if this defect concentration increases with the oxide-growth rate, the increase of ^{18}O FNES amounts with decreasing thicknesses could be explained.

3. The effect could be the presence of charged defects in the oxide and/or the supply of electronic species whose transport properties and injection at the interfaces are impeded for the thicker films.

Possible microscopic interpretation of the phenomenon of ^{18}O fixation near external surface

We noticed that the oxide surface and oxide bulk have a different behavior with respect to molecular oxygen and that network oxygen atoms can migrate by step-by-step motion; we have tried to explain all these experimental observations by a mechanism involving vacancy type defects, alternative to that proposed by Revesz and Schaeffer (3). The basic defects that we consider here are silicon dangling bonds in excess (one Si dangling bond, charged or not, formally corresponds to half an oxygen

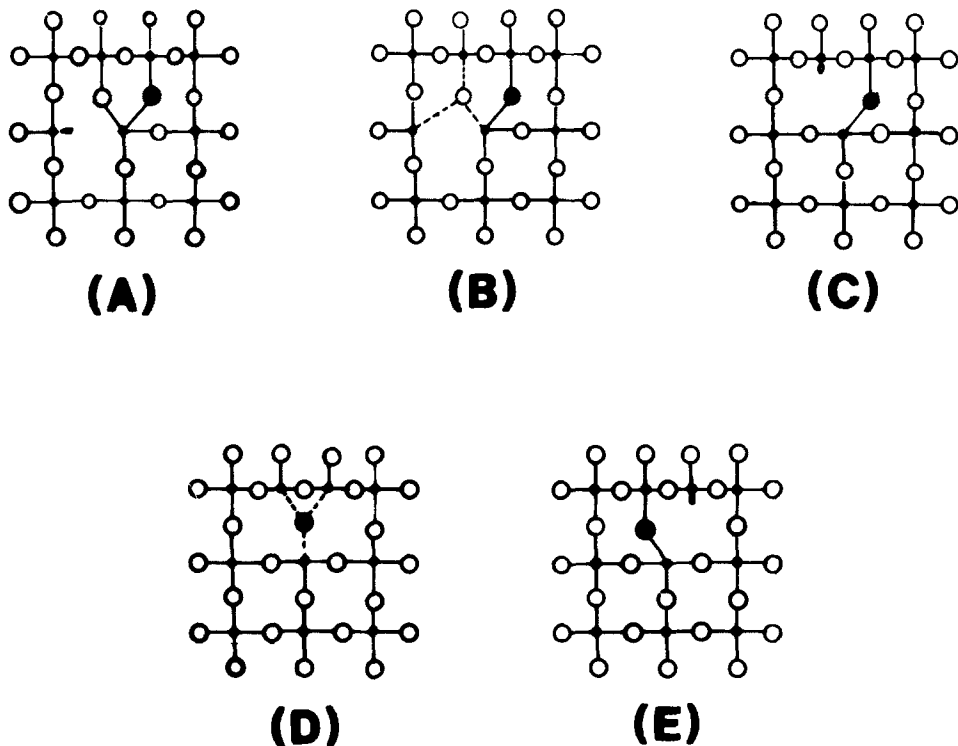

Fig. 6. Schematic drawing of the motion of a labeled oxygen atom of the network when one assumes that the basic oxygen defect is a Si dangling bond. Small circles correspond to Si atoms, and large circles to oxygen atoms (the dark one being a labeled oxygen). Subsequent steps are in alphabetical order. For the sake of simplicity, the charge of the defects (if charged) is not represented.

vacancy). The motion of a labeled oxygen atom is sketched in Fig. 6. In this figure, we describe the motion of the defect considering a threefold-coordinated oxygen as an intermediate step, although the existence of this defect imagined by Lucovsky (44) in bulk silica has been debated (45). As the direct jump of a Si dangling bond would imply the breaking of a Si—O bond in the $\equiv\text{Si}-\text{O}\equiv$ configuration ($d_{\text{SiO}} = 0.6 \text{ nm}$) the breaking of the Si—O bond [$d_{\text{SiO}} = 0.72 \text{ nm}$ (46)] in the threefold-coordinated oxygen configuration would be energetically easier. The particular behavior of the surface compared to that of the bulk is due to the fact that the network is disrupted at the surface. The desorption, adsorption, and breaking of the O_2 molecule at the external surface could be sketched as follows

where two Si dangling bonds (or nonbridging oxygens) are in the vicinity of each other. The symbol — designates a bond between an oxygen atom and a silicon atom; the

symbol \ominus designates a Si or O orbital. For the sake of simplicity, the occupation of these orbitals by electrons (*i.e.*, the charge of the dangling bond) is not represented. The probability of finding such a topological situation is very high at the surface and very small in the bulk. These phenomena are perhaps favored by the supply of electrons at the external surface: an electronic bombardment greatly enhances the oxidation rates even at very low pressure (10^{-3} torr) (47). Figure 7 shows a possible scenario for oxygen exchange between the gas and the network. An interstitialcy mechanism by jumps of $\equiv\text{Si}-\text{O}\cdot$ defects cannot be ruled out. At sufficiently low pressure, where the contribution to growth due to O_2 molecules reacting at the interface Si/SiO₂ might be negligible, the creation of oxygen vacancies in excess might not be necessarily envisaged. As a matter of fact, in low pressure plasma oxidation, no oxidation stacking faults in the Si substrate are observed; apparently, no great amounts of interstitial silicon atoms are generated (48). Consequently, such an interstitialcy mechanism could perhaps exist rather at low pressure.

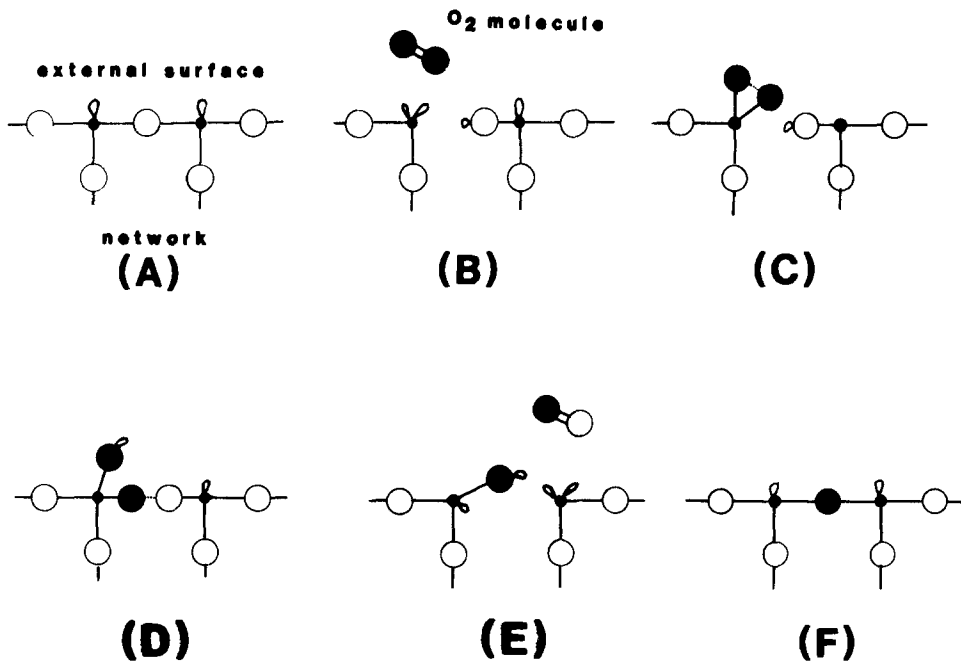

Fig. 7. Schematic drawing of a possible scenario for oxygen exchange between the gas and the network. Small circles correspond to Si atoms. Large circles correspond to oxygen atoms (the dark one being a labeled oxygen). Subsequent steps are in alphabetical order. For the sake of simplicity the charge of the defects (if charged) is not represented.

Fixation near the Si/oxide interface, nature of the migrating oxygen species

As we always find ^{18}O located near the Si/oxide interface, we can wonder about the oxygen species migrating through the film with no interaction with it.

For thick oxide samples (>20 nm), one can think that O_2 molecules are very likely the diffusing species as k_p exhibits a p_{O_2} dependence and an activation energy equal to that found for permeation (1).

For thin oxide samples (<5 nm), for which electrons can tunnel across the film, the dissociation of O_2 molecules into dissociated ions is perhaps enhanced. These hypothetical ions must migrate in the oxide film without interacting with it, as well as O_2 molecules for thicker oxide samples. Mills and Kroger (20) proposed O^{2-} as responsible for ionic conduction. We should notice that this ion is the more energetically difficult to obtain from a free O_2 molecule [462 kcal · mole⁻¹ or 20 eV (49)], but one might wonder why these dissociated species do not apparently interact with the network while migrating. O_2^- species could also be envisaged knowing that at the Si/oxide interface O_2^- can be more easily dissociated as its bond strength is practically that of an O—O single bond [1.5 eV (50)]. As a matter of fact, charged species are involved in a Cabrera-Mott transport mechanism leading to inverse logarithmic laws; such kinetics are observed at pressures under 1 torr (6). Obviously, neutral O_2 molecules are still good candidates for explaining the ^{18}O fixation near the Si/SiO₂ interface even for very thin films. If a Cabrera-Mott mechanism is actually involved for very thin oxide samples and becomes dominant as pressure decreases (6), it may be that the charged species and/or defects accelerated by the electrical field could rather be $\equiv\text{Si}^+$ or $\equiv\text{Si}-\text{O}^-$ defects (or other equivalent defects); in this case the heavy isotope would only be found near the external surface.

Effect of pressure on N_i^{18} and N_s^{18}

Variations of N_i^{18} .—Two cases may be considered. First, that the diffusion of O_2 molecule is the limiting phenomenon. We are only able to conclude that, as the thickness increase is small (<10%), we are not facing a simple bulk-limited diffusion phenomenon where the concentration of diffusing species at the external surface is practically equal to the solubility C^* , this solubility following a Henry's law ($C^* \propto p_{\text{O}_2}$). Second, that a more or less complex reaction of the O_2 molecules at the Si/oxide interface is the limiting phenomenon. Thus, we are not facing a simple first-order reaction, which was already assumed by Ghez and Van der Meulen (7), and later by Blanc (8). A change in O_2 diffusivity connected with a structural change during growth (41) might be also put forward to explain the $p_{\text{O}_2}^{0.62}$ law that we found.

Variations of N_s^{18} .—The variation of N_s^{18} with p_{O_2} for film thicknesses under 5 nm is difficult to interpret at the present time without a better understanding of surface phenomena, bulk diffusion mechanisms, and their relative importance. Nevertheless, noticing that at 10^{-1} torr, N_s^{18} represents more than 80% of the whole heavy isotope amount (see Table V), we could wonder if, in the very small thickness range (<5 nm) and in the range of pressures where our experiments were carried out, we are not facing two concurrent growth mechanisms, one of them related to a vacancy or interstitial type mechanism and much less sensitive pressure decrease.

Conclusion

For oxide thicknesses ranging from 5 to 260 nm, oxygen transport shows two aspects, one being related to oxygen species' migrating through the network with no or little interaction with it (very likely O_2 molecules for thick samples) and reacting with silicon at the Si/oxide interface, and the other being likely related to a step-by-step motion of network oxygen atoms responsible for isotopic exchange near the external surface, this being allowed by some particular nature of the surface. The relative importance of the latter increases as oxide films are thinner and O_2 pressures lower.

Acknowledgments

The authors are very indebted to F. P. Fehlner, E. A. Irene, Sir Nevill Mott, and A. G. Revesz for fruitful dis-

cussions and reading the manuscript. They are very grateful to G. Amsel for his help in the UHVT furnace designing, and to J. Moulin for his technical assistance in the UHTV furnace making. They thank E. d'Artemare and E. Girard for their help in the use of nuclear microanalysis facility of our laboratory. They are indebted to B. Biasse and J. J. Niez from the Laboratoire d'Electronique et de Technologie de l'informatique of Grenoble for their help in ^{18}O oxide preparation. This work was supported by Centre National de la Recherche Scientifique (R. C. P. no. 157) and Centre National d'Etudes des Télécommunications.

The Characteristics of Alumina Scales Formed on Fe-Based Yttria-Dispersed Alloys

T. A. Ramanarayanan,* M. Raghavan, and R. Petkovic-Luton

Exxon Research Center, Linden, New Jersey 07036

ABSTRACT

To provide resistance to aggressive environments at elevated temperatures, especially in excess of $\sim 1000^\circ\text{C}$, alloys or coatings which develop $\alpha\text{-Al}_2\text{O}_3$ scales are the best choice. It has been pointed out that the presence of highly stable rare earth oxide dispersoids in high temperature alloys leads to improvements in the corrosion-resistant properties of Al_2O_3 scales formed on such alloys. The present study is directed toward developing an understanding of how the properties of Al_2O_3 scales formed on Fe-based alloys are influenced by yttrium oxide dispersoids in the alloy. The Fe-based alloy system selected for the current study consists of $\sim 20\%$ Cr, $\sim 4.5\%$ Al, $\sim 0.5\%$ Ti, and $\sim 0.5\%$ Y_2O_3 . The oxidation kinetics of the alloy have been established at various oxygen partial pressures in the temperature range 1000°C - 1200°C . The $\alpha\text{-Al}_2\text{O}_3$ scales which result upon oxidation are observed to be columnar, ultrafine grained, and extremely adherent when thermally stressed. Platinum markers initially placed on the alloy surface are found at the oxide/gas interface at the completion of oxidation, suggesting that scale growth occurs by exclusive inward oxygen migration. The ultrafine grain size ($0.5\text{-}1\ \mu\text{m}$) suggests that grain boundaries in the oxide scale are the preferred path for oxygen migration. The fine dispersoid particles in the alloy ($200\text{-}500\text{\AA}$) transform to coarse ($\sim 0.5\ \mu\text{m}$) yttrium aluminum garnet upon incorporation into the Al_2O_3 scale, leading to a garnet-saturated scale. It is suggested that the remarkable adherence of the $\alpha\text{-Al}_2\text{O}_3$ scales is a consequence of a combination of factors. First, yttrium doping promotes the development of a fine-grained $\alpha\text{-Al}_2\text{O}_3$ scale which can effectively relieve oxide growth stresses by diffusional plastic flow. Second, because the alumina scale grows by exclusive inward oxygen transport, growth stresses arising from Al_2O_3 nucleation within an existing scale are avoided.

High temperature alloys or coatings designed to resist aggressive environments at elevated temperatures should be capable of developing a surface oxide layer which is thermodynamically stable, slow growing, and adherent. The three oxides which fit the requirement of slow growth are Cr_2O_3 , SiO_2 , and Al_2O_3 . Of these, chromia is the fastest growing and alumina is the slowest growing. The thermodynamic stability of these oxides is in the order $\text{Al}_2\text{O}_3 > \text{SiO}_2 > \text{Cr}_2\text{O}_3$. At temperatures exceeding $\sim 1000^\circ\text{C}$, chromium oxide scales tend to become unstable; in environments of relatively high oxygen partial pressure, the oxide can vaporize as CrO_3 (1), while under highly reducing conditions the oxide can transform to other more thermodynamically stable phases (2).

For applications in hostile environments at temperatures in excess of $\sim 1000^\circ\text{C}$, Al_2O_3 and SiO_2 scales should be preferred to provide corrosion resistance. While the kinetic stages leading to the development of a continuous-surface oxide layer are certainly of importance, once such an oxide layer is established, the most important consideration is how well the oxide layer adheres to the alloy surface. The factors which influence the adhesion of oxide scales are not well understood. It has been pointed out by several investigators that small amounts of rare earth oxide dispersoids present in the alloy lead to the formation of a more adherent surface-oxide scale (3-17). The literature information in this area was reviewed recently (18-19).

Several mechanisms have been proposed in the literature to explain the dispersoid effect:

1. The oxide scale develops numerous protrusions/pegs which form around rare earth oxide particles in the alloy. These pegs anchor the oxide scale to the alloy.
2. The rare earth oxide particles react with the main oxide scale and form a mixed-oxide layer between the main scale and the alloy. The mixed-oxide layer acts as a "graded seal" improving the stability of the oxide scale under thermal cycling conditions.

3. The rare earth oxide particles in the alloy act as sites on which vacancies generated by the oxidation process condense. The vacancies thus do not coalesce on the scale/metal interface, a process which could lead to oxide spallation.

4. The rare earth element dissolves into the scale and suppresses Al transport in the scale. Thus, growth stresses, otherwise developed by the formation of alumina within an existing scale, are decreased.

Sufficient experimental evidence does not exist to confirm the above mechanisms. Also, most of the published studies point to a combination of mechanisms rather than a single mechanism being operative. Thus, a consistent picture of the dispersoid effect has not emerged.

The purpose of the present investigation is to improve our understanding of the influence of rare earth oxide dispersoids on oxide-scale properties. As the first of a proposed series of investigations, it was decided to examine the properties of alumina scales developed on an Fe-based alloy system containing yttrium oxide as the dispersoid. The results of this study are contained in the present paper.

Materials and Experimental Procedure

The experimental alloy selected for investigation was alloy MA956, made by the International Nickel Company. Two types of samples were used; one had a fine-grained ($\sim 0.2\ \mu\text{m}$) microstructure typical of the as-received condition, while the other had a coarse-grained structure which results upon heat-treating (Fig. 1). The distribution of dispersoid particles is shown in Fig. 2. The particles have been identified by microdiffraction to be YAlO_3 . The specimens were rectangular, $1 \times 1/2 \times 1/16$ in.; the faces were ground to 600 grit SiC and cleaned ultrasonically in acetone.

The kinetics of oxidation was measured by thermogravimetry using a Cahn 1000 electrobalance. The electrobalance was attached to a vertically placed quartz reactor tube; the sample to be oxidized was hung from the balance by

Fig. 2. Dispersoid distribution in alloy MA956

means of a platinum suspension wire. A platinum resistance furnace surrounded the quartz tube; the furnace could be moved up and down hydraulically. The oxidizing gas entered the quartz tube at the bottom and escaped at the top, where it mixed with an argon stream used to provide an inert atmosphere within the electrobalance assembly.

At the start of an experimental run, the sample to be oxidized was hung from the electrobalance and the quartz reactor tube slid into place, the furnace being in the "down" position. The reactor tube was kept under a purging argon stream, and the furnace brought to the oxidation temperature, the sample still being held at room temperature. The argon flow was then replaced by the oxidizing gas or gas mixture, the flow rate being high enough so that mass transport in the gas phase would not be rate controlling. After an interval of ~30 min, the furnace was hydraulically lifted up around the sample so that the sample was positioned within the constant temperature zone ($\pm 1^\circ\text{C}$) of the furnace. It took approximately 10 min for the sample to attain the experimental temperature. An HP 9845T computer was used to collect and analyze weight-gain data.

The oxidation kinetics were investigated in the temperature range $900^\circ\text{--}1200^\circ\text{C}$. The environments used were undried air, dry oxygen, and CO/CO_2 gas mixtures of varying oxygen partial pressures. The adherence of the oxide scales developed on the alloy surface was inferred by weight changes upon rapidly cooling the sample to room temperature by lowering the furnace and/or temperature cycling by raising and lowering the furnace at specific intervals.

Upon completion of the kinetic runs, the morphology and structure of the oxide scales formed on the alloy surface were examined using scanning electron microscopy, trans-

mission electron microscopy, microdiffraction, and secondary ion mass spectrometry.

Results

Most samples were oxidized for periods ranging from 25 to 100h in the thermogravimetric unit. A few samples were oxidized up to 1000h in a separate furnace; kinetic data are not available for these longer-term experiments. The oxide scales were characterized by their excellent adherence; no oxide spallation could be detected upon quenching the sample to room temperature from oxidation temperatures in the range $900^\circ\text{--}1200^\circ\text{C}$ even after oxidation times as long as 100h.

Most of the experimental data were taken in the temperature range $1000^\circ\text{--}1200^\circ\text{C}$. A parabolic rate was obeyed for oxidation times as long as 100h. The slope of a plot of the square of the oxidation weight gain per unit area vs. time is the parabolic rate constant, k_p ($\text{g}^2 \text{cm}^{-4} \text{s}^{-1}$). The rate constant is plotted as a function of temperature in Fig. 3. The data for the fine- and coarse-grained samples fall on the same regression line, the grain size of the alloy having little influence on the oxidation rate. The rate constant can be expressed by the relationship

$$k_p (\text{g}^2 \text{cm}^{-4} \text{s}^{-1}) = 4.2 \times 10^2 \exp(-92,800/RT) \quad [1]$$

Fig. 3. Parabolic rate constant for $\alpha\text{-Al}_2\text{O}_3$ growth as a function of temperature.

The oxidized samples were fractured under liquid nitrogen and the fracture cross sections examined by SEM. A columnar fine-grained scale morphology was revealed (Fig. 4). The oxide grain sizes were temperature independent when oxidized in the temperature range 1000°-1200°C for times ranging from 25 to 100h, with grains measuring approximately 1-2 μm in length and $\sim 0.5 \mu\text{m}$ across. At 1200°C, upon increasing the oxidation time to 300h, the average grain width increased to 0.75 μm , while after 1000h, the width was approximately 1.25 μm . Thus, the oxide scale remained essentially fine grained even after long oxidation times (Fig. 5). X-ray diffraction analysis showed the scales to be exclusively $\alpha\text{-Al}_2\text{O}_3$.

Fig. 5. Dependence of $\alpha\text{-Al}_2\text{O}_3$ grain width on oxidation time. Top: 24h in air, 1200°C. Center: 300h in air, 1200°C. Bottom: 1000h in air, 1200°C.

In order to characterize the oxide films further, thin films were prepared and examined using a Philips EM 400 transmission electron microscope. The films were prepared by first electropolishing the metal away and then ion thinning the oxide scale. In some cases, only ion thinning was used. The TEM investigations again revealed the fine-grained nature of the oxide scale. A thinned section, viewed perpendicular to the oxide/metal interface, reveals the presence of fine microvoids, $\sim 500\text{\AA}$ in size; the voids occur predominantly at oxide grain boundaries (Fig. 6). Microdiffraction analysis in the TEM confirmed the oxide scale to be $\alpha\text{-Al}_2\text{O}_3$.

Further detailed examination of the scale was carried out in order to detect the YAlO_3 particles originally present in the alloy. The only yttrium containing phase found in the oxide scale was yttrium aluminum garnet, $\text{Y}_3\text{Al}_5\text{O}_{12}$. This phase was typically 0.2-0.5 μm in size, as revealed by the TEM micrograph to the left in Fig. 7. The phase was identified by microdiffraction. The [001] diffraction pattern is shown on the right in Fig. 7. The zero layer in this pattern consists of a square grid of {200} reflections, and the third dimension was calculated from the diameter of the ring to be 12.05 \AA , consistent with the lattice parameter of garnet. The garnet phase was located principally in the vicinity of $\alpha\text{-Al}_2\text{O}_3$ grain boundaries. It is interesting to note the coarseness of the garnet phase when compared with the fine YAlO_3 particles present in the alloy (Fig. 2). The size difference is further revealed in the transmission electron micrograph in the vicinity of an oxide/metal interface (Fig. 8).

Fig. 8. TEM micrograph in the vicinity of the oxide/metal interface showing coarse $Y_3Al_5O_{12}$ in the oxide and fine $YAlO_3$ in the metal.

In order to determine the distribution of the $Y_3Al_5O_{12}$ phase in a thick $\alpha-Al_2O_3$ scale, a MA 956 alloy specimen was oxidized for 1000h at 1200°C in air and examined in cross section using a Cameca secondary ion mass spectrometer. Ion maps for Al^+ and Y^+ are shown in Fig. 9. The field of view in Fig. 9 is 150 μm ; the positive secondary ions were monitored, sputtered, and excited with a 15 keV beam of O_2^+ . Because the spacial resolution of SIMS is $\sim 0.5 \mu m$, the fine yttrium containing oxides in the metal are not resolved. The $Y_3Al_5O_{12}$ phase in the oxide scale is clearly shown; there is some degree of charging in the Y^+ ion map which has exaggerated the size of the garnet phase. It is clearly seen that the fine $YAlO_3$ particles have dissolved upon entering the oxide scale and reprecipitate as garnet.

A limited number of oxidation experiments were carried out at a lower temperature of 900°C at high oxygen partial pressures. A difference in kinetics was noticed upon oxidizing fine-grained MA 956 samples in undried air and dry oxygen. The kinetics were faster in undried air (Fig. 10). Examination of the oxide scales by TEM revealed that in the air-oxidation case, the alumina scale was made up of a mixture of α - and δ -phases, while in the case of dry oxygen, the scale was exclusively the α -phase. A TEM micrograph of the δ -phase and the corresponding [100] microdiffraction pattern are shown in Fig. 11. The microdiffraction pattern shows a rectangular grid of (010) and (002) reflections. The δ -phase is seen to have a faulted structure and probably al-

lows more rapid transport of reactant species, as suggested by the kinetic data shown in Fig. 10.

Discussion

Anion migration through Al_2O_3 scale.—Parabolic kinetics of $\alpha-Al_2O_3$ scale growth suggests that the oxide scale growth is limited by diffusional transport through it. To establish whether oxygen or aluminum is the predominant mobile species in the oxide scale, Pt-wire markers were positioned on the alloy surface prior to oxidation. Upon completion of oxidation, the Pt markers remained at the oxide/gas interface, suggesting that scale growth occurred by oxygen transport (Fig. 12).

The diffusivity of oxygen in single-crystalline and polycrystalline (20-30 μm grain size) $\alpha-Al_2O_3$ at 1200°-1800°C has been measured by Oishi and Kingery (20). Between 1400° and 1800°C their data for oxygen diffusivity in single crystalline and polycrystalline $\alpha-Al_2O_3$ are given, respectively, by

Fig. 9. SIMS ion maps for Al^+ and Y^+ in MA956 at 900°C.

Fig. 12. Platinum marker study showing the inward growth of $\alpha\text{-Al}_2\text{O}_3$ scale by oxygen diffusion

$$D_0^l = 1.9 \times 10^8 \exp(-152,000/RT) \text{ cm}^2/\text{s} \quad [2]$$

$$D_0^{\text{eff}} = 2 \exp(-110,000/RT) \text{ cm}^2/\text{s} \quad [3]$$

where D_0^l denotes the lattice diffusivity of oxygen in the single crystal and D_0^{eff} denotes the effective diffusivity (made up of both lattice and grain-boundary contributions) of oxygen in the polycrystalline sample. Experimental data below 1400°C deviated from the above expressions presumably because of impurities contained in the $\alpha\text{-Al}_2\text{O}_3$ samples.

If the data according to Eq. [2] and [3] are extrapolated to 1200°C , then $D_0^l \sim 5.3 \times 10^{-20} \text{ cm}^2 \text{ s}^{-1}$ and $D_0^{\text{eff}} \sim 9.5 \times 10^{-17} \text{ cm}^2 \text{ s}^{-1}$. The effective diffusivity can be expressed in terms of lattice and grain boundary components as (21)

$$D_0^{\text{eff}} = (1 - f)D_0^l + fD_0^{\text{gb}} \quad [4]$$

where D_0^{gb} represents the grain boundary oxygen diffusivity and f is the fractional volume for grain boundary diffusion. The factor f can be equated to $k\delta/d$ where k is a geometrical constant (k was taken to be 2 in this study), δ is the grain boundary width, and d is the grain width. Thus

$$D_0^{\text{eff}} = D_0^l + \frac{k\delta}{d}(D_0^{\text{gb}} - D_0^l) \cong D_0^l + \frac{k\delta}{d}D_0^{\text{gb}} \quad [5]$$

since $D_0^{\text{gb}} \gg D_0^l$

Using the extrapolated values of D_0^{eff} and D_0^l at 1200°C , it is easily seen that for grain sizes in the 20-30 μm range, the effective oxygen diffusivity in $\alpha\text{-Al}_2\text{O}_3$ is predominantly determined by grain boundary diffusion. Also, in view of Eq. [5], the contribution to grain boundary transport would be even higher as the grain width, d , decreases. It can be concluded that in the $\alpha\text{-Al}_2\text{O}_3$ scales formed on Alloy MA 956, in which $d \sim 1 \mu\text{m}$, oxygen transport occurs almost exclusively through the grain boundary.

Incorporation of YAlO_3 particles into inward growing $\alpha\text{-Al}_2\text{O}_3$ scale: yttrium doping.—As discussed earlier, the YAlO_3 particles in the alloy are in the size range 200-500 \AA . Particles in this size range or of this composition have not been detected in the $\alpha\text{-Al}_2\text{O}_3$ scale. Instead, only coarse yttrium aluminum garnet particles in the size range 0.2-0.5 μm have been detected. This phase forms predominantly in the vicinity of $\alpha\text{-Al}_2\text{O}_3$ grain boundaries. Energy dispersive x-ray analysis of the alumina in the grain boundary and bulk regions reveals a strong tendency for yttrium to segregate to the grain boundary (Fig. 13). The analysis in the grain-boundary region is averaged over a width of $\sim 200\text{\AA}$. Grain boundary segregation of yttrium in alumina has also been reported in a previous study (22).

In view of the above findings, it is suggested that the YAlO_3 particles from the alloy dissolve upon incorporation into the oxide/metal interface region. The yttrium rapidly diffuses along the metal/oxide interface and segregates to the Al_2O_3 grain boundary region as the oxide grows into the metal. At some point, the solubility product for $\text{Y}_3\text{Al}_5\text{O}_{12}$ is exceeded in the vicinity of some of the Al_2O_3 grain bounda-

ries, whereupon this phase is precipitated

The oxygen supply for reaction [6] is provided by grain boundary transport. The suggested mechanism is shown schematically in Fig. 14.

The $\alpha\text{-Al}_2\text{O}_3$ scale formed on the alloy may be considered to be saturated with $\text{Y}_3\text{Al}_5\text{O}_{12}$, and the scale will have a certain doped concentration of yttrium, which is predominantly present in the vicinity of grain boundaries. However, the bulk grain is also probably doped with yttrium at lower concentration levels. It has been proposed that doped yttrium tends to reduce Al transport through bulk $\alpha\text{-Al}_2\text{O}_3$ grains (23, 24). Such an effect cannot be expected if yttrium occupies the Al lattice site in $\alpha\text{-Al}_2\text{O}_3$ as a trivalent dopant with zero effective charge. However, El-Aiat and Kröger (25) argue that yttrium might act as a donor Y_{Al} , a yttrium defect with a positive effective charge. In the present discussion, it is considered that yttrium might act as a donor or an acceptor in accordance with the following defect equilibria

The equilibria [7] and [8] imply that defects generally proposed for bulk grains also prevail in the vicinity of grain boundaries. This is appropriate because the high diffu-

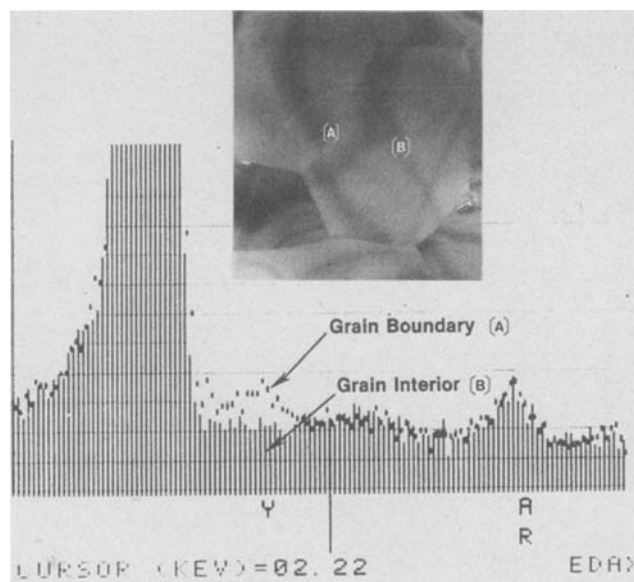

Fig. 13. Grain boundary segregation of yttrium in $\alpha\text{-Al}_2\text{O}_3$

Fig. 14. Mechanism for precipitation of $Y_3Al_5O_{12}$ in $\alpha-Al_2O_3$.

sivity path for rapid transport in the vicinity of an $\alpha-Al_2O_3$ grain boundary is $\sim 100-150\text{\AA}$ wide (26). Wang and Kroger (27) have also used defect descriptions generally used for bulk grains for the grain boundary region.

Alpha Al_2O_3 has a high bandgap of ~ 9.9 eV (28, 29); the concentrations of native defects formed by electronic or ionic disorders is extremely small. Thus, for equilibrium [7], one can use the electroneutrality condition

$$[Y_{Al}'] = 2[O_i''] \quad [9]$$

where [] denotes concentration. Combining the equilibrium constant, K_I , for reaction [7] with Eq. [9],

$$K_I = 64 [O_i'']^3 P_{O_2}^{-3/2} \quad [10]$$

Thus $[O_i''] \propto P_{O_2}^{1/6}$. Since the diffusivity of oxygen will have the same oxygen partial pressure dependence as the major oxygen defect (30)

$$D_0^{gb} = D_0^{*gb} P_{O_2}^{1/6} \quad [11]$$

where D_0^{gb} is the oxygen diffusivity in the vicinity of $\alpha-Al_2O_3$ grain boundary and D_0^{*gb} is the value at 1 atm oxygen partial pressure.

Use of similar arguments to reaction [8] along with the neutrality condition, $[Y_{Al}'] = 2[V_O'']$ leads to

$$K_{II} = 64 [V_O'']^3 P_{O_2}^{3/2} \quad [10.1]$$

$$D_0^{gb} = D_0^{*gb} P_{O_2}^{-1/6} \quad [11.1]$$

Where K_{II} is the equilibrium constant for reaction [8].

Quantitative description of oxidation kinetics.—In the following analysis, the $\alpha-Al_2O_3$ scale is considered to consist of columnar grains having a square cross section of side d . The oxide scale is presumed to grow exclusively by grain-boundary transport of oxygen. The width of the boundary region where rapid transport occurs is designated δ . The oxygen flux during oxide scale growth is considered to occur exclusively in a direction parallel to the grain boundary. The oxygen flux per unit area of the grain boundary is then given by

$$J_0 \text{ (mol cm}^{-2} \text{ s}^{-1}) = -B_0 C_0 \left(\frac{\partial \mu_0}{\partial x} \right) \\ = -\frac{1}{2} B_0 R T C_0 \left(\frac{\partial \ln P_{O_2}}{\partial x} \right) = -\frac{1}{2} D_0^{gb} C_0 \left(\frac{\partial \ln P_{O_2}}{\partial x} \right) \quad [12]$$

where B_0 is the mobility of oxygen (velocity per unit gradient of chemical potential), C_0 is the average oxygen concentration in the oxide in mol cm^{-3} , μ_0 is the chemical potential of oxygen in the oxide, and x the distance coordinate perpendicular to the oxide/metal interface. The oxygen partial pressure at the oxide/gas interface is designated as $P_{O_2}^0$ and at the oxide/metal interface as $P_{O_2}^1$. Per unit area of the oxide scale, the area occupied by grain boundary equals $\sim 2\delta/d$. Thus, the flux, J_0' of oxygen per unit area of the oxide scale is given by

$$J_0' = -D_0^{gb} C_0 \delta d^{-1} \left(\frac{\partial \ln P_{O_2}}{\partial x} \right) \quad [13]$$

Integrating across thickness, Δx , of oxide scale

$$J_0' \Delta x = C_0 \delta d^{-1} \int_{P_{O_2}^1}^{P_{O_2}^0} D_0^{gb} d \ln P_{O_2} \quad [14]$$

Using the relations, $J_0' = 1/16A (d\Delta w/dt)$ and $\Delta x = \Delta w/(\rho_{oxide} f_o A)$, where ρ_{oxide} is the density of $\alpha-Al_2O_3$, Δw is the oxidation weight gain measured thermogravimetrically, A is the cross-sectional contact area between oxide and metal, and f_o is the weight fraction of oxygen, Eq. [14] can be rewritten as

$$\frac{1}{A^2} \int_0^{\Delta w} \Delta w d\Delta w = [16 \rho_{oxide} f_o C_0 \delta d^{-1} \int_{P_{O_2}^1}^{P_{O_2}^0} D_0^{gb} d \ln P_{O_2}] \int_0^t dt \quad [15]$$

Integrating and rearranging

$$\left(\frac{\Delta w}{A} \right)^2 = [59.78 C_0 \delta d^{-1} \int_{P_{O_2}^1}^{P_{O_2}^0} D_0^{gb} d \ln P_{O_2}] t \quad [16]$$

whereby the parabolic rate constant (Fig. 3), k_p , is given by

$$k_p = 59.78 C_0 \delta d^{-1} \int_{P_{O_2}^1}^{P_{O_2}^0} D_0^{gb} d \ln P_{O_2} \quad [17]$$

In integrating Eq. [17], the variation of D_0^{gb} with oxygen partial pressure must be taken into account. If yttrium acts as a donor and leads to the formation of O_i'' defects, then Eq. [11] holds. Combining Eq. [11] and [17]

$$k_p = 358.68 \delta d^{-1} C_0 D_0^{*gb} (P_{O_2}^{0/6} - P_{O_2}^{1/6}) \quad [18]$$

At 1100°C , $p_{O_2}^1 \sim 5 \times 10^{-28}$ atm. The lowest environmental oxygen partial pressure used in the present investigation is $\sim 10^{-14}$ atm. Thus $P_{O_2}^{0/6} \gg P_{O_2}^{1/6}$ so that

$$k_p = 358.68 \delta d^{-1} C_0 D_0^{*gb} P_{O_2}^{0/6} \quad [19]$$

Thus k_p is strongly dependent on the environmental oxygen partial pressure.

If yttrium acts as an acceptor and creates oxygen vacancies as the predominant defects, then, combining Eq. [11.1] and [17]

$$k_p = 358.68 \delta d^{-1} C_0 D_0^{*gb} (P_{O_2}^{-1/6} - P_{O_2}^{0-1/6}) \quad [20]$$

In this case, since $P_{O_2}^{-1/6} \gg P_{O_2}^{0-1/6}$

$$k_p = 358.68 \delta d^{-1} C_0 D_0^{*gb} P_{O_2}^{-1/6} \quad [21]$$

Thus, k_p should be independent of the environmental oxygen partial pressure.

To test whether Eq. [19] or [21] applies, the variation of k_p with oxygen partial pressure has been measured at 1100° and 1200°C . Within limits of experimental error, k_p is found to be independent of the oxygen partial pressure. Typical data at 1100°C are presented in Fig. 15. It is, therefore, suggested that oxygen vacancies rather than interstitials are responsible for grain boundary oxygen transport. Using experimental values for k_p and the average grain width, d , the

Fig. 15. Variation of k_p with oxygen partial pressure.

following expression has been evaluated for the product δD_0^{*sb}

$$\delta D_0^{*sb} (\text{cm}^3 \text{ s}^{-1}) = 4.92 \times 10^{-2} \exp(-133,940/RT) \quad [22]$$

Equation [22] holds for 1 atm oxygen partial pressure. For other oxygen partial pressures

$$\delta D_0^{*sb} = \delta D_0^{*sb} P_{O_2}^{-1/6} \quad [23]$$

The activation energy term in Eq. [22] is made up of contributions from the temperature dependence of δ and the temperature dependence of D_0^{*sb} .

The present results for δD_0^{*sb} may be compared with values for δD_0^{*sb} calculated from Oishi and Kingery (20)

$$\delta D_0^{*sb} = 1.4 \times 10^{-3} \exp(-110,000/RT) \quad [24]$$

and values measured by Reddy (31)

$$\delta D_0^{*sb} = 8.15 \exp(-142,000/RT) \quad [25]$$

However, no oxygen partial pressure dependencies are available for these values.

A mechanism for microvoid formation in $\alpha\text{-Al}_2\text{O}_3$ grain boundaries.—The production of voids in oxide scales growing under an oxygen partial pressure gradient is by no means a new phenomenon. Pores have been observed, for example, in oxidized scales of Fe_3O_4 (32), FeO (33), NiO (34), and Al_2O_3 (35, 36). In Fe_3O_4 , FeO , and NiO , the pores were large enough to be detected by optical metallography. Evidence of pore formation in CoO placed under an oxygen partial pressure gradient was obtained by Yurek and Schmalzried (37). A pellet of CoO , initially equilibrated at $P_{O_2} = 0.2$ atm at 1200°C , was placed in a P_{O_2} gradient so that one face was at 0.2 atm and the other face was at 10^{-9} atm. After 1.5h at 1200°C , the crystal developed ~5 volume percent (v/o) porosity. The authors suggested that the pores are formed as a result of cobalt vacancy diffusion from the high P_{O_2} side and subsequent precipitation at the low P_{O_2} side.

The above examples suggest that the formation of pores in oxide scales placed under a P_{O_2} gradient is related to atomic defects in the crystal and occurs by vacancy condensation. In their work on Al_2O_3 scales formed on Ni-Cr-Al alloys, Smialek and Gibala (35) tentatively proposed a model based on oxygen-vacancy supersaturation and condensation to account for void formation. The voids were present both within the grain and in the grain boundary. The model they proposed is schematically indicated in Fig. 16. Assuming oxygen vacancies to be the predominant migrating defect, the solid line in Fig. 16 represents the oxygen vacancy gradient within the scale at a scale thickness, Δx . Local equilibrium is assumed at the metal/oxide and the oxide/gas interfaces. When the oxide has grown to a thickness, $\Delta x'$, the new oxygen vacancy gradient is represented by the dotted line. This implies a supersaturation of oxygen vacancies in the growing scale, which condenses out as voids in establishing the new equilibrium oxygen vacancy gradient.

Elegant though this mechanism is, it suffers from a flaw; if the oxygen vacancy concentration at the oxide/metal interface exceeds the equilibrium value, the interface cannot move, since this would imply an oxygen concentration below that required for oxide/metal equilibrium. To maintain

the oxygen concentration (and, therefore, the oxygen vacancy concentration) at the oxide/metal interface at the equilibrium value, the arriving oxygen flux must overcome any oxygen vacancy supersaturation within the oxide.

The following mechanism is tentatively proposed to account for grain boundary voids in $\alpha\text{-Al}_2\text{O}_3$ scales of the present study. As yttrium dissolves into the $\alpha\text{-Al}_2\text{O}_3$ scale as the scale grows inward, the oxygen vacancy concentration in the vicinity of oxide grain boundaries increases by virtue of reaction [8]. If Schottky defects are assumed in $\alpha\text{-Al}_2\text{O}_3$, the increase in oxygen vacancy concentration must be accompanied by a decrease in the aluminum vacancy concentration in the vicinity of grain boundaries by virtue of the Schottky defect equilibrium

$$K_s = [V_{O}^{\bullet}]^3 [V_{Al}']^2 \quad [27]$$

where K_s is the Schottky defect equilibrium constant. Thus, in attaining the lower aluminum vacancy concentration required by the increase in the oxygen vacancy concentration, the excess aluminum vacancies must condense out in the grain boundary region; this process generates grain boundary microvoids.

Adherence of $\alpha\text{-Al}_2\text{O}_3$ scales.—Of the effects produced by oxide dispersions on the properties of oxide scales on high temperature alloys, the most significant from a technological point of view is the adherence of the oxide scale. In the sense in which the term "adherence" is used in most of oxidation literature, it refers to the resistance of the scale to spallation under the influence of stresses. In isothermal oxidation, one is mainly concerned with growth stresses. In alloy components used in various high temperature processes, additional stresses arise which are thermally in-

Fig. 16. Schematic oxygen vacancy concentration profile in growing $\alpha\text{-Al}_2\text{O}_3$.

duced (due to temperature oscillations) and/or mechanically induced.

It was pointed out earlier that several mechanisms have been proposed in the literature as contributing to rare earth oxide dispersoid-induced oxide-scale adherence. The most widely accepted mechanism is that the oxide scale develops protrusions (pegs), which form around dispersoid particles in the alloy; these protrusions anchor the scale to the alloy. Giggins and Pettit have suggested the existence of pegs in Co-Cr-Al-Y and Ni-Cr-Al-Y systems (38). Pegs have been observed especially in Hf containing alloys forming alumina, in which internally oxidized HfO_2 particles were present in the alloy subsurface region. Whittle *et al.* (39) have presented evidence for peg formation in Co-Cr-Al-Hf alloys in which the Hf was oxidized to HfO_2 particles. A more dramatic case of pegging has been recently observed by Hindam and Whittle (40) in Fe-10Al-Hf alloys in which subsurface HfO_2 particles were present. They have suggested a mechanism for peg formation according to which HfO_2 particles in the Al_2O_3 scale act as short-circuit paths for oxygen transport. In regions of the scale where HfO_2 particles are present, especially close to the alloy/scale interface, more rapid Al_2O_3 growth occurs, leading to protrusions which envelop HfO_2 .

A detailed examination of the oxide/metal interface was made in the present study to look for any evidence of pegs around dispersoid particles. A TEM micrograph in the vicinity of the oxide/metal interface is shown in Fig. 17. The dispersoid particles are clearly seen in the metal in the vicinity of the oxide/metal interface; there are no pegs around the particles. The absence of pegging is also clearly revealed by the ion maps for Al^+ and Y^+ generated by secondary ion mass spectrometry (Fig. 9). Thus, pegging must be ruled out as a mechanism for adherence in the case of yttria-dispersed alumina forming alloys.

The second mechanism proposed in the literature is that a mixed-oxide phase forms by reaction of the main oxide scale with the rare earth oxide, and this phase is present as a thin layer between the main scale and the alloy. The mixed-oxide phase is supposed to have a thermal expansion coefficient which is intermediate between that for the main scale and the alloy so that a "graded-seal" effect is produced. There is no sound evidence of such a mixed-oxide layer in any reported investigation. In a study of the oxidation of a Cr-5 v/o Y_2O_3 alloy, Seybolt (12) provides tentative evidence for a thin YCrO_3 intervening layer. However, the existence of such a layer has never been confirmed. No mixed-oxide layer could be detected between the $\alpha\text{-Al}_2\text{O}_3$ scale and the alloy in the present investigation.

The third mechanism is based on the argument that vacancies generated in the alloy when an element such as Al is preferentially oxidized can condense at metal/dispersoid interfaces. These vacancies, therefore, are not available to coalesce on the metal/scale interface, a process which can

lead to loss of scale adherence. In their work on the mechanism of oxide-scale adherence on Fe-25Cr-4Al-(Y or Sc) alloys, Tien and Pettit (41) suggested that internally oxidized Sc_2O_3 and Y_2O_3 particles act as sinks for vacancies generated during oxidation. In a comparative study of the oxidation of Ni_3Al and $\text{Ni}_3\text{Al-0.5Y}$ alloys, Kuenzly and Douglass (42) observed condensation of vacancies at the alumina/alloy interface in the case of the yttrium-free alloy. The vacancies were thought to form as the result of a "Kirkendall effect" in the alloy subsurface region upon preferential removal of Al by oxidation. Voids were absent in the yttrium containing alloy and are thought to have condensed around internally oxidized Y_2O_3 particles. However, no microstructural evidence for void condensation around Y_2O_3 particles was presented. Also, the present authors are not aware of published literature data which confirm the presence of voids around dispersoids. Examination of dispersoid particles by TEM in the present study did not show any evidence of void condensation.

In the opinion of the present authors, the improved adherence of $\alpha\text{-Al}_2\text{O}_3$ scales on Y_2O_3 -dispersed alloys is caused by the chemical doping of yttrium into the oxide scale and consequent effects on the relief of growth stresses. It is well documented that during the oxidation process of a metal growth stresses arise. The subject has been reviewed by Stringer (43). It is considered that yttrium doping leads to growth stress relief in two ways: (i) by effecting the formation of a fine-grained oxide scale, and (ii) by retarding Al transport in the scale.

It has been shown that in polycrystalline alumina having grain sizes less than $\sim 15 \mu\text{m}$, diffusional creep is the most important mechanism for plastic deformation (44). The generalized expression for the creep strain rate, $\dot{\epsilon}$, is given by (45, 46)

$$\dot{\epsilon} = \frac{14\Omega}{kTd^2} \left[\frac{(D_{\text{Al}}^{\text{l}} + \pi\delta D_{\text{Al}}^{\text{gb/d}})(D_0^{\text{l}} + \pi\delta D_0^{\text{gb/d}})}{3(D_{\text{Al}}^{\text{l}} + \pi\delta D_{\text{Al}}^{\text{gb/d}}) + 2(D_0^{\text{l}} + \pi\delta D_0^{\text{gb/d}})} \right] \sigma \quad [28]$$

where Ω is the volume of an alumina molecule, the superscripts on D represent the diffusion path (lattice or grain boundary), the subscripts indicate the diffusing species, and σ is the stress under which deformation occurs. It is seen from Eq. [28] that $\dot{\epsilon}$ is extremely sensitive to the grain size. Thus, in the ultrafine-grained $\alpha\text{-Al}_2\text{O}_3$ scale obtained in the present study, plastic deformation can occur with greater ease. The grain size of $\alpha\text{-Al}_2\text{O}_3$ scales grown on dispersoid-free Fe-25Cr-4Al alloys for 1000h at 1200°C is approximately a factor of four larger (47). Thus long-term stability of the oxide scale can be improved by having a fine grain size. Yttrium doping can lead to the retardation of grain growth kinetics in two ways: by forming grain boundary microvoids which, analogous to particles on a grain boundary, can pin the boundary, and by segregating to the grain boundary and decreasing grain-boundary velocity (48).

That relief of growth stresses by plastic flow even when thermally induced stresses are present can improve scale adherence has been shown in an oxidation study of copper carried out some years ago by Sartell *et al.* (49). They showed that when copper is oxidized at a temperature just below 700°C and cooled to room temperature, the oxide scale readily flakes off. However, when the oxidation is carried out at 870°C , the oxide scale remains quite adherent upon cooling to room temperature. The authors argued that in the latter case, growth stresses are relieved by plastic flow at 870°C so that even at a higher level of thermal stresses, the oxide scale formed at the higher temperature is more adherent. Tylecote has shown (50) that above 700°C , copper oxide, Cu_2O , undergoes a transition from elastic to plastic behavior.

The second effect of yttrium doping is to suppress Al transport through $\alpha\text{-Al}_2\text{O}_3$ scales. In their work on Fe-Cr-Al and Fe-Cr-Al-Y alloys, Golightly *et al.* (23, 24) suggested that Y in some unknown fashion decreased the transport of Al in Al_2O_3 . In the yttrium-free alloy, according to these authors, oxygen diffusing inward through $\alpha\text{-Al}_2\text{O}_3$ grain boundaries reacts with Al diffusing outward through $\alpha\text{-Al}_2\text{O}_3$ grains, forming new Al_2O_3 within an existing scale and generating compressive growth stresses. In an effort to relieve these compressive stresses, the oxide tends to grow

Fig. 17. TEM micrograph in the vicinity of oxide/metal interface revealing absence of micropegging.

laterally, resulting in a convoluted morphology, and becomes detached from the alloy at the convolutions. Such detachment leads to loss of oxide scale adhesion.

Our preliminary work on Fe-25Cr-5Al alloys also shows a convoluted oxide-scale morphology (47). Such convolutions are absent in the oxide scale on MA956. Thus, in agreement with Golightly *et al.* (23, 24), the present authors also feel that yttrium doping in α -Al₂O₃ suppresses Al transport and avoids the build up of compressive stresses otherwise generated by Al₂O₃ formation within existing scale.

If it is assumed that Schottky disorder prevails in α -Al₂O₃, then a mechanism can be proposed for the suppression of Al transport as a result of yttrium doping. As explained previously, in fine-grained α -Al₂O₃ grain-boundary oxygen transport predominates, so that one is dealing with a rather low flux of aluminum. In accordance with our proposed defect reaction [8] for yttrium doping, the concentration [V_O^{••}] is increased by yttrium, especially in the vicinity of Al₂O₃ grain boundaries. In accordance with Eq. [27], the concentration of Al vacancies, [V_{Al}[']] is correspondingly reduced. Since oxygen transport occurs through grain boundary, any reaction between Al and O to form Al₂O₃ within an existing oxide scale must occur in the grain boundary region. Such Al₂O₃ formation is prevented by decreasing [V_{Al}[']] in the grain boundary region, which correspondingly decreases the flux of Al to this region.

Concluding Remarks

In the present study, the influence of yttrium oxide dispersoids in Fe-base alloys on the microstructure and adherence of α -Al₂O₃ scales formed on such alloys has been emphasized. The oxide scale grows by inward oxygen grain boundary transport; the yttrium oxide dispersoid particles dissolve upon incorporation into the scale, and yttrium segregates to the α -Al₂O₃ grain boundary; in consequence, it is suggested that grain growth and Al transport in α -Al₂O₃ are suppressed. These effects in turn can relieve and/or decrease growth stresses in α -Al₂O₃ and improve oxide-scale adherence.

In view of the immense technological importance of α -Al₂O₃ scales, it is suggested that more work should be carried out both on the defect structure and doping characteristics of Al₂O₃. Some papers in the literature suggest that whatever the chemistry of the dispersoid used, there is an improvement in the adherence of the α -Al₂O₃ scale formed on the alloy. While this may indeed be so, the doping effects of elements from different groups of the periodic table are clearly different. Thus, there is a need to understand more clearly the role of dispersoid chemistry in the alloy on oxide-scale properties.

Acknowledgment

The authors gratefully acknowledge the efforts of J. Mumford throughout this experimental study. They wish to thank D. P. Leta for performing the SIMS work and Lydia Massey for her skillful assistance in preparing the manuscript.

Capacitance-Voltage Technique for the Determination of Carrier Concentrations in Thin Film Photoanodes

C. S. Blair* and D. W. Hess**

Materials and Molecular Research Division, Lawrence Berkeley Laboratory, and Department of Chemical Engineering, University of California, Berkeley, California 94720

Carrier concentrations in thin film iron oxide and titanium oxide photoanodes are determined using a metal/insulator/semiconductor structure. Capacitance-voltage measurements of this structure are distinct from the usual liquid junction impedance measurements, because results of the present study are not dependent upon electrolyte/semiconductor interface properties. Further, determination of the conductivity of the photoanode films permits the calculation of carrier mobilities.

The electrical properties of materials used as liquid junction solar cells ultimately determine their energy conversion efficiency. Two of the most important electrical properties are the flatband potential and the carrier concentration. The carrier concentration is particularly significant since it determines the space charge region thickness and the depth available for light absorption in the semiconductor surface. These properties are usually determined from impedance measurements of the photoelectrochemical cell by plotting $1/C^2$ vs. voltage, thereby generating a Mott-Schottky plot (1).

Experimental difficulties in performing capacitance measurements of solid/liquid interfaces have been previously discussed (2-6). Most of these difficulties involve complex interactions between the semiconductor and the electrolyte. For instance, specific ion adsorption on the semiconductor surface and variation of the Helmholtz layer capacitance with voltage have been suggested as causes of nonlinear Mott-Schottky plots and non-Nernstian electrode behavior (2). The presence of surface states and electrode surface treatments also have been a strong influence on Mott-Schottky plot linearity (3, 4). Further, the difficulty of interpreting nonlinear Mott-Schottky plots has been addressed (2, 5, 6). In this paper, a technique capable of measuring semiconductor electrode carrier concentration without the use of an electrolyte is described.

Capacitance-Voltage Technique

Impedance measurements in photoelectrochemical cells are used to ascertain the thickness of the semiconductor space charge or depletion region. In n-type semiconductors, this region is initially formed by the net flow of electrons from the semiconductor into the electrolyte. However, a depletion region can also be formed merely by applying an electric field across a semiconductor. If a dielectric layer is present on the semiconductor surface, high electric fields can be applied without initiating current flow. This latter structure is called a metal/insulator/semiconductor (MIS) capacitor, and is the basis of many solid-state devices.

Capacitance-voltage measurements of the MIS structure represent a well-established diagnostic technique utilized in the fabrication of integrated circuits. The usual goal of MIS measurements is the determination of dielectric properties such as dielectric constant and electronic charge levels in the insulating film. In these investigations, the electrical properties of the semiconductor (usually silicon) are well known. However, as will be indicated below, electrical properties of the semiconductor can also be obtained. A number of reviews discuss the high frequency capacitance-voltage technique in detail (7, 8), so only a brief description will be given here.

The total capacitance of the MIS structure is given by the series capacitance of the insulator and the semiconductor

$$1/C = 1/C_I + 1/C_{sc} \quad [1]$$

Here, C is the total capacitance, C_I the insulator capacitance, and C_{sc} the semiconductor space charge capacitance, all per unit area.

If a positive potential is applied to a dielectric layer above an n-type semiconductor, majority carriers (electrons) accumulate at or near the semiconductor/insulator interface, giving essentially zero depletion width. In this case, $1/C_{sc}$ is negligible compared to $1/C_I$, and the total capacitance is the insulator capacitance. As the voltage becomes negative, electrons are driven away from the dielectric/semiconductor interface, and a depletion region is formed. This depletion or space charge region presents an additional capacitance in series with the dielectric capacitance (Fig. 1). As the negative potential is increased, more electrons are repelled from the semiconductor surface, and the depletion region widens, thereby increasing the space charge capacitance, and reducing the overall capacitance due to the series combination given in Eq. [1]. When sufficiently negative voltages are applied so that minority carriers (holes for an n-type semiconductor) are attracted to the surface, the space charge region has reached its maximum value, and the capacitance remains nearly constant with further increases in potential. Of course, the maximum width of the depletion region is dependent upon the doping level and the dielectric constant of the semiconductor.

The maximum and minimum capacitance values can be used to calculate the charge concentration, N , in the semiconductor (8, 9).

Key words: capacitance-voltage, photoanodes, carrier concentration, plasma-enhanced deposition.

$$N = \frac{2C_1^2 \psi_s(\text{inv})}{e\epsilon_s\epsilon_0 \left(\frac{C_{\text{max}}}{C_{\text{min}}} - 1 \right)^2} \quad [2]$$

where

$$\psi_s(\text{inv}) = (\sqrt{\alpha^2 + V'} - \alpha)^2$$

$$\alpha = \frac{1}{C_1} \left(\frac{eN\epsilon_s\epsilon_0}{2} \right)^{1/2}$$

$$V' = V - V_{\text{FB}}$$

In these equations, ϵ_s is the dielectric constant of the semiconductor, e is the electronic charge, ϵ_0 the permittivity of free space, and $\psi_s(\text{inv})$ is the semiconductor surface potential at inversion. The surface potential was estimated by the method of Goetzberger and Nicollian (9). V_{FB} , the flatband potential, was estimated by Heiman's method (10).

The slope of the central portion (depletion region) of the curve is also related to the carrier density by the expression (7)

$$\frac{dC}{dV} = C^3 \frac{1}{\epsilon_0\epsilon_s eN} \quad [3]$$

which upon integration becomes

$$\frac{1}{C^2} = \frac{2}{\epsilon_0\epsilon_s eN} (V - V_0) + \frac{1}{C_1^2} \quad [4]$$

It is important to note that Eq. [3] was obtained in a depletion approximation. However, as long as the space charge layer thickness is greater than twice the extrinsic Debye length, λ , where

$$\lambda = \left(\frac{2kT\epsilon_s\epsilon_0}{e^2N} \right)^{1/2} \quad [5]$$

Equations [3] and [4] represent good approximations (11). In the present case, 2λ is $\sim 20\%$ of the depletion layer thickness at inversion. In Eq. [4], V_0 is a constant which accounts for interface and/or insulator charges. Naturally, this expression is similar to the usual Mott-Schottky relation, but V_0 is not related to the electrolyte dependent flatband potential.

Experimental

All photoelectrodes analyzed in this study were deposited thin films. Iron oxide films were deposited onto iron substrates (Puratronic Foil, Alfa Products) by the RF glow discharge reaction of iron pentacarbonyl and oxygen (12). Substrate temperatures ranged from 350°-500°C, and plasma power densities were 0.079-0.4 W/cm². Under these conditions, α -Fe₂O₃ was the only phase detected by x-ray diffraction in the polycrystalline films. Further, in

all cases, film densities were approximately 90% of the theoretical density. Titanium dioxide films were deposited on titanium substrates by a similar glow discharge process using titanium tetrachloride and oxygen as gas phase reactants (13).

MIS structures were produced by electron beam evaporation (the Temescal electron gun was operated at 7 kV and 400 mA) of a layer (500-3000Å) of quartz on top of the metal oxide films. Electrical contact was made by evaporating aluminum dots (0.46 mm²) onto the quartz film through a shadow mask.

Capacitance was measured with a Boonton Capacitance meter (Model 71A) operating at 1 MHz. A voltage ramp was used to apply dc bias across the film (-10 to +10V) at a scan speed of 0.04 V/s. Small signal capacitance vs. applied voltage at 1 MHz was recorded on a Hewlett-Packard 7045A X-Y recorder. A Keithley Model 179 digital multimeter measured current for resistivity determination. A General Radio Model 1650-A impedance bridge was used for capacitance measurements for Mott-Schottky plots at 1 kHz, and resistance measurements at 1 kHz. Semiconductor resistance and dielectric constant measurements were carried out by evaporating aluminum contacts directly onto the semiconductor films.

Results and Discussion

The results of C-V and other electrical measurements for selected Fe₂O₃ and TiO₂ samples are summarized in Table I. The dielectric constant of the iron oxide films varied from 60 to 113, with high values corresponding to higher RF power levels and substrate temperatures. These values are in reasonable agreement with those reported in the literature for bulk iron oxide [80-120 for the α -crystal form (2, 14), and approximately 10 for the γ -form (15)]. The dielectric constant measured for the titanium dioxide film is consistent with that found for single-crystal rutile (*i.e.*, 180) along the C-axis (16). Iron oxide film resistivity varies over two orders of magnitude, depending upon deposition conditions. Similarly, the resistivity of bulk iron oxide varies from 10 to 10¹⁰ Ω -cm depending on processing conditions (2, 17).

Relative capacitance (C/C_1) data from two Fe₂O₃ films of thickness 1.7 μm (sample 1) and 1.9 μm (sample 2) are shown in Fig. 2. Note that positive bias voltage in this plot refers to that voltage applied to the dielectric of the MIS structure. It is clear that sample 1 shows a nearly theoretical shape (7, 8). Using Eq. [2], the carrier concentration for sample 1 is $5.3 \times 10^{15} \text{ cm}^{-3}$. On the other hand, sample 2 shows somewhat unusual behavior, in that a very large potential (10V) is required to bias the sample into inversion. Such behavior is probably due to the rather thick insulator deposited on this film, and the high dielectric constant iron oxide film. The carrier concentration for the second sample is $1.3 \times 10^{16} \text{ cm}^{-3}$.

According to Eq. [4], a plot of $1/C^2$ vs. bias voltage should yield a straight line. Note, however, in this case voltage is referenced to that applied to the film substrate, rather than to the aluminum contact atop the dielectric. Indeed, in agreement with Eq. [4], both samples 1 and 2 yield a straight line on such a plot (Fig. 3), with carrier

Fig. 2. Variation of relative capacitance with dc voltage for the Al/SiO₂/Fe₂O₃ MIS structure. The SiO₂ thicknesses are 0.064 μm for sample 1 (1.7 μm Fe₂O₃) and 0.125 μm for sample 2 (1.9 μm Fe₂O₃). See Table I for additional information on these samples.

Fig. 3. Analysis of capacitance-voltage data according to Eq. [4], for the samples of Fig. 2. The slopes of the lines are related to the carrier concentrations. Resulting values of the carrier concentration are given in Table I.

concentrations of 6.5×10^{15} and $1.7 \times 10^{16} \text{ cm}^{-3}$, respectively. These values are in reasonable agreement with results given above from application of Eq. [2].

For comparison purposes, a number of the iron oxide samples described in Table I were studied using the Mott-Schottky technique. In nearly all cases, the resulting plots were nonlinear, and the results were difficult to reproduce. For the sample deposited at 500°C and 50W, a linear Mott-Schottky plot was obtained, but the carrier concentration from this plot was $7 \times 10^{18} \text{ cm}^{-3}$, an unexpectedly high value.

The reasons for this discrepancy are not clear. The Mott-Schottky plot measurements were all made using the impedance bridge at 1 kHz, while the C-V plots were performed at 1 MHz. However, variations in the dielectric constant of the various Fe₂O₃ films investigated were insignificant for these two frequencies. Further, the discrepancy does not appear to be due to Helmholtz layer capacitance; such a series capacitance would result in a decrease in the total capacitance. On the other hand, surface states are known to act as an impedance in parallel to the depletion layer capacitance (3, 18). This may lead to the higher capacitance values observed here. Indeed, semiconductor-solution interactions are known to lead to the formation of surface states for Fe₂O₃, TiO₂, and other materials (19-21).

As observed in Table I, carrier concentrations for the plasma-deposited iron oxide films vary over two orders of magnitude, yet no consistent trends relating the effects of film deposition conditions to carrier concentrations are evident. Other workers have also noted the

difficulties of controlling the conductivity of undoped bulk polycrystalline α-iron oxide materials (2).

Electron mobilities of the plasma-deposited films were calculated from the equation

$$\mu = 1/N\rho p \quad [6]$$

where μ is the electron mobility, and ρ is the resistivity of the film. These values are also given in Table I. The present results are within reported values (10^{-1} to $10^{-5} \text{ cm}^2/\text{V}\cdot\text{s}$) for bulk iron oxide (22). Titanium dioxide film mobilities are somewhat low compared to the literature value of $0.1 \text{ cm}^2/\text{V}\cdot\text{s}$ for bulk polycrystalline material (23). However, the literature values are from samples reduced at 1450°C for 2h, thereby resulting in higher electrical conductivities than the samples in this study.

Conclusions

The metal/insulator/semiconductor capacitance-voltage technique appears to be a useful technique for obtaining semiconductor carrier concentrations for thin film photoanodes. This technique allows the measurement of semiconductor properties independent of electrolyte. The properties of thin film SiO₂ insulators are well-known, and interactions between the semiconductor and the insulator are less complex and better understood than those of a liquid junction. The C-V method also displays self-consistency. For example, at positive bias, the capacitance appropriate to the insulator film thickness is obtained. Moreover, the capacitance-voltage data can be analyzed according to Eq. [2] and [4] in order to calculate two independent values of carrier concentration, which serve as an internal check on the experimental technique.

Optimized Collection of AC Impedance Data

M. W. Kendig,* A. T. Allen,* and F. Mansfeld*

Rockwell International Science Center, Thousand Oaks, California 91360

INTRODUCTION

The low corrosion rate of well inhibited systems and high capacitance values make it necessary to extend the collection of electrochemical impedance data to very low frequencies. In addition, several orders of magnitude of the impedance have to be measured accurately between the value for the solution resistance at high frequencies, and the polarization resistance at low frequencies. An additional problem arises from the changes of the corrosion kinetics with time, which occur for the majority of corrosion systems. These factors place severe limitations on the validity of data (and their analysis) obtained in the traditional manner with a transfer function analyzer where the impedance for each frequency is measured individually over several cycles. We have developed a new approach in which the current measuring resistor of an autoranging PAR model 276 interface is adjusted continuously to match the impedance to be measured. The use of a filter allows accurate measurements with only one cycle per frequency at frequencies below 1 Hz. Experimental data have been obtained for iron in tapwater with various inhibitors and in deionized water with low frequency limits between 0.4 and 10 mHz.

EXPERIMENTAL APPROACH

A Solartron 1174 transfer function analyzer (TFA) and a PAR 173 potentiostat containing a model 276 current amplifier interface communicate via an IEEE-488 bus with a HP9825 desktop computer (1). The communication between the 276 interface and the computer allows optimization of the gain of the current amplifier during the collection of the impedance spectrum. For frequencies below 1 kHz, the computer selects the current measuring resistor R_m of the 276 interface so that R_m relates to the impedance modulus $|Z|$ by

$$\log R_m = \text{int} (\log(3|Z|)) \quad [1]$$

*Electrochemical Society Active Member.

The integer function, int , determines the largest integer less than or equal to the argument. This procedure limits the output signal of the interface so as to avoid phase shift errors, but maintains a high enough signal level for accurate measurement of the current. Since no switching occurs during the actual data collection by the TFA, switching transients pose no problems for the measurement. Above 1 kHz, a preselected R_m is used in order to minimize the phase shift of the current amplifier. At each frequency down to 1 Hz, ten cycles are sampled. Below 1 Hz, in addition to optimizing the gain of the interface, the computer signals the interface to introduce a 1 μF capacitor in parallel with R_m thereby giving the interface a low-pass filtering capability. In addition, the computer signals the TFA to reduce the data sampling rate to one cycle of current and voltage signals at each frequency below 1 Hz. Thus, below 1 Hz the speed of the measurement is increased by a factor of ten over the previous method of integration over ten cycles while good signal-to-noise resolution is maintained due to filtering.

EXPERIMENTAL RESULTS

The following experimental results serve as illustration of the type of impedance spectra which have been obtained with the approach discussed above. The electrode was a rotating 4340 steel cylinder (RCE) at 144 rad/s.

Figure 1 shows the results for exposure to 0.5 N NaCl open to air. A simple spectrum is obtained, which is characterized by one time constant in a frequency range between 10^5 Hz and $5 \cdot 10^{-3}$ Hz. Excellent agreement is observed between the experimental results and a fit to a theoretical model of the impedance as:

$$Z = R_\Omega + \frac{R_p}{1 + (j\omega CR_p)^\alpha} \quad [2]$$

where R_Ω is the electrolyte resistance, C the capacitance calculated from the frequency ω_m of

the maximum of the imaginary component Z'' ($C = (\omega_m R_p)^{-1}$), R_p is the polarization resistance and α is the (negative) slope of the capacitive part of the Bode-plot. The parameters used for the curve fitting in Fig. 1 have been obtained with the CIRFIT - computer program (2). The data in Fig. 1 cast some doubt on the results and the model proposed by Bonnel et al. (3) and Duprat et al. (4), who reported the occurrence of a second time constant at low frequencies (<0.1 Hz) for a carbon steel rotating disk electrode in 3% NaCl.

Figure 2 shows Bode-plots in tapwater containing NaNO_2 as inhibitor. Measurements were extended to $0.4 \cdot 10^{-3}$ Hz. Using the integration method (5) R_p was calculated to be $4.15 \cdot 10^6$ ohm ($2.85 \cdot 10^6$ ohm \cdot cm 2) for $t = 2.9$ h. Curve fitting according to Eq. 1 gave good agreement for this R_p -value and $R_Q = 39$ ohm, $C = 29.4$ μF and $\alpha = 0.88$ in the capacitive range. Deviations occur below 10 mHz. The measurement with a lower limit of $5 \cdot 10^{-3}$ Hz was performed in 76 min.

Data obtained in deionized water are shown in Fig. 3 for two exposure times. Despite the low conductivity of this test medium accurate data can be obtained for frequencies below 200 Hz. The fit between the experimental data for an exposure of 2.5 h and the model of Eq. 1 is very good. The solution conductivity increased continuously during the first day of testing due to build-up of corrosion products.

Method for Increasing the Conductivity of Silver-Doped Polyimides

A. Auerbach

General Electric Company, Corporate Research and Development, Schenectady, New York 12301

Recently there have been a number of communications describing the doping of polyamic acids with electropositive metal salts.^{1,2}

The metal cation is reduced to the metal during a cure cycle to obtain metal doped polyimide films. The authors found substantial increases in conductivity as compared to undoped polyimide films. In some cases palladium mirrors formed on the polymer surface. Although most of their work involved palladium salts, they pointed out that other metal salts could be used.

We report an improved processing method which has allowed us to form both silver mirrors and/or thin film silver conductors using silver nitrate dissolved in commercial polyamic acids. Using our technique we have achieved conductivities orders of magnitude above those previously reported, and comparable to vapor deposited silver films.

The method involves spin coating a substrate material (e.g. alumina, glass, polymer coated metal or glass, etc.) with one of the mixtures listed in Table 1. Spin rates between 2000 to 4000 rpm are used, depending on the viscosity of the mixture chosen. The samples are then dried in a cross flow oven to form a dry skin. After drying, the samples can be handled or stored for future use. The last step involves a high temperature bake. The specimens are baked for a period at 360°C under a blanket of carbon powder. The carbon blanket accelerates the reduction of the silver cation to metallic silver; while allowing the polyamic acid to imidize. Lower bake temperatures can be used, but then a longer bake period is required.

Figure 1 shows the silver mirror formed on two substrate materials -- glass and alumina -- using the above processing and mix 1 of Table 1. The mirror formed on the alumina substrate is conductive (100Ω/sq.). More highly conductive films are generated using either mix 8 or 9 in Table 1. A S.E.M. of one such surface is shown in Figure 2.

At 30,000 magnification the small silver ellipsoids are readily apparent and measure from 1000Å to 3000Å across. X-ray analysis of one ellipsoid shows a prominent silver peak. A S.I.M.S. analysis relative to an evaporated silver standard further verified the presence of elemental silver since the two spectra virtually overlapped.

During our investigation of the above reduction reaction to determine the optimum N-methyl pyrrolidone (NMP)/AgNO₃/polyamic acid ratio to use, we observed the following trends. When too much of the solvent NMP is added (i.e. NMP rich ratio), then the evaporation of the NMP during the bake step prevents oxygen from reaching the polymer surface and little reduction occurs during the imidization. When, on the other hand, too much AgNO₃ is added then the reduction interferes with the imidization of the polyamic acid and the film quality is degraded. Also the silver nitrate can be added in one of two ways; either directly to the polyamic acid or via NMP. If added directly, then the weight ratio of AgNO₃ to polyamic acid should be less than or equal to one, so no reaction product forms and thus eliminating the need to filter the solution. If added via NMP, then the excess solvent must be removed prior to the bake or it interferes with both the silver reduction and the imidization. The best results have been achieved using the mixtures and cure schedules listed in Table 1.

In closing, we point out that the present technique is general, and could be used with any electropositive metal salt and polyamic acid. It is a useful method for making metal laced polyimide films. The films are durable and can be patterned and etched, thereby making this a useful alternative to vacuum deposited thin films.

Electroless Deposition of CdTe Thin Films

R. N. Bhattacharya and K. Rajeshwar*

Department of Chemistry, The University of Texas at Arlington, Arlington, Texas 76019-0065

R. N. Noufi*

Solar Energy Research Institute, Golden, Colorado 80401

INTRODUCTION

Of the emerging materials for solar cell applications, CdTe is one candidate which has received much attention in recent years (1). Two features in the optical characteristics of this material are particularly attractive for photovoltaic conversion of sunlight: (a) its energy bandgap of 1.5 eV, which provides an optimal match with the solar spectrum and thus facilitates its efficient utilization; and (b) the direct mode of the main optical transition, which results in a large absorption coefficient and in turn permits the use of thin layers (1-2 μm) of active material.

Electrodeposition methods have been successfully employed for the fabrication of cadmium chalcogenide thin films in general (2) and CdTe in particular (3). In principle, both anodic as well as cathodic deposition is possible, although more precise control of film stoichiometry is obtained with the latter approach. Difficulties have been reported in the introduction of p-type dopants in electrodeposited CdTe layers (3b); however, efficient CdS/CdTe heterojunction devices have been fabricated from either n-CdTe layers (3d) or p-type films obtained by suitable treatment of the electrodeposited n-type material (3e).

In this paper, we describe a new electroless method for the fabrication of CdTe thin films for photovoltaic applications. This method, unlike its closely-related electrochemical counterpart, has the advantage of simplicity in that it does not require instrumentation for potentiostatic or galvanostatic control and is therefore particularly promising for routine fabrication of a large number of thin

films. The electroless method is based on short-circuiting the thin film substrate to an easily oxidizable redox component (e.g. Al, Cd) in the electrolytic bath. This component can be even recycled if necessary in a practical system.

EXPERIMENTAL

Substrates for film growth were either Ti or Nesatron^R glass (PPG Industries, Pittsburgh, Pennsylvania). They were degreased and cleaned prior to use. In the case of Ti, the substrate treatment sequence additionally included an abrading step, a subsequent etch in 10% HF and a final annealing procedure in Ar stream (containing $\approx 0.5\%$ O₂) at 650°C for 5 min. All chemicals were of Analar^R or Pura-tronic^R grade purity. Deionized water was used in all cases.

The electrolytic bath nominally contained 1.0×10^{-2} M CdOAc and 1.0×10^{-2} M TeO₂. The latter was brought into solution in NaOH; the pH being subsequently adjusted to ≈ 2 by addition of 10% H₂SO₄. In a typical electroless deposition run, the bath was first thermostatted at the required temperature. The substrates were then suspended in solution with a Cu alligator clip suitably clamped such that intimate contact of the latter with the solution was facilitated. Film formation was facile and visible to the naked eye. The aluminum contained in the clip screw sets up the short-circuited local cell via the dissolution reaction: $\text{Al} \rightleftharpoons \text{Al}_{(\text{aq})}^{3+} + 3 \text{e}^-$ ($E^0 = 1.66 \text{ V}$). This was confirmed by connecting an Al wire instead to the substrate; film formation was immediately evident. Another variant of this method would be to substitute the CdOAc in the bath with a Cd foil short-circuited to the substrate. This foil

*Electrochemical Society Active Member.

would then act both as a source of Cd species as well as of electrons for the cathodic deposition reaction. (Note that the free-energy gain from the formation of CdTe shifts the Cd deposition potential less negative from the standard value of -0.40 V; cf. Ref. 4).

Deposition was invariably carried out at temperatures above ambient (40 - 60°C). Films thus obtained had better physical characteristics (grain size and morphology) than those deposited at room temperature as shown by scanning electron microscopy (SEM).

X-ray diffraction analyses were obtained on a Rigaku Rotaflex Model RU 200 instrument using $\text{CuK}\alpha$ radiation. EDAX/SEM measurements were done on a Philips Model P 505 unit. Photoelectrochemical (PEC) characterization of majority carrier type in the semi-conducting films was carried out in a conventional three-electrode electrochemical cell using a Princeton Applied Research (PAR) Model 173 potentiostat/galvanostat in conjunction with a Model 175 Universal Programmer and a Model 179 digital coulometer. An alkaline solution of polysulfide (prepared from Na_2S , S and NaOH) was used as the electrolyte in these experiments. To protect the CdTe film from corrosion, a thin (≈ 0.1 μm) layer of α - PbO_2 was deposited on the CdTe surface by electroless deposition from a bath containing 1.0×10^{-2} M PbOAc , 1.2 M NH_4OAc and 6×10^{-2} M $\text{K}_2\text{S}_2\text{O}_8$ (5). The light source for the PEC measurements was an ELH tungsten-halogen lamp whose output intensity was measured on a radiometer/photometer (EG&G Model 450-1). No corrections were made for the attenuation of light by reflection and solution absorption in the PEC cell. Optical measurements on the CdTe thin films were performed on a Cary Model 219 spectrophotometer. Film thicknesses were measured on a Sloan Dektak instrument (Sloan Technology Corp., Santa Barbara, California).

RESULTS AND DISCUSSION

Films of varying thickness in the range 0.15 - 2 μm were routinely grown on both Ti and Nesatron^R substrates. Data from optical measurements on films in the latter case were processed via

the relationship: $\alpha = (d_2 - d_1)^{-1} \ln T_1 T_2$ where d_1 and d_2 are two different film thicknesses and T_1 and T_2 are the corresponding transmittances (6). A typical plot of α^2 vs. energy using these data, is shown in Figure 1. The energy band-gap, obtained from extrapolation of the linear portion of the plot, is 1.4 eV. The difference between this value and that reported for single-crystal CdTe (1.5 eV, cf. Refs. 1, 7) is easily accommodated within the propagated error limits associated with the measurement of d and T .

Although not obvious from these optical data, some free Te was also often incorporated in the fabricated CdTe layers. This is illustrated by the EDAX spectrum (Figure 2a) for a typical CdTe film grown on Ti substrate. The Cd:Te ratio increases from $\approx 25:60$ for the as-deposited film to $\approx 55:45$ for films annealed at 590°C for 30 min (cf. Figure 2b). Further evidence for the compositional changes on annealing is provided by X-ray diffraction data (Table 1). The as-deposited films in this case contained CdTe in both hexagonal and cubic modifications and Te in the hexagonal form. The thermal treatment obviously resulted in the loss of free Te and in complete conversion of CdTe to the hexagonal form.

Figure 3 contains typical results from the PEC experiments. These data are for a CdTe film grown on Ti in the as-deposited condition. The dark current is largely due to the presence of conducting α - PbO_2 on the film surface (see above). On illumination, the film potential shifts in the positive direction at open circuit. The enhancement of cathodic current flow is consistent with the creation of minority carriers (electrons in this case) in the underlying CdTe layer (some contribution to the cathodic photocurrent also comes from the free Te present in this layer). The situation here is akin to the Si/ITO/electrolyte interface studied previously by us (8). That the Te layer is only partially responsible for the p-type conductivity behavior observed here was shown by additional experiments involving electroless CdTe films wherein lower amounts of TeO_2 were incorporated in the initial

deposition bath. Cathodic current flow enhancement on illumination was still observed although X-ray diffractograms showed no evidence for free Te.

After thermal treatment of the CdTe thin films and subsequent growth of a α -PbO₂ layer, the PEC data were consistent with n-type behavior (i.e. enhancement of anodic current flow on band-gap illumination). Apart from the loss of any free Te by the thermal treatment, the Cd:Te ratio in the CdTe phase is also increased by this treatment, finally leading to excess Cd in the film as shown by EDAX. Such changes in the defect chemistry and consequent effects on conductivity on thermal treatment are well-known for CdTe (7).

In summary, a simple electroless method has proved useful for the fabrication of CdTe thin films. The film composition (Cd:Te ratio) can be varied by suitable thermal treatment of these films. A PEC method for ascertaining majority carrier type in semiconductor thin films has been demonstrated. This method is especially suited to cases where more conventional Hall or hot-probe measurements would be precluded by the high conductivity of the substrate.

Further optimization of the electroless method, introduction of various dopants in the film and fabrication of heterojunction devices based on these films are in progress.

INTRODUCTION

Control of electric charge in the surface region of modern miniature Si devices is achieved by shallow ($0.5\mu\text{m}$) dopant implantation followed by a furnace or rapid thermal annealing (RTA) treatment.⁽¹⁾ However, for light impurities, such as B, complete amorphization of the surface layer by ion implantation does not occur even at high doses (10^{15} cm^{-2}) and an extended tail in the B distribution is usually observed due to channeling during implantation.^(2,3) Removal of partially amorphous implantation damage is difficult to achieve on subsequent annealing. Furthermore, high doses of smaller covalent radii dopants create a dislocation network in the implanted region in addition to several other kinds of extended defects. Therefore, recent shallow implants of light impurities are conducted into pre-amorphized Si substrates and then furnace⁽⁴⁾ or rapid thermally annealed⁽⁵⁾ to circumvent the problems addressed above. The pre-amorphization is usually achieved by multiple energy self-implantation of Si to very high doses (10^{-16} cm^{-2}). Since Ge has infinite solid solubility in Si, and it does not appear to alter the electrical properties of Si significantly, we have amorphized Si prior to dopant implant with Ge rather than a typical multi energy Si implant. A similar approach is being investigated by others.^(6,7) The presence of large covalent radius Ge on substitutional site in Si is expected to compensate the lattice strain that arises after subsequent high dose shallow implant/annealing of impurities like B or P. This should prevent the formation of a dislocation network which would otherwise be present without Ge. In this communication, RTA behavior of pre-amorphized surface layers in Si produced by Ge implantation with or without subsequent BF_2 implant is presented. A comparison between RTA results from Si and Ge induced amorphous surface layers is also discussed.

EXPERIMENTAL

Silicon wafers of (100) orientation were implanted with Ge^+ to a dose of 10^{16} cm^{-2} . The implantation was conducted at 300keV at either liquid nitrogen (LN) or room temperature (RT). Some of the wafers were subsequently implanted with 42 keV BF_2^+ at RT to a dose of $2 \times 10^{15}\text{ cm}^{-2}$. Both types of wafers then underwent RTA at 1100°C for 10 seconds in an intense incoherent light system. The structural characterization on all cross-section samples was performed by bright-field transmission electron microscopy (TEM) whereas both bright-field and weak-beam TEM were performed on plan view samples. The atomic profiles of B, F and Ge before and after the RTA were obtained by secondary ion mass spectrometry (SIMS).

RESULTS AND DISCUSSION

Figures 1a and b show typical XTEM micrographs from a Ge implanted (at LN or RT) sample before and after RTA at 1100°C for 10 seconds. From these micrographs and their corresponding diffraction patterns (not shown) it was found that the unannealed sample contained a 4000Å wide amorphous layer extending from the surface (Fig. 1a). Upon annealing at 1100°C for 10 seconds, defect-free regrowth occurred in the amorphous region (Fig. 1b). However, the amorphous/crystalline interfacial region in the annealed sample contained a discrete layer of small dislocation loops typical of the coalescence of straggling ion damage.⁽⁸⁾ The RBS/MeV He^+ channeling from the samples of Figure 1a and b indicated that 92% of Ge occupied substitutional lattice sites after the RTA.⁽⁹⁾ Comparison of the Ge profiles from the unannealed and annealed samples show that very little redistribution of Ge occurs on RTA.⁽⁹⁾

The XTEM micrograph from the subsequently shallow (42 keV) BF_2 implanted but unannealed sample showed that there was no change in the width of the original amorphous layer. The RTA of this sample showed that essentially

defect-free regrowth again occurred in the originally amorphous region (Fig. 1c). Hair-pin shaped dislocations (not shown) were occasionally observed in this region (type II defects in ref. 5). Small dislocation loops due to straggling ion damage were also present in the interfacial region. Although the bright field XTEM micrograph did not show any surface damage (type III in ref. 5), the

Figure 3. SIMS profiles of boron before and after RTA at 1100°C/10 sec.

weak-beam TEM micrograph (Fig. 2b) from a plan view sample corresponding to the surface region of Figure 1c revealed a high density of uniformly distributed fine defect clusters ($\approx 50\text{\AA}$). Such clusters were absent in a similar TEM micrograph (Fig. 2a) from the sample without the BF_2 . A similar phenomenon has been observed on RTA of self-implanted samples with a shallow BF_2 layer. (5)

The B and F profiles from the samples of Fig. 1c before and after the RTA are shown in Figures 3 and 4. The as-implanted profiles of both B and F showed Gaussian distributions with peaks occurring at 300Å (Fig. 3) and 250Å (Fig. 4). The peak concentrations of B and F were found to be $5 \times 10^{20} \text{ cm}^{-3}$ and $8 \times 10^{20} \text{ cm}^{-3}$ respectively. During

RTA,²¹ however, a high concentration ($\approx 10^{21} \text{ cm}^{-3}$) of B was found to segregate toward the surface which created a pile-up there. Pronounced diffusion into the deeper regions (up to $0.2 \mu\text{m}$) also occurred (Fig. 3). The F profile from the RTA sample did not show high surface concentrations. The F peak remained at R_p although it became narrower as compared to that in the unannealed sample indicating its precipitation at this depth. Diffusion of F toward the peak was observed from either side of the peak. Comparison of the weak-beam TEM results with the SIMS data in Figs. 3 and 4 confirms that the fine clusters are related to the presence of B and/or F.

Figure 4. SIMS profiles of fluorine before and after RTA at $1100^\circ\text{C}/10 \text{ sec.}$

From the results presented above, it appears that Ge can be a suitable alternative for pre-amorphization of Si. The structural quality obtained after RTA of the pre-amorphized layer with or without BF_2 is comparable to or better than that achieved in the Si-implanted case.^(5,6) For example, in both procedures three types of major secondary defects are found to be present with BF_2 : (I) surface damage (II) 'hair-pin' shaped dislocations within the implanted region and (III) dislocation loops due to straggling ion damage at the amorphous crystalline interface. However, in the Ge implanted samples the density of type II defects is an order of magnitude less than that in the Si implanted samples. The nature of the surface damage in

Manuscript submitted Dec. 28, 1983;
revised manuscript received Jan. 24,
1984.

the two cases is also found to be different. For example, in the Ge case only uniformly distributed fine defect clusters are observed in the surface region (Fig. 2b). In the Si case microtwins and other irregular structures are observed in addition to the clusters. Comparison of atomic profiles of F show that the redistribution of F in both the unannealed and annealed samples can be significantly reduced in the Ge case. However, the B profiles following BF_2^+ implantation show qualitatively similar results in the two cases although B segregation at the surface is more pronounced in the Ge case than the Si case. Experiments on RTA behavior of shallow B^+ and As^+ into Ge implanted Si are now underway. The electrical results from these samples will be published elsewhere.

ACKNOWLEDGEMENTS

The authors would like to thank Ed Myers, Calvin Carter and Jian Liu of NC State University, Terje Finstead of UNC-CH and Tim Sands of UC Berkeley for stimulating discussions and help provided during the course of this work. Thanks are also due to Dieter Griffis of NC State University for the SIMS measurements and Pam Johnson for typing the manuscript skillfully. This work was partially supported by the ONR.

Simulation of Anomalous Be Diffusion in Semi-Insulating InP

C. W. Farley and B. G. Streetman*

Department of Electrical Engineering, The University of Texas at Austin, Austin, Texas 78712

BACKGROUND

This study considers the anomalous diffusion of implanted Be during thermal annealing reported in this journal by Oberstar et al. (1). Secondary ion mass spectroscopy (SIMS) studies of annealed Be implants into semi-insulating (SI) InP revealed Be profiles with relatively flat tails and abrupt leading edges. Furthermore, the diffusion front penetrated less as the anneal temperature increased (Ref. 1, Figs. 3 and 4), contrary to the expectations of conventional diffusion theory. Concentration dependent diffusion has been reported for both shallow (2-5) and deep (6,7) acceptor impurities in compound semiconductors. In order to understand the anomalous migration of Be we have attempted to simulate the effects of impurity concentration and implantation-related damage on redistribution during annealing.

SIMULATION METHOD AND RESULTS

The unannealed impurity profile is calculated for an implant dose of 10^{15} cm^{-2} , a projected range of 4000 Å and a straggle of 800 Å.

Diffusion simulation is accomplished with a discrete transformation of the continuity equation for the position-dependent diffusion coefficient, reported previously in this journal (Ref. 8, Eq.[16]). In our model we assume that the diffusion coefficient is reduced in regions where the impurity concentration is larger than a specified value C_{max}

$$D_0(T), \quad C < C_{\text{max}}$$

$$D_0(T) \times D_r(T), \quad C > C_{\text{max}}$$

where

$$D_0(T) = D_0 \times \exp[-U_a/kT]$$

$$D_r(T) = D_{r0} \times \exp[U_v/kT]$$

and D_0 and D_{r0} are constants.

The shape of simulated profiles was found to be largely dependent on the degree to which the diffusion coefficient was reduced at high concentrations. For slight redu-

ctions ($D_r > 10^{-2}$) the profiles resemble "ideal" diffusion curves. However, when D_r is less than 10^{-2} the profiles become markedly "non-ideal" and resemble the profiles seen by Oberstar for high dose implants (1). Simulations using this model show retrograde behavior similar to that reported by Oberstar only when $U_a \ll U_v$. However, as the anneal temperature increases simulated profiles become more peaked (Fig. 1) whereas the experimental profiles diffuse and flatten out. Since Oberstar suggested the possible role of defect structures, we modified the reduction factor to include the influence of damage (largely vacancies at the anneal temperatures) so that

$$D_o(C_d) = D_{ro} \quad , \quad C_d < C_{max}$$

$$D_{ro} \times \sqrt{C_{max}/C_d} \quad , \quad C_d > C_{max}$$

where C_d is the defect concentration. These defects are assumed to anneal and diffuse more rapidly at high temperatures. Simulations using various defect diffusion coefficients and annealing rates yield similar results and suggest that initially rapid redistribution at high concentrations is slowed by structures whose gettering ability does not initially decrease upon annealing.

DISCUSSION

Release of Be atoms from regions of high concentration appears to be the rate-limiting factor in the diffusion process. However, the rate of release cannot be described simply by thermally enhanced vacancy generation or by the release of atoms gettered to point defects at or near the peak of the profile since these mechanisms would allow deeper penetration at higher anneal temperatures. It is probable that relatively immobile damage clusters created by the high implant dose do not anneal at lower temperatures but do so at higher temperatures by dissociating into a larger number of rapidly diffusing point defects. Therefore, the gettering ability of the implantation-induced damage should remain constant or possibly increase before declining as the point defects begin to anneal. This model explains the variation with implant dose and annealing time observed by Oberstar (1).

Anomalous Be diffusion was reported only in (SI) and not vapor phase epitaxy (VPE)

material (Ref. 1, Fig. 6). A possible explanation is that the competition of two impurity species (e.g. Be and Fe) for the same lattice sites modifies the diffusion kinetics. If we assume that Be diffuses as a fast interstitial and as a slow substitutional, we would expect to see rapid diffusion in regions where $C_{Be} < C_{Fe}$ since the interstitial fraction of Be should be increased by the presence of Fe. As expected, deep penetration of Be was observed experimentally to occur at levels up to the original concentration of the compensating dopant.

CONCLUSION

In summary, we have developed a model for the diffusion coefficient which gives results similar to those observed by Oberstar for Be-implanted InP. Simulation profiles suggest that Be probably diffuses by an interstitial mechanism and indicate that release of Be from the peak of the profile is a critical determinant of the final distribution. The presence of Fe and Cr on the In sublattice reduces the availability of substitutional sites for Be, which explains why the effect occurs in SI and not VPE material. It is apparent from this and other work that rapid diffusion of acceptors is inherent in SI GaAs and InP and that accurate descriptions of diffusion behavior cannot be simply formulated.

CdGeP₂ Photoelectrochemical Cells

B. Scrosati* and L. Fornarini

Dipartimento di Chimica, University of Rome, Rome, Italy

Substantial interest has been lately devoted to ternary chalcopyrite semiconductors as photoanodes in liquid junction solar cells. So far the attention has been focussed on ternary chalcogenides in the I-III-VI₂ family, such as CuInS₂ (1,2) and CuInSe₂ (3) and in the II-III₂-VI₄ family, such as CdIn₂S₄ (4) and CdIn₂Se₄ (5,6).

These compounds show very promising photoelectrochemical properties (1-6) and this has prompted us to extend the investigation to other ternary semiconductors having chalcopyrite-type structures. In this respect, we have considered the II-IV-V₂ compounds and here we report preliminary results on the photoelectrochemical behavior of n-CdGeP₂ in liquid electrolyte cells.

Samples of CdGeP₂ single crystals have been kindly provided by Bell Laboratories. The experimental techniques for assembling the photoelectrochemical cells and for the measurements of the current-voltage curves, have been described previously (7).

In figure 1, curve *a*, is shown the normalized spectral response of the CdGeP₂ electrode in a Na₂SO₄ aqueous solution. The response at 770 nm indicates an energy gap of 1.6 eV, in good agreement with the literature data (8).

Current-voltage curves of the

the CdGeP₂ semiconductor electrode in the dark and under illumination, reveal a consistent photoeffect (figure 2). Therefore, the behavior of this electrode was evaluated in a regenerative photoelectrochemical cell, using a Pt counter electrode and a I₂/I⁻ redox couple in aqueous solution. The output power characteristic, illustrated in figure 3, shows a good fill-factor (FF=0.37) and a high open circuit voltage (V_{oc}=0.64 V). The photocurrent density and thus the power conversion efficiency are still confined to relatively modest values. This is due to the absorption of the dark iodine solution at short wavelengths (see

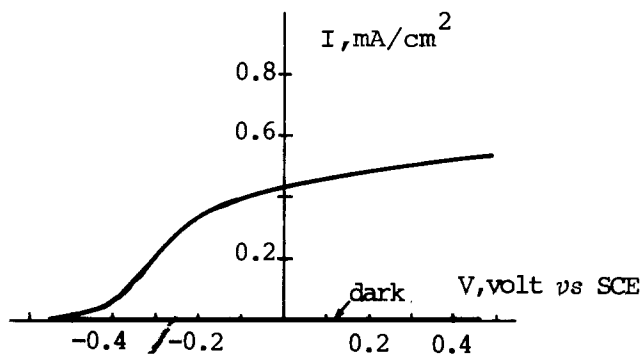

Figure 2-Dark and photocurrent-voltage curves for the n-CdGeP₂ electrode in a 0.5M Na₂SO₄ solution. Illumination: 80 mW/cm².

curve *b* of figure 1) and probably to high surface state recombination, since untreated CdGeP₂ crystals have been used in this preliminary test.

Preliminary results indicate a good stability of the CdGeP₂ photoanode against photocorrosion. Therefore, work is in progress in our laboratory to evaluate the most appropriate electrolyte and the most suitable surface treatments, to finally increase the conversion efficiency of these promising CdGeP₂ photoelectrochemical solar cells.

ACKNOWLEDGEMENTS

The authors wish to thank Dr. J. L. Shay of Bell Laboratories for having graciously provided the CdGeP₂ single crystals and the University of Rome (Progetto di Ateneo) for the financial support.

A Pronounced Cation Effect on Performance and Stability of Cd-Chalcogenide/Polysulfide Photoelectrochemical Cells

S. Licht, R. Tenne, H. Flaisher, and J. Manassen

Department of Plastics Research, The Weizmann Institute of Science, Rehovot 76100, Israel

Variation of the alkali cation in aqueous polysulfide solutions is found to have a dramatic effect on Cd-chalcogenide photoelectrochemical cell (PEC) stability and conversion characteristics. The cation species, although not directly involved in the electrochemical reactions, is important since it is the predominant ionic species in solutions.

Crystals of CdSe (0.25 cm², 5 ohms cm from Cleveland Crystals) were polished with 5 micron alumina powder, etched for twenty seconds in 1:4 (HNO₃/HCl)_{conc} and then submerged in polysulfide solution to dissolve possibly elemental selenium formed. Ohmic contacts were made with In-Ga alloy. Etching procedures were found to be not critical for the effects found. Alkali hydrosulfide solutions were prepared by saturation of the relevant aqueous alkali hydroxide solution with H₂S. Saturation with H₂S was monitored by volume, mass, pH and temperature changes. Polysulfide solutions were obtained by addition of sulfur and alkali hydroxide. Solutions were prepared, stored and utilized under strict exclusion of air. The light source was a stabilized tungsten/halogen lamp. Standard electrochemical equipment was used for measuring the IV and rest potentials.

Solution conductivity was measured with a Radiometer CDM 2d conductivity meter ($\pm 0.5\%$) using a calibrated CDC 104 cell of cell constant one. Cation activity was measured with a calibrated Beckman 39137 cation selective electrode versus standard calomel electrode. The electrode was calibrated against alkali hydroxide and alkali chloride solutions of known activity (1).

Figure 1 presents the output of an etched CdSe electrode as a function of time in four polysulfide solutions containing equal concentrations of, respectively, Li, Na, K and Cs and the striking differences in stability are obvious. The same cationic dependence is found when measuring the current/voltage behavior as shown in Table I, where the short circuit current as well as fill factors are seen to increase appreciably from Li to Cs.

Fig. 1. Output stability of CdSe in polysulfide solutions with different cationic species (2 AM1).

Table I. Experimentally measured rest potentials and calculated photoelectrochemical data for solutions which are 1M in OH⁻, S⁼ and S as a function of cationic species at room temperature.

Cation	Polysulfide rest potential (volts vs. SCE)	Open circuit voltage (volts)	Short circuit current (mA/cm ²)	Relative efficiency
Li ⁺	-0.740	0.650	9.2	1
Na ⁺	-0.748	0.742	17.3	4.06
K ⁺	-0.768	0.747	18.7	5.09
Cs ⁺	-0.775	0.757	20.0	5.67

In order to check whether a similar effect is also found in ordinary electrochemical systems, polarization effects were measured on Cu₂S electrodes under dark conditions. Cu₂S is known to be kinetically fast in the polysulfide system (2). A one cm² Cu₂S electrode, prepared from brass gauze as described in ref. 2 was tested in the one molar, polysulfide solutions. Polarization losses decreased in the order Li > Na > K > Cs, with losses in the Li solution being approximately four times greater than those for the cesium polysulfide electrolyte.

The measured specific solution conductivity and cation activity for the various polysulfide solutions are presented in Table II.

Manuscript received Jan 16, 1984.

Table II. Measured cation activities and specific conductivities for aqueous polysulfide solutions one molar in hydroxide, sulfide and sulfur and containing exclusively lithium, sodium, potassium or cesium cations.

Cation	Li ⁺	Na ⁺	K ⁺	Cs ⁺
Activity	.57	.69	.86	
Conductivity (mho/cm)	.230	.265	.365	.372

The Beckman cation selective electrode was not sufficiently responsive in cesium polysulfide and cesium hydroxide solutions to estimate the cesium ion activity.

The variation of conductivity (Table II) is consistent with the known variation of alkali salt and alkali cation mobilities. However, the variation of activity contradicts the known behavior of the alkali halides. Evidently it is this enhancement of both activity and conductivity which favors the large cation effect observed.

The known decrease in alkali halide activity from lithium to cesium salts is generally understood to reflect the increased hydration of the cations with low atomic number. This results in a decrease in free water and therefore to an increase in effective concentration of the ion. The opposite trend is observed here for the polysulfide solutions and is similar to the observed trend for alkali hydroxides.

The experimental effects are consistent with the model of localized hydrolysis introduced by Robinson and Harned (3), as will be elaborated in a future publication.

The Weizmann Institute of Science assisted in meeting the publication costs of this article.

New Binder System for Low Temperature Alkaline Electrodes

L. B. Berk and C. T. Liu

Westinghouse Electric Corporation, Research and Development Center, Pittsburgh, Pennsylvania 15235

INTRODUCTION

A binder for a hydrophobized, porous, gas-fed electrode must perform two fundamental tasks, it must blend the support and catalyst into a conductive, gas-and-electrolyte-permeable structure and it must impart hydrophobicity to the electrode without substantially decreasing the activity of the electrode. Presently, polytetrafluoroethylene (PTFE) and fluorinated polyethylene (FEP) are the binders of choice for gas-fed electrodes. Prior to this wide-spread acceptance of PTFE, polypropylene and polyethylene whiskers and powders were used as binders. The PTFE electrodes quickly supplanted these electrodes due to better performance and life characteristics. However, the extreme hydrophobicity of PTFE (which necessitates a compromise between long life and good performance), its difficult processing characteristics (high temperatures and toxic fumes) and its high cost have limited the optimization of PTFE-bound electrodes. This has led to a search for a replacement for PTFE as a binder for low-temperature, gas-fed electrodes.

NOVEL BINDER

Two alternative binders have been found to replace PTFE and FEP. These binders are fibrillated polyethylene and fibrillated polypropylene marketed by Hercules/Solvay under the tradenames Pulpex E (polyethylene) and Pulpex P (polypropylene). Table I, taken from Pulpex product literature, lists the characteristics of the Pulpex materials. Their most important features, as will be described in a more complete paper to be published later, are their high surface area ($10 \text{ m}^2/\text{gm}$), large diameter (20μ), and length (1mm). The high surface area gives the fiber strong binding ability and decreases the amount of Pulpex necessary. The large diameter compensates for lower chemical stability in the presence of superoxides and peroxides. Further, polyethylene and polypropylene are sufficiently hydrophobic to be used as hydrophobizing agents in the absence of PTFE or FEP.

EXPERIMENTS AND RESULTS

The Pulpex was obtained in both P (polypropylene) and E (polyethylene) forms. The fibers turned from white to gray when trace amounts of carbon were introduced, which showed a high degree of interaction between the fibers and carbon. Initial tests on 40 cm^2 , 0.03 cm thick electrodes in 25% KOH showed no electrolyte leakage at room temperature for over 1500 hours in the absence of potential. Thus encouraged, 40 cm^2 , two-layer electrodes were fabricated and tested in 25% KOH. The electrodes were cycled against a nickel counter on a 4 hour $12.5 \text{ mA}/\text{cm}^2$ charge and a 4 hour $25 \text{ mA}/\text{cm}^2$ discharge.¹ Two effects were noted. When electrodes made with Pulpex E were hot-pressed at 125°C the electrodes performed well but leaked quickly. When electrodes made with Pulpex E were hot pressed at 135°C they performed poorer than the 125°C electrodes but had a much longer leak-free life. Therefore electrodes were made using the additive package shown in Table II using Pulpex P (melting point 165°C) in the active, hydrophilic layer and Pulpex E (melting point 132°C) in the hydrophobic layer. The electrodes were pressed at 135°C . The small amount of PTFE was added as a dusting agent.

The performances of two such electrodes are shown in Figure 1. The electrodes were cycled in the bifunctional mode (25 mA discharge for four hours, 12.5 mA charge for four hours). Performance is better than similar, Teflon-based electrodes of the same structure. Figure 2 shows a similar Pulpex electrode run in discharge only.

One interesting feature of the Pulpex-bound electrode is that the hydrophobicity is controlled more by the processing temperature than the amount of the binder and even the presence or absence of small amounts of PTFE. Processing the electrode above the melting point of the polymer makes leak-resistant electrodes without comprising gas-permeability. This ability to use two distinct by interchangeable polymers is an advantage not

available with PTFE.

SUMMARY

Suitable alternatives to PTFE and FEP have been found in fibrillated polyethylene and fibrillated polypropylene. The materials can be used with or without the fluorocarbons. The new binders have processing advantages over PTFE (two distinct forms, lower pressing temperatures). Further the cost (approximately \$1.50/lb) is significantly lower than PTFE. Preliminary tests on the binders have shown them to be competitive with PTFE in terms of performance and cycle life.

ACKNOWLEDGMENT

We would like to thank DOE and Lawrence Livermore Laboratories for supporting this work under Contract 7335709. We would also like to thank Hercules/Solvay for supplying samples of Pulpex.

Time-Resolved Microwave Conductivity (TRMC): Photoeffects at Semiconductor/Electrolyte Interfaces

M. Kunst, G. Beck, and H. Tributsch

Hahn-Meitner-Institut für Kernforschung Berlin, Bereich Strahlenchemie, D-1000 Berlin 39, Germany

We report a method to study charge generation and transport at interfaces by following the change of the conductivity induced by a light pulse, via detecting the corresponding change of microwave absorption. The possibilities of the methods are demonstrated in an investigation of charge carrier generation and transport at the semiconductor/aqueous electrolyte interface. The method presented here has been originally applied to the study of charge carriers in homogeneous non- and low-conductivity compounds (1,2) and is here firstly applied to interfacial systems.

The method uses the proportionality between the relative change of reflected microwave power $\frac{\Delta p}{p}$ and the conductivity $\Delta\sigma$ induced by a light pulse in a solid embedded in a waveguide system (2,4):

$$\frac{\Delta p}{p} = A \Delta\sigma$$

$\Delta\sigma$ is composed of two parts (3,4), i.e. $\Delta\sigma_i$ the induced conductivity of free ionic and electronic charge carriers and $\Delta\sigma_p$ the conductivity due to electric energy absorption of induced dipoles. Although TRMC can also be used to investigate light-induced changes of dipole moments, $\Delta\sigma_i$ dominates in semiconductors with high quantum yields and mobilities in the initial charge separation processes (2,3).

key words: photoelectrochemistry, microwave absorption, interfaces, charge separation, electrode reactions

Hence:

$$\frac{\Delta p}{p} = A \Delta\sigma_i = A \sum_i N_i \mu_i e$$

N_i : concentration of induced charge carriers of the i th kind,
 μ_i : respective mobility; and
 e : elementary charge

The electrochemical cell consists of a plastic tube screwed into the center of a short-circuited waveguide section (Fig. 1). The tube is closed at one end by the semiconductor working electrode, which in our experiment is a thin platelet of n-WSe₂. The tube is filled with supporting electrolyte (K₂SO₄). A Pt-wire is used as counter- and reference-electrode during the measurement.

Microwaves (30 GHz) are directed in a waveguide system (Fig. 2) to the semiconductor electrode positioned perpendicular to the direction of microwave propagation. The reflected microwaves from the semiconductor/electrolyte interface are directed via a circulator to the detector. The detector output signal, which is proportional to the change of microwave power for small signals as in our experiment, is recorded on a storage oscilloscope as a function of time after excitation. Excitation is provided by a frequency-doubled Nd:YAG laser ($\lambda = 530$ nm, pulse width 20 ns FWHM).

The Current Voltage curves (Fig. 3) show increases in photocurrent with electrode potential up to 6 V without saturation. The induced conductivity (inserts Fig. 3) shows a fast decaying part (decay time mainly determined by

the laser pulse) giving way to a much slower decay. Two observations are made: a) The signal maximum and the height of the slower decaying part increase with electrode potential. b) The increase of the slower part is relatively larger (Fig. 4).

Both the peak amplitude of the TRMC signal and the electrode photocurrent vary at fixed potential approximately in a linear way with the light intensity (illumination with laser light - producing up to 10^{14} photons per pulse - and with a Xe-lamp - up to 500 mWcm^{-2} - respectively). The geometry of the front contact has within the accuracy of the measurements no influence on the time constants observed. Experiments with ring contacts yielded analogous results.

The results can be interpreted in terms of recombination in the space charge region (fast decay) and the consumption of the separated charge carriers (slower decay). The fact that under illumination with a Xe-lamp saturation of photocurrent is not observed indicates that substantial polarization losses occur at the n-WSe₂/electrolyte interface. The increase of the maximum signal height under anodic polarization thus represents an enhancement of the initial yield by an increase of the electric field in the space charge region (reduced geminate recombination). The larger electric field leads also to a higher concentration of separated charge carriers due to diminished recombination. This results in the more pronounced increase of the slower decaying part.

Charge transfer reactions in the surface can be identified by several decay constants in the slowly decaying part which can be distinguished at longer timescales not displayed here. The qualitative conductivity data can be expressed in absolute conductivity units by a calibration procedure (4). However, the most difficult problem confronting quantitative evaluation in terms of mobilities, cross sections and concentration of reaction partners of the induced charge carriers appears to be the inhomogeneous absorption of the exciting light and consequently

the inhomogeneity of the kinetics of the produced charge carriers still enhanced by the space charge field.

From the above it is evident that TRMC can be used to monitor charge separation and transport at the semiconductor/electrolyte interface to obtain information not easily accessible otherwise. Quantitative evaluation should permit determination of cross sections of the various charge carrier reactions. An intriguing possibility is also acquisition of data concerning the intensity and depth of the space charge field from the influence of the electrode potential on the cross sections and on the initial yield where measurements at several wavelengths of the exciting light can be used. As TRMC permits measurements without supporting electrolyte, the influence of the double layer can be investigated.

The use of TRMC is not limited to the study of transient conductivity changes at semiconductor/electrolyte interfaces. Other interfacial systems (e.g. semiconductor/metal) can be studied with the set-up shown here and a small adaptation permits also to investigate the steady-state case.

ACKNOWLEDGEMENT

The Rates of Oxidation of HCOOH and DCOOH at Lead Adatom-Covered Pt Anodes

Anjam Razaq and Derek Pletcher*

Department of Chemistry, The University, Southampton SO9 5NH, England

During the last six months, there have been two international symposia on electrocatalysis (1,2). At both, there have been extensive discussions on the mechanism of formic acid oxidation and these have served to highlight the fundamental difference between the accepted mechanisms at Pt electrodes and at Pt surfaces in the gas phase. Electrochemists have generally accepted the mechanism proposed by Capon and Parsons (3), i.e.

where the initial step is cleavage of a C-H bond in a dissociative adsorption process. In contrast, the data from the study of the decomposition of formic acid at a gas-Pt interface has generally been interpreted in terms of initial cleavage of the O-H bond, i.e.

The main evidence for step [1] as the rate determining process in anodic oxidation is the absence of a strong pH effect. In this note we wish to report further evidence based on the measurement of the rate of oxidation of HCOOH and DCOOH, using the now, well-known Pb adatom effect to overcome the poisoning of the Pt surface (4). In earlier papers (5,6) we have shown that the rate of oxidation of formic acid is determined either by diffusion in solution or a chemical reaction sensitive to surface conditions and taken to be reaction [1] above. In addition, we described an analysis of the chronoamperometric data leading to a rate constant for the chemical step. We believed that the observation of a strong kinetic isotope effect between the acids DCOOH and HCOOH would support the conclusion of the

*Electrochemical Society Active Member.

cleavage of the C-H, but not the O-H bond, in the determining step.

Experimental.--All the procedures have been described in detail elsewhere (5,6). The DCOOH was formed by dissolving Merck DCOOD in the HClO₄ electrolyte.

Results and Discussion.--Cyclic voltammograms were run for a Pt electrode in solutions of (a) 0.1M HCOOH and (b) 0.1M DCOOH both in 1M HClO₄ containing 1 mM Pb²⁺. Figure I shows the forward sweeps for experiments at 0.1V s⁻¹. It can be seen that the I-E curves are very similar in shape and the main

Figure I I-E curves for (a) 0.1M HCOOH and (b) 0.1M DCOOH in 1M HClO₄ + 1mM Pb²⁺

features are the high current density peaks, E_p close to +0.60V vs NHE although it is also clear that the peak current densities are quite different, that for DCOOH being lower by a factor of 2.7. The curve for HCOOH is identical to that reported earlier (5,7) and the peak has been interpreted in terms of the coverage by Pb adatoms. The peak potential corresponds to θ_{Pb} = 0.5, the most active surface, where the adatoms are arranged over the surface so as to give a maximum number of two Pt surface atoms adjacent to each other for reaction [1] to occur but few sites where there are sufficient Pt sites for poison to form. At lower potentials some of the surface is completely covered by Pb and at higher potentials θ_{Pb} < 0.5 and some of the surface becomes poisoned.

While the difference in peak current

densities for HCOOH and DCOOH clearly implies cleavage of the C-H bond in the rate determining step, it is difficult to estimate a ratio of rate constants from the linear sweep curves. Hence the chronoamperometric technique was used. For each acid in 1M HClO₄ + 1 mM Pb²⁺, the potential was stepped from +0.2V (where the surface is fully covered by Pb) to +0.6V (where $\theta_{Pb} = 0.5$ and oxidation of formic acid occurs at a maximum rate) and the I-t responses were recorded over the time range 0.1 to 100 s. In both cases, falling I-t transients were observed and these were analysed by plotting It^2 vs t^2 , see figure II.

Figure II Chronoamperometric data for 0.1M HCOOH & DCOOH in 1M HClO₄ + 1mM Pb²⁺.

The curve for HCOOH is very similar to that expected for an electrode reaction under mixed diffusion-kinetic control. Initially It^2 increases but beyond 10 s it reaches a plateau value from which the diffusion coefficient may be evaluated as $0.83 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$. With DCOOH the response is not so ideal. It will be shown below that the curve again fits well to mixed control but only up to 4 s; at longer times the value of It^2 falls below the expected value, never reaching the diffusion limit (the same plateau as for HCOOH) and indeed It^2 passes through a peak and then falls. This is the behaviour expected if the electrode surface poisons slowly; certainly it would not be surprising if the DCOOH were to contain a higher level of impurity than the Analar HCOOH.

The I-t data was further analysed using a modification of the procedure of Delahay and Oka (8) developed earlier (5) for the case where the kinetic limitation arises from reaction [1]. In this method the ratio I/I_D at each t on the rising part of the It^2 vs t^2 plot is used to calculate a value of $k \theta_{Pb}(1-\theta_{Pb})t^{3/2}/D$ which can then be replotted versus $t^{3/2}$. Such plots should be linear and k may be estimated from the slope since D is known and $\theta_{Pb} = 0.5$ at 0.6V. Figure III shows such plots for HCOOH and DCOOH where the data for the latter acid was evaluated assuming the true diffusion limited current is the same as

Figure III Analysis of chronoamperometric data.

for HCOOH. Good linear plots are obtained and the values of k for HCOOH and DCOOH were 7.6×10^{-3} and $2.9 \times 10^{-3} \text{ cm s}^{-1}$ respectively.

The ratio of the rate constants, $k_{\text{HCOOH}}/k_{\text{DCOOH}}$, of 2.6 clearly supports the hypothesis that it is the C-H bond which is cleaved in the chemical process leading to the kinetic limitation of the current. Hence it remains our conclusion that at Pt/Pb surfaces, the oxidation of formic acid is under mixed control by diffusion and a chemical process leading to cleavage of the C-H bond and whose rate reflects the surface, both coverage (4,5,7) and choice of adatom (6). The mechanism [1] - [3] meets all the requirements.

Electrochemical Intercalation of Lithium into an Active Carbon

Yoshio Takasu*, Masao Shiinoki, and Yoshiharu Matsuda*

Faculty of Engineering, Yamaguchi University, 2557 Tokiwadai, Ube 755, Japan

INTRODUCTION

Besides metal oxides, sulfides and fluorocarbons, materials such as polyacetylene and carbon fiber have recently been proposed for cathode of lithium cells.¹⁻⁶ Many investigators insisted that some cathode reactions in lithium cells involve the intercalation of lithium into the cathode. Active carbon can also be expected to offer incorporation sites for lithium because it is composed of many fine graphite-like crystallites (i.e. turbostratic structure).⁷⁾ Lithium might intercalate into the inter-layer of the crystallites.

In this research, the authors have examined whether lithium ions intercalate into an active carbon cathode in an organic solvent containing a lithium salt.

EXPERIMENTAL

Active carbon made from coal (Futamura Chemicals Co. Ltd., Taiko-GL-30) and graphite powder (Nakarai Chemicals Co. Ltd., C-325) were used as active materials. X-ray diffraction spectra of these active materials are shown in Fig.1. In this region graphite has a strong diffraction peak from the plane at 26.5° which is characteristic of the graphite structure. On the other hand, active carbon has only a weak peak at this angle, but has three broad peaks around 21.2° , 23.5° , and 43° . These peaks originate from graphite-like crystallites having turbostratic structure. Active carbon (or graphite powder) [150 mg] was dried at 60°C , mixed with polyethylene powder [25 mg], and then press-molded [4500 kg cm^{-2}] to a tablet cathode [13 mm in diam, ca.1 mm in thickness]. The tablet was mounted on a frame made of poly-tetrafluoroethylene, and the electrical contact was made with a platinum plate [13 mm in diam] connected to a spring wire. This platinum plate was brought into contact with the tablet cathode. Since the geometric area of the cathode faced to the electrolyte solution was 0.95 cm^2 (corresponding to 72% of the cross section of the tablet cathode), about 108 mg of carbon material would be effective as the active material. The electrolytic cell was a glass beaker filled with 100 ml of an electrolyte solution composed of a mixture of propylene carbonate and 1,2-

dimethoxyethane in volume ratio of 1 : 1 containing 1.0 mol dm^{-3} of LiClO_4 . The counter electrode and the reference were a platinum plate [2 x 3 cm^2] and SCE, respectively. Prior to electrical measurements, the electrolyte solution was deoxygenated by blowing high purity nitrogen. The electrolytic cell was thermostated at 25°C . The amount of lithium intercalated (or partly adsorbed) into active carbon was determined by an atomic absorption spectrometry, after the cathode material was ignited and dissolved in nitric acid.

RESULTS AND DISCUSSION

Figure 2 shows the discharge curves of the carbon cathodes at 0.21 mA cm^{-2} current density. The electrode potential of active carbon cathode gradually dropped with an increase of discharge time, reached a minimum value, ca. -1.4 V vs. SCE , at 0.3 A h g^{-1} discharge, and then rose slowly. On the other hand, that of the graphite cathode rapidly dropped with the discharge. Figure 3 shows the relation between the amount of lithium detected in the cathode and the charge passed. The straight line in the figure shows a theoretical value assuming that all the charge passed is utilized for the discharge of lithium ions. After about 0.3 A h g^{-1} discharge, the derivation of experimental value from the theoretical line was observed. This discharge capacity corresponds to that during a period from the start of discharge to the time at which the cathode potential gave the minimum value. The X-ray diffraction spectrum (c) in Fig.1 is of the cathode after 0.6 A h g^{-1} discharge. The appearance of some new diffraction peaks around 32° , 37° , and 40° suggests that the discharged lithium intercalates into active carbon. Adsorption of lithium over the active carbon might partly occur, however, it would occur no change in the X-ray diffraction spectra. Beyond ca. 0.3 A h g^{-1} discharge, other cathodic reaction without the adsorption and/or intercalation of lithium into active carbon would dominantly occur, because the electrode potential rose again and the amount of lithium taken into active carbon showed a deviation from the value theoretically presumed. One of the probable reaction beyond ca. 0.3 A h g^{-1} discharge is the cathodic reduction of some organic ions which were formed on the platinum anode as a result of anodic solvent decomposition. To prove this possibility, analyses of the electrolytes are now being made.

* Electrochemical Society Active Member

If we assume that the active carbon was composed only of carbon before the discharge, and lithium homogeneously intercalated into the active carbon, the composition of sample (e) (e.g., in Fig.3) should be LiC_5 .

Transport Properties of Aluminum Chloride-Thionyl Chloride-Based Electrolytes

S. Szpak*

Naval Ocean Systems Center, San Diego, California 92152

H. V. Venkatesetty*

Honeywell Corporate Technology Center, Bloomington, Minnesota 55420

ABSTRACT

Conductance, viscosity, and density of $\text{AlCl}_3\text{-SOCl}_2$ -based electrolyte solutions with and without sulfur dioxide and sulfur and varying concentration of lithium chloride have been determined as a function of temperature. While the data on $\text{AlCl}_3\text{-SOCl}_2$ system can be interpreted in terms of solute-solvent interaction forming adducts, those in the presence of sulfur dioxide and lithium chloride have been interpreted in terms of ion-ion and ion-solvent interactions and equilibria involving ion pairs and triple ions with complex anions such as Al_2Cl_7^- and $\text{Al}_3\text{Cl}_{10}^-$. Data on energy of activation for conductance and for viscous flow along with Walden product are in agreement with this interpretation. The unusually high electrolytic conductance observed for these concentrated electrolyte solutions and the energy of activation data are interpreted in terms of the hopping mechanism for conductance. The implication of increased complexity of solution structure on mass transport during Li/SOCl_2 battery discharge is discussed.

The development of a Li/SOCl_2 battery capable of high discharge rates has only recently been undertaken. To achieve this goal, two design approaches are being explored: the thin cell technology and the use of flowing electrolyte (1). In both approaches, the battery performance is believed to be limited by the positive electrode.

The relationship between the electrode structure and performance at low discharge rates was examined by, among others, Dey (2) and Christopulos and Gilman (3). The effect of electrocatalysts was explored by Venkatesetty (4). At high discharge rates, structural characteristics of the electrode, its catalytic surfaces, as well as the physico-chemical properties of the electrolyte, are expected to play a dominant role. This was confirmed, in part, by results of Klinedinst and Domeniconi (5), Dey and Bro (6), and, most recently, Szpak and Driscoll (7).

The least explored aspect of Li/SOCl_2 technology is the transport properties of the $\text{AlCl}_3\text{-SOCl}_2\text{-LiCl}$ electrolyte. As Li/SOCl_2 cells are discharged, composition of the electrolyte changes and becomes complex due to the formation of LiCl , sulfur dioxide, and sulfur. In particular, as the concentration of these products builds up, the structure and, therefore, transport properties of the electrolyte solution change, and this change will affect the battery performance.

The purpose of this communication is to extract structural information and transport modes from the data on conductance, viscosity, and density of AlCl_3 in SOCl_2 containing known concentrations of sulfur and sulfur dioxide and varying concentrations of LiCl as a function of temperature.

Experimental

Thionyl chloride was mixed with triphenylphosphite [16 volume percent (v/o)] while cooling and then distilled under positive pressure of dry nitrogen. The distillate was redistilled with a cutoff point at 80°C ; the middle fraction of the second distillation was used in this study. An anhydrous AlCl_3 (Fluka, AG) and an anhydrous, AR grade LiCl (Malinkrodt) were used as received. Sulfur, U.S.P. powder, sublimed, and anhydrous SO_2 were used without additional purification. All chemicals were weighed inside a dry box and maintained under dry argon. Solutions were prepared in another dry box. A known volume of the electrolyte solution was placed in an Erlenmeyer flask fitted with a sidearm bubbler, through which SO_2 was passed from a lecture bottle. Precautions were taken to minimize any loss of SOCl_2 . After admitting SO_2 , the flask was stoppered, volume change and weight were noted, and the concentration of dissolved SO_2 was calculated.

Conductivity measurements were carried out in specially designed cells, as shown in Fig. 1. The electrode assembly (A) consisting of platinum rods sealed into glass tubes and attached to a glass joint, was placed into a graduated cylinder (B). As illustrated, this cylinder is connected through a side arm and a two-way stopper to another graduated cylinder (C), in which the concentrated solution is stored. The desired composition of solution was obtained upon mixing of electrolyte in B with a calculated quantity admitted from C. Because of the electrode assembly design, mixing was continued until a constant conductivity was measured. The conductance cell was thermostated in an oil bath and/or water-methanol bath, and the deviations in temperature were 0.1° , 0.05° , and 0.5°C in the ranges of -20° to 0°C , 0° to 50°C , and 50° to 70°C , respectively. Low temperature was maintained in water-methanol bath with a Brinkmann Lauda IC-6 cooler.

EST

Fig. 1. Conductance dilution cell. A: electrode assembly. B: dilution cell. C: graduated cylinder for storage of concentrated solutions.

Density data were used to make corrections for concentrations at different temperatures.

Conductance cell calibration and solution conductance measurements were made using a Jones bridge and accessories previously described (8). The solution resistances were measured at frequencies of 1, 3, 5, and 10 kHz and extrapolated to an infinite frequency.

Viscosities of the solutions were measured using the Cannon-Ubbelohde dilution viscometer immersed in a suitable bath with a guard-tube attachment to exclude moisture from the solution. The bath temperatures were controlled to within 0.1°C and the time to within 0.1s. The viscometer constant was determined using viscosity standards provided by the Cannon Instrument Company (9).

The densities of the electrolyte solutions were determined using Pyrex dilatometers sealed at the top and calibrated with methanol and distilled water.

Results

Extensive experimental data on transport properties of the $\text{AlCl}_3\text{-SOCl}_2\text{-LiCl}$ system have been presented elsewhere (10). Here, only a limited set of data, needed to illustrate specific points, will be used.

Conductance.—The conductance data are given in the following order: specific conductance, equivalent conductance, and energy of activation.

Specific conductance, σ .—Results, shown in Fig. 2, indicate no substantial change in specific conductance with a three-fold increase in the AlCl_3 concentration. In contrast, upon addition of even small amounts of LiCl , a significant increase in conductance is observed, as seen in Fig. 3. This observation suggests that the

($\text{SOCl}_2 \cdot \text{AlCl}_3$) adduct does not increase the self-ionization of the SOCl_2 except at higher concentrations.

Addition of SO_2 renders the $\text{AlCl}_3\text{-SOCl}_2\text{-LiCl}$ system more conductive. As illustrated in Fig. 4 and 5, this increase depends on temperature and, for a selected

AlCl₃ concentration, the amount of dissolved SO₂ (Fig. 4) and dissolved LiCl (Fig. 5).

Equivalent conductance, Λ .—As shown in Fig. 3, the specific conductance of the (SOCl₂ · AlCl₃ + SOCl₂) electrolyte increases by an order of magnitude upon the addition of LiCl. This behavior suggests that the dissolved LiCl provides the conducting species and that the equivalent conductivities can be calculated accordingly.

Plots of equivalent conductivities vs. the square root of LiCl concentration, shown in Fig. 6, indicate that these solutions are weak electrolytes. This behavior is expected if we consider that the (SOCl₂ · AlCl₃ + SOCl₂) is a low dielectric solvent (11). Evidently, as the concentration of LiCl increases, the equivalent conductance at first decreases rapidly, and then changes moderately; it tends to exhibit a minimum particularly at higher AlCl₃ concentrations.

Energy of activation.—The energy of activation for conductance in the AlCl₃-SOCl₂-LiCl system is tabulated in Table I. Evidently, in the absence of LiCl, the energy of activation increases with the AlCl₃ concentration. Such a trend indicates the formation of large aggregates involving AlCl₃ and SOCl₂ components.

It is noteworthy that energies of activation for this system are considerably larger than those measured for the solutions of LiAlCl₄ in SOCl₂ (8).

Viscosity, η .—Additional structural information can be obtained from the analysis of viscosity data. To facilitate this analysis, the viscosity data are assembled in the form of Batschinski-Hildebrand plots (12, 13) and a Jones-Dole relation (14). The tabulation of energies of activation for the viscous flow completes the presentation of experimental data results (Table I).

Batschinski-Hildebrand equation.—The Batschinski-Hildebrand equation, Eq. [1], relates the fluidity, ϕ ,

Fig. 6. Equivalent conductance as a function of LiCl concentration. Electrolyte: AlCl₃-SOCl₂-xLiCl; temperature = 20°C. Curve A: 1.5M AlCl₃. Curve B: 3.0M AlCl₃. Curve C: 4.5M AlCl₃.

to the specific excess volume, $(v - v_0)$, alternatively, to the ratio of occupied to unoccupied volume, $(v - v_0/v_0)$

$$\phi = B(v - v_0)/v_0 \quad [1]$$

The B constant is not an adjustable parameter, but a property of a liquid measuring its ability to absorb momentum generating the newtonian flow (13). Thus, its value depends on the molecular size and shape, and, in a qualitative way, may yield information on the molecular structure. The intrinsic volume, v_0 , is defined by Eq. [2]

$$v_0 = \lim_{\phi \rightarrow 0} v \quad [2]$$

i.e., it is obtained by an extrapolation of the $\phi(v)$ curve to zero. Physically, v_0 is the specific volume of a substance in the solid state provided that on solidification molecules preserve all of their degrees of freedom (13).

A typical plot of the $\phi(v)$ curves for the AlCl₃-SOCl₂-LiCl system, and specifically for the 1.5M AlCl₃, is shown in Fig. 7. Plots for other concentrations are

similar; the corresponding B and v_0 values are tabulated in Table II. It is noteworthy that, in the absence of dissolved SO_2 , the curvature of $\phi(v)$ is substantially reduced.

Jones-Dole equation.—Because the AlCl_3 - SOCl_2 -LiCl system contains charged species, it is expedient to examine the viscosity data in terms of the Jones-Dole equation, which is only valid for moderate concentrations, Eq. [3]

$$\eta = \eta_s(1 + A\sqrt{c} + Bc) \quad [3]$$

Here η is the shear viscosity of the electrolyte, η_s is that of the solvent, and c is the concentration of the ion producing salt. A is a positive constant which can be calculated theoretically and which accounts for the contribution due to the ion-ion interaction. The B coefficient, on the other hand, is an empirical constant and can be either positive or negative (14).

The B coefficient is obtained from the plot of $(\eta_r - 1)/\sqrt{c}$ vs. \sqrt{c} , where $\eta_r = \eta/\eta_s$. Examples of the Jones-Dole plots are shown in Fig. 8 for the SOCl_2 -1.5M AlCl_3 and for the 1.5M AlCl_3 - SOCl_2 - $x\text{LiCl}$ systems. In the AlCl_3 - SOCl_2 system, the B coefficient is small and positive (curves a and b at 0° and 50°C, respectively). Upon addition of LiCl, the B coefficient becomes negative (curves a' and b' at 0° and 50°C, respectively). Evidently, in the first case, SOCl_2 is the solvent and AlCl_3 is the salt, whereas in the second case 1.5M $\text{AlCl}_3 + \text{SOCl}_2$ is the solvent and LiCl is the salt.

Energy of activation, E_η .—At high concentrations, structural information is usually sought through the determination of the energy of activation. Temperature effects, expressed in terms of energy of activation, are summarized in Table I and in Fig. 9 and 10. In particular, Fig. 9 shows the energy of activation for SOCl_2 (curve A) and SOCl_2 containing dissolved AlCl_3 (curves B, C, and D for 1.5, 3, and 4.5M solutions of AlCl_3 , respectively). Evidently, the addition of AlCl_3 increases the energy of activation for the viscous flow, with the increase being quite noticeable at higher AlCl_3 concentrations. The effect of the addition of LiCl is illustrated in Fig. 10. It is seen that the $\log \eta$ vs. $1/T$ lines are parallel and displaced upwards with the increase in the LiCl concentration.

Discussion

Measurements of transport properties, e.g., viscosity, diffusivity, and conductivity, are often the source of information concerning molecular aspects of liquids (15-17). These are phenomenological coefficients describing the response of a structureless liquid to the

Fig. 8. Effect of LiCl concentration on B coefficient in the Jones-Dole equation. Curves a and b for the SOCl_2 - AlCl_3 system at 0° and 50°C, respectively. Curves a' and b' for 1.5M AlCl_3 - SOCl_2 - $x\text{LiCl}$ at 0° and 50°C, respectively.

action of forces generated by the velocity, chemical, and electrical potential gradients, respectively. On the microscopic level, however, liquids are not homogeneous entities, *i.e.*, the condition of continuum cannot be satisfied. In concentrated solutions, especially in solvents of low dielectric constant, new ionic and molecular species appear. Moreover, ion pairs, triple ions, etc., may interact with solvent dipoles, forming complex structures, thus making interpretation of conductance and viscosity data difficult and, at times, ambiguous.

To obtain progressively better insight into the molecular structure of this system, we start with the discus-

sion of relevant elements of coordination chemistry and examine the conductance and viscosity data against this background.

The SOCl₂-AlCl₃-LiCl system.—Thionyl chloride is a nonaqueous, aprotic solvent that undergoes a process of self-ionization to yield SOCl⁺ and Cl⁻ ions with $K = 10^{-4}$ (18). It has a tetrahedral arrangement of electron pairs with three σ bonds and a lone pair of electrons. Its molecular shape is that of a triangular pyramid. It is an exceedingly weak donor, with a donor number of 0.4 on the Gutmann scale (19). Because it possesses a strong affinity to Cl⁻ ions, it is useful in the synthesis of chloro-complexes.

The covalent AlCl₃ is a strong acceptor, and its dissolution in SOCl₂ can be viewed as the donor-acceptor reaction

Both 1:1 and 1:2 adducts have been isolated (20, 21). In the solution, particularly when an excess of SOCl₂ is present, the 1:1 adduct, an undissociated compound, is dominant. As the AlCl₃ concentration is increased, the formation of a quasi 1:2 adduct is favored. However, spectroscopic evidence suggests that the 1:2 adduct is, in fact, the 1:1 adduct with a loosely attached second AlCl₃ molecule (20). Three structures are possible for the SOCl₂ · AlCl₃ complex

Of these, the Raman spectra are consistent with the first structure, *i.e.*, where the oxygen atom is the donor.

In the presence of Cl⁻ ions, generated by either self-ionization of SOCl₂ or by the addition of LiCl, the SOCl₂ · AlCl₃ adduct forms anionic complexes with a simultaneous release of SOCl₂

If the source of Cl⁻ ions is the self-ionization of SOCl₂, then, with an increase in the AlCl₃ concentration, the acidity of solution increases and shifts the equilibrium in the direction to promote the formation of higher complexes, *e.g.*, Al₂Cl₇⁻, Al₃Cl₁₀⁻, particularly at higher temperatures.

Sulfur dioxide, which has been added to simulate actual conditions in a discharging cell, is a nonlinear molecule with a triangular planar arrangement of electron pairs with two σ bonds and a lone pair of electrons. It can act both as Lewis acid or base, depending upon environment, and, when dissolved in another solvent, such as SOCl₂, it can also act as a cosolvent (22), but it does not interact chemically (19). It can function as an acceptor toward Cl⁻ ions, forming SO₂ · Cl⁻ complex (19, 23); it can also enter preferentially into Li⁺ ion solvation sheet (24).

The dissolved sulfur exists as a S₈ molecule, which, at low concentrations, exhibits weak electrolytic dissociation: S₈ \rightleftharpoons S₂²⁺ + S₆₋₂²⁻ (18).

Conductance.—The conductance in molecular liquids is, as a rule, a specific function of the solvent-solute system (17). This assertion is particularly true if the solute is potential electrolyte, *i.e.*, a covalent salt, and if its dissolution occurs only on account of reaction between the solute and the solvent: here, between AlCl₃ and SOCl₂ (Eq. [I]). In this system, therefore, electrostatic considerations are likely to play a lesser role than the molecular forces, and the dependence on square root of concentration should be limited. However, it would appear that electrostatic considerations should dominate the dissolution of an ionic salt such as LiCl. However, the dissolution of LiCl in the (SOCl₂ · AlCl₃ + SOCl₂) solvent does not occur via

the weakening of electrostatic forces, but rather through a chemical reaction of an anionic complex formation (Eq. [I]). Consequently, when we increase the concentration of LiCl, it may not necessarily be the number of Li⁺ ions but their interaction with a solvent that determines the conductance.

Because the 1:1 SOCl₂ · AlCl₃ adduct remains undissociated, the addition of AlCl₃ to SOCl₂ should not substantially change the solution conductivity. However, at high concentrations of AlCl₃ the 1:2 adduct dominates, new equilibria are established, and the number of charged species increases, principally due to a higher affinity for complex formation. The temperature effects (Fig. 2) substantiate this conclusion.

Upon addition of even small amounts of LiCl, the solution conductivity increases many fold, as shown in Fig. 3. This marked increase in conductivity, their linear dependence on concentration of LiCl, and temperature effects, suggest that both the number of charged species and their mobility are affected, in accordance with Eq. [II].

The equivalent conductance data (Fig. 6) indicate that the AlCl₃-SOCl₂-LiCl solutions behave as weak electrolytes. Equivalent conductances decrease with increasing LiCl concentration, reaching what appears to be a minimum, especially at higher AlCl₃ concentrations. This behavior is in agreement with theoretical predictions that the decrease in conductance with an increasing concentration of the electrolyte is due to the formation of ion pairs, triple ions, and more complex aggregates (25).

Plots of log Λ vs. log c are linear with an approximate slope of $-\frac{1}{2}$, thus confirming the formation of ion pairs (11). Further support for the formation of ion pairs and other complex aggregates is to be found in the observed effect of the dissolved SO₂ on the electrolyte conductivity, illustrated in Fig. 4 and 5, which is due, probably, to an increase in the number of charged species by a mechanism identical to that suggested by Moshtev and Zlatilova (23)

The dissolved SO₂ molecules form adducts with Cl⁻, alternatively, with AlCl₃ and thus reduce the ion pair formation

The effect of SO₂ is more pronounced in the case of 1.5M AlCl₃-SOCl₂-LiCl solutions than in the case of 3M AlCl₃. At the present time, it is not possible to provide adequate interpretation because of enormous complexity of this system.

Viscosity.—The $\phi(v)$ relationship for the SOCl₂, with the B value of 11.2 cP⁻¹, is typical for many molecular liquids, e.g., CCl₄. Evidently, the addition of small amounts of AlCl₃ does not substantially change the capacity of SOCl₂ to absorb the momentum generating the newtonian flow, since curve b is nearly parallel to curve a in Fig. 7. The addition of larger amounts of AlCl₃ decreased the numerical value of the B constant somewhat, thus indicating moderate changes in molecular structure. This moderate change in structure is consistent with the formation of the 1:2 adduct (20).

The addition of LiCl, however, clearly affects the numerical value of the B constant, indicating substantial structural changes. Of special interest is the development of a curvature at low $(v - v_0)/v_0$ ratios (i.e., at low temperatures). The development of such curvatures indicates that molecular crowding has occurred (12). Another feature of the $\phi(v)$ plots is the independence of the intrinsic specific volume with LiCl concentration, i.e., the linear portion of the $\phi(v)$ curve intersects the V -axis at the same point. The intrinsic volume is thus affected by the addition of AlCl₃, but not by the addition of LiCl. Such a behavior is consistent

with an increase in the number of molecules and is in accordance with the hole theory of liquids (11). It can be interpreted as indicating that the addition of LiCl breaks up the adduct molecules, in agreement with Eq. [II].

Stokes and Mills (21) express the left-hand side of Eq. [3] as a sum of contributions due to ion-ion interaction (η_{10}) and ion-solvent interaction (η_{20}). The latter can be further split to account for the size and shape of an ion, inclusive of solvation sheet (η_{21}), alignment of polar molecules by local electric field, a kind of molecular stiffening (η_{22}), and finally to the destruction of solvent structure (η_{23}). Of these, all are positive contributors, except for the last, which is negative.

The small and positive B coefficient indicates a low concentration of charged species when AlCl₃ is the only component dissolved in SOCl₂. This observation is in agreement with the conductance measurements (Fig. 2) and with the Batschinski-Hildebrand plots (Fig. 7); both suggest negligible change in SOCl₂ structure, except at much higher AlCl₃ concentrations. Upon addition of LiCl to the (1.5M)AlCl₃-SOCl₂ solution, the B coefficient becomes negative. Since η_{21} and η_{22} are positive contributors, it follows that $\eta_{21} + \eta_{22} < \eta_{23}$, i.e., it is consistent with the conductance data.

The Jones-Dole equation is valid for moderate concentrations. At higher concentrations, the structural information is usually sought through the energy of activation measurements. To bring into focus the relationship between the energy of activation and the fluid structure, we apply the Eyring equation in the form of

$$\eta = (Nh/V_m) \exp(\Delta G^*/RT) \quad \text{[4]}$$

where N is the Avogadro number, V_m is the molar volume, h is the Planck constant, and ΔG^* is the minimum value of additional free energy needed, or the smallest amount of work that must be done, to bring the system into the intermediate position. Upon substitution $\Delta G^* = \Delta H^* - T\Delta S^*$, Eq. [4] has the same form as the empirical equation

$$\eta = A \exp(E_a/RT) \text{ with } \Delta H^* = E_a \quad \text{[5]}$$

where $A = f(\Delta S)$ has a physical meaning indicating an ordering process when the molecules pass from the initial to the transition state. Temperature effects, expressed in terms of energy of activation, are summarized in Table I and in Fig. 9 and 10. In particular, Fig. 9 shows the energy of activation of SOCl₂ (curve a) and for SOCl₂ containing dissolved AlCl₃.

Walden product.—The Walden rule states that, if the moving charged particle is the same, then the product remains constant in solvents of different viscosities. This rule follows from the applicability of the Stokes law, and, in general, is a good approximation in aprotic solvents. The constancy of the product is assured when the energy of activation for the viscous flow and the migration in an electric field are the same, which, in turn, implies that the same or similar configurational changes occur when the system responds to either driving force.

A plot of the product, constructed for the 1.5M AlCl₃-SOCl₂-LiCl, as a function of temperature and LiCl concentration is shown in Fig. 11. Evidently, the product is not constant, i.e., in agreement with the energy of activation data tabulated in Table I. The variation of the product in the same solvent arises from a number of reasons: (i) the Stokes law is not applicable, i.e., on the microscopic scale the solvent is not continuous, or the transport in an electric field occurs via the jumping of charged species between neighboring aggregates, Eq. [IV]; (ii) size of the charged particle varies with temperature and/or concentration, i.e., the degree of dissociation may change; and (iii) in a complex system, new equilibria may be

Fig. 11. Plot of Walden product as function of composition and temperature. Electrolyte: 1.5M AlCl₃-SOCl₂-xLiCl.

established with a change in composition and temperature.

In a system where $E_{\eta} > E_{\Lambda}$, in particular when $E_{\eta} = nE_{\Lambda}$ ($n > 1$) there exists a relationship

$$\Delta^n \eta = \text{const.} \quad [6]$$

Consequently, plots of $\log \eta$ vs. $\log \Lambda$ should be linear with the slope giving the value of n . Such a relationship was found with n values from 1.33 for 1.5M AlCl₃ to 4.5 for 4.5M AlCl₃ electrolytes. These values indicate that larger configurational changes take place at high AlCl₃ concentrations and suggest that conductance is controlled by small, positive ions (most likely solvated Li⁺ ions), whereas the viscous flow is governed by large negative aggregates.

Mechanism of conductance.—One of the characteristics of the AlCl₃-SOCl₂-LiCl system, with or without dissolved sulfur and sulfur dioxide, is its fairly high conductance in a solution of high viscosity. The high viscosity is attributed to the formation of large ionic aggregates, thus suggesting that small positive ions have high transference number. The failure of the applicability of Stokes law is consistent with the hopping mechanism of the type proposed by Reger *et al.* (25)

In this mechanism, the Li⁺ ion jumps between successive molecules (aggregates). Evidently, the larger the aggregates, the larger the distance between the incoming and leaving Li⁺ ion and, therefore, the higher the conductivity. Because of the existence of a number of aggregates of various sizes in equilibrium with each other, further analysis would be hopeless.

Relevance to battery technology.—The operational characteristics of batteries, especially those employing porous electrodes, depend on the kinetics of charge transfer reaction, the transport in the electrolyte phase, and the resistivity of the electrode matrix. In Li/SOCl₂ batteries, the first two factors play a major role because they change with the change in electrolyte composition, *i.e.*, with the degree of battery discharge.

Regarding the electrolyte as a ternary system, *i.e.*, omitting dissolved SO₂ and elemental sulfur, we can follow the change in the composition on the Gibbs' triangle, shown in Fig. 12. Hence, the pure components, *i.e.*, SOCl₂, LiCl, and AlCl₃, are represented at respective apexes, the binaries of the system are read along the sides of a triangle, and the ternary points are found within the domain of a triangle. The change in

Fig. 12. Representation of structural changes on the Gibbs' triangle.

the composition for the initial 3.0M AlCl₃ in SOCl₂ is shown in Fig. 12 by the heavy line. In practice, initial conditions are chosen to assure maximum conductivity and maximum amount of SOCl₂.

Structural changes and, therefore, transport properties change with composition. Thus, pure SOCl₂ is a molecular liquid. Upon addition of AlCl₃, the viscosity and conductivity data indicate a weak interaction along the binary AlCl₃-SOCl₂, except when $x > 0.3$, *i.e.*, where some structural changes occur. These changes are associated with the formation of new aggregates. Because of limited conductivity, those compositions are not suitable electrolytes for high discharge-rate applications.

Substantial structural changes occur with the addition of LiCl. Formation of ionic complexes (Eq. [I]) results in an increased conductivity. The low ratio of E_{η}/E_{Λ} suggests that transport properties are controlled by hole formation, and a correlation between the diffusion coefficient and viscosity can be used in examining the mass transport. Such a correlation becomes less valid as the battery is being discharged, *i.e.*, along the heavy line in Fig. 12. As we approach curve c, and especially close to the line indicating precipitation of LiCl, the formation of triple ions and other aggregates dominates the electrolyte structure. Within this region, the electrolyte is better represented by molten salt. Here, the conductance most likely occurs through a hopping mechanism, and transport is by migration rather than diffusion. It is also likely that the mechanism of SOCl₂ reduction changes when less SOCl₂ is available.

Conclusions

1. In AlCl₃-SOCl₂ solutions containing low AlCl₃ concentrations, the same structural changes affect conductance and viscosity governed by hole formation. As the AlCl₃ concentration increases approaching 4.5M, structural changes and adduct formation take place.

2. Addition of LiCl at all levels of AlCl₃ concentration increases electrolytic conductance. Formation of ion pairs, triple ions, and large aggregates becomes dominant. The analysis of viscosity data suggests the destruction of solvent structure.

3. Sulfur dioxide in the AlCl₃-SOCl₂ system acts as a cosolvent with increased conductance, particularly at low AlCl₃ concentration and low temperatures. This is attributed partly to SO₂ · Cl⁻ interaction minimizing ion pair formation and partly to preferential solvation of lithium ion by SO₂.

4. The Walden product and then energy of activation for conductance and viscous flow indicates that the

conductivity at high AlCl_3 concentration and in the neighborhood of neutral solutions is governed by positively charged small ions, whereas the viscous flow is controlled by the negatively charged large aggregates.

5. A hopping mechanism for conductance seems to be operative in concentrated solution of $\text{AlCl}_3\text{-SOCl}_2$ containing lithium chloride.

ABSTRACT

Infrared, x-ray, and electron spin resonance spectroscopic studies of laboratory-synthesized $\text{Li}_2\text{S}_2\text{O}_4$ are reported. Spectra of cathode samples from Li/SO_2 cells discharged at -30° , 25° , and 70°C are compared with the spectra of the laboratory-prepared $\text{Li}_2\text{S}_2\text{O}_4$. The principal discharge material is confirmed to be $\text{Li}_2\text{S}_2\text{O}_4$. The 70°C discharge is shown to produce a different set of products from the discharges at the lower temperatures.

Although lithium dithionite, $\text{Li}_2\text{S}_2\text{O}_4$, has been assumed to be the sole discharge product of Li/SO_2 batteries, the evidence has been based on qualitative information (1) and various voltammetric investigations often performed under conditions dissimilar to commercial cells. Quantitative analysis of commercial Li/SO_2 cells discharged at 25°C at low current densities has recently been performed (2, 3). Under these conditions, $\text{Li}_2\text{S}_2\text{O}_4$ is the discharge product. However, preliminary chemical analysis performed at NSWC on Li/SO_2 cells discharged under more abusive conditions

such as high temperature discharge, revealed the presence of other sulfur products.

The principal discharge product, $\text{Li}_2\text{S}_2\text{O}_4$, has recently been synthesized and its thermal decomposition studied (4). Differential thermal analysis of the synthetic material reveals that it decomposes exothermally releasing approximately $3.4 \text{ kcal mol}^{-1}$. The products formed in the decomposition are Li_2SO_3 , SO_2 , and S.

Previous spectroscopic studies of dithionites have centered on the sodium salt (5). The current study examines the laboratory-prepared $\text{Li}_2\text{S}_2\text{O}_4$ by x-ray, infrared, and electron spin resonance spectroscopies and compares the spectroscopic characteristics with

* Electrochemical Society Active Member.
Key words: $\text{Li}_2\text{S}_2\text{O}_4$, Li/SO_2 cells.

those of the discharge products of the Li/SO₂ cell formed under various discharge temperatures.

Experimental

The Li₂S₂O₄ was synthesized in the manner previously described (4). It was determined to be 92% pure by the method of Kilroy (6). The lithium salts used for comparison were obtained commercially and used without further purification. The Li/SO₂ cell cathode discharge products were obtained by discharging a series of ½ A-size commercial Li/LiBr/SO₂ cells at a constant 40 mA at various temperatures (−30°, 25°, 70°C) to a 2.0V cutoff. The cells were equilibrated 1h at the discharge temperature prior to discharge. After discharge, the cells were opened under helium, whereupon the cathodes were powdered in an agate mortar and divided. Half of the cathode was washed several times with doubly distilled and oxygen-free acetonitrile. Duplicate discharges were run at each temperature.

X-ray diffraction patterns were recorded using a GE XRD-5 diffractometer with a copper target operated at 50 kV and 20 mA. The scan rate was 2° min^{−1} with a chart speed of 1 in. min^{−1}. The signal levels ranged between 500 and 5000 cps for the maxima and were recorded with a time constant of 0.5 or 1.0s.

The samples were prepared by grinding the solid material with an agate mortar and pestle in a dry box continually flushed with dry nitrogen. The ground material was uniformly applied to a microscope slide coated with silicone vacuum grease. The slides were transported to the diffractometer in a desiccator, which was placed inside a nitrogen-filled glove bag specially mounted over the goniometer. The slides with samples were mounted on the goniometer, and the diffraction patterns were recorded. All powder patterns were recorded at room temperature.

The infrared spectra were recorded using a Nicolet 7199 FT-IR spectrometer employing a bandpass between 4000 and 400 cm^{−1} with 4 cm^{−1} resolution. The samples used to obtain the infrared spectra were prepared by grinding approximately 1–2 mg of sample with 100 mg of dry infrared-grade KBr in an agate mortar and pestle for 4 min. The grinding was done in a dry box. The mixture was pressed into a pellet 1 cm in diam and 0.5 mm thick. The sample compartment was swept with dry nitrogen during the recording of the spectrum.

A Varian 4502 spectrometer operating at 9.1 Gc with the Varian temperature accessory was used to obtain the ESR spectra at various temperatures. The temperature was monitored with a Chromel-constantan thermocouple inserted into a sample tube filled with DC200 silicone fluid. The sample temperature was determined in the cavity both before and after each spectrum was taken. The G values were obtained by comparison with a standard sample of known G value, diphenylpicrylhydrazyl.

The Li₂S₂O₄ samples for ESR were contained in Varian cylindrical, 5 mm id, thin-wall quartz cells open at the top to permit the escape of any SO₂ produced. Samples sealed under vacuum or under dry nitrogen gave the same results. ESR spectra could not be obtained for cathode samples contained in a 5 mm tube, so the samples were contained in a capillary positioned in the center of a 5 mm sample tube.

Results and Discussion

X-ray spectroscopy.—An analyzed sample of Li₂S₂O₄ was prepared electrochemically by one of us (2); the x-ray pattern of this same sample has been previously reported (7). This study compares the x-ray diffraction patterns of duplicate cathode samples from commercial cells discharged at several temperatures with that of a synthetic Li₂S₂O₄ sample. The results are shown in Table I. In each cathode sample, the peaks

observed in the synthetic sample of Li₂S₂O₄ are present, although not always with exactly the same intensity ratios. This result indicates that Li₂S₂O₄ is the major crystalline cathode product resulting from the discharge of a commercial Li/SO₂ cell. Small crystals of a nearly colorless material which could be seen in the cathode material prior to sample preparation are quite likely crystals of Li₂S₂O₄, which is insoluble in the electrolyte, acetonitrile.

However, some additional peaks were noted in the x-ray diffraction patterns. In the pattern from the unwashed cathode material discharged at −30°C two peaks (*d* = 3.98 and 2.84Å) attributable to LiBr, the battery electrolyte, were recorded. These two peaks disappeared upon washing the cathode material with dry doubly distilled acetonitrile. The resulting pattern after washing contained only those peaks recorded in the synthetic Li₂S₂O₄ pattern. The intensity distribution from the washed cathode sample was not the same as the pattern from the highest purity Li₂S₂O₄, but did resemble that of a synthetic Li₂S₂O₄ of lower purity. The diffraction pattern from a cathode sample washed with CS₂ still showed the peaks attributed to LiBr. The presence of LiBr was not clearly detected in the diffraction patterns from other unwashed cathode samples.

Other additional peaks were noted in the diffraction pattern of an unwashed cathode sample discharged at 70°C according to the procedure followed for the other discharges. A minor peak (*d* = 2.88Å) can be attributed to LiBr. The major additional peaks match up with two major peaks of a Li₂SO₃ · H₂O sample recorded for comparison (*d* = 3.14 and 4.15Å). Li₂SO₃ is a decomposition product of Li₂S₂O₄. Exposure of the unwashed cathode to air increased the background intensity at *d* = 3.93Å, indicative of Li₂SO₄ · H₂O resulting from air oxidation of an oxy-sulfur compound. None of the cathode samples gave diffraction patterns that would indicate the presence of Li₂S, which has its most intense peak at *d* = 3.29Å. However, analyses on cathodes from cells discharged at 70°C reveal that sulfide is present (8, 9). The sulfide is present in less than 10% of the overall sulfur species and appears bound in the carbon infrastructure. This may account for its absence in the x-ray spectra.

Infrared spectroscopy.—Infrared analyses studies of sodium salts and available lithium salts were compared with the infrared bands obtained from several SO₂ cells discharged at various temperatures. Table II summarizes the composite frequencies of the vibration bands and relative intensities of the sodium and lithium dithionites and cathode samples. Three factors combine to hinder interpretation of portions of the spectra: (i) with the exception of a few, lithium oxy-sulfur compounds are not available; (ii) the lab-synthesized Li₂S₂O₃ is 90% pure, containing primarily sulfite and some other impurities, such as thio-sulfate, which may introduce weak bands or shoulders; (iii) the carbon-Teflon cathode introduces a matrix which introduces heterogeneity into the sample or dilutes the spectra. This latter factor may explain some subtle differences in the spectra of Fig. 1. This is most apparent with the O-S-O symmetric bending vibration occurring at 647 cm^{−1}.

Dithionite spectra.—The dithionite ion should show four fundamental S-O stretching frequencies, two symmetric modes, and two asymmetric modes. The two asymmetric S-O stretching modes which occur at higher frequency than the symmetric modes are split more in Li₂S₂O₄ than in Na₂S₂O₄. The symmetric stretching modes are not perceptibly split in Na₂S₂O₄, whereas in Li₂S₂O₄ the fundamental is shifted to lower frequency and shows a pronounced intense shoulder on the high energy side. Such differences may be attributed to the differences on the force field exerted by the sodium and lithium ions in the crystal. The

possibility also exists that the two salts have different crystal structures. However, the IR spectrum of the lithium salt sufficiently resembles that of the sodium salt to suggest that the $\text{S}_2\text{O}_4^{2-}$ ion geometry in crystalline $\text{Li}_2\text{S}_2\text{O}_4$ is C_{2v} , as it is in the sodium salt.

The IR spectra of 92% pure $\text{Li}_2\text{S}_2\text{O}_4$ has been previously reported by the authors (10); the IR bands are tabulated in Table II. The top of Fig. 1 shows the IR spectra of 85% pure $\text{Li}_2\text{S}_2\text{O}_4$. The three principal bands at 1082, 1034, and 899 cm^{-1} , and two moderate bands at 540 and 506 cm^{-1} , are essentially the same as that reported for the purer sample. Some weak bands and shoulders may be caused by impurities, i.e., the 647 cm^{-1} band in the 92% sample is attributed to the principal impurity, Li_2SO_3 . Additional weak bands or shoulders occur in the 85% sample (Fig. 1) at 1182, 963, and 639 cm^{-1} , which are in excellent agreement with the 1180, 965, and 642 cm^{-1} bands of hydrated Li_2SO_3 . The band near 1130 cm^{-1} may be due to sulfate.

IR spectra of cells discharged at -30° and 25°C.—The infrared spectra of cathode samples discharged at -30° and 25°C are compared with $\text{Li}_2\text{S}_2\text{O}_4$ in Fig. 1. The spectra of these cathodes strongly resemble the spectrum of $\text{Li}_2\text{S}_2\text{O}_4$. Washing the cathode material with acetonitrile has a negligible effect on the infrared spectra of these samples. The major discharge product

at these two temperatures is $\text{Li}_2\text{S}_2\text{O}_4$, a result in accord with the x-ray results. The weak bands reported in Table II appear to be due to trace amounts of decomposition or oxidation products.

IR spectra of cells discharged at 70°C.—Major bands.—The infrared spectra of cathodes from cells discharged at the higher temperature (70°C) are shown in Fig. 2. Obvious differences from those discharged at the two lower temperatures are observed. The spectra resemble those of $\text{Li}_2\text{S}_2\text{O}_4$, but the intensity pattern of the bands is altered. The strong peaks at 1091, 1021, and 910 cm^{-1} correspond to the strong peaks in the $\text{Li}_2\text{S}_2\text{O}_4$ spectrum. The moderately weak bands at 545 and 503 cm^{-1} match well with the moderate asymmetric bending vibrations occurring at 542 and 507 cm^{-1} for $\text{Li}_2\text{S}_2\text{O}_4$. However, the infrared spectral evidence strongly shows that the higher temperature discharge produces a different distribution of products than the discharges at lower temperature. Four new moderately intense bands appear at \sim 1244, 1165, 970, and 663 cm^{-1} . In addition, discharge of other cathodes reveal the appearance of bands at \sim 1110, 1130, 944, and 630-640 cm^{-1} .

The high frequency IR band observed at 1240 cm^{-1} (1242 and 1238 cm^{-1} in Fig. 2) can be generated by S-O stretching vibrations of several oxy-sulfur anions,

Fig. 1. Infrared spectra of $\text{Li}_2\text{S}_2\text{O}_4$ and the cathode product from a Li/SO_2 cell discharged at -30° and 25°C .

including pyrosulfate $\text{S}_2\text{O}_7^{2-}$, dithionate $\text{S}_2\text{O}_6^{2-}$, and polythionates $\text{S}_x\text{O}_6^{2-}$ ($x = 3 \rightarrow 6$). The presence of pyrosulfate can be ruled out due to the absence of bands in the 700 and 800 cm^{-1} region of the infrared spectrum (11). The di- or poly-thionates have their most intense bands at $\sim 1240 \text{ cm}^{-1}$ (12-14). Polythionates differ by exhibiting a strong IR band near 1035 cm^{-1} (12, 15). This was confirmed by comparing the IR spectra of the sodium di- and tetra-thionates. The tetrathionate had characteristic bands at 1238, 1030, and 635 cm^{-1} . The anhydrous dithionate exhibited strong bands at 1244 and 998 cm^{-1} , a moderate triplet at $\sim 590, 580$, and 560 cm^{-1} , and had a weak band at $\sim 528 \text{ cm}^{-1}$. The critical distinction between the dithionate (995-1000 cm^{-1} band) and the polythionate (1035-1045 cm^{-1} band) is masked in the mixture containing $\text{Li}_2\text{S}_2\text{O}_4$, which absorbs at 1034 cm^{-1} . Additional precaution is warranted on evaluating the 1240 cm^{-1} region. Very pure $\text{Na}_2\text{S}_2\text{O}_6$ exhibits a relatively simple IR pattern at 1244 cm^{-1} , whereas spectral data reported for $\text{K}_2\text{S}_2\text{O}_6$ reveal a complex IR spectra in this region (16). In the absence of the lithium polythionates, dis-

Fig. 2. Infrared spectra of cathodes taken from two different Li/SO_2 cells discharged at 70°C . Curve a: washed cathode no. 1. Curve b: unwashed cathode no. 2.

tinction between the di- and poly-thionates cannot be unambiguously determined by IR in the presence of $\text{Li}_2\text{S}_2\text{O}_4$. Analysis employing the method of Murthy (17), currently in progress at NSWC (8), indicates dithionate formation. A hint of the 998 cm^{-1} band appears near the 1021 cm^{-1} peak, but is not obvious in the spectra. A band at 560 cm^{-1} is observed, which may or may not be associated with a lithium thionate. The thionate concentration may be insufficient in the presence of the predominant dithionite ($\text{S}_2\text{O}_4^{2-}$) for this band to be observed. The presence of a di- or tri-thionate can be explained by the redox scheme

The presence of sulfur was confirmed in the 70°C discharged cathode. The cathodes were washed with carbon disulfide. The carbon disulfide was evaporated, and the residue was confirmed to be sulfur by spot tests and differential scanning calorimetry. The sulfur could be produced through the above mechanism or as a result of the thermal decomposition of the lithium dithionite.

An unidentified band appears at $\sim 1160\text{ cm}^{-1}$ (1165 and 1155 cm^{-1} in Fig. 2) in the 70°C discharge which is not present in the low temperature discharges. Although S_2O has been observed as a minor constituent by mass spectroscopy and has IR bands at 1165 and 679 cm^{-1} (a shoulder at 679 cm^{-1} is seen in Fig. 2), this possibility appears remote, since S_2O is unstable at ambient temperature. A solution of SO_2 in CH_3CN exhibits a predominant peak at 1160 cm^{-1} . However, the possibility of the carbon cathode retaining the $\text{CH}_3\text{CN-SO}_2$ only at the 70°C and not at the -30° and 25°C discharges rules out $\text{CH}_3\text{CN-SO}_2$. Anhydrous Li_2SO_4 has a strong broad-band centered near 1140 cm^{-1} , whereas the hydrate displays split peaks at 1170 and 1110 cm^{-1} (18). Moisture content of the carbon may influence the position of the sulfate band. Although the presence of sulfate is strongly suggested by other bands, e.g., 661 cm^{-1} , an unequivocal assignment cannot be determined, since the unavailable lithium polythionates are likely to also absorb in this region.

A strong IR band is observed at 968 cm^{-1} . Recently, a similar band at 970 cm^{-1} was reported by Bowden *et al.*, which they attributed to be dithionate based on a comparison with IR spectra of $\text{Na}_2\text{S}_2\text{O}_6$ (19). However, a sample of $\text{Na}_2\text{S}_2\text{O}_6$, analyzed at $>99\%$ purity by standard methods, exhibited a band at 998 cm^{-1} . We attributed the band at 968 cm^{-1} to the presence of Li_2SO_3 . This was confirmed by comparing the spectra with that of Li_2SO_3 , which displayed a strong band at 967 cm^{-1} . The symmetric and asymmetric O-S stretching modes of the sodium salt give rise to a strong absorption around 970 cm^{-1} , and often the two fundamentals are seen separately at 970 and $930\text{--}940\text{ cm}^{-1}$ (12, 20). Such a splitting as observed in Fig. 2b explains the peak at 908 cm^{-1} and the shoulders observed from 940 to 949 cm^{-1} . Similarly, the symmetric S-O bend observed at $630\text{--}640\text{ cm}^{-1}$, which appears in the spectra of the unwashed cathode of Fig. 2b, is also attributed to Li_2SO_3 . The presence of Li_2SO_3 was observed in the x-ray pattern of this same cathode.

The washed cathode has a moderate band at $\sim 661\text{ cm}^{-1}$ and the hint of a weak peak near 612 cm^{-1} . The location of these bands are in excellent agreement with the IR spectra of anhydrous Li_2SO_4 , which exhibit strong and moderate bands at 660 and 612 cm^{-1} , respectively. The intensity and frequency of these bands may be influenced by the moisture content of the carbon cathode. Instead of two sharp bands, hydration produces a single broad-band near 634 cm^{-1} (18).

The spectra of the unwashed cathode (Fig. 2b) reveals a more complex IR pattern. In addition to the band near 657 cm^{-1} , there is another band in the $630\text{--}640\text{ cm}^{-1}$ region with a shoulder at $\sim 613\text{ cm}^{-1}$. The band at 657 cm^{-1} (664 and 657 cm^{-1} in Table II) and shoulder at 613 cm^{-1} appear consistent with the spectra of anhydrous Li_2SO_4 . The peak in the $630\text{--}640\text{ cm}^{-1}$ region is attributed to sulfite.

The bands $540\text{--}545\text{ cm}^{-1}$ and $504\text{--}500\text{ cm}^{-1}$ are in excellent agreement with similar bands observed for $\text{Li}_2\text{S}_2\text{O}_4$.

Minor IR bands.—The IR spectra of one of the unwashed cathodes from the 70°C discharged cells displayed several minor peaks and shoulders.

The shoulder at 1122 cm^{-1} could be due to the S-O stretching high frequency bands of sulfate, sulfite, or SOBr_2 ; the latter displays a single high frequency band at 1121 cm^{-1} (12).

The small shoulder at 1110 cm^{-1} is consistent with the presence of sulfate or sulfite. The hydrated lithium salts showed bands at 1113 cm^{-1} [1110 cm^{-1} , Ref. (18)] and $\sim 1108\text{ cm}^{-1}$, respectively. An infrared spectrum of a cathode sample from a -30°C discharged cell that had been exposed to air for 4 days developed an intense band at 1113 cm^{-1} . X-ray analysis confirmed this to be lithium sulfate. Similarly, the IR spectrum of a

washed cathode from a 70°C discharged cell that had been stored 4 months in a vacuum desiccator showed the development of a shoulder near 948 cm^{-1} as well as a peak at 1108 cm^{-1} . On opening the desiccator, a strong odor of SO_2 was noticed. These peaks may be due to sulfite, resulting from limited oxidation in an SO_2 atmosphere or slow decomposition of $\text{Li}_2\text{S}_2\text{O}_4$. Unlike the sodium salt, $\text{Li}_2\text{S}_2\text{O}_4$ is unstable. When 92% pure $\text{Li}_2\text{S}_2\text{O}_4$ was stored in a closed vial at ambient temperature, iodometric analysis nearly 1 yr later revealed only $\sim 8\%$ dithionite remaining.

The peaks at $630\text{--}646\text{ cm}^{-1}$ (Table II) and shoulder at $\sim 513\text{ cm}^{-1}$ are attributed to lithium sulfite. The IR pattern of $\text{Li}_2\text{SO}_3 \cdot 3\text{H}_2\text{O}$ has bands at 643 and 511 cm^{-1} . The nonappearance (Fig. 2a) and appearance (Fig. 2b) of the ($940\text{--}949\text{ cm}^{-1}$) band is consistent with the behavior previously reported for sulfite (12).

The incongruous bands at 1009 and 560 cm^{-1} in one of the 70°C cathodes could be an artifact, but might be a part of the spectrum of an unavailable lithium salt, such as a di- or poly-thionate.

The possibility of thiosulfate ($\text{S}_2\text{O}_3^{2-}$) and/or metabisulfite ($\text{S}_2\text{O}_5^{2-}$) cannot be ruled out under some discharge conditions. The spectra of $\text{Li}_2\text{S}_2\text{O}_3$ and $\text{Na}_2\text{S}_2\text{O}_5$ were recorded and have several bands in common with the observed cathode spectra. Thiosulfate has been reported in D-size Li/SO_2 cells (21), and iodometric studies on these same $\frac{1}{2}$ A-size cells indicate thiosulfate (2, 8). Additionally, hydrolysis of dithionite in an aqueous acid medium is well known to produce thiosulfate. Mass spectroscopy studies on carbon cathodes from commercial SO_2 cells were found to contain as much as 18% water upon heating to 275°C (8). Moist carbon cathodes may be a suitable acidic medium to promote hydrolysis. Similarly, water has been reported to promote the decomposition of dithionite to both thiosulfate and metabisulfite (22).

The spectra of $\text{Li}_2\text{S}_2\text{O}_3$ has major broad bands at ~ 1112 and 1000 cm^{-1} , a moderate band near 680 cm^{-1} , and a weak band at 550 cm^{-1} . The 1000 and 550 cm^{-1} bands are not far removed from the observed incongruous peaks, and a hint of a 679 cm^{-1} shoulder is present in Fig. 2.

Sodium metabisulfite—displayed bands at ~ 1180 , a $1056\text{--}1068$ doublet, 978 , 653 , 568 , and 415 cm^{-1} resemble the pattern, if not the intensity, of several weak to moderate bands in Table II. However, the absence of the strong bands in the $\sim 1060\text{ cm}^{-1}$ region is an argument against the presence of metabisulfite. Since acceptance of this manuscript, a recent paper has reported that metabisulfite is present in cells discharged at 72°C (24).

ESR spectroscopy.—Electron spin resonance (ESR) studies were carried out on the cathodes from the discharged cells and compared with laboratory-synthesized $\text{Li}_2\text{S}_2\text{O}_4$. The solid $\text{Li}_2\text{S}_2\text{O}_4$ synthesized in the laboratory displays a strong ESR signal with G values of 2.0076 , 2.0053 , and 2.0036 . The signal has been attributed to the presence of the SO_2^- radical anion in the sample (5), and arises from the homolytic cleavage of the disulfide bond in dithionite.

The effects of temperature on the ESR spectra of $\text{Li}_2\text{S}_2\text{O}_4$ can be seen in Fig. 3. At low temperature the signal is broad. It sharpens and splits as the temperature is raised. The intensity of the signal increases dramatically with temperature reaching a maximum at 220°C , corresponding to the approximate exothermic decomposition temperature of the dithionite, whereupon the ESR signal decays quickly and irreversibly. This behavior implicates SO_2^- in the thermal decomposition of $\text{Li}_2\text{S}_2\text{O}_4$.

The half-field signal ($\Delta m = 2$) at low temperatures for crystalline $\text{Li}_2\text{S}_2\text{O}_4$ has been reported (4). The presence of the half-field signal is evidence for the interaction of trapped pairs of radicals in well-defined

Fig. 3. The effects of temperature on the ESR spectra of Li₂S₂O₄

Fig. 4. ESR spectra of unwashed cathodes from discharged Li/SO₂ cells (a, top curve) -30°C, (b, middle curve) 25°C, (c, bottom curve) 70°C. All spectra taken at room temperature.

locations within the lattice. Intensity considerations indicate that the splitting of the $\Delta m = 1$ transition should be considerable. However, paired $\Delta m = 1$ transitions attributable to interacting radicals could not be identified, most probably because of dipolar broadening from a large anisotropic zero field splitting. In addition, no ³³S hyperfine splittings were observed in the Li₂S₂O₄ samples.

ESR spectra of unwashed cathode samples are shown in Fig. 4. Washing the cathode samples with acetonitrile did not significantly affect the spectra. The cathodes discharged at -30° and 25°C differ little from each other, with the exception that the 25°C cell has more of a lower field signal, which is attributed to the dithionite. The obvious reason for this is that the 25°C cell has more capacity than the -30°C cell, and consequently more dithionite. The spectra of the cathode material discharged at 70°C are similar to those of the lower temperature discharges, but they are broader and less structured, indicating a greater amount of radical interaction or the presence of new radical species.

As shown in Fig. 5, the cathode spectra from the 25° and -30°C discharges have been interpreted as a sum of the spectra of two species: one due to the Li₂S₂O₄, and the other due to a radical species associated with the cathode carbon material, Shawinigan black. The spectra could be reproduced reasonably well by a mixture of ~5% Li₂S₂O₄ in carbon. It is not clear what role, if any, the carbon-based radical plays in the decomposition or discharge chemistry.

Conclusion

Laboratory synthesized Li₂S₂O₄ has been characterized by x-ray, infrared, and electron spin resonance spectroscopy.

The spectroscopic characteristics of the Li₂S₂O₄, together with the IR spectra of Li₂SO₃, Li₂S₂O₃, Li₂SO₄, and several sodium salts, were used to study the cathode products from Li/SO₂ cells discharged at -30°, 25°, and 70°C. Li₂S₂O₄ was confirmed to be essentially the major product formed at -30° and 25°C using x-ray and IR spectroscopy. The 70°C discharged cathode revealed a different set of products. The principal prod-

Fig. 5. ESR spectra for shawinigan black, solid $\text{Li}_2\text{S}_2\text{O}_4$, and carbon cathode from a Li/SO_2 cell discharged at 25°C .

uct was dithionite. The presence of sulfite, sulfur, and $\text{Li}_2\text{S}_2\text{O}_6$ or $\text{Li}_2\text{S}_n\text{O}_6$ was confirmed. Sulfate also appears to be present. Some thiosulfate or metabisulfate may be present.

Thermal decomposition of dithionite (4, 23), as indicated below

may account for some of these products. Thermal stability studies of dithionite are in progress.

Results of ESR studies on $\text{Li}_2\text{S}_2\text{O}_4$ at different tem-

peratures implicate the SO_2^- radical in the thermal decomposition mechanism of $\text{Li}_2\text{S}_2\text{O}_4$. A radical species associated with the cathode carbon material is also present.

Mathematical Modeling of the Lithium, Thionyl Chloride Static Cell

I. Neutral Electrolyte

Keh-Chang Tsauro* and Richard Pollard**

Department of Chemical Engineering, University of Houston, Houston, Texas 77004

ABSTRACT

A mathematical model of the Li-LiAlCl₄, SOCl₂-C static cell with neutral electrolyte is presented. The model considers a whole prismatic cell consisting of negative electrode, separator, electrolyte reservoir, and positive electrode. Physical phenomena described are ohmic potential drop and diffusion potential in the electrolyte, changes in porosity and electrolyte composition due to electrochemical reactions, local reaction rates, and diffusion, convection, and migration of electrolyte. The theoretical results show the trends in behavior observed experimentally. The effects of state of charge, initial electrolyte composition, electrode thickness and porosity, and current density are presented, and factors that can limit cell performance are identified.

The Li-LiAlCl₄/SOCl₂-C primary cell has received considerable attention as a high energy density power source (1-4). A mathematical model is needed to predict the operational characteristics of the system and to assess the influence of changes in design parameters on the cell performance.

Models have been proposed to describe the behavior of flooded porous electrodes (5). Specific systems that have been investigated include electrodes with sparingly soluble reactants such as the Ag-AgCl and Cd-Cd(OH)₂ couples (6), and electrodes of zinc (7) and of lead dioxide (8, 9).

Far less effort has been directed toward modeling complete cells and, up until now, only the lead acid battery (10, 11) and the LiAl/FeS molten salt battery (12, 13) have been analyzed in detail. In this paper, a one-dimensional model is presented for the lithium, thionyl chloride system with a neutral electrolyte. A whole prismatic cell is considered, consisting of negative electrode, separator, electrolyte reservoir, and positive electrode (see Fig. 1). The model can be used to identify system limitations and to help guide experimental research.

Model Development

The analysis is based on the macroscopic theory of porous electrodes in which the solution and matrix phases are treated as superposed continua without regard for the geometric details of the pores (14). With this approach, one can obtain a consistent framework for the description of isothermal transport processes in the electrolyte (5).

A material balance for species *i* is given by

$$\frac{\partial(\epsilon c_i)}{\partial t} = a_{j_{in}} - \nabla \cdot \underline{N}_i \quad [1]$$

where \underline{N}_i is the flux of species *i* in the pore solution averaged over the cross-sectional area of the electrode and where $a_{j_{in}}$ represents the transfer rate of species *i* from the solid phases to the pore solution per unit electrode volume. The superficial current density in the pore solution is due to the movement of charged species

$$\underline{i}_2 = F \sum_i z_i \underline{N}_i \quad [2]$$

and, as a consequence of electroneutrality, the divergence of the total current density is zero. For a single electrode reaction of the form

Faraday's law can be expressed as

$$a_{j_{in}} = - \frac{s_{ij}}{nF} = - \frac{s_i}{nF} \nabla \cdot \underline{i}_2 \quad [4]$$

provided that double-layer charging is ignored.

A material balance on the solid phases indicates how the electrode porosity changes with the extent of reaction at each location within the electrode (5)

$$\frac{\partial \epsilon}{\partial t} = \sum_{\text{solid phases}} \frac{\tilde{V}_i}{nF} \nabla \cdot \underline{i}_2 \quad [5]$$

The flux of mobile species in the electrolyte can be attributed to the combined effects of diffusion, migration, and convection. For the neutral Li/SOCl₂ cell, the electrolyte is regarded as a concentrated mixture of lithium cations and chloroaluminate anions in thionyl chloride. Inversion of the multicomponent diffusion equations yields explicit relationships for the fluxes (5, 15)

$$\underline{N}_+ = -\epsilon D \nabla c_e + \frac{t_+ \underline{i}_2}{z_+ F} + c_+ \underline{v} \quad [6]$$

$$\underline{N}_- = -\epsilon D \nabla c_e + \frac{t_- \underline{i}_2}{z_- F} + c_- \underline{v} \quad [7]$$

$$\underline{N}_o = -\epsilon D \nabla c_o + c_o \underline{v} \quad [8]$$

where the subscripts +, -, e, and o refer to Li⁺, AlCl₄⁻, LiAlCl₄, and SOCl₂, respectively, and where *D* is the effective diffusion coefficient of the electrolyte. The volume average velocity, $\underline{v} = \sum_i \tilde{V}_i \underline{N}_i$, has been

Fig. 1. Schematic diagram of Li-LiAlCl₄/SOCl₂-C static cell

** Electrochemical Society Active Member.

Key words: porous electrodes, cell performance, galvanostatic discharge.

chosen as the reference frame because physical data for LiAlCl_4 , SOCl_2 electrolytes are often correlated with the concentration (see Appendix). Substitution of Eq. [6]-[8] into the material balance Eq. [1] and rearrangement gives an overall conservation equation

$$\frac{\partial e}{\partial t} + \nabla \cdot \underline{v} = a \left[\nabla_{\text{O}^{\ominus}} j_{\text{O}^{\ominus}} + \frac{\nabla_{\text{e}^{\ominus}} t_{+}^{\ominus}}{\nu_{+}} j_{+n} + \frac{\nabla_{\text{e}^{\ominus}} t_{-}^{\ominus}}{\nu_{-}} j_{-n} \right] - \nabla_{\text{e}^{\ominus}} \frac{i_2 \cdot \nabla t_{+}^{\ominus}}{z_{+} + \nu_{+} F} - \epsilon \frac{D}{c_0 \bar{V}_0} (\nabla c_e) \cdot \nabla \bar{V}_e \quad [9]$$

The movement of electrons in the matrix phase is governed by Ohm's law

$$\underline{i}_1 = -\sigma \nabla \Phi_1 \quad [10]$$

where σ is the effective matrix conductivity. In the electrolyte, the variation in solution potential is given by (5)

$$\frac{i_2}{\kappa} = -\nabla \Phi_2 - \frac{1}{F} \left(\frac{s_{+}}{\nu_{+}} + \frac{t_{+}^{\ominus}}{z_{+} + \nu_{+}} - \frac{s_0 c_e}{n c_0} \right) \nabla \mu_e \quad [11]$$

where Φ_2 is measured with a reference electrode that has stoichiometric coefficients s_i and number n of electrons transferred, and μ_e is the chemical potential of the electrolyte (16)

$$\mu_e = \nu RT \ln (c_e f_{+} - a^{\theta} -) \quad [12]$$

Equation [10] may be subtracted from Eq. [11] to obtain variations in the overpotential $\eta = \Phi_1 - \Phi_2$ directly (17).

Polarization equations are needed to express the dependence of the local rate of each reaction on the various concentrations and on the potential difference driving force at the reaction interface. Electrode kinetics do not follow fundamental laws that can be expressed as reliably as Ohm's law or the law of conservation of matter. Therefore, the polarization relationships will be subject to further refinement as one tries to account not only for the charge transfer mechanism but also for electrode morphology, formation of covering layers, and mass transport to and from reaction sites. It is common to begin with a polarization equation of the form

$$j = a i_0 [e^{\alpha_s F \eta_s / RT} - e^{-\alpha_c F \eta_s / RT}] \quad [13]$$

where η_s is the local value of the surface overpotential, $\eta_s = \eta - U_w$, and where the exchange current density i_0 can be written as

$$i_0 = i_{0,\text{ref}} \pi \left(\frac{c_{i,w}}{c_{i,\text{ref}}} \right)^{\gamma_i} \frac{\pi a_k \gamma_k}{k} \quad [14]$$

The activity a_k for a pure solid reactant or product may be taken as unity. The theoretical open-circuit potential for a reaction is given by (18)

$$U_w = U^{\theta} - U_{\text{re}}^{\theta} + \frac{RT}{n_{\text{re}} F} \sum_i s_{i,\text{re}} \ln \left(\frac{c_{i,\text{re}}}{\rho_0} \right) - \frac{RT}{nF} \sum_i s_i \ln \left(\frac{c_{i,w}}{\rho_0} \right) \quad [15]$$

provided that activity coefficient corrections can be neglected. The potential U_w is equal to zero if the reference electrode has a reaction of the same kind as the working electrode, measured at the composition prevailing locally at the surface of the working electrode.

The complicated processes in the positive electrode are represented by (19)

It is assumed that the S and SO_2 produced by reaction [I] dissolve in the electrolyte (20). Furthermore, the

model supposes that, as a result of low solubility in the neutral electrolyte (20, 21), pure LiCl precipitates instantaneously and passivates a fraction of the active surface area of the carbon matrix in accordance with

$$a = a^{\circ} [1 - (\epsilon_{\text{LiCl}} / \epsilon_p)^p] \quad [16]$$

The magnitude of the exponent p reflects the morphology of the LiCl precipitate: large values represent long, needle-like crystals, whereas small values imply that flat, passivating films are produced (6, 22). Inclusion of the initial porosity in Eq. [16] corresponds, indirectly, to a dependence of crystallite shape on mechanical constraints (23). Any effects of factors such as temperature, current density, or impurities on the morphology are not considered in the initial analysis.

The overall discharge reaction at the negative electrode is

A LiCl film forms over the surface of the lithium by a reaction of the type (24)

It is assumed that reaction [II] occurs at the lithium surface, and that lithium ions are transported through the LiCl film and transferred to the electrolyte. The LiCl film can be described as a solid electrolyte interphase (SEI) with an outer porous layer (25, 26). However, neither detailed transport properties for the SEI nor local porosities for the porous layer are available. Consequently, the present analysis makes several simplifying assumptions. The film is regarded as a homogeneous region that can be characterized by a single bulk conductivity. This conductivity is used in Eq. [10] to calculate the potential drop across the film. The potential difference η_s at the Li/LiCl film interface is determined from Eq. [13] with j/a replaced by I and with i_0 independent of concentration. As a discharge proceeds and lithium is consumed, it is assumed that growth of the LiCl film and forces from outside the cell or from LiCl precipitation in the cathode maintain contact between Li, LiCl film, and separator. If a gap does develop in the anode, the potential drop across this region would need to be included in the calculation of electrode resistance.

With the simplified model for the anode, it is not necessary to determine the concentration profile for lithium ions in the film. However, the SOCl_2 flux N_0 across the film must be calculated to assess the changes in film thickness. If convection terms are omitted from Eq. [6]-[8] and physical properties are taken as constant, the SOCl_2 concentration profile within the film is linear. Under these circumstances, the SOCl_2 flux is given by

$$N_0 = \frac{D_f}{\delta_f} [(c_0)_b - (c_0)_a] \quad [17]$$

where D_f is an effective diffusivity for SOCl_2 in the film, δ_f is the film thickness, and $(c_0)_b$ and $(c_0)_a$ are reactant concentrations at the separator and lithium interfaces, respectively. Reaction [III] is expected to be very fast, and, therefore, $(c_0)_a$ is taken to be zero. The flux in Eq. [17] is equal to the reaction rate r_{III} per unit separator area.

The production of LiCl by reaction [III] can alter either the porosity or the thickness of the protective film (25, 26). If only thickness changes are significant, a mass balance gives

$$\frac{d\delta_f}{dt} = s_{\text{LiCl,III}} \tilde{V}_{\text{LiCl}} r_{\text{III}} \quad [18]$$

As a discharge proceeds, increases in δ_f tend to lower the conversion rate, as predicted by Eq. [17]. A reduction in film porosity would also show this trend,

but indirectly, through changes in the effective diffusivity D_f .

The temperature is assumed to be uniform throughout the cell sandwich, but it can change with time in response to reversible heat effects, Joule heating, overpotentials associated with electrode reactions, and corrosion at the negative electrode. The first law of thermodynamics gives

$$C \frac{dT}{dt} = \left(U_o - V - T_o \frac{\partial U_o}{\partial T} \right) I - h_o(T - T_A) + (\Delta H_R)r_{III} \quad [19]$$

where C is the cell heat capacity per unit separator area, and h_o is the heat transfer coefficient between the cell and the surroundings. The total cell voltage V is obtained by integration of local matrix and electrolyte potential gradients in the electrodes and separator, in accordance with Eq. [10] and [11]. Kirchhoff's voltage law requires inclusion of the surface overpotentials (with appropriate signs) at the front of each electrode, as well as the difference in potential between the two types of reference electrode at one location. Resistances of the electrolyte reservoir and current collector can also be included.

The Li-LiAlCl₄/SOCl₂-C system can be described by local variables c_e , \underline{v} , ϵ , j , i_2 , and η and by the governing Eq. [1] (for the electrolyte), [4], [5], [9], [11] (in conjunction with Eq. [10]), and [13], subject to the following boundary conditions: (i) at the LiCl film/separator interface

$$\begin{aligned} \text{(a) } i_2 &= I \\ \text{(b) } c_i, \underline{N}_i &\text{ continuous} \end{aligned} \quad [20]$$

(ii) at the positive electrode/reservoir interface

$$\begin{aligned} \text{(a) } i_2 &= I \\ \text{(b) } c_1 &\text{ continuous} \\ \text{(c) } \frac{\partial}{\partial t} \left(\frac{V_R}{A} c_1 \right) &= \underline{N}_I - \underline{N}'_I \end{aligned} \quad [21]$$

(iii) at the positive electrode/current collector interface

$$\begin{aligned} \text{(a) } i_2 &= 0 \\ \text{(b) } \underline{v} &= 0 \\ \text{(c) } \underline{N}_I &= 0 \end{aligned} \quad [22]$$

where \underline{N}_i and \underline{N}'_i in Eq. [21] are the species fluxes that enter and leave the reservoir, respectively. (It should be noted that the subscript i in Eq. [20]-[22] refers to any species in the electrolyte. Also, the term "continuous" means that a variable is assigned only one value at the location in question, but that this value can change with time during cell discharge.) The electrolyte composition is assumed to be uniform across the reservoir. In the separator, the governing equations can be simplified with

$$\begin{aligned} \text{(a) } i_2 &= I \\ \text{(b) } j &= 0 \\ \text{(c) } \epsilon &= \epsilon_s \end{aligned} \quad [23]$$

The initial conditions are taken as

$$\begin{aligned} \text{(a) } c_i &= c_i^o \\ \text{(b) } \epsilon &= \epsilon^o \end{aligned} \quad [24]$$

The governing equations constitute a set of coupled, ordinary, nonlinear differential equations at each time step which are cast into finite difference form accurate to $O(h^2)$, and solved simultaneously by a numerical technique (16). Each nonlinear equation is linearized properly to assure convergence, and each time-dependent equation is programmed symmetrically between the old time-step and the present one, in order to attain stability.

Results and Discussion

Figure 2 shows composition profiles across a typical cell sandwich at several times during a constant current discharge of 80 mA/cm². When the discharge is started, lithium ions are introduced into the electrolyte by passage through the LiCl film at the negative electrode. They are then transported across the porous separator to the positive electrode, where they can react cathodically to form LiCl, in accordance with Eq. [1]. A concentration profile develops because the transference number of Li⁺ is not unity and because a chemical reaction can occur at the surface of the negative electrode. Consequently, diffusion aids migration in the transport of lithium ions across the cell.

The details of the composition variations can be attributed to the combined effects of diffusion, migration, convection, and electrochemical reaction. An

Fig. 2. Position dependence of electrolyte composition at different utilizations. Utilization is calculated on the basis of moles of SOCl₂ available: (a) 0.58%; (b) 3.70%; (c) 9.10%. Simulation parameters are presented in Tables I and II and in the Appendix.

almost constant composition gradient is established across the separator that corresponds to the flux of lithium ions needed for the specified current density. Porosity changes in the positive electrode accentuate local composition changes, and this, in turn, tends to raise the overall concentration level in the separator as discharge proceeds. The contribution of convection, which arises primarily from the influx or squeezing out of electrolyte as the porosity alters, is expected to be small for this system, ($v \sim O(10^{-5})$ cm/s). However, it is included in the analysis to ensure that the accuracy of the electrolyte material balances is retained (12).

The transfer current in the positive electrode is shown in Fig. 3, for several utilizations. The large electrode surface area of a typical carbon matrix material such as Shawinigan black (27) helps to create fast reaction kinetics. As a result, a highly nonuniform reaction distribution, dominated by ohmic effects, is obtained. Throughout the discharge, most of the reaction occurs near the electrode/reservoir interface and, because $\sigma/\kappa \gg 1$ (14), only a small amount of current is transferred near the back of the electrode. Precipitation of LiCl at the reaction zone close to the front of the electrode reduces the surface area available for reaction. This tends to increase the penetration depth (5) for the reaction and make the reaction distribution more uniform. Precipitation also reduces the porosity and, hence, the local effective conductivity of the electrolyte. For this reason, the transfer current in the region of lowest porosity (at the front face of the electrode) is larger at higher utilizations (see Fig. 3, curves b and c). The transfer current near the back of the electrode decreases in response to the concentration dependent term in the Ohm law relationship for the electrolyte.

Figure 4 shows microstructures in the positive electrode at a given depth of discharge for three discharge rates. The volume fraction of LiCl ($\epsilon_{\text{LiCl}} = \epsilon_p^0 - \epsilon_p$) corresponds directly to the cumulative reaction distribution, as dictated by integration of Eq. [5]. Most of the precipitation occurs near the electrode/reservoir interface, in keeping with the transfer current profiles

Fig. 3. Reaction distribution in the positive electrode at different utilizations. (a) 0.58%; (b) 3.70%; (c) 9.10%. Simulation parameters as in Fig. 2.

presented in Fig. 3. At higher current densities, the distribution is less uniform, particularly at the front of the electrode. The effect of current density on the porosity at this location is more noticeable at greater depths of discharge.

Figure 5 shows the predicted dependence of total cell voltage on utilization for three discharge rates. The increase in electrolyte conductivity in the separator, which results from a local change in solution concentration (see Fig. 2), overcomes the increase in potential drop associated with growth of the LiCl film and gives a small voltage rise shortly after the beginning of discharge. At higher current densities, the electrolyte concentration in the separator increases more rapidly, and this makes the initial voltage rise more distinct. However, an initial voltage rise is not predicted for cells with $c_e^0 \gtrsim 1.5M$ because changes in electrolyte conductivity are less significant at high concentrations (see Eq. [A-1]). For all three curves, the sharp reduction in cell voltage at the end of discharge is caused by the localized porosity reduction at the front face of the positive electrode. The plugging of porous electrodes has been cited as a possible cause of failure in other cells (7, 12, 28). Before the onset of failure, the cell voltage remains relatively constant. The shape of the voltage curve is steeper and the cell lifetime is shorter at higher current densities because the reaction distribution in the positive electrode is less uniform and, to a lesser extent, because there is less time for diffusional processes to take place. The triangle on the 40 mA/cm² curve indicates the onset of precipitation of sulfur in the cell. This is calculated on the basis of a saturation concentration of 1M, a uniform sulfur distribution, and the stoichiometry of Eq. [I]. In principle, sulfur deposition could reduce the porosity close to the reaction front in the cathode and hence control the cell lifetime. However, experimental evidence (23) indicates that sulfur precipitates in voids away from the LiCl, and does not interfere with discharge significantly. Therefore, formation of solid sulfur has not been included in the present model.

The dependence of cell lifetime on initial porosity in the positive electrode and on galvanostatic discharge rate is summarized in Fig. 6. With a smaller ϵ_p^0 , less space is available to accommodate LiCl crystals and the pores at the cathode face are blocked more readily. In the absence of reaction distribution effects, the lifetime-porosity relationship would be linear (29). The predicted nonlinearity results from the dependence of deposit morphology on ϵ_p^0 (see Eq. [16]).

Figure 7 shows that cell lifetime is expected to increase with electrode thickness, but that the effect is relatively small above a certain value of L_p . Overall, variations are caused by changes in local reaction rates within the electrode. If an electrode is thinner than the penetration depth of approximately 0.3 mm (see Fig. 4), the magnitude of the transfer current is higher locally in order to satisfy the total current density

$$I = \int_0^{L_p} j dy \quad [25]$$

The increase in j is most significant at the front face of the electrode, and the cell fails rapidly by plugging of pores with LiCl at this location. For electrodes thicker than the penetration depth, small but finite transfer currents are predicted behind the reaction front (see Fig. 3). This gradually accounts for a larger proportion of the total current density as thickness is increased and, as the distribution of reaction and LiCl precipitation become more uniform, cell lifetime is extended.

The influence of initial electrolyte concentration on cell lifetime is presented in Fig. 8. As c_e^0 is increased from zero, the electrolyte conductivity becomes larger, the reaction distribution becomes more uniform and,

Fig. 4. Distributions of ϵ_{LiCl} in the positive electrode at different discharge rates for a utilization of 3.4%. Parameters as in Fig. 2, except as indicated.

Fig. 5. Theoretical discharge curves at different constant current densities. Parameters as in Fig. 2, except as indicated.

hence, the discharge lasts longer. At higher concentrations, the conductivity approaches a constant value (see Eq. [A-1]), and the concentration dependence of the exchange current density dominates the cell behavior. A higher value of i_0 reduces the penetration depth in the cathode, forces the reaction closer to the front of the electrode, and, in turn, reduces the cell lifetime.

Many of the theoretical results described above are in close agreement with experimental observations. It is difficult to make detailed quantitative comparisons

because published experimental results do not include all the input data required for the model. However, the maximum in cell lifetime at $c_e^0 = 1.5M$ compares favorably with the optimum of $1.6M$ obtained in the laboratory (21). Also, the trends in behavior shown in Fig. 6 and 7 are supported by experimental results (22, 30-32), as are details such as the initial voltage rises in Fig. 5 (21, 30) and the LiCl distributions in Fig. 4 (31). Nevertheless, it is necessary to compare additional factors and to access critically the sensitivity of model predictions to the input data.

Fig. 6. Dependence of cell lifetime on discharge current density and initial electrode porosity. Simulation parameters as in Fig. 2, except I and ϵ_p^0 . The lifetime of the cell described in Fig. 2 is denoted by t_{cell}^* .

Fig. 7. Dependence of cell lifetime on positive electrode thickness. Simulation parameters as in Fig. 2, except L_p ; t_{cell}^* as defined for Fig. 6.

One difference between theoretical and experimental results is that predicted cell voltages are approximately 500 mV higher than those obtained in actual cells (30). The sensitivity of model predictions to several parameters that could affect cell voltage is discussed below.

1. *Positive electrode matrix conductivity.*—If σ_p is reduced by a factor of 200, the predicted voltage only falls by 170 mV. Also, significant LiCl deposition is

Fig. 8. Dependence of cell lifetime on initial electrolyte concentration. Simulation parameters as in Fig. 2, except c_e^0 ; t_{cell}^* as defined for Fig. 6.

predicted near the current collector, which is contrary to experimental observations (23, 31).

2. *Exchange current density for positive electrode reaction.*—Figure 9 indicates that reducing $a^0 i_{o,ref}$ by two orders of magnitude has a relatively small effect on the total cell voltage but extends the cell lifetime significantly. To reduce the cell voltage to the experimentally observed value of approximately 3V, it would be necessary to use $a^0 i_{o,ref} = O(10^{-6})$ A/cm². With this value, the reaction distribution in the cathode is relatively uniform, and predicted utilizations are considerably greater than those attainable in practice.

3. *Exchange current density for negative electrode reaction.*—With a smaller value of i_o , the potential drop across the Li/LiCl interface is increased and, hence, the cell voltage is lowered. If, for example, i_o is reduced by a factor of 100 to 1.0×10^{-8} A/cm², the cell voltage becomes approximately 3.1V for $I = 80$ mA/cm². In contrast to 1 and 2 above, this change does not introduce other discrepancies with experimental observations.

4. *Conductivity of LiCl film at negative electrode.*—A straightforward reduction of σ_f reduces the cell voltage V , but gives a much larger dependence of V on discharge rate than is actually obtained (30, 31).

Table I. Kinetic parameters used in model

Parameter	Negative electrode		Positive electrode	
	Value	Value	Value	Parameter
$\alpha_a = \alpha_c$	0.5	1.0	1.0	$\alpha_a = \alpha_c$
η	1.0	2.0	2.0	η

$\sigma_{LiCl, III}$	2.0	1.0×10^{-8}	1.0×10^{-8}	$c_{o,ref}$ (mol/cm ³)

Fig. 9. Dependence of galvanostatic discharge curve on $a^{\circ}i_{o,ref}$. Simulation parameters as in Fig. 2, except $a^{\circ}i_{o,ref}$.

However, this does not exclude LiCl film resistance as an explanation for the voltage discrepancy, because the nature of the film, and hence σ_f , might change with current density (25, 26). This possibility is supported by the dependence of cell coulombic efficiency λ on discharge rate. If a constant value of D_f is used in the simulations, λ is almost independent of current density. It is necessary to assume that D_f depends on I (see Table II) to give coulombic efficiencies that are close to experimental values (21). Theoretical predictions for λ are given in Table III. A large value of σ_f also imparts too great a slope to the discharge curves because the film thickness increases during discharge (see Eq. [18]). However, in practice, disruption of the film could give an effective film resistance that is less dependent on utilization.

These results suggest that factors 3 and 4 are more likely to be responsible for the voltage discrepancy than factors 1 and 2.

With values for the total cell voltage that are too high, the magnitude of the heat-generation rate will be underestimated (see Eq. [19]). Consequently, predicted cell temperatures are expected to be lower than those obtained experimentally. However, it should be noted that overall cell temperature changes depend markedly on experimental conditions: test cells might be operated isothermally, adiabatically, or with well-

defined heat-transfer conditions, and battery modules might include facilities for thermal management.

Temperature changes during discharge can have a significant impact on cell behavior. As the temperature rises, increases in the conductivity and diffusivity of the electrolyte, and a reduction in the driving force term $F\eta/RT$ for the electrochemical reaction, make the reaction distribution more uniform and prolong the cell lifetime. However, an increase in positive electrode exchange current density would tend to offset this change. With the assumption of constant i_o , isothermal and adiabatic runs give the shortest and longest cell lifetimes, respectively. For the 80 mA/cm² discharge in Fig. 5, the model predicts a 14% difference in t_{cell} for these two extreme cases. This is in qualitative agreement with experimental data (30). In both cases, the rate of heat generation by chemical reaction declines during discharge, primarily because the film thickness increases and the SOCl₂ flux through the film is reduced (see Eq. [18]). The magnitude of this effect is illustrated by the changes in coulombic efficiency with depth of discharge, as shown in Table III.

In addition to the cell temperature and the positive electrode exchange current density, several other factors can influence cell lifetime:

1. *Electrode expansion.*—In practice, the plugging of pores at the end of discharge may be delayed by swelling of the positive electrode as a result of LiCl precipitation. If expansion occurs to accommodate the volume made available by consumption of lithium, it is possible that additional LiCl will precipitate before cell failure. For the operating conditions specified in Fig. 2, a 75% increase in LiCl deposition is feasible, provided that it can occupy all the free space generated. The maximum usable cell capacity can be sensitive to the

Table II. Physical parameters used in analysis

Parameter	Value
U_o (1, 30, 38) (V)	3.64
$\partial U_o / \partial T$ (38) (V/K)	1.026×10^{-3}

f_{+}	1.0

Table III. Dependence of coulombic efficiency (%) on discharge rate and utilization. Simulation parameters as in Fig. 2.

Utilization (%)	I (mA/cm ²)		
	40	80	120
1	89.4	84.3	80.6
5	90.6	86.9	84.4
9	91.5	88.5	86.2

details of the expansion process because (i) increases in free volume for LiCl and in utilization are, in principle, synergistic, and (ii) the matrix conductivity can change locally and alter the cell behavior (see above).

2. *Transfer coefficients for positive electrode reaction.*—If the values of α_a and α_c are changed from 1.0 to 0.5, the reaction distribution becomes more uniform and, to a first approximation, the cell lifetime is doubled.

3. *Polarization equation for positive electrode.*—If the anodic term in Eq. [13] is neglected (on the basis of the irreversibility of reaction [I] (33)), the relationship between j and η_s is modified at small values of η_s . With the relation

$$j = -ai_0 e^{-\alpha_c F \eta_s / RT} \quad [26]$$

the reaction distribution is less uniform and, hence, the maximum cell lifetime is reduced. For the cell in Fig. 5 with $I = 80 \text{ mA/cm}^2$, t_{cell} is reduced by 25%. However, the use of Eq. [26] rather than Eq. [13] does not alter the overall trends in cell behavior significantly.

4. *Cation transference number.*—If a larger value of t_+ is used in the analysis, the concentration and reaction distributions become more uniform, and the cell lifetime increases (see Table IV). Changes in t_{cell} are dictated by a reduction in the magnitude of the concentration dependent term in the Ohm law relationship for the electrolyte rather than by variations in local solution conductivity or exchange current density. Table IV also indicates that composition variations do not control the dependence of usable cell capacity on discharge rate.

5. *Electrolyte diffusion coefficient.*—By analogy with changes in t_+ , an increase in D reduces concentration gradients and increases cell lifetime. With twice the value of D given in the Appendix, the model predicts an 8% increase in maximum utilization at 80 mA/cm^2 .

6. *Temperature dependence of cell potential.*—Recent experimental results (34) indicate that a negative value for $\partial U_o / \partial T$ (cf. Table II) may be more appropriate. In this case, the rate of heat generation within the cell will be higher. For nonisothermal systems, this will lead to an increase in t_{cell} (see above).

7. *Reservoir volume.*—An increase in V_R^0/A attenuates the composition changes at the front of the positive electrode. With $c_e^0 \approx 1.5M$, this reduces the electrolyte conductivity and, in turn, the cell lifetime. The effect is relatively small: a tenfold increase in V_R^0/A is needed to reduce the lifetime by 9% at 80 mA/cm^2 .

8. *Morphology parameter, p .*—The extent to which LiCl crystals reduce the surface area available for further reaction can have a profound effect on the discharge characteristics. If the value of p is increased from 0.1 to 0.3 and 0.5, the cell lifetime declines by 28% and 38%, respectively. This is a direct result of an increase in local values for ai_0 during discharge and, correspondingly, a less uniform cumulative reaction distribution.

Equation [16] assumes implicitly that some surface area remains active until the local porosity reaches zero. If the deposit morphology causes passivation before plugging occurs, the reaction would be able to

Table IV. Dependence of dimensionless cell lifetime ($t_{\text{cell}}/t_{\text{cell}}^*$) on discharge current density and cation transference number. Simulation parameters as in Fig. 2.

I (mA/cm ²)	t_+		
	0.5	0.75	1.0
80	1.00	1.12	1.21
120	0.53	0.61	0.66

penetrate further into the cathode and the discharge time would be extended. As with electrode swelling, this change would make the decline in cell voltage near t_{max} less sharp. Longer cell lifetimes may also be predicted if a significant quantity of LiCl can dissolve into the electrolyte and diffuse away from the reaction zone to favorable sites for precipitation.

The sensitivity of t_{cell} to the parameter p suggests that the effectiveness of additives (35, 36) on increasing cell lifetime could be associated with changes in the deposit morphology. However, it is necessary to isolate the influence of additives on each of the possible effects described above to help clarify their impact on the cell performance.

Conclusions

A mathematical model has been developed that can describe the time-dependent and position-dependent behavior of a complete Li-LiAlCl₄/SOCl₂-C static cell with neutral electrolyte. Composition and reaction distributions can be predicted, as well as variations in volume fractions of individual phases and electric potential across the cell. The results of the theoretical analysis show the general trends in discharge behavior that are observed experimentally. The model predicts that high internal resistance can develop in the positive electrode as a result of low local porosities which are, in turn, caused by large-volume, solid reaction products. Consequently, the maximum usable cell capacity can be dictated by the nonuniformity of the reaction distribution at the front of the positive electrode. Variations in cell design or operation that alleviate local plugging of pores should be able to prolong cell lifetime. The model also indicates an optimum initial electrolyte concentration of approximately 1.5M and a range of acceptable positive-electrode thicknesses.

APPENDIX

Physical properties of the Li-LiAlCl₄/SOCl₂-C system

Electrolyte conductivity.—The dependence of bulk electrolyte conductivity on composition and temperature is described by

$$\kappa_e = \begin{cases} ac_e e^{-E/T} & c_e \leq 1M \\ b(1 - e^{-dc_e + f}) e^{-E/T} & 1M < c_e < 1.73M \\ be^{-E/T} & c_e \geq 1.73M \end{cases} \quad [A-1]$$

where $a = 48.97$, $b = 6.843 \times 10^{-2}$, $d = 4032.0$, $f = 2.9$, and $E = 361.0 \text{ K}$ (1, 41). The effective conductivity in the porous media is estimated from

$$\kappa = \epsilon \kappa_e / \zeta^2 \quad [A-2]$$

where the tortuosity factor ζ^2 is directly related to porosity by

$$\zeta = e^{(1-q)/2} \quad [A-3]$$

and the constant q is taken as 1.5 (42).

Diffusion coefficient.—The diffusion coefficient is assumed to be independent of electrolyte concentration, and to have the same dependence on temperature as electrolyte conductivity

$$D_e = 3.35 \times 10^{-5} e^{-361/T} \quad [A-4]$$

The molecular diffusion coefficient in the porous media can be characterized by

$$D = D_0/\zeta^2 \quad [\text{A-5}]$$

together with Eq. [A-3].

Matrix conductivity.—In general, the matrix conductivity can be influenced by the volume fraction of the conducting phases, the inherent conductivity of each solid phase, and the manner in which the particles of conducting phases are interconnected. However, in the present model, the matrix conductivity is assumed to be unaffected by precipitation of LiCl, and is expressed as

$$\sigma_p = \sigma_{p,0}(1 - \epsilon_p^0)^q \quad [\text{A-6}]$$

where (27) $\sigma_{p,0} = 45.5$ mho/cm and $q = 1.5$.

LIST OF SYMBOLS

a	interfacial area per unit electrode volume (cm^{-1})
a_k	relative activity of solid species k
$a^{\theta+}$	property expressing secondary reference state (cm^3/mol)
A	cross-sectional area of electrode (cm^2)
c_e	$= c_+/\nu_+ = c_-/\nu_-$ molar concentration of electrolyte (mol/cm^3)
c_i	concentration of species i (mol/cm^3)
C	cell heat capacity ($\text{J}/\text{cm}^2 \cdot \text{K}$)
D	diffusion coefficient (cm^2/s)
D_f	effective diffusivity of SOCl_2 in LiCl film (cm^2/s)
f_{+-}	mean molar activity coefficient of electrolyte
F	Faraday's constant (96,487 C/eq)
h	mesh size (cm)
h_0	heat transfer coefficient ($\text{W}/\text{cm}^2 \cdot \text{K}$)
ΔH_R	heat of reaction for the reaction defined by Eq. [III] (J/mol of SOCl_2 consumed)
i_0	exchange current density for positive electrode reaction (A/cm^2)
i_0'	exchange current density for negative electrode reaction (A/cm^2)
i_1	superficial current density in matrix phase (A/cm^2)
i_2	superficial current density in pore phase (A/cm^2)
I	superficial current density to an electrode (A/cm^2)
j	$= \nabla \cdot i_2$, transfer current per unit electrode volume (A/cm^3)
j_{in}	pore wall flux of species i ($\text{mol}/\text{cm}^2 \cdot \text{s}$)
L	electrode thickness (cm)
M_i	symbol for the chemical formula of species i
n	number of electrons transferred in electrode reaction
N_i	superficial flux of species i ($\text{mol}/\text{cm}^2 \cdot \text{s}$)
p	morphology parameter defined by Eq. [16]
Q	cell capacity (based on moles of SOCl_2) (C/cm^2)
r_{III}	reaction rate of chemical reaction (mol of SOCl_2 consumed/ $\text{cm}^2 \cdot \text{s}$)
R	universal gas constant ($8.3143 \text{ J}/\text{mol} \cdot \text{K}$)
s_i	stoichiometric coefficient of species i in electrode reaction
t	time (s)
t_{cell}	cell lifetime (s)
t_{cell}^*	lifetime of the cell described in Fig. 2 (s)
t_i^{\square}	transference number of species i with respect to the volume average velocity
T	absolute temperature (K)
T_A	temperature of surroundings (K)
T_0	initial temperature (K)
U_w	theoretical open-circuit potential for the reaction at the composition prevailing locally at the electrode surface, relative to a reference electrode of a given kind (V)
U^{θ}	standard electrode potential for reaction (V)
U_0	open-circuit cell potential (V)
\bar{v}^{\square}	volume average velocity (cm/s)
\bar{V}	total cell voltage (V)
\tilde{V}	molar volume (cm^3/mol)
\tilde{V}_i	partial molar volume of species i (cm^3/mol)
V_R	reservoir volume (cm^3)
z_i	valence or charge number of species i

Greek Letters

α_a	transfer coefficient in anodic direction
α_c	transfer coefficient in cathodic direction
γ_i, γ_k	exponents in Eq. [14]

δ_f	LiCl film thickness (cm)
ϵ	porosity or void volume fraction
ϵ_{LiCl}	volume fraction of LiCl
ζ	tortuosity defined by Eq. [A-3]
η	$\Phi_1 - \Phi_2$
κ	effective solution conductivity (mho/cm)
λ	coulombic efficiency
μ_e	chemical potential of electrolyte (J/mol)
ν	$= \nu_+ + \nu_-$, number of mols of ions into which a mol of electrolyte dissociates
ν_+, ν_-	number of cations and anions into which a molecule of electrolyte dissociates
ρ_0	density of pure solvent (g/cm^3)
σ	effective matrix conductivity (mho/cm)
Φ_1	electric potential in the matrix (V)
Φ_2	electric potential in the solution (V)

Mathematical Modeling of the Lithium, Thionyl Chloride Static Cell

II. Acid Electrolyte

Keh-Chang Tsaur* and Richard Pollard**

Department of Chemical Engineering, University of Houston, Houston, Texas 77004

ABSTRACT

A mathematical model for a complete Li/SOCl₂ static cell with acid electrolyte is presented. Concentrated solution theory is extended to account for the presence of two neutral species in the electrolyte. The effects of initial acid concentration, positive electrode thickness, and galvanostatic discharge rate on cell performance are elucidated. Results are compared with equivalent cells that use a neutral electrolyte.

The discharge capacity of a Li/SOCl₂ reserve cell can be increased by addition of excess AlCl₃ to the electrolyte (1). A mathematical model is needed to explain the effects of the acid on cell behavior and to assess the influence of changes in design parameters on the system performance. For this analysis, it is necessary to extend concentrated solution theory to account for the presence of AlCl₃ in the electrolyte.

The multicomponent diffusion equation has been used to describe the effects of convection, diffusion, and migration in concentrated solutions with two or more electroactive constituents (2-4), and in mixtures of two binary molten salts with a common ion (5). In this paper, a consistent set of transport equations is presented for a binary electrolyte in two neutral solvents. The equations are used in conjunction with the macroscopic theory of porous electrodes (6) to describe the behavior of the Li-LiAlCl₄, AlCl₃/SOCl₂-C primary cell. System limitations are identified and results are compared with cells that use a neutral electrolyte (7). The cell configuration that is analyzed is shown in Fig. 1 of Ref. (7).

Model Development

The material balance equation, the relationship for the superficial current density in the pore solution, and Ohm's law for the solid phases are the same as in the neutral electrolyte model (7). However, many of the other governing equations need to be modified to include simultaneous electrochemical and chemical reactions and the details of the transport phenomena in the acid electrolyte.

For simultaneous reactions of the form

Faraday's law can be expressed as

$$a_{j,in} = - \sum_j \frac{s_{i,j}}{n_j F} a_{i,nj} + s_{i,0} R_0 \quad [2]$$

provided that double-layer charging can be ignored. The last term on the right side of Eq. [2] represents the production of species *i* by a chemical reaction with stoichiometric coefficient *s*_{*i,0*} and reaction rate *R*₀. The transfer current per unit electrode volume $\nabla \cdot i_2$ is related to the average transfer current density for each reaction by

$$\nabla \cdot i_2 = \sum_j (a_{i,n})_j \quad [3]$$

A material balance on the solid phases indicates how electrode porosity changes as a result of chemical and electrochemical reactions at each location within the electrode

$$\frac{\partial \epsilon}{\partial t} = \sum_{\text{solid phases}} \left(\sum_j \frac{s_{i,j} \tilde{V}_1}{n_j F} (a_{i,n})_j - s_{i,0} \tilde{V}_1 R_0 \right) \quad [4]$$

The complicated acid electrolyte (1) is regarded as a concentrated mixture of Li⁺ ions and AlCl₄⁻ ions in AlCl₃ and SOCl₂ (species 1, 2, 3, and 4, respectively). Inversion of the multicomponent diffusion equations yields explicit relationships for the fluxes

$$\begin{aligned} N_1 &= -\epsilon v_1 D_1 \nabla c_e - \epsilon v_1 D_3 \nabla c_3 + \frac{t_1 \square i_2}{z_1 F} + c_1 \underline{v} \square \\ N_2 &= -\epsilon v_2 D_1 \nabla c_e - \epsilon v_2 D_3 \nabla c_3 + \frac{t_2 \square i_2}{z_2 F} + c_2 \underline{v} \square \\ N_3 &= -\epsilon D_2 \nabla c_e - \epsilon D_4 \nabla c_3 + \frac{t_3 \square i_2}{F} + c_3 \underline{v} \square \\ N_4 &= -\epsilon D_5 \nabla c_e - \epsilon D_6 \nabla c_3 + \frac{t_4 \square i_2}{F} + c_4 \underline{v} \square \end{aligned} \quad [5]$$

where the diffusion coefficients and the transference numbers are related to binary interaction parameters, as shown in the Appendix. The six independent transport properties for this system are chosen to be D_1 , D_2 , D_3 , t_1^\square , t_3^\square , and the electrolyte conductivity κ . If D_2 and D_3 are taken to be zero (see Appendix), substitution of the fluxes in Eq. [5] into the material balance relation (Eq. [1] of Ref. (7)) yields

$$\frac{\partial e}{\partial t} + \nabla \cdot \mathbf{y}^\square = a \left[\frac{t_2^\square \bar{V}_e}{\nu_1} j_{1n} + \frac{t_1^\square \bar{V}_e}{\nu_2} j_{2n} + \bar{V}_3 j_{3n} + \bar{V}_4 j_{4n} \right] - \bar{V}_e \frac{i_2 \cdot \nabla t_1^\square}{\nu_1 z_1 F} - \epsilon D_1 \nabla c_e \cdot \nabla \bar{V}_e - \epsilon D_5 \nabla c_e \cdot \nabla \bar{V}_4 - \epsilon D_4 \nabla c_3 \cdot \nabla \bar{V}_3 - \epsilon D_6 \nabla c_3 \cdot \nabla \bar{V}_4 \quad [6]$$

The dependence of solution potential on the current density i_2 can be derived by inversion of the multi-component diffusion equations (5). For the LiAlCl_4 , AlCl_3 electrolyte, one obtains

$$\frac{i_2}{\kappa} = -\nabla \Phi_2 - \frac{1}{F} \left(\frac{t_1^\square}{z_1 \nu_1} + \frac{s_1}{n \nu_1} - \frac{s_4 c_e}{n c_4} \right) \nabla \mu_e - \frac{1}{F} \left(t_3^\square + \frac{s_3}{n} - \frac{s_4 c_3}{n c_4} \right) \nabla \mu_3 \quad [7]$$

where Φ_2 is measured with a reference electrode that has stoichiometric coefficients s_1 and number n of electrons transferred. The composition dependent terms on the right side of Eq. [7] include the diffusion potentials of the electrolyte and the acid. The chemical potentials μ_e and μ_3 are defined in Eq. [A-5] and [A-6], respectively.

The Butler-Volmer equation is used to represent the dependence of the local current density due to reaction j on the surface overpotential $\eta_{sj} = \eta - U_{j,w}$

$$a i_{nj} = a i_{oj} [e^{\alpha_{sj} F \eta_{sj} / RT} - e^{-\alpha_{sj} F \eta_{sj} / RT}] \quad [8]$$

where the exchange current density i_{oj} can be written as

$$i_{oj} = i_{oj,ref} \pi \left(\frac{c_{i,w}}{c_{i,ref}} \right)^{\gamma_i} \quad [9]$$

and the theoretical open-circuit cell potential for reaction j is given by (8)

$$U_{j,w} = U_j^\theta - U_{re}^\theta + \frac{RT}{n_{re} F} \sum_i s_{i,re} \ln \left(\frac{c_{i,re}}{\rho_o} \right) - \frac{RT}{n_j F} \sum_i s_{i,j} \ln \left(\frac{c_{i,w}}{\rho_o} \right) \quad [10]$$

The discharge processes in the positive electrode are represented by two simultaneous reactions (1)

Equation [8] is used to describe the rate of each reaction, and changes in the active surface area of the carbon matrix are predicted with (7)

$$a = a^0 [1 - (\epsilon_{\text{LiCl}}/\epsilon_p^0)^p] \quad [11]$$

At the negative electrode, the overall discharge reaction is

and the LiCl film formation reaction is (9)

The SOCl_2 flux through the LiCl film to the Li surface is related to the rate of chemical reaction [IV] by Eq. [17] of Ref. (7). In addition, the LiCl at both electrodes can be dissolved chemically by the acid in accordance with

The dissolution rate at the negative electrode is assumed to be proportional to the acid concentration at the LiCl/separator interface

$$r_v = k_1 (c_a)_b \quad [12]$$

It is assumed that dissolution depends on the local acid concentration, the volume fraction of LiCl crystals, and the morphology parameter p

$$R_o = k_2 c_a (\epsilon_{\text{LiCl}})^p \quad [13]$$

The thickness of the protective film on the lithium surface can be altered by reactions [IV] and [V]. If the film porosity is constant, a mass balance gives

$$\frac{d\delta_f}{dt} = (s_{\text{LiCl,IV}} r_{\text{IV}} + s_{\text{LiCl,O}} r_v) \bar{V}_{\text{LiCl}} \quad [14]$$

The heat-balance equation is modified to account for simultaneous chemical and electrochemical reactions

$$C \frac{dT}{dt} = \sum_j \left[\left(U_{oj} - T_o \frac{\partial U_{oj}}{\partial T} \right) \int_0^{L_p} \frac{(-a i_{nj})}{I} dy - V \right] I - h_o (T - T_A) + (\Delta H_{R,\text{IV}}) r_{\text{IV}} + (\Delta H_{R,\text{V}}) \left(r_v + \int_0^{L_p} R_o dy \right) \quad [15]$$

The Li-LiAlCl₄, AlCl₃/SOCl₂-C system can be described by the local variables c_e , c_a , \mathbf{v}^\square , ϵ , $a i_{n\text{I}}$, $a i_{n\text{II}}$, i_2 , and η , and by the governing Eq. [3], [4], [6], [7], and [8], together with material balances for acid and electrolyte. The initial conditions and the boundary conditions for these equations have been presented previously (7). These relationships constitute a set of coupled, ordinary, nonlinear differential equations at each time step which are cast into finite difference form accurate to $O(h^2)$, and solved simultaneously by a numerical technique (10).

Results and Discussion

Composition profiles for acid and electrolyte and the corresponding reaction distributions in the positive electrode are shown in Fig. 1 and 2, respectively, at several times during galvanostatic discharge of a typical cell sandwich. The open-circuit potential for reaction [I] is significantly larger than the one for reaction [II] (see Table I), and, therefore, reaction [I] prevails early in the discharge. This lowers the overall level of acid in the cell and raises the electrolyte concentration above its original value. The positive slopes for the acid concentration curves at the negative electrode/separator interface result from chemical dissolution of the LiCl film at the anode. The discontinuities in concentration gradients at the front of the positive electrode reflect the presence of the reservoir at this location and the porosity difference between the separator and the cathode. The production of electrolyte by reaction [I] makes this effect more noticeable than in cells with neutral electrolyte.

The initial current density distribution for electrochemical reduction of acid (see curve a, Fig. 2) represents a balance between the low κ/σ ratio, which makes the reaction rate highest at the cathode face, and $a^0 i_{o,ref}$, which is low enough to allow the reaction to penetrate into the electrode. As discharge proceeds, the current density at the front of the positive electrode is maintained by diffusion of acid from the reservoir and sepa-

The lower curves represent acid concentration profiles, the upper curves electrolyte concentration profiles. Simulation parameters are presented in Table I, and in Fig. 2 of Ref. (7).

rator and by an increase in the driving force for electrochemical reaction. However, the electrolyte becomes depleted in acid directly behind this region, and the transfer current tends to zero locally (see curves c).

After approximately 31s, the potential difference, $\Phi_1 - \Phi_2$, becomes large enough to initiate the neutral reaction as a sharp front at the electrode/reservoir interface. Once the neutral reaction has begun, it dominates the cell behavior. Reaction [I] continues at the back of the electrode, but the acid concentration

is very low and only a small fraction of the current is transferred in this way. Also, acid that remains in the separator continues to diffuse into the cathode and react, but the effect is negligible for the discharge conditions specified in Fig. 1 and 2. The neutral reaction distributions are not influenced significantly by the cell history or the acid reaction, and they correspond closely to those predicted for cells with neutral electrolyte (7).

The independent nature of the two electrochemical reactions in the cathode is also illustrated by the total cell-voltage characteristics shown in Fig. 3. For each discharge curve, the higher voltage region is associated with the acid reaction, and the lower voltage plateau is representative of the neutral reaction. The cell behavior on the lower plateau is very similar to that for the neutral electrolyte system (7), and the cell fails by plugging of pores with LiCl at the front face of the cathode. The major contribution of the acid reaction is to delay the onset of LiCl formation in the positive electrode and, therefore, to extend the cell lifetime. The shape of the theoretical discharge curves agrees closely with experimental results for comparable cells (1, 11). Reasons for discrepancies in the exact values of the voltages have been discussed in detail previ-

ously (7). These differences do not alter the physical interpretation of the cell behavior described below.

The small voltage rise shortly after the beginning of discharge is caused by an increase in electrolyte conductivity in the separator as the local electrolyte concentration changes. The rises are slightly more pronounced than those predicted for comparable neutral cells because, initially, chemical dissolution of LiCl at the negative electrode is faster than the film formation reaction [IV], so that the thickness and the resistance of the LiCl film decreases.

The acid portion of each curve declines from a maximum voltage as acid is consumed at the front of the positive electrode and the surface overpotential becomes more negative (see Eq. [8]). The width of the acid region of the voltage-utilization curve depends primarily on the quantity of acid available for reaction near the cathode/reservoir interface, but it is also affected by the discharge rate. At higher current densities, there is less time for the chemical reaction to take place at the anode, and, consequently, a greater proportion of the original acid can react electrochemically in the positive electrode. However, higher values of I also necessitate higher surface overpotentials, and the cell voltage is lower. This can allow the neutral reaction, and hence the lower plateau, to begin at a smaller utilization (see Fig. 3). Subsequently, the acid and neutral reactions can occur simultaneously in the positive electrode for a longer period of time, but this does not alter the voltage of the lower plateau significantly.

Other factors also influence the shape of the acid region of a discharge curve. Reductions in the values of the kinetic parameters (α_{ol}^0 , α_{al} , α_{cl}) are analogous to an increase in I : the driving force needed to transfer current is larger, and this leads to a smaller voltage maximum and to earlier initiation of reaction [II]. An increase in the initial acid concentration gives a higher electrolyte resistance at $t = 0$, but the voltage rises quickly due to rapid dissolution of LiCl at the anode (see Eq. [12]). This reduces the resistance across the negative electrode and, through changes in κ , across the separator. Also, the surface overpotential for the cathode reaction is smaller, in accordance with Eq. [8]. For these reasons, the predicted voltage maximum is higher for cells with large values of c_a^0 . In addition, more acid is available for reaction in the cathode, and

the width of the acid region, and hence the cell lifetime, is increased.

Figure 4 shows the dependence of the increase in lifetime on c_a^0 with $c_{e,a}^0 = 1M$. If the acid cell is compared with an identical cell that uses neutral electrolyte with initial concentration

Fig. 4. Dependence of increase in cell lifetime on initial acid concentration. Δt = lifetime of acid cell - lifetime of comparable neutral cell that has initial electrolyte concentration $c_{e,n}^0$, as defined by Eq. [16]. Curve a represents values calculated from the stoichiometry of reaction [1]. Curve b represents values predicted with the heat capacity data given in Table II of Ref. (7). Curve c represents values predicted under isothermal conditions. Simulation parameters as in Fig. 1, except as indicated.

$$c_{e,n}^0 = c_{e,a}^0 + c_a^0 \quad [16]$$

the increase in lifetime is almost identical to the value calculated from the stoichiometry of reaction [I]. Very similar behavior is predicted with different values of $c_{e,a}^0$ and I . This result indicates that, over a wide range of operating conditions, cells with acid electrolyte can be regarded as a combination of (i) a neutral electrolyte cell with $c_{e,n}^0$ given by Eq. [16], and (ii) an acid reservoir that delays formation of LiCl crystals in the positive electrode. However, it should be noted that the closeness of curves a and b in Fig. 4 is rather fortuitous. As c_a^0 is increased, the rate of the chemical-dissolution reaction at the anode becomes faster, and a smaller proportion of the acid is available for electrochemical reaction (see above). This is compensated for by the heat of the reaction $\Delta H_{R,V}$, which raises the average cell temperature and hence increases the usable cell capacity on the lower voltage plateau (7). The magnitude of these effects is indicated by curve c, which shows the predicted effect of c_a^0 for an identical cell that is operated isothermally. In practice, the proximity of the actual time increase and the one based on stoichiometry will depend on factors such as the thermal characteristics of the system, the details of the dissolution reaction at the anode, the presence of impurities, and the mechanism for the chemical and electrochemical reactions of $AlCl_3$ in the cathode.

At present, there is considerable uncertainty concerning the complex physical processes that take place at the negative electrode under acid and neutral conditions. The model for the LiCl film described in Ref. (7) is an oversimplification, and it cannot be expected to explain observed behavior completely. In particular, theoretical values for the coulombic efficiency λ (see Table II) are close to the results for neutral cells (7), whereas experimental values are typically 10-20% lower (11). The predicted dependence of λ on I and utilization is a direct consequence of the reduction in film thickness by dissolution with acid and the corresponding increase in the flux of $SOCl_2$ to the lithium surface. With larger values for the rate constant k_1 , only small increases in dissolution rate can be obtained because a mass transfer limitation is reached [$(c_a)_b = 0$]. Even if all the acid available in the separator and reservoir (26% of the total) could react chemically at the anode, λ could only be close to the experimental result at low utilizations. At higher depths of discharge, when no acid remains, the LiCl film grows and the efficiency increases (7). Alteration of the film structure by the acid, e.g., higher porosity, or disruption of the film during discharge may be able to explain experimental observations. Also, formation of adducts (12) or complexes (1) may reduce the rate of $AlCl_3$ consumption in the cathode. This could allow more $AlCl_3$ to be transported to the anode and hence could lead to greater film dissolution by reaction [V].

In the simulations presented above, all the $AlCl_3$ is used up before cell failure. With thicker electrodes, a proportion of the acid remains at the back of the electrode at the end of discharge. Figure 5 shows that, under these circumstances, the increase in lifetime will be smaller than that calculated on the basis of the total amount of original acid and the stoichiometry of reaction [I]. This implies that, if it is considered desirable to use large quantities of acid in the cell, it may be

Fig. 5. Dependence of increase in cell lifetime on positive electrode thickness. The basis of comparison is described in Fig. 4. The straight line represents values predicted from the stoichiometry of reaction [I]. Simulation parameters as in Fig. 1, except as indicated.

preferable to add a large reservoir at the front of the cathode rather than increase the electrode thickness. However, at lower discharge rates or with higher diffusion coefficients, the amount of unused acid is reduced. This is because more acid is able to reach the front of the electrode and delay the onset of reaction [II]. In all cases, acid from the separator, the reservoir, and the front region of the cathode is expected to react completely before the cell fails. The overall effect of this acid is independent of whether it reacts chemically or electrochemically because the net effect is always a delay in plugging of the electrode pores. With the particular rate constants used in the simulations, the electrochemical reaction dominates.

Conclusions

A mathematical model has been developed that can describe the time-dependent and position-dependent behavior of a complete Li/ $SOCl_2$ static cell with acid electrolyte. In many respects, a cell with acid electrolyte can be regarded as a combination of an equivalent neutral electrolyte system and an acid reservoir. At the cathode, the $AlCl_3$ reacts preferentially at small depths of discharge. This delays the precipitation of LiCl crystals at the front of the electrode and, therefore, extends the cell lifetime. The theoretical predictions suggest that the increase in cell lifetime depends primarily on the quantity of acid added to the electrolyte. However, if the cathode is too thick, a proportion of the acid will be isolated at the back of the electrode and will be unable to react before the end of discharge. It should also be noted that the results depend on the model chosen to represent dissolution and formation of LiCl at the anode and on the thermal characteristics of the cell.

APPENDIX

Derivation of Transport Equations

The multicomponent diffusion equation for an isothermal, isobaric system is expressed as (10)

$$c_i \nabla \mu_i = \sum_j K_{ij} (\underline{v}_j - \underline{v}_i) = RT \sum_j \frac{c_i c_j}{c_T \mathcal{D}_{ij}} (\underline{v}_j - \underline{v}_i) \quad [\text{A-1}]$$

For a mixture of n species, a set of $(n-1)$ independent force balances defines the binary interaction parameters \mathcal{D}_{ij} , which are functions of temperature, pressure, and composition. In porous media, each \mathcal{D}_{ij} is related to the transport coefficient \mathcal{D}_{ij}^0 for the bulk electrolyte by $\mathcal{D}_{ij} = \mathcal{D}_{ij}^0/\xi^2$, where ξ is a tortuosity factor. The parameter ξ is a characteristic of the microscopic electrode structure and can be associated with the porosity by a relation of the form (6), $\xi^2 = 1/\sqrt{\epsilon}$. The number of independent transport properties in Eq. [A-1] is $n(n-1)/2$ because \mathcal{D}_{ii} is not defined and, by Newton's third law of motion, $\mathcal{D}_{ij} = \mathcal{D}_{ji}$. Specific combinations of these properties correspond to transport parameters that can be measured directly.

For the Li^+ , AlCl_4^- , AlCl_3 , and SOCl_2 system, the three independent diffusion equations may be rearranged, with the introduction of the superficial current density, to give expressions for fluxes based on a reference velocity representative of the bulk motion of the electrolyte. For example, with the solvent reference velocity \underline{v}_4 , one obtains

$$\begin{aligned} \underline{N}_1 &= c_1 \underline{v}_1 = -\frac{\epsilon v_1 c_e^2}{\alpha} \nabla \mu_e \\ &\quad - \epsilon v_1 c_e c_3 \left(\frac{K_{13} + K_{23}}{\alpha \psi} \right) \nabla \mu_3 + \frac{t_1^4 t_2}{z_1 \mathbf{F}} + c_1 \underline{v}_4 \\ \underline{N}_2 &= c_2 \underline{v}_2 = -\frac{\epsilon v_2 c_e^2}{\alpha} \nabla \mu_e \\ &\quad - \epsilon v_2 c_e c_3 \left(\frac{K_{13} + K_{23}}{\alpha \psi} \right) \nabla \mu_3 + \frac{t_2^4 t_2}{z_2 \mathbf{F}} + c_2 \underline{v}_4 \\ \underline{N}_3 &= c_3 \underline{v}_3 = -\frac{\epsilon c_3^2}{\psi} \left[1 + \frac{(K_{13} + K_{23})^2}{\alpha \psi} \right] \nabla \mu_3 \\ &\quad - c_3 c_3 \frac{(K_{13} + K_{23})}{\alpha \psi} \nabla \mu_e + \frac{t_3^4 t_2}{\mathbf{F}} + c_3 \underline{v}_4 \\ \underline{N}_4 &= c_4 \underline{v}_4 \end{aligned} \quad [\text{A-2}]$$

where

$$\begin{aligned} \mu_e &= v_1 \mu_1 + v_2 \mu_2 \\ \psi &= K_{13} + K_{23} + K_{34} \\ \alpha \psi &= K_{34} (K_{13} + K_{23}) + (K_{14} + K_{24}) \\ &\quad (K_{13} + K_{23} + K_{34}) \\ t_1^4 &= \frac{1}{\alpha \psi} (K_{23} + K_{24}) (K_{13} + K_{23} + K_{34}) \\ &\quad - (K_{13} + K_{23}) K_{23} \\ t_2^4 &= 1 - t_1^4 \\ t_3^4 &= \frac{c_3}{\psi} \left(\frac{K_{13} t_1^4}{z_1 c_1} + \frac{K_{23} t_2^4}{z_2 c_2} \right) \end{aligned} \quad [\text{A-3}]$$

and the subscripts 1, 2, 3, and 4 represent Li^+ , AlCl_4^- , AlCl_3 , and SOCl_2 , respectively.

In the computer simulation, the volume average velocity, defined by

$$\underline{v}^\square = \sum_i \bar{V}_i \underline{N}_i \quad [\text{A-4}]$$

is used as the reference frame for the diffusion flux because physical data for the LiAlCl_4 , AlCl_3 , SOCl_2 electrolyte are correlated with concentration. Substitution of the thermodynamic relations

$$\mu_e = \nu RT \ln (c_e f_{12} a_{12}^0) \quad [\text{A-5}]$$

$$\mu_3 = RT \ln (c_3 f_3 a_3^0) \quad [\text{A-6}]$$

and Eq. [A-4] into Eq. [A-2] gives Eq. [5] in the main text. The transport properties in Eq. [5] are related to the friction coefficients K_{ij} by the following equations

$$\begin{aligned} D_1 &= \frac{c_e}{\alpha \psi} \nu RT \left(1 + \frac{d \ln f_{12}}{d \ln c_e} \right) [c_4 \bar{V}_4 \psi + c_3 \bar{V}_3 K_{34}] \\ D_2 &= \frac{c_3}{\alpha \psi} \nu RT \left(1 + \frac{d \ln f_{12}}{d \ln c_e} \right) [K_{13} + K_{23} \\ &\quad + c_3 \bar{V}_3 K_{34} + \psi (c_4 \bar{V}_4 - 1)] \\ D_3 &= \frac{c_e}{\alpha \psi} RT \left(1 + \frac{d \ln f_3}{d \ln c_3} \right) [c_4 \bar{V}_4 (K_{13} + K_{23}) \\ &\quad - c_3 \bar{V}_3 (K_{14} + K_{24})] \\ D_4 &= \frac{c_3}{\alpha \psi} RT \left(1 + \frac{d \ln f_3}{d \ln c_3} \right) [(1 - c_3 \bar{V}_3) \\ &\quad (K_{14} + K_{24}) + c_4 \bar{V}_4 (K_{13} + K_{23})] \\ D_5 &= \frac{c_4}{\alpha \psi} \nu RT \left(1 + \frac{d \ln f_{12}}{d \ln c_e} \right) [c_3 \bar{V}_3 K_{34} \\ &\quad - (1 - c_4 \bar{V}_4) \psi] \\ D_6 &= \frac{c_4}{\alpha \psi} RT \left(1 + \frac{d \ln f_3}{d \ln c_3} \right) [(c_4 \bar{V}_4 - 1) \\ &\quad (K_{13} + K_{23}) - c_3 \bar{V}_3 (K_{14} + K_{24})] \end{aligned} \quad [\text{A-7}]$$

$$t_1^\square = t_1^4 - c_1 z_1 Q' - c_1 z_1 \bar{V}_3 t_3^4$$

$$t_2^\square = t_2^4 - c_2 z_2 Q' - c_2 z_2 \bar{V}_3 t_3^4$$

$$t_3^\square = -c_3 Q' + (1 - c_3 \bar{V}_3) t_3^4$$

$$t_4^\square = -c_4 Q' - c_4 \bar{V}_3 t_3^4 \quad [\text{A-8}]$$

where

$$Q' = \frac{t_1^4 \bar{V}_1}{z_1} + \frac{t_2^4 \bar{V}_2}{z_2} \quad [\text{A-9}]$$

In addition, the effective conductivity within the pores (5) may be written in terms of K_{ij} as

$$\frac{1}{\kappa} = \frac{1}{\epsilon z_1 c_1 \mathbf{F}^2} \left[\frac{t_3^4 K_{23}}{c_3} - \frac{t_2^4}{z_2 c_2} (K_{23} + K_{24}) + \frac{K_{12}}{z_1 c_1} \right] \quad [\text{A-10}]$$

Only six of the transport properties defined in Eq. [A-7], [A-8], and [A-10] are independent. The quantity Q' cannot be measured, but it can arbitrarily be taken to be zero (6). In the analysis of the Li/SOCl_2 acid electrolyte cell, it is assumed that the contribution of diffusion to the flux of a species arises solely from the concentration gradient of that species. In this way, the parameters D_2 and D_3 are taken to be zero. Furthermore, the effect of migration on the flux of AlCl_3 is neglected, so that the transference number t_3^\square also becomes zero. The three independent transport properties that can still be chosen are taken to be D_1 , t_1^\square , and κ . The other properties (D_4 , D_5 , and D_6) are expressed in terms of these variables, for example

$$D_4 = \frac{\left(1 + \frac{d \ln f_3}{d \ln c_3} \right) \bar{V}_e}{\left(1 + \frac{d \ln f_{12}}{d \ln c_e} \right) \nu \bar{V}_3} \cdot D_1 \quad [\text{A-11}]$$

LIST OF SYMBOLS

a	interfacial area per unit electrode volume (cm^{-1})
$a^{\theta_{12}}, a^{\theta_3}$	property expressing secondary reference state (cm^3/mol)
c_a	molar concentration of AlCl_3 (mol/cm^3)
c_e	$= c_1/\nu_1 = c_2/\nu_2$ molar concentration of electrolyte (mol/cm^3)
$c_{e,a}^{\circ}$	initial electrolyte concentration of a cell that uses an acid electrolyte (mol/cm^3)
$c_{e,n}^{\circ}$	initial electrolyte concentration of a cell that uses a neutral electrolyte (mol/cm^3)
c_i	molar concentration of species i (mol/cm^3)
C	cell heat capacity ($\text{J}/\text{cm}^2 \cdot \text{K}$)
\mathcal{D}_{ij}	diffusion coefficient for interaction of species i and j (cm^2/s)
D_i	($I = 1 - 6$), diffusion coefficient defined by Eq. [A-7] (cm^2/s)
f_{12}	mean molar activity coefficient of electrolyte
f_3	molar activity coefficient of AlCl_3
F	Faraday's constant (96,487 C/eq)
h	mesh size (cm)
h_0	heat transfer coefficient ($\text{W}/\text{cm}^2 \cdot \text{K}$)
$\Delta H_{R,IV}$	heat of chemical reaction (J/mol of SOCl_2 consumed)
$\Delta H_{R,V}$	heat of chemical reaction (J/mol of LiCl dissolved)
i_0	exchange current density (A/cm^2)
\underline{i}_2	superficial current density in pore phase (A/cm^2)
i_{nj}	local current density due to reaction j (A/cm^2)
I	superficial current density to an electrode (A/cm^2)
j_{in}	pore wall flux of species i ($\text{mol}/\text{cm}^2 \cdot \text{s}$)
k_1	rate constant of reaction [V] at anode (cm/s)
k_2	rate constant of reaction [V] at cathode ($1/\text{s}$)
K_{ij}	friction coefficient for interaction of species i and j ($\text{J} \cdot \text{s}/\text{cm}^5$)
L	electrode thickness (cm)
M_i	symbol for the chemical formula of species i
n_i	number of electrons transferred in electrode reaction j
\underline{N}_i	superficial flux of species i ($\text{mol}/\text{cm}^2 \cdot \text{s}$)
\underline{p}	morphology parameter defined by Eq. [11]
Q	cell capacity (based on moles of SOCl_2) (C/cm^2)
Q'	parameter defined by Eq. [A-9]
r_{IV}	reaction rate of chemical reaction [IV] (mole of SOCl_2 consumed/ $\text{cm}^2 \cdot \text{s}$)
r_V	reaction rate of chemical reaction [V] at anode (mol of LiCl dissolved/ $\text{cm}^2 \cdot \text{s}$)
R	universal gas constant (8.3143 J/mol \cdot K)
R_0	reaction rate of chemical reaction [V] at cathode ($\text{mol}/\text{cm}^3 \cdot \text{s}$)
$s_{i,i}$	stoichiometric coefficient of species i in electrode reaction j
$s_{i,0}$	stoichiometric coefficient of species i in chemical reaction [V]
$s_{i,IV}$	stoichiometric coefficient of species i in chemical reaction [IV]
t	time (s)
t_i^{\blacksquare}	transference number of species i with respect to the volume average velocity
t_i^{Δ}	transference number of species i with respect to the velocity of SOCl_2
Δt	lifetime of acid cell — lifetime of comparable neutral cell that has an initial electrolyte concentration $= c_{e,n}^{\circ}$ (s)
T	absolute temperature (K)
T_A	temperature of surroundings (K)
T_0	initial temperature (K)
$U_{j,w}$	theoretical open-circuit potential for reaction j at the composition prevailing locally at the electrode surface, relative to a reference electrode of a given kind (V)
U_j^{θ}	standard electrode potential for reaction j (V)
U_0	open-circuit cell potential (V)
$\underline{v}^{\blacksquare}$	volume average velocity (cm/s)
\underline{v}_i	velocity of species i (cm/s)
\bar{V}	total cell voltage (V)
\tilde{V}	molar volume (cm^3/mol)
\bar{V}_i	partial molar volume of species i (cm^3/mol)
z_i	valence or charge number of species i

Greek Letters

α	a combination of friction coefficients defined by Eq. [A-3] ($\text{J} \cdot \text{s}/\text{cm}^5$)
α_a	transfer coefficient in anodic direction
α_c	transfer coefficient in cathodic direction
γ_i	exponent in Eq. [9]
δ_f	LiCl film thickness (cm)
ϵ	porosity or void volume fraction
ϵ_{LiCl}	volume fraction of LiCl
ζ	tortuosity factor
η	$\Phi_1 - \Phi_2$
κ	effective solution conductivity (mho/cm)
λ	coulombic efficiency
μ_i	chemical potential of species i (J/mol)
ν	$= \nu_1 + \nu_2$, number of mols of ions into which a mol of electrolyte dissociates
ν_1, ν_2	number of cations and anions into which a molecule of electrolyte dissociates
ρ_0	density of pure solvent (g/cm^3)
σ	effective matrix conductivity (mho/cm)
Φ_2	electric potential in the solution (V)
ψ	a combination of friction coefficients defined by Eq. [A-3] ($\text{J} \cdot \text{s}/\text{cm}^5$)

Accelerated Evolution of Hydrogen on Freshly Generated Metal Surfaces in Aqueous Solution

G. T. Burstein and M. A. Kearns

Department of Metallurgy and Materials Science, University of Cambridge, Cambridge, CB2 3QZ, England

ABSTRACT

Data have been obtained which describe quantitatively the rate of evolution of hydrogen on freshly generated surfaces of Fe, Cr, and their binary alloys. At low electrode potentials, creation of the new metal surface causes large acceleration of the rate of hydrogen evolution. The succeeding decay of cathodic current with time is relatively small; long after its creation, the new surface remains catalytically active towards hydrogen evolution provided the potential remains low. The kinetics of each stage of the process are defined and presented as a function of the metal composition.

The scratched rotating disk electrode has proved a valuable probe for the investigation of the rapid initial reactions which occur when metal surfaces are generated in aqueous electrolytes under potential control (1-7). Efforts have so far been focused on the elucidation of anodic processes occurring in a range of metal/electrolyte systems. These have included measurements of the rapid initial rates of anodic reactions (1-9), kinetics of oxide film growth (8, 9), and the effects of anions on these (1, 2). Although cathodic current transients have been documented at sufficiently low potentials (2-9), these have not been analyzed in detail.

Preliminary work on the scratched chromium electrode at low electrode potential in alkaline solution has shown that the hydrogen evolution reaction can be accelerated on scratching, and that the accelerated rate of reaction can continue for periods long after the scratching process is complete (10). The present work sets out the results of similar studies of iron, chromium, and a range of their binary alloys in a potential range where scratching gives rise to a net cathodic current due to the hydrogen evolution reaction occurring upon the scratch surface.

The phenomenon of enhanced or retarded diffusivity of hydrogen atoms through metals accompanying plastic deformation has been studied for some time (11). Despite the recent debate (12-14) concerning the measurements and mechanism of this process, enhanced diffusion of hydrogen in metals undergoing plastic deformation may well be involved in the mechanisms of some localized environment-dependent failure modes, such as corrosion fatigue and hydrogen embrittlement (15-17). For the scratched electrode, enhanced rates of hydrogen evolution are possible (10), and there thus exists the likelihood of a combination of enhanced hydrogen discharge and subsequent rapid transport through the metal substrate. Such processes may be envisaged as having repercussions for environment-sensitive failure of metals.

Experimental

Full details of the potentiostatically controlled scratched electrode technique have been presented previously (1-7). The technique is designed for measurement of both the instantaneous and subsequent events that occur when a fresh metal surface is created in solutions under electrochemical control. The disk electrodes used in this work were made from Cr, Fe, and a range of iron/chromium binary alloys of compositions 5%, 20%, and 50% Cr. These are designated as Fe-5Cr, Fe-20Cr, and Fe-50Cr, respectively. The metals were pure (Fe, BISRA, impurities in weight percent [w/o]: C 0.006, Si 0.006, S 0.0066, Al 0.004, O 0.001, N 0.016, Mn <0.005, and Cr Ex-iodide, 99.995%); the alloys were synthesized by arc melting in a copper hearth. The melts were inverted several times, cooled to room temperature, homogenized at ~1473 K and annealed at ~873 K. They were ground to a 1200 grit finish before

use. Some work was also carried out on pure nickel (Johnson Matthey, Specpure). Scratches generated on rotating disks of these materials were of different widths and depths according to the hardness of the metal. Thus for Fe, Fe-5Cr, and Fe-20Cr the scratches measured ~2 mm × 40 μm × 4 μm, for Fe-50Cr, ~2 mm × 35 μm × 3 μm, and for pure Cr, ~2 mm × 26 μm × 2 μm. The stylus contact time for an electrode rotation rate, ω , of 100 Hz was ~1 ms.

The electrolyte used throughout this work was 1.0M KOH prepared from AR reagent and doubly distilled water. It was deoxygenated by thorough purging with purified nitrogen before and during use. Experiments were performed at ambient temperature of 292 ± 2 K.

Electrodes were controlled to constant potential for a period of time sufficient to produce a steady-state current on the whole electrode before a scratch was initiated. In some cases, the surface consisted of the initial air-formed film before cathodization. In other cases, a preprogrammed anodic treatment in the working electrolyte was provided before cathodic treatment. This is described below.

Cathodic current transients due to scratching were recorded on a range of transient recorders set to different sensitivities and time scales so that the entire event could be recorded for as long as necessary. Some transients were prepared with the transient recorders set to the pretrigger mode so that any possible pre-trigger events could also be recorded.

Results

In this work, only scratches which gave rise to a net cathodic current transient are discussed. Anodic current transients will be presented elsewhere.

Figure 1a shows a current transient generated by scratching Cr in 1.0M KOH at a potential of -1405 mV (NHE). The base current, which represents the steady-state current flowing from the entire electrode surface before scratching is negative and is due to steady-state evolution of hydrogen. The potential is more negative than the thermodynamic equilibrium potential for the hydrogen electrode reaction of -827 mV (NHE) at pH 14, 1 atm of H₂. The scratch is initiated at the point identified by A in Fig. 1a and lasts for ~1 ms. This period is the stylus contact time, t_c , after which the scratching process is complete.

From this region of machining by the diamond stylus, it is possible to define the maximum observed current density flowing on the scratch surface by measuring the maximum rate of current generation as the scratch is being formed. It is given by (2)

$$i_s = \frac{1}{2\pi r \omega y} \frac{dI}{dt} \quad [1]$$

where dI is the increase in total current in time dt , y the scratch width, and r is its distance from the center of rotation.

Fig. 1. Cathodic current transient recorded on scratched Cr in 1.0M KOH at a potential of -1405 mV(NHE). The diagram shows the use of different current sensitivities and time scales (a and b) to detect the current decay. The time interval A to B is equal to the stylus contact time, t_c .

For Fig. 1a the current increases in the cathodic direction during scratching. After completion of the scratch, the current decays with time; at any instant t , the current density on the scratch is given by

$$i_s(t) = \frac{[I(t) - I_b]}{2\pi r \omega y t_c} \quad [2]$$

where $I(t)$ is the total current flowing from the whole electrode at time t and I_b is the base current flowing from the whole electrode before scratching. The quantity $2\pi r \omega y t_c$ is the surface area of the scratch. It is not corrected for the depth of the scratch (which is small, see above); neither is it corrected for the microscopic surface roughness. This form of Eq. [2] is only valid if the creation of the scratch makes a negligible difference to the base current density, i_b . For most practical purposes this is true; however, as $i_s(t)$ decays towards i_b , the formula must be modified to incorporate the change in I_b which occurs on scratching. The modification in essence allows for the fact that $i_s(t)$ decays towards i_b , and not towards zero. In such a case

$$i_s(t) = \frac{[I(t) - I_b]}{2\pi r \omega y t_c} + i_b \quad [3]$$

and in practice this occurs for $i_s(t) < \sim 10i_b$.

Figure 1b shows the same current transient as Fig. 1a recorded on a more sensitive current scale for a far greater period of time; it is immediately clear that the scratch current does not decay back to the base level I_b , even after 5s. The final steady-state scratch current density is denoted by $i_s(\infty)$ (calculated from Eq. [2])

and provides the new steady state of the scratch surface. This new steady-state cathodic reaction is accelerated when compared with the original steady state, i_b .

The base current I_b , displayed in Fig. 1a, shows a small decrease immediately prior to stylus contact. This feature is common to all such cathodic transients and is caused by interference with the original steady-state evolution of hydrogen by the approaching diamond stylus. It is thus necessary to examine the pre-trigger base current in detail to provide an accurate measure of I_b . Figure 2 shows another transient, this time with the transient recorder set in the pretrigger mode. The current before scratching is now displayed for a period of 1s, and the current after scratching for 1s. Since in the experiments the stylus requires some 30–40 ms to reach the surface, Fig. 2 gives an accurate measure of the variation in I_b both before and during the trigger period. It demonstrates that the approach of the stylus provides only a very small change in I_b , and the difference $I(t) - I_b$ used to evaluate $i_s(\infty)$ (see Eq. [2]) is not significantly affected.

Current transients of the type shown in Fig. 1 and 2 were recorded for Fe, Fe-5Cr, Fe-20Cr, Fe-50Cr, and Cr, over a range of potentials in 1.0M KOH. The values of i_s for pure Cr are shown in Fig. 3 as a function of potential together with measured values of i_b (the steady-state current density flowing from unscratched rotating electrodes [also 100 Hz]). The values of i_s lie almost 2 orders of magnitude higher than i_b . Also shown plotted in Fig. 3 are the values of the new steady-state cathodic current density $i_s(\infty)$. These also lie at considerably higher values than i_b . The potential marked with an arrow in Fig. 3 gives the bare surface mixed potential, E_{ms} ; at more positive potentials, the scratch current transients give net anodic currents.

Figure 3 shows that Tafel's law is obeyed for each of i_b , i_s , and $i_s(\infty)$. The measured range of these graphs for i_s and $i_s(\infty)$ is necessarily somewhat limited because of both the proximity of E_{ms} and the very high current densities involved. Nevertheless, Tafel's law is obeyed over some 1.5 orders of magnitude in $i_s(\infty)$ and ~ 1 order in i_s . The Tafel slopes are listed in Table I. At high current densities, the graphs deviate from linear Tafel behavior, a consequence of the ohmic resistance of the electrolyte. This resistance and consequent ohmic potential drop is smaller for the scratch (7) than it is for the disk (18) at similar current den-

Fig. 2. Cathodic current transient recorded on pure Cr in 1.0M KOH at a potential of -1305 mV (NHE), in the pretrigger mode. It shows the steady-state base current for 1s prior to the scratch event and clearly illustrates the difference in steady-state current density on the electrode before and after scratching.

Fig. 3. Cathodic current density on pure Cr as a function of potential. Instantaneous scratch current density, i_s (\square). Steady-state scratch current density, $i_s(\infty)$ (\circ). Steady-state current density on unscratched Cr, i_b (\bullet).

sities. Thus i_b deviates from Tafel's law at lower values than i_s and $i_s(\infty)$.

Similar data were obtained for pure Fe and for the three Fe-Cr alloys (Fe-50Cr, Fe-20Cr, and Fe-5Cr). These are present in Fig. 4-7, respectively. Each of the five metals displays linear cathodic Tafel behavior for i_s , $i_s(\infty)$, and i_b and the Tafel slopes are listed in Table I. For constant potential the i_s values show an increase with increase in the Fe content. The same trend is found for i_b value for the five metals.

To estimate the effects of anodic pretreatment of the electrodes before cathodic scratch transients were prepared, an experiment was performed in which pure chromium was subject to different anodic potentials, each for a period of 30s. Each electrode was then potentiostatically pulsed to the cathodic region (-1345 mV [NHE]), allowed to achieve a steady state, and scratched. Graphs of i_b , i_s , and $i_s(\infty)$ are shown as a function of the potential of anodic pretreatment of Cr in Fig. 8. Also shown are the corresponding parameters for Cr which carried simply the original air-formed film; these are plotted at $E = -355$ mV (NHE) since this was the steady-state open-circuit potential. Each of the three values of current density is independent of electrode pretreatment.

Discussion

Since in this electrolyte, only H_2O is capable of electrochemical reduction, the current transients described above are due to accelerated evolution of hydrogen on the scratch. It is quite remarkable that a high rate of hydrogen evolution continues long after the scratch has

Table I. Cathodic Tafel slopes for hydrogen evolution in 1.0M KOH

been formed. The effect of $i_s(\infty)$, which represents a new steady-state rate of hydrogen evolution long after the scratch has been formed, can be observed visually by applying a scratch to a stationary specimen held at constant potential within the required range (see Fig. 3-7). Under these circumstances, the effect is seen as a string of hydrogen bubbles decorating the scratch surface. Photomicrographs of this phenomenon are shown in Fig. 9. The photograph 9a was taken ca. 10s after completion of the scratch; 9b was taken ca. 600s

Fig. 5. Cathodic current density vs. potential for Fe-50Cr. Instantaneous scratch current density, i_s (\square). Steady-state scratch current density, $i_s(\infty)$ (\circ). Steady-state current density on unscratched Fe-50Cr, i_b (\bullet).

Fig. 6. Cathodic current density vs. potential for Fe-20Cr. Instantaneous scratch current density, i_s (\square). Steady-state scratch current density, $i_s(\infty)$ (\circ). Steady-state current density on unscratched Fe-20Cr, i_b (\bullet).

after scratching. Both depict a scratch on pure chromium in 1.0M KOH at $E = -1255$ mV (NHE). The figures show a high density of hydrogen bubbles along the length of the scratch, and this has been observed to persist for >1.2 ks. It is clearly a permanent feature of the newly created surface. The effect of the scratch is therefore irreversible.

The cathodic Tafel slopes described in Table I are all of similar magnitude and represent a single-electron transfer reaction as the rate-determining step. This is

Fig. 7. Cathodic current density vs. potential for Fe-5Cr. Instantaneous scratch current density, i_s (\square). Steady-state scratch current density, $i_s(\infty)$ (\circ). Steady-state current density on unscratched Fe-5Cr, i_b (\bullet).

Fig. 8. Dependence of cathodic current density i_s (\square), $i_s(\infty)$ (\circ), and i_b (\bullet) at $E = -1345$ mV (NHE) on the anodizing potential for Cr in 1.0M KOH.

consistent with Tafel slopes found in the steady state for hydrogen evolution in alkaline solutions on a range of metals (19, 20). The reaction may be written as

where H(s) is a hydrogen atom adsorbed to the surface. The kinetics of the reaction follow

$$i = i_0 \exp \left[\frac{\beta F \eta}{RT} \right] \quad [4]$$

and this equation is obeyed for each of i_b , i_s , and $i_s(\infty)$. Recombination of the adsorbed hydrogen atoms must be fast.

Values of the exchange current densities are clearly different for each of these current density parameters. They are evaluated by extrapolation of each of the Tafel lines to $E = -827$ mV (NHE), which is the equilibrium potential for the hydrogen evolution reaction at pH 14 and 1 atm of H_2 . The exchange current densities are designated as i_{b0} , i_{s0} , and $i_{s0}(\infty)$, and are listed in Table II.

The values of i_{b0} which represent the unscratched steady-state surface show an increase with decrease in Cr content of the alloy. The value found for pure Fe (2×10^{-5} A cm^{-2}) is about an order higher than that recorded earlier ($\sim 10^{-6}$ A cm^{-2}) (19, 20). Variation of i_{b0} with the mol fraction of Cr, X_{Cr} in the alloy is shown in Fig. 10.

A similar trend with mol fraction of Cr is found for i_{s0} , and this too is shown in Fig. 10. The variation of both $\log i_{b0}$ and $\log i_{s0}$ is linear in X_{Cr} and gives $\partial \log i_{b0} / \partial X_{\text{Cr}} = -1.14$ and $\partial \log i_{s0} / \partial X_{\text{Cr}} = -1.03$. The two values are very similar.

Table II. Exchange current densities for the hydrogen electrode reaction in 1.0M KOH

Metal	i_{b0} (A cm^{-2})	$i_{s0}(\infty)$ (A cm^{-2})	i_{s0} (A cm^{-2})
Fe	1.9×10^{-5}	3.2×10^{-5}	1.05×10^{-3}
Fe-5Cr	8.3×10^{-6}	3.0×10^{-5}	1.0×10^{-3}

Cr	6.7×10^{-7}	3.0×10^{-5}	8.5×10^{-5}

Fig. 9. Photomicrographs of H_2 bubbles evolved from the scratched area of a pure Cr electrode under potentiostatic control at -1255 mV (NHE) in $1.0M$ KOH. A, top: picture taken ca. 10s after scratching. B, bottom: picture taken ca. 600s after scratching.

The new steady-state current density on the scratch, $i_{s0}(\infty)$, is, however, invariant with X_{Cr} (see Fig. 10). It is striking that all these scratch surfaces, after re-establishment of a steady state, exhibit such similar activity towards hydrogen evolution.

It should be noted that the experimental data obtained for both Cr and Fe (Fig. 3 and 4) extend to potentials below those for which the metals can equilibrate with their bulk oxides at pH 14 (21). This implies that the original oxide films are not totally reduced electrochemically since the post-scratch steady-state current density [$i_s(\infty)$] is greater than the pre-scratch steady state (i_b) even at potentials where electrochemical reduction is possible. Only mechanical

Fig. 10. Variation of exchange current densities i_{s0} (\square), $i_{s0}(\infty)$ (\circ), and i_{b0} (\bullet) with alloy composition for the Fe-Cr binary alloy system in $1.0M$ KOH.

methods can remove these oxide films entirely, and, provided the electrode potential remains low, such oxides cannot reform.

The decay in cathodic current density from its maximum value of i_s to the new steady-state $i_s(\infty)$ is explicable in a number of ways. For iron, all the cathodic scratch data lie below the thermodynamic equilibrium potential for bulk oxide formation, as shown in Fig. 4 (20). Nevertheless, some evidence exists for the presence of a monolayer of adsorbed FeOH on Fe at very low potentials (3, 4), and it seems likely that this monolayer could form over the surfaces generated as described above. Such a monolayer of film would retard evolution of H_2 and thereby reduce i_s to $i_s(\infty)$. Similar behavior is expected to occur for Cr at very low potentials: much of the data shown in Fig. 3 occurs, however, at potentials where bulk oxides can form, and the presence of such oxides would retard hydrogen evolution further. For the alloys one therefore expects the newly created oxide to contain more Cr than Fe (Fig. 5-7), and it is expected that an increase in Cr content would give a decrease in i_{b0} , since reduction of H_2O would occur on surfaces carrying increased amounts of bulk chromium oxides. The difference in the oxide composition before and after scraping gives rise to the difference between i_b and $i_s(\infty)$.

Alternatively, hydrogen bubbles may be generated beneath the film at the metal film interface and cause continuous disruption of the film. If this occurred only on the newly created film, then $i_s(\infty)$ would again be different from i_b . The third possibility is the saturation of the surface with H atoms from the reduction process. Such adsorbed H atoms can follow either of two possible paths after discharge: they can form H_2 bubbles which leave the surface, or they may be absorbed into the metal matrix. These H atoms can also give rise to reduction of any oxide film being formed over the scratch surface. The relative rates of each of these processes must be that which controls the new steady-state $i_s(\infty)$. It is clearly not possible to achieve this steady state electrochemically in the absence of fresh surface generation. This mechanism is still under investigation.

The catalytic effect can be described by a catalytic acceleration factor, defined by the ratio $i_{so}(\infty)/i_{bo}$. This ratio is independent of electrode potential for each metal. The quantity is shown in Fig. 11 as a function of the mol fraction of Cr (X_{Cr}) in the alloy. It is greatest for pure Cr. For comparison the instantaneous catalytic acceleration factor (i_{so}/i_{bo}) is also shown: this value is approximately independent of X_{Cr} .

It is noteworthy that not all metals which display underpotential behavior of the type thought to give rise to FeOH [e.g., CuOH on Cu (6)] display the behavior described above. Attempts to establish the behavior for Cu and Ni in 1.0M KOH gave no evidence of the existence of a new steady state after scratching at very negative potentials. A cathodic scratch transient for Ni is shown in Fig. 12. Decay of this cathodic current transient is complete in ~ 20 ms to within the lower limits of current detection in these experiments. The acceleration, if it exists, is therefore small.

The effect may have important repercussions with respect to the hydrogen embrittlement and stress-corrosion cracking of steels. Several articles have already been published concerning the effects of plastic strain applied to metals on the hydrogen diffusivity through the metals (11-14). For nickel, the presence of plastic strain appears to enhance the diffusivity of hydrogen in thin membranes; for $2\frac{1}{4}$ Cr-1 Mo steel, diffusion is retarded. The diffusion rate must, at least initially, depend on the surface activity of adsorbed hydrogen atoms, which in turn depends on the rate of discharge. It may also be important in stress-corrosion and corrosion fatigue crack propagation where the bare metal surface created by plastic strain (15) may cause enhanced discharge of hydrogen as the cathodic process to reoxidation of the bare metal at the crack tip. If the electrochemical potential at the crack tip remains low, hydrogen discharge will occur rapidly and permanently. The consequent increased diffusion rate of H atoms into the metal ahead of the crack tip may accelerate the onset of embrittlement. This situation will arise where the propagating crack is a region of restricted access to oxygen and the environment of poor conductivity.

Fig. 11. Graphic representation of catalytic acceleration factor for evolution of hydrogen in 1.0M KOH: $\frac{i_{so}}{i_{bo}}$ (□) and $\frac{i_{so}(\infty)}{i_{bo}}$ (○) for Fe-Cr binary alloys.

Fig. 12. Cathodic scratch current transient for Ni in 1.0M KOH at a potential of -1155 mV (NHE) recorded in the pretrigger mode. Within the resolution of the transient, the decay in current is complete.

Conclusions

1. Generation of a bare metal surface on Fe, Cr, and Fe-Cr alloys at low potential in aqueous solution causes accelerated evolution of hydrogen.
2. This accelerated reaction is a permanent feature of the newly created metal surface. Such surfaces cannot repair themselves without alteration of the electrode potential.
3. The behavior occurs both above and below the thermodynamic reversible potential for equilibrium between Cr and its oxides.
4. The steady-state rate of hydrogen evolution after generation of the new metal surface is similar for Fe, Cr, and their binary alloys.

The Electrochemistry of Glassy 60Ni-40Nb in Aqueous Media

N. C. Grant and M. D. Archer*

Department of Physical Chemistry, University of Cambridge, Cambridge CB2 1EP, England

ABSTRACT

The electrochemistry of glassy melt-spun 60 atom percent (a/o) Ni-40 a/o Nb was investigated at moderate temperatures in various aqueous media. The alloy was very corrosion resistant to most acids and alkalis, but it was attacked by aqueous HF. Cyclic voltammograms of the glassy alloy in 15M NaOH indicated the existence of a thin nickel oxide corrosion layer from which niobium was absent. Linear sweep voltammetry in the oxygen evolution region, constant current chronopotentiometry, and rest potential decay measurements confirmed that the alloy surface in alkali consisted of nickel oxides. Chronopotentiometry in 0.5M H₂SO₄ at 30°C indicated the formation of a thin niobium oxide corrosion film which did not prevent oxygen evolution. Anodization in concentrated neutral KCl caused severe corrosion. On cathodization in acid, the glassy alloy absorbed ca. 14 a/o hydrogen and was severely embrittled. Attempted hydrogen permeation experiments caused ribbon fracture; as-quenched and low temperature-annealed glasses behaved differently in this respect.

The vitrification of metallic alloys affects all their properties, including their electrochemistry. The novel and useful combination of toughness, strength, and corrosion resistance which can be produced (1, 2) has stimulated much research into the electrochemistry of glassy metals. To date, most work has been on Fe- and Ni-based glasses containing ca. 20 atom percent (a/o) metalloid (3), some of which have remarkable magnetic properties (4). This paper is a contribution to the work on metal-metal glasses and examines the electrochemical properties of melt-spun glassy 60Ni-40Nb in a range of aqueous media at or near room temperature. The behavior of this alloy in more aggressive high-temperature aqueous media is reported in the following paper (5). The alloy 60Ni-40Nb was chosen as a typical representative of the T₁T₂ type of metallic glass, in which T₁ is an early transition metal and T₂ a late one.

Relatively little electrochemical work has been carried out on metal-metal glasses. Glassy Cu-Zr (6), Ti-Ni (7), and Al-Fe (8) have been investigated, and there is only one brief report on glassy (100-x) Ni-xNb (9). Polyphasic crystalline Ni-Nb alloys have been examined by Trusov *et al.* (10) in 3M HCl and 1M H₂SO₄ and by Sugimoto *et al.* (11, 12) in 25 weight percent (w/o) KOH.

The composition 60Ni-40Nb is very close to one of the eutectic compositions in the Ni-Nb phase diagram (13), so glasses of this composition are readily formed, though a wider compositional range is possible; Giesen *et al.* (14) have reported the melt spinning of Ni-Nb glasses containing 25-60 a/o Ni. Glassy Ni-Nb alloys were first prepared in 1967 (15), and since then they have been well characterized. Data are available on their structure (16-18), electronic structure (19), electrical resistivity (20), mechanical properties (14, 21), and some thermal properties (14). Information on the production of amorphous 60Ni-40Nb (22) and 50Ni-50Nb (23) by laser glazing, and on ion implantation damage in amorphous and crystalline 60Ni-40Nb (24), is available.

Experimental

Three electrode voltammetry was performed with a Hi-Tek DT 11001 potentiostat and PPR1 function generator. Galvanostatic experiments were made using a Time Electronics constant current source. Solutions

were prepared from AR-grade chemicals and triply distilled water, and were sparged with nitrogen.

Ni and Nb electrodes were made from Specpure materials (Johnson Matthey, Royston, Herts). Cylinders of metal were embedded in thermosetting plastic to give circular electrodes of diameter 0.7 cm (Nb) and 0.5 cm (Ni). Crystalline ingots of 60Ni-40Nb were produced by melting appropriate masses of Ni (99.99%) and Nb (99.9%) (Goodfellow Metals, Limited, Cambridge) under argon in an arc furnace. Glassy 60 a/o Ni-40 a/o Nb ribbons, typically 2 mm wide and 20 μm thick, were formed by the melt spinning technique (25). The ribbons were spun in air and hence possessed a thin, air-formed film. No crystallinity was discernible by x-ray diffractometry. Glassy 60Ni-40Nb electrodes of known area were made by affixing lengths of ribbon to glass supports and masking the edges with epoxy cement. All electrodes were polished before use with Hyprez 1 μm diamond paste, washed with ethanol, and dried. Ag/AgCl (3M or saturated KCl) reference electrodes were used in acid solutions, and Hg/HgO (1M NaOH) reference electrodes were used in alkaline solutions. The reference electrodes were housed in Luggin capillaries positioned within 0.5 mm of the working electrode surface. IR compensation was not applied, because IR drop was negligible except at the highest current densities used in Fig. 3.

The transport of hydrogen through the glassy alloy was studied using the dual electrochemical permeation cell of Devanathan and Stachurski (26). The ribbons under study, which were all ca. 30 μm thick, were mounted between two Teflon flanges in which slits had been machined to expose 0.288 cm² of ribbon on either side. The two flanges were then sandwiched between the two glass vessels which formed the two compartments of the cell. The inner faces of the two Teflon flanges were coated with epoxy cement prior to assembly to ensure a watertight seal. In one compartment of the assembled cell, hydrogen was generated at constant current on the ribbon surface, which acted as a cathode. The galvanostatic circuit comprised a dc power supply, a large resistor, and a platinum anode isolated behind a frit. In the other cell compartment, the other surface of the ribbon was the anode of a three-electrode potentiostatic experiment, in which the reference electrode was Hg/Hg₂SO₄ (saturated K₂SO₄). The potential of this face of the ribbon was maintained at 0.256V NHE, which is sufficiently positive to oxidize all hydrogen permeating

* Electrochemical Society Active Member.
 Key words: glassy metal, Ni-Nb alloy.

the ribbon. Thus, the permeation current is a measure of the instantaneous flow of hydrogen out of the ribbon.

In both compartments of the permeation cell, the electrolyte was 0.56M H₂SO₄. Initially, both compartments were sparged with nitrogen, but it was subsequently found that background currents were negligible in aerated solution, so the practice was discontinued. All permeation experiments were performed at room temperature.

Results and Discussion

Glassy 60Ni-40Nb proved to be generally very resistant to electrochemical corrosion. In 30 day immersion tests in aerated, unstirred 1M HCl, 30% NaOH, 10% FeCl₃, and aqueous polythionic acid (27), the weight loss of freely corroding specimens was undetectable (<0.3 mg dm⁻² day⁻¹); the samples appeared unchanged at the end of the tests. Sugimoto *et al.* (12) have reported that crystalline Ni-Nb alloys containing >47% Ni also showed negligible weight loss in 20 day immersion tests in aerated 25% KOH at 25°C. The only aqueous medium that caused evident attack on freely corroding glassy 60Ni-40Nb was hydrofluoric acid; in aerated, unstirred 5% HF at room temperature, the weight loss in an 80h test corresponded to a corrosion rate of 142 mg dm⁻² day⁻¹, and the samples were blackened and embrittled. Under the same conditions the corrosion rate of crystalline Ta is >593 mg dm⁻² day⁻¹ (28). Figure 1 shows the free corrosion potentials E_{corr} of Ni, Nb, and glassy 60Ni-40Nb in 5% HF and three other media. In HF, Nb adopts a free corrosion potential close to that of the Nb/NbF₇²⁻ couple [$E^\circ = -0.355\text{V NHE}$ (29)] and dissolves as fluoride complexes. Ni is extremely resistant to HF, being protected by a layer of insoluble fluorides, and the glassy alloy adopts an intermediate corrosion potential. Nb also dissolves slowly in 1M NaOH, forming niobates. Ni is resistant to alkalis, being protected by a film of hydrated oxides, and as the corrosion potentials (Fig. 1) show, the glassy alloy again adopts a potential intermediate be-

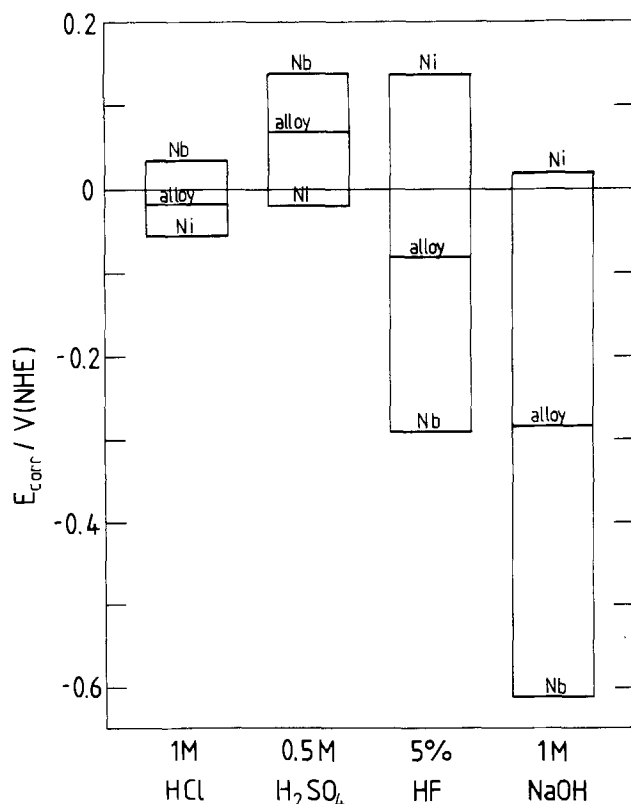

Fig. 1. The free corrosion potential E_{corr} adopted by Ni, Nb, and glassy 60Ni-40Nb in aqueous media at 19°C. Glassy 60Ni-40Nb is indicated by the word "alloy."

tween those of its two components. In 1M HCl and 0.5M H₂SO₄, Ni dissolves and Nb is passivated by a layer of Nb₂O₅, so that Nb adopts a more noble corrosion potential than Ni, and the glassy alloy again exhibits an intermediate corrosion potential.

We established from high temperature electrochemical work (5) that, in alkaline media at 150° and 300°C, Nb is leached from the alloy surface, leaving a nickel oxide corrosion layer, whereas in acidic media Ni is leached from the alloy surface, leaving a niobium oxide scale. At these high temperatures, the corrosion layers reach a thickness of the order of microns, and the dissolved component is chemically detectable in solution. At room temperature, similar chemical behavior is likely, although the corrosion films are evidently much thinner and the quantities of Ni dissolving in acid, and Nb in alkali, will be correspondingly much smaller. Results to be described (Fig. 3 and 6) provide confirmatory evidence that the corrosion films formed on the glassy alloy at room temperature are indeed chemically similar to those formed at higher temperatures. However, in room temperature tests on the glassy metal, we could not detect any dissolution of Ni in acid or of Nb in alkali. In the first test, 1 cm⁻² of abraded ribbon surface was polarized at 100 $\mu\text{A cm}^{-2}$ for 17.5h in 1 cm³ of 0.5M H₂SO₄. No nickel was detected in the resulting solution by the dimethyl glyoxime test, implying a Ni dissolution rate of <0.08 mg dm⁻² day⁻¹. [We note that Trusov *et al.* (10) have reported an apparently abrupt cessation of the ability of Nb to passivate Ni-Nb crystalline alloys in 1.5M H₂SO₄ and 3M HCl between the compositions 75Ni-25Nb and 85Ni-15Nb.] In the second test, 1 cm² of abraded ribbon surface was polarized at 10 mA cm⁻² for 17.5h in 1 cm³ of 30% KOH. No precipitate of Nb₂O₅ appeared on neutralization and dilution of the resulting solution.

The cyclic voltammograms (CV's) of the glassy alloy were recorded in a range of aqueous media corrosive either to nickel or to niobium. No features other than oxygen and hydrogen evolution were observed (at a sensitivity of 1 $\mu\text{A cm}^{-2}$) in the case of the following room temperature solutions: acidic NaClO, 10M NH₄F, 10% FeCl₃, 1M Na₂S₂O₃, 0.6M Na₂S₂O₃ + 0.9M KCl, 1M H₃PO₄, 0.5M H₃PO₄ + 0.5M HCl, 1M HCl + 0.5M H₂SO₄. The CV's in the region of hydrogen evolution, particularly in 1M H₃PO₄, resembled those of palladium in acid. This suggested that the glassy alloy absorbed some of the evolved hydrogen.

The only procedure we discovered which caused thick corrosion layers to be produced on glassy 60Ni-40Nb at room temperature was anodization in strong neutral chloride solutions. Chlorine evolution from concentrated KCl produced Ni(II) in solution and a cloudy precipitate of Nb₂O₅. A thick (~10 μm) striated corrosion layer, shown in section in Fig. 2a, was formed on the glassy metal. The face of the scale was cracked into blocks, as shown in Fig. 2b. It seems probable that the presence of chloride or chlorine causes the growing corrosion layer to crack and hence be unprotective. The films formed by oxygen evolution do not crack, being totally featureless at magnifications up to 5000 \times ; hence, they are protective and much thinner.

It is of interest to note that Trusov *et al.* (10) observed a current efficiency of only $2 \times 10^{-3}\%$ for anodic dissolution from a crystalline 75Ni-25Nb alloy polarized at 50 mA cm⁻² in 3M HCl for 24h. We also found no evidence of corrosion when the glassy alloy was anodized in 1M HCl. The much greater corrosive power of neutral KCl must be attributed to the higher pH.

Figure 3 shows the CV's of the glassy alloy and crystalline Ni and Nb in 15M NaOH at room temperature. Nb (Fig. 3b) gives a large anodic peak at low potential due to dissolution as a niobate, and partial passivation occurs at higher potentials. Sugimoto *et al.*

Fig. 2. Scanning electron micrographs of the corrosion layer formed on glassy 60Ni-40Nb by chlorine evolution at room temperature. A, above: sectional view. B, right: face-on view. The sample was anodized for 10 min at 100 mA cm^{-2} in 1 M KCl .

(12) have reported similar behavior for Nb in 25% KOH at 25°C . Ni (Fig. 3c) shows no active dissolution region, but rather a conjugate pair of peaks, I and II. The glassy alloy (Fig. 3a) shows a very similar pair of peaks, I at 0.43V and II at 0.29V NHE. We ascribe these features to a composite $\text{Ni}_3\text{O}_4/\text{Ni}_2\text{O}_3/\text{NiO}_2$ surface transformation, for reasons discussed below in connection with Fig. 5. The CV of the glassy alloy (Fig. 3a) does not show the Nb dissolution region of Fig. 3b, indicating that the nickel oxide surface film formed in NaOH contains very little elemental Nb. Any Nb originally present in the glassy alloy surface (probably as an oxide) must have dissolved chemically before the first electrochemical experiment. At lower concentrations of NaOH, the nickel oxide transformation peaks in the CV of the glassy alloy are much less pronounced; in 1 M NaOH , they were not observable.

The linear sweep voltammograms (LSV's) of glassy 60Ni-40Nb and crystalline Ni in the oxygen evolution region are shown in Fig. 4. The medium chosen (30% KOH at 70°C) is typical of those used in alkaline water electrolyzers. Freshly polished electrodes were used for comparability, because the behavior of these anodes is fairly time dependent, although not very sweep-rate-dependent, as a comparison of Fig. 4b and 4c shows. The oxygen evolution characteristics of the glassy alloy (Fig. 4a) closely resemble those of Ni, which is consistent with the view that the alloy surface is composed of nickel oxides.

The redox transformations of the corrosion films formed on the glassy alloy in 30% KOH at 70°C were further investigated by constant-current chronopotentiometry and by measurement of the decay of the rest potential after anodic potentiostasis. Curve 1 of Fig. 5a shows the first galvanostatic experiment on a freshly polished electrode. At $t = 0$, prior to the passage of current, the rest potential of the glassy alloy was -0.75V NHE, and when the anodic current of 10 mA cm^{-2} was applied, the potential rose rapidly to a plateau at 0.47V , maintained for 0.29s , before it rose further to a second plateau at 0.67V , at which point

oxygen evolution occurred. When the current was reversed, the potential fell to a plateau at 0.365V , maintained for 0.21s , and then fell rapidly again to a second plateau at -1.27V , at which point hydrogen evolution occurred. A train of successive anodic and cathodic half-cycles of 2.8s duration was applied. The second, seventh, and tenth cycles are also shown in Fig. 5a. The cathodic plateau at 0.365V lengthened slightly with sweep number, but the general features of the chronopotentiogram were reproducible. Figure 5b shows the decay in rest potential of a glassy alloy electrode after it had been held at a potential of 2.1V for 5s . This decay curve is qualitatively very similar to the cathodic chronopotentiograms, showing a potential arrest at 0.365V , although the decay takes much longer at open circuit than when a cathodic current is passed. Similar work on Ni in alkali produces charging curves very similar to those of Fig. 5. For example, the anodic and cathodic plateaus observed by Briggs *et al.* (30) in 1 M KOH at 25°C and a charging current of 2 mA cm^{-2} were 0.53 and 0.47V NHE, respectively.

Equilibrium thermodynamics must be cautiously applied in considering these results, since the temperatures are moderate and the rates of change of current and potential are high. However, the two processes most probably responsible for these features, and their redox potentials, E_1 and E_2 , interpolated or calculated from the literature (31, 32) for (i) 15 M NaOH at room temperature (calculated pH 17) and (ii) 30% KOH at 70°C (calculated pH 14.9), respectively, are

$$E_1 \quad E_2$$

The literature on the electrochemical formation of these nickel oxides on nickel is conflicting. Macdonald and Owen (33), from a consideration of the thermodynamics, assign the potential arrests in the chronopotentiogram to the conversion of Ni_2O_3 to NiO_2 , but the observation, by x-ray diffractometry of *in situ* elec-

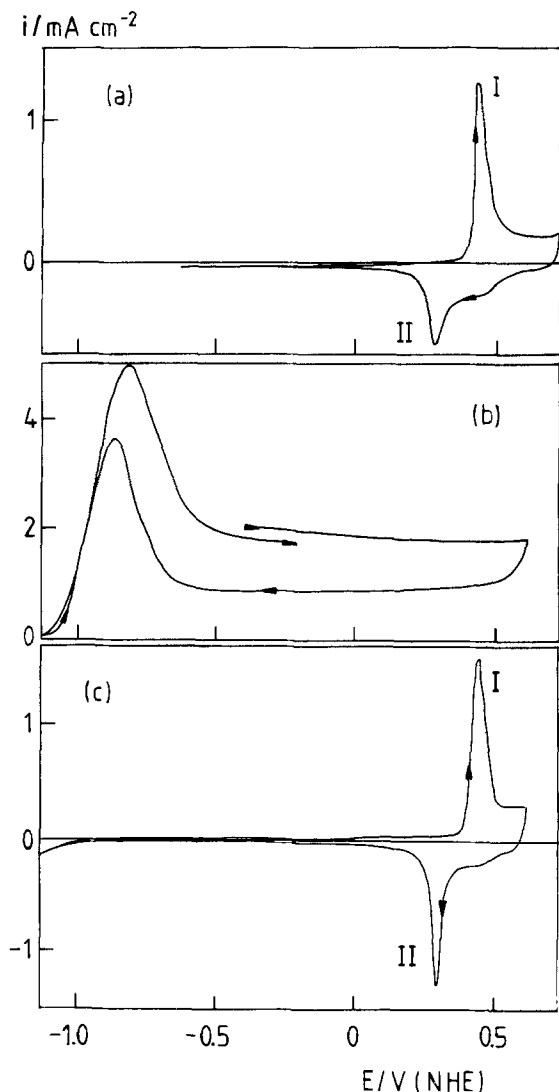

Fig. 3. Cyclic voltammograms of (a, top) glassy 60Ni-40Nb, (b, center) Nb, and (c, bottom) Ni in 15M NaOH at room temperature. Sweep rate: 100 mV s⁻¹.

trodes (34, 35), of the conversion of Ni(OH)₂ to β -NiOOH at this potential cannot be lightly dismissed. However, NiO₂ is reported to be amorphous to x-rays (32, 33), and there is magnetic evidence for the production of Ni(IV) in the electrochemical oxidation of Ni(OH)₂ (38, 39).

At 150° and 300°C in alkali, two closely spaced but distinct peaks are observed in the CV's of both Ni and glassy 60Ni-40Nb (5). We have ascribed these to the Ni₃O₄/Ni₂O₃ and Ni₂O₃/NiO₂ transformations. At lower temperatures, these transformations will be slower. As we have already noted, the potential arrests observed in the galvanostatic experiment of Fig. 5 (0.47 and 0.365V) are comparable with the anodic and cathodic peak potentials (0.43 and 0.29V, respectively) in the CV of the glassy alloy (Fig. 3c). From a comparison of these potentials with E_1 and E_2 above, we conclude that the peaks of Fig. 3 and the potential arrests of Fig. 5 are probably composites of the Ni₃O₄/Ni₂O₃ and Ni₂O₃/NiO₂ redox processes.

The constant-current chronopotentiograms of glassy 60Ni-40Nb and crystalline Nb in 0.5M H₂SO₄ at 30°C are shown in Fig. 6a. On passage of the anodic current, the potential of the glassy alloy rises smoothly and then levels off as oxygen evolution occurs. When the current is reversed, the potential falls rapidly to the hydrogen evolution plateau at -0.38V NHE, although there is a brief arrest at -0.10V. The decay of the rest potential of a glassy alloy electrode after anodic

Fig. 4. Linear sweep voltammograms of freshly polished electrodes in 30% KOH at 70°C. Curve a: glassy 60Ni-40Nb; sweep rate 1 mV s⁻¹. Curve b: Ni, sweep rate 1 mV s⁻¹. Curve c: Ni, sweep rate 10 mV s⁻¹.

potentiostasis (Fig. 6c) is qualitatively similar, though again much slower. The glassy alloy is exhibiting a niobium oxide-like surface in this acidic medium, although niobium itself behaves rather differently on anodic charging. The Nb potential continues to rise without oxygen being evolved, as a resistant layer of Nb₂O₅ thickens on the surface. As the potential passes through the range 10-150V, the film exhibits the expected range of interference colors. Film breakdown occurs at about 160V.

The smooth rise in potential of the glassy alloy on passage of the anodic current can be ascribed to thickening of the film, which is evidently less resistive when formed on the glassy alloy substrate than on pure Nb. It is never possible to grow thick Nb₂O₅ films on the glassy alloy surface in acidic conditions because oxygen evolution occurs at quite modest overpotentials. The features in the glassy alloy discharge curve cannot be assigned with certainty. However, the rapidity of the potential decay in Fig. 6b compared with the potential rise is worthy of note: in the film growth region ($t = 0$ to $t = 104$ s in the anodic half-cycle) the charge passed was 10.4 mC cm⁻², whereas in the cathodic half-cycle ($t = 0$ to $t = 10$ s after current reversal) the charge passed before the onset of hydrogen evolution was only 1 mC cm⁻². The potentials of all the Nb/Nb oxide couples are so low that it is quite possible that a niobium oxide film persists on the electrode during hydrogen evolution.

The kinetics of hydrogen evolution on glassy 60Ni-40Nb in acidic solutions are complicated by absorption of hydrogen into the alloy, which readily occurs on cathodization. This uptake of hydrogen manifests itself both physically and electrochemically. Physically, the absorption of hydrogen results in the expansion of the metal (as shown by the curling of an initially straight piece of ribbon when hydrogen is evolved on one side only) and its embrittlement. Prolonged hy-

Fig. 5. A, left: galvanostatic charging curves of glassy 60Ni-40Nb in 30% KOH at 70°C. Between $t = 0$ and $t = 2.8$ s, the anodic current density was 10 mA cm^{-2} . At $t = 2.8$ s (marked with a vertical arrow) the current was reversed. The electrode was polished before the first cycle only. B, right: decay of open-circuit potential of glassy 60Ni-40Nb in 30% KOH at 70°C after potentiostasis at 2.1V NHE for 5s.

Fig. 6. A, left: galvanostatic charging curve of glassy 60Ni-40Nb (indicated by the word "alloy") in 0.5M H₂SO₄ at 30°C. Anodic current density $100 \mu\text{A cm}^{-2}$. The anodic charging curve for Nb under the same conditions is shown for comparison. B, center: discharge curve for glassy 60Ni-40Nb after current reversal (at $t = 300$ s in Fig. 6a). C, right: decay of open-circuit potential of glassy 60Ni-40Nb in 0.5M H₂SO₄ at 30°C after potentiostasis at 2.2V NHE for 300s.

drogen evolution causes the alloy to become friable and to disintegrate. Electrochemically, the absorption of hydrogen results in non-Tafel behavior and time dependence in the hydrogen evolution region, the overpotential increasing with time and the Tafel slope decreasing from its initial value of $115 \text{ mV decade}^{-1}$. This time dependence was not noted by Naka *et al.* (9), but they showed that the hydrogen evolution overpotential increases with increasing x in the alloys $(100 - x)\text{Ni}-x\text{Nb}$.

Considerable quantities of hydrogen are dissolved by glassy 60Ni-40Nb on cathodization. For example, after 70h potentiostasis at -0.3V NHE in $1\text{M H}_2\text{SO}_4$ at room temperature, the hydrogen content (measured with a Strohlein H-mat) corresponded to the atomic composition 86.5(60Ni-40Nb)-13.5H. Even after this time, the hydrogen content was still rising slowly, so this is not a limiting composition. The composition 78(60Ni-40Nb)-22H was reached by three days cathodization at 1A in $0.56\text{M H}_2\text{SO}_4$. The high solubility of hydrogen in the glassy alloy is not surprising since both its components form hydrides: up to $\text{NbH}_{2.97}$ (40) and a distinct $\text{NiH}_{0.7}$ phase (41) can be formed electrochemically. Crystalline 10Ni-90Nb and 31Ni-69Nb are also hydrogen embrittled by cathodic polarization in 25% KOH (11); the spalled surface layers produced

by 20 days' immersion at the free corrosion potential had the composition $\text{NbH}_{0.89}$ (12).

These indications of the absorption of hydrogen by the glassy alloy led us to the permeation experiments illustrated in Fig. 7-9, initially undertaken with the aim of measuring the diffusion coefficient of hydrogen in the material. Figure 7 shows typical transients for as-quenched, polished ribbons and two different generating currents i_{gen} . Experiments on different ribbon samples yielded qualitatively similar results. The permeation current did not increase smoothly with time to a constant limiting current, as it does for simple diffusion, but rather exhibited pronounced variations about a roughly linearly increasing mean. The breakthrough time (*i.e.*, the time at which the permeation current is first observed) was long and irreproducible, varying by an order of magnitude. This is probably due to varying amounts of residual or reformed oxide film on the ribbon surfaces. When the generating currents were switched off the permeation currents fell rapidly to zero, as illustrated in Fig. 7a. This indicates that mechanical failure of the alloy had occurred, shorting the ribbon bielelectrode.

Figure 8 illustrates the rather different transients obtained on ribbons annealed *in vacuo* for 30 min at 642°C : this anneal produced no crystallinity detectable

Fig. 7. Electrolytic hydrogen permeation currents for unannealed, polished glassy 60Ni-40Nb foils for generating currents i_{gen} of (a, top) 20.8 mA cm^{-2} and (b, bottom) 3.8 mA cm^{-2} . The vertical arrow indicates the time at which the generating current was switched off.

by x-ray diffractometry. The rising transient for the annealed glassy alloy is much smoother, though the shape is still not that predicted theoretically for simple diffusion under well-defined boundary conditions. The breakthrough times are still very irreproducible. The decay on switching off i_{gen} remains very abrupt, whereas for simple diffusion it should be gradual. Figure 8b shows a transient obtained with an annealed ribbon, cold-rolled to 95% of its original thickness, and subsequently polished. Evidently cold-rolling has little effect on the permeation characteristics: even severe cold-rolling to 75% of the original thickness did not modify the general form of the transients observed on annealed ribbons.

These results differ greatly from those obtained from permeation experiments on crystalline metals such as Pd and Ni (42) or Fe (43). Hydrogen atoms diffuse through these metals in an essentially non-cooperative manner, so that permeation currents rise and fall smoothly. The cause of the behavior observed with glassy 60Ni-40Nb is not the glassy structure per se, for Latanision *et al.* (6) and Lin and Johnson (44) have observed normal permeation transients for Fe-Ni-P-B glasses; rather, we attribute the observed behavior to the mechanical damage inflicted on the Ni-Nb alloy by hydrogen uptake. Ribbon fracture occurs as the permeation experiment progresses. This is made evident in two ways. First, leakage between the two cell compartments can be observed, and the ribbon dis-

Fig. 8. Electrolytic hydrogen permeation currents for glassy 60Ni-40Nb foils. A, top: ribbon annealed and polished. B, bottom: ribbon annealed, cold-rolled, and polished. The generating current was 3.8 mA cm^{-2} for both a and b, and the ribbons were annealed *in vacuo* for 30 min at 642°C . The vertical arrows indicate the times at which the generating currents were switched off.

integrates on handling. Second, the permeation current becomes equal to the generating current: this occurs when a sufficiently large channel of electrolyte is formed by cracking the ribbon to short the bielectrode completely out of the circuit. This condition is attained in Fig. 9a and 9b, which were obtained using lower generating currents on annealed ribbons. Little or no hydrogen permeates the ribbons before the abrupt increase in permeation current that indicates mechanical failure. Fragments of fractured ribbon examined microscopically at magnifications up to $1500\times$ showed brittle fracture surfaces which were often decorated with microcracks.

The very irregular form of the permeation transients obtained for the as-quenched ribbons as compared with the much smoother transients for the annealed ribbons is of interest. In as-quenched melt-spun ribbons, a high concentration of diffuse defects exists. In particular, excess free volume may be distributed over a number of atomic sites (45). Annealing relaxes the glassy structure and reduces the excess free volume. Low temperature annealing often causes some loss in ductility (46), and does so in 60Ni-40Nb. Cold-rolling introduces shear bands. The similarity of Fig. 8a and 8b shows that the introduction of shear bands does not significantly alter the permeation of the annealed alloy by hydrogen. Since it is unlikely that the surface films (which are no doubt present on both ribbon faces) are significantly different for annealed as com-

Fig. 9. Electrolytic hydrogen permeation currents for annealed, polished glassy 60Ni-40Nb foils for generating currents of (a, left) $695 \mu\text{A cm}^{-2}$ and (b, right) $174 \mu\text{A cm}^{-2}$.

pared with as-quenched ribbons, it follows that the difference in bulk structure must be responsible for the difference in permeation behavior. Hydrogen embrittlement is thought to occur by concentration of the hydrogen in regions in which its Gibbs energy is lowest. This causes local expansion of the solid; cracking then occurs in response to the stress created by nonuniform expansion. In the as-quenched glass, hydrogen could accumulate in the quenched-in diffuse defects, resulting in a nonuniform distribution of hydride phase and severe embrittlement: this occurs when crystalline Nb is cathodically charged (40, 47). In the annealed material, the structure is much more homogeneous, and thus the absorbed hydrogen is likely to be less localized. Consequently, the annealed glassy alloy fails in a less dramatic manner than the as-quenched material.

Acknowledgments

The Electrochemistry of Glassy 60Ni-40Nb in Some High Temperature Aqueous Media

N. C. Grant and M. D. Archer*

Department of Physical Chemistry, University of Cambridge, Cambridge CB2 1EP, England

ABSTRACT

The high temperature aqueous electrochemistry of glassy melt-spun 60Ni-40Nb was investigated. Glassy 60Ni-40Nb subjected to cyclic voltammetry (CV) in 1*m* NaOH at 150°C undergoes corrosion, which produces niobates in solution and a thick scale of nickel oxide on the alloy. The latter yields CV peaks due to the Ni₃O₄/Ni₂O₃ and Ni₂O₃/NiO₂ transformations. In 1*m* NaHSO₄ at 300°C, the glassy alloy corrodes to yield Ni(II) in solution, and an adherent layer of Nb₂O₅ is formed on the electrode surface. The glassy alloy takes up substantial quantities of hydrogen at its rest potential in this medium. In 1*m* Na₂CO₃ at 150°C, behavior similar to that in 1*m* NaOH is observed, except that the glassy alloy takes up some hydrogen at its rest potential. In 1*m* Na₂CO₃ at 300°C, some hydrogen uptake again occurs at the rest potential, and a scale of nickel oxide is formed on the glassy alloy, but no oxide transformation peaks are observed in the CV because they are obscured by facile oxygen evolution at this high temperature. The assignment of features in the CV of glassy 60Ni-40Nb was made by comparison with similar experiments on crystalline Ni and Nb, and with thermodynamic data at the same temperature, and by *ex situ* microscopical examination of ZnSe-coated cross sections of the corroded electrodes.

In the preceding paper (1), we showed that glassy 60Ni-40Nb is extremely resistant to most forms of electrochemical attack at room temperature except hydrogen embrittlement. Alloys generally exhibit electrochemical properties characteristic of all their principal ingredients. Binary Ni-Nb alloys should possess the resistance to acidic media characteristic of Nb and the resistance to alkaline media characteristic of Ni. However, crystalline Ni-Nb alloys are brittle, whereas the glassy alloy is tough and flexible. This useful combination of good mechanical properties and high resistance to room-temperature corrosion stimulated the present study of the behavior of glassy 60Ni-40Nb under more extreme conditions, in four acidic and alkaline media at 150° or 300°C. As far as we know, no previous studies on high temperature aqueous electrochemistry of glassy alloys have been reported. Glassy 60Ni-40Nb is well suited to such a study, since its crystallization temperature is 650°C (2), so there is no risk of crystallization occurring during work at 300°C.

Experimental

Glassy 60Ni-40Nb ribbons, typically 2 mm wide and 20 μm thick, were formed by the melt-spinning technique (3) as previously described (1).

Conventional three-electrode experiments were carried out using a Chemical Electronics linear sweep generator and TR40/3A potentiostat, and a Bryans XY 26000 A4 chart recorder. The electrochemical experiments were performed in a PTFE beaker housed in a mild steel autoclave. Standpipes in the autoclave lid carried the electrode and thermocouple leads and access to an argon line. The temperature of the autoclave was controlled by a Perkin-Elmer precision oven.

Working electrodes of glassy 60Ni-40Nb were produced by spot-welding 5 cm lengths of ribbon to a platinum wire which passed through the appropriate standpipe. 1 mm diam wires of Ni (99.999%) and Nb (99.95%), obtained from Johnson Matthey Limited, Royston, Herts., England, were also used as working electrodes. The welded joint between the platinum and the electrode material was positioned well above the solution meniscus. Nevertheless, it is likely that the platinum was in exiguous contact with the solution. Prior experiments on the electrochemistry of platinum in aqueous solutions at high temperatures showed that any current derived from the platinum was negligible compared with those derived from the working electrode proper.

* Electrochemical Society Active Member.

Key words: glassy metal, nickel-niobium alloy, high temperature electrochemistry.

The counterelectrode was a concentric cylinder of platinum gauze. A dynamic hydrogen electrode (DHE) polarized at 1 mA cm⁻² (4) was used as the reference electrode. The potential of this electrode lies 50 ± 20 mV below the reversible hydrogen evolution potential at each temperature and pH (5). The potential of the DHE with respect to the normal hydrogen electrode (NHE) is given, therefore, by

$$E(\text{NHE}) = (RT/F) \ln [H^+] - 0.05V$$

Since the pH dependence of the thermodynamic potentials for oxygen evolution, hydrogen evolution, and oxidation state transformations of metal oxides (e.g., Ni₃O₄/Ni₂O₃) is the same as that of the DHE, the potentials observed for such processes *vs.* the DHE at various pH's can be compared with the corresponding standard potential on the NHE scale simply by addition of 50 mV to the potential observed *vs.* DHE

$$E(\text{DHE}, \text{pH} \neq 0) = E(\text{NHE}, \text{pH} = 0) - 0.05V$$

The DHE was used in this work because it is one of the few reference electrodes robust enough to withstand temperatures of 300°C. The hydrogen generated during its use is sufficient to saturate the solutions at both 150° and 300°C, but hydrogen is very sparingly soluble at these temperatures.

Aqueous solutions of NaOH, NaHSO₄, and Na₂CO₃, of concentration 1*m* at room temperature, were prepared from AR chemicals and doubly distilled water. 80 cm³ of solution were used in each experiment. The working electrodes were cleaned before each run by washing, first in acetone and then in distilled water. The autoclave was assembled and flushed three times with high purity argon at 1000 psi. It was then sealed under 400 psi argon, placed in the oven, and heated. Heating to 150°C took about 1h, and heating to 300°C about 1.5h; during this period the working electrodes were at open circuit. It was not possible to apply cathodic protection against corrosion during the warm-up period because glassy 60Ni-40Nb is subject to severe hydrogen embrittlement (1).

Heating the solutions changes their densities and causes appreciable loss of water by evaporation. The calculated molality and pH of each high temperature solution used are given in Table I. The vapor pressure and density of pure water were used in calculation of these figures, which are therefore approximate. The equilibrium constants needed for the pH calculations were taken from the literature (6, 7). In calculating the current density, the immersed area of each

Table I. Calculated molality and pH of nominally 1m solutions

Medium	Molality	pH (molal units)
NaOH 150°C	0.99	11.2
NaHSO ₄ 300°C	0.94	3.2
Na ₂ CO ₃ 150°C	0.99	11.0
Na ₂ CO ₃ 300°C	0.94	11.3

working electrode was corrected for the effects of evaporation and the change in solution density.

Used working electrodes and free corrosion specimens were mounted in a thermosetting plastic and ground and polished to expose a cross section. This procedure fractured the mechanically weaker specimens. The samples were examined with an optical microscope and with a Cambridge Instruments S410 scanning electron microscope equipped with an EDAX facility. The samples for optical examination were coated with a thin (<100 nm) film of vapor-deposited ZnSe (8, 9). The purpose of this coating is illustrated in Fig. 1. The color produced by destructive interference between light reflected from the air-film and the film-substrate interfaces depends on the optical properties, and hence on the chemical identity, of the substrate. Thus chemically different areas in the substrate appear differently colored. ZnSe is used because its high refractive index produces good color contrast. By examination of one specimen both by EDAX and by ZnSe interferometry, the interference colors can be chemically assigned. Many specimens can then be quickly identified by the ZnSe technique. Uniformity of thickness in the ZnSe coating is required for this technique to be reliable. This was assessed by reference to a steel washer placed next to the specimen. ZnSe deposition was continued until the color of the coated washer was the same in all samples. Unfortunately, the black-and-white reproductions of Fig. 4, 7, and 10 do not convey all the detail of the colored originals.

Pourbaix Diagrams

Thermodynamic data on the Ni-H₂O and Nb-H₂O systems assist the assignment of features in the cyclic voltammograms. Figure 2a, taken from Cowan and Staehle (10), shows the Pourbaix diagram for Ni at 300°C, which is broadly similar to the room temperature diagram. Some extrapolations and approximations were used in the compilation of the high temperature diagram, which must therefore be used with caution. Table II summarizes the relevant data for the anhydrous oxides. Hydration of the oxides shifts these standard potentials only slightly. For example, at room

Fig. 1. Metallographic examination of corrosion films by ZnSe coating technique.

temperature the Ni/Ni(OH)₂ potential is only 6 mV below the Ni/NiO potential (11).

Figure 2b shows our calculated Pourbaix diagram for Nb at 300°C. The diagram shows data for the phases Nb, NbO, NbO₂, and Nb₂O₅ only, because of the lack of thermodynamic data on niobium hydrides and niobates. However, Nb₂O₅ does dissolve in strong alkali to form niobates. Figure 2b was calculated from enthalpy and heat capacity data on niobium and its oxides (12) and on water (13). The equilibrium potentials of the niobium/niobium oxide couples are all well below the hydrogen evolution potential. The effect of temperature is again slight, as shown in Table III.

It is worth noting that at 150°C, and more particularly at 300°C, oxide-transformation CV peaks usually appear much nearer their thermodynamic potentials

Fig. 2. Pourbaix diagrams for (a, left) Ni and (b, right) Nb at 300°C. The concentration of dissolved ions in the Pourbaix diagram of Ni is 10⁻⁶M. The upper faint line represents oxygen evolution, and the lower, hydrogen evolution.

than at room temperature, because they are usually kinetically controlled and hence occur faster at higher temperatures. Thus Pourbaix diagrams are a more reliable guide to peak assignment at high temperatures than they are at room temperature.

Results and Discussion

0.99M NaOH at 150°C.—Figure 3 shows steady-state cyclic voltammograms (CV's) for glassy 60Ni-40Nb and crystalline Nb and Ni. Niobium (Fig. 3b) dissolves freely as niobates in this strongly alkaline medium at low potentials, and shows some tendency to passivate at higher potentials. The rest potential E_r (see Table IV) was very low (-0.315V DHE): niobate and hydrogen formation are presumably the balancing processes at E_r . Nb behaves similarly at room temperature in 15M NaOH although the active dissolution peak is then smaller (1). Macleary (14) records the corrosion rate of Nb in 5% NaOH at 98°C as 9390-18,780 mg dm⁻² day⁻¹, which is equivalent to a corrosion current density of 1.15-2.3 mA cm⁻².

Nickel did not dissolve on repeated cycling between 0.02 and 1.55V DHE, i.e., within the effective hydrogen and oxygen evolution potentials in this medium. Its CV (Fig. 3c) showed two reproducible peaks, I and II, which can be assigned by comparison with the thermodynamic data of Table II. Peak I in Fig. 3c is at 1.39V DHE, and peak II is at 1.22V. The mean value, 1.30V, agrees well with Eq. [5] of Table II for the Ni₃O₄/Ni₂O₃ couple. Over the sweep rate range 0.5-2.5 mV s⁻¹, the charge under peak II was constant at 118 ± 10 mC cm⁻², confirming that reaction of a surface, rather than a dissolved, species is occurring.

Glassy 60Ni-40Nb has a CV (Fig. 3a) that indicates Ni-like behavior of the surface. Nb was detected in solution after this experiment by the precipitation of Nb₂O₅ on neutralization, and the ZnSe technique (Fig. 4) showed that only nickel oxide was present in the corrosion layer. Nb also dissolved from specimens freely corroding in this medium. We conclude that,

Table IV. Rest potentials E_r in V vs. DHE

Medium		60Ni-40Nb	Ni	Nb
1M NaOH	150°C	0.625-0.725	0.775	-0.315
1M NaHSO ₄	300°C	0.015-0.060	0.052	-0.030-+0.030
1M Na ₂ CO ₃	150°C	0.020	0.455	-0.27
1M Na ₂ CO ₃	300°C	0.01-0.07	—	—

Fig. 3. CV's of (a, top) glassy 60Ni-40Nb, (b, center) Nb, and (c, bottom) Ni in nominally 1M NaOH at 150°C. Sweep rates: (a) 25.5, (b) 30, and (c) 25.8 mV s⁻¹.

during the warm-up period for the experiment of Fig. 3a, Nb has dissolved and the CV consequently shows the transformations of the nickel oxide corrosion layer remaining. In addition to peaks I and II, which were also obtained on crystalline Ni, an additional cathodic peak IV was observed at 1.39V DHE. This peak did not appear unless the anodic sweep limit was above 1.49V. We infer that there is an anodic peak (peak III) concealed under the current due to oxygen evolution, and

Fig. 4. Optical micrograph of ZnSe-coated cross section of glassy 60Ni-40Nb after the experiment of Fig. 3a.

Fig. 5. Scanning electron micrograph of the surface of glassy 60Ni-40Nb after the experiment of Fig. 3a.

that peak IV is its conjugate reduction peak. [Peak III can be seen in the CV of Ni in $1\text{m Na}_2\text{CO}_3$ at 150°C (Fig. 8a)]. The potentials of peaks I and II in Fig. 3a are 1.44 and 1.30V DHE, respectively, and, as for Ni itself, we ascribe these to the $\text{Ni}_3\text{O}_4/\text{Ni}_2\text{O}_3$ transformation. Assuming that the concealed peak III is at 1.49V, the average of the peak potentials of peaks III and IV is 1.44V DHE, in agreement with Eq. [6], and we therefore ascribe these two peaks to the $\text{Ni}_2\text{O}_3/\text{NiO}_2$ transformation.

At 150°C in 1m NaOH , the rest potentials (Table IV) of Ni and the glassy alloy are high and approach the $\text{NiO}/\text{Ni}_3\text{O}_4$ potential. It is noteworthy that at 150°C , the CV's show distinct $\text{Ni}_3\text{O}_4/\text{Ni}_2\text{O}_3$ and $\text{Ni}_2\text{O}_3/\text{NiO}_2$ transformations at roughly the thermodynamically predicted potentials. At room temperature in 15M NaOH (1), these two peaks were not resolvable.

Fig. 8. CV's of (a, top) glassy 60 Ni-40Nb, (b, middle) Nb, and (c, bottom) Ni in nominally 1M Na_2CO_3 at 150°C. Sweep rates: (a) 26.5, (b) 30, and (c) 25.5 mV s^{-1} .

the peaks. The charge under either peak I or peak II in Fig. 3a is 13.8 mC cm^{-2} . Assuming that the surface density of Ni atoms is the mean of that for $\text{Ni}_3\text{O}_4 \cdot 2\text{H}_2\text{O}$ ($7.93 \times 10^{14} \text{ cm}^{-2}$) and Ni_2O_3 ($1.073 \times 10^{15} \text{ cm}^{-2}$), this charge is equivalent to the transformation of about 40 monolayers. The corrosion scale formed by CV is much thicker than this, as is evident from Fig. 4. Only the superficial region of the corrosion layer is redox-active in cyclic voltammetry.

Figure 4 shows a ZnSe photograph of the cross-sectioned glassy electrode of Fig. 3a. The corrosion layer was not strongly adherent, and, on drying the electrode, part of it spalled off, as shown in the scanning electron micrograph of Fig. 5. The scale was lifted entirely off the substrate by the mounting and cross sectioning procedure, as can be seen in the upper fragment of Fig. 4. This has a central portion of uncorroded alloy, which appears orange in color under the ZnSe coating, encased in a corrosion layer ca. $6 \mu\text{m}$ thick, which, from its purple color, can be identified by comparison with the corrosion scale formed on nickel itself as nickel oxide. The lower fragment shown in Fig. 4 contains no uncorroded alloy and consists entirely of nickel oxide. We could not reliably distinguish between the possible oxidation states of this scale by the ZnSe interference colors, but it appeared to be duplex in nature.

0.94M NaHSO_4 at 300°C.—Crystalline Ni dissolves so rapidly in this acidic medium that no cyclic voltammogram could be obtained for it. The behavior of Nb and glassy 60Ni-40Nb is shown in Fig. 6, from which it is apparent that in this medium the alloy exhibits a Nb-

like surface. This is confirmed by the ZnSe photograph of a free corrosion specimen (Fig. 7). This shows a central orange portion of uncorroded alloy covered by an adherent, featureless film ca. $8 \mu\text{m}$ thick that appears colorless under the ZnSe coating. This was shown by EDAX to be a niobium oxide, presumably Nb_2O_5 . Analysis of the solution after the experiment of Fig. 6a showed no dissolved Nb, but rather a high concentration of dissolved Ni. Of the nickel initially present in the glassy alloy sample, about one-third was present as Ni(II) in solution at the end of the experiment.

As Fig. 6 indicates, neither Nb nor glassy 60Ni-40Nb initially yielded a steady-state CV in 1M NaHSO_4 . During the warm-up period, both specimens assumed rather low rest potentials (Table IV). A large anodic peak at 0.30V was seen on the first positive-going sweep (numbered 1 in Fig. 6), but this decreased in magnitude with each succeeding sweep until after about five it was completely absent. In the case of the alloy, it would be possible to attribute this peak to Ni(II) formation. However, this cannot be the case for Nb, and the similarity in the CV's of the two materials suggests that they have the same cause. We tentatively ascribe this transient peak to the oxidation of hydrogen generated

Fig. 9. CV's of (a, top) glassy 60Ni-40Nb, and (b, bottom) Ni in nominally 1M Na_2CO_3 at 300°C. Sweep rates: (a) 0.4 and (b) 22.2 mV s^{-1} .

at E_r and absorbed by the niobium or the Nb-like surface of the glassy alloy during the warm-up period. The rest potentials are sufficiently negative to indicate hydrogen generation and Nb_2O_5 film growth (and, in the case of the alloy, Ni(II) formation) as probable balancing processes at E_r . Moreover, other evidence supports the hypothesis that these two materials are likely to take up hydrogen at their rest potentials in acidic solution: the glassy alloy dissolves substantial quantities of hydrogen on cathodization (1). Niobium is also known to form hydrides on cathodization (15, 16).

The charges under the first sweep peaks were 0.29 and 0.07 C cm^{-2} for the glassy alloy (Fig. 6a) and Nb (Fig. 6b), respectively. Oxidation of a monolayer of hydrogen atoms requires only *ca.* 1.5 mC cm^{-2} , so if the peaks are due to the oxidation of absorbed hydrogen, substantial amounts of hydrogen have been generated on, and absorbed by, both Nb and 60Ni-40Nb at E_r in the warm-up period. Possibly some of the hydrogen generated by the reference electrode is also absorbed during warm-up. The decline of the peak with sweep number would be expected, because once the potential cycling has started, the amount of hydrogen generated by the relatively brief excursions to negative potentials would be negligible on this current scale. The large concentration of Ni(II) found in solution after the experiment of Fig. 6a must have dissolved during the warm-up period, since no peak due to Ni(II) formation appears in the steady-state CV of the glassy alloy.

0.99m Na₂CO₃ at 150°C.—Figure 8 shows CV's of 60Ni-40Nb, Nb, and Ni in nominally *1m Na₂CO₃* at 150°C. Behavior broadly similar to that in *1m NaOH* at 150°C is observed. Nb (Fig. 8b) has a very low rest potential in this medium (Table IV). A substantial peak at -0.091V , due to dissolution of Nb as niobates, and a tendency to passivate at higher potentials are again observed in its CV: however, the critical current density and passivation potential are both lower than in the more alkaline *1m NaOH* (Fig. 3b). Ni does not dissolve in *1m Na₂CO₃*, and its CV (Fig. 8c) again indicates the surface transformations $\text{Ni}_3\text{O}_4/\text{Ni}_2\text{O}_3$ (peaks

I and II, centered at 1.28V DHE) and $\text{Ni}_2\text{O}_3/\text{NiO}_2$ (peaks III and IV, centered at 1.35V DHE). These potentials are slightly low compared with the thermodynamic values of Eq. [5] and [6] of Table II, but this is partly because the peak maxima are shifted by the steep backgrounds against which they appear. It is interesting that peak III, ascribed to the superficial oxidation of Ni_2O_3 to NiO_2 , is observed in *1m Na₂CO₃*, but not in *1m NaOH*, at 150°C. Glassy 60Ni-40Nb (Fig. 8a) also shows the Ni oxide transformation peaks I, II, and IV, less well defined than in *1m NaOH*, but peak III is here obscured. The midpoint potentials for the $\text{Ni}_3\text{O}_4/\text{Ni}_2\text{O}_3$ and $\text{Ni}_2\text{O}_3/\text{NiO}_2$ peaks in Fig. 8a are 1.36 and 1.43V DHE, respectively. The ZnSe technique confirmed that the corrosion scale formed on the glassy alloy was nickel oxide.

The first sweep conducted on the glassy alloy (numbered 1 in Fig. 8a) differed from that observed in *1m NaOH* at 150°C in that a substantial peak at 0.27V was observed on the first sweep, but not on subsequent ones. This could be due either to the oxidation of hydrogen absorbed during the warm-up period, as proposed for the transient 0.30V peak observed in the CV in *1m NaHSO₄* (Fig. 6a), or to niobate formation: the position of this peak, 0.36V positive of the niobate formation peak of Fig. 8b, and the rest potential (0.02V DHE) suggest that the oxidation of absorbed hydrogen is probably predominant, but the shoulder at 0.077V might be niobate formation. The rest potential of the glassy alloy is much higher in *1m NaOH* at 150°C than it is in *Na₂CO₃*, and it is therefore to be expected that no transient hydrogen oxidation peak should appear in the first sweep in NaOH. No niobate was found in the cooled solution after the experiment of Fig. 8a, although the above evidence shows that it must have dissolved from the alloy during warm-up. However, the corroded electrode was covered with a crystalline niobate that presumably precipitated from the carbonate solution on cooling.

0.94m Na₂CO₃ at 300°C.—At positive potentials, Nb dissolved in this medium so rapidly that no CV was obtainable. The behavior of glassy 60Ni-40Nb and Ni

Fig. 10. Optical micrograph of ZnSe-coated cross section of a free corrosion specimen of 60Ni-40Nb after immersion in nominally *1m Na₂CO₃* at 300°C for 24h.

is shown in Fig. 9a and 9b, respectively. The ZnSe photographs showed that both electrodes had developed thick (ca. 10 μm) nickel oxide corrosion scales during an experiment of 20h duration. The previously observed $\text{Ni}_3\text{O}_4/\text{Ni}_2\text{O}_3$ and $\text{Ni}_2\text{O}_3/\text{NiO}_2$ transformations are, however, now not seen in either CV, presumably because they are hidden under the current due to oxygen evolution. Instead of being subject to a substantial overpotential as it is at lower temperatures, this now appears in the region of the standard $\text{O}_2/\text{H}_2\text{O}$ potential, which at 300°C is 1.07V DHE, below the higher oxide conversion potentials (Eq. [5] and [6], Table II). On both glassy 60Ni-40Nb and Ni, oxygen evolution reaches a current density of 1 mA cm^{-2} at ca. 1.2V DHE. The nickel oxide corrosion layer is evidently able to sustain oxygen evolution at a negligible overpotential at this temperature. Miles *et al.* (17) have reported that the exchange current for oxygen evolution on Ni in 50 weight percent KOH increases sharply between 150° and 264°C. By contrast, on the Nb_2O_5 layer formed on the glassy alloy in 1M NaHSO_4 (Fig. 6a), oxygen evolution commenced only above 1.5V DHE even at 300°C, and this layer is presumably rather resistive.

The CV of nickel showed two sharp peaks at low potentials, V and VI in Fig. 9b, which were not observed at 150°C. These occur at 0.26 and 0.06V DHE, respectively. Peak V is probably due to a surface reaction, rather than to the oxidation of a solution species. This was shown by stopping the CV at the cathodic limit or just negative of peak V for various lengths of time. The height of peak V was unaffected in both cases, so the hypothesis that peak VI is caused by generation of hydrogen in solution, and peak V by its oxidation, is probably wrong. Reference to Table II shows that peaks V and VI could be due to the Ni/NiO transformation, although the absence of any peaks due to the NiO/Ni₃O₄ transformation is then anomalous.

Peak VII (Fig. 9a) at 0.15V DHE, observed only during the first positive going sweep on the glassy alloy, is also difficult to assign. It is possible that the cathodic peak VI would have appeared in this CV had the potential been taken lower, but lower potentials were avoided because they caused hydrogen embrittlement. It is not possible to decide whether peak VII is due to oxidation of absorbed hydrogen or to niobate formation: both of these were also thought possible in the CV obtained at 150°C (Fig. 8a).

Figure 10 and 11 show ZnSe photographs and Ni and Nb EDAX maps of the same portion of a specimen of glassy 60Ni-40Nb freely corroded in 1M Na_2CO_3 at 300°C for 20h. (Corroded working electrodes gave very similar results.) All three pictures show a central portion, appearing orange under the ZnSe coating, which from its Ni:Nb ratio can be positively identified as the uncorroded alloy. The duplex corrosion film contains Ni, but not Nb. Some Nb containing crystals can be seen in Fig. 11c to have formed on top of this corrosion film. These are the niobates which dissolved from the alloy at 300°C, but which precipitated on cooling because they are insoluble at room temperature. As for 1M Na_2CO_3 at 150°C, no Nb was detected in the cooled solution after CV of the glassy alloy.

Conclusions

In the high temperature acidic medium (1M NaHSO_4 at 300°C), some Ni dissolves from glassy 60Ni-40Nb at its free corrosion potential, and the alloy surface becomes covered by a strongly adherent layer of Nb_2O_5 . In the three high temperature alkaline media (1M Na_2CO_3 at 150° and 300°C, and 1M NaOH at 150°C), niobium dissolves as niobates and the alloy becomes covered by a scale of nickel oxide, which is less adherent than the acid-formed Nb_2O_5 layer. Thus, as at room temperature (1), the glassy alloy possesses a combination of the corrosion-resistant properties of

Fig. 11. a, top: scanning electron micrograph of the area shown in Fig. 9, b, center: Ni EDAX map of the same area, c, bottom: Nb EDAX map of the same area.

Ni and Nb, though the corrosion scale formed at 150° and 300°C is too thick with respect to the ribbon thickness to regard the material as usefully resistant to corrosion at high temperatures in these aggressive media.

An Examination of Current Fluctuations during Pit Initiation in Fe-Cr Alloys

Ugo Bertocci* and Ye Yang-Xiang†

National Bureau of Standards, Center for Materials Science, Washington, DC 20234

ABSTRACT

Random fluctuations of the passive current for Fe-Cr alloys of various Cr content were examined, in borate buffer and in the same solution with 0.1M NaCl added. Frequency spectra of these fluctuations were recorded before and during pit initiation. No detectable fluctuations were observed in the absence of chlorides, where pitting does not occur. Comparison with the current noise measured before pit initiation indicates that the most important role of the aggressive ions is that of increasing the chance of local breakdown of the passive film. Frequency spectra give information concerning the time constants of the various processes, including repassivation. No correlation was found between the rate of attack during pitting and noise amplitude.

During the induction period leading to pitting, a number of workers have observed, under potentiostatic conditions, sudden current bursts (1), but little is known about their shape and frequency content. Some authors (2) have proposed that a dynamic equilibrium exists between random events of breakdown of the passive film and its repair by repassivation, and that pitting would occur when the repassivation rate is too slow compared to the rate of local attack. Such a description of the processes leading to the breakdown of a passive film suggests that random fluctuations (that is, current noise) should be observed.

The availability of sensitive methods for detecting and analyzing current fluctuations under potentiostatic conditions (3) and previous experimental results showing a large increase in the amplitude of the noise spectra after the onset of pitting (4) suggest that it would be useful to examine in detail the current noise during the induction period before pitting starts, as well as during the pitting transients. Also of special importance is the examination of the role of alloy composition on the current fluctuations under pitting and nonpitting conditions.

The purpose of this work was to collect data concerning the amplitude and frequency of the current noise

before and after the onset of pitting and to examine the influence of metal composition and, to a limited extent, of the electrode potential on the noise spectra. As materials to be studied, three Fe-Cr alloys were chosen, with increasing Cr concentrations ranging from 5 to 12 to 20 atom percent (a/o) in Cr, so as to increase their resistance to corrosion and pitting.

Experimental Procedures

Materials, chemicals, and cells.—The electrodes were small rods prepared by vacuum melting, followed by swaging and annealing. The rods were sheathed in polytetrafluoroethylene and their cross sections, with a surface of 0.1 cm², were mechanically polished down to 600 grit paper. The solution employed for most of the experiments was a 1:1 mixture of saturated boric acid and saturated sodium tetraborate (B:B), to which 0.1M NaCl was added. The pH of the solution was about 8. Some measurements were made in B:B without addition of chloride. All chemicals were of analytical grade and the water was doubly distilled.

The cell employed for the measurements had a Pt counterelectrode, separated from the working electrode compartment by a coarse glass frit, and two reference electrodes, one made of a large Pt sheet, which was used as the sensor for the potentiostat, and a saturated calomel electrode (SCE), which was used to monitor the electrode potential. The Pt electrode, in spite of its lack of a well-defined potential, was fairly stable, drifting a few mV in the course of several

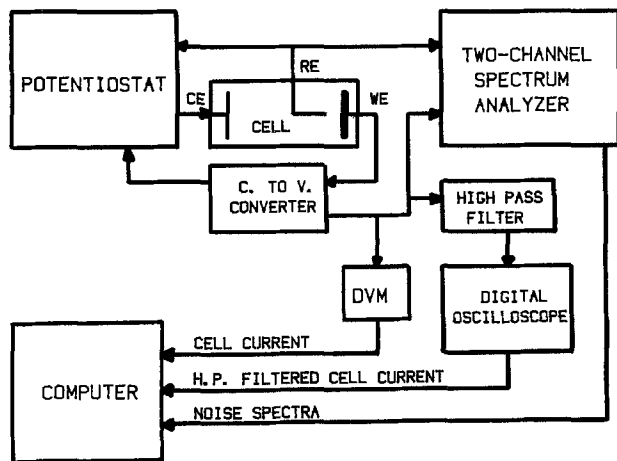

Fig. 1. Block diagram of the measuring system

hours. The atmosphere above the solution was air, and the cell was shielded mechanically with foam rubber and electrically by a double enclosure of mu-metal sheet.

Instrumentation.—The instrumentation employed was very similar to that described previously (3), with modifications in the layout as shown in Fig. 1. The three measuring instruments, that is, spectrum analyzer, DVM reading the dc current, and digital oscilloscope recording the high-pass filtered current, were connected to a computer, which was capable of triggering and controlling them and monitoring the spectrum analyzer for overloads.

For the study of the pitting transients the digital oscilloscope, connected in parallel to the current channel of the spectrum analyzer, started storing the trace when the fluctuations exceeded a set value. The onset of pitting was monitored by the dc current read by the DVM: when the current density exceeded a few microamperes per square centimeter, the computer triggered the spectrum analyzer while taking a current reading every second for 200s. For every pitting transient so examined, therefore, the data obtained were: (i) an unfiltered current density vs. time curve, sampled at 1s intervals, showing the increase in current due to pit formation; (ii) an oscillographic record of the current, sampled at 20–50 ms intervals, high-pass filtered at 30 mHz, which lasted from 50 to 100s and included a portion of the time immediately pre-

ceding the start of pitting, showing any fluctuations before pit initiation; and (iii) noise spectra of the voltage and the current, as well as the cross-power spectrum, taken from the moment the pit started and averaged over a time of a few minutes.

Data processing.—The processing of the spectra taken followed the method described in a previous paper (4), but was executed under computer control (5), so that the separation between the stochastic and deterministic part of the signal, after subtraction of the average instrumental noise, was accomplished for all 128 frequency values of a spectrum in less than 1 min after completion of the acquisition, and plots and printouts were immediately produced.

Optical examination.—The presence of pits on the surface after the pitting transients was confirmed by optical microscopy. The correlation with the current data was 100%.

Selection of the conditions for observing pitting.—Because of the large gain of the amplifiers and the low cutoff frequency of the high-pass filters, it was necessary to have a sufficiently long period, of the order of several minutes, from the establishment of the potential chosen for the pitting experiment to the actual pit initiation, in order for the instrumentation to recover from the overload caused by the manual adjustment of the potentiostat control voltage. However, it was highly desirable to cut the induction period relatively short. With these limits in mind, a number of preliminary tests, either slow potentiodynamic scans or long duration potentiostatic runs, was carried out, observing the effect of pH, chloride concentration, and potential-time schedules on the onset of pitting.

The procedure adopted after these tests was to employ a neutral borate buffer containing 0.1M of NaCl as the solution, to carry out the experiments at 300 mV vs. SCE for the 20% Cr alloy, at 100 mV for the 12% Cr alloy, and at -50 mV for the 5% Cr alloy. The other important point was that the surface had to be immersed into the solution less than 20 min after polishing. As for the manner of setting the desired potential, an operation which was found to be one of the most critical points, the procedure consisted in turning the potentiostat on at the open-circuit potential and then raising to the desired value manually by 50 mV steps and waiting 3–4 min at each potential.

The potentials chosen for the study are obviously higher than the "pitting potential." For instance, if the potential was raised quickly, pitting occurred with

Fig. 2. High-pass filtered time record of the current fluctuations of a Fe-12% Cr electrode in borate buffer plus 0.1M NaCl, before pit initiation. $E = 50$ mV vs. SCE. H. P. filter: 3 dB down at 30 mHz. Sampling rate: 50 ms.

high probability 50-100 mV below the value selected. If the potential was raised very slowly, with long pauses to let the passive film grow, it could be raised even a few hundreds of mV higher without observing any pit information, at least for a few hours.

Noise Spectra in the Absence of Pitting

Spectra of the current fluctuations were taken in boric acid/borate buffer without chlorides, where pitting does not occur. All three alloys were tested, and measurements taken at the same potentials at which pitting was studied in the NaCl-containing solutions. After subtraction of the instrumental noise, no electrode-generated random noise could be detected. In these conditions, therefore, taking the surface area into account, a maximum limit for the electrochemical noise can be established; this limit is of the order of $0.1 \text{ nA/cm}^2 \sqrt{\text{Hz}}$ between 1 Hz and 1 kHz, increasing to about $10 \text{ nA/cm}^2 \sqrt{\text{Hz}}$ at 50 mHz, because of the increasing instrumental noise at lower frequencies.

Noise data could also be collected in boric acid/borate buffer plus 0.1M NaCl before pitting started. During this induction period, isolated current transients were observed, as shown, for instance, in Fig. 2. Because of the low number of such current spikes, the averaging procedure of the spectrum analyzer tends to distort the results so that spectra taken in different frequency ranges (and therefore with different acquisition times) are not consistent in amplitude with one another. However, comparison between spectra of different alloys acquired under the same conditions are valid. Figure 3 shows that the noise increases with decreasing Cr content, and that the amplitude of each spectrum is essentially independent of frequency. This suggests that the current transients before pitting occur at random intervals and are spikes with rise and decay times shorter than 10 ms. This is in agreement with the oscillographic records such as Fig. 2, where only sudden transients can be seen. The spikes also disappear suddenly (at the sampling rate of 50 ms). The subsequent undershoots are an artifact of the 30 mHz high-pass filter.

Low frequency fluctuations, however, were detected on a 5% Cr alloy which had a freshly prepared surface and was brought rapidly at the measurement potential, another indication that film thickness and stability are critically dependent on the previous history of the electrode, particularly the duration of the various potentials. The record of the fluctuations before and at the moment of the start of the first pit is shown in

Fig. 4. High-pass filtered time record of the current fluctuations of a Fe-5% Cr electrode in borate buffer plus 0.1M NaCl, during pit initiation. $E = -50 \text{ mV}$ vs. SCE. H. P. filter: 3 dB down at 30 mHz. Sampling rate: 50 ms.

Fig. 3. Spectra of the random current fluctuations in borate buffer plus 0.1M NaCl before the onset of pitting.

Fig. 4, while spectra are shown in Fig. 5 for two potentials, both lower than the one employed for the pitting experiments. At -100 mV the amplitude plateau and the slope, close to -20 dB/decade , indicate fluctuations with a frequency of about 0.2 Hz and an amplitude of $1 \mu\text{A/cm}^2$. At even lower potential, the frequency of the large fluctuations is less than 0.1 Hz. For the higher Cr alloys, no such low frequency noise was observed before the start of pitting.

Pitting Transients

Once a pit starts growing, the current density increases in a roughly linear fashion, at least for 300-400s. It is impossible, therefore, to have strictly stationary conditions. However, if a high-pass filter eliminates the very low frequency components of the current density, remarkably consistent and reproducible spectra can be obtained, averaging over the period of linear increase of the current. The linearity can be taken as an indication that the growth of only one pit is being observed.

Examples of the current density vs. time plots recorded from the beginning of the pit growth are shown in Fig. 6. Average slopes and their standard deviations are given in Table I. A more detailed view of the

Fig. 5. Spectra of the random current fluctuations of freshly prepared Fe-5% Cr electrode in borate buffer plus 0.1M NaCl, before the onset of pitting.

fluctuations during pit initiation is given by the high-pass filtered record shown in Fig. 7.

No significant difference could be found between the slopes of the 12% and the 20% alloys, while the pits on the 5% Cr alloy grew almost twice as fast. If one considers the potential applied, it is evident that even after the protective film has been broken (pitting initiated), the higher Cr content slows down the attack.

The spectra of the random fluctuations of the current during the pitting transients are shown in Fig. 8, 9, and 10. The scatter from test to test was found to be in general less than 10 dB at the same frequency. It appears, therefore, that the difference in the results at 200 and 300 mV for the 20% Cr alloy (Fig. 8) is significant.

The tendency to larger amplitudes with higher potentials regardless of Cr concentration is detectable, although the difference between the spectrum of the 5% Cr alloy at -50 mV and the 12% Cr alloy at 100 mV is very small. It should be pointed out, however, that the amplitude of the current fluctuations does not

seem to be closely correlated with the magnitude of the corrosion current, which, on the average, increased twice as fast on 5% Cr than on the other two alloys.

The spectra, except possibly for the 20% Cr alloy, decrease monotonically with increasing frequency. A tendency to a low frequency plateau in Fig. 8 would indicate fluctuations of a period of about 10s and an amplitude of $100 \mu\text{A}/\text{cm}^2$. The spectra of the 5% and 12% Cr alloys break clearly into two segments, with a low frequency slope of about 30 dB/decade and a high frequency slope of about 15 dB/decade, beginning at 20 Hz. They cannot, therefore, be interpreted in terms of an exponential decay of the fluctuations, which would give a 20 dB/decade slope, but point to a more complex kinetics. The two slopes are less clearly evident for the 20% Cr alloy. The high frequency slope is close to 20 dB/decade and begins approximately at 10 Hz for the 200 mV data and 20 Hz at 300 mV.

Discussion

The results presented here show that in the absence of an aggressive ion such as Cl^- there are no detectable random fluctuations in the current density. Therefore, the description of a passive film as being in a continuous state of local breakdown, followed by rapid repassivation of the exposed surface, is not supported by the experimental evidence, unless the occurrence of these breakdown events is well below one every 10 min and/or it does not involve more than 10^5 atoms. Such a number is obtained by considering that a current burst of $3 \cdot 10^{-10}\text{A}$ for $3 \cdot 10^{-3}\text{s}$ would clearly contribute to the noise spectrum. The charge involved would correspond to the oxidation of some $3 \cdot 10^5$ atoms, a surface area of $0.03 \mu\text{m}^2$, or less, if the oxide is more than 1 atom layer thick.

Fig. 7. High-pass filtered time record of the current fluctuations of a Fe-20% Cr electrode in borate buffer plus 0.1M NaCl during pit initiation. $E = 400$ mV vs. SCE. H. P. filter: 3 dB down at 30 mHz. Sampling rate 20 ms.

In the presence of chlorides, current transients can be detected during the induction period, the spikes being of the order of $1 \mu\text{A}$ (see Fig. 2 and 3). Smaller, frequent fluctuations have been observed only for the 5% Cr alloy, for which the low chromium content confers little corrosion resistance. For the 12% and 20% Cr alloys, these current spikes are rather rare: Fig. 2 was chosen because there was a somewhat larger number of them in a limited time (about one every 3s), but it was more common to see a spike every 0.5 min. On the 20% Cr alloy, the transients not immediately followed by the start of the pitting were even rarer, and between them no fluctuations could be observed at a detection limit of the order of 30 pA. The conclusion one draws is that for the corrosion resistant alloys during the induction period very few points on the surface undergo a burst of dissolution, and therefore each point where passivity fails momentarily has a

relatively large probability (for the 20% Cr at 300 mV, of the order of 0.5) to develop into a pit. Considering that no such transients are observed in the absence of chlorides, the conclusion is that the most important effect of the Cl^- lies in increasing the chance of local breakdown rather than in affecting the repassivation rate.

The flat spectra of Fig. 3, as well as the corresponding time records as in Fig. 2, indicate that the corrosion resistant alloys repassivate rapidly, in times less than 10 ms, even in the presence of chlorides. These values are shorter than the repassivation time constants of about 15 ms reported by Kruger and Ambrose (6) for steels with similar Cr content, but in more concentrated chloride solutions.

Once the pits have started, the spectra of the fluctuations represent the complex interplay of the progressive spreading of the pit-area, local repassivation at

Fig. 8. Spectra of the random current fluctuations of Fe-20% Cr electrode in borate buffer plus 0.1M NaCl during pitting.

Fig. 9. Spectra of the random current fluctuations of Fe-12% Cr electrode in borate buffer plus 0.1M NaCl during pitting.

the edges and of fluctuations of the composition of the solution inside the pit, which probably account for the large amplitudes, close to $10 \mu\text{A}$, with periods of tens of seconds. The fact that amplitude plateaus are not observed once pitting starts is not due to the limited frequency range investigated, but is probably because the condition is nonstationary, with pits growing and current steadily increasing. Nonstationarity has been invoked as an explanation for low frequency noise (7).

It is likely that the fastest process observed is still repassivation, which determines the high frequency

end of the spectra. For the 20% Cr alloy where the high frequency slope is close to 20 dB/decade, such an interpretation seems reasonable: the time record of Fig. 7, for instance, shows that often the decreases in current are faster than the increases. A comparison of the spectrum of Fig. 8 with that obtained before pitting initiation (Fig. 3) shows that for the same amplitude of about -170 dB the induction period spectrum is flat up to 100 Hz, while after pit initiation the amplitude decreases. The time constant for repassivation has be-

Fig. 10. Spectra of the random current fluctuations of Fe-5% Cr electrode in borate buffer plus 0.1M NaCl during pitting.

come longer than 10 ms, reflecting the more aggressive local environment in the pit.

Finally, fluctuation amplitudes do not seem to be related to the magnitude of the average current density; rather, they increase with the degree of resistance to corrosion of the alloy. For the 20% and 12% Cr alloys, the fluctuations represent a larger fraction of the average current than for the 5% Cr alloy. For instance, at 0.1 Hz, the amplitude of the fluctuations is of the order of $3 \cdot 10^{-5}$ A/cm² for the high Cr alloys and about $7 \cdot 10^{-6}$ A/cm² for the 5% Cr alloy, while the rate of attack, as shown in Fig. 6, is about twice on the latter. Therefore, in this case, where localized corrosion is the source of the current, no correlation between total current density and noise amplitude has been found, as reported for generalized corrosion (8).

Development of a High Temperature pH Electrode for Geothermal Fluids

Leonard W. Niedrach* and William H. Stoddard

General Electric Company, Corporate Research and Development Center, Schenectady, New York 12301

ABSTRACT

This work demonstrates the applicability of a stabilized zirconia pH sensor to high temperature measurements on brines containing as much as 20 weight percent NaCl and 100 ppm hydrogen sulfide. Throughout the program, stable operation was achieved, and measured pH values from 3 to 9 were in good agreement with calculated values. Differences were generally less than 0.5 pH unit at 285°C, and it is not yet certain whether the discrepancies are associated with the measured or calculated values of the pH. Two sensors were operated at 285°C for periods of 11 days, and one was employed in successive tests for a total of 37 days. At the end of this period, the sensor was still satisfactory, and it was forwarded to the sponsoring laboratory, PNL, for further tests. Although most of the work was performed at 285°C, a limited amount of testing was done at lower temperatures: 95°, 150°, and 225°C. Sensors prepared from in-house tubes and from tubes obtained from an outside supplier performed well at 95°C for extended periods, in spite of earlier difficulties with the standard ceramic at this temperature. There is still, however, some uncertainty concerning the adequacy of our seals, particularly in cycling between 285°C and lower temperatures. In a brief experiment, one sensor was operated satisfactorily at 285°C and 5000 psi pressure. (Normal operation was at 1200 psi.)

In previous papers (1, 2), a new approach to high temperature pH measurements was described, in which an oxygen ion conducting ceramic membrane—stabilized zirconia—is employed in a sensor somewhat analogous to the glass electrode. The new sensor retains the specificity of the glass electrode, is equally insensitive to interference from redox active species, and possesses markedly superior resistance to attack by aqueous media at high temperatures.

Although the earlier work has established the feasibility of the concept, the performance of the new sensor has not been demonstrated under a wide variety of conditions. Its applicability to measurements on geothermal brines has been the focus of the present work.

A major aim has been to demonstrate that the performance of the sensor does not suffer in the presence of hydrogen sulfide and high concentrations of saline. The test system, protocols, and experimental results with simulated brines are discussed in the present paper.

Experimental

Sensor design.—Figure 1 shows the structural details of the sensor used in most of the work. The ceramic was a ¼ in. od tube of yttria-(8.0 weight percent [w/o]) stabilized zirconia (obtained from Corning Glass Works, Ceramics Products Division, Solon, Ohio, their composition 1372). It was retained in a Conax Type EG-125 Gland (Conax Corporation, Buffalo, New York) with a seal consisting of Teflon,¹ Vespel,¹ silver, and alumina elements as shown. On the basis of previous work (1, 2), we selected a dry copper/cuprous oxide mixture as our preferred internal junction. This was done for several reasons: (i) we had found it to be readily prepared by simple mixing of the powders and packing into the tube, (ii) when prepared in this fashion, it had been found to be extremely stable and reproducible, (iii) unlike aqueous internals, it permits ready designation of the active region of the sensor because it does not wet the wall with a conducting film, and (iv) in the absence of an internal aqueous phase, seal fabrication is simplified.

* Electrochemical Society Active Member.

Fig. 1. Schematic diagram of preferred sensor for use with geothermal brines.

For the junction we employed a 1:1 (by weight) mixture of finely divided copper and cuprous oxide (Fisher Copper Metal-Electrolytic Dust, purified; Baker Cuprous Oxide Powder, Analyzed Reagent) to a depth of 2 in. A 30 mil copper wire served as the contact and lead from the sensor.

Test equipment.—A diagram of the test system is shown in Fig. 2. Fabricated of titanium and glass, it paralleled a stainless steel system used earlier (1, 2).

Provision was made for pumping water, acid, base, and simulated brines containing carbonate buffers and sulfides into the heated and pressurized titanium autoclave which had a capacity of 1 liter. It was also possible to introduce aliquots of more concentrated acid or base to bring about more rapid changes in pH. The main pump was a Pulsfeeder Model LS-20 with a titanium head manufactured by the Interpace Corporation, Rochester, New York. All fittings and other parts of the pressurized section were also made of titanium.

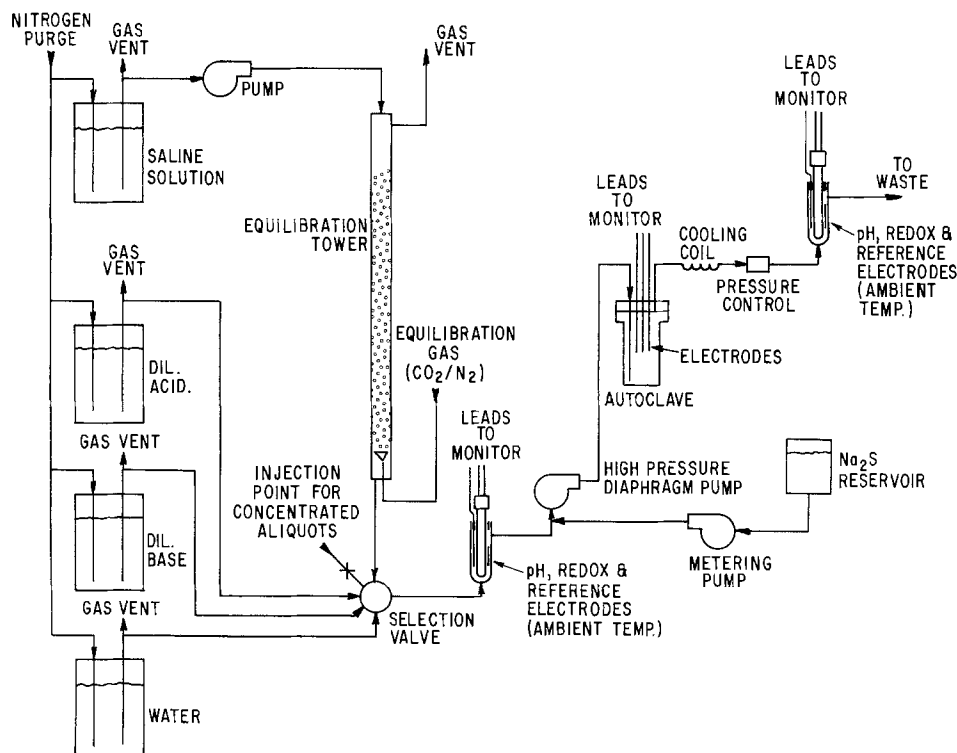

Inserted into the head of the autoclave were the sensor, a platinized platinum electrode (for monitoring the redox potential of the solution), and two reference electrodes. The latter were essentially like those described by Danielson (3), but we eliminated his zirconia thread. As a result, bubbles that formed upon depressurization of the system during cooling resulted in open circuits. Generally one reference electrode was freshly charged with 0.1M KCl in each run.

All streams that entered the autoclave were purged with nitrogen to reduce the oxygen concentration to low levels. To control the pH of the brine solutions before they entered the autoclave, they were contacted with carbon dioxide-nitrogen mixtures in a packed column following a procedure described by Syrett, *et al.* (4). The pH and redox potential of the solutions entering the autoclave were monitored at ambient conditions with a commercial glass combination electrode (Ingold)² and a platinum flag, respectively, both referred to a common reference electrode. Similar measurements were made at ambient conditions on the stream emerging from the autoclave. In this way, irreversible chemical changes occurring during passage through the autoclave could be detected. Provision was also made for sampling the streams and for checking the flow rate.

Rather than incorporate low concentrations of sulfide in the master feed solutions, from which it might be lost through volatilization or oxidation, we elected to inject a more concentrated solution of sodium sulfide into the brine stream just before it entered the high pressure diaphragm pump. The injection point is indicated in Fig. 2. A Harvard Syringe Pump Model 1100 with a 20 ml syringe was used for the injection.

² Registered trademark of Ingold Electrodes, Incorporated, Andover, Massachusetts.

Fig. 2. System for evaluating sensors with simulated geothermal brines.

Temperature of the autoclave was controlled with a Leeds and Northrup Electromax III proportional controller. High temperature pH and potential measurements were made with a Keithly Type 616 electrometer multiplexed with an Orion 855 Electronic Switch. The potentials of the pH sensor, the platinized-platinum redox probe, the autoclave, and the second reference electrode were all measured against the same primary reference electrode. The lower temperature measurements (pH and redox potential of the inlet and outlet streams to the autoclave) were made with an Orion Model 801 Digital pH meter, again multiplexed with an Orion Model 855 Electronic Switch. All potentials and the temperature were recorded on a Linear Instruments Corporation three-channel recorder.

Test protocols.—The initial series of tests were designed to determine the stability of the sensors under a variety of conditions. A key element was an exposure for several days to simulated brines covering a range of pH values. In each case, a calibration curve was obtained during the first two days by determining the response to a change from 1 mm HCl to 1 mm NaOH. Then the sensor was aged for about a week in a selected saline solution covering a range of conditions. During this period, potentials were monitored to check for drift or degradation. The carbon dioxide level of the brine solution was then changed to induce a pH change, and the response of the sensor was monitored and compared with the best estimate that could be made theoretically for the high ionic strength solutions involved. Finally, after an overnight flush of the system with water, the calibration curve was rechecked by determining the response of the sensor to a transition from 1 mm acid to 1 mm base. In a few runs, additional steps were introduced into the test protocols.

Sulfide analysis.—In order to control the sulfide concentration in the entering solution and to ascertain that it was maintained during passage through the autoclave, sulfide analyses were required on an occasional basis. For this purpose, a colorimetric method involving the reduction of methylene blue was found satisfactory. The procedure is provided in the "Methods Manual" (5) for a Hach Direct Reading Engineer's Laboratory, Model DR-EL/4, which was used for the analyses. With proper care to protect samples, reagents and diluting water from air, quite satisfactory results were obtained.

pH calculations.—In order to estimate the pH values of the brine solutions, we adapted a computer program developed by Syrett *et al.* (4) which was directed towards saline solutions containing varying amounts of carbonic acid and hydrogen sulfide, but which made no provision for the presence of salts of the above acids. As described elsewhere (6), we broadened the program to allow for the presence of such salts by including a term in the overall equation for mass and charge balance for the equivalent base required to form such salts from the acids; *i.e.*, the last term in the following equation

$$a_{H^+} + a_{H_2S} - a_{H^+} (K_3[H_2S] \gamma_0 + K_1[H_2CO_3] \gamma_0 + K_W) - 2(\gamma_1/\gamma_2)(K_1K_2[H_2CO_3]\gamma_0 + K_3K_4[H_2S]\gamma_1) + a_{H^+} + 2\gamma_1 \sum_0^m m [M^{m+}] = 0 \quad [1]$$

We have also added terms for the activity coefficients of the undissociated acids, since these deviate significantly from 1.0 in concentrated brines, as evidenced by solubility data in the presence of salts (7, 8).

In order to relate directly to our experimental protocols, an additional variation was introduced into the program to permit the derivation of the ambient temperature 25°C composition on the basis of the NaCl

content, the equivalent base concentration (from the amounts of sodium bicarbonate, sodium carbonate, and sodium sulfide added) of the starting solution, and the percent carbon dioxide in the equilibrating gas. Following this the composition at a second temperature of interest (285°C in most of our experiments) is made from the 25°C values.

The dissociation constants and most of the additional thermodynamic data required for the calculations were those used by Syrett *et al.* which they, in turn, had adopted from Naumov *et al.* (9). In addition, we employed data from Seidell (7) to derive the solubility coefficient for carbon dioxide at 25°C in terms of the partial pressure as well as γ_0 at 25°C. In turn, γ_0 at 285°C was estimated from the data of Ellis and Golding (8) for the solubility of carbon dioxide in water and sodium chloride solutions above 100°C. For extrapolation to 4.278m, their data, which extended only to 2.0m NaCl, was fitted by least squares to the Setchenow equation

$$\log \gamma_0 = \log (K/K^\circ) = BC \quad [2]$$

where K° is the solubility coefficient in water, K is the coefficient in brine at concentration C , and B is a constant. For the more dilute brines having an ionic strength of about 0.1m or less, γ_0 was assumed to be equal to 1.0.

To obtain the pH for any given set of conditions, Eq. [1] in combination with the various dissociation equilibria for the two acids is solved using the Newton-Raphson iterative technique. This, in turn, permits the calculation of the concentrations of all other relevant species. Using this program, the ambient temperature and 285°C pH values and concentration profiles for all of the carbonate solutions used in this work were calculated. Details of the program and a full tabulation of the calculated results will be found elsewhere (6).

Results and Discussion

Operation on brines at 285°C (runs GB-1 through GB-6).—This series of experiments was performed with a group of brines covering a variety of conditions, including high and low salinity (20% and 0.2% NaCl), a range of pH (3.2-9.1 at 285°C), and a range of hydrogen sulfide concentrations (0.0-100 ppm). All of the conditions, including calculated pH values, are listed in Table I. For each run, the solution employed during the extended aging period is marked with an asterisk in Table I. The other solutions were employed more briefly, in order to obtain response data over a wide range of conditions. In general, the sensors were exposed to the aging solution for periods of from 4 to 10 days, but, as will be noted, one sensor was used for three successive runs and accumulated over 37 days exposure to a variety of conditions at 285°C. In one run, GB-2, the sensor cracked and no useful data were obtained.

Run GB-1.—Virgin sensor Y-45 was employed along with two identical, newly fabricated reference electrodes, RD-9 and RD-10, both filled with 0.1m KCl. Both reference electrodes had potentials of 97 mV against a commercial silver-silver chloride electrode containing 3.0m KCl (Ingold) when immersed in 0.1m KCl at 25°C. Their resistances measured under the same conditions were 3.0×10^5 and $2.2 \times 10^5 \Omega$, respectively.

The run extended over a period of 11 days; operating conditions and potentials of the glass electrodes in the ambient temperature streams as well as those of the zirconia electrode as measured against their respective references are summarized in Fig. 3. Only data obtained with the acidic, alkaline, and saline solutions are shown because considerable scatter was present with the unbuffered water.

In greater detail, the system was brought to temperature with aerated water flowing through the auto-

* Solution used for aging tests.

** From added sodium bicarbonate and carbonate and the injected Na₂S.

clave. Initial calibration was accomplished with aerated sulfuric acid and sodium hydroxide, the standard procedure used in earlier work (2). The system was then flushed with water and was subsequently deaerated. Additional calibrations were then undertaken with deaerated hydrochloric acid and sodium hydroxide. Upon observation that the potentials from the latter solutions were in satisfactory agreement with those from the former aerated solutions, operation was shifted to the brine equilibrated with 1% carbon dioxide in nitrogen. Operation on this solution was continued for 4 days.

Prior to termination, the brine was equilibrated with 100% carbon dioxide in order to introduce a pH change. About 4h were required before the potentials from the various monitoring points were on plateaus. The system was then flushed with water, and the following day transitions to 0.001*m* hydrochloric acid and then to 0.001*m* sodium hydroxide were undertaken in order to obtain new calibration points that could be compared with the starting values. Finally, the system was flushed with water and cooled.

Upon opening the autoclave and examining the sensor, it was found to be sound and showed no visual signs of degradation. The two reference electrodes,

Table II. Comparison of measured and calculated values of pH: run GB-1. Sensor Y-45. *T* = 285°C.

Solution	pH

however, did contain gas bubbles, and their rest potentials could not be compared with their initial values against a commercial reference electrode.

Although very little drift occurred with the ambient temperature sensors throughout the run, some did occur at 285°C. This point is brought out more clearly by the data in Fig. 4, which shows calibration curves at the start and finish of the run. Similar drift was observed at 285°C with the platinum electrode.

The pH values for the brine solutions derived from the calibration curves in Fig. 4 are summarized in Table II. Because of the drift and the fact that the data points were obtained closer to the final than the initial calibration, the high temperature pH values were determined on the basis of the final calibration curve for the zirconia sensor.

Fig. 3. Potentials of zirconia sensor at 285°C and glass electrodes at 25°C vs. their respective reference electrodes during run GB-1.

Fig. 4. Calibration curves for zirconia sensor at 285°C (run GB-1)

The drift in the calibration curve with time is a phenomenon that we have encountered previously (2). It appears to be associated with changes in the internal chloride concentration in the reference electrode. Because such drift was not reported in the original description of the electrode (3), it may reflect our omission of the internal zirconia thread from the structure. Such a thread might reduce convection in the internal electrolyte and thereby improve stability. Alternatively, our zirconia junction might have been more porous than that used previously.

Run-GB-3.—This was essentially a repeat of run GB-1, with the exception that sulfide was introduced into the brine. A new sensor Y-47 was employed. The two reference electrodes were also new; RD-13 was filled with 0.1*m* KCl and RD-14 with a 20 w/o NaCl solution.

Following the initial calibration steps, two additional steps were introduced when the system was operated briefly with brines 3A and B containing 0.00109*m* HCl and NaOH, respectively, both in 20% NaCl. This was followed by the transition to the carbonate buffered brine solution equilibrated with 1% CO₂ in N₂. After

Table III. Sulfide analyses of stock solution and effluent

Day of run	Brine	Stock solution* (ppm)	Effluent (ppm)
5	Cs	1162	9.3
9	Cs	1040	7.3
11	Cs		8.3
11	Ds		7.7

* Nominally 1200 ppm. At the flow ratios employed, 1200 ppm in the stock solution would give 11 ppm in the feed to autoclave.

a day's operation on the simple brine, sulfide injection was started to maintain the level at about 10 ppm for a period of 7 days. No detectable change occurred in the output of the pH sensor upon the addition of the sulfide. At the conclusion of this aging period, a pH change was induced by equilibrating the brine with carbon dioxide while retaining the sulfide concentration at 10 ppm. Finally, the sensor was recalibrated with acid and base after flushing the brine from the system with water.

The complete run lasted 11 days. Conditions and potentials of the ambient and high temperature pH sensors vs. their respective reference electrodes are summarized in Fig. 5. During operation on the sulfide, analyses of the stock solution and the effluent were performed with the results in Table III. Since input conditions were adjusted for 11 ppm in the feed to the autoclave, a small loss on passage through the system seems to have occurred. This is undoubtedly real and probably reflects reaction with metal and corrosion products in the system.

The potentials of the two nonidentical reference electrodes were found to converge during the run. Initially, the electrode containing 20% NaCl was 40-50 mV negative to that containing the 0.1*m* KCl. At the end of the run this difference had fallen through zero and was slightly positive. Upon draining the filling solutions from the two, they were both found to contain ~ 1.5*m* NaCl. Clearly the concentrations had converged during exposure to the brine. It is probable, however, that considerable dilution may have occurred during the last day or so of operation on the calibrating solutions and the water and during cool down.

At the conclusion of the run, pH values of the various solutions were read from the calibration curves. Those for the brines containing HCl and NaOH were read from the initial curve, and those containing the carbonate from the final. The measured and calculated values are listed in Table IV. Moderate deviations of the same order of magnitude are seen in all cases. In

Fig. 5. Potentials of zirconia sensor at 285°C and glass electrodes at 25°C vs. their respective reference electrodes during run GB-3.

Table IV. Comparison of measured and calculated values of pH at 285°C

Solution	Calculated	Measured	Δ	$\gamma_{H^+}(\gamma_{OH^-}) \cdot \text{Calc. from measured pH}$
A	3.5	4.1	+0.6	0.079
B	7.8	7.1	-0.7	0.057
Cs	8.6	8.2	-0.4	—
Ds	7.8	7.4	-0.4	—

$$\gamma_{H^+} = a_{H^+}/C_{H^+} = 10^{-pH}/C_{H^+}$$

$$\gamma_{OH^-} = K_w/(a_{H^+} \cdot C_{OH^-}) = K_w/(10^{-pH} \cdot C_{OH^-}).$$

an effort to assess the cause of the discrepancies, it is of interest to calculate activity coefficients for the hydrogen and hydroxide ions from the experimental data obtained with the simpler solutions, A and B. These values, listed in Table IV, are considerably lower than a value of 0.288 derived from the computer program.

It is suggested that the observed deviations in pH result more from a failure of the computer program to properly estimate activity coefficients of the "trace" constituents (*i.e.*, the hydrogen and hydroxide ions) of the brine solutions than from shortcomings in the measurements with the sensor-reference electrode combination. This suggestion is supported by experience with mixed electrolytes at lower temperatures (10, 11). Much available data indicates that the activity coefficients of trace constituents differ markedly from those of macro constituents in mixed electrolytes. The model of Syrett *et al.*, from which the present computer program was derived, assumes that all are the same.

Run GB-4.—This run was similar to GB-3 except that the brine used for aging was more acidic. A new sensor Y-48 was employed along with two new reference electrodes, one containing 0.1M KCl, the other 3.0M KCl. About 10 ppm of hydrogen sulfide was added to the brines from the start. Aging on the more acidic brine extended over a period of 7 days. Summary data are recorded in Fig. 6. Again some drift was evident, but, as expected, this was greater with the 0.1M KCl reference electrode than with the more concentrated. A comparison of measured and calculated pH values for this and the next two runs will be included in a more general discussion that follows.

Run GB-5.—This run differed from the previous four in that the brine concentration was at the 0.2% level.

The hydrogen sulfide concentration was maintained at the 10 ppm level. Sensor Y-48 was continued in use from the previous run, but new reference electrodes containing 0.1M KCl and 0.2% NaCl solutions were employed. Aging was performed in the more alkaline brine for a period of about 10 days.

In contrast to the earlier runs, the drift in potentials with time was towards lower values rather than higher. This is to be expected for the 0.1M KCl reference because chloride should be lost to the more dilute brine solution being monitored. It would be expected that the output of the sensor *vs.* the 0.2% NaCl reference would have remained constant, but some drift did occur in this case as well. The summary data are recorded in Fig. 7.

Run GB-6.—This run was carried out as a continuation of the previous one without changing the sensor or the reference electrodes. Only the brine was changed to one of more acidic character by lowering the equivalent base concentration from 0.1 to 0.001M. Conditions and data are summarized in Fig. 8. After about 7 days' operation on the brines containing 10 ppm hydrogen sulfide, the level was raised to 100 ppm for 2 days. This had no apparent effect apart from that associated with the pH change resulting from the introduction of an increased amount of equivalent base in the form of the sodium sulfide. Later in the run, the sensor was exposed successively to 0.2% brine solutions 6E through 6I containing different levels of free hydrochloric acid and sodium hydroxide. Operation was straightforward throughout, and the sensor remained in excellent condition after 37 days of almost continuous operation through three consecutive runs.

General.—It has been evident above that quite satisfactory agreement has been seen between measured and calculated pH values in the individual runs. The accumulated data from the several individual experiments are combined and interrelated in Fig. 9 and 10. The former includes all of the data from runs GB-1 through GB-4 with the 20% brines, and the latter the data from runs GB-5 and GB-6 for the 0.2% brines. It is again clear that the data correlate extremely well and cluster about the line representative of perfect agreement over the full pH range from 3 to 9. As discussed in connection with run GB-3, the deviations between the measured and calculated values may well reflect shortcomings in the calculations rather than the sensors.

Fig. 6. Potentials of zirconia sensor at 285°C and glass electrodes at 25°C vs. their respective reference electrodes during run GB-4.

Fig. 7. Potentials of zirconia sensor at 285°C and glass electrodes at 25°C vs. their respective reference electrodes during run GB-5.

Reproducibility of performance.—An indication of the reproducibility of the sensor-reference electrode combination is given in Fig. 11, in which calibration curves from five different runs are shown. In each case, the initial calibration curve was obtained with a fresh reference electrode containing 0.1m KCl. Three different sensors were involved in these measurements: Y-45 in runs GB-1 and GB-2, Y-47 in GB-3, and Y-48 in GB-4 and GB-5. A spread of about 0.5 pH unit is evident for a given output voltage among the initial calibration curves.

If such reproducibility could be maintained, it would probably be acceptable for many applications without the need for later recalibration. Unfortunately, significant shifts in the calibration curves occur after prolonged operation because of the exchange of chloride between the reference electrode and the solution being monitored. In monitoring a brine, the extent of the shift is limited because of the finite concentration of chloride in the solution. In monitoring a 20% brine (4.278m NaCl) using a reference containing 0.1m KCl, the theoretical limit on the drift is $\log(4.278/0.1)$ or 1.6 pH units. The maximum drift observed during the present tests fell short of this limit by a factor of about two. In monitoring solutions containing no chloride,

larger drifts are possible through continuous loss of chloride to very low concentrations.

While considerable displacement of the calibration curves is encountered, the slope remains quite stable. This suggests that in operation single-point calibrations might prove highly satisfactory. In view of the relative stability of the calibration curve obtained against the reference containing 20% sodium chloride in run GB-3, there would seem the real possibility that a reference electrode might be devised to match a given brine field and thereby give very stable performance in that field. This would be somewhat dependent upon the actual stability of brine levels in the field. Even in such a case occasional recalibration would seem in order.

Performance of sensors at lower temperatures (runs GB-7 and GB-11/13).—As noted in an earlier report (12), the standard ceramic has a history of becoming sluggish in response during continuous operation at 95°C. The performance at 95°C has also been poor after brief operation at 285°C, even though the same sensor might again perform excellently for weeks at the higher temperature. This behavior has been attributed, at least in part, to structural shortcomings in the

Fig. 8. Potentials of zirconia sensor at 285°C and glass electrodes at 25°C vs. their respective reference electrodes during run GB-6.

Fig. 9. Correlation between measured and calculated pH at 285°C for all 20% brines.

ceramic (12). For this reason, low temperature testing was delayed until the end of the present program in order to take advantage of the possible availability of improved materials at that time. This was indeed the case, and four new experimental tubes—all yttria-stabilized zirconia—were used in tests at lower temperatures. One of these was a dense ceramic made in house. Used for the fabrication of sensor SP-8 it was similar to the material used for sensor SP-4 in Ref. (6), which performed well at 95°C for over a month of continuous operation. The other three tubes were obtained from NGK-Locke Insulators, Limited, of Japan. Used in sensors NGK-A2, NGK-B, and NGK-C1, they were prepared with different process modifications, all of which gave dense ceramic. The tube in NGK-C1 differed from normal in that it incorporated a larger diameter collar on the open end of the tube. This permitted a seal modification that more closely resembled that of a conventional Conax fitting, which, it was hoped, would solve some of our seal problems. Unfortunately, this hope was not realized: stress con-

Fig. 10. Correlation between measured and calculated pH at 285°C for all 0.2% brines.

Fig. 11. Data showing reproducibility of calibration curves from run to run. All reference electrodes initially contained 0.1M KCl.

centration at the junction of the larger diameter collar with the smaller diameter tube resulted in circumferential cracking at that location. Although a disappointment, these initial failures would not seem to be intrinsic to the structure.

None of the new tubes were of the same diameter as those normally employed, and slight modifications to the Conax fittings were required. To expedite the tests, it was necessary to employ stainless steel fittings for the purpose, and for this reason all of the tests were performed with simple aqueous solutions rather than brines, i.e., in water, dilute sulfuric acid, and dilute base. This was not felt to be a serious shortcoming because excellent correlation between the performance of the zirconia sensor on such simple solutions and on brines had by this time been demonstrated in the tests at 285°C.

In run GB-7, three sensors SP-8, NGK-A2, and NGK-B were tested in parallel at temperatures of 95°, 150°, 225°, and 285°C. Both the pH response and the resistance of each sensor were determined at each temperature. In order to ascertain whether deleterious changes occurred at the elevated temperatures, a retest at 95°C was performed after each step to a higher temperature. The test results are summarized in Fig. 12.

It is evident that sensor NGK-A2 was erratic from the start, and distinct evidence of failure was obtained from the resistance measurement during the second test at 95°C. Quite clearly, a crack had developed to allow shunting across the ceramic.

The other two sensors performed excellently up through the operation at 285°C, although one set of response data for NGK-B at 95°C was lost through an instrument malfunction. Following the exposure at 285°C, the subsequent response at 95°C was poorer for both. In the case of NGK-B the low resistance at this point again indicated a shunt across the ceramic, most likely because of a crack. The resistance of SP-8 remained high, however. It is therefore difficult to reach a firm conclusion concerning its decline in performance at 95°C. It could result from degradation of the ceramic, but it could also result from leakage of electrolyte

Fig. 12. Response and resistance data for several sensors tested alternately at 95°C and higher temperatures.

around the seal to form an electrolytic shunt sufficient to degrade performance. We have long suspected such a possibility in connection with our present seals, but further work will be required to confirm it.

In view of the declining performance at 95°C, a final test was performed on SP-8 at 285°C. As anticipated from past experience, the response remained excellent at the higher temperature. At this point, the run was terminated and the system cooled to ambient for removal of the sensors. Both NGK-A2 and NGK-B were found to be cracked. Sensor SP-8 remained solid. However, because a curvature had developed during firing it had been necessary to assemble this sensor *in situ* while the Conax fitting was mounted in the lid of the autoclave. We were unsuccessful in removing the sensor from the lid without cracking the ceramic tube.

Sensor NGK-C1 was evaluated in a separate test, run GB-11/13. It was first assembled with a new seal adapted to the collar on the as-received tube. Circumferential cracking occurred during initial operation at 95°C, and again later in the tests. As a result, inconclusive data were obtained with this sensor.

Although the present series of tests were not completely satisfying, they do indicate that ceramics can

be made that are more stable in low temperature service than the standard Corning ceramic used in the bulk of the tests and most of the earlier work. It is, however, not yet clear whether the degradation in performance of the new ceramics at low temperatures is a reflection of changes in the ceramic or of defects in the seals. While we strongly suspect the latter, this point requires resolution. In the interim, it appears likely that it will be possible to operate sensors employing one of the new ceramics for extended times at low temperature (i.e., 95°-150°C) if excursions to higher temperatures are avoided.

Operation at 5000 psi.—The ability of the new pH sensor to operate at 5000 psi and 285°C was demonstrated in a single experiment in which only water, dilute sulfuric acid, and dilute sodium hydroxide were employed as test fluids. Data obtained from the short run are summarized in Table V. They demonstrate the ability of the sensor to withstand the 5000 psi pressure at 285°C and to respond to a pH transient under these conditions. Upon completion of the test, the pH sensor remained intact.

Conclusions

It is concluded from this work that the present sensors should perform well in geothermal brines over a range of temperatures if given sufficient attention to calibration and seal maintenance. Clearly, however, care must be exercised to obtain high quality ceramics, particularly with regard to surface integrity and freedom from surface pores. Improved seals between the ceramic tubes and the metal fittings are also required for long-term, routine use in the field.

Considerations of the Stability of Pit Repassivation during Pitting Corrosion of Passive Metals

T. Okada

Industrial Products Research Institute, M.I.T.I., Yatabe, Tsukuba, Ibaraki 305, Japan

ABSTRACT

The repassivation of pits, by which pitting corrosion initiated in an aggressive environment ceases, is studied from the kinetic point of view. Consideration of irreversible thermodynamic stability suggests that the repassivation process starts as soon as the monolayer formation of the metal oxide becomes stable at the bottom of the pit. The critical pitting potential is defined so that the rate of the monolayer formation of the metal oxide overcomes the rate where the monolayer oxide changes to the halide. It is shown that the repassivation potential is very close to the critical pitting potential, whereas the pit initiation potential is intrinsically different and coincides only when the passive film is very thin. The present study presents the theoretical significance of the repassivation potential as a characteristic value of pitting.

The pitting potential, an important characteristic of the pitting of passive metals, is of practical significance because this value gives some indication of the relative pitting resistance of the metal in a corrosive environment. However, different workers have obtained different values, even for the same metal in the same environment (1-3). For example, there are two kinds of potentials observed experimentally: the potential at which the first pit appears when a specimen is positively polarized in a solution containing aggressive ions,¹ and the potential below which pits, once initiated, can be stopped.² These two potentials are experimentally distinguished from each other. However, they occasionally appear to be coincident, if determined in a way that eliminates time lag (9, 10).

Pitting is a complex series of processes consisting of corrosion, material transport, induced local polarization, and the subsequent local concentration of ionic species. Theoretical attempts have been made considering the thermodynamic stability of newly formed phases (11), ionic exchange (12), passive film flaws and crystallographic factors (3, 13, 14), mechanical factors (6, 15), and transport of ionic species (16, 17), but these attempts have not been successful in explaining the kinetic features of pitting.

Key words: pitting corrosion, irreversible thermodynamics, repassivation, oxide film.

¹This potential is called the pitting potential (4) or the breakdown potential (5, 6).

²The protection potential (7) or the repassivation potential (8).

An irreversible thermodynamic consideration has been applied successfully to pitting (18). The complicated phenomena of pitting can be treated by considering the stability of the whole system undergoing pitting corrosion. It has further been shown that pit initiation in an aggressive environment can be thought of as a probability event (19).

It should be recognized that very few theoretical attempts have been successful in predicting the occurrence of the two kinds of characteristic potentials stated above. They are assumed to coincide if the time required for their occurrence is eliminated (9), but they are considered experimentally to be intrinsically different from each other (20, 21).

In this study, the repassivation process of hemispherical pits is discussed in relation to the irreversible thermodynamic stability theory, to see if there is any relationship between pit initiation and the repassivation processes.

Theory

It is sometimes observed in hemispherical pits that dissolution at the pit bottom resembles anodic brightening. Hoar *et al.* (6, 13) reported that the "contaminated oxide" film forms on metal surfaces during anodic brightening, and that the metal dissolves rapidly through this film. Although it is not clear whether this kind of film also forms at the pit bottom during pitting corrosion, it is plausible that a nonprotective salt film composed of dissolved metal cations and concentrated

aggressive anions occurs at the pit bottom, and dissolution of the metal is greatly enhanced.

In order for the repassivation of pits to occur, oxygen atoms need to be supplied to the corroding metal surface in sufficient quantity. According to Hoar (22) H₂O plays an important role in the initial passivation processes of metals. Therefore, H₂O should occur in the nonprotective film which is formed at the pit bottom, and take part in the repassivation process by concentration at the metal surface.

Assume that the nonprotective film is a "hydrous metal halide" with a large ionic conductivity.³ According to the linear phenomenological equations of irreversible thermodynamics, fluxes participating in the entropy production are expressed as linear formulas of all conjugated forces (23). A concentration gradient of H₂O would arise so as to counteract the H₂O flux accompanying the ionic fluxes (24). The flux of the dissolving metal cation would be the largest, and the concentration of H₂O would be lower in the inner part of the hydrous halide layer, if the pitting reaction proceeds quickly. However, as the potential of the metal decreases, it will bring about a decrease in the rate of the metal dissolution reaction and also an increase in H₂O concentration at the metal surface, so that the repassivation process can be initiated. The potential at this point is referred to as the repassivation potential.

Repassivation process.—Oxide film thickening.—Suppose that at the pit bottom where metal is dissolving beneath the nonprotective film of thickness, l , a metal oxide with an area s_0 and a thickness d is formed on the metal surface. Figure 1 shows this system schematically. l is assumed to be much smaller than the size of the pit, so that material transport in this system can be expressed by one-dimensional formulas with the axis normal to the metal surface. The model of the system is depicted in Fig. 2, in which each portion of the phase is denoted by numerals.

Consider the change in entropy production $\delta^d P$ caused by the increase in oxide film thickness from d to $d + \delta d$, with its area s_0 remaining constant. $\delta^d P$ can be divided into two parts, $\delta_J^d P$ due to the change in fluxes and $\delta_X^d P$ due to the change in forces

$$\delta^d P = \delta_J^d P + \delta_X^d P \quad [1]$$

According to the general evolution criterion of irreversible thermodynamics, a system in a fixed boundary condition moves toward the direction where $\delta_X^d P$ decreases until it reaches a steady state (25)

$$\delta_X^d P \leq 0 \quad [2]$$

Changes in the system resulting from the oxide film thickening from d to $d + \delta d$ are: a change in material transport in the oxide film, a change in the reaction at the interface between the oxide and the hydrous halide, a change in material transport in the hydrous halide, a change in the reaction at the interface between the hydrous halide and the electrolyte solution, and a change in material transport in the solution. Other changes are considered to be trivial. The contributions of these changes to $\delta_X^d P$ will be denoted as $\delta_X^d P_{MO}$, $\delta_X^d P_{MO/MX}$, $\delta_X^d P_{MX}$, $\delta_X^d P_{MX/S}$, and $\delta_X^d P_S$, respectively. Here it is assumed that all these changes occur in the area shadowed by s_0 , and changes in the other portions are ignored,⁴ since the ionic conductance of the hydrous halide is very large. It is also assumed that heat flux is neglected because the temperature is kept constant throughout the system.

³ Perhaps this is not the same in composition as the "halide nuclei" which have been assumed to form in a passive film (19). The halide nuclei break through the passive film, whereas the nonprotective film forms on the bare surface of the metal, and the rate of metal dissolution is much larger. Here the differences between them are disregarded as far as notations are concerned.

⁴ Actually, the change in the reaction which occurs on the passive film surface would contribute to $\delta_X^d P$, but the result remains unchanged even if this contribution is taken into account.

Fig. 1. Illustration of a pit which is repassivating. M: metal. MO: oxide film. MX: nonprotective metal halide. Sol.: solution.

In the oxide film, ionic conduction J_M and J_O of M^{z+} and O^{2-} ions is caused by the potential drop $\Delta\Phi_0$ across the film. The changes in the affinity in this phase are mainly due to the change in $\Delta\Phi_0$, so that

$$T\delta_X^d P_{MO} = (zFJ_M - 2FJ_O) \left(\delta\Delta\Phi_0 - \frac{\Delta\Phi_0}{d} \delta d \right) s_0 \quad [3]$$

with the flux J_i ($i = M, O$) expressed by the exponential formula (19, 26).

At the oxide-hydrous halide interface, metal dissolution

and oxide formation

take place simultaneously. The current density for each reaction is

$$i_M = k_M \exp\left(\frac{\mu_M(1)}{RT}\right) \exp\left(\frac{\nu_X \mu_X(2)}{RT}\right) \exp\left(\frac{\alpha_M z F \Delta\Phi_{MO/MX}}{RT}\right) \quad [5.1]$$

$$i_O = k_O \exp\left(\frac{\mu_W(2)}{RT}\right) \exp\left(\frac{2\alpha_O F \Delta\Phi_{MO/MX}}{RT}\right) \quad [5.2]$$

in which k_M and k_O are rate constants, $\mu_i(p)$ ($i = M, X, W; p = 1, 2$) is the chemical potential of M^{z+} , X^- , and H_2O in each phase, ν_X is the stoichiometric coefficient of X^- participating in the metal dissolution reaction, α_M and α_O are "transfer coefficients," and $\Delta\Phi_{MO/MX}$ is the Galvani potential difference at the interface between the oxide and the hydrous halide. Then

$$T\delta_X^d P_{MO/MX} = \frac{i_M s_0}{zF} [\delta\mu_M(1) - \delta\mu_M(2) + zF\delta\Delta\Phi_{MO/MX}] + \frac{i_O s_0}{2F} [\delta\mu_W(2) - 2\delta\mu_H(2) - \delta\mu_O(1) + 2F\delta\Delta\Phi_{MO/MX}] \quad [6]$$

Fig. 2. Schematic representation of phases at the pit bottom. M: metal. MO: oxide film. MX: nonprotective metal halide. Sol.: solution. Numerals indicate portions in each phase.

Linear phenomenological equations (23, 24) can be applied to the material transport in the hydrous halide, because the ionic conductance in this phase is very large. Fluxes J'_w , J'_M , J'_X , and J'_H of H_2O , M^{z+} , X^- , and H^+ are expressed by

$$J'_w = L'_{ww}\Delta\mu'_w + L'_{wi}\Delta\tilde{\mu}'_i \quad [7.1]$$

$$J'_i = L'_{iw}\Delta\mu'_w + L'_{ik}\Delta\tilde{\mu}'_{k \neq i} + L'_{ii}\Delta\tilde{\mu}'_i, \quad i = M, X, H \quad [7.2]$$

where L' are phenomenological coefficients and $\Delta\mu'$ or $\Delta\tilde{\mu}'$ are gradients of chemical or electrochemical potentials in the halide

$$\Delta\mu'_w = \frac{\mu_w(2) - \mu_w(3)}{l - d} \quad [8.1]$$

$$\Delta\tilde{\mu}'_i = \frac{\tilde{\mu}_i(2) - \tilde{\mu}_i(3)}{l - d} = \frac{\mu_i(2) - \mu_i(3)}{l - d} + \frac{z_i F \Delta\Phi_X(2, 3)}{l - d} \quad [8.2]$$

and $\Delta\Phi_X(2, 3)$ is the potential drop across the hydrous halide at the shadowed area by s_0 . Rewriting Eq. [7.2]

$$J'_i = \bar{n}'_i v'_i \Delta\tilde{\mu}'_i \quad [7.3]$$

and regarding for simplicity the component given by the following equation as constant

$$L'_{iw} \frac{\Delta\mu'_w}{\Delta\tilde{\mu}'_i} + L'_{ik} \frac{\Delta\tilde{\mu}'_{k \neq i}}{\Delta\tilde{\mu}'_i} + L'_{ii} = \bar{n}'_i v'_i \quad [9]$$

here \bar{n}'_i and v'_i are the mean concentration and the mobility per unit force of i , respectively, in the hydrous halide. The following is then obtained

$$T\delta_X^d P_{MX} = \sum_{i=W, M, X, H} J'_i \left\{ \delta\mu_i(2) - \delta\mu_i(3) + z_i F \delta\Delta\Phi_X(2, 3) - [\mu_i(2) - \mu_i(3) + z_i F \Delta\Phi_X(2, 3)] \frac{\delta(l - d)}{l - d} \right\} s_0 \quad [10]$$

Metal ions dissolves at the interface between the hydrous halide and the electrolyte solution

The current density of this reaction is

$$i'_M = k'_M \exp\left(\frac{\mu_M(3)}{RT}\right) \exp\left(\frac{\nu_H \mu_H(4)}{RT}\right) \exp\left(\frac{\alpha'_M z F \Delta\Phi_{MX/S}}{RT}\right) \quad [12.1]$$

where ν_H is the stoichiometric coefficient of H^+ participating in the metal dissolution reaction and $\Delta\Phi_{MX/S}$ is the Galvani potential difference at the interface between the hydrous halide and the solution. It is assumed that the hydrous halide is in equilibrium between formation and decomposition

so that the following equilibrium condition holds

$$F\Delta\Phi_{MX/S} = \mu_X(3) - \mu_X(4) \quad [12.2]$$

Then it is obtained

$$T\delta_X^d P_{MX/S} = \frac{i'_M s_0}{zF} \{ \delta\mu_M(3) - \delta\mu_M(4) + zF\delta\Delta\Phi_{MX/S} \} \quad [13]$$

Assuming linear phenomenological equations for material transport in the electrolyte solution

$$J''_w = L_{ww}\Delta\mu''_w + L_{wi}\tilde{\Delta\mu}''_i \quad [14.1]$$

$$J''_i = L_{iw}\Delta\mu''_w + L_{ik}\tilde{\Delta\mu}''_{k \neq i} + L_{ii}\tilde{\Delta\mu}''_i, \quad i = M, X, H \quad [14.2]$$

in which L are phenomenological coefficients and

$$\Delta\mu''_w = \frac{\mu_w(4) - \mu_w(5)}{\Delta} \quad [15.1]$$

$$\Delta\mu''_i = \frac{\tilde{\mu}_i(4) - \tilde{\mu}_i(5)}{\Delta} = \frac{\mu_i(4) - \mu_i(5)}{\Delta} + \frac{z_i F \Delta\Phi_S(4, 5)}{\Delta} \quad [15.2]$$

where Δ is the thickness of the diffusion layer which extends from the interface to the bulk of the solution and $\Delta\Phi_S(4, 5)$ is the potential drop across this layer. Taking as previously

$$L_{iw} \frac{\Delta\mu''_w}{\Delta\tilde{\mu}''_i} + L_{ik} \frac{\tilde{\Delta\mu}''_{k \neq i}}{\Delta\tilde{\mu}''_i} + L'' = \bar{C}_i v_i \quad [16]$$

to be constant, where \bar{C}_i and v_i are the mean concentration and the mobility per unit force of i , respectively, in the solution. Assuming Δ to be unchanged

$$T\delta_X^d P_S = \sum_{i=W, M, X, H} J''_i \{ \delta\mu_i(4) - \delta\mu_i(5) + z_i F \delta\Delta\Phi_S(4, 5) \} s_0 \quad [17]$$

The current density passing through the oxide film changes from i to $i + \delta i$ when the oxide film thickness changes from d to $d + \delta d$. Suppose that the change occurs so slowly that no charges or materials are accumulated locally in the area shadowed by s_0 , similar to a steady-state condition. In this case, equations of continuity hold with respect to the current (19).

Chemical potentials of M^{z+} and O^{2-} ions in the oxide film are described by the equilibrium condition (27)

$$2\delta\mu_M(1) + z\delta\mu_O(1) = 0 \quad [18]$$

Also, equilibrium conditions are assumed for chemical potentials of M^{z+} and O^{2-} or H^+ and X^- , in the hydrous halide

$$\delta\mu_M(p) + z\delta\mu_X(p) = 0, \quad p = 2, 3 \quad [19.1]$$

$$\delta\mu_H(p) + \delta\mu_X(p) = 0, \quad p = 2, 3 \quad [19.2]$$

The chemical potential of H_2O at the hydrous halide-solution interface is assumed to remain constant

$$\delta\mu_w(3) = 0 \quad [19.3]$$

Equation [8.2] combined with the continuity equation gives

$$\Delta\mu'w = c'i + c'_M\Delta\mu'_M + c'_X\Delta\mu'_X + c'_H\Delta\mu'_H \quad [20.1]$$

with

$$c'_1 = \frac{1}{zFL'_{MW} - FL'_{XW} + FL'_{HW}} \quad [20.2]$$

$$c'_i = \frac{zFL'_{Mi} - FL'_{Xi} + FL'_{Hi}}{zFL'_{MW} - FL'_{XW} + FL'_{HW}}, \quad i = M, X, H \quad [20.3]$$

An equilibrium condition is assumed for the chemical potentials of H^+ and X^- , in the solution

$$\delta\mu_H(4) + \delta\mu_X(4) = 0 \quad [21]$$

Concentrations of species are fixed in the bulk of the solution

$$\mu_i(5) = \mu_i^S, \quad i = M, X, H \quad [22]$$

It is obtained from Eq. [14.2] and the continuity equation that

$$\Delta\mu''w = c_1i + c_M\Delta\mu''_M + c_X\Delta\mu''_X + c_H\Delta\mu''_H \quad [23.1]$$

with

$$c_1 = \frac{1}{zFL_{MW} - FL_{XW} + FL_{HW}} \quad [23.2]$$

$$c_i = \frac{zFL_{Mi} - FL_{Xi} + FL_{Hi}}{zFL_{MW} - FL_{XW} + FL_{HW}} \quad [23.3]$$

Fluxes of X^- and H^+ in the diffusion layer of the solution are very small compared with that of M^{z+} in the area shadowed by s_0 , because of their small consumption rate in that area

$$J''_i \ll J''_M, \quad i = X, H \quad [24]$$

It is seen from Eq. [11.2] that $\delta i'_M \doteq \delta i$. For simplicity, put $\nu_X \doteq z$.

Following the similar treatments as in literature (19), the force component of the entropy change $\delta_X^d P$ can be expressed as follows

$$\begin{aligned} T\delta_X^d P &= T\delta_X^d P_{MO} + T\delta_X^d P_{MO/MX} + T\delta_X^d P_{MX} \\ &\quad + T\delta_X^d P_{MX/S} + T\delta_X^d P_S \\ &= (A - B)s_0\delta i + (C - D)s_0\delta(l - d) \\ &\quad + E\delta\Delta\Phi_{MO/MX} + F\delta\Delta\Phi_{MX/S} + G\delta\Delta\Phi_S(4, 5) \end{aligned} \quad [25.1]$$

Here A, B, C, D, E, F , and G are positive variables, and

$$\begin{aligned} A &\equiv \frac{RT}{zF} \left(1 + \frac{i_0}{i_M} \right) + \frac{RT}{(z + \nu_H)F} \\ &\quad + \frac{RTid}{\alpha^{\circ}_M z F a_i^{\circ} + 2\alpha^{\circ}_O F a_i^{\circ}} + \frac{i(l - d)}{\Delta_X} \\ &\quad + \frac{i_{0W}}{F} c'_w(l - d) \\ &\quad + \left\{ c_1 J''_w + (J''_M + c_M J''_w) \frac{1}{zF\bar{C}_M\nu_M} \right\} \Delta \end{aligned} \quad [25.2]$$

$$B \equiv \frac{i'_M \Delta}{z^2 F^2 \bar{C}_M \nu_M} \quad [25.3]$$

$$C \equiv \frac{i_{0W}}{F} c'_w i - J'_w c'_w i \quad [25.4]^5$$

$$D \equiv \frac{i^2 \lambda_X}{\Delta_X} \quad [25.5]$$

$$E \equiv \left\{ i - \frac{1}{zF} \left(1 + \frac{i_0}{i_M} \right) (i_M \alpha_M z F + 2i_0 \alpha_O F) \right\} s_0 \quad [25.6]$$

$$F \equiv i'_M \frac{z(1 - \alpha'_M)}{z + \nu_H} s_0 \quad [25.7]$$

⁵ See Appendix A.

$$G \equiv i'_M s_0 \quad [25.8]$$

$$\text{with } i^{\circ}_M = zFJ_M \quad [25.9]$$

$$i^{\circ}_O = -2FJ_O \quad [25.10]$$

$$\Delta_X \equiv z^2 F^2 \bar{n}'_M \nu'_M + F^2 \bar{n}'_X \nu'_X + F^2 \bar{n}'_H \nu'_H \quad [25.11]$$

$$\frac{i_{0W}}{F} \equiv \left\{ \frac{1}{zF'} - \frac{1}{zF} \left(1 + \frac{i_0}{i_M} \right) \right\} i_0 + J'_w \quad [25.12]$$

$$c'_w \equiv c'_1 + \frac{c'_M z F - c'_X F + c'_H F}{\Delta_X} \quad [25.13]$$

$$c'_w i \equiv c'_1 i + \frac{c'_M J'_M}{\bar{n}'_M \nu'_M} + \frac{c'_X J'_X}{\bar{n}'_X \nu'_X} + \frac{c'_H J'_H}{\bar{n}'_H \nu'_H} \quad [25.14]$$

and λ_X is a positive constant of the order of magnitude of 1 (19), which satisfies

$$\frac{\lambda_X}{\Delta_X} i^2 = -\frac{1}{\Delta_X} i^2 + \frac{J'_M{}^2}{\bar{n}'_M \nu'_M} + \frac{J'_X{}^2}{\bar{n}'_X \nu'_X} + \frac{J'_H{}^2}{\bar{n}'_H \nu'_H} \quad [25.15]$$

The current density i passing through the oxide film is controlled mainly by the resistance of the film, and it can be expressed by an exponential formula with respect to the electric field in the oxide, then

$$\delta i = -\frac{zF}{RT} \frac{\alpha^{\circ} a}{d} \Delta\Phi_0 i \frac{\delta d}{d} \quad [26]$$

It is easily seen that B in Eq. [25.3] cancels the sixth member of A in Eq. [25.2] so that $A - B > 0$, and also clearly $C - D < 0$, then using Eq. [26]

$$(A - B)s_0\delta i + (C - D)s_0\delta(l - d) < 0 \quad [27]^6$$

Ignoring the terms $\delta\Delta\Phi_{MO/MX}$, $\delta\Delta\Phi_{MX/S}$, and $\delta\Delta\Phi_S$ (4, 5), because the change in $\Delta\Phi_0$ due to the oxide film growth is the major contribution

$$T\delta_X^d P < 0 \quad [28]$$

is obtained. This shows that the oxide film formed on the metal surface at the pit bottom continues to grow until it reaches a steady state and stops growing, provided that the film is not very thin.⁷

Repassivation process.—Oxide film extension.—Suppose that the oxide film extends its area from s_0 to $s_0 + \delta s_0$ with thickness d remaining constant. At the portion δs_0 the reaction

ceases and a series of reactions appear

Here the reaction [31.1] consists of two steps

The current density and the affinity of reactions [30], [31], and [29] are denoted as i_1, i_2 , and i_3 , and A_1, A_2 , and A_3 , respectively

⁶ See Appendix B.

⁷ I was shown in a previous paper on pit initiation (19) that hemispherical halide nuclei produced on the surface of the passive film can grow inwards when the radius surpasses the critical value r^* . A concentration of the current to local points on the surface is needed for this. Actually, if the halide layer was in contact with the passive film and consumed it from the outside, it would not have resulted in the breakdown of passivity but only a thinning of the passive film, which would stop as the steady state is reached. This is shown by the similar consideration stated in this section.

⁸ The conclusion remains unchanged if the reaction [30] is replaced by $M + zH_2O \rightarrow M(OH)_z + zH^+ + ze$.

$$i_1 = k_{MO} \exp\left(\frac{\nu_W \mu_W(0')}{RT}\right) \exp\left(\frac{\alpha_{MO} z F \Delta \Phi_{M/MO}}{RT}\right) \quad [32.1]$$

$$i_2 = k_{OX} \exp\left(\frac{\mu_M(1)}{RT}\right) \exp\left(\frac{\nu_X \mu_X(2)}{RT}\right) \exp\left(\frac{\alpha_{OX} z F \Delta \Phi_{M/MOX}}{RT}\right) \quad [32.2]$$

$$i_3 = k_{MX} \exp\left(\frac{\nu'_X \mu'_X(0')}{RT}\right) \exp\left(\frac{\alpha_{MX} z F \Delta \Phi_{M/MOX}}{RT}\right) \quad [32.3]$$

and

$$A_1 = \mu_M + \frac{z}{2} \mu_W(0') - \frac{1}{2} \mu_{M_2O_z} - z \mu_H(0') + z F \Delta \Phi_{M/MO} \quad [33.1]$$

$$A_2 = \mu_M(1) - \mu_M(2) - z F \Delta \Phi_{M/MOX} \quad [33.2]$$

$$A_3 = \mu_M + z \mu_X(0') - \mu_{MX_z} + z F \Delta \Phi_{M/MOX} \quad [33.3]$$

The thickness of the oxide film d remains unchanged, so that

$$\mu_O(1) + 2\mu_H(2) - \mu_W(2) - 2F \Delta \Phi_{M/MOX} = 0 \quad [33.4]$$

If at least one atomic layer of the oxide is involved, $i_1 \stackrel{*}{=} i_2$, then the force component of the entropy production caused by the above reaction is

$$T \delta_X^s P_{MXO} = \frac{i_1 + i_2}{2zF} (A_1 + A_2 - A_3) \delta s_O$$

$$= \frac{i}{F} \left\{ \frac{1}{2} [\mu_W(0') - \mu_W(2)] - [\mu_H(0') - \mu_H(2)] + F (\Delta \Phi_{M/MO} - \Delta \Phi_{M/MOX}) \right\} \delta s_O \quad [34]$$

The following equations are used in the above formula

$$\frac{i_1 + i_3}{2} = i \quad [35]$$

$$\mu_M(1) + \frac{z}{2} \mu_O(1) = \frac{1}{2} \mu_{M_2O_z} \quad [36.1]$$

$$\mu_M(2) + z \mu_X(0') = \mu_{MX_z} \quad [36.2]$$

The increase in the area of the oxide film by δs_O , with thickness d constant, causes further changes: a change in material transport in the hydrous halide, a change in the reaction at the interface between the hydrous halide and the solution, and a change in material transport in the solution. The force components of the entropy production changes due to these processes are designated as $\delta_X^s P_{MX}$, $\delta_X^s P_{MX/S}$, and $\delta_X^s P_S$, respectively.

The total change in the entropy production $\delta_X^s P$ due to the change in forces is, neglecting for simplicity, the flux of X^- in the solution which accompanies the reaction [29]

$$T \delta_X^s P = T \delta_X^s P_{MXO} + T \delta_X^s P_{MX} + T \delta_X^s P_{MX/S} + T \delta_X^s P_S$$

$$= (A' - B') (1 - \epsilon) (i_1 - i_3) \delta s_O - (C' - D') i \delta s_O \quad [37.1]$$

where ϵ is a correction due to the secondary current in the area shadowed by δs_O , and A' , B' , C' , and D' are positive variables defined by

$$A' \equiv \left(J'_W - \frac{i}{2F} \right) c'_W (l - d) + \frac{i}{\Lambda_X} + \frac{RT}{(z + \nu_H) F}$$

$$+ \left\{ c_I J''_W + (J''_M + c_M J''_W) \frac{1}{z F \bar{C}_M \nu_M} \right\} \Delta \quad [37.2]$$

$$B' \equiv \frac{i'_M \Delta}{z^2 F^2 \bar{C}_M \nu_M} \quad [37.3]$$

$$C' \equiv \frac{1}{F} \delta \mu_H(2) - \frac{z(1 - \alpha'_M)}{z + \nu_H} (1 - \epsilon) \delta \Delta \Phi_{MX/S}$$

$$- (1 - \epsilon) \delta \Delta \Phi_S(4, 5) \quad [37.4]$$

$$D' \equiv \Delta \Phi_{M/MO} - \Delta \Phi_{M/MOX} \quad [37.5]$$

The following relationships are used in the above equation

$$\delta i = (i_1 - i_3) \frac{\delta s_O}{|\delta s_O|} \quad [37.6]$$

$$\mu_W(0') - \mu_W(2) \stackrel{*}{=} -\delta \mu_W(2) = c'_W \delta i \quad [37.7]$$

where Eq. [37.7] is obtained from Eq. [7.3], [9], [19.2], [19.3], and [20.1] with $\delta(l - d) = 0$.

Taking into account that the fourth member of A' cancels B' , it is seen that $A' - B' > 0$. For a very thin oxide film $\Delta \Phi_{M/MOX} \stackrel{*}{=} \Delta \Phi_{M/MO}$, so that $D' = 0$. It is apparent also that $i_1 - i_3 < 0$. Then Eq. [37.1] becomes

$$T \delta_X^s P < 0 \quad [38]$$

It is shown therefore that the oxide film formed on the pit bottom by reaction [30] leads to the repassivation of pits, if the rate of the oxide formation surpasses the rate at which it dissolves by [31.1], so that at least a monolayer oxide film can exist

$$i_1 > i_2, \text{ at } d = a \quad [39]$$

If the film thus extending is too thick, D' should rise in Eq. [37.1], and the above conclusion cannot necessarily hold. This suggests the repassivation mechanism, whereby a very thin (but more than monolayer) oxide film first appears and extends over the whole active surface on the pit bottom, then increases its thickness, resulting in complete repassivation.

The repassivation potential.—It has been shown by the above considerations that the oxide film formed on the pit bottom which satisfies Eq. [39] can grow continuously and lead to repassivation. A critical condition exists, at which $i_1 = i_2$ for a monolayer oxide film. The potential at this condition shall be called the critical pitting potential E_{cp} . Substituting Eq. [33.4] into Eq. [32.2] for i_2 and equating it with Eq. [32.1] for i_1

$$\Delta_c \Phi_{M/MO} = \frac{RT}{\alpha_{MO} z F} \ln \left(\frac{k_{OX}}{k_{MO}} \right) + \frac{1}{\alpha_{MO} z F} \left\{ \mu_M(1) - \nu_X \mu_X(2) + \frac{z}{2} \alpha_O [\mu_O(1) + 2\mu_H(2) - \mu_W(2)] - \nu_W \mu_W(0') \right\} \quad [40]$$

The chemical potential of H_2O in the hydrous halide should attain a critical value at this condition at the interface with the metal

$$\mu_W(0') = \mu_W(2) = \mu^*_{W} \quad [41.1]$$

During pitting corrosion, a concentration of X^- and H^+ in the solution in contact with the hydrous halide should be kept above critical values (28, 29), so that

$$\mu_X(4) = \mu^*_{X} \quad [41.2]$$

$$\mu_H(4) = \mu^*_{H} \quad [41.3]$$

From Eq. [7.3], [9], [12.2], [14.2], [15.2], [16], [22], [33.4], [40], [41.2], and [41.3], the potential of the metal E_{cp} at this critical condition is

$$E_{cp} = \Delta_c \Phi_{M/MO} + \Delta_c \Phi_{M/MOX} + \Delta_c \Phi_{MX}(2, 3)$$

$$+ \Delta_c \Phi_{MX/S} + \Delta_c \Phi_S(4, 5) = E^*_{cp} + \frac{\nu_X - z \alpha_{OX}}{\alpha_{MO} z} [\Delta_c \Phi_{MX}(2, 3)$$

$$+ \Delta_c \Phi_{MX/S}] + \frac{1}{\alpha_{MO} z F} \left\{ \frac{\nu_X J'_X}{\bar{n}'_X \nu'_X} + \frac{z(\alpha_{MO} + \alpha_{OX}) J'_H}{\bar{n}'_H \nu'_H} \right\} l$$

$$+ \frac{RT}{F} \ln \left(\frac{\gamma_X(4) C^*_{X}}{\gamma_X S C_{X^s}} \right) - \frac{\Delta}{F} \frac{J''_X}{\bar{C}_X \nu_X} \quad [42.1]$$

with

$$E^*_{cp} \equiv \frac{RT}{\alpha_{MO}zF} \ln \left(\frac{k_{OX}}{k_{MO}} \right) + \frac{1}{\alpha_{MO}zF} \left[\mu^*_{MO} - \left\{ \frac{z(\alpha_{MO} + \alpha_{OX})}{2} + \nu_W \right\} \mu^*_W + \nu_X \mu^*_X + z(\alpha_{MO} + \alpha_{OX}) \mu^*_H \right] \quad [42.2]$$

where μ^*_{MO} is the chemical potential of the metal oxide of stoichiometric composition $M_2O_{z(\alpha_{MO} + \alpha_{OX})}$

$$\mu^*_{MO} \equiv \mu_M(1) + \frac{(\alpha_{MO} + \alpha_{OX})}{2} \mu_O(1) \quad [42.3]$$

and $\gamma_X(4)$ and γ_X^S are the activity coefficients, C^*_X is the critical X^- concentration, and C_X^S is the concentration of X^- in the bulk of the solution

$$\mu_X(4) = \mu^*_X = \mu^\circ_X + RT \ln [\gamma_X(4) C^*_X] \quad [42.4]$$

$$\mu_X^S = \mu^\circ_X + RT \ln (\gamma_X^S C_X^S) \quad [42.5]$$

Fluxes of species other than M^{z+} should be very small at the stage where the oxide film is formed, so that $J'_X \approx 0$, $J'_H \approx 0$, and $J''_X \approx 0$. Because of the large electrical conductance of the hydrous halide and the small current density during repassivation, it is seen that

$$\Delta c_{\Phi_X}(2,3) + \Delta c_{\Phi_{MX/S}} = \Delta \Phi^*_{MX/S} = \text{const.} \quad [42.6]^9$$

From the above equations it follows that

$$E_{cp} = E^*_{cp} + \frac{RT}{F} \ln \left(\frac{\gamma_X(4) C^*_X}{\gamma_X^S C_X^S} \right) \quad [43]$$

A critical potential at which the monolayer of oxide can appear is thus determined.¹⁰

In order for the repassivation to proceed, i_1 should be larger than i_2 at the appearance of the monolayer of the oxide so that it can grow. The rates i_1 , i_2 , and i_3 of the reactions [30], [31.1], and [29] at the pit bottom are illustrated schematically in Fig. 3. In the figure, the repassivation starts as the potential of the metal becomes $E < E_{cp}$. It should be noted, however, that the oxide film needs to grow, and this growth results in the decrease in the current, and hence the decrease in concentration of X^- and H^+ below the critical values given by Eq. [41.2] and [41.3] so that protection of metal surface is completely accomplished against corrosion. Then pitting stops absolutely. From this it follows that the repassivation potential is not strictly consistent with the critical pitting potential defined by Eq. [43], but the two potentials may be considered to be quite closely related to each other.

Discussion

If the potential of a metal is decreased from the state where pitting is in progress, it eventually brings about repassivation and stops the pitting. The steps in repassivation are as follows: a thin oxide film forms on the metal surface which, in contact with the nonprotective film, is strongly corroding at the pit bottom, then the oxide film extends over the active area of the pit, and finally becomes a passive film which prevents dissolution of the metal (see Fig. 4).

The pit repassivation potential referring to this stage sometimes shows discrepancies with the pit initiation potential by several tenths of a volt (1, 7, 21). Theories of pitting corrosion with considerations of local destruction-repair processes of a passive film (30), local dissolution through passive film flaws (14), or

⁹ If the rate of formation of the hydrous halide is considered to be so small that $l \rightarrow 0$, then $\Delta \Phi^*_{MX/S} \approx 0$.

¹⁰ It was not explicitly taken into account in Eq. [43] that the oxide film formed on the metal surface becomes stable through the amount of surface free energy. Actually this contribution should be included in μ^*_{MO} in Eq. [42.3].

Fig. 3. Variations of i_1 , i_2 , and i_3 as a function of the potential of the metal E . Units of axes are arbitrary. i_1 : rate of the oxide formation. i_2 : rate of the oxide dissolution. i_3 : rate of the metal dissolution. E_{cp} : critical pitting potential.

Fig. 4. Illustration of a process leading to pit repassivation. M: metal. MO: oxide film. MX: nonprotective metal halide. Sol.: solution.

thermodynamic stability of forming phases (11, 12) cannot successfully explain the existence of the above two potential values. The transport-based acidification theory (31, 32) explained the phenomena, but it could not always be the case for hemispherical brightening pits.

The present theory suggests that the repassivation potential is very close to the critical pitting potential defined by Eq. [43]. However, the pit initiation potential includes probability factors due to fluctuations, as reported previously (19), and thus depends on the history of the specimen, such as the passive film thickness or other experimental conditions. The case can exist where a high anodic polarization is required for pit initiation or, in an extreme case pits cannot be initiated at all. This is in contrast to the case of repassivation, and this discrepancy comes from the difference in the electrical conductance of the passive film and the nonprotective halide film.

The pit initiation potential coincides with the critical pitting potential E_{cp} only when the passive film becomes very thin (Appendix C). This is in accordance with the experimental results using the "scratch method" (9). Among various methods of measuring pitting potentials, the potentiokinetic method seems advantageous because of its ease, but application merits caution because of the time lag for the occurrence of pitting (1). If the critical pitting potential defined by Eq. [43] is recognized as a characteristic value of pitting, then the repassivation potential determined experimentally acquires practical importance, because it can be repeatedly measured by a potentiokinetic method as compared to the pit initiation potential (21). Thus, the significance of the pit repassivation potential should be stressed, both theoretically and experimentally (7, 20, 21).

APPENDIX A

It is obtained from Eq. [7.2], [7.3], [20.2], and [20.3]

$$-J'_{\text{w}} \left(c'_{\text{i}} + \frac{c'_{\text{M}}J'_{\text{M}}}{\bar{n}'_{\text{M}}v'_{\text{M}}} + \frac{c'_{\text{X}}J'_{\text{X}}}{\bar{n}'_{\text{X}}v'_{\text{X}}} + \frac{c'_{\text{H}}J'_{\text{H}}}{\bar{n}'_{\text{H}}v'_{\text{H}}} \right) s_0 =$$

$$-J'_{\text{w}}c'_{\text{I}}(zFL'_{\text{MW}} - FL'_{\text{XW}} + FL'_{\text{HW}})\Delta\mu'_{\text{w}}s_0 \quad [\text{A-1}]$$

as $c'_{\text{I}} < 0$ and $\Delta\mu'_{\text{w}} < 0$, the right-hand side becomes positive.

APPENDIX B

It is seen from Eq. [25.4] and [25.5] that $C \ll D$. Using Eq. [25.2], [25.3], and [26], and assuming a constant thickness of the hydrous halide l

$$(A - B)s_0\delta i + (C - D)is_0\delta(l - d) =$$

$$- \left\{ O \left(\frac{\Delta\Phi_0}{d} \right) - O \left(\frac{i\lambda_{\text{X}}}{\Delta x} \right) \right\} is_0\delta d \quad [\text{B-1}]$$

The electric field in the oxide film is much stronger than that in the hydrous halide, so that above equation becomes negative with the increase in d .

APPENDIX C

In order for pitting to occur on the passive metal, hemispherical halide nuclei whose radius is larger than the critical value r^* should be generated in the passive film (19). In Eq. [51] of Okada (19), a small thickness of the passive film, and hence a large current density passing through the halide nuclei, results in a small r^* , and pitting is more easily initiated. In the extreme case when the thickness of the passive film is as small as the order of a , $i = i_1 = i_2$ at the critical pitting potential E_{cp} and becomes even greater as the potential is raised. A critical condition is realized in this case for pit initiation, in which the halide nuclei with the smallest size of a can grow and lead to pitting. Moreover, the potential drop across the halide nuclei takes a minimum value of about RT/F , so that the potential at this condition is very close to E_{cp} . If the potential is lower than this value, an oxide film of any thickness can grow, and is not broken by the halide nuclei.

Dye Loaded Polymer Electrodes

III. Generation of Photogalvanic Effects at n-SnO₂ Electrodes Coated with Poly(4-Vinyl Pyridine) Films Containing Rose Bengal

Prashant V. Kamat and Marye Anne Fox*

Department of Chemistry, University of Texas, Austin, Texas 78712

ABSTRACT

Conducting SnO₂ electrodes precoated with poly(4-vinyl pyridine) can electrostatically bind an anionic dye, rose bengal, within the protonated polymer matrix. When this modified electrode was dipped into an aqueous solution containing a suitable redox couple and illuminated in the dye absorption band, anodic photogalvanic effects were seen. The improved photogalvanic performance of the dye-loaded polymer electrodes has been attributed to high dye concentrations near the electrode surface, longer lived excited states, and stabilization of the photogenerated electroactive species.

One area of recent interest relevant to the direct conversion of light energy to electrical energy is the study of dye-redox systems capable of generating photogalvanic effects (1, 2). Despite continuing efforts to improve the performance of photogalvanic cells, the sunlight engineering efficiency has remained low.

* Electrochemical Society Active Member.

Key words: photogalvanic effects, polymer-coated electrodes, rose bengal, modified electrodes, semiconductor electrodes.

Thionine-Fe(II) system, a widely studied photogalvanic system, has yielded important information on the photochemical and electrochemical determinants of power conversion efficiency in photogalvanic cells (4-6). High concentrations (0.01-0.1M) of the light absorbing dye are thought to be necessary to optimize the efficiency of these photogalvanic cells (7), but recent work suggests that use of such high dye concentrations in homogeneous solution may lead to wastage

of absorbed quantum energy via self-quenching and competitive absorption (8).

Other attempts to improve the performance of photogalvanic cells have involved either improved cell design [e.g., thin layer cells with transparent electrodes (3)] or the use of nonhomogeneous media [e.g., microemulsions (9a), gels (9b), membranes (10), or chemical bonding of the dye to a polymer chain (11)]. So far, however, no major breakthroughs in improving the efficiency of light-to-electrical energy conversion have been achieved.

In our earlier studies, we showed that anionic dyes can be successfully incorporated into protonated poly(4-vinyl pyridine) (PVP) films (12). The electroactivity of these dyes could still be retained in the films, and these dye-loaded polymer electrodes exhibited several interesting electrocatalytic properties (12, 13). Furthermore, the excited states of several xanthene dyes could be stabilized by dispersing them in a polymer film (14). Up to an order of magnitude enhancement in fluorescence yield was seen on microencaging the dye within a polymer (15).

In our continuing investigation of dye-loaded polymer electrodes, we have sought to generate and study photoelectrochemical effects at these modified electrodes. We now present our results on the photogalvanic effects induced by sensitization by rose bengal 1

electrostatically held within a PVP film coated on conducting SnO₂ electrodes and immersed in an aqueous solution containing a suitable galvanic redox couple.

Experimental

Materials.—Rose bengal, 1 (Fisher Scientific), was chromatographically purified (16) over 200-300 mesh silica (E. Merck) using a 35:65 mixture of acetone:ethanol as the eluent. Poly(4-vinyl pyridine), PVP, was used as supplied by Polysciences. All other chemicals were analytical reagents and were used without further purification. All aqueous solutions were made with Millipore-filtered water.

Preparation of dye-loaded polymer electrodes.—Highly conducting SnO₂ electrodes, cut from NESA glass (PPG Industries), were cleaned and dried (13). The conductive surface of the glass plate was then coated with a PVP film by applying a solution of 1% PVP in ethanol and allowing the solvent to evaporate. The PVP-coated electrode (SnO₂/PVP) was then soaked for 10 min in an aqueous solution of 1 (ca. 1 mM) buffered to pH 3 with 0.1M CF₃COONa and CF₃COOH. The electrode was then washed thoroughly with water. Coloration of the PVP film confirmed the incorporation of the dye into the polymer film. Such electrodes will be referred to as SnO₂/PVP/1. Typically, the polymer films were 0.1 μm thick (as determined with a Sloan Dektak surface profilometer) and had a surface coverage of 2-10 × 10⁻⁹ mol/cm² of the dye. (In other words, one could achieve a dye concentration up to 1M in the polymer film.) Dye deposited within the polymer was tightly bound and did not leak into solution during the time scale of the experiment.

Photoelectrochemical measurements.—The photoelectrochemical cell was a standard three-compartment cell equipped with Pt foil (2 cm²) as counterelectrode and a saturated calomel electrode (SCE) as reference. The SnO₂/PVP/1 electrode (2 cm²) was illuminated with a collimated beam from a 250W halogen lamp, filtered with a 460 nm cutoff filter (Corning). The illuminated semiconductor was placed within 1 cm of the dark metallic counterelectrode. The equilibrated solution resistance was ~1 kΩ. Light intensity at the illuminated electrode was 120 mW/cm². For excitation with selected wavelengths, a Bausch and Lomb high intensity grating monochromator was inserted in the path of illumination beam. Absorption spectra were recorded with a Hewlett Packard 8450 spectrophotometer. Photovoltages and photocurrents were measured with a Keithley (Model 177) microvoltmeter. Flash photolysis and pulse radiolysis experiments were carried out with standard equipment available at the Center for Fast Kinetic Research, University of Texas at Austin. Details of analogous pulse experiments have been reported elsewhere (14).

Results and Discussion

Excited state characteristics.—A typical absorption spectrum of SnO₂/PVP/1 is shown in Fig. 1. 1 incorporated within the polymer film retains its absorption characteristics, but exhibits a red shift in its absorption maximum (λ_{max} = 572 nm in the PVP film, 558 nm in ethanol). Such a red shift in the absorption maximum has been attributed to microencagement of the dye by the polymer, consequences of which have been discussed in detail elsewhere (14). A high monomer-to-dimer ratio, determined by the relative intensity of the absorbance at the peak maximum (monomer) and at the (dimeric) shoulder, indicated little aggregation of the dye in the polymer film. Thus, despite achieving high dye concentrations (around 1M) in the 0.1 μm thick PVP film, most of the dye is held in monomeric form.

With SnO₂ electrodes coated by direct electron deposition of thionine (12), the dye absorption spectrum exhibited a broadened absorption band, suggesting substantial aggregation form. Since aggregated dye does not significantly contribute to the generation of photogalvanic effects (18), observation of only small currents with such modified electrodes is understandable. With our present dye-loaded polymer electrodes, in contrast, it is possible to achieve relatively high concentrations of photoactive monomeric dye near the electrode surface. Dye loaded films of optical densities near 1.0, which allowed efficient absorption of the incident photons, could be prepared easily.

Other excited state properties of 1 in homogeneous and polymer containing solutions are given in Table I. An interesting feature of polymer microencagement is seen in the stabilization of the triplet state of the dye. A similar increase in the excited-state lifetimes of xanthenes was also seen upon incorporating them into the polymer films cast on SnO₂ electrodes (14). An increased dye excited-state lifetime is expected to increase the efficiency of generation of electroactive

reduced forms of the dye by enhancing the effective Fe(II) electron transfer quenching sphere.

Photogalvanic effects in homogeneous solution.—Photogalvanic effects produced by 1 and several redox systems in homogeneous solution have been described before. With a solution containing 1 and EDTA, a photovoltage and a photocurrent of 19 mV and 0.025 $\mu\text{A}/\text{cm}^2$, respectively, are observed (19) with light intensities such as we used here. This photocurrent is two orders of magnitude lower than that attained with our polymer-modified electrode (see below).

The results of photogalvanic experiments obtained by backface illumination of SnO₂ in contact with a homogeneous solution containing the Fe(II)/(III) couple are listed in Table II. Upon excitation in the absorption band of the dye, Fe(II) ions quench the excited dye, producing an electroactive reduced form of 1. The specific rate of quenching of triplet 1 ($2.0 \times 10^{-5}\text{M}$) by Fe(II), monitored with nanosecond laser flash kinetics, was $4.5 \times 10^8 \text{M}^{-1} \text{s}^{-1}$ in 0.1M CF₃COONa (pH 3.5). A longer lived transient of $\sim 800 \mu\text{s}$ lifetime, observed by recovery from bleaching of 1 at 540 nm, was also detected. We believe this long-lived transient, which was identical with one produced by pulse radiolysis of an aqueous solution of 1 (probably a reduced form of 1), is produced as a result of electron transfer between triplet 1 and Fe(II) and that it is responsible for the observed photogalvanic effect.

The maximum photovoltage and photocurrents obtained at unmodified SnO₂ electrodes were -30 mV and $0.35 \mu\text{A}/\text{cm}^2$. The poor performance of this photo-

galvanic cell could be attributed to the low concentration of the electroactive reduced dye at the electrode surface and to the competition between dye and Fe^{III} in quenching the anodic current by back electron transfer at the working electrode.

Photogalvanic effects at SnO₂/PVP/1.—When the unmodified SnO₂ electrode was replaced by SnO₂/PVP/1 in the same solution, the magnitude of the photogalvanic effect was greatly enhanced. Since the major contribution to the observed effect came from the dye present in the film rather than from dye in solution (Table II), optimal photoeffects were obtained with the SnO₂/PVP/1 in the absence of dye in the electrolyte. The optimum electrolyte Fe(II) concentration was found to be $\sim 0.01\text{M}$. This same concentration of Fe(II) was then employed in the experiments to be discussed below.

A typical photogalvanic response at SnO₂/PVP/1 to illumination is shown in Fig. 2. The response was instant and reproducible in the presence of Fe(III)/Fe(II). Even after extended irradiation periods (several hours), more than 75% of the original photovoltage is retained. Upon increasing the dye content in the polymer film (Table III), increased photocurrents were observed with dye surface coverage up to $4.5 \times 10^{-9} \text{ mols}/\text{cm}^2$. Further increase in the dye coverage, i.e., to concentrations giving optical densities >0.5 , did not increase the photocurrents.

Our dye-loaded polymer electrodes could be illuminated from either the back face or through solution (Scheme 1). With front-face illumination, only a small fraction of the light reaches the electrode surface

^c Photovoltage and photocurrent refer to open-circuit and short-circuit conditions, respectively.

Fig. 2. Response of photogalvanic effect at (A) $\text{SnO}_2/\text{PVP}/\underline{I}$ and its stability over extended period of illumination. Film thickness = $0.1 \mu\text{m}$. Surface coverage of $\underline{I} = 4 \times 10^{-9} \text{ mol/cm}^2$. Electrode area = 2 cm^2 . Electrolyte = 0.01M FeSO_4 , $0.1\text{M CF}_3\text{COONa}$ (pH 3).

and, in fact, front-face illumination of $\text{SnO}_2/\text{PVP}/\underline{I}$ led to a drastic decrease in the short-circuit current at high dye surface coverages. Since nearly the same photocurrents were observed when the illumination was done from the front or back face of dye containing polymer-coated electrodes of lower optical density, these observations suggest that the dye molecules dispersed close to the electrode surface, i.e., the first few monolayers, are responsible for generating the photogalvanic effect. Thicker films led to decreased photocurrents in both front- and back-face illumination, presumably because of reduced mass transport through the thick layer. A similar dependence of the magnitude of the photocurrent on the polymer film thickness was observed with Nafion-coated SnO_2 electrodes loaded with $\text{Ru}(\text{bpy})_3^{2+}$, where slow charge transport in the thick films limited the generation of photocurrent (20).

Figure 3 shows the photoaction spectrum observed at $\text{SnO}_2/\text{PVP}/\underline{I}$. The maximum observed around 565 nm coincides with the (S_0 - S_1) absorption band of the dye. This confirmed our suspicion that the observed effect was initiated upon dye excitation. The observed photocurrent spectrum is rather broad due to the wide-band excitation source, but the correspondence of the single peak in the photoaction spectrum with the monomer absorption band confirms the previously reported observation (18) that only monomeric dye is active in producing photogalvanic effects.

The dependence of photocurrent and photovoltages on light intensity are shown in Fig. 4. The photocurrent varied linearly, while the photovoltage increased logarithmically with the incident light intensity. Similar dependence on the light intensity has been observed also in homogeneous thionine-ferrous systems (4, 9, 18).

^b $0.1 \mu\text{m}$ thick film.

^c $0.5 \mu\text{m}$ thick film.

The influence of a sacrificial redox system on the magnitude of the observed photogalvanic effect at $\text{SnO}_2/\text{PVP}/\underline{I}$ was also determined. When an aqueous solution of 0.02M EDTA was employed as the redox electrolyte, up to 250 mV of photovoltage and $2 \mu\text{A/cm}^2$ of photocurrents were observed. However, the photocurrents observed with EDTA were neither as reproducible nor as stable as with the Fe(II)/Fe(III) redox system. Decreased photovoltages and photocurrents were seen in successive illumination periods. After $\sim 10 \text{ min}$ illumination, the initial photocurrent had diminished to less than half of its original value. Presumably, the dye in the polymer film undergoes some irreversible photochemical reaction with EDTA and hence loses its photoelectrochemical activity.

Mechanism.—Our earlier electrochemical studies have indicated that the electroactivity of anionic dyes incorporated in the protonated PVP film could be retained almost completely when in contact with a reversible aqueous redox system (12-14). The polymer film can be regarded as the statistical equivalent of several monolayers (21), where charge propagation occurs through electron hopping between adjacent reduced and oxidized states.

We therefore propose the following mechanism to account for photocurrent production. Upon illumination of $\text{SnO}_2/\text{PVP}/\underline{I}$, dye \underline{I} in the PVP film is excited. Fe(II) , also present in the PVP film (22), quenches the long-lived triplet state of the dye, producing an electroactive reduced form of \underline{I} (Eq. [1] and [2])

If the back electron transfer (Eq. [3]) is retarded, \underline{I}^- undergoes heterogeneous electron transfer to the SnO_2 electrode, leading to an anodic current flow. While \underline{I}^- generated close to the surface can quickly transfer charge to the electrode, a species further from the electrode surface must propagate its charge via either diffusion or an electron hopping mechanism. The results of front- and back-face illumination (Table III) experiments suggest that this propagation is not efficient and that only the dye molecules in the first few monolayers (close to the electrode surface) contribute to the generation of photogalvanic effects.

Photochemically generated Fe(III) , Eq. [2], because of additional electrostatic repulsion between cationic PVP and the more positively charged Fe(III) , is repelled from the film into solution. Fe(III) then will ultimately be reduced at the counterelectrode, thereby completing the redox cycle. The net electrochemical reactions can therefore be represented as

Fig. 3. Photocurrent action spectrum of $n\text{-SnO}_2/\text{PVP}/\underline{I}$ in $0.01M \text{FeSO}_4$, $0.01M \text{CF}_3\text{COONa}$ ($\text{pH } 3$). Film thickness $0.1 \mu\text{m}$. Surface coverage of $\underline{I} = 4 \times 10^{-9} \text{ mol/cm}^2$.

Thus, reactions [1]-[5] constitute a photogalvanic conversion of light energy into electricity without an accompanying net chemical change in the electrolyte.

Power characteristics and sunlight engineering efficiency.—The current-voltage power characteristics of a photogalvanic cell consisting of $\text{SnO}_2/\text{PVP}/\underline{I}$ as the photoanode, Fe(II)/Fe(III) as the mobile redox carrier, and Pt foil as the dark cathode are given in Fig. 5. The load resistance was varied with a $100 \text{ k}\Omega$ variable resistor. The maximum power output (P_{max}) obtained was $0.1 \mu\text{W/cm}^2$ at an incident white light intensity of 100 mW/cm^2 . The fill factor for the photogalvanic cell employing $\text{SnO}_2/\text{PVP}/\underline{I}$ was 0.31, comparable to the values reported for photogalvanic cells employing the thionine-ferrous system (3).

The overall engineering efficiency of this solar energy conversion as determined from the ratio of

power output of the photogalvanic cell to the incident power was found to be $\sim 10^{-2}\%$. Because of the limited absorption of the visible light by the dye \underline{I} ($\lambda_{\text{max}} = 570 \text{ nm}$), more than 80% of the incident light is not utilized. Nonetheless, this efficiency is an order of magnitude higher than that obtained in an analogous photogalvanic cell in which this same dye is dissolved in or adsorbed from homogeneous solution.

The important feature of such dye-loaded polymer electrodes in improving the performance of photogalvanic cells are that very high dye concentrations (up to $1M$) can be achieved near the electrode surface, that dye aggregation is minimal, and that retardation of self-quenching leads to longer lived excited states, which in turn increases the efficiency of generation of the electroactive reduced species. Furthermore, specific electroselectivity of the modified electrodes is an important criterion in achieving better efficiency in pho-

Fig. 4. Light intensity dependence of anodic photocurrent (i) open-circuit photovoltage (OCP) of a photogalvanic cell employing $n\text{-SnO}_2/\text{PVP}/\underline{I}$ in $0.01M \text{FeSO}_4$, $0.1M \text{CF}_3\text{COONa}$ ($\text{pH } 3$). Film thickness = $0.1 \mu\text{m}$. Surface coverage of $\underline{I} = 4 \times 10^{-9} \text{ mol/cm}^2$.

Fig. 5. Characteristics of photogalvanic cell with $n\text{-SnO}_2/\text{PVP}/\text{I}$ photoanode and Pt "dark" cathode in 0.01M FeSO_4 , 0.1M CF_3COONa (pH 3). Photovoltage V (\blacksquare), anodic photocurrent i (\bullet), power output, P (\times) at varying load resistance. Film thickness = 0.1 μm . Surface coverage of I^- = 4×10^{-9} mol/cm². Electrode area = 2 cm².

photogalvanic cells (6, 17). The electroselectivity of the polymer-coated photoanode towards the I^-/I couple is increased because alternate quenching redox couples, e.g., species of increased positive charge like Fe(III) , are electrostatically repelled from the cationic film. The expulsion of Fe(III) from the PVP film also serves to retard the back electron transfer between reduced form of I^- and Fe(III) . This, in turn, stabilizes the electroactive reduced species in the polymer film. Similar arguments have been put forth for a thionine-ferrous system in membrane-mediated reactions (10).

Conclusions

A simple technique has been developed to incorporate an anionic dye into a cationic polymer film coated on a conductive SnO_2 electrode. Excitation of the dye-loaded polymer films adhering to optically transparent electrodes immersed in a solution containing a suitable redox couple led to photogalvanic effects. The enhanced photogalvanic performance of this system has been attributed to the presence of a high dye concentration at the electrode surface, to longer lived excited states of the dye in the polymer film, and to the electrostatic characteristics of the polymer in controlling access of charged redox couples to the illuminated electrode. These dye-loaded polymer electrodes should improve the fabrication of thin layer photogalvanic cells.

Semiconductor Electrodes

LV. Differential Photocurrent Determination of Absorption Coefficient and Diffusion Length in p-GaP Photoelectrochemical Cells

Bob L. Wheeler, G. Nagasubramanian, and Allen J. Bard

Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712

ABSTRACT

The differential photocurrent (DPC) method, which involves simultaneous modulation of the incident radiation (at f_1) and the applied potential (at f_2) with detection of the intermodulation photocurrent (at $|f_2 - f_1|$), was employed in the determination of α and L for p-GaP in contact with aqueous solutions of Eu^{3+} . Typical values of α determined by this technique were (450 nm) $6.9 \times 10^4 \text{ cm}^{-1}$ and (400 nm) $8.1 \times 10^4 \text{ cm}^{-1}$. The value of L obtained was $0.10 \pm 0.01 \mu\text{m}$, which is smaller than that found for high purity p-GaP in solid-state devices and is attributed to traps or recombination centers in the p-GaP electrode material.

Radiant-to-electrical energy conversion at a semiconductor electrode in contact with an electrolyte in a liquid junction photoelectrochemical (PEC) cell is often controlled by the optical absorption coefficient, α , and the minority carrier diffusion length, L , of the semiconductor. In principle, by measuring the photocurrent under monochromatic illumination as a function of potential, one can obtain the necessary information for the computation of α and L . The Gärtner model and its variations (1-5) are the simplest models for the photocurrent density, j , at the semiconductor/liquid interface. This model assumes that minority carriers generated within the electric field of the space-charge layer (scl) are swept to the interface where they react; recombination within the scl is neglected. Carriers generated outside the scl must diffuse to it. Only those carriers within a distance L of the edge of the scl [where $L = (D\tau)^{1/2}$; D is the diffusion coefficient and τ is the lifetime of the minority carriers] are swept to the interface. More rigorous and complex models for the photocurrent have been proposed (4, 5); these include the effects of surface recombination, bulk and scl recombinations, slow charge-transfer kinetics at the interface, etc. These models are much more difficult to apply to actual experimental studies, however, because they involve many adjustable parameters and numerical solutions or digital simulations rather than analytical solutions. Hence, the Gärtner-like model is frequently used, and we apply this model here in a first attempt at determining α and L by the differential photocurrent (DPC) method—a method first proposed for solid-state devices by Sukegawa *et al.* (6).

The Gärtner equation can be written (1-3)

$$j = KqI\{1 - [e^{-\alpha w}/(1 + \alpha L)]\} \quad [1]$$

where w is the thickness of the scl and is a function of the potential, V , with respect to the flatband potential V_{FB} , and is given by

$$w = [(2\epsilon\epsilon_0/qN)(|V - V_{\text{FB}}|)]^{1/2} \quad [2]$$

ϵ is the dielectric constant of the semiconductor and ϵ_0 is the permittivity of free space, N is the donor or acceptor density, and V is the applied potential with respect to the flatband, V_{FB} . When an ac voltage of amplitude V_0 is superimposed on the dc potential, the variation in space-charge layer thickness, Δw , is given by

$$\Delta w = \epsilon\epsilon_0 V_0 / qNw \quad [3]$$

These equations were used by Sukegawa *et al.* (6). In Eq. [1], K includes terms that are independent of V and the intensity, I , such as the reflectivity of the electrode, etc. The photocurrent density can thus be represented as a function of $|V - V_{\text{FB}}|$ or w (Fig. 1). As

$w \rightarrow \infty$; $j \rightarrow j_{\text{sat'd}} = KqI$. At $V = V_{\text{FB}}$ or $w = 0$, j is given by

$$[j]_{w=0} = KqI[\alpha L/(1 + \alpha L)] \quad [4]$$

The slope of the j vs. w curve at any point is given by

$$(dj/dw) = KqI\alpha e^{-\alpha w}/(1 + \alpha L) \quad [5]$$

In particular, at $w = 0$

$$(dj/dw)_{w=0} = KqI\alpha/(1 + \alpha L) \quad [6]$$

Within the framework of the model, α and L can be obtained from Eq. [4]-[6], since

$$j_{w=0}/(dj/dw)_{w=0} = L \quad [7]$$

$$\ln(dj/dw) = \ln[KqI\alpha/(1 + \alpha L)] - \alpha w \quad [8]$$

with α obtained from the slope of the plot of $\ln(dj/dw)$ vs. w . Note that transformation of the experimentally accessible j vs. V to j vs. w plot requires knowledge of V_{FB} and N ; these can be obtained from a Mott-Schottky plot ($1/C^2$ vs. V) (7). In principle, the actual photocurrent-potential plots could be used in Eq. [7] and [8]. However, since the value of j at $w = 0$ can be very small, the values of L computed from directly measured j vs. V plots are inaccurate. Sukegawa *et al.* (6) developed the differential photocurrent (DPC) technique for obtaining the equivalent data for the determination of α and L .

Basis of DPC method.—The DPC method involves the modulation of the applied potential with a small amplitude (*e.g.*, 12 mVpp) sine wave at a frequency f_2 and the simultaneous modulation of the light intensity at a frequency f_1 with detection of the intermodulated photocurrent at $|f_2 - f_1|$. The intensity of the modulated light is maintained at a low level to prevent changes in dopant density and space-charge layer width from photoeffects alone (8). Figure 2 illustrates these principles. The small signal ac voltage brings about a change (Δw) in the space-charge layer width (w). This change in w produces a change in j , and this change in photocurrent, Δj , is represented by Eq. [5] (*i.e.*, $\Delta j/\Delta w$ approaches dj/dw for small depths of modulation). When the applied potential $V + V_0 \sin \omega_2 t$, where V_0 is the peak amplitude of the small superimposed ac voltage and $\omega_2 = 2\pi f_2$ is the ac angular frequency

$$\Delta w = \epsilon\epsilon_0 V_0 \sin(\omega_2 t) / qNw \quad [9]$$

In the course of one ac cycle, the maximum change in the scl width would be proportional to $2V_0$. However, a more meaningful value for use as the voltage change during a cycle would be the effective voltage or root-mean-square (rms) voltage. The peak-to-peak ac voltage ($2V_0$) is related to the rms voltage (V_{rms}) by

$$V_{\text{rms}} = 0.707 V_0 \quad [10]$$

* Electrochemical Society Active Member.

Fig. 1. A, left: plot of photocurrent (j) vs. applied dc bias (V) for a hypothetical case. B, right: plot of j vs. w , the space-charge layer width for the same case.

Hence, $2V_{rms}$ was employed in the computation of Δw from Eq. [3]. When the incident photon flux is modulated with angular frequency of $\omega_1 = 2\pi f_1$, the intensity of illumination varies as

$$I(t) = I_0(1 + m \sin \omega_1 t) \quad [11]$$

where m is the depth of modulation and $2I_0$ is the maximum incident photon flux. In our experiments, the depth of modulation can be set approximately equal to 100%, and, hence, Eq. [11] reduces to

$$I(t) = I_0(1 + \sin \omega_1 t) \quad [12]$$

It is evident from Eq. [1] that upon changing the space charge layer width w by Δw there is a corresponding change in j by Δj . This is expressed by the following relationship

$$\begin{aligned} J &= j + \Delta j = KqI \{1 - [e^{-\alpha(w+\Delta w)/(1+\alpha L)}]\} \\ &= KqI \{1 - [e^{-\alpha w/(1+\alpha L)}](e^{-\alpha \Delta w})\} \\ &= KqI \{1 - [e^{-\alpha w/(1+\alpha L)}](1 - \alpha \Delta w)\} \\ j + \Delta j &= KqI \{1 - [e^{-\alpha w/(1+\alpha L)}]\} \\ &\quad + KqI \alpha \Delta w e^{-\alpha w/(1+\alpha L)} \quad [13] \end{aligned}$$

Substitution of the time varying quantities $I(t)$ and

Δw from Eq. [12] and [9] into Eq. [13] gives the amplitude of the photocurrent, j , at ω_1

$$j(\omega_1) = KqI_0 [1 - e^{-\alpha w/(1+\alpha L)}] \quad [14]$$

and the differential photocurrent, Δj at Δw

$$\Delta j(\Delta w) = (KqI_0/2) [\alpha/(1+\alpha L)] (e^{-\alpha w}) (\epsilon \epsilon_0 V_0/qNw) \quad [15]$$

The derivations of Eq. [14] and [15] are given in the Appendix.

The values of Δw can be computed from Eq. [3] and [10] as a function of w .

Two lock-in amplifiers, one set at ω_1 and the other at $|\omega_1 - \omega_2|$, were used to detect the photocurrent; thus, both j (at ω_1) and Δj (at $|\omega_1 - \omega_2|$) can be recorded simultaneously. From the computed values of Δw and measured Δj , one can make a plot of $\ln(\Delta j/\Delta w)$ vs. w (Eq. [8]). The slope of the plot yields α at the wavelength of measurement. The Y-intercept of the plot, corresponding to $w = 0$, yields $[\Delta j/\Delta w]_{w=0}$. The value of α obtained previously, can be inserted in Eq. [1], and a plot of j vs. $e^{-\alpha w}$ extrapolated to $e^{-\alpha w} = 1$ (corresponding to $w = 0$) yields $[j]_{w=0}$. From these values, L can be computed from Eq. [7]. In addition to the DPC technique, a wealth of information pertaining to the experimental determination of L is available in the literature. These include the surface photovoltage technique (9-11), the electron bombardment of Schottky barriers (12), the photoluminescent-saturation measurement (13), and various other techniques (14-18). In most of these studies, one needs to know α to evaluate L . Since in many cases α is not known, it has to be determined separately, usually from absorbance measurements (19-24).

We report here DPC studies of single-crystal p-GaP and n-MoSe₂ semiconductors contacting liquid electrolytes containing Eu^{3+/2+} and K₄Fe(CN)₆, respectively, as redox couples. The adaptation of this method reported here has the advantage that the measurements are conducted with the semiconductor in the same configuration normally used in PEC cells, unlike the other techniques mentioned. One drawback, however, is that any deleterious effects the electrolyte has on the semiconductor, such as surface recombination or formation of surface states, could affect the measurement. An example of this is the absorption of light by redox couples. In solid-state measurements, no new chemical species are formed, and the light incident on the semiconductor is constant with respect to time. This is not necessarily the case with semiconductors in PEC cells. Species are generated at the photoelectrode with different absorption characteristics than the original form. If these generated species absorb at the wavelength of interest, errors will be caused by the time-

Fig. 2. Schematic of energy-band diagram illustrating the principle of measurement. Φ is the incident photon flux density chopped at an angular frequency of $\omega_1 = 2\pi f_1$; $2V_0$ is the peak-to-peak amplitude of the small signal ac voltage at an angular frequency of $\omega_2 = 2\pi f_2$; V is the applied dc reverse bias; $x = 0$, w , and B represent, respectively, the interface, space-charge layer width, and the back of the crystal where the ohmic contact is made; E_c = conduction bandedge; E_F = Fermi level; E_V = valence bandedge; E_{redox} = redox potential.

dependent filter effect. For this reason, as well as the good kinetics, $\text{Eu}^{3+/2+}$ and $\text{Fe}(\text{CN})_6^{3-/4-}$ were chosen as redox couples.

Experimental

The single-crystal semiconductors employed in this study were p-GaP and n-MoSe₂. The procedures for mounting and etching the electrodes are given elsewhere (25). The solution used with p-GaP was 0.1M EuCl_3 in 1M HClO_4 , and that used with n-MoSe₂ was 0.2M $\text{K}_4\text{Fe}(\text{CN})_6$ adjusted to pH 8 with KOH. Solutions were bubbled with prepurified N_2 prior to use, and N_2 was passed over the solutions during the experiment. A single-compartment electrochemical cell of 40 ml capacity with an optically flat window was used for all experiments. The counterelectrode was a large-area (40 cm²) Pt gauze, and the reference electrode was a saturated calomel electrode (SCE) with a KCl-saturated agar plug immersed directly into the cell. All potentials are expressed relative to the SCE unless otherwise specified.

A PAR Model 173 Potentiostat and a PAR Model 175 Universal Programmer (Princeton Applied Research Corporation, Princeton, New Jersey) were used to obtain the cyclic voltammograms, which were recorded on a Model 2000 X-Y recorder (Houston Instruments, Austin, Texas).

The ac impedance studies (26) utilized the lock-in amplifier technique, which yields the in-phase and the out-of-phase components of an ac signal superimposed on a dc voltage ramp. The ac signal (12 mV peak to peak) at different frequencies was obtained for input into the potentiostat from a Model 200 CD wide-range oscillator (Hewlett-Packard, Palo Alto, California). The output from the potentiostat, which was a voltage proportional to the current flowing between the working electrode (semiconductor) and the counterelectrode, was separated into its components at 0° and 90° with respect to the sine wave input by using a PAR Model 5204 lock-in amplifier and recorded with a Model 6432 (Soltec, Sun Valley, California) X-Y₁Y₂ recorder.

The experimental apparatus used for obtaining the differential photocurrent is shown in Fig. 3. A 2.5 kW Xe lamp (Schoeffel Instrument Company, Westwood, New Jersey) and monochromator (Jarrell-Ash Model 82560, Waltham, Massachusetts), with appropriate slits to achieve a bandpass of ~10 nm, were used as the

monochromatic light source. The light was modulated at 1111 Hz with a PAR Model 192 variable-frequency chopper. The ac frequency from the wide-band oscillator was adjusted to 1511 Hz with an amplitude of 12 mV peak to peak at the input of the potentiostat. A PAR Model 5204 lock-in amplifier was used to measure the photocurrent, j , which is the magnitude of the current present at the input of the lock-in with a frequency equal to the light chopping frequency, 1111 Hz. The much weaker (~1000×) differential photocurrent signal, Δj , was measured with a Model 5206 lock-in amplifier (EG&G, Princeton, New Jersey) equipped with an EG&G Model 5010 plug-in filter operated in the bandpass mode. The differential photocurrent is the magnitude of the current at the input of the lock-in with a frequency equal to the difference in the light chopping frequency and the ac modulation frequency, here arbitrarily kept at 400 Hz (1511 Hz - 1111 Hz). This signal was more conveniently recorded as $\log \Delta j$ by using the log of the magnitude output of the Model 5206. A reference signal for the lock-in at this beat frequency was obtained by passing f_1 from the chopper and f_2 from the oscillator, both adjusted to 0.8V peak to peak with voltage dividers, into the multiplier-filter circuit. The multiplier was constructed with an MC 1494L chip (Motorola, Incorporated) with the attendant circuitry as described in the product application information (27). The output, which consisted of a signal with frequency components at $f_1 + f_2$ and $f_2 - f_1$, was filtered to obtain only $f_2 - f_1$. This filter consisted of the bandpass output of a variable gain, state variable filter (28) constructed from an ECG 997 quad operational amplifier chip (Sylvania, Waltham, Massachusetts). Further filtering or amplification was found to be unnecessary for the reference channel of the EG&G 5206. Power for the circuit was supplied by a Harrison 6205B dual dc power supply (Hewlett-Packard). The potentiostat, programmer for dc ramp (2 mV/s), and X-Y₁Y₂ recorder were the same as mentioned previously.

As an independent check, L was determined by the surface photovoltage technique. The procedure used was that reported previously by Kamieniecki (29) and others (30). A tungsten-halogen lamp with power input controlled with an autotransformer was used as a light source. Monochromatic light was obtained with a grating monochromator (Model 7240, Oriel Corporation, Stamford, Connecticut). The lock-in amplifiers and

chopper are the same as previously described. The light intensity was monitored with a pyroelectric detector with a quartz window (Model P1-45Q, Molectron Corporation, Sunnyvale, California). In the surface photovoltage measurements, the solvent was acetonitrile (Spectrum Chemical Manufacturing Corporation, Gardena, California, spectrophotometric grade) and the electrolyte 0.01M tetra-n-butylammonium tetrafluoroborate (Southwestern Analytical Chemicals, Austin, Texas) which had been dried under vacuum at 100°C for 24h after recrystallization from acetone-ether. The solvent-electrolyte solution was stirred with activated alumina (Woelm Alumina N-Super I, Woelm Pharma GmbH and Company, Eschwege, Germany) decanted into the cell and deaerated and kept under a He atmosphere. The reference and counterelectrodes were the same as those used in the DPC measurement.

Results and Discussion

Computation of w and Δw .—For the determination of both w and Δw , one needs to know the value of N , the net doping density, and V_{FB} ; these can be obtained from the Mott-Schottky plot (7). The values of N and V_{FB} obtained from such a plot for p-GaP are $3.7 \times 10^{17} \text{ cm}^{-3}$ and $+0.22\text{V vs. SCE}$, respectively, in $\text{Eu}^{3+/2+}$ aqueous solution. The space-charge layer width, w , is related to N and V (where V is the applied potential) by Eq. [2]. Upon inserting the values of N and V into Eq. [2], the resulting plot of w vs. V for p-GaP in aqueous $\text{Eu}^{3+/2+}$ solution is obtained (Fig. 4). The values of Δw at different potentials were computed by Eq. [3]; the corresponding values of w were taken from Fig. 4. For computation of Δw , a value of $2V_{\text{rms}}$ instead of $2V_0$ was used. The reasons for this are discussed in detail above. The values of w and Δw from Eq. [2] and [3], respectively, are given in Table I as a function of V . Note, in Table I, that as the space-

Fig. 5. j and Δj vs. V for p-GaP in aqueous solution containing Eu^{3+} as redox couple. The wavelength of irradiation is 400 nm. $f_1 = 1.111 \text{ kHz}$ and $f_2 = 1.511 \text{ kHz}$.

charge layer width increases, Δw decreases at a given ac modulation.

Plots of Δj and j vs. V .—Under reverse bias conditions, the dark current densities for the semiconductors used in this work were less than $1 \mu\text{A}$. Typical plots of Δj at $\Delta f = 400 \text{ Hz}$ (1511 Hz) and j at 1111 Hz vs. applied bias, V , are given in Fig. 5 for p-GaP in aqueous solution containing $\text{Eu}^{3+/2+}$ as the redox couple. Frequencies 1111 and 1511 Hz correspond, respectively, to the chopping frequency f_1 , of the incident photon flux and the small signal ac frequency, f_2 , superimposed on the dc ramp, V . The plots in Fig. 5 are given for an incident photon energy of 3.1 eV (corresponding to 400 nm). The ordinate for the Δj (400 Hz) vs. V plot is given on a logarithmic scale. Similar results were obtained when the two modulating frequencies f_1 and f_2 were varied by $\pm 20\%$ while maintaining the Δf constant at 400 Hz for ease of filtering. Similar plots of Δj (400 Hz) and j were obtained for irradiation energies in the range 2.7–3.54 eV. Consider Fig. 5, where the photocurrent rises steadily reaching saturation around -0.1V . As j rises, Δj decreases monotonically tending to 0 at -0.1V where j reaches saturation.

Determination of α and L .—From the values of Δw in Table I and the Δj values at corresponding poten-

tials, from Fig. 5, plots of $\ln \Delta j/\Delta w$ vs. w were obtained (Fig. 6). The Δj and $\ln \Delta j/\Delta w$ values from these plots for p-GaP are given in Table I. A least squares fit was made for the computation of the slope and the Y-intercept. In this fit, a few points very close to V_{FB} were not included, since these points do not fall on the same line as data obtained at larger bias further into the depletion region. The reasons for the deviation are discussed below. The Y-intercept and the slope give, respectively, $(\Delta j/\Delta w)_{w=0}$ and the absorption coefficient, α . The α and $(\Delta j/\Delta w)_{w=0}$ at different wavelengths are given in Table II. This value of α is in good agreement with literature values (31), and is in the range 10^4 - 10^5 cm^{-1} at the wavelengths studied. The value of α at a particular wavelength was inserted into Eq. [1] and a plot of j vs. $e^{-\alpha w}$ obtained (Fig. 7). The j values corresponding to various selected potentials were obtained from Fig. 5. The $[j]_{w=0}$ obtained by extrapolating the plot in Fig. 7 to $e^{-\alpha w} = 1$ correspond-

ing to $w = 0$ at different wavelengths is given in Table II. The extrapolation was made by least squares analysis. Once again, for the least squares fit, values of j close to V_{FB} were neglected. The probable reasons for this positive deviation at small values of V can be attributed to a nonuniform doping density and near-surface recombination. If the impurity concentration is not uniform, w will be different in different regions of the semiconductor, since w varies as $N^{-1/2}$. For example, very close to the surface, if N is larger than the bulk doping density ($3.7 \times 10^{17} \text{ cm}^{-3}$), the actual value of w will be smaller than the computed one, giving a larger Δw . Moreover, if j rises sluggishly to saturation, the Δj will be larger than if j rises precipitously to saturation. The sluggish rise to saturation may be due to the recombination of photogenerated carriers. Thus, the larger Δj and smaller Δw can give rise to a positive deviation. No attempt was made, however, to account for this positive deviation, since one

needs to know the values of different parameters, such as surface recombination rate, bulk recombination rate, etc., under actual use conditions. Since these parameters are not easily determined, the values of j and $(\Delta j/\Delta \omega)$ close to V_{FB} were neglected.

The minority carrier diffusion length, L , was obtained from Eq. [7] from the values of $[j]_{\omega=0}$ and $(\Delta j/\Delta \omega)_{\omega=0}$. The values of L at different wavelengths are given in Table II. The literature values of L for p-GaP span a range 0.1-3 μm (15, 31). The minority carrier diffusion length, L , is related to the minority carrier lifetime, τ , and diffusion coefficient, D , by $L = (D\tau)^{1/2}$. The defects and the steps existing in the crystal can act as killer traps or recombination centers for minority carriers resulting in a drastic reduction in the minority carrier lifetime (32). Further, ions adventitiously incorporated into the lattice can also reduce the lifetime, τ . For example, Partin *et al.* (33) have shown that diffusion of cobalt into VPE n-GaAs_{0.6}P_{0.4} produced a considerable reduction of the diffusion length. Although L has been shown to be a function of doping density (15), the values of L obtained here ($\sim 0.1 \mu\text{m}$) are at the lower end of the range of values reported for similar doping densities. This suggests that the sample studied has a rather high number of recombination centers. Note that the value of L at 350 nm appears to be practically zero because the condition $\alpha\omega < 1$ is not satisfied. If $\alpha\omega > 1$, all the light will be absorbed within the space-charge layer with the result that there is no photocurrent attributable to diffusion of carriers from the semiconductor bulk.

Surface photovoltage measurement.—The value of L determined by the DPC technique was independently

checked by the surface photovoltage (SPV) technique (9-11, 29, 30). In this technique, the semiconductor electrode at open circuit is illuminated with chopped monochromatic radiation of energy slightly greater than the bandgap (E_g) of the semiconductor. The accumulation of minority carriers at the surface of the semiconductor produces a SPV. The SPV signal is capacitively coupled into the 10 Mohm impedance of a lock-in amplifier for amplification and measurement. The light intensity is adjusted to produce the same value of SPV at different wavelengths of excitation. The monochromatic light intensity required to produce this constant SPV signal is plotted against the reciprocal absorption coefficient for each wavelength. The α values for the wavelength range (500 nm – 440 nm) studied were those reported by Beckmann and Memming (34). The resultant linear plot is extrapolated to zero intensity, and the negative intercept value is the effective diffusion length. The results obtained by this technique are given in Fig. 8 for the same p-GaP sample studied by the DPC technique. The value of L obtained by least squares analysis of the data was $0.2 \pm 0.1 \mu\text{m}$. The uncertainty was the standard deviation of the values of L obtained from four different surface photovoltage values. The value of L agrees, within experimental uncertainty, with the value obtained by the DPC technique.

Effects of surface states on Δj - V behavior.—The claim by Sukegawa *et al.* (6) that this DPC technique is free from the effects of surface states does not appear to be valid. Surface states are known to affect the I-V behavior and may cause Fermi level pinning. These can be identified in different ways, including ac impedance measurements (26) and low frequency capacitance methods (35). We have studied the surface states on n-MoSe₂ in aqueous $\text{K}_4\text{Fe}(\text{CN})_6$ solutions by the ac conductance method (36). A typical plot of G_p (0° component) *vs.* V at 100 Hz is given in Fig. 9. The large hump in the range 0.1-0.45V can be attributed to the presence of surface states. DPC measurements were made with this electrode and plots of j and Δj *vs.* V are shown in Fig. 10. The dip in the Δj *vs.* V plot occurs in the same potential range in which G_p *vs.* V exhibits

Fig. 8. Relative photon intensity (I_0 in arbitrary units) *vs.* inverse absorption coefficient (α^{-1}) for p-GaP in acetonitrile, 0.01M tetra-n-butylammonium tetrafluoroborate. Chopped at 87 Hz. Surface photovoltage was kept at: (a) 0.075 mV, (b) 0.1 mV, (c) 0.25 mV, and (d) 0.5 mV. The sensitivity of I_0 for SPV = 0.5 mV was $0.5 \times$ all others.

Fig. 9. G_p (in-phase component) vs. V for n-MoSe₂ in aqueous solution containing K₄Fe(CN)₆ as redox couple. $f = 100$ Hz.

a hump; this dip is also ascribed to surface states. Consider the functional relationship between j and Δj . While j increases steadily, Δj decreases monotonically, and when $j \rightarrow j_{\text{sat}}$, $\Delta j \rightarrow 0$. However, when there is an inflection in the steady increase in j , there is a dip in the Δj vs. V plot. This inflection in the increase in j can be attributed to surface states acting as recombination centers. While the functional relationship between

j and Δj explains qualitatively the dip in Δj vs. V , a quantitative estimate of the density of surface states and the time constant of the surface states still needs to be addressed.

Conclusions

To our knowledge, this is the first time that the DPC method has been employed in liquid junction PEC cells. The absorption coefficient, α , for p-GaP is in the

Fig. 10. j and Δj vs. V for n-MoSe₂ in aqueous solution containing K₄Fe(CN)₆ as redox couple. The wavelength of irradiation is 500 nm. Modulation frequencies: $f_1 = 1.111$ kHz and $f_2 = 1.511$ kHz.

range 10^4 - 10^5 cm^{-1} in the wavelength range studied. This is in good agreement with that reported in the literature. However, L for our p-GaP is much smaller than the literature value for good-quality GaP crystals. This may be due to the existence of steps, defects, or incorporated metal ions. Finally, the results on n-MoSe₂ suggests that this method can be used to locate and identify surface states. The DPC method cannot be used in liquid junction PEC cells to determine α and L when surface states are present, the semiconductor decomposes under optical illumination, or the diffusion length is larger than the width of the crystal. These three factors precluded the measurement of α and L for Si, GaAs, and InP by this method in PEC cells.

APPENDIX

Introduction of the expression for the two modulated quantities, illumination ($I(t)$, Eq. [12]) and Δw (expressed as applied voltage, Eq. [9b]) into Eq. [13] leads to the total time dependent photocurrent.

$$J(t) = KqI_0(1 + \sin \omega_1 t) [1 - e^{-\alpha w} / (1 + \alpha L)] \\ + KqI_0(1 + \sin \omega_1 t) [e^{-\alpha w} \alpha / (1 + \alpha L)] \\ [(\epsilon_0 / qNw) V_0 \sin \omega_2 t] \quad [\text{A-1}]$$

or collecting terms

$$J(t) = KqI_0(1 + \sin \omega_1 t) [1 - e^{-\alpha w} / (1 + \alpha L)] \\ + KqI_0 [\alpha / (1 + \alpha L)] (e^{-\alpha w} \epsilon_0 V_0 / qNw) \\ \times [\sin \omega_2 t + (\sin \omega_1 t) \sin \omega_2 t] \quad [\text{A-2}]$$

From trigonometric identity

$$\sin A (\sin B) = 1/2 [\cos (A - B) - \cos (A + B)]$$

Equation [A-2] can be rewritten as

$$J(t) = KqI_0(1 + \sin \omega_1 t) [1 - e^{-\alpha w} / (1 + \alpha L)] \\ + KqI_0 [\alpha / (1 + \alpha L)] (e^{-\alpha w} \epsilon_0 V_0 / qNw) \times [\sin \omega_2 t \\ + 1/2 [\cos (\omega_1 - \omega_2) t - \cos (\omega_1 + \omega_2) t]] \quad [\text{A-3}]$$

Of the various signals present in the second term in Eq. [A-3], the major difference frequency component ($|\omega_2 - \omega_1|$) can be separated using a lock-in amplifier. The first term on the right-hand side in Eq. [A-3] is proportional to the photocurrent j , and the amplitude is given by

$$j(\omega_1) = KqI_0 [1 - e^{-\alpha w} / (1 + \alpha L)] \quad [\text{A-4}]$$

The amplitude of the major difference frequency ($|\omega_2 - \omega_1| = \Delta\omega$) component, the second term on the right-hand side in Eq [A-3] is expressed as

$$\Delta j(\Delta\omega) = (KqI_0/2) [\alpha / (1 + \alpha L)] e^{-\alpha w} \epsilon_0 V_0 / qNw \quad [\text{A-5}]$$

Dividing Eq. [A-4] by Eq. [A-5] gives

$$j_{w=0} / [\Delta j / \Delta w]_{w=0} = KqI_0 L [\alpha / (1 + \alpha L)] \\ / [(1/2) KqI_0 \alpha / (1 + \alpha L)] = 2L$$

Therefore

$$L = j_{w=0} / 2 [\Delta j / \Delta w]_{w=0}$$

Effect of Contact Between a Current Collector and a Polyacetylene Electrode on Electrochemical Behavior in Polyacetylene/Lithium Batteries

Show-An Chen and Yeong-Cherng Chiou

Chemical Engineering Department, National Tsing Hua University, Hsinchu, Taiwan 300, China

ABSTRACT

Organic batteries with a polyacetylene film (PA) as the anode, a lithium strip as the cathode, and lithium perchlorate dissolved in propylene carbonate as the electrolyte are constructed. Charging and discharging characteristics of three batteries with different types of PA electrode are investigated. Type a PA electrode involves mechanical pressed contact of nickel gauze with the upper portion of the PA electrode; charging and discharging of the battery are difficult due to the semiconducting characteristic of the PA. Type b involves a PA film which has one side coated with a sputtered palladium (Pd) film; good contact of the Pd current collector with the PA electrode makes charging and discharging easily manageable. Type c involves an iodine-doped PA film; the battery is easily charged and discharged, but cleaning the surface of the lithium electrode is necessary after a few cycles.

Organic batteries, in which one or two electrodes are composed of organic polymer, have drawn great attention because of its lightweight and high energy density since MacDiarmid's team discovered a battery with polyacetylene (PA) electrodes (1-4). Immediately after this discovery, other conducting polymers, such as poly(p-phenylene) (PPP), were also found to be potential material for the electrodes (5-7). In these two polymers, PA was investigated more for its use as an electrode than PPP in the open literature (1-4) for its higher durability and ease in being prepared. In the battery, a salt, lithium perchlorate, dissolved in an organic solvent, propylene carbonate, was usually used as an electrolyte. During charging, the PA, connected to a positive terminal of dc power source, was partly oxidized to polycarbonium ions $[(CH)^{y+}]_x$ with a corresponding number of counter A^- ions adsorbed and changed to $[(CH)^{y+}A_y^-]_x$. The PA connected to the negative terminal was partly reduced to polycarbanion $[(CH)^{y-}]_x$ with a corresponding number of counter M^+ ion adsorbed and changed to $[(CH)^{y-}M_y^+]_x$. During discharge, the former electrode was reduced and the latter oxidized, with both tending to recover their original states although it was claimed that PA could be used for both electrodes. However, the battery was not investigated in detail for its charging and discharging characteristics. Among the reports on organic batteries involving PA, lithium is usually used as a counterelectrode (2-4).

Since the pristine PA is a semiconductor, good contact between the current collector and PA is essential for efficient charging and discharging. Two types of current collectors were reported in the literature on the PA electrode: (i) a metal wire such as platinum (Pt) which was attached to the PA by mechanical-pressed contact (3, 4); and (ii) a piece of 52 mesh platinum gauze, similar in area to the PA film, was connected to the lead, a platinum wire, by spot welding (8). Differences between these two types in charging and discharging were not reported.

In this work, we investigate the charging and discharging characteristic of the first type current collector mentioned above and two other types: (i) a thin film of palladium (Pd) which was formed on one side of a PA electrode by using sputtering technique; and (ii) iodine-doped PA (this electrode itself also served as a current collector).

Experimental

Materials.—The PA film was synthesized using Shirakawa's method (9). Identification of the film, produced

through the use of IR, density measurement, DSC, and porous surface area measurement, was made in the previous paper (10). The lithium strip was obtained by cutting a lithium rod of synthetic grade (Merck). Lithium perchlorate used as an electrolyte was of analytical grade from Fluka. Propylene carbonate of synthetic grade and toluene and tetrahydrofuran (THF) of LC grade from Merck were purified by adding molecular sieves and then storing for three days to remove a minor amount of moisture. The iodine was reagent grade from Wako.

The PA electrode, which had one side coated with a Pd film, was obtained by sputtering Pd on one side of the PA film in argon gas at a pressure between 10^{-7} and 10^{-2} torr for 8 min at room temperature, using a sputter SPF-210B from Aneva Company. The amount of Pd deposition was about 1.36 mg/cm^2 . The resulting Pd-coated PA film was tested to see whether the Pd was uniformly and continuously distributed on the PA surface by measuring the resistivity on the Pd-coated side. The resistivity was about $10\text{-}40\Omega$ everywhere as measured by making contact between two probes (0.5 cm apart) and the Pd surface. This indicates that the Pd coating was a continuous film.

The iodine-doped PA electrode was obtained by immersing the pristine PA film in iodine/toluene (163 mg/20g) solution for 30 min and then washed successively with toluene for at least three times until no appreciable color appeared in the toluene. The resulting PA film was stored in toluene for one day. The toluene appeared to be clear during the storage. The film was then dried in a dynamic vacuum for at least 30 min. This doped PA film $[(CH)I_{0.028}]_x$ had a conductivity of $0.093 (\Omega\text{-cm})^{-1}$ as measured by the two-probe method.

Construction of organic batteries.—The dimensions of the PA films used as electrodes were about 4 cm in length, 1 cm in width, and 0.1-0.4 mm thick, unless specified otherwise. For all cases, the upper 0.5 cm portion was clipped with a folded nickel gauze, which had the same width as the film, by a pressure of about 7000 lb/cm^2 . After pressing, a conductivity measurement was made by connecting one probe to the nickel gauze and the other probe to the other end of the PA film, in order to assure that the film was not damaged by the pressing. The PA electrode and the counterelectrode (a lithium strip of about 3.5 cm in length, 1 cm in width, and 0.3 cm thick), separated by a glass filter paper, were then installed in a vacuum-tight glass vessel. These two electrodes were about 1 cm apart. The lower part of the vessel was for storing the electrolyte solution (0.3M lithium perchlorate in

Key words: conduction, diffusion, polymer.

propylene carbonate) of about 20 ml. The upper part was equipped with a Teflon valve and two tungsten wires, with their middle parts sealed in the glass wall. The outer ends of the wires were connected to the power source, while the two inner ends were each welded with a small steel clamp for connecting to the electrode. In the cell, about 3 cm of the PA electrode was immersed in the electrolyte solution.

After the whole assembly was set up, the electrolyte solution was injected. The apparatus was connected to a vacuum line, pumped for 5 min, and then introduced with argon gas. During dynamic vacuum pumping, small bubbles arising from the film were observed, indicating that the gas inside the porous area of the PA was pumped out. Since propylene carbonate has a high boiling point and a very low vapor pressure at room temperature, this pumping did not affect the concentration of the electrolyte solution. This cycle of pumping and adding argon gas was repeated three times. The cell was then ready for the charging experiment.

During charging, a constant voltage of 4-6V was applied for a certain period of time. The current passing through was recorded.

During discharge, the two electrodes were brought into contact with or without a standard resistor. The current discharged and voltage across the electrodes were recorded using a digital multimeter and recorder.

Results and Discussion

Results of the charging and discharging of the three types of batteries having various current collectors for the PA electrodes are given below. In each case, the counterelectrode was a lithium strip, and the electrolyte solution used was the same.

Type a.—PA film having the upper portion clipped with a folded nickel gauze.—Charging this battery was accomplished by first applying 1V to the whole PA electrode (45 mg) immersed in the electrolyte solution, supplying a current of 2.5 μ A to begin and rising to 4 μ A. This was to increase the conductivity of the portion of the PA in contact with the nickel gauze and also that above the liquid level. After 2 min, the PA electrode was raised so that its top edge was 1 cm above the liquid level. The applied voltage was then increased to 4V, and the current was increased to 10 μ A and after 2 min, to 13 μ A. The applied voltage was further increased to 5V, which gave a current of 27 μ A. Keeping the applied voltage at 5V for 26h, it finally gave a steady current of about 285 μ A. The resulting open-circuit voltage (OCV) was 3.85V, and the initial short-circuit current (SCC) was 3.21 mA. As described above, the rate of charging was slow.

In order to understand the distribution of perchlorate ions in the PA electrode after charging and discharging, the PA electrode, after charging, was washed with THF, dried in a dynamic vacuum for three cycles, and then subjected to resistivity measurement in an argon atmosphere using a pair of probes which were bound together and had a fixed distance of 0.12 cm. Note that the measured values were dependent on the pressure applied to the two probes. The data shown in Fig. 1(a) are the minimum resistivity at each location. The resistivity of the portion immersed in the electrolyte solution during charging had a resistivity lower than that above the solution.

After the resistivity measurement, the PA electrode was again placed with the battery which gave an OCV of 3.85V and an initial SCC of 102 μ A. After a short-circuit current for 120 min, the SCC was reduced to 15 μ A, and the total charges released were $Q_{out} = 0.16C$. The PA electrode was then washed with THF and dried in a dynamic vacuum for three cycles. Its resistivity was then measured in various locations. The differences in resistivity between the portion in contact with nickel gauze and that immersed in solution

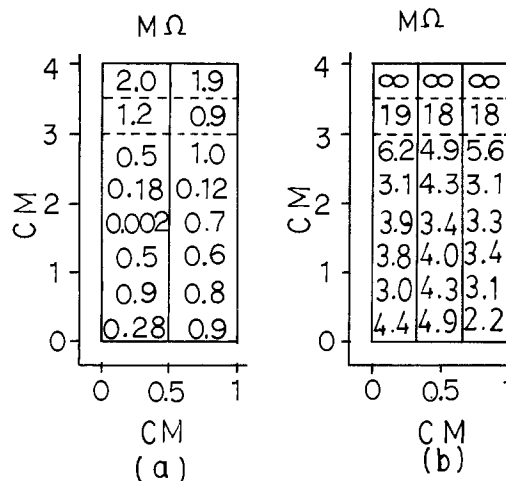

Fig. 1. (a) Resistivity of type a polyacetylene electrode after charging by applying a constant voltage of 5V for 26h; (b) resistivity of type a polyacetylene electrode after discharging without an external resistor for 120 min.

are shown in Fig. 1(b). The former had extremely high resistance while the latter had considerably lower resistance. The residual anions adsorbed in the PA fibrils diffused to the solution during discharging at an extremely slow rate, since electrons were difficult to transfer to the nickel gauze due to the decreased conductivity of the PA. A similar experiment was performed by MacDiarmid (2, 3), in which platinum wire 0.1 cm diam instead of nickel gauze was wound on the same portion of the PA electrode. The same difficulty in charging and discharging was found. Thus, the current collector in contact with the upper part of the PA film is not suitable for the organic battery.

Type b.—PA film having one side coated with palladium.—PA, 2.9 cm long, 1 cm wide, and 0.12 mm thick (14 mg), and coated with Pd on one side by the sputtering method, was used as an anode. Charging of the battery was performed by applying a constant voltage of 4.3V for 35 min; the current *vs.* time is shown in Fig. 2 where Q_{in} was 2.2C. This battery had an OCV of 3.87V and initial SCC of 17.4 mA. In comparison to type a, the rate of charging was much faster. SCC *vs.* time is also shown in Fig. 2 where $Q_{out} = 1.575C$ and the coulombic efficiency $\eta (= Q_{out}/Q_{in})$ was 0.72. It was then recharged under the same constant voltage of 4.3V for 102 min, giving an OCV of 3.8V. The SCC *vs.* time curve is shown in Fig. 3 where $Q_{in} = 6.3C$. It was then discharged by connecting it to an external resistor of 33.6 k Ω and stopped at the voltage, 1.2V. The curves of current and voltage *vs.* time are shown in Fig. 3 where $Q_{out} = 5.33C$ and η was 0.84. The actual coulombic efficiency would have been higher than 0.84 if discharging was stopped at zero voltage. It seems that lower rate of withdrawn current would lead to a higher coulombic efficiency. This, together with the electrochemical behavior of the PA electrode are demonstrated below.

For the first cycle of charging in Fig. 2, the current was high at first and then decreased to a nearly constant level. This indicates that PA fibrils [the PA used had fibrillar morphology (11)] having direct contact with the Pd would first lose electrons easily, allowing a high rate of perchlorate ion diffusion to the surface and interior of the PA fibrils accompanying a charge transfer. This made the initial current high. After these fibrils were oxidized by the perchlorate ions (the first in 5 min), they then became more conductive, causing the other fibrils next to them to lose electrons easily to the Pd current collector. These pristine fibrils started being oxidized by perchlorate ions. This electron transfer process was slower than that for the fibrils in direct contact with the Pd, making the cur-

Fig. 2. Current variations with time of the battery with type b polyacetylene electrode during the first cycle charging by applying a constant voltage of 4.3V for 35 min and first cycle discharging without an external resistor.

rent drop to a lower level. This process continued until all the fibrils were oxidized sufficiently by perchlorate ions at the applied voltage. During discharge without external resistance, the rate of current withdrawn was so fast that most charges were withdrawn within 5 min. This rapid diffusion of perchlorate ions from the surface and interior of the fibrils in direct contact with the Pd coating would cause these fibrils to become less conductive. This caused the perchlorate ions bonded on the surface of the fibrils, located far from the Pd coating and parts of those located inside the interior of the fibrils, difficult to diffuse out. After 15 min discharging, the current dropped to zero, but perchlorate ions that originally oxidized the PA were still retained in the fibrils.

Fig. 3. Current and voltage variations with time of the battery with type b polyacetylene electrode during the second cycle charging by applying a constant voltage of 4.3V for 102 min and second cycle discharging with an external resistor of 33.6 k Ω .

For the second cycle of charging in Fig. 3, the current was high at the first instant, dropped quickly within 2 min, increased to its maximum at 25 min, and then dropped slowly. This can be attributed to the fact that the PA fibrils in direct contact with the Pd were reduced to a nearly neutral state from the discharging of the first cycle and electrons would be lost easily at first, making the initial current high. The rest of the PA fibrils (without direct contact with Pd) would still retain a certain amount of perchlorate ions after discharging in the first cycle and would provide reasonable conductivity for the transfer of electrons to the Pd coating. They were all able to release electrons and to be oxidized by the diffused-in perchlorate ions. The more they were oxidized by the perchlorate ions the more conductive they were, leading to an increase in current until saturation was reached at the fibril surface where the current was at a maximum. After this stage, the perchlorate ions started to diffuse into the interior of the fibrils. Since the diffusion is more difficult inside the solid, the rate of diffusion was slower than that of the surface oxidation stage. Thus, the current started to fall. This charging characteristic of the battery after the first cycle remained the same for another five cycles. The discharging curve (for the case with an external resistor of 33.6 k Ω) in Fig. 3 shows that the lower rate of current withdraw for the second cycle provided higher coulombic efficiency than the higher rate of current withdraw for the first cycle. This is due to the fact that slow release of current would allow more perchlorate ions located inside the fibrils and on the surface of the fibrils far from the Pd coating to diffuse out.

Note that this battery with Pd-coated PA as an anode has a coulombic efficiency similar to that proposed by Kaneto *et al.* (8) in which Pt gauze, having the same area as a PA electrode, was used as a current collector. However, the present method provides a lighter current collector.

For practical uses, good reversibility and stability of the cell are of importance. The PA/Li cells were found to be reversible if the extent of oxidation of PA was low, about 2.2%, under an applied voltage below about 3.75V (8). Above this voltage, degradation of PA due to reaction with the propylene carbonate and lithium perchlorate might occur. In our case, the applied voltage (4.3V) was higher and the degradation of PA could occur. But within 20 cycles of charge-discharge, no appreciable degradation was observed. As to cell stability, contamination of the electrolyte and electrodes by oxygen and moisture is highly probable during installation of the cell or due to insufficient purification and should be reduced to a minimum. Any trace of air can cause the cell voltage to fall sharply on standing. The stability can be increased after several charge-discharge cycles, possibly because the $(\text{CH}^{\nu+})_x$ species acted as a scavenger for impurities initially, as observed by Kaneto *et al.* (8). The same result was also obtained in our case.

Type c.—Iodine-doped PA film.—For the iodine-doped PA electrode, 18.4 mg of pristine PA was doped with 5.03 mg of iodine to give $[(\text{CH})\text{I}_{0.028x}]$. A battery with it as an anode was charged by applying a constant voltage of 6V for 0.5h to give an OCV of 4.2V and a SCC of 22.4 mA. The current input increased slightly with time with $Q_{1,\text{in}} = 14\text{C}$, as shown in Fig. 4. The discharging curve (without an external resistor) in Fig. 4 gave $Q_{1,\text{out}} = 5.28\text{C}$ and $\eta = 0.38$. In the second cycle, charging for 0.5h under 6V gave an OCV of 4.08V, a SCC of 14 mA, and $Q_{2,\text{in}} = 8.64\text{C}$, while discharging gave $Q_{2,\text{out}} = 3.6\text{C}$ and $\eta = 0.42$. The increase in η in the second cycle is due to the part of the perchlorate ions in and on the fibrils during the first cycle that was not completely released. In the charging of the second cycle, small streams with brown color were bleeding from the PA electrode during the first 5-10 min, within which the rate of increasing current

Fig. 4. Current variations with time of the battery with type c polyacetylene electrode during the first and second cycle chargings by applying a constant voltage of 6V for 30 min and, during this two cycle discharging, without external resistor.

was high. This indicates that molecular iodine was released to the solution.

Note that during charging, current variations with time for the first and second cycles are different. For the first cycle, it increased linearly with time. This indicates that the PA electrode was quite conductive everywhere. As the degree of oxidation by perchlorate ions increased, it became more conductive. However, even at the end of charging, the PA was not oxidized to an equilibrium state at the applied voltage. For the second cycle, the current was low first then increased rapidly in 8 min to a higher level. This can be attributed to the fact that the applied voltage not only oxidized the PA, but also the ions, I^- , I_3^- , and I_5^- . After discharging, most perchlorate ions were driven off to the solution, making the PA electrode less conductive. However, as more perchlorate ions doped on the PA electrode, it became more conductive, leading to an increase in the charging current. This charging characteristic remained the same after the first cycle for another four cycles. After the fifth cycle, the surface of the lithium electrode became darker, due to the reaction with iodine from the solution. The charging became more difficult, and the SCC was lower. However, if the surface of the lithium electrode was scratched to remove the reaction product, lithium iodide, the battery was recovered to its original capacity for energy storage.

Conclusion

1. Pristine polyacetylene, without good contact and a large contacting area with a current collector, is not

suitable for use as an electrode due to its semiconducting characteristic when dopant ions are lost.

2. Good contact of a current collector with a polyacetylene electrode is essential for efficient charging and discharging. Thin coating of an inert metal on one side of the polyacetylene film obtained by sputtering method is a promising current collector. This allows the polyacetylene film to become a workable electrode.

3. Directly increasing the conductivity of a polyacetylene film by adding dopant is also a possible way to promote the polyacetylene film for use as an electrode, provided that the dopant concentration in the electrolyte solution is not harmful for the lithium electrode.

Piezo-Electrocapillary Effect: A New Effect Observed in Porous Anodic Oxide Films

J. J. Bernstein*¹ and R. M. White*

Department of Electrical Engineering and Computer Sciences, University of California, Berkeley, California 94720

ABSTRACT

A new effect, the Piezo-Electrocapillary (PEC) effect, has been observed in wet, porous anodic Al_2O_3 films subject to ultrasonic bulk compressional waves. When wetted with a high resistivity polar liquid, these films behave as if they were piezoelectric in that they act as transducers for ultrasonic waves. This is due to the motion (in response to an acoustic wave) of charged liquid located within a Debye length of the inner pore walls which creates an electrical current and externally measurable alternating voltage. As derived in this paper and confirmed by experiments, the voltage output depends on the resistivity, compressibility, and viscosity of the liquid. Transducer sensitivity equal to that of sputtered ZnO $10\ \mu\text{m}$ thick has so far been obtained.

The PEC effect is explained here in detail for the first time, although it has been reported previously (1). Because of this effect, wet porous anodic-oxide films act much like piezoelectric films in response to bulk compressional ultrasonic waves. The porous anodic-oxide films studied here are known to have an array of very fine pores aligned with their axes parallel to the film normal (2). Anodic Al_2O_3 films are also known to have residual electric space charge frozen in the oxide, resulting from the ionic currents which form the oxide during anodization (3-7). This results in a considerable effective surface charge on the Al_2O_3 surface. The liquid in the pores contains a compensating charge equal and opposite to the charge in the porous oxide; the liquid moves relative to the porous oxide in response to an acoustic wave (Fig. 1), creating an alternating electrical current and voltage.

The PEC effect is an extension to ultrasonic frequencies of the electroosmotic effect (8), which describes the steady-state coupling between mass flow and electrical current in a charged capillary. Although we have assumed an array of circular cross section pores in our analysis, any two-phase medium with a charged interface oriented parallel to the direction of acoustic wave propagation should exhibit the PEC effect. In the anodic films studied here, the large specific interfacial area, the large difference in the acoustic phase velocities of the oxide and the liquid, and the large interfacial charge density make the effect very strong, resulting in transducer sensitivity comparable to piezoelectric films such as sputtered ZnO that is $10\ \mu\text{m}$ thick.

In our theoretical treatment of the PEC effect, we first derive the fluid flow in a narrow capillary with a compressional wave propagating along the capillary axis. We then combine this flow with the charge distribution in the capillary to derive the voltage (potential difference from one end of the capillary to the other) across the porous film. In the Experimental Results section, we demonstrate the agreement of this theory with the measured dependence of the PEC voltage on liquid parameters such as resistivity, compressibility, and viscosity.

Experimental Procedures

Porous anodic films were produced by anodizing aluminum at a constant current density of $160\ \text{A}/\text{m}^2$ for 0.5 and 2.5h at 20°C in 10 weight percent (w/o) H_2SO_4 . Before anodization, the aluminum sheet substrates (alloy 5052-H32) were mechanically polished to a $0.25\ \mu\text{m}$ surface finish with diamond polishing compound. This alloy contains 2.5% Mg, 0.1% Cu, Mn, and Zn, 0.25% Cr, and a sum of Si + Fe = 0.45%. Before testing, and between tests with different liquids, the porous anodic films were cleaned ultrasonically in methanol and dried.

Film thickness was measured by abrading a cylindrical groove in the film (Philtec 2015 sectioner) and then profiling the groove with a Tencor Alpha-Step. We consider this to be more reliable than ellipsometry on porous films. The 0.5h anodized film was $8\ \mu\text{m}$ thick, and the 2.5h anodized film was $32\ \mu\text{m}$ thick.

The arrangement used to measure the PEC voltage is shown in Fig. 2. A piezoelectric transducer (Panametrics V311,10) was electrically pulsed by a Panametrics 5052PR pulser to provide a short duration acoustic signal centered at 10 MHz. The maximum particle displacement of the acoustic pulse was 1.6 nm. The acoustic waves were delayed by an aluminum buffer rod (to prevent electromagnetic interference between the pulser's electric signal and the PEC signal), passed through the liquid-filled gap, and into the porous film (Fig. 2). The PEC voltage signal was taken between the body of the anodized aluminum sample and the buffer rod. Some experiments were also performed with the sample inverted, in which case a voltage sensing electrode was placed on top of the anodic film. The PEC voltage was the same whether the acoustic waves were incident from the front of the sample (the anodic film side) or the back (the aluminum substrate).

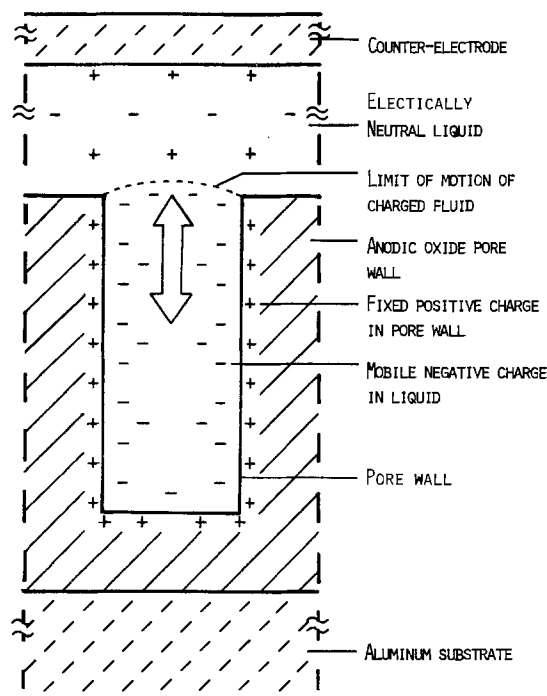

Fig. 1. Motion of charged fluid in a pore, shown here in cross section, produces a current in response to an oscillating acoustic wave (elements not drawn to scale). The boundary between charged and neutral fluid regions is shown as a curved, dotted line at the pore mouth, although the boundary is actually about 1 Debye length thick.

Acoustic Wave Motion in a Capillary

Biot's theory (9) of acoustic waves in two-phase media shows that there exist two bulk compressional modes in a fluid-filled porous medium: a fast mode, in which the fluid and solid move in phase, and a slow mode, in which they move out of phase. In addition, recent experimental work (10) has shown that efficient mode conversion from an incident compressional wave to the slow-wave mode can occur at the boundary of the porous layer.

The velocity distribution for a compressional acoustic wave at frequency ω propagating along a fluid-filled pipe in the z direction is (11)

$$v_z(r,z) = v_z(z) \left(\frac{2}{kR} \right)^2 \left(\frac{J_0(kr)}{J_0(kR)} - 1 \right) \quad [1]$$

where J_0 is the Bessel function of the first kind of order 0, r is the radial distance from the center of the pipe, R is the pipe inner diam, and k is a complex constant given by

$$k = (1 - j) \sqrt{\frac{\omega}{2\nu}} \quad [2]$$

where ω is the angular frequency of the acoustic excitation and ν is the kinematic shear viscosity of the fluid in the pipe (Fig. 3). For $kR \ll 1$ (the case of interest for a capillary), Eq [1] reduces to

$$v_z(r,z) = v_z(z) \left(1 - \frac{r^2}{R^2} \right) \quad [3]$$

which is the familiar case of Poiseuille flow. Note that $v_z(r,z)$ has been separated into a product of $v_z(r) \times v_z(z)$ so that each one can be dealt with separately.

In the absence of an acoustic wave, the net charge of liquid plus oxide in a thin layer between z and $z + dz$ is zero. We are interested in the flow of liquid relative to the pore wall, since only relative flow can produce a net charge in a pore cross section and hence a local change in the net charge. One boundary condition on $v_z(z)$ is

$$v_z(r,L) = 0 \quad [4]$$

at the closed end of the capillary. We assume that the acoustic wave creates a known oscillating z -directed particle velocity v_0 at the pore mouth ($z = 0$) and this is the other boundary condition

$$v_z(0,0) = v_0 \quad [5]$$

The equation of motion of a compressible viscous fluid in a capillary of radius R is (12)

$$\frac{\partial^2 v_z(z)}{\partial z^2} = -\alpha \rho_m \omega^2 v_z(z) + \frac{8j\omega\alpha\mu}{R^2} v_z(z) \quad [6]$$

Fig. 3. Diagram of pore, showing coordinates used in the derivation of the PEC effect.

where $v_z(z)$ is the particle velocity in the z direction at $r = 0$, α is the isothermal compressibility of the fluid ($\alpha = -1/V \partial V / \partial P$), ρ_m is the mass density of the fluid, V is volume, P is pressure, and μ is the viscosity of the fluid. The first term on the right represents the inertial reaction of the fluid, and the second term represents the viscous damping. For the films we studied and for frequencies below the GHz range, the inertial term is negligible, yielding

$$\frac{\partial^2 v_z(z)}{\partial z^2} = \frac{8j\omega\alpha\mu v_z(z)}{R^2} = 2j\beta^2 v_z(z) \quad [7]$$

where $\beta = [4\omega\alpha\mu/R^2]^{1/2}$. The solution to this equation is simply

$$v_z(z) = A_1 e^{\beta z(1+j)} + A_2 e^{-\beta z(1+j)} = v_0 e^{-\beta z} \cos(\beta z) \quad [8]$$

The velocity wave oscillates and decays with a characteristic length of $1/\beta$, which implies that increasing the film thickness beyond $2/\beta$ should have little effect on the voltage output. Unfortunately, we cannot compare film thickness to $1/\beta$ because R and hence β are unknown for our experimental films.

The strain in the fluid in the z direction is the derivative with respect to z of the z -directed particle displacement

$$S_z(z) = \frac{\partial u_z}{\partial z} = \frac{1}{j\omega} \frac{\partial v_z(z)}{\partial z} = \frac{-\sqrt{2}\beta v_0}{j\omega} e^{-\beta z} \cos\left(\beta z - \frac{\pi}{4}\right) \quad [9]$$

The strain as a function of z and r is

$$S_z(r,z) = S_z(z) \left(1 - \frac{r^2}{R^2} \right) = \frac{-\sqrt{2}v_0}{j\omega} e^{-\beta z} \cos\left(\beta z - \frac{\pi}{4}\right) \left(1 - \frac{r^2}{R^2} \right) \quad [10]$$

This strain will be used to compute the net charge density when an acoustic wave perturbs the charge in a fluid-filled capillary.

Perturbation of Charge in a Capillary by an Acoustic Wave

In this section we calculate how the acoustic wave perturbs the fluid charge and gives rise to the PEC effect.

In cylindrical coordinates, the solution of Poisson's equation for the charge density ρ_{e0} in a capillary unperturbed by any acoustic wave is (13)

$$\rho_{e0}(x) = \frac{\sigma I_0(x)}{\lambda I_1(x_0)} \quad [11]$$

where λ is the Debye length in the fluid, σ is the surface

charge density on the capillary wall, $x = r/\lambda$, $x_0 = R/\lambda$, and $I_0(I_1)$ is the modified Bessel function of the first kind, of order zero (one). For $\lambda \gg R$ ($x_0 \ll 1$), the radial charge distribution is approximately constant and equal to $\rho_{e0} = 2\sigma/R$. For $\lambda \ll R$ ($x_0 \gg 1$), $I_0(x)$ is approximately exponential, and the charge density becomes negligible at distances greater than several Debye lengths from the pore wall

$$\rho_{e0} \approx \frac{\sigma}{\lambda} e^{x-x_0} \left(\frac{x_0}{x}\right)^{1/2}, \quad x_0 \gg 1 \quad [12]$$

The net charge in a pore cross section between z and $z + dz$ is zero in the absence of an acoustic wave, since the charge on the pore wall and the charge in the fluid cancel each other. A positive strain S (a dilation) in the negatively charged fluid reduces the local charge density and creates a net positive charge $\rho_e(z)$ which is equal to the integral of the strain S times the unperturbed charge distribution ρ_{e0} over the cross section. The net charge is

$$\begin{aligned} \rho_e(z) &= -\int_0^R \rho_{e0} S_z(r, z) 2\pi r dr \\ &= -\frac{\sigma S_z(z)}{\lambda I_1(x_0)} \int_0^R I_0(x) \left(1 - \frac{r^2}{R^2}\right) 2\pi r dr \\ &= S_z(z) (2\pi R \sigma) \gamma(x_0) \end{aligned} \quad [13]$$

where we have defined a function $\gamma(x_0)$ to take into account the overlap of the charge distribution $I_0(r/\lambda)$ and the r dependence of the z velocity, $(1 - r^2/R^2)$

$$\begin{aligned} \gamma(x_0) &= \frac{\int_0^R \rho_{e0}(r) \left(1 - \frac{r^2}{R^2}\right) 2\pi r dr}{\int_0^R \rho_{e0}(r) 2\pi r dr} \\ &= \frac{1}{x_0 I_1(x_0)} \int_0^{x_0} I_0(x) \left(1 - \frac{x^2}{x_0^2}\right) x dx \end{aligned} \quad [14]$$

Notice that since the velocity peaks at the pore axis and the charge density peaks at the pore wall, significant overlap of charge and velocity occurs only if $\lambda \geq R$. In the limiting case $\lambda \gg R$ (very dilute solution) $I_0(x) \approx 1$, $I_1(x) \approx x/2$, and $\gamma(x_0) \approx 1/2$. In the other limiting case of concentrated solutions, we can use the asymptotic forms of the Bessel functions and integrate (14), obtaining $\gamma(x_0) \approx 2/x_0 = 2\lambda/R$.

Having integrated out the r dependence of the charge distribution and condensed it into the variable γ , we now examine the z dependence as given in the strain wave [9]. Substituting the strain [9] into Eq. [13] gives the charge distribution as a function of z (Eq. [15]), but we have left out an important part of the charge. The narrow region near the pore mouth (Fig. 1) contains charged fluid which, on alternate half cycles, is uncompensated by pore wall charge. We approximate this uncompensated fluid charge as a delta function at the pore mouth ($z = 0$) of sufficient magnitude to satisfy electrical neutrality over the entire pore. Since the liquid only moves about 1 nm, the delta function approximation is a good one. Without this approximation, the problem is very difficult because both the charge distribution and the fluid flow are no longer confined to the pore and are therefore three dimensional. For an oxide with n pores/m²

$$\begin{aligned} \rho_e(z) &= \frac{2\pi n R \sigma \gamma}{j\omega} \left(\frac{\partial v_z(z)}{\partial z} + \delta(z) v_z(z) \right) \\ &= \psi \left(\frac{\partial v_z(z)}{\partial z} + \delta(z) v_z(z) \right) \end{aligned} \quad [15]$$

where we have temporarily combined all the constants in the term ψ .

The voltage across the film, V_{out} can be written as a function of the charge density using the fundamental laws of electrostatics

$$\begin{aligned} V_{out} &= \frac{-1}{\epsilon_{pore}} \int_0^L \rho_e(z) (L - z) dz \\ &= \frac{-\psi}{\epsilon_{pore}} \int_0^L (L - z) \left(\frac{\partial v_z(z)}{\partial z} + \delta(z) v_z(z) \right) dz \end{aligned} \quad [16]$$

where ϵ_{pore} is an area weighted average of the dielectric constants of the oxide and the liquid. Integration of Eq. [16] by parts yields

$$V_{out} = \frac{\psi}{\epsilon_{pore}} \int_0^L v_z(z) dz \quad [17]$$

Substituting for $v_z(z)$ from Eq. [8] and integrating gives

$$\begin{aligned} V_{out} &= -\frac{\psi v_0}{\epsilon_{pore} 2\beta} = -\frac{2\pi n R \sigma \gamma v_0}{j\omega \epsilon_{pore} 2\beta} \\ &= \frac{\pi n R^2 \sigma \gamma v_0}{j\omega^{3/2} \epsilon_{pore} 2(\alpha\mu)^{1/2}} \end{aligned} \quad [18]$$

The sensitivity of the film as a transducer can be expressed as the output voltage per unit particle displacement

$$\frac{V_{out}}{u_z(0)} = \frac{j\omega V_{out}}{v_0} = \frac{(\pi n R^2) \sigma \gamma}{2\omega^{1/2} \epsilon_{pore} (\alpha\mu)^{1/2}} \quad [19]$$

in units of V/m. This is the main theoretical result of the paper, and will now be discussed in order to find the conditions of greatest transducer output.

The term $(\pi n R^2)$ is the pore area fraction. It is typically about 0.5 and can never be greater than one. The term σ , the surface charge density on the inner pore wall, depends on the conditions of the anodization in a poorly understood fashion. Thus far, an empirical approach has been taken to optimize σ . The term γ can be assumed to be 0.5 for liquids of sufficiently high resistivity such as deionized water and reagent-grade solvents. For a given anodic film, the main parameters affecting the magnitude of the PEC effect are the resistivity, compressibility α , and viscosity μ ; therefore these were chosen for experimental study.

Experimental Results

Using the arrangement shown in Fig. 2, various liquids were tested in two different porous anodic films using the same acoustic excitation. The measured PEC voltages are plotted in Fig. 4 as a function of $(\alpha\mu)^{-1/2}$. Although there is some experimental scatter, the data from each film appear to lie on a straight line, as predicted by [19].

It was experimentally observed that nonpolar liquids such as benzene, CCl₄, and cyclohexane resulted in the same PEC voltage as a dry film, about 30 times smaller than and opposite in polarity from the PEC voltage obtained with a liquid such as methanol. The nonpolar liquids apparently do not solvate the ions remaining after anodization on the inner pore wall and therefore result in an effectively zero Debye length.

The resistivity of the liquid can affect the PEC voltage in two ways: first, by its effect on the Debye length and therefore γ , as outlined previously, and second, by its effect on dielectric relaxation for frequencies $f \leq (2\pi\rho\epsilon)^{-1}$ (where ρ is the resistivity and ϵ is the dielectric constant of the liquid). Figure 5 shows PEC voltages for a given film wetted with a series of aqueous K₂SO₄ solutions prepared by successive dilutions. The large change in PEC voltage occurs at the resistivity predicted by dielectric relaxation, 2300 Ω -cm.

If we assume the dropoff in PEC voltage with increasing salt concentration is due to the decrease in Debye length and therefore γ , we can calculate the pore diameter from the condition $\gamma = 1/4 \approx 2\lambda/R$, or $R \approx 8\lambda$. Using the measured concentration at which the PEC voltage falls to half its maximum value (1.4×10^{-3} M), the pore radius is

Fig. 4. Measured PEC voltages in two porous anodic films (anodized for 0.5 and 2.5h, respectively) as a function of the compressibility-viscosity ($\alpha\mu$) product of the test liquid for a variety of liquids.

calculated to be 4.7 nm, which is comparable to the results of published TEM studies on similar porous anodic-oxide films (2).

Summary and Conclusions

A new effect has been observed, in which porous, wet anodic-oxide films act as transducers for ultrasonic waves. A theory was derived to explain this effect using the known equations for the fluid flow and charge distribution in a capillary. The derived equations have been confirmed by experiments showing the dependence of PEC output voltage on the resistivity, compressibility, and viscosity of the liquid saturating the film. Based on Eq. [19], the optimal fluid for a PEC transducer is polar, has a small viscosity times compressibility product, and has a high resistivity. When used with methanol, these anodic Al_2O_3 films have shown themselves to be as sensitive to 10 MHz ultrasonic waves as sputtered ZnO films that are 10 μm thick.

Stability Analysis of Electrochemical Reactors via Liapunov Theory

I. The CSTER System

Thomas Z. Fahidy

Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario, N2L 3G1 Canada

ABSTRACT

The effect of perturbations in the concentration and temperature of the inflow electrolyte and electrolytic current on the steady-state concentration and temperature of the electrolyte in the reactor are studied by an algebraic theory, in terms of appropriate Liapunov functions. The analysis is illustrated by the stability behavior of an electrolytic copper recovery process.

The purpose of studying the stability of an electrolytic reactor is to find out what the effect of perturbations in process variables is on overall reactor performance. One may specifically ask whether a reactor perturbed via changes in electrolyte flow rate, inlet concentration and/or temperature, electric current, etc. will eventually regain its prior steady state, or reach a new steady state. Such information is of obvious importance for the design and control of electrolytic reactors. There are, in principle, two ways of obtaining information on stability on the basis of a mathematical model. First, one may solve the governing set of differential equations for every kind of perturbation as an input function. This is a time consuming and wasteful exercise, since a stable solution to a nonlinear differential equation upon one particular forcing function does not guarantee stability under different forcing. A second and much more powerful approach is via Liapunov functions which allow an essentially algebraic analysis of the stability problem, thus offering a significant shortcut. The purpose of this paper is to present a stability analysis of a certain class of electrolytic reactors which can be modeled as a continuous-flow stirred-tank system (CSTER), in terms of a suitable set of Liapunov functions. The analysis is illustrated numerically by a copper-ion recovery process where the results of the Liapunov approach and simulated transient responses are compared. The analysis of electrolytic reactors modeled in terms of distributed parameters will be the subject of further communications.

Theory

Fundamental notions of Liapunov analysis.—A non-autonomous dynamic system represented by its governing set of differential equations

$$\dot{x} = f(x, t) \quad [1]$$

is asymptotically stable within a region R if there exists at least one scalar function $V(x, t)$ which satisfies the following conditions

$$V(x, t) > 0 \text{ for } x \neq 0, t \geq 0 \quad [2]$$

$$V(0, t) = 0; t \geq 0 \quad [3]$$

$$\dot{V}(x, t) = \frac{\partial V}{\partial t} + x \cdot \text{grad } V(x, t) < 0; x \neq 0, \text{ in R} \quad [4]$$

Then, $V(x, t)$ is a Liapunov function of this system in R. The elements of vector x are the state variables of the system whose steady state is 0. If R is the entire vector space, the system is asymptotically stable in the large (ASL). Rigorous definitions (not needed for the purpose of this paper) and detailed proofs of associated theorems are available in the literature (e.g. Ref. 1-6).

Among the large variety of Liapunov functions proposed by numerous researchers, certain quadratic forms have been found to be particularly powerful. For autonomous systems with governing equation $\dot{x} = f(x)$, the ma-

trix Q and its Liapunov function $V(x) = x'Qx$ has to be positive definite in such a manner that the time derivative $\dot{V}(x) = \dot{x}'Qx + x'Q\dot{x}$ is negative definite. The extension of this principle to arbitrary nonautonomous systems is by no means straightforward, as shown by Petrovski (7); an elegant method based on the convex/concave properties of functions by Mangasarian (8) and the averaging of radius curvature method by Luus (9) require a good deal of mathematical sophistication. When the nonautonomous system is represented by the governing set of equations

$$\dot{x} = f(x) + \xi(t) \quad [5]$$

one appropriate Liapunov function may be defined, following Berger (10, 11), as

$$V(x, t) = x'Qx + \int_t^\infty \xi'(\theta)M\xi(\theta) d\theta \quad [6]$$

where Q and M are appropriately chosen positive definite matrices. This approach may lead to rather cumbersome algebraic manipulations and a better alternative may be to choose

$$V(x, t) = y'Qy + \int_t^\infty \xi'(\theta)M\xi(\theta) d\theta \quad [7]$$

where $y = x - \phi$; $\phi = \int_0^t \xi(\theta) d\theta$. In the sequel, this alternative will be further explored.

It is instructive to note at this point that failure of finding a suitable Liapunov function does not prove system instability, although there exist specific Liapunov-based methods, such as Chetaev's instability theorem (2), for proving instability. The strength of the approach lies in its converse: even if only one single Liapunov function can be found (which satisfies Eq. [2]-[4]), stability within a certain region R is guaranteed. The size of the stability region depends, however, on the Liapunov function chosen, and a systematic search for the true stability domain may not be a trivial exercise.

State variable representation of an electrolytic reactor represented by a CSTER model.—Consider an electrolytic reactor consisting of a rectangular tank with a single pair of parallel-plate electrodes. The electrolyte is well mixed, and during (potentiostatic or galvanostatic) electrolysis there is one dominant reaction occurring at each electrode. Then the governing set of equations is the mass balance and the heat balance (12)

$$V_t \dot{c} = qc_0 - qc - I/zF \quad [8]$$

$$m_e C_p \dot{T} = GC_p T_0 - GC_p T - Q_L + I^2 R_e - I \Delta H_H / zF \quad [9]$$

The heat loss term may be written as

$$Q_L = \frac{k_1}{d_1} A_1 (T - T_f) + \sum_{i=2}^6 U_i A_i (T - T_a) + h_6 A_6 (T - T_a) \quad [10]$$

In steady state, there is no variation with time, hence $\dot{c} = \dot{T} = 0$ and Eq. [8]-[10] may be solved for steady-state

values c_0^* , c^* , T_0^* , T^* , and I^* , assuming that T_r and T_a remain constant and that the various physical parameters are constant (or may be approximated by appropriately computed average values). Dimensionless state variables can then be defined as $x_1 \equiv (T - T^*)/T_0^*$ and $x_2 \equiv (c - c^*)/c_0^*$, while the dimensionless forcing functions are taken as $\xi_1 \equiv (T_0 - T_0^*)/T_0^*$ and $\xi_2 \equiv (c_0 - c_0^*)/c_0^*$. Further, the following dimensionless quantities may be assigned

$$R \equiv \frac{kV_t}{m_e q C_p T_0^*} \left(\frac{I^2}{\sigma} - \frac{I^{*2}}{\sigma^*} \right) \quad [11]$$

$$S \equiv \frac{V_t \Delta H_R}{m_e q C_p T_0^* z F} (I - I^*) \quad [12]$$

$$Q \equiv \frac{1}{q z F c_0^*} (I - I^*) \quad [13]$$

$$\psi \equiv 1 + \frac{V_t k_1 A_1}{q m_e c_p d_1} + \frac{V_t}{q m_e C_p} \left[\sum_{i=2}^5 U_i A_i + h_6 A_6 \right] \quad [14]$$

$$\theta \equiv \frac{q}{V_t} t \quad (\text{dimensionless time})$$

Then, the dimensionless state equations equivalent to Eq. [8] and [9] are

$$\frac{dx_1}{d\theta} = -\psi x_1 + R - S + \xi_1 \quad [15]$$

$$\frac{dx_2}{d\theta} = -x_2 - Q + \xi_2 \quad [16]$$

where ξ_1 and ξ_2 represent time varying perturbations in the electrolyte inlet temperature and concentration. Note that R is nonzero, since $\sigma \neq \sigma^*$ due to variations in T and c .

Liapunov analysis of perturbations decaying in time.—If sporadic (random) disturbances are disregarded, perturbations in an electrolytic reactor may be broadly classified as either time decaying or persistent. In the former case, the decaying perturbation $\xi(t)$ would be bounded by a properly chosen exponential envelope

$$\left| \xi_i(t) \right| \leq A_i e^{-\lambda_i t} \quad i = 1, 2 \quad [17]$$

where A_i and λ_i are constant parameters. In galvanostatic electrolysis, Eq. [15] and [16] are simplified to

$$\frac{dx_1}{d\theta} = \psi x_1 + R + \xi_1 \quad [18]$$

$$\frac{dx_2}{d\theta} = -x_2 + \xi_2 \quad [19]$$

In potentiostatic electrolysis, this simplification is not possible, but the principle of the approach presented below is similar. Considering Eq. [5] and [7] and given the decaying nature of $\xi(t)$, the Liapunov derivative may be written as

$$\dot{V}(x, \theta) = y' Q y + y' Q \dot{y} - \xi'(t) M \xi(t) \quad [20]$$

where the overdot denotes differentiation with respect to dimensionless time θ . The matrix Q will be constructed as

$$\begin{pmatrix} 1 & \beta \\ \beta & \alpha^2 \end{pmatrix}; \alpha^2 - \beta^2 > 0 \text{ and matrix } M \text{ will be constructed as}$$

$$\begin{pmatrix} 2\mu_1 & 0 \\ 0 & 2\mu_2 \end{pmatrix}; \mu_1 > 0; \mu_2 > 0; \text{ thus, both } Q \text{ and } M \text{ are posi-}$$

tive definite. A convenient choice is $\beta = 0$; consequently, if the inequality

$$\begin{aligned} \dot{V}/2 = & -\psi x_1^2 - \alpha^2 x_2^2 - \mu_1 \xi_1^2 - \mu_2 \xi_2^2 + \\ & \psi x_1 \xi_1 + R x_1 - R \xi_1 + \alpha^2 \xi_2 < 0 \end{aligned} \quad [21]$$

$$x_1 \neq 0; x_2 \neq 0$$

is satisfied within a certain region R of electrolyte temperature and concentration, then any perturbation originating within this region will allow the system to regain asymptotically its 0 steady state. At small times past the onset of a perturbation, x_1 , x_2 , their time derivatives and R are reasonably close to zero, thus if μ_1 and μ_2 are sufficiently large positive scalars, Eq. [21] will be satisfied. At large times, ξ_1 and ξ_2 will be reasonably close to zero, hence

$$\lim_{t \rightarrow \infty} \dot{V}/2 = -\psi x_1^2 + R x_1 - \alpha^2 x_2^2 \quad [22]$$

which represents the autonomous case, *i.e.*, when $\xi = 0$. It follows that the stability of CSTER exposed to decaying perturbations of the form given by Eq. [17] is essentially determined by its stability conditions related to sudden changes in its state variables (*i.e.*, electrolyte temperature and concentration). The analysis is therefore, reduced to the one previously discussed (12). In the case of potentiostatic electrolysis, the foregoing analysis has a straightforward extension, provided that variations in the electric current are not strong enough to generate secondary (parasitic) reactions. If, for instance, current is the only forcing function, Eq. [15] and [16] may be modified to

$$\frac{dx_1}{d\theta} = -\psi x_1 + \Gamma_1(\theta); \Gamma_1(\theta) \equiv R(\theta) - S(\theta) \quad [23]$$

$$\frac{dx_2}{d\theta} = -x_2 + \Gamma_2(\theta); \Gamma_2(\theta) \equiv -Q(\theta) \quad [24]$$

and if an exponential decay-envelope condition

$$\left| \Gamma_i(\theta) \right| \leq \beta_i e^{-\gamma_i \theta}; i = 1, 2 \quad [25]$$

may again be assigned in the manner of Eq. [17], similar results are obtained. Note that the minimum numerical value of α is determined by the autonomous subsystem, and so long as $\alpha \geq \alpha_{\min}$, its magnitude is immaterial.

Liapunov analysis of persistent perturbations.—In this section, the theorem of Malkin (2), described in the Appendix, is employed to study CSTER stability in the case of persistent perturbations in electric current. The state variable equations are rewritten as

$$\frac{dx_1}{d\theta} = -\psi x_1 + R(\theta) - S(\theta) + \xi_1(\theta) \quad [26]$$

$$\frac{dx_2}{d\theta} = -x_2 - Q(\theta) + \xi_2(\theta) \quad [27]$$

The Malkin formalism requires rearrangement in the vector form

$$\begin{pmatrix} \frac{dx_1}{d\theta} \\ \frac{dx_2}{d\theta} \end{pmatrix} = \begin{pmatrix} -\psi x_1 \\ -x_2 \end{pmatrix} + \begin{pmatrix} R(\theta) - S(\theta) + \xi_1(\theta) \\ -Q(\theta) + \xi_2(\theta) \end{pmatrix}$$

or its equivalent

$$\frac{dx}{d\theta} = X(x, \theta) + Y(x, \theta) \quad [28]$$

In fact, X is not dependent implicitly on time and

$$V(x) = x' Q x \quad [29]$$

$$= x_1^2 + \alpha^2 x_2^2 \quad (\beta = 0) \quad [30]$$

is one of its Liapunov functions. Proceeding now to the perturbed system, if m_1 and m_2 are the largest magnitudes of x_1 and x_2 , respectively, due to a persistent perturbation, then by inspection.

$$W(x) = 0 \quad [31]$$

$$W_1(x) = m_1^2 + \alpha^2 m_2^2 \quad [32]$$

and since, $\dot{V}(x) = -2\psi x_1^2 - 2\alpha^2 x_2^2$, an obvious choice is

$$W_2(x) = \psi x_1^2 + \alpha^2 x_2^2 \quad [33]$$

To find the bound M on the partial spatial derivatives of $V(x)$, we obtain from Eq. [30] $\partial V/\partial x_1 = 2x_1$ and $\partial V/\partial x_2 = 2\alpha^2 x_2$; hence an obvious bound is

$$M = \sqrt{2(m_1^2 + \alpha^2 m_2^2)} \quad [34]$$

Let $\Omega(A)$ denote the region of stability of subsystem $X(x)$, defined by the $\|x\| < A$ inequality; a suitable numerical value of A is obtained from the $\dot{V}(x) < 0$ condition, differentiating Eq. [30]. If the magnitude of the persistent perturbation is bounded, so will be R , S , Q , and ξ , hence there exists a non-negative scalar μ_2 such that

$$\|Y(x, \theta)\| = \sqrt{(R - \xi + \xi_1)^2 + (-Q + \xi_2)^2} \leq \eta_2 \quad [35]$$

If, for instance, the persistent perturbation is a sinusoidal current wave, and ξ has the form of Eq. [17], η_2 may be chosen as the magnitude of Y at zero time and $\epsilon = \sqrt{m_1^2 + m_2^2}$. Since at large times the response x will be confined in a stricter sense, i.e., $\lim_{t \rightarrow \infty} |x_1| \leq a_1$ and $\lim_{t \rightarrow \infty} |x_2| \leq a_2$ such that $a_1 < m_1$ and $a_2 < m_2$, that stability region

$$\lim_{t \rightarrow \infty} \epsilon = \sqrt{a_1^2 + a_2^2}$$

may replace for practical purposes the rigorous but cautious result of Malkin's theorem, when the transient effects have vanished. Finally, the $\|x(0)\| < \eta_1$ condition is clearly satisfied for any $\eta_1 > 0$ if the system is initially at rest. Hence a CSTER obeying the conditions stated in this section is stable in the Malkin sense; its electrolyte temperature and concentration will fluctuate within finite limits so long as persistent perturbations in the CSTER are bounded. It follows immediately that if the perturbations are oscillatory, then so will be the electrolyte temperature and concentrations, with magnitudes eventually bounded by bounds related to the numerical values of a_1 and a_2 .

Application: Stability Analysis of a Metal Recovery Process

For the sake of numerical illustration and comparison with simulated transient response a CSTER, where copper is deposited from an aqueous cupric sulfate solution on a metal cathode and oxygen is generated at an inert anode, is considered. The following data apply: $d_1 = 7$ mm; $V_t = 0.3881$ m³; $k_1 = 0.313$ W/m²·K; $h_1 = 4.61$ W/m²·K, $i = 2, \dots, 5$; $h_6 = 18$ W/m²·K; $k = 1.47$ m⁻¹; $s = 0.68$ m; $A_E = 0.4624$ m²; $d_E = 0.002$ m; $m_e = 425.5$ kg; $C_p = 4186$ J/kg·K; $\Delta H_r = 221.6$ kJ/mol Cu; $C_o^* = 850$ mol/m³; $G = 0.3$ g/s; $I^* = 41.6$ A (18% of the limiting current); $T_o^* = 25^\circ\text{C}$; $T_A = 20^\circ\text{C}$; and $T_F = 20^\circ\text{C}$. The dependence of electrolyte density and conductivity on concentration and temperature is represented by statistical regressions based on literature data (13)

$$\rho = 1014.3 + 0.1484c - 0.5T \text{ kg/m}^3 \quad [36]$$

$$\sigma = 6.5676 \times 10^{-3} C^{0.706} T^{0.55} \text{ S/m} \quad [37]$$

$$c: \text{ mol/m}^3; T: ^\circ\text{C}$$

valid for the $98.9 < c < 1322$ and $20 < T < 70$ range. Under these circumstances, $c^* = 62.06$ and $T^* = 69$ represent the steady state. It is assumed that Eq. [36] and [37] hold for temperatures and concentrations encountered under the stated conditions, although they may be somewhat outside the validity range of the regression.

Case I: galvanostatic electrolysis, perturbation occurring in the electrolyte inlet concentration and temperature.—Assuming that the effect of temperature and

concentration on m_e , C_p , and ΔH_r is negligible, Eq. [11]–[14] yield $S = 0$, $Q = 0$, $\psi = 32.657$, and

$$R(\theta) = \frac{81.0292}{\sigma} - 65.1842 \quad [38]$$

As shown previously (12), the expression in Eq. [22] is less than zero for $\alpha > 3.4$, and if the magnitude of perturbations $\|\xi\|$ does not exceed the region R defined by the validity domain of Eq. [36] and [37], asymptotic stability is

Fig. 1. Simulated variation of the transient electrolyte temperature with time in the copper-recovery process.

Fig. 2. Simulated variation of the transient electrolyte concentration with time in the copper-recovery process (as in Fig. 1).

guaranteed by the choice of sufficiently large values of μ_1 and μ_2 in Eq. [21]. Typical transients for this case are shown in Fig. 1 and 2 where the numerical form of Eq. [18] and [19]

$$\frac{dx_1}{d\theta} = -32.657x_1 + R(\theta) + \xi_1^0 \epsilon^{-5\theta} \quad [39]$$

$$\frac{dx_2}{d\theta} = -x_2 + \xi_2^0 \epsilon^{-10\theta} \quad [40]$$

was solved via digital computer; the numerical values $\lambda_1 = 5$ and $\lambda_2 = 10$ were arbitrarily chosen. Note that Eq. [40] has the analytical solution

$$x_2 = \frac{\xi_2^0}{\lambda_2 - 1} \left[\epsilon^{-\theta} - \epsilon^{-\lambda_2 \theta} \right] \quad [41]$$

but Eq. [39], being a nonlinear equation coupled with Eq. [38], has to be solved by a numerical technique. The course of curves can be explained by qualitative reasoning: consider, *e.g.*, the instance where ξ_1^0 and ξ_2^0 are both positive, meaning a positive perturbation in T_0 and C_0 , resulting in an increase in σ , and a decrease in R . Since electrolysis is galvanostatic, the increase in σ means a decrease in the rate of Joule heat generation, which leads to a drop in the electrolyte temperature. As time progresses, the decrease in T leads to a decrease in σ , and hence R and the rate of Joule heat generation begins to increase. The net result is that $dx_1/d\theta$ will be less and less negative and $dx_2/d\theta$ less and less positive. They both become zero at a crossover point ($\theta \approx 0.3$ in the simulated example). Past the crossover point, continuing increases in the rate of Joule heat generation and electrolyte conductivity result in a monotonic increase in T and a monotonic de-

crease in c until they reach the previous steady state, at sufficiently large times. A similar (although inverse) argument applies to the $\xi_1^0 < 0$, $\xi_2^0 < 0$ set.

Case II. electrolysis with a sinusoidal perturbation in electric current and decaying perturbation in electrolyte inlet concentration and temperature.—As before, $\psi = 32.657$ but Eq. [11]–[14] yield

$$R(\theta) = 0.046829 \frac{I^2}{\sigma} - 65.1974 \quad [42]$$

$$S(\theta) = 0.03658 I - 1.5216 \quad [43]$$

$$Q(\theta) = 0.009029 I - 0.3756 \quad [44]$$

The electric current is assumed to have the functional form

$$I = 41.6 + 3.4 \sin 51.06\theta \text{ amp} \quad [45]$$

with an oscillation angular frequency of $\omega = 1 \text{ h}^{-1}$. The numerical form of Eq. [18] and [19]

$$\frac{dx_1}{d\theta} = -32.657 x_1 + R(\theta) - S(\theta) + \xi_1^0 \epsilon^{-5\theta} \quad [46]$$

$$\frac{dx_2}{d\theta} = -x_2 - Q(\theta) + \xi_2^0 \epsilon^{-10\theta} \quad [47]$$

can be solved via a digital computer if ξ_1^0 and ξ_2^0 are specified; a typical solution is shown in Fig. 3, illustrating bounded oscillations predicted by Liapunov analysis via Malkin's theorem. In this instance ($\xi_1^0 = 1.0$; $\xi_2^0 = 0.1176$), the variation domains are $0.2 \leq x_1 \leq 0.24$ and $-0.0036 \leq x_2 \leq 0.0023$, corresponding to variation domains $64 \leq T \leq 75$ and $59 \leq C \leq 64$. Since the variation of R between -13.8 and $+17.26$ is much larger than the varia-

$$R(\theta) = 0.046829 \left(\frac{I^2}{\sigma}\right) - 65.1974. S(\theta) = 0.03658I - 1.5216. Q(\theta) = 0.009029I - 0.3756. I = 41.6 + 3.4 \sin 51.06 \theta, \text{ amp.}$$

Table II. The effect of the current perturbation amplitude on the stability parameters

A (amp)	η_2	α_1	α_2	m_1	m_2	M_{\min}	ϵ
1.8	12.13	0.160	0.00065	0.254	0.00911	0.36	0.254
2.5	14.34	0.225	0.00918	0.318	0.00916	0.45	0.318
3.4	18.14	0.300	0.00120	0.400	0.00920	0.57	0.400

$\xi_1^\circ = 1.0. \xi_2^\circ = 0.1176. R(\theta), S(\theta),$ and $Q(\theta)$: as in Table I. $I = 41.6 + A \sin 51.06 \theta, \text{ amp.}$

tion of Q (-0.03; -0.104) or S (-0.14; 0.124), Eq. [35] may be simplified to $\|Y(x, \theta)\| \approx \sqrt{(R + \xi_1)^2 + \xi_2^2} \leq \eta_2$. Similar arguments may be made for all initial perturbation conditions $\xi(0)$; pertinent Malkin parameters for selected cases (including the computer-simulated case) are shown in Table I. The effect of the current perturbation amplitude on the stability parameters is indicated in Table II; it is interesting to note that the $\eta_2(\epsilon)$ relationship is essentially linear in this particular case

$$\eta_2 = 1.83 + 40.68 \epsilon \quad [48]$$

Thus, if the amplitude of the current oscillation is known, the norm of the oscillatory temperature/concentration response can be quickly estimated without an experimental determination or a computer simulation of their variation with time. This is an important property of the Liapunov-function-based approach to stability.

The foregoing analysis, although powerful within its scope, suffers from one restriction: the dependence of pertinent physical parameters on electrolyte concentration and temperature has to be known in the form a quantitative relationship (e. g., Eq. [36] and [37]). This restriction applies equally to the simulation of the CSTER model, and, for that matter, to any attempt of quantitative performance analysis. In the absence of reliable physical and chemical data for a given electrolyte, the power of the stability study described in this paper is limited. When such data are available, its usefulness for electrolytic process control is rather obvious; much more work will, however, be required to explore its full potential.

APPENDIX

Malkin's Stability Theorem for Systems Under Persistent Perturbations

In this section, Malkin's theorem for the stability of a system described by its governing equation (Eq. [28]) is summarized; for a proof, consult Ref. (2). Here, $Y(x, \theta)$ represents persistent perturbations and $X(x, \theta)$ the dynamic system subjected to such perturbations. It is assumed that if there are no perturbations, the nonautonomous system

$$\frac{dx}{d\theta} = X(x, \theta); X(0, t) = 0 \quad [A-1]$$

(all $t \geq 0$)

has a Liapunov function $V(x, t)$ in a region $\Omega(A)$ where A is a suitably chosen bound on $\|x\|$; i.e., $\|x\| < A$. For t

≥ 0 , the subsystem [A-1] is asymptotically stable within this region. Let there exist three positive definite functions such that for $t \geq 0$

$$W(x) \leq V(x, t) \leq W_1(x) \quad [A-2]$$

$$\dot{V}(x, t) \leq -W_2(x) \quad [A-3]$$

within Ω . Furthermore, let all partial spatial derivatives of $V(x, t)$ be bounded, i.e., there exists a positive scalar M such that for $t \geq 0$, the condition

$$\left| \frac{\partial V}{\partial x_i} \right| \leq M; i = 1, 2, \dots, n \quad [A-4]$$

is satisfied within Ω . Then, given a positive scalar ϵ such that $0 < \epsilon < A$, the system given by Eq. [28] is stable in the following sense

$$\|x(0)\| < \eta_1(\epsilon); \eta_1 > 0 \quad [A-5]$$

$$\|x(t)\| < \epsilon; t > 0 \quad [A-6]$$

provided that $\|Y(x, t)\| < \eta_2(\epsilon), \eta_2 > 0$; for all $\|x\| < \epsilon$ and $t \geq 0$, i.e., the perturbations are bounded. Thus, the system will not leave a certain domain of its state variables, although it may never reach a constant steady state. Equations [A-5] and [A-6] are the mathematical expression of Malkin stability.

LIST OF SYMBOLS

A_1	area of the electrolytic tank bottom
A_i	$i = 2, \dots, 5$ the four sidewall areas of the electrolytic tank
A_6	area of the electrolyte surface
c	electrolyte concentration. c^* : its steady-state value.
c_0	inlet electrolyte concentration. c_0^* : its steady-state value.
C_p	specific heat capacity of the electrolyte
d_b	thickness of the electrolytic tank bottom
F	Faraday's constant
G	inlet mass flow rate of electrolyte
h_6	heat transfer coefficient related to the electrolyte surface (including evaporation)
I	electric current
k	geometric shape factor (for resistance calculations)
k_t	thermal conductivity of the electrolytic tank
m_e	mass of electrolytic in electrolytic tank
q	inlet volumetric flow rate of electrolyte
R_e	electric resistance of electrolyte in the electrolytic tank
T	electrolyte temperature. T^* : its steady-state value.
T_0	inlet electrolyte temperature. T_0^* : its steady-state value.
T_a	ambient temperature
T_f	temperature of the electrolyte tank floor
t	time
U_i	$i = 2, \dots, 5$ overall surface-to-ambient heat-transfer coefficient related to the four sidewalls of the electrolytic tank
V_r	effective volume of the electrolytic reactor
z	number of electrons participating in the electrode reaction of interest
ΔH_R	heat of reaction of electrode reaction of interest
ρ	density of electrolyte
σ	electric conductivity of electrolyte

Mass Transfer in Parallel Plate Electrolyzers with Two-Phase Liquid-Liquid Flow

Po-Yen Lu^{*,1} and Richard C. Alkire*

Department of Chemical Engineering, University of Illinois, Urbana, Illinois 61801

ABSTRACT

The enhancement of mass transfer to a solid surface by addition of a dispersed immiscible second liquid phase was investigated with use of the electrochemical limiting current method. The electrolyzer consisted of a divided parallel plate cell in which electrolyte flowed upward past vertical electrodes. Three electrolytes were used: aqueous ferricyanide, aqueous ferricyanide containing inert dispersed droplets of toluene, and aqueous iodide containing dispersed toluene droplets in which was dissolved the reactant, iodine. Experiments were carried out under controlled variation of flow rate, droplet size, organic volume fraction, and electrode material. Experiments were performed both with and without use of a turbulence promoter. It was found that the overall mass-transfer rate could be separated into three elements: (i) the single-phase mass-transfer rate, (ii) the enhancement of mass transfer owing to the physical action of dispersed liquid droplets, and (iii) the still further enhancement of mass transfer owing to the presence of reactants dissolved in the dispersed droplets. For sparingly soluble reactants, it was found that the mass-transfer enhancement achieved by extraction of reactants from a dispersed second liquid phase could be orders of magnitude larger than the other two mass-transfer mechanisms.

The attainment of high mass-transfer rates is important for many electrochemical processes, but is difficult to achieve when the reacting species are sparingly soluble. Under such conditions, two approaches are generally used. The first approach emphasizes increasing the solubility of reactant species, for example, by adjustment of pH, by using a cosolvent, by using a solvent other than water, or by using surfactant salts which solubilize micelles of reactant molecules. The second approach emphasizes increasing the mass-transfer coefficient by using high flow rates, turbulence promoters, or porous electrodes. While each of these procedures exhibit certain advantages, the search for still superior methods continues.

In this investigation, the enhancement of mass transfer to an electrode surface by addition of a dispersed second liquid phase was studied. The use of two liquid phases in an electrolytic operating scheme has the attractive feature that mass-transfer rates can be significantly improved while also maintaining high ionic conductivity and low pressure drop across the cell.

The advantages associated with using an emulsion as an electrochemical feedstock were recognized in the 1903 patent of Kempf (1) who oxidized benzene in sulfuric acid to produce quinone and hydroquinone. More recent electroorganic synthesis examples include those reported by Dey (2), Udupa (3), Fremery (4), Millington (5), and Seco (6), among others. Additional applications may be found in the field of flow batteries and hydrometallurgy. While these processes depend critically upon two-phase operation for their success, there are relatively few papers which investigate the fundamental principles which are involved.

The events which occur in such systems are complex and include, for example, modification of the flow field

near the electrode surface by the dispersed droplets, and perhaps also wetting the electrode surface by the dispersed phase. Such events exert a profound influence on mass-transfer processes near the electrode surface, particularly when reactants are sparingly soluble in the continuous phase but highly soluble in the dispersed phase.

While the mass-transfer literature in the field of liquid-liquid systems is voluminous (7), most of these nonelectrochemical studies do not include all of the salient features needed for application of the results to electrochemical applications. In particular, electrochemical processes require that reactants be supplied from the two-phase mixture to an adjacent solid surface where electrochemical reaction occurs and, in addition, that electrical current be able to flow through the solution by an ionic path to the reactive region on the electrode surface. The following paragraphs summarize recent studies on several aspects of the overall electrochemical problem.

The effect of inert dispersed particles on mass transfer to a solid electrode has been investigated recently for several systems. These systems include mass transfer of dissolved oxygen to the wall of a corroding pipeline through which a slurry of sand flows (8), and mass-transfer enhancement at a rotating disk electrode by action of impinging solid particles dispersed in the solution (9). These studies illustrate that significant mass-transfer enhancement occurs owing to the presence of a second (solid) phase dispersed in the electrolyte.

The effect of dispersed liquid droplets upon mass transfer at a solid electrode surface was studied by Dworak *et al.* (14-16). The studies were conducted on a horizontal electrode facing upward, operated under turbulent flow conditions. It was found that the addition of hexane (density: 0.6 g/cm³) had no effect on the rate of mass transfer of ferricyanide to the electrode, but that the addition of carbon tetrachloride (density: 1.6 g/cm³) enhanced mass-transfer rates by up to 30%. These studies differ from the present investigation in which laminar flow conditions were studied at vertical electrodes past which fluid flowed in an upward direction.

Dworek *et al.* also reported that the use of highly turbulent emulsion flow prevented contact between the emulsified phase and the electrode. In related studies, Kinoshita *et al.* (17) indicated that the interfacial contact area between electrode and droplets of the dispersed phase is an important parameter which influences the magnitude of mass-transfer enhancement which is observed. These observations indicate that partial wetting of the surface by the dispersed phase may be critically important for enhancing mass-transfer rates.

While the effect of turbulence promoters on mass transfer has been studied in one-phase electrolytic systems (18-20), no previous mass-transfer measurements are known to exist for the use of turbulence promoters in two-phase systems.

The influence of rising gas bubbles at vertical electrodes has been widely studied (10), as has been the influence of electrolytic gas evolution, which creates intense local stirring (11). The combined effect on mass transfer of rising bubbles plus bubble evolution, as observed in chlorate electrolysis, was found to be a linear addition of two mass-transfer coefficients (12, 13). This concept will be used in the present study, and appears in the form of Eq. [1] below.

The foregoing survey indicated that there have been relatively few measurements of mass-transfer rates in electrochemical systems having liquid-liquid electrolyte. The purpose of this investigation was to characterize experimentally the different phenomena which control the overall mass-transfer process, and to establish the dependence of the different phenomena upon operating conditions (21).

The hypothesis for the present study, which was verified by the results presented below, was that the overall mass-transfer limiting current is a linear sum of three effects: (i) the mass transfer caused by the flow of the continuous phase, (ii) the mass-transfer enhancement caused by physical disruption of the mass-transfer boundary layer near the electrode surface owing to the presence of dispersed droplets, and (iii) the still further mass-transfer enhancement which arises from extraction of reactive species from the dispersed droplets, which may be in intimate contact with the electrode and thus serve as a source of reactant deep within the mass-transfer boundary layer. The three elements of the overall process are characterized below by three coefficients (k_i) according to the equation

$$i_L = nFk_1c_1 + nFk_2c_1 + nFk_3c_2 \quad [1]$$

The first term (nFk_1c_1) is the one-phase convective flow term where the mass-transfer coefficient k_1 is that which is commonly reported for single-phase flow, and the concentration c_1 is the concentration of reactant in the continuous phase. The second term (nFk_2c_1) represents the mass-transfer enhancement by the disturbance mechanism. The third term (nFk_3c_2) represents the mass-transfer enhancement which is brought about by the extraction mechanism, where the concentration c_2 is the concentration of reactant in the discontinuous phase from which extraction occurs. Measurements of k_1 , k_2 , and k_3 are reported in this paper for a parallel plate electrochemical cell through which flows electrolyte containing two solvent phases.

Apparatus

Electrochemical cell.—Figure 1 shows a diagram of the cell assembly in which the path of electrolyte flow in both electrode compartments is indicated. The cell was positioned vertically so that fluid entered at the bottom, flowed upward past the electrodes, and exited at the top. The cell was machined from two blocks of polypropylene which were clamped together with a silicon O-ring seal. Electrical contact to electrodes was made with titanium screws pressed into the back side of the electrodes. The cross section of the flow channel in the working electrode compartment was 0.2×3.0 cm.

Fig. 1. Cross-sectional view of electrochemical cell, not drawn to proportion. Arrows indicate fluid flow path in the two-compartment cell. Components include: (1) reference electrodes; (2) planor working electrode; (3) porous counterelectrode, and (4) separator.

Two types of working electrode materials were investigated: graphite (Poco) and ruthenized titanium (DSA, Diamond Shamrock). The area of the working electrode which was exposed to the electrolyte was 3×27 cm. The surface roughness of the graphite electrode was $< 1 \mu\text{m}$, and of the DSA was $< 4 \mu\text{m}$. The surface roughness was less than 10% of the thickness of the mass-transfer boundary layer, and may, therefore, be regarded as "smooth." Two reference electrodes were positioned in the cell, at the entrance and exit region as illustrated in Fig. 1. The reference electrodes were of the same composition as the working electrode and had an exposed area of 3×10 cm in contact with the electrolyte. The counterelectrode was made of porous ruthenized titanium (Gould Incorporated, and Diamond Shamrock), through which electrolyte flowed as indicated in Fig. 1. The counterelectrode had the same exposed area as the working electrode.

A separator of microporous polypropylene (Daramic, W. R. Grace & Company) was used for most of the experiments reported below for which turbulence promoters were not placed in the working electrode compartment. The separator had support ribs in the direction of flow so that the working electrode compartment was thereby segmented into four channels, each of which measured 0.2×0.75 cm. For a small number of experiments, a turbulence promoter (Vexar 549V300BD, E.I. du Pont de Nemours and Company) was used in which case a membrane (Nafion, N-415, E.I. du Pont de Nemours and Company) was used to prevent cross-flow between the two compartments.

Flow system.—A diagram of the flow system is shown in Fig. 2 and includes five flowmeters denoted FA through FE (Gilmont 4, Ti float), five valves denoted VA through VE (glass/Teflon stopcocks), a glass reservoir (4 liters), and two pumps (March, TE-MDX-MT3). In the res-

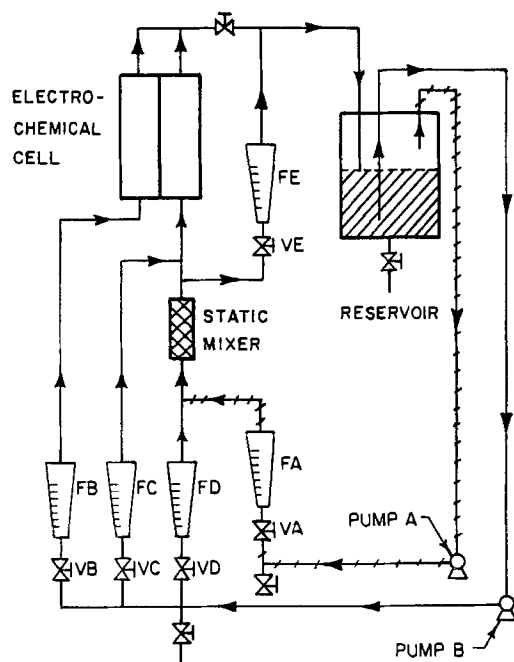

Fig. 2. Flow system used for preparation and recirculation of two-phase liquid-liquid mixtures.

ervoir, the two-phase mixture separated cleanly into aqueous and nonaqueous layers. All tubing was 3/8 in. id polypropylene except for the section between the static mixer and the cell inlet, which was 1/4 in. id; the same id as the static mixer.

An in-line static mixer was used to generate droplets of the organic phase dispersed in the continuous aqueous phase (Kenics, 1/4"-40-174-0), with 20 Ti elements in 1/4 in. glass housing). The correlation between mean droplet size and the Weber number was available from the manufacturer (22).

Valves VA and VD were used to control the two-phase volume fraction and droplet size produced in the static mixer. Valve VE was used to bypass some of the fluid around the cell so that the combination of small droplets and slow flow past the electrode could be investigated. Similarly, valve VC was used to add aqueous phase to the flow exiting from the static mixer so that the combination of large droplets and fast flow past the electrode could be studied. Valve VB was used to control the flow through the counterelectrode compartment.

Electrical system.—The measurement of electrical current at various applied potentials between working and reference electrode was made with a potentiostatic power supply (built in-house) driven by a function generator (PAR 175) and displayed on an X-Y recorder (Houston, 2000).

Procedures

Solutions were prepared by mixing analytical grade reagents, and deionized distilled water. The solution for measurement of the single-phase mass-transfer coefficient k_1 was 0.01M potassium ferricyanide, 0.01M potassium ferrocyanide, and 0.2M sodium sulfate in water. The solution for measurement of the disturbance mechanism coefficient, k_2 , was the same ferric/ferrous cyanide solution except that toluene was added. The solution for measurement of the extraction mechanism coefficient, k_3 , was 0.01M potassium iodide and 0.2M sodium sulfate in water equilibrated with a toluene solution containing 0.165N iodine. The concentrations of ferricyanide and of iodine were determined by titration (23).

The interfacial tension between aqueous and organic phases was measured with the duNouy method which used a tensiometer (Fisher, Model 20). The density was measured by weighing a known volume of solution, and the viscosity was determined with an Ostwald viscome-

ter. The diffusion coefficients of electroactive species were measured by using a rotating disk electrode.

Current-voltage traces were obtained under steady flow conditions with use of a scan rate of 5 mV/s. Additional details may be found in the original thesis (21).

Results and Discussion

The experimental strategy for obtaining mass-transfer coefficients k_1 , k_2 , and k_3 (see Eq. [1]) was as follows: (i) The one-phase convection mass-transfer coefficient, k_1 , was found from measurement of the mass-transfer limiting current in a one-phase aqueous solution containing ferricyanide. (ii) The effect of an inert second phase (disturbance mechanism) was found by dispersing toluene in the solution of ferricyanide. The inert toluene droplets served to disturb flow near the electrode surface and, thus, to enhance the mass transfer of ferricyanide to the electrode surface. The limiting current was thus attributed to the one-phase rate (nFk_1c_1) plus the physical disturbance owing to the inert dispersed droplets (nFk_2c_1). By subtracting nFk_1c_1 found previously from the measured limiting current, the enhancement owing to disturbance alone was thus obtained. (iii) The effect of a reactive second phase (extraction mechanism) was investigated with use of water/toluene dispersions containing the iodine/iodide redox couple. The iodine reactant is highly soluble in the dispersed organic phase. The reactive droplets serve both to disturb and also to replenish the mass-transfer boundary layer near the electrode surface. The limiting current was thus attributed to the one-phase rate (nFk_1c_1) plus the disturbance attributed to the dispersed droplets (nFk_2c_1) and the replenishment of iodine reactant by extraction from the droplets (nFk_3c_2). By subtracting nFk_1c_1 and nFk_2c_1 (found previously) from the measured limiting current, the enhancement owing to the extraction mechanism was obtained. Since the partition constant of iodine between the toluene and the aqueous phases was approximately 100 to 1, the mass-transfer resistance of iodine in the organic phase could be ignored (24, 25).

The physical properties of the solutions used in this study are summarized in Table I. The Reynolds numbers reported below were calculated on the basis of the hydraulic diameter of the working electrode compartment which, for the channels measuring 0.2×0.75 cm, was 0.315 cm.

It was found that repeated experiments were reproducible to within 1% for one-phase flow, and to within 10% for two-phase flow. The interested reader may refer to the original thesis for additional details (21).

One-phase results.—For fully developed laminar flow between two parallel plates, the average limiting current density over an electrode may be found by integration of Eq. [105-9] in Ref. (26).

$$i_L = 1.4675 \frac{nFDc_1}{s} \left(\frac{\nu}{hDL} \right)^{1/3} \quad [2]$$

Table I. Physical properties

Aqueous ferricyanide solution:			
Density		1.06 g/cm ³	
Viscosity		0.94 cP	
Diffusion coefficient of ferricyanide ion		6.5 × 10 ⁻⁶ cm ² /s	
Aqueous iodide solution:			
Density		1.06 g/cm ³	
Viscosity		0.94 cP	
Diffusion coefficient of iodine (or triiodide)		8.0 × 10 ⁻⁶ cm ² /s	
Iodine-toluene solution equilibrated with aqueous iodide solution:			
Iodine conc in toluene phase	Interfacial tension (dyn/cm)	Density (g/cm ³)	Viscosity (cP)
0.1N	30.67 ± 0.42	0.868	0.546
0.2N	30.73 ± 0.46	0.877	0.550
0.4N	29.37 ± 0.32	0.897	0.554
0.6N	29.00 ± 0.50	0.918	0.571

In this study, the Reynolds number based on hydraulic diameter was used to compare mass-transfer results. Over the range $130 < Re < 1000$, experimental data agreed with Eq. [2] to within 3%. Above $Re = 1000$, experimental data lie slightly above Eq. [2], probably owing to hydrodynamic entrance effects. For example, at $Re = 1250$ (the maximum value used in this study), the limiting current was observed to be 20% greater than expected by Eq. [2]. Limiting current data were obtained with both graphite and DSA, and showed no dependence upon electrode material.

Two-phase results.—In this section, results are given for the disturbance mechanism (k_2), the extraction mechanism (k_3), and for the effect of turbulence promoters.

Because toluene is lighter than water, droplets tend to rise as they are carried upward by flow through the cell. In this study, the maximum slip velocity of droplets, computed from Stokes' law, was 1 cm/s; most experiments were carried out under conditions where the slip velocity was significantly less than 1 cm/s. In addition, the average flow rate (for both phases combined) varied from about 30 cm/s down to about 1 cm/s. Thus, the effect of gravitational forces on the data reported below should be negligible. The conditions where gravitational forces are most likely to influence data are for slow flow of solutions containing large droplets and large volume fractions of the organic phase; such operating conditions, however, lead to poor mass-transfer enhancement and would not, therefore, be likely to be of practical interest.

Disturbance mechanism.—Based on Eq. [1] in the absence of the extraction mechanism ($k_3 = 0$), simple rearrangement gives

$$i_L - nFk_1c_1 = nFk_2c_1 \quad [3]$$

The data shown in Fig. 3(a) represent the quantity nFk_2c_1 (that is, measured limiting current density minus nFk_1c_1) for various conditions of reactant concentration, flow rate, droplet size, volume fraction, and electrode material. All data illustrate a linear relationship between nFk_2c_1 and reactant concentration; therefore, it was concluded that the disturbance mechanism is an additive effect as expressed in Eq. [1]. In the act of "subtracting nFk_1c_1 ," the experimental data reported above were used rather than the theoretical results expressed by Eq. [2]. The following paragraphs summarize the effect of important variables on the disturbance coefficient k_2 .

Volume fraction influences mass transfer as indicated in Fig. 4(a) for graphite electrodes and Fig. 4(b) for DSA electrodes. For both types of materials, the enhancement of mass transfer was greatest at a volume fraction of about 40% organic. Above about 80% organic, the mass-transfer is less than would be found in the absence of the organic phase. The loss of reactivity at high volume fraction may either be owing to coverage of the electrode by the nonconducting organic phase, or to coalescence by large droplets which are less effective in enhancing mass transfer.

Droplet size influences the mass-transfer rate as illustrated in Fig. 5(a) for graphite and Fig. 5(b) for DSA electrodes. For the size range studied, it was found that smaller droplets and higher organic volume fractions gave slightly better mass-transfer enhancement. The difference between behavior of graphite and of DSA was found to be small. Because the mass-transfer enhancement by smaller droplets was not dramatic, and because the energy required to generate droplets increases as the 3.5 power of the diameter, it may not be worthwhile to employ extremely small droplets. This study did not, however, include consideration of surfactants which would stabilize suspensions of very small droplets.

Velocity increases the mass-transfer rate. Figure 6(a) illustrates the velocity dependence of that portion of the overall rate attributable to the disturbance mechanism. That is, the ordinate of every point was obtained by subtracting the corresponding value of nFk_1c_1 from the measured value. The slopes of the lines shown in Fig. 6(a) vary between 0.7 and 1.0, and are thus appreciably greater than the velocity dependence of k_1 , the one-phase coefficient (0.33) indicated by Eq. [2]. That is, the relative significance of the disturbance mechanism increases with flow velocity.

Electrode material has a generally small influence on the disturbance mechanism as may be seen by comparing Fig. 4(a) with Fig. 4(b), and Fig. 5(a) with Fig. 5(b). These results suggest that there was no significant difference between electrodes in coverage of electrode surface by the organic phase, and that the enhancement owing to the disturbance mechanism was controlled primarily by flow conditions.

Extraction mechanism.—Rearrangement of Eq. [1] gives

$$i_L - nFk_1c_1 - nFk_2c_1 = nFk_3c_2 \quad [4]$$

Fig. 3. Demonstration of the validity of the linear additive model, Eq. [1]. (a, left) data are for disturbance mechanism, (b, right) data are for extraction mechanism.

Fig. 4. Effect of electrode material and volume fraction on mass-transfer rate in two-phase flow. (a, left) data are for graphite electrodes, $c_1 = 0.0076N$ (b, right) data are for DSA electrodes, $c_1 = 0.0095N$.

The data shown in Fig. 3(b) represent the quantity nFk_3c_2 (that is, measured limiting current density minus nFk_1c_1 and minus nFk_3c_1) for various conditions of reactant concentration, flow rate, droplet size, volume fraction, and electrode material. It should be noted that the quantity nFk_3c_2 is as large as, or larger than, the limiting current for the one-phase base case. All data illustrate a linear relationship between nFk_3c_2 and reactant concentration in the dispersed phase. Therefore, it was concluded that the extraction mechanism is an additive effect as expressed in Eq. [1]. The following paragraphs summarize the effect of important variables on the extraction coefficient k_3 .

Volume fraction influences the extraction mechanism as indicated in Fig. 7(a) and Fig. 7(b) for graphite and DSA electrodes, respectively. The data in Fig. 7 illustrate only the effect of the extraction mechanism (nFk_3c_2) in that the effects of one-phase transfer and of the disturbance mechanism have been subtracted off as indicated by Eq. [4]. A significant difference is seen between the behavior of the two electrode materials. Also, in contrast to data shown in Fig. 4, the extraction mechanism does not exhibit a volume fraction at which the effect passes through a maximum. It is therefore suggested that, for high volume fractions, the surface becomes wetted with

Fig. 5. Effect of dispersed droplet size on mass-transfer rate in two-phase flow. (a, left) data are for graphite electrodes, $c_1 = 0.0076N$; (b, right) data are for DSA electrodes, $c_1 = 0.0095N$.

Fig. 6. Effect of velocity on mass-transfer enhancement in two-phase flow. (a, left) data are for disturbance mechanism, (b, right) data are for extraction mechanism.

the organic phase and that, although a portion of the surface may thus be shielded by nonconducting liquid, the shielding is more than compensated by the highly concentrated reactants which are thereby brought into intimate contact with the remaining reactive portion of the electrode surface.

Droplet size influences mass transfer by the extraction mechanism as shown in Fig. 8(a) and Fig. 8(b) for graphite and DSA electrodes, respectively. It may be seen that the enhancement was much more pronounced on the graphite electrode than on the DSA electrode even though the reactant concentration used for the DSA electrodes was about twice that used for the graphite electrodes. On

graphite, the enhancement was larger for the smaller droplets.

Based on Fig. 8, it is suggested that the graphite electrode is partially wetted by the dispersed phase. Small droplets probably hit the electrode and adhere as small puddles, while larger droplets adhere as larger puddles. For the same coverage of electrode by the organic phase, small puddles provide a larger total perimeter for supplying the reactant to the electrode surface, and thus serve to enhance the mass-transfer rate by the greater amount.

By comparison of Fig. 8(a) with Fig. 8(b), it is seen that the DSA electrode exhibited negligible mass-transfer en-

Fig. 7. Effect of electrode material and volume fraction on mass-transfer enhancement by the extraction mechanism. (a, left) data are for graphite electrodes, $c_2 = 0.165N$; (b, right) data are for DSA electrodes, $c_2 = 0.32N$.

Fig. 8. Effect of electrode material and droplet size on mass-transfer enhancement by the extraction mechanism. (a, left) data are for graphite electrodes, $c_2 = 0.165N$; (b, right) data are for DSA electrodes, $c_2 = 0.32N$.

enhancement by the extraction mechanism. It is therefore suggested that the DSA material is not wet by the reactive dispersed droplets.

Velocity effect for the extraction mechanism alone is shown in Fig. 6(b) for both graphite and DSA electrodes. For the graphite electrode, the enhancement by extraction depends upon flow rate to the power of between 0.6 and 1.0, while, for DSA electrodes, the enhancement is independent of flow rate. The difference lies in the ability of the two electrode materials to utilize the reactive droplets which are brought to the surface region by the fluid flow conditions.

Electrode materials clearly exhibit a profound influence upon the extraction mechanism, in contrast to a minor influence upon the disturbance mechanism. It is suggested that the affinity between the surface and the dispersed phase controls the extraction mechanism. The DSA electrode is an oxide surface which is quite polar in comparison with graphite; by the same token, water is a strong polar molecule in comparison with toluene. Therefore, the nonpolar organic droplets are more likely to wet the nonpolar graphite electrode surface than the polar DSA surface. The absence of significant mass-transfer enhancement observed by Dworak *et al.* (14-16) may be in part owing to their use of Ni electrodes.

Turbulence promoter.—When a turbulence promoting grid is placed into a flow channel, then the definition of Reynolds number becomes ambiguous since it is no longer clear which characteristic dimension should be used to correlate results. Therefore, for evaluation of turbulence promoters, mass-transfer rates were compared on the basis of the volumetric flow rate through the cell instead of the Reynolds number. For one-phase flow, Fig. 9 provides experimental mass-transfer data and, for comparison, also shows the prediction of Eq. [2] for the expected mass-transfer rate without the turbulence promoter. It may be seen that an enhancement of up to sevenfold in mass-transfer rate was achieved by use of the turbulence promoter. Such enhancement, however, was achieved at the expense of substantially increased pumping power.

For two-phase flow containing an inert dispersed phase and a turbulence promoter, the mass-transfer rates

shown by the dashed lines in Fig. 10 were found. By comparison of these data with Fig. 9, it was found that the addition of the inert second phase degraded mass-transfer performance in cells containing turbulence promoters. It is suggested that the plastic turbulence promoter was easily wet by the dispersed phase, and thus facilitated coverage of the electrode surface by the nonconducting inert organic phase. In addition, the mass-transfer rate in the presence of the turbulence promoter was not influenced by the droplet size of the inlet fluid; evidently, the turbulence promoter acted as a static mixer and produced its own two-phase flow conditions regardless of variation in droplet size in the feed stream.

For two-phase flow containing a reactive dispersed phase, the data connected by solid lines in Fig. 10 illustrate results on graphite electrodes for several conditions of flow rate, droplet size, and volume fraction. It may be seen that the enhancement by presence of the second

Fig. 9. Effect of turbulence promoter on mass-transfer rate in one-phase system, graphite electrodes, $c_1 = 0.00154N$ ferricyanide.

Fig. 10. Effect of turbulence on mass-transfer rate in two-phase system, with variation of volume fraction, flow rate, and droplet size. Graphite electrodes with Vexar 549V300 turbulence promoter. (Dashed line) data are for an inert dispersed phase, $c_1 = 0.00154N$ (solid line) data are for a reactive dispersed phase, $c_1 = 0.00102N$ and $c_2 = 0.08N$.

phase occurs but achieves a maximum at 10% volume fraction or less. The enhancement improves with flow rate but is insensitive to droplet size in the feed stream. Above a volume fraction of 10%, there is a decay in mass-transfer performance, owing probably to electrode coverage by organic phase.

Examples.—It should be emphasized that the concentration of reactive species used in the solutions investigated in this study was kept low in order to simplify measurement of mass-transfer limited behavior. As a consequence, the current densities reported in the figures are much lower than would be required of industrial processes. However, the use of higher reactant concentrations, particularly in the dispersed organic phase, would increase current density significantly. For example, consider Fig. 7(a) in which a current density of 2.5 mA/cm² is obtained from dispersed droplets containing reactant at 0.165*N*. If, instead, an organic reactant dissolved at 10*M* would be used in the dispersed phase, then mass-transfer limiting current density would increase to on the order of 150 mA/cm².

For typical operating conditions ($Re = 1000$, $V_t = 10\%$, $d = 500 \mu m$, graphite electrode), if the value of k_1 is unity (a reference value), then Fig. 4(a) suggests that k_2 is also about unity, and Fig. 8(a) indicates that k_3 is about 0.1. Thus, the relative importance of the individual mechanisms can be ascertained if these mass-transfer coefficients are multiplied by the corresponding concentrations as shown for several cases in Table II. It may be seen that the extraction mechanism dominates the other two mechanisms when the solubility of the reactant in the continuous phase is less than 10% of the solubility in the dispersed phase. For low solubility of reactant in the continuous phase (Case 1), the extraction mechanism serves to increase the mass-transfer rate by a factor of 1000 over that obtained with one-phase flow. If the solubility of the reactant in the aqueous solution is greater than that in the dispersed phase (Case 5), then the presence of the second phase serves to approximately double the mass-transfer rate, but at the expense of increased process complexity.

The relative importance of the individual mass-transfer mechanisms can be used in the design of two-phase sys-

Table II. The relative importance of the mass-transfer enhancement mechanisms with respect to the reactant concentrations in both the continuous and the dispersed phase solutions ($k_1 = 1$, $k_2 = 1$, $k_3 = 0.1$)

Case	c_1 (mol/ liter)	c_2 (mol/ liter)	$k_1 c_1$ One-phase convective flow mechanism	$k_2 c_1$ Disturbance mechanism	$k_3 c_2$ Extraction mechanism
1	0.001	10	0.001	0.001	1
2	0.01	10	0.01	0.01	1
3	0.1	10	0.1	0.1	1
4	1.0	10	1.0	1.0	1
5	10.0	10	10.0	10.0	1

tems. For example, if the largest term in Eq. [1] is $nFk_1 c_1$, then there is no advantage in introducing the dispersed phase into the cell; increasing the reactant solubility in the aqueous solution, or mass-transfer coefficient k_1 , would be the best procedure. If the largest term in Eq. [1] is $nFk_2 c_1$, then any inexpensive and stable inert dispersed phase could be introduced into the cell in order to enhance mass transfer. But if the largest term in Eq. [1] is $nFk_3 c_2$, then the reactant should be introduced in the dispersed phase.

Conclusions

Mass transfer in parallel plate electrolyzers with two-phase liquid-liquid flow was investigated by the electrochemical limiting current method. The overall mass-transfer rate was found to follow a linear additive model, expressed in Eq. [1], for which contributions to the overall rate included the one-phase convective flow (k_1), the disturbance by presence of the second phase (k_2), and the replenishment of reactant by extraction from the second phase (k_3). The experimental approach enabled the overall mass-transfer rate to be separated into the individual mechanisms. The important variables for coefficients k_2 and k_3 included dispersed phase volume fraction, droplet size, flow velocity, electrode material, and the presence of a turbulence promoter.

The significant results of this investigation are summarized as follows: (i) mass-transfer enhancement by the disturbance mechanism k_2 is insensitive to electrode material, while enhancement by the extraction mechanism k_3 is higher on nonpolar (graphite) than on polar (DSA) electrode surfaces. (ii) An increase in organic phase volume fraction leads to mass-transfer enhancement by both disturbance and extraction mechanisms, over a volume fraction range of about 0-80%. (iii) The effect of flow rate is to increase all mass-transfer coefficients; the velocity dependence of the coefficients is 0.33 for k_1 , 0.7-1.0 for k_2 for both types of electrode materials, and 0.6-1.0 for k_3 on graphite. With DSA electrodes, there was no discernible improvement in k_3 upon increasing flow velocity. (iv) Over the range of droplet sizes studied, the coefficients k_2 and k_3 varied by less than a factor of two, and were greatest for high volume fractions, for small droplets, and on graphite. (v) Mass-transfer enhancement by the disturbance mechanism k_2 was small in comparison with that achieved by a turbulence promoter in one-phase flow. Mass-transfer enhancement by the extraction mechanism k_3 can be significantly greater than that achieved with a turbulence promoter in one-phase flow.

In this study, emphasis has centered on mass-transfer enhancement. Other reasons for introducing a dispersed immiscible second phase may also exist for electrochemical applications. For example, extraction of a desired reaction product into a second phase may help protect it from undergoing further degradation reactions to unwanted by-products. Also, a second phase may be useful for continuous extraction of unwanted reaction products from a cell during operation, for example, polymeric surface tars. For these reasons, the continued investigation of electrolysis in the presence of two-phase liquid systems appears to be warranted.

A macroscopic approach was used in the present study in order to separate the overall mass-transfer sequence

into several component steps. Further study will require improved understanding of microscopic features such as interaction of dispersed droplets with the mass-transfer boundary layer, as well as mass transfer during droplet impingement and wetting of the electrode surface. The consideration of surfactants would add a major new variable to those included in this study. Surfactants would be expected to play an influential role both in two-phase flow and wetting phenomena, and also in the electrochemistry of the surface reactions.

The experimental results reported in this study represent only a small number of possible combinations of important variables. In particular, only one mixture of solvents was studied, and only one reactor configuration was used. Additional experimental studies in different systems would contribute toward better understanding of enhancement coefficients k_2 and k_3 in order that they may be related to system parameters with use of generalized dimensionless correlations.

LIST OF SYMBOLS

c_1	reactant concentration in the aqueous phase solution, mol/cm ³
c_2	reactant concentration in the organic phase solution, mol/cm ³
d	dispersed droplet size, μm
D	diffusion coefficient, cm ² /s
F	Faraday's constant, 97,487 C/equiv
h	gap of the flow channel, cm
i_L	average limiting current density over the electrode length L , A/cm ²
k_1	mass-transfer coefficient due to the one-phase convective flow, cm/s
k_2	mass-transfer coefficient due to the disturbance mechanism, cm/s
k_3	mass-transfer coefficient due to the extraction mechanism, cm/s

L	length of electrode, cm
n	Faraday's per mol of substance electrolyzed
Re	Reynolds number based on hydraulic diameter
S	electrode material
s	stoichiometric coefficient of species in electrode reaction
v	fluid velocity, cm/s
v_1	organic dispersed phase volume fraction

Zinc Selenide Photoelectrodes

Efficient Radiative Recombination in a Stable Photoelectrochemical Cell

Patricia M. Smiley, Richard N. Biagioni, and Arthur B. Ellis*

Department of Chemistry, University of Wisconsin-Madison, Madison, Wisconsin 53706

ABSTRACT

Photoluminescence (PL) and electroluminescence (EL) from single-crystal, n-type, Al-doped ZnSe (ZnSe:Al) electrodes have been studied. These samples exhibit both edge emission ($\lambda_{\text{max}} \sim 460$ nm) and subbandgap emission when excited at several ultrabandgap wavelengths. The latter PL band is particularly intense, with a measured radiative quantum yield of $\sim 10^{-1}$ to 10^{-2} ; the transition appears to be at least partially self-activated (SA) in origin, based on previously reported PL data. Excited-state communication involving the two emissive states is inferred from time-resolved PL measurements. Stable photoelectrochemical cells (PEC's) can be constructed from n-ZnSe:Al electrodes and aqueous diselenide or ditelluride electrolytes. Applied potential quenches both of the photoanodes' PL bands roughly in parallel. The extent of PL quenching is consistent with a dead-layer model previously used to describe quenching in Au-ZnSe Schottky diodes. When used as a dark cathode in aqueous, alkaline peroxydisulfate electrolyte, EL from ZnSe:Al electrodes is observed. PL and EL spectral distributions are similar and indicate that the same emissive excited states are populated in the two experiments. Measured EL efficiencies, $\sim 10^{-4}$ to 10^{-6} at -2.2 and -1.8 V vs. SCE, respectively, are much smaller than PL efficiencies. Possible sources of the discrepancies are discussed.

Keen interest in photoelectrochemical cells (PEC's) has focused attention on the excited-state properties of the semiconductor electrodes which serve as the key element of these devices (1). We and others have studied photoluminescence (PL) and electroluminescence (EL) from a variety of II-VI and III-V semiconductor electrodes in an effort to determine the effect of PEC parameters on the solids' excited-state deactivation routes (2). In general, measured radiative quantum yields, ϕ_r , of these materials have been small, $\sim 10^{-3}$ - 10^{-5} . We describe in this paper an electrode, n-ZnSe:Al, whose emission competes favorably ($\phi_r \sim 10^{-1}$ - 10^{-2}) with other deactivation paths in stable, efficient PEC's. As observed with other semiconductor electrodes (3), the PL of n-ZnSe:Al electrodes can be perturbed and EL initiated by interfacial charge-transfer processes. We show that PL quenching by applied potential is compatible with a dead-layer model used to describe such quenching in other PEC's (4, 5) and in Au-ZnSe Schottky diodes (6).

Experimental

Materials.—Single crystal (111) plates of n-type ZnSe:Al (~ 2 ppm Al based on arc emission spectroscopy) were generously provided by North American Philips Corporation, Briarcliff Manor, New York; the samples ($\sim 5 \times 5 \times 0.25$ mm) had been cut from boules which were obtained from Eagle-Picher Industries, Miami, Oklahoma, and had been subsequently heat-treated in molten Zn at 950°C for 24h to lower their resistivity to ~ 1 - 10 Ω -cm. Twinned areas may be present below the surface in some of the samples employed. Sample carrier concentrations of $\sim 10^{17}$ - 10^{18} cm^{-3} were estimated from both dc Hall measurements (7) and Mott-Schottky data. In the former measurement, a Varian Associates Model V-2301-A dc electromagnet producing a field of ~ 0.5 kG was employed. Capacitance measurements of the ZnSe:Al electrodes were made at 1.0 and 0.8 kHz in 1M OH^- and diselenide electrolytes, respectively, using an Ithaco Dynatrac 391 lock-in voltmeter, EG&G PAR Models 173 potentiostat and 175 programmer, and a Wavetek Model 182A 4MHz function generator. Electrodes were prepared by etching the solids for 20s with 1:40 Br_2/MeOH (v/v), making ohmic contact to the Se-rich crystal face by soldering with In, and then mounting the solid as an electrode as described previously (8). Resistivity in some samples was deliberately enhanced by heat-treatment with Se (Alfa; m3N purity). For these experiments, an ~ 10 mg sample of ZnSe:Al was placed in a quartz tube with ~ 0.2 mg of Se. The quartz ampul was evacuated (~ 0.1 torr), sealed to a volume of ~ 3 cm^3 , and heated at 700°C in a Lindberg furnace for ~ 30 s.

After its removal from the ampul, the solid was etched until bright PL was observed; then it was mounted as an electrode. Sulfide, diselenide, and ditelluride electrolytes were prepared as described previously (9, 10), except that after the solid Na_2Se was washed with NaOH, it was dissolved in conc KOH to yield solutions whose compositions were ~ 10 M KOH/0.25M Se^{2-} . During PEC experiments, the electrolytes were vigorously stirred and blanketed with N_2 . Preparation of peroxydisulfate electrolyte has been described (11). MgO powder was obtained from Baker Chemical Company.

PL properties.—Front-surface PL spectra at ambient temperature and at 77 K were obtained with the Aminco-Bowman spectrophotofluorometer described previously (3). The high pressure Xe lamp of the instrument was used in conjunction with an interference filter (Edmund Scientific) for 405 nm excitation; a Corning 3-72 filter was used to prevent this light from reaching the detection optics. All PL and EL spectra were corrected for detector sensitivity from 350 nm to 800 nm using a procedure previously described (3). The correction factors were incorporated into a computer program for use with an Apple II Plus Computer. Spectra were digitized, corrected by the program, and plotted on an Epson printer.

Measurements of ϕ_r were made by placing the ZnSe:Al samples and MgO powder (reference) in turn in a quartz cuvette positioned in the Aminco-Bowman spectrometer's sample compartment as previously described (3, 12). The sample was irradiated "head on" with the spectrometer's high pressure Xe lamp; interference filters (FWHM is ~ 10 nm, except for 366 nm, where it is ~ 30 nm) were used to isolate the desired excitation wavelengths. Both the reflected and emitted intensities were corrected for relative detector response.

The dependence of ϕ_r on incident intensity was probed using the near-UV lines of a Coherent Radiation CR-12 Ar⁺ laser (351 and 364 nm doublet). Samples were mounted with epoxy on a glass rod and positioned at $\sim 45^\circ$ to both the laser beam and the emission detection optics. PL spectra were run as a function of incident intensity which was varied with Melles Griot neutral density filters; the EG&G radiometer was used to measure incident intensity in conjunction with a glass slide serving as a beam splitter.

Time-resolved PL data were obtained in air with a pulsed N_2 laser (337 nm) and N_2 -pumped dye laser (460 nm) using instrumentation and techniques previously reported (13). Peak intensities of ~ 3 and 30 kW/cm^2 were used in these experiments with essentially no difference in the resulting decay curves.

PEC experiments.—A flat-faced quartz cell equipped with a side arm was employed for most PEC measure-

ments. Long-term stability experiments in diselenide and ditelluride electrolytes were conducted as described previously with an n-ZnSe:Al working electrode and a Pt foil counterelectrode (8). A polyethylene bag was attached to the top of the cell and purged with N₂ during the experiments.

Photoaction spectra were obtained as previously described (14) using transparent selenide electrolyte. The output of a 150W Xe lamp (Oriel) was monochromatized for excitation; lamp intensity was measured with the EG&G radiometer whose response from 350-800 nm was corrected with the manufacturer's calibration factors. Photocurrents were measured at -1.0V vs. SCE.

A standard three-electrode potentiostatic setup was used for obtaining *i*LV data. Excitation at 366, 405, and 436 nm (200W, high pressure Osram Hg lamp with interference filters) was used; lenses and masks were used to fill the exposed electrode area with light. Electrochemical measurements were made with an EG&G PAR Model 174 potentiostat; *i*-V curves were recorded on a Houston Model 2000 X-Y recorder. Steady-state PL intensity in operating PEC's was influenced by production of colored Se₂²⁻ and Te₂²⁻ species. A pulse technique was employed to minimize this problem during the generation of *i*LV curves. The technique consisted of pulsing the electrode between open circuit and increasingly positive potentials. Typically, the electrode sat at open circuit for 500 ms, then was pulsed for 57 ms to a potential which increased by 5 mV with each cycle. The *i*-V curves obtained in this manner were identical to steady-state *i*-V curves. PL was detected with the EG&G radiometer covered by a 600 nm interference filter. Output signals were displayed on a Tektronix Model RM503 oscilloscope equipped with a camera; sweep rates which resulted in potential steps of ~10 mV/s permitted an entire PL intensity-V curve to be photographed with one exposure of ~2 min. Incident light intensity was measured by inserting a mirror (~80% reflectivity) and reflecting the light into the EG&G radiometer. The weakness of the edge PL required use of the near-UV lines of the Ar⁺ laser and the Aminco-Bowman spectrometer for generation of *i*LV curves in which both PL bands could be monitored.

EL properties.—EL spectra were obtained in 5M NaOH/0.1M K₂S₂O₈ electrolyte by pulsing the electrode between 0.0V (8s) and a potential cathodic of ~ -1.7V vs. SCE (1s), while slowly scanning the monochromator of the emission spectrometer (12 nm/min), as described previously (11). At potentials where they could be obtained, steady-state EL spectra were essentially identical to those generated by the pulse technique.

Instantaneous EL efficiencies were determined as described previously (3). The total emitted energy per pulse measured with an EG&G Model 550-3 pulse integration module was converted to 600 nm photons using the manufacturer's correction factor at that wavelength.

Results and Discussion

Single crystal samples of cubic n-ZnSe doped with Al (~2 ppm) and having carrier concentrations of ~10¹⁷–10¹⁸ cm⁻³ were employed in these studies. Sections below describe the PL properties of these solids, their perturbation by PEC parameters, and EL from the solids.

PL spectra.—Near-UV excitation of n-ZnSe:Al crystals produces effulgent, orange emission. The 295 K PL spectrum of the material (Fig. 1) is dominated by a broad band (FWHM ~115 nm) with λ_{max} ~ 600 nm; a weaker, sharper band (FWHM ~10 nm) peaking at ~460 nm is also present. The latter transition, whose intensity is reported to be very sensitive to preparative conditions (15), occurs near the bandgap energy [E_g ~ 2.7 eV (16)]. Although the band's origin in our samples is unknown, its designation as edge emission appears apt based on its energetic proximity to E_g and its temperature dependence: Fig. 1 indicates that the band blue shifts by ~0.09 eV to 445 nm upon cooling to 77 K, consistent with the temperature co-

Fig. 1. Corrected, front-surface PL spectra of n-ZnSe:Al at 295 K (dashed line) and 77 K (solid line). Both spectra were taken at the same sensitivity (a 100-fold increase in sensitivity was used in scanning the 410-480 nm region). The sample was excited with identical intensities of 405-nm light without disturbing the experimental geometry.

efficient of -4.1×10^{-4} eV/K reported for exciton emission from cathodoluminescence studies (16b).

An intense orange band at ~630 nm has been reported for many ZnSe samples and assigned as self-activated (SA) PL; the transition is believed to involve a deep trapping level arising from a complex based on a Zn vacancy, V_{Zn}, and a next-neighbor donor impurity such as Al_{Zn} (Al on a Zn site) (17). Our spectra are somewhat more complex, but accord well with spectra reported by Bouley *et al.* (15). Figure 1 reveals that the band at 600 nm seen at 295 K splits into two bands with λ_{max} ~ 630 and 550 nm at 77 K. The former, likely the SA band, has been assigned to complexes involving a neutral (V_{Zn}Al_{Zn}) or ionized defect [(V_{Zn}Al_{Zn})⁻], while the latter was ascribed to a defect involving Al and an alkali metal impurity (15). For convenience, we will refer to the 600 nm transition as a SA band, although we emphasize that its origin is not fully established in our samples.

PL efficiency.—As previously noted, samples of n-ZnSe:Al are highly emissive. We have employed a technique to obtain φ_r values which, using a common geometry, compares light reflected from a nonabsorbing material with light reflected and emitted from a sample (12). Table I presents a compilation of measured φ_r values obtained in air for the SA emission using several different excitation wavelengths. The tabulated values, uncorrected for self-absorption and internal reflectivity, are substantial, ranging from ~2-5%. Large radiative efficiencies are also supported by the modest doubling of φ_r observed when samples are cooled to 77 K. Similar efficiencies and thermal behavior were reported for the ZnSe:Al samples studied by Bouley *et al.* (15). The decline in φ_r with excitation wavelength (Table I) suggests the presence of a nonemissive near-surface region: reported absorptivities increase substantially below 460 nm (18), so that a nonemissive layer is expected to reduce φ_r as it absorbs larger fractions of incident light.

PL decay times.—Time-resolved PL properties were studied in air using the 337 and 460 nm outputs of a N₂ laser and N₂-pumped dye laser, respectively. Measurements of the edge PL band were limited by the duration of the laser pulse, indicating a decay time of ≤7 ns. A similar limitation was observed for the risetime of the SA band and its initial decay. After the peak intensity of the band had dropped ~30%, however, a much longer nonexponential decay was observed with typical τ_{1/e} values being ~1 μs. These properties were independent of the excitation wavelengths employed and of the PL wavelength monitored.

^a PL properties related to use of n-ZnSe:Al electrodes in PEC's. Most of the properties are derived from iLV curves generated with a three-electrode potentiostatic setup (n-ZnSe:Al working electrode, Pt foil counterelectrode, and SCE reference electrode). To optimize transparency, experiments with 366 nm light were conducted in 10M KOH/0.25M Se²⁻/0.001M Se₂²⁻ electrolyte; for 405 and 436 nm light, an electrolyte of 8M KOH/0.2M Te²⁻/0.002M Te₂²⁻ was employed. The electrode, having an exposed surface area of ~0.25 cm², was excited with ~0.5-2.0 mW of power.

^b The n-ZnSe:Al sample was used either "as received" or treated with Se as described in the Experimental section and text.

^c Excitation wavelength. A 150W high pressure Xe lamp or 200W high pressure Hg lamp equipped with interference filters was employed for ϕ_r data and iLV curves, respectively.

^d Radiative quantum efficiencies obtained in air for the SA band. Values are uncorrected for self-absorption and internal reflectivity.

^e Measured photocurrent quantum efficiency at -1.0V vs. SCE. Values are uncorrected for solution absorption and reflective losses.

^f Fractional PL quenching between -1.0V vs. SCE and the flatband potential, approximated here as the open-circuit potential. PL intensity was monitored at 600 nm.

^g Measured photocurrent quantum efficiency at the potential corresponding to maximum optical-to-electrical energy conversion efficiency.

^h Output voltage at the maximum energy conversion point. The diselenide and ditelluride redox potentials were -0.95 and -1.10V vs. SCE, respectively.

ⁱ (Maximum electrical power out divided by input optical power) \times 100.

Mechanistically, the different temporal behavior of the edge and SA bands is an important result in that it indicates that the corresponding excited states are not thermally equilibrated (19). Initiation of the SA emission is also addressed by the data. Although the rapid risetime for the SA band could reflect population via the excited state responsible for edge emission, our data are also consistent with population from a yet higher energy state when ultrabandgap wavelengths are employed; in the latter case, the strong lattice coupling characteristic of deep traps provides a relaxation mechanism for rapid population of the SA state in parallel with population of the state leading to edge emission. Excited-state communication by either of the schemes outlined is also supported by steady-state measurements using the near-UV lines of an Ar⁺ laser; over an incident intensity range of $\sim 10^{-2}$ - 10^1 mW/cm², the intensities of the edge and SA PL bands maintain a constant ratio.

PEC properties.—Although n-ZnSe has been used as an electrode in PEC's (18, 20), the material has not, to our knowledge, been stabilized to the extent that it can be used for efficient conversion of optical energy to electricity; decomposition according to Eq. [1] has previously been observed in several electrolytes (20a, 20b, 20f). The ability to stabilize n-CdX (X = S, Se, Te) electrodes with polychalcogenide

electrolytes suggested their use with n-ZnSe electrodes (9). In an initial experiment with sulfide electrolyte (1M OH⁻/1M S²⁻), decomposition still obtained: photocurrent

fell rapidly, and pitting of the surface occurred. However, PEC's constructed from n-ZnSe:Al, a Pt counterelectrode, and (di)selenide or (di)telluride electrolyte were stable. Table II demonstrates that little electrode weight loss accompanies long-term experiments in these electrolytes. Other evidence of stability includes relatively constant photocurrents and lack of surface damage in the prolonged experiments, as well as observation of competitive electrolyte oxidation (9).

We obtained photoaction spectra of our samples near short circuit in a transparent selenide electrolyte. Figure 2 reveals that, as expected, photocurrent rises sharply at ~460 nm, roughly the bandgap energy. The enhanced efficiency of e⁻-h⁺ pair separation with decreasing wavelength is consistent with the reported trend in absorptivities (18) and with the decline in electric field strength with distance from the interface (21).

Current-voltage curves, shown in Fig. 3, reveal that photocurrent in diselenide electrolyte onsets at ~-2.0V vs. SCE at moderate light intensities of ~10 mW/cm², yielding an open-circuit voltage of ~1.0V. The photocurrent quantum efficiency, ϕ_x , is relatively low for these PEC's. Table I shows that even the least deeply penetrating wavelength, 366 nm, yields a short-circuit ϕ_x value of only ~0.4. We attribute the low ϕ_x values to narrow depletion widths, W , and short hole diffusion lengths, L_p , in these materials: W is calculated to be ~300-1000Å at short circuit in our materials,¹ and L_p has been reported to be only ~10²Å for comparably doped ZnSe materials (20e). We estimate from PL data (*vide in-*

¹ A static dielectric constant of 8.7 was used in calculating W (20d).

^a All experiments were run under N₂ in stirred solutions in a two-electrode PEC (working electrode and Pt foil counterelectrode) in diselenide or ditelluride electrolyte.

^b Electrolyte compositions are given in Table I. The initially colorless solutions became dark brown and deep purple as Se_n²⁻ and Te_n²⁻ were formed, respectively, during the course of the experiments. Final Se_n²⁻ and Te_n²⁻ concentrations were ~0.002 and 0.004M, respectively.

^c Mols of crystal determined by weight before and after photoelectrochemistry. Crystals used in experiments 1, 2, and 3 chipped while being demounted and were not fully recovered. Surface areas were 0.08, 0.18, 0.09, and 0.12 cm² for the solids of expt. 1-4, respectively.

^d Mols of electrons in the external circuit determined by integrating photocurrent-time plots.

^e Average photocurrent passed during experiment; for current densities, divide by the electrode areas given in c above.

^f Excitation wavelength provided by a 200W high pressure Hg lamp equipped with interference filters.

Fig. 2. Photoaction spectrum for a n-ZnSe:Al-based PEC in optically transparent selenide electrolyte; the electrode was held at $-1.0V$ vs. SCE. The plotted values of relative photocurrent have been corrected for variation in light intensity as a function of wavelength. Although the optical pathlength was minimized, the spectrum is not corrected for electrolyte absorption.

fra) that the 366 nm absorptivity of ZnSe is $\sim 6.8 \times 10^4 \text{ cm}^{-1}$, so that a significant fraction of e^-h^+ pairs would be created beyond the depth where holes can be collected by diffusion into the drift region. Despite the modest ϕ_x values, Table I demonstrates that n-ZnSe:Al-based PEC's can still yield substantial efficiencies for the conversion of monochromatic light to electricity, values of $\sim 5\text{-}7\%$ for 366 nm excitation being typical. In the protracted experiments of Table II, energy conver-

Fig. 3. Photocurrent (bottom frame) and PL intensity (top frame) monitored at $\lambda_{\text{max}} \sim 600 \text{ nm}$ vs. potential for a n-ZnSe:Al electrode excited at 366 nm in $10M \text{ KOH}/0.25M \text{ Se}_2^-/0.001M \text{ Se}_2^{2-}$ electrolyte. The incident light irradiated the $\sim 0.2 \text{ cm}^2$ exposed area of the electrode with $\sim 0.60 \text{ mW}$ of power. The iLV curves were generated using a pulse technique described in the Experimental section. The electrolyte redox potential was $-0.95V$ vs. SCE.

sion efficiencies of up to $\sim 3\text{-}4\%$ (366 nm experiments) were sustained for several days.

Of particular interest to us are changes in PL properties which accompany the use of the semiconductor as an electrode. Figure 4 demonstrates that in passing from open circuit to short circuit, the two PL bands are quenched roughly in parallel by the applied electric field. The spectral distribution is invariant over the potential range of Fig. 3, permitting changes in PL intensity to be monitored at a single wavelength. Simultaneous measurements of current, PL intensity, and potential (iLV) data are illustrated in Fig. 3 and summarized in Table I. The table reveals that PL quenching obtains with all of the excitation wavelengths employed.

Quenching of semiconductor PL by applied potential is a well-documented phenomenon in both semiconductor/metal- (6, 22) and PEC-based (2, 3) Schottky-barrier systems. A dead-layer model which quantifies PL quenching in the solid-state systems has recently been found applicable to PEC's based on n-CdSe and n-GaAs (4, 5). In its simplest form, the model states that e^-h^+ pairs formed within some fraction of the depletion width are swept apart by the field and do not contribute to PL. The mathematical form of the model is given by Eq. [2]

$$\frac{\phi_r}{\phi_{\text{rFB}}} = \exp(-\alpha'D) \quad [2]$$

where D is the dead-layer thickness; ϕ_r and ϕ_{rFB} are the radiative quantum efficiencies at an in-circuit potential and at flatband potential (approximated here as the open-circuit potential); and $\alpha' = \alpha + \beta$ with α and β the solid's absorptivities for the exciting and emitted light, respectively.

The dead-layer model was recently shown to be applicable to PL from a Au-ZnSe Schottky diode; PL intensity-voltage curves obtained with 442 nm light could roughly be fit by assuming that D has a functional dependence like that of W [D proportional to $(V - V_{\text{rFB}})^{1/2}$] (6). For the n-ZnSe:Al-based PEC's, PL quenching curves like that shown in Fig. 3 can be similarly fit, although discrepancies occur near open circuit. Such discrepancies, also noted for n-GaAs-based PEC's, may indicate that potential applied in this regime is partitioned between the semiconductor and the Helmholtz layer (4).

Another quantitative test of the dead-layer model, independence of D on optical penetration depth, is presently precluded by a lack of reliable absorptivities for n-ZnSe:Al. However, qualitative accord is indicated by the enhanced PL quenching at short circuit with de-

Fig. 4. Corrected PL spectra of a n-ZnSe:Al electrode excited with the near-UV lines (351, 364 nm) of an Ar^+ laser in the diselenide electrolyte of Fig. 3. Curves A and B were taken at -2.0 (open circuit) and $-1.0V$ vs. SCE, respectively. Both spectra were taken in an identical sample geometry.

creasing wavelength and penetration depth, Table I. If the dead-layer model is assumed applicable to these PEC's, it yields, using $\alpha \sim 3 \times 10^4 \text{ cm}^{-1}$ for 436 nm light (6), absorptivities of $\sim 4 \times 10^4$ and $6 \times 10^4 \text{ cm}^{-1}$ at 405 and 366 nm, respectively.

The effect of carrier concentration on PL quenching was also qualitatively consistent with the dead-layer model. As was found in the solid-state study (6), more resistive samples, prepared by heating ZnSe:Al in an evacuated ampul with Se, exhibited greater PL quenching, as shown in Table I. The wider electric fields of these samples were also manifest in larger ϕ_r values. Taken as a unit, we believe our data provide good evidence for describing PL quenching in n-ZnSe:Al-based PEC's in terms of a dead-layer model.

A final point of interest concerns the parallel quenching of the two PL bands illustrated in Fig. 4. Although we are unable to definitively establish the mechanism for populating the SA state (*vide supra*), the parallel quenching is consistent with separation of e^-h^+ pairs prior to population of this state.

EL properties.—We have found that n-ZnSe:Al electrodes mimic other II-VI electrodes (3) in exhibiting EL when used as a cathode in aqueous, alkaline, peroxydisulfate electrolyte. EL from n-ZnSe under anodic polarization has also been reported (23). The key step involved in populating the emissive excited state has been proposed to be hole injection by $\text{SO}_4^{\cdot -}$ radical anions formed by reduction of $\text{S}_2\text{O}_8^{2-}$ (24). As in previous studies, we have obtained EL spectra using a pulse technique: while the emission monochromator is swept, the electrode is pulsed repetitively between a potential where no current is observed (0.0V for 8s) and a potential sufficiently cathodic to initiate EL (1s pulse). We find that EL is initiated to the dark-adapted eye at $\sim -1.7\text{V vs. SCE}$, roughly the onset of dark cathodic current in the electrolyte of $5\text{M OH}^-/0.1\text{M S}_2\text{O}_8^{2-}$.

Figure 5 presents the EL spectrum of an n-ZnSe:Al electrode. Both the edge and SA emission bands are evident, and a comparison with Fig. 1 indicates that the relative intensities of the bands are similar in the two spectra. The overall spectral similarity indicates that the same two emissive excited states are populated in both experiments.

Besides spectral distributions, we have also measured lower limit integrated EL efficiencies, $\bar{\phi}_{\text{EL}}$, using techniques and approximations previously described (3). For n-ZnSe:Al electrodes, we obtain $\bar{\phi}_{\text{EL}}$ values of $\sim 10^{-6}$ and 10^{-4} at -1.8 and -2.2V vs. SCE , respectively. These num-

Fig. 5. Corrected EL spectrum of a n-ZnSe:Al electrode obtained in $5\text{M OH}^-/0.1\text{M S}_2\text{O}_8^{2-}$ electrolyte. The electrode was continuously pulsed between 0.0 (8s) and -2.0V vs. SCE (1s), while the emission spectrometer was swept at 12 nm/min . A 100-fold increase in sensitivity was used in scanning the 400-480 nm spectral region.

bers are of interest because $\bar{\phi}_{\text{EL}}$ (photons emitted per holes injected) can be factored into an efficiency for excited-state population, ϕ_{ES} (excited states populated per holes injected) and the PL radiative efficiency, ϕ_r (photons emitted per excited states populated). Samples of n-CdS_xSe_{1-x} ($0 \leq X \leq 1$) exhibit $\bar{\phi}_{\text{EL}}$ and ϕ_r values which are nearly equal, suggesting ϕ_{ES} is near unity for these samples. In contrast, our $\bar{\phi}_{\text{EL}}$ values for n-ZnSe:Al are lower than the measured ϕ_r of $\sim 10^{-1}\text{--}10^{-2}$ by a factor of $10^{-2}\text{--}10^{-4}$. The discrepancy in the two efficiencies may be due to a low value of ϕ_{ES} but more likely reflects the different spatial regions involved in the two modes of excited-state population. In particular, EL is expected to originate, on average, from nearer the semiconductor surface than PL, owing to its initiation by interfacial charge transfer. A lower ϕ_r value for the (near-)surface region due to nonradiative surface recombination could then account for the observed low EL efficiencies. Such a nonemissive near-surface region has already been suggested to account for the variation of PL efficiency with excitation wavelength. Reduction of the electrode surface during the EL experiment (3) may also contribute to the discrepancy.

Interdiffusion in Cryolite Melts

I. LiF-AlF₃

E. W. Dewing*

Alcan International, Limited, Kingston Laboratories, Kingston, Ontario, K7L 4Z4, Canada

ABSTRACT

The modifications to equations based on Fick's laws necessary when density changes are caused by electrolysis are considered. The quantity found experimentally is D/α , where D is the diffusion coefficient and α is $\partial \ln c / \partial \ln N$, N being the equivalent fraction, and c the concentration. For melts with $N_{\text{AlF}_3} = 0.136$, chronopotentiometric experiments gave $D/(\text{m}^2 \text{s}^{-1}) = \exp\{[-3980 \pm 221]/T - [15.904 \pm 0.184]\}$, with a standard deviation of $\pm 3.9\%$ in the range $1128 < T < 1273$ K. For melts with $N_{\text{AlF}_3} = 0.25$, $D/(\text{m}^2 \text{s}^{-1}) = \exp\{[-5532 \pm 266]/T - [14.609 \pm 0.225]\}$ with a standard deviation of $\pm 3.3\%$. For melts with higher AlF_3 contents, where chronopotentiometry was not applicable, the relaxation of EMF-time transients after electrolysis on copper cathodes was determined. With a melt with $N_{\text{AlF}_3} = 0.25$, for which D is given above, the contribution to the EMF of changing electrolyte composition at the interface could be calculated and subtracted to yield the transient due to the Al-Cu alloy formed on the surface of the wire. For other electrolyte compositions, this contribution of the alloy could then be subtracted. The Fick's law values of D were extraordinarily high, rising to $10^{-7} \text{ m}^2 \text{ s}^{-1}$ at $N_{\text{AlF}_3} = 0.685$ and $T \sim 1270$ K. This seems to be due to the strong thermodynamic driving force in the system since multiplying D by $\partial \ln c / \partial \ln N$ gives thermodynamic diffusivities in the normal range of $0.5\text{--}5 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$.

To understand mass-transfer phenomena in aluminum electrolysis cells, a knowledge of interdiffusion coefficients in cryolite systems is needed. Although the NaF-AlF₃ system is obviously of chief interest, the LiF-AlF₃ system is much easier to work with and has been used to develop methods.

There are two barriers to be surmounted before any results can be achieved. On the theoretical side, cryolite melts show quite nonideal density behavior, so that the usual assumption of no volume change during diffusion is not valid. At the same time, the melts show strong negative deviations from thermodynamic ideality. On the experimental side, there is no satisfactory way of making a small electrode of known surface area from liquid aluminum, and chronopotentiometry, which is the best method available for dilute solutions, is not suitable for the concentrated mixtures which are the subject of interest.

To look first at the experimental problems, all electrochemical methods for studying diffusion rely on measuring a perturbation of potential caused by a transient current (or vice versa); they differ only in the form of the transient. Chronopotentiometry is unique in that the excursion in concentration of the species of interest is great enough that it drops to zero. The resulting change of potential is large and easily detected, and any distortion of the shape of the potential-time curve by overpotentials or other factors is of no importance. Likewise, it matters little in what form the electrolysis product is left; provided the reactant is removed from solution, a transition in potential will be observed. Thus the method is very simple, provided that the solution is sufficiently dilute that the diffusion coefficient can be regarded as constant between the starting concentration and zero; if not, as in all other transient techniques, analysis of precise measurements of electrode potentials must be made.

To interpret a potential-time transient, it is not necessary that the solutions be ideal, but it is necessary that the

thermodynamics be known so that potential changes can be interpreted as concentration changes. Fortunately, for LiF-AlF₃ melts, this is the case (1, 2). However, even then there are two problems: (i) if current is passing at the time of the measurement there will be a resistive drop and there may be an activation (or other) overpotential, and (ii) if, in the present case, Al is being deposited as an alloy rather than as pure metal, there will be an $(RT/3F) \ln \alpha_{\text{Al}}$ term of unknown magnitude and varying with time. The solution to the first of these problems is to use a relaxation method where a current is passed and then switched off, the decay of the potential towards its initial value being observed. [Wen, *et al.* (3) have used such a method in studying diffusion in solid "LiAl."] The second problem is more difficult. It cannot be obviated by using a pure Al electrode, since there seems to be no way of defining a known (small) area and making electrical connection without contamination from insulator and conductor materials. The solution has been to deposit Al on a solid metal (Cu) substrate and accept the fact that the surface will be an alloy of varying composition. The contribution of this alloy to the electrode potential will not be a function of the melt composition, so that if it can be determined in any one melt where the diffusion coefficient can be found by other methods, its value can be applied to all other compositions.

The course of action has thus been (i) determine the diffusion coefficient by chronopotentiometry in a fairly dilute [10 mol percent (m/o)] solution of AlF₃, (ii) make relaxation measurements at the same composition to determine the contribution of the Al-Cu alloy to the total potential, and (iii) subtract that contribution from measurements with other melts.

Theory

The theory of the effect of volume changes during diffusion has been considered by Vallet *et al.* (4) in connection with the analogous LiF-BeF₂ system. They employed the methods of irreversible thermodynamics. An alternative treatment solely in terms of Fick's laws is given here.

*Electrochemical Society Active Member.

Key words: fused salts, chronopotentiometry, EMF, relaxation.

The problem is that volume changes during electrolysis can of themselves modify concentration gradients.

We start with Fick's first law

$$J = -D \frac{\partial c}{\partial x} \quad [1]$$

in the one-dimensional case as the definition of D , the chemical diffusion coefficient. (Common symbols not defined in the text are listed at the end.) In the steady-state, neither concentrations nor volumes are changing with time and no problem exists.

Let us now consider the unsteady state, and derive a modified form of Fick's second law. Any change of composition is sufficiently small that D can be taken as constant. Two parallel planes, normal to the X-axis and a distance δx apart, cut off a volume v , in a channel of unit cross section. Because it has unit cross section, δx and v are numerically equal. If the number of equivalents of the substance in question in the given volume is n , then

$$c = n/v \quad [2]$$

and its differential, in the case where v is not constant, is

$$\begin{aligned} dc &= (1/v)dn - (n/v^2)dv \\ &= (1/v)dn - c(d \ln v) \end{aligned} \quad [3]$$

The volume v is now defined as holding a constant number of fluoride ions, *i.e.*, only Li^+ and Al^{3+} ions are allowed to cross the bounding planes, and the resulting composition and density changes may cause a change in volume. Electrical neutrality requires that the fluxes of Li^+ and Al^{3+} be chemically equivalent so that c can represent the concentration of either AlF_3 (most convenient) or LiF .

In a time interval dt the change in n is given by the difference of the fluxes in and out of the volume, or

$$dn = (J_x - J_{x+\delta x}) dt = -(\partial J/\partial x) \cdot v \cdot dt \quad [4]$$

since $v = \delta x$. From Eq. [3] and [4]

$$\begin{aligned} \partial c/\partial t &= (1/v)(\partial n/\partial t) - c(\partial \ln v/\partial t) \\ &= -(\partial J/\partial x) - c(\partial \ln v/\partial t)(\partial c/\partial t) \end{aligned} \quad [5]$$

and hence, by differentiation of Eq. [1]

$$\partial c/\partial t = D(\partial^2 c/\partial x^2) - c(\partial \ln v/\partial t)(\partial c/\partial t) \quad [6]$$

Rearrangement gives

$$[1 + c(\partial \ln v/\partial t)](\partial c/\partial t) = D(\partial^2 c/\partial x^2) \quad [7]$$

In the case that v is constant, this reduces to the usual form of Fick's second law. The term in brackets can be written

$$\begin{aligned} 1 + c(\partial \ln v/\partial t) &= 1 + (c/v)(\partial v/\partial t) \\ &= (v \partial c + c \partial v)/(v \partial c) \\ &= (1/v)(\partial cv/\partial c) \\ &= (1/v)(\partial n/\partial c) \end{aligned} \quad [8]$$

At this point we must note that, if V is the volume containing 1 mol of F^- ions and N is the equivalent fraction of the species in question, then

$$n/v = N/V = c \quad [9]$$

so that

$$(1/v)dn = (1/V)dN \quad [10]$$

and

$$\begin{aligned} 1 + c(\partial \ln v/\partial t) &= (1/V)(\partial N/\partial c) \\ &= \partial \ln N/\partial \ln c \end{aligned} \quad [11]$$

Thus Eq. [7] can be written

$$\partial c/\partial t = D(\partial \ln c/\partial \ln N)(\partial^2 c/\partial x^2) \quad [12]$$

$$= \alpha D (\partial^2 c/\partial x^2) \quad [13]$$

where $\alpha = \partial \ln c/\partial \ln N$. Equation [13] is exactly like Fick's second law except that αD has replaced D , and if a similar substitution is made in the first law (which is used in re-

lating flux J to current density i in setting boundary conditions), then all the usual solutions to the equation are valid. Thus, in the case of constant i , and with a transport number of Li^+ ions of t_{Li^+} (with respect to F^-)

$$\alpha i t_{\text{Li}^+}/\mathbf{F} = \alpha J = -\alpha D(\partial c/\partial x) \quad [14]$$

and the Sand equation for the reduction of concentration in time t becomes

$$\begin{aligned} c^0 - c &= (2\alpha i t_{\text{Li}^+}/\mathbf{F})(t/\alpha\pi D)^{1/2} \\ &= (2i t_{\text{Li}^+}/\mathbf{F})(\alpha t/\pi D)^{1/2} \end{aligned} \quad [15]$$

c goes to zero at the transition time $t = \tau$. Thus, what one measures is not αD but D/α .

Just as it is assumed that the changes in concentration are sufficiently small for D to be considered constant, so α also is assumed constant.

Vallet *et al.* (4) found that in the $\text{LiF}-\text{BeF}_2$ system the partial equivalent volumes were not only effectively constant across the system but also almost equal to one another so that, in fact, there was no volume change during diffusion. That is not the case in the present system. Figure 1 shows the value at 1200 K of the term α (with c being taken as the concentration of AlF_3) based on the density measurements of Matiašovský and Malinovský (5). It is within 10% of unity in the range from pure LiF up to $N_{\text{AlF}_3} = 0.5$ (*i.e.*, the Li_2AlF_6 composition, since N_{AlF_3} is the equivalent fraction), and then drops to less than 0.1 as $N_{\text{AlF}_3} = 0.75$ (*i.e.*, LiAlF_4) is approached.

In a system with significant deviations from thermodynamic ideality it is of interest to calculate a diffusivity (D_{th}) based on the thermodynamic driving force, which is the gradient of the chemical potential. Thus Fick's first law (Eq. [1]) is written

$$J = -cD_{\text{th}}(\partial \ln a/\partial x) = -(cD_{\text{th}}/RT)(\partial \mu/\partial x) \quad [16]$$

so that $D_{\text{th}} = D$ if $a \propto c$. In general (6, 7)

$$D_{\text{th}} = D(\partial \ln c/\partial \ln a) \quad [17]$$

In the $\text{LiF}-\text{AlF}_3$ system, the transport number of Li^+ ions is essentially equal to unity, and has been taken as such. [The experimental value (2) is $t_{\text{Li}^+} = 0.957$ at 1073 K and $N_{\text{AlF}_3} = 0.5$.]

For the relaxation measurements, it is necessary to know the relationship between EMF and composition for the cell

and it is (2)

$$E = (RT/3\mathbf{F})(\ln[a_{\text{AlF}_3}/a^0_{\text{AlF}_3}] - 3 \ln[a_{\text{LiF}}/a^0_{\text{LiF}}]) \quad [18]$$

Fig. 1. Variation with composition of the term α for AlF_3 in the system $\text{LiF}-\text{AlF}_3$.

where a and a^0 represent activities on the two sides. It has been found that the activities can be represented adequately by an association model (1, 2)

for which the equilibrium constant in terms of mol fractions is given by

$$\ln K = 6104/T - 2.987 \quad [20]$$

and this expression has been used.

Experimental

The heart of the data gathering system was a Hewlett-Packard 3437A voltmeter connected to an HP85 computer. Resolution was 0.1 mV up to ± 199.9 mV and 1 mV up to ± 1.999 V, with a maximum sampling rate of 4000 readings/s. Each time a reading was taken, an output pulse was available from the voltmeter, and a simple counting circuit with a transistor switch turned the current on and off at the times required. In this way, the experiment was synchronized with the voltmeter operation, rather than vice versa.

Melts were made up by weight from reagent-grade LiF and sublimed AlF_3 , and were contained in copper crucibles made from 13 mm pipe. A 25 mm length was cut off, and its end was squeezed closed in a vise and welded with a gas-oxygen torch; the metal was then cleaned with nitric acid. The crucible was suspended in a vertical tube furnace by Chromel and Alumel wires attached to two holes drilled near its top. The temperature could be determined by measuring the EMF between them, and they also served as current and potential leads for the electrolysis (see Fig. 2).

About 200 mg of Al was added to the crucible so that when it served as anode Al would dissolve and not Cu.

The furnace tube was stainless steel of 35 mm id. Argon was passed in at the bottom, and the top was covered with a sheet of FIBERFRAX.

The cathode and the reference electrode were made from 0.5 mm copper wire, and were held in place by a twin-bore alumina insulator. This was mounted at the top in the stage of an old microscope, so that the wires could be positioned horizontally and moved vertically through a precise distance. After the wires had been in the furnace for at least 10 min and thermal expansion had ceased, the tip of the cathode was positioned at the surface of the melt by observing the sudden change of amplitude of an applied ac signal when the wire made contact. The wire was then lowered by a measured distance (usually 7 mm). The reference wire, immersed approximately the same distance, was plated with Al. Its absolute potential was

Fig. 2. Schematic diagram of electrochemical cell

not known, but all that was required was that its potential stay constant for the 1s needed to make a measurement.

The dc current supply was a Hewlett-Packard 6224B which delivered up to 3A in the constant-current mode. The starting transient was reduced by disconnecting the output capacitor and by setting the voltage limit only about 1V above the value needed to pass the desired current. Current densities were 7-22 A cm^{-2} . A Tektronix 7623A storage oscilloscope was useful in setting up experiments, but it proved inadvisable to connect it and the HP-3437A voltmeter at the same time as some electrical interference occurred.

When the voltmeter was used on its most sensitive range for the relaxation measurements an arbitrary bias was inserted into the reference circuit to ensure that the voltmeter remained on scale.

A typical chronopotentiometric plot is shown in Fig. 3. The point of inflection was found by numerical differentiation of the readings in the computer.

Diameters of the wires used ranged from 0.5-0.65 mm and were measured with a micrometer. In calculating the surface area, allowance was made for the expansion of the diameter between room temperature and the temperature of the experiment. (Since the immersion was set after the wire was hot, no correction for length was necessary.)

Results

Chronopotentiometry.—The correction for curvature of the wire is given by MacDonald (8) as

$$c^0 - c = 2i\sqrt{t}/(nF\sqrt{\pi D}) - it/(2nF\tau) + \dots \quad [21]$$

where τ is the radius of the electrode. The first term is the Sand equation, while the second is the correction. For chronopotentiometric experiments, it is easiest to make the correction by defining an effective concentration c' as

$$c' = c^0 + it/(2nF\tau) \quad [22]$$

and then using the Sand equation as usual.

Provided transition times were not longer than 0.75s, the values of D calculated were independent of current density. For longer times the apparent values of D increased, and beyond about 1s disturbances appeared in voltage-time curves, so there is little doubt that convec-

Fig. 3. Typical chronopotentiometric plot

Fig. 4. Chronopotentiometric diffusion coefficients for AlF_3 in LiF-AlF_3 melts

tion was starting. Only measurements with transition times $\leq 0.75\text{s}$ were accepted.

Figure 4 shows the results obtained for melts with $N_{\text{AlF}_3} = 0.136$ and 0.25 (5 and 10 m/o). Although at any one temperature the values of D do not differ significantly with composition, thereby satisfying one of the essential conditions for use of the Sand equation, the Arrhenius slopes are significantly different. With one result out of 36 rejected, the rest may be expressed by

$$N_{\text{AlF}_3} = 0.136$$

$$D/(\text{m}^2 \text{s}^{-1}) = \exp[-3980 \pm 221/T - [15.904 \pm 0.184]] \quad [23]$$

$$N_{\text{AlF}_3} = 0.250$$

$$D/(\text{m}^2 \text{s}^{-1}) = \exp[-5532 \pm 266/T - [14.609 \pm 0.225]] \quad [24]$$

where the uncertainties are statistical standard errors, and the standard deviations are, respectively, $\pm 3.9\%$ and $\pm 3.3\%$.

The relaxation method.—The relaxation method is handled formally by starting a current i at time zero, and superimposing on it a current $-i$ at time t_1 , at which time the current is turned off. Thus the characteristic quantity $i\sqrt{t}$ in the Sand equation is replaced by $(i\sqrt{t} - i\sqrt{t-t_1})$, a quantity which is conveniently represented by m' . [This symbol is adopted since, apart from the factor $2/\sqrt{\pi}$, it is the same as the semi-integral of the current used by Grenness and Oldham (9) and given the symbol m . m' has been used previously by Dewing *et al.* (10).] The melt composition at the interface should depend only on the value of m' , regardless of the combination of i , t , and t_1 used to obtain it.

When electrolysis occurs at a copper wire and Al-Cu alloy forms, the composition of the alloy on the surface varies with time. If the penetration of Al into Cu is also a diffusion-limited process the same parameter m' should serve to characterize the extent to which such diffusion has occurred, even though several phases of alloy, with differing diffusion coefficients, participate. For a given value of m' there should then be the same composition of alloy on the surface and the same contribution to the potential of the electrode. As an example, Fig. 5 shows some results at 950°C . Three curves for different current densities have been superimposed as well as can be by adding constants to the EMF's. (This is permissible and necessary because the absolute potential of the reference electrode is not known and varies from run to run. It is thus only differences of potential which mean anything.)

The discrepancies at high values of m' (*i.e.*, for 10-20 ms after turning off the current) show that some stage of the

Fig. 5. Variation of potential after turning off current at time t_1

overall process is not entirely diffusion limited, implying a departure from local equilibrium. In principle, it could be in the alloy or it could be in the melt. If the latter, it would presumably be due to unequal rates of discharge of AlF_4^- and AlF_6^{3-} ions. If the former, it would probably be due to slow crystallization of a solid phase from the liquid alloy initially formed. In the calculations which follow, it will be assumed for the moment that the melt is at equilibrium and the departure lies with the alloy; if the ultimate results are not satisfactory, it could suggest that the converse is true.

Experimentally, the contribution of the Al-Cu alloy to the total EMF was determined with the $N_{\text{AlF}_3} = 0.25$ mixture, for which the diffusion coefficient is now known from Eq. [24]. For any given value of m' , the composition of the melt in contact with the electrode can be calculated, and hence $\partial c/\partial m'$, and from the activity model values of $\partial E/\partial c$ are found (Table I). Multiplication gives $\partial E/\partial m'$ for the electrolyte, and subtraction from the experimental value gives the contribution of the Al-Cu alloy. This is shown in Fig. 6 (which represents the same runs as Fig. 5). The steep rise in EMF at the left-hand side almost certainly represents a surface which is no longer liquid; the almost-flat plateau probably represents a two-phase solid-liquid region (in which, of course, at equilibrium the potential should be completely constant).

From the point of view of measuring diffusion coefficients, the higher current densities appear to be preferable. The region of steeply rising potential below $m' = 7$ is best avoided, since a small error in m' will cause a large error in the potential. On the other hand, values of m' high enough to be in the region where the curves di-

verge mean that any results are suspect. At current densities of $140\text{--}220 \text{ kA m}^{-2}$, therefore, results are only accepted for $8 < m' < 18$ (at 950°C). In this region, moreover, the curves are substantially straight, and that greatly facilitates the calculations since the slope can be determined by least squares. Table I shows the region of m' accepted at each temperature and the calculation of the contributions due to the $N_{\text{AlF}_3} = 0.25$ melt and to the Cu-Al alloy. No curvature corrections were made since all the times involved were short.

Table II shows results for $N_{\text{AlF}_3} > 0.5$. Runs where the standard deviation of the points from the least squares straight line was greater than ± 1 mV were rejected.

Figure 7 shows the values of $-\partial E/\partial m'$ at 950°C as a function of composition; the upward trend is obvious. The contribution of the composition of the Al-Cu alloy is seen to be a relatively small part of the total.

Fig. 6. Variation of potential of Al-Cu alloy after turning off current at time t_1 .

The calculation of the diffusion coefficient is straightforward. $\partial c/\partial E$ is calculated from the thermodynamic model and the densities, and the quantity α is also found from the densities. It will be seen that for the $N_{\text{AlF}_3} = 0.685$ melt, α is very small and, since it varies very rapidly with composition, correspondingly uncertain.

Discussion

There have been no previous diffusion measurements in LiF-AlF₃ melts with which the present results can be compared.

Fig. 7. Slope of the plateau on the plot of potential against m' at 950°C

Fig. 8. Thermodynamic diffusivity

Despite the introduction of the density-correction term α , the most conspicuous feature of Table II is that some of the values of D , especially at the $N_{\text{AlF}_3} = 0.685$ composition, are extraordinarily high. Values above $10^{-8} \text{ m}^2 \text{ s}^{-1}$ are unusual, and above $10^{-7} \text{ m}^2 \text{ s}^{-1}$ are, as far as the author is aware, unprecedented. And yet the values of $\partial E/\partial m'$ measured in the experiments vary (with composition) by less than a factor of 3 (see Fig. 7) and the upward trend in $-\partial E/\partial m'$ with composition would in itself correspond to a downward trend in D .

Values of D_{th} calculated from Eq. [17] are shown in Fig. 8. Whereas the Fick's law diffusion coefficients vary (at a given temperature) over a range of a factor of 20, the thermodynamic values cover only a factor of 3.5. Furthermore, the values are nearly all in the range $0.5\text{--}5 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$, which is quite normal. It is thus clear that the very high Fick's law values originate from the high thermodynamic driving force in these nonideal melts. Since NaF-AlF₃ melts show even greater deviations from ideality, one may anticipate that high diffusion coefficients will again be observed.

The thermodynamic diffusivity decreases substantially between $N_{\text{AlF}_3} = 0.136$ and 0.5, but thereafter remains constant. The drop is presumably associated with the appearance of the bulky AlF_6^{3-} and AlF_4^- groups.

Acknowledgments

The experimental measurements were made with the cooperation of Mr. G. Stratford, and the pulse counting circuit and switch were designed and made by Mr. W. J. A. Green. I am indebted to Dr. J. Braunstein of the Oak Ridge National Laboratory, Oak Ridge, Tennessee, for discussion of the problems associated with density changes, and to the referees for valuable suggestions.

Reactions of Coal and Model Coal Compounds in Room Temperature Molten Salt Mixtures

David S. Newman,^{*,1} Randall E. Winans, and Robert L. McBeth

Argonne National Laboratory, Chemistry Division, Argonne, Illinois 60439

ABSTRACT

A 2:1 AlCl_3 -pyridinium chloride molten salt solution was used as the reaction medium for the alkylation of diphenylethane and a bituminous coal by 2-propanol. Probably accompanying the room temperature Friedel-Crafts alkylation is a reduction of $\text{C}=\text{O}$ to $\text{C}-\text{OH}$. Completely deuterated 2-propanol did not react at all with the pyridinium ring. The pyridinium chloride serves to lower the temperature at which the AlCl_3 is able to catalyze the reactions. The pyridinium chloride also catalyzes the Friedel-Crafts alkylation.

In recent years, many authors have focused their attention on organic reactions in molten salt mixtures containing aluminum chloride (1-4) and on organic reactions in molten antimony trichloride (5, 6). Both AlCl_3 and SbCl_3 are strong Lewis acids and are good catalysts for Friedel-Crafts alkylations.

Schlossberg and co-workers have shown that alkylation is a beneficial treatment for coal prior to liquefaction by alkylating several different coals under Friedel-Crafts conditions in an autoclave at 373-423 K (7). Larsen and Kuemmerle discussed the F-C alkylation and depolymerization of coal in a review article (8) and suggested that an understanding of the mechanism of these reactions would considerably increase our understanding of the solubilization of coal and, by implication, our ability to liquefy coal.

Based on these studies, we undertook an investigation of systems in which F-C alkylations would proceed with ease and with minimal damage to the molecular subunits making up the coal macromolecule. The reaction medium we selected was a 2:1 mixture of AlCl_3 and pyridinium chloride, $\text{C}_5\text{H}_6\text{NCl}$. This mixture is liquid at or near room temperature, relatively easy to prepare, and inexpensive—a very important consideration for coal chemistry. Moreover, the melt and the pyridinium salt have both been fairly well characterized (9-11). All of our alkylation reactions were done under nitrogen at or near room temperature. Diphenylethane (bibenzyl) was used as our model coal compound because it has both aryl and alkyl bonds typical of those in coals, and it has been extensively studied under a variety of conditions. The coal chosen for our initial investigation was a high sulfur, high volatile C bituminous coal, and 2-propanol was used as the alkylating agent.

Experimental Details

Preparation of the coal.—A 10g sample of PSOC-244 high sulfur coal [C 55.8%, H 7.5%, N 0.95%, S 7.5% (total), ash 19.5%, and O 12% (by difference)] was ground with water in a shatter box for 15 min and then, after drying, was demineralized using an aqueous HF/HCl solution. The demineralization was carried out by adding 100 ml concentrated HCl to the coal slurry which had been placed in a Teflon beaker. To this mixture, we added 100 ml of 48% HF and allowed the system to react for 48h. The resulting demineralized coal was filtered, vacuum dried, and analyzed. [C 64%, H 5%, N 1.1%, S 6.23% (total), ash 3.9%, and O 19.8% (by difference).] The HCl/HF treatment removed most of the silicate and other inorganic material from the coal.

Preparation of reaction media.—Reagent grade anhydrous aluminum chloride (Cerac 99.9%) and $\text{C}_5\text{H}_6\text{NCl}$ (Eastman Kodak), which had been distilled at 219°C and thoroughly dried, were used without further purification because the impurities in these compounds are far fewer than impurities originating from random fluctuations in composition in any given coal sample.

In a dry box, a 2:1 mixture of the AlCl_3 and $\text{C}_5\text{H}_6\text{NCl}$ was prepared by weighing the requisite amount of AlCl_3 into a 100 ml three-neck flask. To the AlCl_3 was added the appropriate amount of $\text{C}_5\text{H}_6\text{NCl}$. The mixture would spontaneously melt, forming a clear to grayish viscous liquid. The liquid was decanted and maintained indefinitely in a dry box. We then added weighed amounts of coal or model compounds, alkylating agents, etc., to portions of this melt. The reaction vessel was removed from the dry box, placed in a constant temperature bath, and the reaction mixture stirred with a magnetic stirrer. A nitrogen atmosphere was maintained in the three-neck flask throughout the course of the reaction.

Treatment and characterization of reaction products.

—After the predetermined requisite amount of time had elapsed, the reaction was carefully quenched by first cooling the closed reaction vessel in ice water and then dropping small pieces of ice, one at a time, into the reaction vessel so as not to raise the melt temperature substantially. After all of the AlCl_3 had reacted with the water, the aqueous slurry was extracted with various organic solvents and the extracted material analyzed by high performance liquid chromatography (HPLC), gas chromatography-mass spectrometry (GC/MS) (12, 13), and a gas chromatograph-microwave plasma detector-computer system (GC/MPD) (14).

The main feature of the GC/MPD-computer system is an Applied Chromatography System MPD-850 which is an emission spectrometer with a helium plasma source. The spectrometer is connected to a GC and is able to simultaneously detect the elements C, H, D, S, F, Cl, O, or N. The output from the spectrometer is amplified digitally and transferred to a VAX 11/780. By using suitable standards, we can obtain empirical formulas or detect the presence of deuterium in labeling experiments with these instruments with an accuracy of $\pm 5\%$. An inlet system allowing direct entry of solid coal into the MPD was designed to facilitate the analysis of nonvolatile coal or coal products. This inlet system or "solid probe" consists of a platinum tube which serves as a furnace and is heated directly by two leads connected to the output of a dc power supply (HP 6259 B). Both the rate and the amount of heating can be controlled by the power supply. The temperature inside the inlet tube is easily monitored by means of a thermocouple. A Teflon T tube connector, attached to the inlet tube by one of its arms and to a gas source by its central channel, conducted the necessary carrier gas or gases into the system. The sample itself was held in a hollow cylinder of platinum gauze welded to a platinum rod and inserted directly into the furnace through the unattached arm of the T tube (along the principal axis of the platinum furnace). With the sample in place and the carrier gas flowing, the sample was heated to the desired temperature, usually 1100°C, to ensure complete combustion. The combustion products were fed directly into the MPD. The combustion of coal can be described by the equation

The products of this reaction are atomized by the plasma and the emission spectra of the atoms analyzed by the MPD. The GC/MPD was also used to quantitatively analyze the coal for the presence of deuterium. In our original study (15), we were unable to obtain quantitative information and were able to detect the presence of deuterium only qualitatively. A weighed deuterated coal sample was pyrolyzed at 800°C under high vacuum and the pyrolysis products collected in three different fractions each of known weight. The first fraction was volatile material trapped at liquid nitrogen temperatures. The second fraction was CH_2Cl_2 soluble material and the third fraction was residual char. The trapped volatiles were taken up in CH_2Cl_2 , injected into the GC/MPD, and the elements C, H, and ^2H were analyzed. The second CH_2Cl_2 fraction was analyzed the same way. Using suitable deuterium labeled standards, the areas under the chromatogram peaks were calibrated and the percentage of each element in the two fractions was calculated. The char was assumed to contain no deuterium.

Measurement of the coal solubility in molten salt.—The solubilities of the starting coal and the alkylated coal were measured by filtering at temperature a slurry of coal in the melt using a medium porosity glass frit in the cell, shown schematically in Fig. 1. The cell itself was maintained in a constant temperature glass-enclosed oven. The molten salt-coal solution passed through the frit when a positive nitrogen pressure was maintained in the top portion of the cell and a partial vacuum was maintained in the bottom portion. The solubility was simply the percentage weight difference between the original coal and the coal residue that did not pass through the frit.

Results and Discussion

Model compounds and solvent system.—In order to characterize the role of the solvent and assess the extent of

Fig. 1. Glass frit filter cell

autoalkylation of the 2-propanol or the bibenzyl, a series of experiments was performed in which either the 2-propanol or the bibenzyl or a mixture of the two was allowed to react in the melt.

Autoalkylation of 2-propanol formed an orange red material which contained a series of high molecular weight polymers, most of which were nonvolatile. No alkylated pyridines were identified.

Autoalkylation of bibenzyl gave a series of polymers as well as a low yield of monomeric material. The compounds, produced by the bibenzyl reaction and identified by gel permeation chromatography and GC/MS, are listed in Fig. 2. Our results are consistent with those of Heredy and Neuworth (16) who used model compounds in phenol to show that, under Friedel-Crafts conditions, methylene chains can be broken and the resulting species can alkylate other aromatic compounds. In our system, which lacked phenol or another hydrogen source, alkylation proceeded faster than bond cleavage although aryl and methylene bonds were indeed broken at the low reaction temperatures. The molecular weights of the alkylation products were determined by gel permeation chromatography and ranged from 78 (benzene) to approximately 10,000. One aspect of this reaction which deserves comment is the formation of compound 5 which was identified by its mass spectrum. For this compound to form, the aryl carbon bond of bibenzyl had to cleave even though the temperature was less than 40°C. The bond energy for this bond is 414 kJ/mol which means that either the AlCl_3 or the $\text{C}_5\text{H}_6\text{NCl}$ or both are catalyzing the reaction.

To discover if the pyridinium ion would react with alkylating agent under reaction conditions, 1.6g of 2-propanol- d_8 and 1.8g bibenzyl were allowed to react in the 2:1 $\text{AlCl}_3/\text{C}_5\text{H}_6\text{NCl}$ solution at 30°C for 4h. The reaction was quenched with water, as described previously, and extracted with hexane. The aqueous layer was neutralized with NaOH and an aliquot passed through the MPD. No deuterium was detected in the instruments' deuterium channel, indicating that no ring proton exchange or alkylation of the pyridine ring occurred despite the favorable environment for alkylation reactions (17). This means the principal role of the pyridinium chloride in the

melt is to lower the temperature at which the AlCl_3 catalyzes the various reactions. The 2-propanol- d_6 reacted with the bibenzyl to form a series of alkylated phenyl derivatives (Fig. 2) as expected. Approximately 85% of the initial bibenzyl reacted within the 4h and about 40% of its aliphatic carbon bonds were cleaved. The alkylation products were identified by GC/MPD and GC/MS. From these results, we conclude that the alkylating agent preferentially alkylates bibenzyl rather than itself. The earlier experimental results, in which no deuterium was found on the pyridine ring, still did not indicate if the nitrogenic proton of the pyridinium ion, N-H^+ , had exchanged with any of the 2-propanols' deuterium atoms. To ascertain whether or not exchange had occurred, the $^1\text{H-NMR}$ spectrum of a 2:1 $\text{AlCl}_3/\text{C}_5\text{H}_5\text{NCl}$ melt was obtained on a CFT-80 with variable temperature capability. The spectrum showed a striking nitrogen broadened triplet at 70°C (Fig. 3) indicating that, in the pure melt, exchange was not occurring because if it was, the proton could not reside on the nitrogen long enough to couple with it, but would give a sharp singlet (10, 11). Our spectrum is similar to that reported by Angell and Shuppert (9) for a similar melt at 148°C , but our ring proton resolution is not as good because of our lower temperature. This spectrum, incidentally, is excellent evidence for the fact that there are few, if any, free Cl^- ions in the melt. If a substantial concentration of free Cl^- ions were present, the N-H^+ would appear as a sharp singlet in the $^1\text{H-NMR}$ spectrum (11). The dominant anionic species is probably Al_2Cl_7^- as suggested by Gale and Osteryoung (18, 19). The cation is, of course, the pyridinium ion, and the environment is distinctly unfavorable for exchange.

When a quantity of 2-propanol- d_6 , equivalent to the $\text{C}_5\text{H}_5\text{NCl}$, is added to the melt, the brownish-orange polymeric material formed again and remained suspended. The $^1\text{H-NMR}$ spectrum changed markedly with respect to the nitrogen-broadened triplet, so prominent in the pure melt, and formed a very broad singlet peak. The integrated area under the N-H^+ peak was reduced from approximately one-sixth that of the ring proton area to approximately one-twelfth, indicating that exchange was complete and the system had equilibrated. It is assumed that it was the hydroxyl deuterium that exchanged with the N-H^+ . This implies that the N-H^+ is available to catalyze various proton catalyzed reactions and broadens the scope of the $\text{AlCl}_3/\text{C}_5\text{H}_5\text{NCl}$ melt as a reaction medium.

Reactions with coal.—A sample of the HF/HCl demineralized HVC coal was added to the $\text{AlCl}_3/\text{C}_5\text{H}_5\text{NCl}$ melt and allowed to mix with it for 20h at 30°C . The black slurry was then quenched and the coal separated from the melt and analyzed to assure us that no substantial elemental changes had occurred. No distinction was made between the melt soluble and melt insoluble coal fractions; both were combined. The elemental analysis was substantially the same as before [C 66%, H 4.8%, N 1.25%, S 6.46% (total)]. To detect changes in average molecular

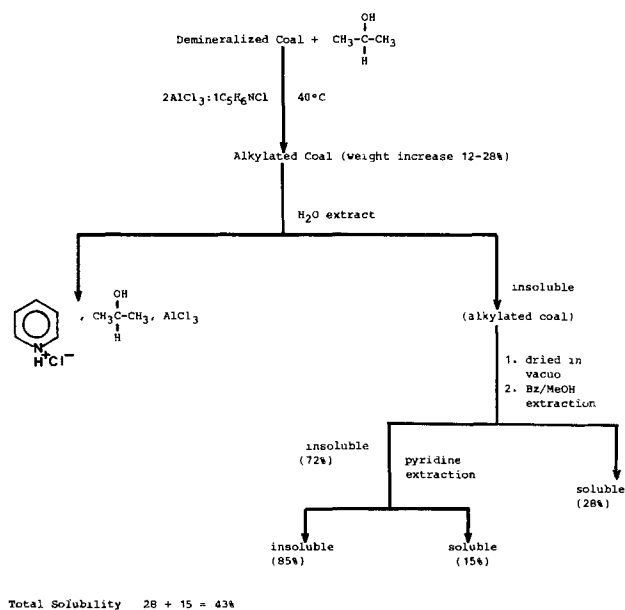

Fig. 3. $^1\text{H-NMR}$ spectrum of $2\text{AlCl}_3/\text{C}_5\text{H}_5\text{NCl}$ at 70°C

weight of the coal that may have occurred through bond cleavage, autoalkylation, etc., the solubility of the reacted coal in a 3:1 benzene-methanol solution was compared with that of the unreacted coal in the same solvent. The solubility of the reacted coal was 6.3% by weight and the solubility of the unreacted coal was 9.8% by weight. Considering the errors involved in recovery and the relatively low solubilities of the two coals, there is not very much difference. Nevertheless, it is possible that some internal change such as autoalkylation did occur while the coal was in the melt.

The reaction between the demineralized coal and the 2-propanol is shown schematically in Fig. 4. We initially used long reaction times ($> 15\text{h}$) and low temperatures (30°C), but subsequently found that shorter reaction times and higher temperatures (40°C - 45°C) gave smaller weight increases, lower ash content, and higher solubilities in organic solvents. From our model compound reactions and chemical analyses, we can say with some assurance that the increase in weight is due to isopropyl groups bonding to the coal.

The larger weight increases that we were able to achieve with this reaction represent the addition to the coal of approximately 15 alkyl groups per 100 carbons, which is more than the number reported by Kroger for the alkylation of high vitrinite coals using isopropyl chloride and AlCl_3 in CS_2 at 45°C (20, 21). This strongly suggests that the 2:1 $\text{AlCl}_3/\text{pyrCl}$ melt is the best medium yet found for Friedel-Crafts alkylation of coal and may, in fact, have general synthetic importance (22).

The molecular weight distribution of the benzene/methanol soluble fraction of the alkylated coal was obtained by gel permeation chromatography with a UV detector set at 254 nm. Four μ -styrogel columns were used in series for the separation. Three had 100\AA nominal pore diameters and one had 500\AA nominal pore diameters. The chromatogram is shown in Fig. 5. The molecular weights ranged from 4400 to less than 100 with the largest fraction being in the neighborhood of 560. Since 254 nm is the region of the spectrum in which aromatic molecules strongly absorb light, a conclusion that can be drawn from this chromatogram is that there are either polymers containing aromatic units or double and triple bonds (which also absorb at 254 nm) dissolved in the benzene/methanol solution. These entities could not have easily originated from the alkylating agent and, therefore, had to come from the coal. The average molecular weight distribution of the soluble fraction of alkylated coal is quite low and is preliminary evidence for concluding that depolymerization is accompanying alkylation (23, 24).

Total Solubility $28 + 15 = 43\%$

Fig. 4. Schematic diagram of the reaction between 2-propanol and demineralized P50C-244 coal.

Fig. 5. Gel permeation chromatogram of the benzene/methanol soluble portion of alkylated coal.

A portion of the benzene/methanol soluble fraction of the alkylated coal was analyzed via the solid probe of the GC/MPD and was found to contain sulfur in about the same proportion as in the original coal. This was considered proof that at least some of the original coal was dissolving. It is impossible for the sulfur to have originated from the alkylating agent. The sulfur compounds probably were liberated by breaking a methylene-sulfur bond (25).

To further characterize the alkylation reaction and understand its effect on the coal's solubility, as well as to prove beyond a reasonable doubt that the 2-propanol alkylated the coal rather than polymerized and then attached itself loosely to the coal's surface, we decided to measure the net solubility of the coal rather than the solubility of coal plus added alkyl groups, which is the quantity usually reported in the literature. To do this, we alkylated a 0.722g sample of coal with 2-propanol- d_8 . The coal increased its weight 0.084g or about 12%. We then extracted 0.6482g of this deuterated coal with benzene/MeOH (3:1) and pyrolyzed the residue, which weighed 0.481g. The three fractions were analyzed for C, ^1H , and ^2H , using the technique described earlier. The residue contained 0.0146g of ^2H . The ^2H initially present in the starting sample weighed 0.018g. This means that the insoluble coal remaining after benzene/MeOH extraction contained 81.11% of its original ^2H and 18.9% of the deuterated alkylating agent dissolved along with the coal. The net coal solubility is therefore

$$100 \times \left[\frac{0.167 \times (0.189 \times 0.0675)}{0.684 - \left[\frac{(0.648 \times 0.084)}{0.806} \right]} \right] = 28\%$$

This should be compared with the 6.3-9% solubility of the nonalkylated coal and represents a significant increase in solubility with relatively little alteration of the structural units that comprise the coal. An interesting result of this experiment, besides proving that the 2-propanol alkylated the coal and not itself, is that at least 10% more coal dissolved than alkylating agent. In all likelihood, the principal reason for the increase in the alkylated coal's solubility is a decrease in the cross-linking between the coal macromolecules, which causes the coal to swell. In several of our alkylation reactions, the coal and 2-propanol, which were in the form of a slurry in the media, turned to a "pudding-like" material. We interpreted this to be partially caused by a swelling of the coal. In our system, the decrease in the extent of cross-linking is due to the scission of methylene and aryl-methylene bonds which is a

secondary, but important, by-product of the Friedel-Crafts alkylation, as shown in our model compound studies. The decrease in cross-linking permits the solvent to solvate previously inaccessible interior units of the coal macromolecule, which may not have been as completely alkylated as exterior portions, and increase the coal's solubility above what it would have been in the absence of alkylation. Stating this conclusion slightly differently, swelling of the coal, which is a result of a by-product of the Friedel-Crafts reaction, is the important process for increasing the coal's solubility and causing the substantial solubility differential between alkylating agent and coal. To sharpen this argument, we measured the alkylated coals' solubility in the molten salt because coals are notoriously insoluble in highly polar or ionic solvents. The original demineralized coal had a molten salt solubility of 6.5% while the alkylated coals' solubility was 15.9%. The most plausible explanation for this substantial increase in solubility is the Al_2Cl_7^- and $\text{C}_5\text{H}_8\text{H}^+$ ions were able to penetrate the interstices of the coal macromolecule and solvate severed sections of the coal.

Comparing the solubilities of the alkylated and nonalkylated coals in various solvents shows that the alkylated coal is in all cases considerably more soluble. Since increased cross-linking, Scholl reactions and autoalkylation are also possible (17) in the melt; an obvious conclusion that can be drawn from our results is that at low temperatures (40°C), alkylation, depolymerization, and reduction of intermolecular cross-linking are proceeding at a faster rate than Scholl reactions, autoalkylation, and internal cross-linking. This means that alkylation by 2-propanol in $2\text{AlCl}_3 \cdot 1\text{C}_5\text{H}_8\text{NCl}$ is a useful technique for coal solubilization. It also means that coal solubility is not a linear function of weight increase, but depends in a complex manner on all of the external conditions.

Reaction mechanisms.—The reaction mechanisms that can be given in detail and with some degree of confidence are those involved with autoalkylation of bibenzyl and the alkylation of bibenzyl with 2-propanol. The first step in the autoalkylation of bibenzyl is the removal of a hydride ion from the bibenzyl to generate the carbonium ion

Another bibenzyl molecule then attacks the carbonium ion and the reaction proceeds via the scheme shown below

Both compounds **6** and **7** were identified by GC/MS and HPLC, and R^+ continues the chain reaction. This scheme is quite similar to the Friedel-Crafts transalkylation mech-

anism suggested by Roberts and Roengsumran for isotopically labeled *n*-propylbenzene (26).

The alkylation of the bibenzyl by the 2-propanol has for its initial step

The propyl carbonium ion is then attacked by the bibenzyl forming the various products we have isolated. It should be kept in mind that we did not observe extensive autoalkylation of bibenzyl in the presence of 2-propanol.

In all likelihood, the principal reaction mechanism for the coal alkylation by 2-propanol is similar to Eq. [5] with the carbonium ion then reacting with aryl sites in the coal

Competing with this reaction are Scholl type reactions of the form (27)

Surprisingly, Scholl reactions did not occur to any great extent in the bibenzyl-2-propanol experiments, but there was evidence for this type of reaction in the bibenzyl autoalkylation.

As a result of the formation of compounds 5 and 6 (Eq. [4] as well as the slight decrease in the solubility of the demineralized coal in benzene/methanol, one cannot rule out the possibility that Eq. [7] is competing with Eq. [6]. The substantial increase in the alkylated coal's benzene/methanol solubility relative to the nonalkylated coal, even taking into account that some of the soluble material was the alkylating agent, together with the production of toluene, benzene, ethyl benzene, and other reduced species in the model compound reaction, suggests that a reduction reaction of some sort is also occurring in addition to the other processes already mentioned. Moreover, a similar study of I11 no. 6 coal has given us spectroscopic evidence for the reduction of a carbonyl group to a hydroxyl group (28). This reduction probably results from the protonation of a carbonyl oxygen and the subsequent hydride extraction from either the isopropyl alcohol or hydride donors in the coal itself. Isopropyl alcohol is known to be a good hydride donor, and acetone was observed as a reaction product.

Conclusion

A 2:1 $\text{AlCl}_3/\text{C}_5\text{H}_5\text{NCl}$ solution is an excellent reaction medium for both Friedel-Crafts alkylation and depolymerization of coal. The low temperatures at which the reactions occur in this melt further enhance the ease of handling of the reaction products and prevent the decomposition of the molecular subunits comprising this coal. However, a large variety of coals and model coal compounds remain to be studied before a firm conclusion as to the detailed mechanisms and scope for these intriguing reactions can be determined. It is also our opinion, in agreement with other authors, that alkylation is a beneficial treatment of coal prior to liquefaction, and if combined with an oxyalkylation like that described by

Liotta, may become an extremely important method of liquefying coal (29, 30).

Equilibrium Concentrations of FeS₂ and FeS in LiCl-KCl Eutectic Melts

Ram A. Sharma and Randall N. Seefurth*

General Motors Research Laboratories, Warren, Michigan 48090-9055

ABSTRACT

Solubilities of FeS₂ in LiCl-KCl eutectic melts between 720 and 900 K are represented by the equation

$$\log(\text{mol fraction, } X_{\text{FeS}_2}) = -\frac{5157.33}{T} + 0.666 \pm 0.125$$

They were measured by a new optical technique. This was necessitated by an excessive scatter in the solubility data determined by chemical analysis of the melts after establishing equilibria between the melts and FeS₂ by diffusion and counterdiffusion. The solubility of FeS in these melts determined chemically also had an excessive scatter. In addition, the optical technique was inadequate, as no solid FeS sample could be satisfactorily used. Therefore, the solubilities were calculated from the equilibrium constant of the reaction

using relevant thermodynamic data.

Rechargeable cells are being developed using Li-Al or Li-Si negative electrodes, iron sulfide or iron disulfide positive electrodes, and LiCl-KCl melts contained in boron nitride cloth separators as electrolytes (1-3). These cells have performed for over 10,000h (2), but the specific energy starts declining after about 3000h. Post-test examination of some of the compact cells which had Li-Al electrodes indicated very fine iron particles associated with lithium sulfide particles within the boron nitride separators (4). The degradation in performance of these cells may be caused by the loss of positive electrode active materials through their solubilities in the electrolyte. The iron sulfides in the positive electrodes themselves might have dissolved slightly in the electrolyte and reacted with dissolved lithium yielding iron and lithium sulfide particles. Boron nitride fibers could provide nucleating sites for their deposition. Therefore, it is necessary to have solubility data for the iron sulfides to evaluate this hypothesis. The following investigation was a part of this effort and was conducted to measure the solubilities of FeS and FeS₂ in LiCl-KCl eutectic electrolyte at different temperatures.

As a first attempt, the solubilities were measured by equilibrating the LiCl-KCl melts with the respective solutes inside specially designed sealed silica capsules at different temperatures and determining the solute contents by chemical analysis. A large scatter was observed in these measurements. This scatter was caused by the difficulty in chemically determining the very low contents of the solutes in the equilibrated melts. Therefore, a new optical technique was developed. In general, this technique consists of sealing weighed amounts of solute and solvent inside a transparent silica capsule under vacuum. The capsule is slowly heated inside a furnace equipped with viewing ports. After the electrolyte has melted, the solid solute particle is observed occasionally with a microscope. At a certain temperature, the solute dissolves completely in the melt, and the solubility is determined from the weighed amounts of solute and solvent and the observed temperature of dissolution. The technique was tested by determining the solubilities of Li₂S in LiCl-KCl eutectic melts. These solubility data were in agreement with data in the literature (5).

Experimental

Materials.—Electrolytes obtained from two sources were used in these studies. First, LiCl of 99.6% purity and KCl of 99.9% purity were combined to form the eutectic mixture [58 mol percent (m/o) LiCl-42 m/o KCl; mp = 625 K (6)]. This mixture was purified by bubbling chlorine through the melt at 775 K for 4h, and subsequently

*Electrochemical Society Active Member.

removing the chlorine by bubbling with helium for 1h. Second, a high purity eutectic was obtained from Anderson Physics Laboratory and used for the majority of the tests.

A section of a large naturally occurring crystal of pyrite (FeS₂) was cleaved off and broken into sample-size pieces. These pieces were analyzed under a microscope capable of 30X magnification, and only pieces having smooth and shiny surfaces [indicating no entrapped silica (SiO₂) impurities] were selected for testing. Chemical analyses of such specimens revealed an iron content of 46.3 weight percent (w/o) compared to the theoretical value of 46.55 w/o.

Inside a helium-atmosphere dry box, a quantity of high purity FeS (63.1 w/o Fe by chemical analysis against 63.53 w/o theoretical Fe) was placed in a graphite container with a tightly fitting cover which was cleaned by firing at about ~1300 K in a helium atmosphere. The container was placed in a flat-bottom silica tube which was closed with a rubber stopper having helium inlet and outlet ports. The silica tube was taken out of the dry box and positioned in a high frequency furnace heating coil. The graphite container was heated to ~1550 K, kept at this temperature for about 30 min, and then cooled in flowing helium. The silica tube with its content was transferred into a dry box. The FeS lump was taken out of the graphite container and crushed into small pieces for use in the solubility measurements using the chemical technique.

Apparatus and procedure.—*Chemical analysis technique.*—Sealed silica (Vycor) capsules of different designs, as shown in Fig. 1, were used to hold the melts. These different designs were tested in an attempt to minimize the convective transport of fine undissolved solute particles during equilibration (*i.e.*, to attain equilibrium by diffusion and counterdiffusion only) and to minimize compositional changes due to transport of the melt from the different compartments of the capsule during quenching. To further reduce the chances of convective transport of the solute particles, silica shot was placed on the inner small solute tube. Any errors due to segregation were avoided by using the whole amount of melt from the lower limb. The results from these different designs were similar, therefore, the capsule of the design shown in Fig. 1a was arbitrarily used.

Before use, the silica capsules were cleaned a few times with soap and water, then with alcohol, and dried at 475 K. They were fired in hydrogen at 1100 K for 1h.

Inside a helium-atmosphere dry box, enough LiCl-KCl eutectic mixture was melted in the silica capsules (Fig. 1A, 1B, 1C) to fill only the bottom extensions. After removing gas bubbles from the melt, the second smaller

Fig. 1. Schematic representation of the silica containers used for solubility measurements (chemical technique).

tube with the solute reactant pieces (FeS or FeS₂) was placed inside the silica capsule. An additional amount of LiCl-KCl mixture was slowly added, taking care to keep the mixture molten and to submerge the smaller tube completely. The melt was slowly solidified, avoiding gas bubble entrapment. The silica capsules were then taken out of the dry box and sealed under a vacuum of $\sim 10^{-3}$ torr.

A layer of thermal insulation was placed in the bottom of a stainless steel container, 200 mm long and 57 mm id. Eight stainless steel tubes, 150 mm long and 14 mm id, were positioned in the container, and the annular space was filled with sand. The sealed silica capsules were placed inside the smaller stainless steel tubes which were then covered by another layer of thermal insulation.

A vertical tubular furnace (450 mm long, 75 mm diam) with a uniform temperature zone about 150 mm long was used to heat the melts. The other instruments used in conjunction with the furnace included a proportional band temperature controller, a potentiometer, and calibrated Chromel-Alumel thermocouples.

The stainless steel container was placed in the predetermined uniform temperature zone of the vertical tubular furnace, and the empty space in the furnace was packed with thermal insulation. The furnace was heated to a desired temperature and kept at this temperature for the equilibration period. From the results of experiments carried out for different lengths of time, the equilibration period was determined to be about 15 days. However, the test samples were generally allowed to equilibrate about 30 days, and in some cases even 55 days. At the end of the equilibration period, the samples were quenched in oil, the limb containing the equilibrated solidified melt was broken off, and the solubility was determined by chemical analysis of the total contents in the limb for iron.

In the case of silica capsule D (Fig. 1), the same preparatory procedure was followed except the smaller silica tube with the solute was positioned at the very beginning, the LiCl-KCl mixture was added in stages and melted until the level of the melt was above the capillary. During the equilibration period, the silica capsule was not placed in the smaller stainless tube; rather, it was submerged into the sand inside the bigger stainless steel container.

Optical technique.—The transparent test capsules were made by closing one end of a 10 cm-long piece of 25 mm od silica tube and adding a neck (20 cm long by 15 mm od) to the open end. A ground glass joint was attached to the neck, while the base of the capsule was provided with a small protrusion (3 mm deep by 5 mm id) for facilitating sample location. The capsules were washed with soap and water, acetone, and finally distilled water using an ultrasonic cleaner. They were oven dried at 375 K and cooled to room temperature. A preweighed solute sample was inserted into each capsule which was then transferred into a helium-atmosphere (typically less than 1

ppm O₂, N₂, or H₂O) dry box. Predetermined amounts of LiCl-KCl eutectic were weighed inside the dry box and placed inside the respective capsules. Each capsule was closed inside the dry box, using a ground glass joint and stopcock assembly. The loaded capsule was then removed from the dry box and sealed at the base of the neck under a vacuum of $\sim 10^{-3}$ torr using common glass-blowing techniques. A liquid nitrogen cold trap was used between the mechanical pump and the capsule to prevent back diffusion of vapors from the pump into the sample zone.

A description of the apparatus used in this optical technique is shown in Fig. 2. Briefly, the sealed capsule, together with three calibrated thermocouples and two optical prisms, was mounted in a stainless steel test fixture to insure system rigidity. Two of the thermocouples were positioned near the bottom of the melt area, the other near the top. This fixture was inserted into a two-zone, vertical tubular clamshell heating element furnace (3.8 cm id by 40 cm long). One of the lower thermocouples was used in conjunction with a proportional-band temperature controller to control the temperature of the lower furnace zone. The other two thermocouples were used in conjunction with a digital temperature-readout system and a data-acquisition system to monitor the melt temperature. The top furnace zone (above the sample zone) was heated only to maintain a constant temperature throughout the test zone. It was regulated manually by means of an autotransformer.

Initially, the furnace was equipped with two viewing ports, which with the aid of the prisms, allowed transmission of light from the source through the test capsule to the microscope. Later, a third port, opposite the lower port, was introduced for versatility in lighting and observing the sample. The ports were covered with transparent silica plates to eliminate air circulation, while the top and bottom of the furnace were closed with thermal insulation. A 300W xenon lamp was used to illuminate the sample capsule, and a stereomicroscope capable of 70X magnification was used to view the sample.

After the electrolyte was melted, the solid solute particle was observed occasionally with the microscope. The temperature was slowly raised in steps. Near the dissolution temperature, it was increased in approximately 5° increments and kept at each temperature at least 6h. At a certain temperature, the solute would dissolve completely in the melt, and the solubility was determined from the weighed amounts of solute and solvent and the observed temperature of dissolution.

Results and Discussion

FeS₂ solubility.—The solubilities of FeS₂ in LiCl-KCl eutectic melts at different temperatures determined by the

Fig. 2. Schematic diagram of the solubility apparatus (optical technique)

Fig. 3. Solubility of FeS₂ (pyrite) in LiCl-KCl eutectic electrolyte melts. Δ : optical technique. \square : chemical technique. \diamond : Hall (7).

chemical analysis technique are presented in Fig. 3. An excessive scatter in the data is observed. This scatter may be due to the difficulty in determining the very low solute content of the solidified melt by chemical analysis. However, the lower limits of the solubility are in agreement with those determined by a filtration technique (Fig. 3) reported by Hall (7).

The solubility of 12 FeS₂ samples in LiCl-KCl eutectic electrolyte at different temperatures determined using the optical technique are given in Table I. They are also represented graphically in Fig. 3, where the solid line represents a least squares fit to the data. The FeS₂ solubility data between 720 and 900 K can be further represented by the equation

$$\log X_{\text{FeS}_2} = -\frac{5157.33}{T} + 0.666 \pm 0.125 \quad [1]$$

where X_{FeS_2} = mol fraction of FeS₂ in eutectic salt and T = temperature in degrees K. The error caused by the uncertainties in the weights and temperature measurements fall within the scatter of the data. These results indicate FeS₂ is markedly less soluble in eutectic than that determined by the above equilibrium techniques. At comparable temperatures, the solubility appears to be two to three orders of magnitude less than in the above studies.

The slope from Fig. 3 can be used to calculate the relative partial molar enthalpy of solution of FeS₂ in the LiCl-KCl melt. At equilibrium between the pure solid FeS₂ and the melt

$$\mu_{(s)} = \mu_{(l)} \quad [2]$$

where $\mu_{(s)}$ and $\mu_{(l)}$ are the chemical potentials of FeS₂ in the solid and liquid phases, respectively. If pure solid FeS₂ is defined as the standard state, then

$$\mu_{(s)} - \mu_{(s)}^0 = \mu_{(l)} - \mu_{(s)}^0 = \overline{\Delta H} - T \overline{\Delta S} = 0 \quad [3]$$

Table I. Solubility of FeS₂ (pyrite) in LiCl-KCl eutectic melts

Sample	FeS ₂ wt (μg)	Eutectic wt (g)	Mol Fraction FeS ₂	Dissolution Temp (K)
1	26	11.15	1.09×10^{-6}	782
2	45	12.51	1.68×10^{-6}	808
3	14	10.57	6.17×10^{-7}	764
4	9	11.70	3.58×10^{-7}	721
5	800	40.00	9.32×10^{-6}	893
6	245	40.00	2.85×10^{-6}	824
7	62	30.00	9.63×10^{-7}	783
8	171	30.00	2.66×10^{-6}	828
9	73	30.00	1.13×10^{-6}	783
10	117	30.00	1.82×10^{-6}	800
11	40	30.00	6.21×10^{-7}	745
12	10	10.00	4.66×10^{-7}	727

where $\overline{\Delta H}$ is the relative partial molar enthalpy of solution and $\overline{\Delta S}$ is the relative partial molar entropy of solution. In addition

$$\mu_{(l)} - \mu_{(s)}^0 = RT \ln a_{\text{FeS}_2} = RT \ln \frac{X'_{\text{FeS}_2}}{X_{\text{FeS}_2}} \quad [4]$$

where R is the gas constant, a_{FeS_2} is the activity of FeS₂ with respect to pure solid FeS₂, X'_{FeS_2} is any mole fraction of FeS₂ below the solubility limit, and $1/X_{\text{FeS}_2}$ is the activity coefficient of FeS₂ on the assumption that it remains constant below its solubility limit. Also

$$\overline{\Delta S} = \overline{\Delta S}^{\text{ex}} + \overline{\Delta S}^{\text{id}} = \overline{\Delta S}^{\text{ex}} - R \ln X'_{\text{FeS}_2} \quad [5]$$

where $\overline{\Delta S}^{\text{ex}}$ is the excess partial molar entropy of solution and $\overline{\Delta S}^{\text{id}}$ is the ideal partial molar entropy of solution.

By substituting the value of $\mu_{(l)} - \mu_{(s)}^0$ from Eq. [4] and that of $\overline{\Delta S}$ from Eq. [5] into Eq. [3], and rearranging the terms, the following equation can be obtained

$$\ln X_{\text{FeS}_2} = -\frac{\overline{\Delta H}}{RT} + \frac{1}{R} \overline{\Delta S}^{\text{ex}} \quad [6]$$

Therefore, the slope of a plot between $\ln X_{\text{FeS}_2}$ and $1/T$ will be equal to $-\overline{\Delta H}/R$.

Proceeding in this manner, the partial molar enthalpy of solution of FeS₂ was calculated from the data presented in Fig. 3. It was calculated to be 23.5 kcal/mol, which is about twice that of Li₂S [13 kcal/mol (5)]. This higher enthalpy indicates a greater degree of difficulty for FeS₂ to be accommodated into the melt.

FeS solubility.—The solubilities of FeS determined by the chemical analysis technique (Fig. 4) had an excessive scatter similar to that observed in the case of FeS₂ solubilities. In addition, an attempt at measuring the solubility of FeS by the optical technique was unsuccessful. The FeS samples (Appendix A) appeared to absorb electrolyte, increase in size, and develop tree-like structures on their upper surfaces. They dissolved in the electrolyte only after the temperature surpassed ~ 900 K. The tree-like structure and slow dissolution prior to 900 K may be due to the formation of "J-phase" (8). Therefore, the solubilities were calculated as follows.

Calculation of the Solubility of FeS

The dissolution of FeS in LiCl-KCl melts may be represented by the reaction

This reaction has been used in the reverse direction by Saboungi *et al.* (8), to determine the solubility of FeS in the electrolyte by an electrochemical technique. The equilibrium constant (K) for the reaction in terms of the activities (a_i) of the reactants and products is given by

$$K = \frac{a_{\text{FeCl}_2}^* a_{\text{Li}_2\text{S}}}{a_{\text{LiCl}}^2 a_{\text{FeS}}} \quad [8]$$

where $a_{\text{FeCl}_2}^*$ is the activity of FeCl₂ with respect to an infinitely dilute solution as the standard state, such that $a_{\text{FeCl}_2}/X_{\text{FeCl}_2} = 1$ when X , the mole fraction of FeCl₂ $\rightarrow 0$. The activities of the other compounds are with respect to pure solids as their standard states. Therefore $a_{\text{FeS}} = 1$ and

$$K = \frac{X_{\text{FeCl}_2} X_{\text{Li}_2\text{S}} \gamma_{\text{Li}_2\text{S}}}{a_{\text{LiCl}}^2} \quad [9]$$

where $\gamma_{\text{Li}_2\text{S}}$ is equal to the reciprocal of the saturation mole fraction of Li₂S, $X_{\text{Li}_2\text{S}}^{\text{sat}}$. This is true on the assumption that the activity coefficient of Li₂S is constant below the saturation mole fraction. This assumption is reasonable when the values of the saturation mole fractions are very small (Table II). As per the dissolution reaction, $X_{\text{Li}_2\text{S}}$ is equal to X_{FeCl_2} , then

$$K = \frac{X_{\text{FeCl}_2}^2 \gamma_{\text{Li}_2\text{S}}}{a_{\text{LiCl}}^2} \quad [10]$$

Fig. 4. Solubility of FeS in LiCl-KCl eutectic electrolyte melts. □: chemical technique. ○: optical technique. △: Saboungi *et al.* (8). ◇: Hall (7). X: present calculated values.

The standard free energy change (ΔG^0_R) of reaction [7] is given as

$$\Delta G^0_R = \Delta G^0_{Li_2S} + \Delta G^*_{FeCl_2} - \Delta G^0_{FeS} - 2\Delta G^0_{LiCl} \quad [11]$$

The standard state of $\Delta G^*_{FeCl_2}$ is again an infinitely dilute solution such that $a_{FeCl_2}/X_{FeCl_2} = 1$ when $X_{FeCl_2} \rightarrow 0$, while the standard states for the other compounds are pure solids. Using Eq. [11] and the data given in Table II, ΔG^0_R is calculated to be 27,909, 28,232, and 28,793 cal at 673, 723, and 800 K, respectively. Since

$$\Delta G^0_R = -RT \ln K \quad [12]$$

by substituting Eq. [10] into Eq. [12] we get

$$\Delta G^0_R = -RT \ln \frac{X^2_{FeCl_2} \gamma_{Li_2S}}{\alpha^2_{LiCl}} \quad [13]$$

The α_{LiCl} in the LiCl-KCl eutectic melts at different temperatures has been reported elsewhere (9) and is given in Table II. It is assumed that the α_{LiCl} remains constant on the dissolution of FeS in the LiCl-KCl melt.

Taking the values of ΔG^0_R calculated above and the data in Table II the mol fractions of FeCl₂ were calculated using Eq. [13]. They were found to be 6.5×10^{-7} , 1.5×10^{-6} , and 4.16×10^{-6} at 673, 723, and 800 K, respectively (Fig. 4). As per reaction [7], these equilibrium concentrations of FeCl₂ are also the solubilities of FeS in LiCl-KCl eutectic melts at the respective temperatures.

The standard free energy change of reaction [7] can also be calculated by considering the following individual reactions

Table II. Pertinent thermodynamic data used for calculating the equilibrium constant for reaction [7] and the FeS concentration in LiCl-KCl melts

Temp (K)	α_{LiCl}	$X^{sat}_{Li_2S}$	ΔG^0 , cal per mol, for

α_{LiCl} from Ref. (9). $X^{sat}_{Li_2S}$ from Ref. (5). ΔG^0 for LiCl from Ref. (12). ΔG^* for FeCl₂ from Appendix B. ΔG^0 for FeS from Appendix C. ΔG^0 for Li₂S from Appendix D.

which add up to

Tomczuk *et al.* (10) report the potential of reaction [14] to be 1.343, 1.338, and 1.333V at 673, 723, and 773 K, respectively. Sharma and Seefurth (11) report the potentials for reaction [15]. Calculating the free energy changes of reactions [14] and [15] and combining them with the free energy changes of reaction [16] (12) and reaction [17] (Appendix B), the free energy change (ΔG^0_R) for reaction [7] was calculated to be 27,760, 28,284, and 28,013 cal at 673, 723, and 773 K, respectively. Proceeding as before, the solubility of FeS in LiCl-KCl eutectic melts was calculated from the values of ΔG^0_R for reaction [7]. The solubility was found to be 6.9×10^{-7} , 1.6×10^{-6} , and 3.2×10^{-6} at 673, 723, and 773 K. These values are in good agreement with the values calculated above and with those reported by Saboungi *et al.* (8) from their measurements and from similar calculations using the solubility product concept, etc. (Fig. 4). In addition, two FeS samples having dissolution temperatures above 900 K were run using the optical technique. The solid line in Fig. 4, representing a least squares fit to the calculated solubility data, extrapolates well through these high temperature points. Also, the calculated FeS solubility values are comparable with the solubilities of FeS₂ in the LiCl-KCl eutectic melt at corresponding temperatures.

Proceeding as in the case of FeS₂, the partial molar enthalpy of solution for FeS was calculated from the slope of Fig. 4. It was found to be 15.6 kcal/mol.

Calculation of the solubility of FeS in Li₂S-saturated electrolyte.—Since the cell electrolyte is saturated with Li₂S during discharge, it is of significant importance to determine the solubility of FeS in the saturated melt. This can be determined from relation [13], where α_{Li_2S} becomes unity upon saturation. Using the values of ΔG^0_R calculated above and the data in Table II, the mol fraction of FeCl₂ in Li₂S-saturated LiCl-KCl eutectic melts were calculated to be 7×10^{-10} , 2×10^{-9} , and 4.5×10^{-9} at 673, 723, and 773 K, respectively. These mol fractions which are equivalent to the solubilities of FeS at the respective temperatures are about three orders of magnitude smaller than those in the unsaturated melt.

Solubilities of Other Iron Sulfide Containing Compounds

The determination of the solubilities of the compounds, Li₂S · FeS (13), Li₂Fe₂S₄ (13), and Li_{2+x}Fe_{1-x}S₂ (13) in the

eutectic electrolyte is not possible, because at equilibrium, most of the Li_2S is leached out of these compounds by the electrolyte, leaving behind iron compounds in the solid state. In this situation, final iron sulfide concentration in the electrolyte will be that of the electrolyte saturated with Li_2S . Under the assumption that there is an equilibrium between the compound and the electrolyte, then the concentrations of iron sulfide and Li_2S in the electrolyte will correspond to their activities in the compound. These concentrations should be smaller than those in the electrolyte in equilibrium with the pure phases of unit activities. The compound $\text{Li}_3\text{Fe}_2\text{S}_4$ coexists with FeS_2 , so the iron concentration and sulfur concentration of species in the electrolyte should be the same whether the compound is equilibrated with FeS_2 or $\text{Li}_3\text{Fe}_2\text{S}_4$. That means if there is no polysulfide in the electrolyte in equilibrium with FeS_2 or Li_2S , then there should not be any polysulfide in the electrolyte in equilibrium with $\text{Li}_3\text{Fe}_2\text{S}_4$. The same reasoning can be extended to discount the presence of polysulfide in the electrolyte in equilibrium with $\text{Li}_{2+r}\text{Fe}_{1-r}\text{S}_2$, etc.

APPENDIX A

Preparation of FeS Samples for the Optical Technique

Two batches of FeS were prepared for use as solubility samples for the optical technique. The first batch was made by fusing 99% pure FeS, as described earlier. Chemical analyses of postfusion samples indicated an overall purity of >99.6% and an iron content of 63.77 w/o Fe compared to 63.53 w/o theoretical Fe. When tested, these samples did not dissolve uniformly in the electrolyte. Evidently a phase change occurred which slowed down the dissolution process.

The second batch of FeS was prepared from FeS_2 . Twenty-five mg of FeS_2 particles were placed in a small pyrolytic graphite crucible, and together with another crucible of Fe particles (105 mg) were sealed under vacuum in a quartz vessel. This vessel was heated to ~915 K and allowed to equilibrate for 6 days. The resultant particles were porous appearing under a microscope, indicating loss of sulfur, but there was not enough sample for chemical analysis. When tested, these samples were not wetted and floated on top of the electrolyte.

APPENDIX B

Calculation of ΔG^* for FeCl_2

The standard potential (E^0) of a Fe/FeCl₂ electrode vs. a Pt(II)-Pt(O) reference electrode in a LiCl-KCl eutectic melt at 723 K has been reported to be 1.171V by Laitinen and Liu (14). This is for an infinitely dilute solution as the standard state such that $a_{\text{FeCl}_2}/X_{\text{FeCl}_2} = 1$ when $X_{\text{FeCl}_2} \rightarrow 0$. They have also reported E^0 for a Cl_2/Cl^- electrode vs. the reference in the eutectic at 723 K to be 0.216V (14). Therefore, the standard formation potential of FeCl_2 with infinite dilution as the standard state can be calculated by combining the following reactions

and obtaining

Since

$$\Delta G^*_{\text{FeCl}_2} = -n\mathbf{F}E^0_3 \quad [\text{B-4}]$$

where n is the number of equivalents and \mathbf{F} is the Faraday constant, then $\Delta G^*_{\text{FeCl}_2}$ is calculated to be -63,985 cal/mol at 723 K.

A check of this $\Delta G^*_{\text{FeCl}_2}$ calculation was made by using the standard potential of Li(O)-Li(I), which was computed to be -3.410V for a 17.39 molar Li(I) concentration in LiCl-KCl eutectic solvent (14), and considering the following reactions

Proceeding as above, ΔG^0 for reaction [B-7] was calculated to be 103,290 cal at 723 K. The $\Delta G^*_{\text{FeCl}_2}$ can then be calculated from the relation

$$\Delta G^*_{\text{FeCl}_2} = 2\Delta G^*_{\text{LiCl}} + \Delta G^0 \quad [\text{B-8}]$$

In this case, ΔG^*_{LiCl} is assumed to be ΔG^0_{LiCl} , the standard free energy of formation of pure LiCl. This assumption indicates that the activity of LiCl in the eutectic is not much different from its mole fraction. Using $\Delta G^*_{\text{LiCl}} = -83,425$ cal/mol (12), the $\Delta G^*_{\text{FeCl}_2}$ was calculated by relation [B-8] to be -63,560 cal/mol at 723 K. This value is in excellent agreement with the -63,985 cal/mol calculated above.

The value of $\Delta G^*_{\text{FeCl}_2}$ at other temperatures (673 and 800 K) was calculated using the temperature coefficient of the standard free energy of formation of pure solid FeCl_2 . This temperature coefficient was calculated to be 28.335 cal/K from the data reported in the JANAF tables (12). The values of $\Delta G^*_{\text{FeCl}_2}$ at 673 and 800 K were calculated to be -65,402 and -61,803 cal/mol, respectively.

A second check of the $\Delta G^*_{\text{FeCl}_2}$ calculations can be made using the work of Saboungi *et al.* (8). They report the potential (E) of a Fe/FeCl₂ electrode vs. a AgCl/Ag electrode (8.4×10^{-3} mol fraction AgCl) in a LiCl-KCl eutectic melt to be 256.66, 231.58, and 209.09 mV at 673, 723, and 773 K, respectively. The potential of the Fe/FeCl₂ electrode vs. a standard AgCl/Ag electrode (standard state such that $a_{\text{Ag}}/X_{\text{Ag}} = 1$ when $X_{\text{Ag}} \rightarrow 0$) was calculated to be 0.5339, 0.5294, and 0.5275V at the respective temperatures, and the corresponding standard free energies were found to be -24,630, -24,422, and -24,335 cal/mol at the same temperatures. The standard formation potential of a Fe/FeCl₂ electrode vs. a Cl^-/Cl_2 electrode was then calculated by combining the reactions

and

to obtain

Using the potentials 0.637 and 0.216V for reactions [B-10] and [B-11] reported by Laitinen and Liu (14), and 0.5294V for reaction [B-9] (derived above), the potential of reaction [B-12] was calculated to be 1.382V at 723 K. Proceeding as above, $\Delta G^*_{\text{FeCl}_2}$ was then calculated to be -63,754 cal/mol at 723 K, once again in good agreement with the value derived above.

A second method was used to check the values of $\Delta G^*_{\text{FeCl}_2}$ at other temperatures. The standard free energy of formation of AgCl, ΔG^*_{AgCl} , was calculated using the $\Delta G^*_{\text{FeCl}_2}$ value and the standard free energy change of reaction [B-9] (-24,422 cal/mol, reported above). It was found to be -19,666 cal/mol at 723 K. The values of ΔG^*_{AgCl} at 673 and 773 K were then calculated using the temperature coefficient of the standard free energy of formation of pure solid AgCl (15). The temperature coefficient was found to be 11 cal/K between 600 and 700 K, and 8 cal/K between 700 and 800 K (15). The ΔG^*_{AgCl} was calculated to be -20,216 and -19,266 cal/mol at 673 and 773 K, respectively. Using these values and the standard free energy changes for reaction [B-9] (-24,630 and -24,335 cal/mol, reported above), the values of $\Delta G^*_{\text{FeCl}_2}$ were calculated to be -65,062 and -62,867 cal/mol at 673 and 773 K, respectively. These values are once again in very good agreement with the values of $\Delta G^*_{\text{FeCl}_2}$ calculated above.

APPENDIX C

Calculation of ΔG^0 for FeS

Rosenqvist (16) represents the standard free energy change for the reaction

by the equation

$$\Delta G^{\circ} = 71,500 + 25.25 T \quad [\text{C-2}]$$

Richardson and Jeffes (17) give the value of ΔG° at different temperatures for the reaction

Combining reactions [C-1] and [C-3] gives the following reaction

The standard free energies of formation of FeS were calculated from reaction [C-4] using Eq. [C-2], and the corresponding values for reaction [C-3] from Ref. (17). The ΔG° for FeS was calculated to be -24,143, -24,317, and -24,600 cal/mol at 673, 723, and 800 K, respectively.

APPENDIX D

Calculation of ΔG° for Li₂S

The heat of formation, ΔH_{298} , for Li₂S was obtained from the literature. It is reported to be -107, 400 ± 200 cal by Juza and Uphoff (18).

Assuming

$$\frac{S_{298} \text{ of Cu}_2\text{S}}{S_{298} \text{ of Cu}_2\text{O}} = \frac{S_{298} \text{ of Li}_2\text{S}}{S_{298} \text{ of Li}_2\text{O}} \quad [\text{D-1}]$$

the entropy, S_{298} , for Li₂S was calculated from literature data (19). It was determined to be 11.605 cal/deg/mol. The relevant data for lithium ($S_{298} = 6.95 \pm 0.1$ cal/deg/mol, $\Delta H_m = 700$ cal, and mp = 454 K) and for sulfur ($S_{298} = 7.78$ cal/deg/mol, $\Delta H_m = 400$ cal, and mp = 392 K) were also taken from Ref. (19). Combining these data, the entropy of formation, ΔS_{298} , for Li₂S was calculated to be -10.075 cal/deg/mol.

Using the equation

$$\Delta G^{\circ} = \Delta H^{\circ} - T\Delta S^{\circ} \quad [\text{D-2}]$$

and taking into consideration the free energy of fusion of the components (see above), the standard free energy of formation, ΔG° , for Li₂S was calculated at various temperatures. These values are reported in Table II. Re-

cently, ΔG° for Li₂S was measured using an EMF method (10). The reported value of -100,220 cal at 700 K is in good agreement with the values calculated above.

Electrochemical Measurements on Pt, Ir, and Ti Oxides as pH Probes

K. Kinoshita*¹ and M. J. Madou*

SRI International, Menlo Park, California 94025

ABSTRACT

Open-circuit potential and impedance measurements were performed on Ti, Pt, and Ir oxides. It was found that the pH dependence of the open-circuit potential of the various oxide electrodes shows a Nernstian behavior and that the response time of the potential to a change in pH for the more conductive oxides on Pt and Ir is comparable to that of the commercial glass pH electrode. Impedance measurements allowed flatband potential determinations on polycrystalline TiO₂ only in highly conductive solutions. In these solutions, the pH dependence of the flatband potential is Nernstian. For less conductive solutions, it was impossible to deduce the exact flatband potential from the intercept of $1/C_s^2$ vs. V on the V -axis.

The results of an electrochemical study on Zr-ZrO₂ electrodes for possible use to monitor pH of aqueous solutions from measurements of open-circuit potential (OCP) and flatband potential (V_{FB}) were presented elsewhere (1). In general the OCP on conductive metal oxides gives a fast Nernstian response to pH; the problem is that the OCP also is influenced by other redox couples (e. g., O₂), since the Helmholtz potential drop in such cases is dominated by electron exchange reactions. Measurements of V_{FB} on appropriately doped oxides, on the other hand, are usually independent of the redox potential of the solution

since the potential drop in the Helmholtz layer is dominated here by adsorption/desorption of specific ions (e. g., H⁺). Because a too insulating oxide film is formed on Zr, the Zr-ZrO₂ electrode in its present state of development does not appear to offer much promise for measuring pH via OCP. The V_{FB} method for pH probing failed also in this case because we were unable to dope the ZrO₂ appropriately (1). In the present paper, data are presented on the continuation of electrochemical studies on metal oxide electrodes, which are intended for monitoring pH at high temperature (up to 300°C), where glass pH electrodes, e. g., would be unstable. Measurements of OCP and V_{FB} at room temperature of Ti, Pt, and Ir oxides prepared by anodic and thermal oxidation are discussed in this paper. Platinum and titanium oxides were selected because of their anticipated stability in water at tempera-

Key words: flatband potential, Mott-Schottky curves, anodic oxide, space charge capacitance.

tures from 25° to 300°C (2). Iridium oxide is also supposedly stable between 25° and 250°C (3, 4). In a future publication, we will report on pH measurements with these oxides at higher temperatures and pressures.

Experimental Details

Preparation of oxide electrodes.—The TiO₂ electrodes were prepared from coupons of Ti foil (0.2 mm thick, 99.9+%, Astro Metallurgical Corporation, Wooster, Ohio), etched in HF/HNO₃ solution, and then electrochemically or thermally oxidized. The anodic oxide films were produced by using a constant voltage of 40 (T-79A) or 80V (T-79B) applied between the Ti coupon and a Pt counter-electrode in 1N H₂SO₄. An anodic oxidation time of 15 min was used. The oxide film obtained at 40V was light green and that at 80V was purple.

If we use the potential dependence of 14 Å/V reported by Schultze *et al.* (5), the oxide thicknesses at 40 and 80V are 560 and 1120Å, respectively. Note that higher values of the potential dependence have also been used to calculate the thickness of the TiO₂ layer. For example, Archibald (6) used 20 Å/V in his calculations.

Thermally grown TiO₂ films (T-87) were produced by heating Ti coupons at 550°C for 1h in flowing O₂ that was saturated with water vapor at 23°C. A gray oxide film was obtained that was identified by x-ray diffraction to be rutile. The oxide film thickness of 650Å was calculated using the rate constant for parabolic oxidation reported by Kubaschewski and Hopkins (7).

The procedure used to prepare the Ir oxide electrodes was similar to that described by Ardizzone *et al.* (8). A small Ti coupon (0.2 mm thick, 1 cm²) was dipped into an aqueous solution containing dissolved IrCl₃. The coupon was removed and gently heated with an air gun to crystallize the IrCl₃ (dissolved in water) on the titanium surface. After each deposition, the coupon was heated in an air oven for about 10 min to decompose the chloride salt. This procedure was repeated three times, and then a final heat-treatment was conducted at the same temperature for 4h. Two temperatures were used to form IrO₂: 400°C (I-47) and 500°C (I-54).

X-ray diffraction analysis indicated that IrO₂ was obtained by this procedure. The oxide surfaces were not examined in detail by electron microscopy, and no estimate of the oxide thickness is available. Ardizzone *et al.* found by scanning electron microscopy of IrO₂, which was produced by a method similar to the one used in our study, that a cracked, dry mudlike layer was obtained.

Several methods were used to obtain Pt oxide layers on Pt electrodes. Initially, the oxide was produced by oxidation of a Pt bead electrode that was immersed in molten NaNO₃ at 420°C; this procedure was used by Dobson *et al.* (4) in their studies of metal-metal oxide electrodes. A variation of this method was also used to produce a Pt oxide film. In this method, NaNO₃ and Na₂PtCl₆ were dissolved in water. The tip of a Pt bead electrode was dipped into the solution and then gently heated after removal from solution to coat the electrode surface with a mixture of the two salts. The electrode was next heated at 500°-550°C for 2h in air to form the oxide layer. This procedure was repeated three times to form an orange-brown oxide layer.

Another method to produce an oxide layer on Pt involved coating the bead electrode with Pt(NH₃)₂(NO₂)₂ dissolved in nitric acid and then heating to 400°C in air for 10 min. This procedure was repeated three times, and then a final heat-treatment at the same temperature for 3.5h was used (electrode P-57). X-ray diffraction analysis of the oxides obtained by the methods described here indicate the presence of PtO, but not PtO₂. The study by Dobson *et al.* (4) showed that only PtO₂ was obtained by oxidation in molten NaNO₃. However, Every and Grimsley (9) reported that a mixture of PtO and PtO₂ was obtained by oxidation of Pt in KNO₃ at 400°C. Furthermore, the predominant oxide was PtO and not PtO₂; the mol ratio of PtO to PtO₂ was approximately 7.

Electrochemical measurements.—The methods and procedures that were used to measure the OCP and impedance of the metal oxide electrodes are described elsewhere (1). Because TiO₂ showed a photoresponse to the fluorescent lights in the laboratory, the electrochemical studies were conducted with the oxide electrode in the dark.

The response time of Pt and Ir oxide electrodes to changes in pH was compared with that of a commercial glass pH electrode. This comparison was made by using the metal oxide electrode and a glass pH electrode for indicator electrodes in a potentiometric titration of H₃PO₄ with NaOH. About 100 ml of H₃PO₄ solution containing the glass pH electrode and either the Pt or Ir oxide electrode was deaerated by nitrogen. Then controlled amounts of 5N NaOH were added as the titrant, and the potential of the two electrodes was recorded on a strip chart recorder.

Discussion of Results

Open-circuit potential measurements.—The OCP of TiO₂ electrodes, which were prepared by thermal and anodic oxidation, are plotted as a function of pH in Fig. 1. In general, the OCP measurements were conducted for about 24h in each buffer solution, although the steady-state potential (± 4 mV) was reached in about 6h. The data in Fig. 1 show that the TiO₂ prepared by thermal oxidation (T-87) has an OCP-pH response with a slope of -59 mV/pH, which is indicative of a Nernstian behavior for this electrode. But the TiO₂ prepared by anodic oxidation at 40V (T-79A) and 80V (T-79B) does not show a Nernstian response to pH. At pH 2-6, these oxide electrodes showed only a weak response of OCP to pH (-0.031 mV/pH), while at higher pH, OCP was essentially unchanged.

The IrO₂ obtained by thermal decomposition of IrCl₃ on a Ti substrate yielded the OCP-pH curves shown in Fig. 2. The OCP measurements that were made on the electrodes soon after the thermal treatment ("fresh" electrode) are represented in Fig. 2 by the solid symbols. The OCP responds to pH of the buffer solution in a manner predicted by the Nernst equation. Furthermore, the relationship of OCP to pH closely agrees with the data reported by Ardizzone *et al.* (8), which is represented by the dashed line in Fig. 2.

Immediately after testing, the fresh oxide electrodes were stored in distilled water for 2 weeks. The OCP measurements were repeated with the electrodes ("aged" electrode), and the data are represented in Fig. 2 by the open symbols. It is apparent that the aged electrodes still exhibit the Nernstian behavior in the buffer solutions, but

Fig. 1. Open-circuit potential of TiO₂ electrodes in different pH buffers: (◇) T-79A, (△) T-79B, and (○) T-87.

Fig. 2. Open-circuit potential of fresh (solid symbols) and "aged" (open symbols) iridium oxide electrodes (\blacktriangle , \triangle) I-47, (\bullet , \circ) I-54. Dashed line is the OCP-pH dependence for Ir_2O_3 electrode reported by Ardizzone *et al.* (8).

OCP has shifted in the negative direction by about 0.080V. The OCP measurements on the oxide obtained by thermal decomposition of IrCl_3 at 400° (I-47) and 500°C (I-54) showed similar response of the fresh and aged electrodes. Apparently, the oxides formed by decomposition of IrCl_3 at 400° and 500°C are not significantly different to affect the OCP response; and the OCP of both electrodes became more negative by the same amount upon aging in distilled water.

Extrapolating the OCP in Fig. 2 to pH = 0 gives a value of 0.902V (SHE) for the aged oxide electrode. The value for OCP of the fresh electrode at pH = 0 is 0.982V (SHE), which Ardizzone *et al.* (8) reported is close to the equilibrium potential for the reaction

Pourbaix (10) listed two other reactions that have the same equilibrium potential (*i.e.*, 0.926V)

and

Insufficient information is available from the present study to unequivocally determine which reaction represents the OCP-pH dependence shown in Fig. 2. As the IrO_2 was deposited on a Ti substrate, possibly no metallic iridium is present, and the reaction proposed by Ardizzone *et al.* (8) seems more likely. The shift of OCP in the negative direction that is observed with the aged electrode suggests that a change in the properties of the oxide film occurs during storage in distilled water. Pourbaix (10) summarized some of the observations that have been reported on the stability of IrO_2 . Apparently, $\text{IrO}_2 \cdot \text{H}_2\text{O}$ prepared by treating a boiling solution of alkali metal iridochloride with KOH or NaOH in air is soluble in HCl, HNO_3 , and H_2SO_4 . However, on aging the oxide becomes practically insoluble in all acids.

This observation suggests that the IrO_2 undergoes a physical/chemical change to produce a more corrosion-resistant oxide. The shift in OCP with aging of the iridium oxide electrodes in Fig. 2 may possibly be due to a change in the oxide with time. For example, Buckley *et al.* (11)

suggest that the oxide film on Ir, which consists of oxygen-bridged hydrated oxy-hydroxide species, can undergo a structural change with the formation or destruction of an iridium/oxygen bridge by a process such as

The water remains in the oxide. Accompanying the structural change in the oxide is a change in the equilibrium potential of the oxide.

We want to caution here that extrapolation and comparison to Pourbaix data for the present oxide might be somewhat dangerous; our oxides here are highly defective and partially hydrated compared to the well-defined oxide phases used to construct the Pourbaix diagrams. These comparisons and extrapolations for IrO_2 and the other oxides described here should only be used as a guide for trends.

The Nernstian behavior of a Pt oxide electrode (P-57) is illustrated in Fig. 3, along with data for the OCP-pH response of oxide electrodes of Ir, Ti, and Zr (1). The OCP at pH = 0 for the Pt oxide electrode is 0.982V (*vs.* SHE). This potential is in good agreement with the equilibrium potential (11) for the reaction

which has E° (25°C) = 0.980V at pH = 0. The corresponding electrochemical reactions for PtO/PtO_2 and $\text{PtO}_2/\text{PtO}_3$ have equilibrium potentials of 1.045 and 2.000V, respectively (12). On the basis of the close agreement between the equilibrium potential and OCP, the reaction given above can adequately describe the pH response of the Pt electrode, P-57. Furthermore, support for the above reaction is provided by the results of the x-ray diffraction analysis, which detected the presence of PtO on the Pt electrode. This implies a solid-state-type reaction where a water-related species diffuses in and out of the PtO film during oxidation/reduction cycles.

The pH dependence of OCP for the various oxide electrodes that appear to show a Nernstian behavior (except Zr oxide electrode at alkaline pH) are plotted in Fig. 3. The OCP for the four metal oxide electrodes at a given pH decreases in the following order: Pt, Ir, Ti, and Zr oxides. Several interesting parallels between this order and chemical/electrochemical properties of these metal oxides can be drawn (see data in Table I). The general trend in the order of OCP follows that of E° and the free energy for the selected couples listed in Table I. However, the difference in OCP between the oxides of Ir and Ti and between the oxides of Ti and Zr is less than the corresponding differences in E° .

The oxides of Pt and Ir are good electronic conductors (15) that exhibit a Nernstian response to pH. Moreover, the OCP values extrapolated to pH = 0 are close to the E° for some possible redox reactions involving the oxidation-reduction of the metal itself. A Mott-Schottky type of measurement on such oxides to obtain the V_{FB} as a means of pH measurement is impossible (see impedance results). Thus with these oxides, OCP is the parameter that can be used to monitor pH.

The oxide on Zr is very insulating, and a Nernstian behavior in response to pH is only approached (very slowly)

Table I. Comparison of OCP, E° , and V_{FB} for various metal oxide electrodes at pH = 0 and free energy of formation of metal oxides

Oxide	OCP <i>vs.</i> SHE (V)	E° <i>vs.</i> SHE (V) ^a	V_{FB} <i>vs.</i> SHE (V)	Free energy (cal/mol) ^a
Pt	0.982	0.982 (Pt/PtO)	NA	-11,510 (PtO)
Ir	0.902	0.926 (Ir/IrO ₂)	NA	-28,000 (IrO ₂)
Ti	0.642	-0.910 (Ti ₂ O ₃ /TiO ₂) ^c	0.150 ^e	-196,300 (TiO ₂) ^b

^a Values obtained from Pourbaix (12).

^b Hydrated oxide.

^c Value obtained by extrapolation of data by Vandermolen *et al.* (14) to pH = 0.

^d Value obtained by extrapolation of data by Clechet *et al.* (13) to pH = 0.

Fig. 3. Open-circuit potential of metal oxide electrodes in different pH buffers. Metal oxides of (∇) Pt, (\square) Ir, (Δ) Ti, and (\circ) Zr. Solid line has slope of -59 mV/pH.

by either the "bare" Zr surface or by certain ZrO_2 films, presumably containing pinholes (1). Extrapolating OCP to $pH = 0$ yields OCP approximately equal to 0.39 V (vs. SHE), which cannot be readily associated with any of the equilibrium reactions presented by Pourbaix (12) for the Zr- H_2O system (see also Table I). It is most likely that we are dealing with a mixed potential in this case. If ZrO_2 could be appropriately doped, V_{FB} determination for pH measurements should be possible (1).

Anodically and thermally grown TiO_2 films on Ti form an intermediate case, since they behave as highly doped semiconductors (see impedance results). It was shown that the OCP response was better for thermally grown TiO_2 (T-87) than for anodically grown TiO_2 (T-79A and T-79B). We believe that this is because the thermally grown film has more pinholes than an anodically grown one. Equilibrium might be reached faster at these sites where the thin oxide is present. The OCP response to pH for thermally grown TiO_2 is better than for ZrO_2 , and V_{FB} determination with Mott-Schottky-type measurements is possible. Our impedance results will show, though, that V_{FB} determination on polycrystalline TiO_2 poses some problems, especially in low conductivity media. Extrapolating OCP to $pH = 0$ yields an OCP that cannot be readily associated with any E° for the Ti- H_2O system (see also Table I) and presumably indicates that the measured OCP here is a mixed potential.

As a general rule, the more insulating a material, the less likely a pH probe can be developed on the basis of an OCP measurement. But, the more insulating the oxide, the better the possibility for a pH probe based on V_{FB} determination on the appropriately doped material.

The transient potential response of the metal oxide electrodes and the glass electrode during the potentiometric titration of H_3PO_4 by $5N$ NaOH is represented by the results in Fig. 4. In this figure, the potential transients for the glass electrode and the Pt oxide electrode (P-57) in the same solution are recorded during the addi-

Fig. 4. Transient response of potential of metal oxide electrodes and glass pH electrode during addition of various amounts of $5N$ NaOH titrant.

tion of two aliquots of titrant. The potential transients for the Ir oxide electrode (I-47) were recorded during the potentiometric titration of another H_3PO_4 solution. The potential transients for the Ir oxide electrode show the response after the addition of four aliquots of $5N$ NaOH of different volumes. In these experiments, small amounts of $5N$ NaOH were added from a burette to the deaerated acid solution after a steady-state potential was established.

The data in Fig. 4 are representative of the type of transient potential response that was observed during the titration experiments. As expected, when NaOH is added to the acid solution the steady-state potentials that are recorded change in the direction indicative of higher pH. The apparent overshoot in the potential transient that is evident after addition of the titrant, which then returns to a steady-state potential, is believed to be an artifact (insufficient stirring, for example) related to the experimental arrangement and procedure. The results in Fig. 4 show that the response of the potential of the metal oxide electrodes to changes in pH is comparable to that of the commercial glass pH electrode. At least under the conditions of these titration experiments, the two metal oxide electrodes show a satisfactory response to rapid changes in solution pH.

Impedance measurements.—Impedance measurements on Pt oxide electrodes were performed with a frequency response analyzer (Solartron Model 1172) controlled by a microcomputer. A plot of the imaginary component of the impedance at 1000 Hz of a Pt oxide electrode in an aqueous solution of $1M$ KCl + HCl ($pH = 1.4$) vs. the applied voltage showed several humps (see also Ref. (16), Fig. 3b) and did not lead to a linear $1/C_s^2$ vs. V plot (with C_s the apparent series capacitance).

If C_s could be identified with C_{sc} , the space charge capacitance inside the oxide, C_s would be expected to follow a Mott-Schottky relationship

$$\frac{1}{C_s^2} = \frac{2}{qN_D\epsilon\epsilon_0} (V - V_{FB} - \frac{kt}{q}) \quad [1]$$

for an n-type oxide semiconductor. In this equation, N_D is the donor density, ϵ is the dielectric constant of the semiconductor, ϵ_0 is the dielectric constant in vacuum, and q is the charge of the electron.

The slope of the Mott-Schottky plot is proportional to the concentration of dopant in the semiconductor, and

the intercept with the V-axis at $1/C_s^2 = 0$ yields V_{FB} (if the term kT/q is neglected). The value of $1/\omega C_s$ at 1000 Hz and +2V SCE was only a few ohms per cm^2 of electrode area. Most of the change in the potential drop at this conductive metal oxide electrode interface occurs in the Helmholtz layer, and C_s does not correspond to the capacitance of the space charge layer (C_{sc}) inside the oxide. Impedance measurements on Ir oxide were not attempted, since the conductivity of this oxide is high (15). It is also expected that here V_{FB} determination with the Mott-Schottky plots will be impossible.

Impedance measurements on polycrystalline TiO_2 on Ti that is anodically or thermally grown lead to Mott-Schottky plots exhibiting a break. This is illustrated in Fig. 5 for an oxide that is anodically grown at a constant voltage of 40V in 1N H_2SO_4 (T-79A) and measured in a solution of 1M KCl + HCl (pH \approx 1.4 specific resistivity = 9.6 Ω cm). The value of $1/\omega C_s$ for T-79A at 1000 Hz and +2V vs. SCE in this solution was around 200 Ω/cm^2 of electrode area, about a factor of 100 higher than for the platinum oxide electrode. In this case, a major fraction of the change in potential drop occurs in the space charge layer of the semiconductor, and Mott-Schottky type measurements are possible. Sample T-79B (anodically grown at 80V in 1N H_2SO_4) and T-87 (thermally grown oxide) also showed a break in the Mott-Schottky plots and had similar values for $1/\omega C_s$ at the same potential and frequency.

A break in the Mott-Schottky plots and the frequency dispersion observed in Fig. 5 were not expected. The type of frequency dispersion, where the different Mott-Schottky curves measured at different frequencies converge to one point on the V-axis, as observed in the lower part of the Mott-Schottky curves in Fig. 5, is described in more detail in Ref. (17) and (18). In Ref. (17) it is shown that this type of frequency dispersion (B-type behavior) does not prohibit true V_{FB} determination. A break in the Mott-Schottky plots, as illustrated in Fig. 6, was also shown [e.g., Kennedy *et al.* (19)] for sintered titanium dioxide and sintered iron dioxide, and by P. Richardson *et al.* (20) for flamed iron and titanium foils. Schultze *et al.* (5) showed a Mott-Schottky plot for thin anodically formed films on Ti foil that had three regions with different slopes. These authors discussed different possible explanations for the change in the slope of Mott-Schottky plots: different kinds of donors contributing to the measured capacitance, inhomogeneous doping, layers of different properties, and, at higher potential, the whole film being totally depleted of charge carriers (exhaustion).

At high anodic potentials (> 2V vs. SCE in solution of pH \approx 1.4) specimen T-79A (40V sample) and T-79B (80V sample, double the thickness of T-79A) have almost the same value of $1/\omega C_s$ for the same frequency. Therefore we can exclude the possibility of exhaustion, since, in that case, $1/\omega C_s$ would have been proportional to the thickness of the whole film. It is not easy to distinguish between the other possibilities. Assuming that two different kinds of donors contribute to the measured capacitance, we can calculate approximately the concentration of each donor.

Fig. 5. Plot of $1/C_s^2$ vs. potential of TiO_2 electrode (T-79A) in a solution of 1M KCl + HCl (pH \approx 1.4). Specific resistivity \approx 9.6 Ω cm.

Fig. 6. Plot of $1/C_s^2$ vs. potential of TiO_2 electrode (T-79A) in a commercial buffer solution (pH = 7) (○) and in a 1M KCl solution (pH \approx 6.8) (×). Electrode surface area, 0.455 cm^2 . Frequencies used: from highest curves in each set towards lowest curve, 1000, 316, and 100 Hz.

From the highest slope of the Mott-Schottky curve at 1000 Hz in Fig. 5, a donor concentration of $1.6 \times 10^{19} \text{ cm}^{-3}$ is estimated, and from the lowest slope, $3.9 \times 10^{19} \text{ cm}^{-3}$. These calculations assume a semiconductor dielectric constant ϵ of 173 (see Eq. [1]).

The photocurrent on anodically grown TiO_2 (T-79A) under intense UV illumination in the same solution as for the measurements represented in Fig. 5 exhibited an onset occurring at about the same voltage as the intercept on the V-axis of the lower part of the $1/C_s^2$ vs. V plots (\approx 0.0V vs. SCE) shown in Fig. 5, indicating that this intercept corresponds indeed to the true V_{FB} of this material.

The intercept with the V-axis of the part of the Mott-Schottky plot with the highest slope is pH dependent, and changes in high conductivity solutions (1M KCl + HCl or KOH; specific resistivity \approx 10 Ω cm) by roughly -60 mV per pH unit. The -60 mV/pH unit slope was observed by other authors on single-crystalline TiO_2 in highly conductive media (21-23). Significantly, it was also shown by Dutoit *et al.* (23) that for TiO_2 the V_{FB} was independent of the redox couple present in solution. The independency of the V_{FB} on redox potential in solution for most wide bandgap semiconductors is discussed in detail in reference (24). The V_{FB} of polycrystalline TiO_2 electrodes that were anodically grown could thus be used to monitor pH; unfortunately, the accuracy of the determination is poor (\pm 50 mV). The reproducibility is poor also because of changes in the slope of the Mott-Schottky curves and the consequent changes in the extrapolated V_{FB} as a function of time of exposure to the electrolyte. For practical use of the V_{FB} for monitoring pH, the measurements must also be possible in electrolyte solutions at low concentration.

In Fig. 6, we show Mott-Schottky curves at three different frequencies on sample T-79A in a commercial buffer solution of pH = 7 (specific resistivity = 176 Ω cm) and in a 1M KCl solution at a pH of \approx 6.8 (specific resistivity = 8.9 Ω cm). Mott-Schottky curves obtained in the low conductivity solution have an intercept with the V-axis that is shifted towards cathodic potentials with respect to the intercept of the curves measured in the high conductivity solution of the same pH. The values for $1/C_s^2$ at the same potential are larger and show more frequency dispersion in the case of the low conductivity solution. This is because the Helmholtz layer capacitance in the low conductivity solution is comparable in magnitude to the space charge capacitance. The total measured capacitance is then given by

$$\frac{1}{C_s} = \frac{1}{C_{sc}} + \frac{1}{C_H} \quad [2]$$

with C_{sc} being the semiconductor space charge capacitance, and C_H the Helmholtz capacitance.

De Gryse *et al.* (25) have shown that under those circumstances Eq. [1] should be replaced by

$$\frac{1}{C_s^2} = \frac{1}{C_H^2} + \frac{2}{qN_D\epsilon\epsilon_0} (V - V_{FB} - kT/q) \quad [3]$$

In this case, the Mott-Schottky plot will be parallel to the one measured in the high conductivity solution, and the intercept with the V-axis is

$$V_o = V_{FB} + kT/q - \frac{qN_D\epsilon\epsilon_0}{2C_H^2} \quad [4]$$

From Fig. 6 it is clear that the predicted parallel shift is only observed at high anodic potential. At potentials closer to the V_{FB} , the two sets of Mott-Schottky curves are not parallel, and Eq. [3] does not apply. Thus the V_{FB} on anodically grown polycrystalline TiO_2 cannot be obtained in low conductivity solutions from Eq. [4], as we are unable in this case to relate V_{FB} directly to V_o . In another publication (18), we show that V_{FB} measurements in high resistivity solutions (between 10^4 and $10^5 \Omega \text{ cm}$) are possible by a careful choice of electrode material (low N_D , low ϵ) and cell arrangement. Flatband potential measurements are thus an important alternative to OCP measurement, but the selected oxide semiconductor should not only have a wide bandgap but also a low dielectric constant and a low doping level. The anodically grown TiO_2 formed here clearly does not provide such a film.

Conclusion

This study shows that the pH response of the OCP of the highly doped conductive oxides on Pt and Ir provides a sensitive and fast means of pH measurements in aqueous solutions at room temperature; unfortunately, the OCP is also dependent on the oxidation/reduction potential of the solution. The OCP response to pH for the less conductive TiO_2 films is in general less reliable than for Pt and Ir oxides. The determination of V_{FB} as a means of measuring pH turned out to be possible only for the polycrystalline TiO_2 films in highly conductive solutions. The V_{FB} is less influenced than the OCP by the oxidation/reduction potential of a certain solution because the Helmholtz potential drop is dominated by adsorption/desorption phenomena of protons rather than electron exchange. If semiconductor electrodes could be used that have a higher impedance in depletion than the TiO_2 films used here, then V_{FB} determination could be done also in solutions of lower conductivity.

ABSTRACT

The effect of nickel electrode partial coverage with polytetrafluoroethylene (PTFE) on the electrode performance for the hydrogen evolution reaction (HER) was investigated. We show that for low current densities the only effect of the electrode coverage is to decrease the effective area. For medium current densities ($>10 \text{ mA/cm}^2$), coverage with PTFE has an overall beneficial effect in the electrode performance even with the resulting decrease in electrode surface area. Finally, for high current densities, in a regime of violent bubble release (1 A/cm^2), coverage effect is decreased but still significant.

In a gas evolving electrode, due to the magnitude of the diffusion coefficients, only a fraction of the electrode surface will interchange electrons at any given moment. This is due to partial surface coverage by bubble formation, which blocks part of the electrode surface. As a result, localized high current densities are observed on certain parts of the electrode surface. Recently, metal perforated diaphragms were partially coated with PTFE and were tested as water electrolyzer separators (1). It was shown that the PTFE coated metal is a bubble scavenger, having an overall beneficial effect on electrolyzer performance. Teflon bonded electrodes have also been used in water electrolyzers. However, it is still not clear how much, if at all, the performance of Teflon bonded porous electrodes is better than platinized or plain electrodes for gas evolution reaction and what the overall effect of PTFE on the performance of gas evolving electrodes is (2, 3).

In this work, we investigated the effect of partial electrode surface coverage with PTFE on the electrode performance for the hydrogen evolution reaction (HER).

Experimental

Circular stainless steel plates with an area of 10 cm^2 and 1 mm thick were initially plated in a Watts solution at 80°C . The plated sample was rotated about its axis at a constant speed in order to smooth out local electric field differences. All samples were prepared from the same stainless steel plate. The plate was initially washed in a detergent solution, mechanically scrubbed, and then cleaned in the following sequence (4): (i) degreasing in methanol for 15 min; (ii) washing in an alkaline bath (KOH 10%) for 5s; (iii) rinsing in distilled water; (iv) washing in an acid bath (H_2SO_4 5%) for 5s; and (v) washing in distilled water.

The nickel-plating solution consisted of the following compounds dissolved in distilled water: $\text{NiSO}_4 \cdot 6\text{H}_2\text{O}$, 300 g l^{-1} , $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$, 45 g l^{-1} , and H_3BO_3 , 30 g l^{-1} . The resulting solution was stirred at 80°C in a Pyrex beaker. The counterelectrode was a nickel sheet. The solution was heated to 80°C prior to each experiment. The total nickel plating time was 12 min. The current density was approximately 10 mA/cm^2 . After plating, the plates were washed with distilled water and dried.

PTFE T30 Teflon dispersion was dialyzed against water to remove the stabilizing surfactant and diluted to ca. 1% in distilled water. The dispersion was then allowed to settle within long (ca. 60 cm) glass cylinders for 15 min, after which time the lower 10% of the cylinder contents were discarded. The dispersion was allowed to settle again, and after 1h the upper half of the cylinder contents were also discarded. To prevent excessive coagulation, 1% sodium laurylsulfate was added to the remaining dis-

persion, for storage. Prior to use, it was drained from a stored, settled dispersion and replaced by distilled water.

PTFE T30 Teflon¹ dispersion was sprayed onto the electrode surface, allowed to dry, and heated in an oven preheated to 370°C . It was left at this temperature for 15 min and cooled by direct exposure to room air. The electrode surface was then washed in an acidic solution to remove the oxides formed, and another layer of nickel was electrolytically deposited on the electrodes. The purpose of this second deposition is to give mechanical stability to the Teflon layer. A photograph of the resulting surface is shown in Fig. 1. If a second nickel layer is not deposited, due to bubble formation, most of the Teflon will be removed from the surface by adsorbing to the gas-liquid interface. Deposition of a second nickel layer prevents the release of the Teflon layer even for high current densities (1 A/cm^2). During the second deposition, the current density was the same as in the first one.

The electrolytic cell employed for current density vs. potential drop measurements was a straight-walled cylindrical Pyrex beaker with a PTFE cover machined to fit (5). The cell containing 30 weight percent (w/o) KOH electrolyte was immersed in a water bath at 80°C . The test electrode and a larger planar platinum electrode were positioned facing each other at a distance of about 4 cm. The electrodes were soldered to a copper wire, and this connection was insulated with silicone rubber. The anode was not submitted to any special treatment. A membrane was inserted between them and kept fixed by a supporting frame. Mercury-mercury oxide electrodes were used as reference electrodes. ($E_{\text{Hg}/\text{HgO}} = 43 \text{ mV/NHE}$ in 5N

KOH solution). The Hg/HgO electrode was inserted into a Luggin probe. The Luggin tip was positioned at the center of the working electrode. The characterization of the electrode was done by measuring cell voltage drop during electrolysis at different conditions, using a current interrupter technique (6) in order to obtain the IR-free electrode voltage.

Results

A number of electrodes was prepared, within surface coverage ranging from zero (uncovered) to 60%. Surfaces of the electrode samples were examined by optical mi-

croscopy. A typical micrograph is shown in Fig. 1. The irregular light (white) pattern observed corresponds to the PTFE deposit, and the dark areas are those of uncovered nickel. The picture was taken after the electrode was operated in HER regime for more than 2h at 1 A/cm². The light and dark tones indicate an irregular topography of the deposit surface. One may clearly observe that the PTFE particles are partially covered by nickel to aid their retention, mechanically. Nickel overlayers give mechanical strength to the Teflon deposits. The edge of the nickel deposit should operate very efficiently since the edges of electrodes are known to operate as efficient bubble generators. Since the metal is better wetted than PTFE, these bubbles should move from the nickel edges to the PTFE surface spontaneously.

Results of current vs. voltage measurements for the electrodes tested are shown in Fig. 2. The current densities shown in Fig. 2 are obtained by dividing the total current I by the geometric area of the circular electrodes (10 cm²). It may be seen that Teflon coverage has a significant effect on the electrode performance. Teflon coated electrodes operated at 500 mA/cm² have lower overvoltage than plain electrodes and are thus more efficient than these.

Discussion

The electrode area covered by PTFE does not participate in electron-transfer reactions, but it draws gas bubbles from the metallic sites, thus leaving more free to adsorb ions from the electrolytic solution and to reduce them. The electrode surface may be seen, then, as a mosaic of regions with different degrees of hydrophobicity, some more hydrophobic (PTFE coated) which can thus draw gas bubbles from the more hydrophilic ones (non-PTFE coated). Current density electrode potential curves obtained by the galvanostatic pulse method show three distinct regions. First, at low current densities (<10 mA/cm²), hydrogen is obtained at sufficiently low rates to diffuse away into the solution without bubble formation. In this region, PTFE coverage is not effective, and uncovered electrodes perform better than the coated ones. Above 10 mA/cm², the uncovered electrodes' overvoltage increases sharply due to bubble formation and concurrent loss of electroactive area. This is not observed in the

Fig. 3. Current densities versus surface coverage for a voltage of (A, left) $V = 1.2V \times Hg/HgO$ and (B, right) $V = 1.6V \times Hg/HgO$

coated electrodes, which perform better in this region because of the bubble scavenging action of the Teflon coated sites, as predicted by the Marangoni effect.

The size of the bubbles in the electrolyte increase when we have PTFE partial covered electrodes due to hydrophobicity of PTFE coating. The effect of the PTFE coverage on the cell ohmic resistance is discussed in Ref. (1).

Once formed in an electroactive (metallic) surface site, a gas bubble may stay there for a relatively long time until removed by convection, stirring, or flotation. A neighboring PTFE surface will cause bubble displacement, leading to lower total interfacial free energy and leaving metallic surface free for further action. Of course, this will not be observed when metal-electrolyte and PTFE-electrolyte contact angle are close.

At very high current densities ($>1 \text{ A/cm}^2$), violent bubble release and thermal convection should be the major factors leading to surface uncoverage. However, at the highest current density used in our experiments, most coated electrodes were more efficient than the uncoated ones.

Figures 3a and 3b showing current densities as a function of electrode surface coverage at given voltages (V) x Hg/HgO can further elucidate the points under discussions. At $V = 1.2$, current densities decrease linearly with coverage, due to surface loss. The straight line between 0% and 100% coverage represents the expected behavior based on surface availability. At $V = 1.6$, current densities are up to 12 times larger than in uncovered electrodes, but they decrease at higher degrees of surface coverage.

Of course, at very high coverages, current densities should approach zero.

In this work, we chose to cover nickel electrodes with Teflon particles in the 10-100 μm size range, following a simple argument: gas bubbles in the 10 μm (and up) radius range should float rapidly in aqueous media. Bubbles much smaller than this would tend to remain dispersed in water, increasing electrolyte resistance and should thus be avoided. Further theoretical and experimental work is required to define the optimum Teflon-particle size and surface coverage to achieve lower electrode overvoltages.

Technical Note

Ionization of Trifluoromethane Sulfonic Acid in Phosphoric Acid Raman Studies

R. Kötz,¹ S. Clouser,^{*2} S. Sarangapani,^{*3} and E. Yeager^{*}

Case Center for Electrochemical Sciences and the Chemistry Department, Case Western Reserve University, Cleveland, Ohio 44106

Much effort has been directed by various investigators (1-3) to optimize platinum catalysts for O_2 reduction in concentrated phosphoric acid. Relatively little attention, however, has been given so far to the acid-base properties of this electrolyte, and the possibility of modifying these properties so as to improve the current-voltage characteristics of platinum catalyzed O_2 cathodes. Through modifications of the acid-base properties, it may also be possible to increase the stability of dispersed Pt and slow down the oxidation of the carbon support.

The proton activity of concentrated H_3PO_4 can be controlled by treating the acid as a parent solvent system and changing its acid-base properties by the addition of strong acids and strong bases. Trifluoromethane sulfonic acid (TFMSA) is one of the strongest protonic acids (4) and, when added to concentrated H_3PO_4 , is expected to increase the proton activity according to the following ionization reaction

^{*} Electrochemical Society Active Member.

In addition to providing a source of protons, this fluorinated acid may also increase the solubility and perhaps also the diffusion coefficient of O_2 . The solubility of O_2 in fluorinated solvents is known to be relatively high (5-8).

In the present work, the acid-base properties of the $\text{H}_3\text{PO}_4\text{-CF}_3\text{SO}_3\text{H}$ have been studied using Raman spectroscopy (for the first time).

Experimental

85% orthophosphoric acid was obtained from Mallinckrodt and purified by treating it first with hydrogen peroxide, then with hydrogen over Pt black, and finally by conventional pre-electrolysis. The details of this purification method have been described elsewhere (9). Higher concentrations of the acid were obtained by distilling water out of the 85% acid. TFMSA was purchased from Alfa-Ventron and distilled twice in an all-glass vessel in an N_2 environment before use. The first 10% of the distillate and last 10% of the residue were discarded. As obtained, the TFMSA was pale straw colored but the doubly distilled acid was colorless.

The Raman spectra were recorded with a Spex Ramanlog spectrometer and Coherent Radiation Model CR-8 argon ion laser. The power output of the laser was 150 mW at the sample at 514.5 nm. The $\text{C}13$ NMR spectra of the doubly distilled $\text{CF}_3\text{SO}_3\text{H}$ and also a 10% $\text{CF}_3\text{SO}_3\text{H}$ solu-

tion in 85% H_3PO_4 were checked with a Varian XL-100 Fourier transform NMR spectrometer and found to contain only the four peaks expected for the CF_3 group. This provides evidence for only one type of carbon in a CF_3 environment to within $\sim 0.1\%$ purity.

The boiling point of the purified $\text{CF}_3\text{SO}_3\text{H}$ was 162°C as compared with a literature value of 162°C (4) at 1 atm. It is unlikely that the purified acid contained significant water since the temperature was constant to within at least 0.5°C during the second distillation. The boiling point of the monohydrate was 210°C .

Results and Discussion

The Raman studies⁴ have been carried out in the $\text{CF}_3\text{SO}_3\text{H}\text{-H}_3\text{PO}_4$ mixtures principally to establish whether the $\text{CF}_3\text{SO}_3\text{H}$ is completely ionized in the mixture, and to see if there are any unusual species present in the mixtures.

In Fig. 1 are compared the Raman spectra obtained in doubly distilled pure TFMSA (spectrum A), purified 85% H_3PO_4 corresponding to a mol fraction $X_{\text{H}_3\text{PO}_4} = 0.5$ (spectrum B), and a 10% by volume solution of TFMSA in 85% H_3PO_4 corresponding to $X_{\text{TFMSA}} = 0.0426$, $X_{\text{H}_3\text{PO}_4} = 0.479$, and $X_{\text{H}_2\text{O}} = 0.479$ (spectrum C).

The insert in this figure indicates the Raman spectrum for 10% by volume TFMSA in 100% H_3PO_4 corresponding to $X_{\text{TFMSA}} = 0.062$. The spectrum for the TFMSA- H_3PO_4 solution is the sum of spectra A and B with the exception of an additional vibrational band at 1033 cm^{-1} , which is due to the S—O stretching vibration of the $[\text{CF}_3\text{SO}_3]^-$ anion. This frequency assignment has been made in accord with the published infrared spectra of aqueous solutions of TFMSA and mixtures of TFMSA with other acids (10). Since the TFMSA molecule has no center of symmetry, most of the observed Raman lines are also present in the infrared absorption spectrum.

It is not clear whether the $[\text{CF}_3\text{SO}_3]^-$ ion indicated by the Raman band at 1033 cm^{-1} is formed as a result of the formation of a $[\text{H}_4\text{PO}_4]^+$ cation or H_3O^+ from H_2O in the concentrated H_3PO_4 , according to the reactions

⁴ Some consideration is also being given to carrying out infrared measurements which should be more directly sensitive to the H_3O^+ vs. H_4PO_4^+ species, but cell windows present a problem.

Fig. 1. Raman spectra of (A) pure TFMSA, (B) 100% H_3PO_4 , (C) 10% (volume) TFMSA in 85% H_3PO_4 . Insert: 10% TFMSA in 100% H_3PO_4 . Excitation: 514.5 nm argon ion laser line; slit width: $400\ \mu\text{m}$; resolution: 5 cm^{-1} . Relative sensitivity: (A) 500 k, (B) 50 k, and (C) 100 k.

If reaction [3] is predominant, the H_3O^+ species would differ from that encountered in ordinary acid solutions because there would be insufficient water to solvate it to the usual hydronium ion $[\text{H}_3\text{O} \cdot 3\text{H}_2\text{O}]^+$ or $[\text{H}_9\text{O}_4]^+$. Rather, the $[\text{H}_3\text{O}]^+$ could probably be solvated predominantly by H_3PO_4 to form $[\text{H}_3\text{O} \cdot 3\text{H}_3\text{PO}_4]^+$ with the protons of the $[\text{H}_3\text{O}]^+$ interacting with the O of the O = P of the H_3PO_4 .

To check into this further, the dependence of the intensity of the 1033 cm^{-1} peak on TFMSA concentration has been examined in the H_3PO_4 . The integrated peak intensity of the vibrational band at 1033 cm^{-1} (corresponding to the S—O stretch in the CF_3SO_3^- anion) has been measured relative to that of the 772 cm^{-1} peak as a function of the concentration of the TFMSA added in pure water and 85% H_3PO_4 (see Fig. 2). The band at 772 cm^{-1} is attributed to the C-S vibration of both the TFMSA molecule and its anion and hence depends only on the total amount of TFMSA added. Consequently, the I_{1033}/I_{772} ratio is related to the fraction of the TFMSA which is ionized. This intensity ratio is related to the concentrations of the ionized (C_1) and unionized (C_2) $\text{CF}_3\text{SO}_3\text{H}$ by an equation of the form

$$I = \frac{I_{1033}}{I_{772}} = \frac{(k_1)_{1033}C_1}{(k_1)_{772}C_1 + (k_2)_{772}C_2} = \frac{(k_1)_{1033}X_1}{(k_1)_{772}X_1 + (k_2)_{772}X_2} \quad [4]$$

where X_i is the mol fraction of the subscripted species and $(k_1)_{1033}$, $(k_1)_{772}$, and $(k_2)_{772}$ are the molar Raman scattering coefficients and will be assumed to be constant [see, e.g., Ref. (12)]. Note that the total number of mols is not changed by reactions [2] and [3]. If the equilibrium constants for the reactions are larger compared to unity, then for $X_1 < 0.5$

$$X_1 = X_{\text{H}_3\text{PO}_4}^0 + X_{\text{H}_2\text{O}}^0 \quad [5]$$

and

$$X_2 = X_{\text{CF}_3\text{SO}_3\text{H}}^0 - X_1 \quad [6]$$

where the superscripted symbols correspond to the mol fractions on the basis of the initially added components. Equation [4] can then be rearranged to the form

Fig. 2. Ratio of integrated peak intensity of the 1033 cm^{-1} Raman peak (corresponding to S—O in CF_3SO_3^-) to that of the 772 cm^{-1} peak (corresponding to C-S) as a function of the TFMSA concentration. Laser excitation: 514.5 nm (argon). Open points: TFMSA in H_2O ; solid points: TFMSA in 85% H_3PO_4 ; full line: calculation for TFMSA in H_2O assuming that one H_2O is needed to ionize one TFMSA and $(k_1)_{772} = (k_2)_{772}$.

$$\frac{y}{I} = \frac{(k_2)_{772}}{(k_1)_{1033}} - \left[\frac{2(k_2)_{772} - (k_1)_{772}}{(k_1)_{1033}} \right] \cdot y \quad [7]$$

where

$$y = 1 - X_{\text{CF}_3\text{SO}_3\text{H}} = X_{\text{H}_3\text{PO}_4} + X_{\text{H}_2\text{O}}$$

An identical equation is obtained for the $\text{CF}_3\text{SO}_3\text{H}-\text{H}_2\text{O}$ mixture except that $y = X_{\text{H}_2\text{O}}$. If only the water in the $\text{H}_3\text{PO}_4/\text{H}_2\text{O}$ system is capable of solvating the proton, then Eq. [7] is replaced by

$$\frac{y}{I} = \frac{2(k_2)_{772}}{(k_1)_{1033}} - \left[\frac{3(k_2)_{772} - (k_1)_{772}}{(k_1)_{1033}} \right] \cdot y \quad [8]$$

Thus, a comparison of the plots of y/I vs. y for the $\text{CF}_3\text{SO}_3\text{H}-\text{H}_2\text{O}$ and the $\text{CF}_3\text{SO}_3\text{H}-\text{H}_3\text{PO}_4-\text{H}_2\text{O}$ can indicate whether the H^+ of the $\text{CF}_3\text{SO}_3\text{H}$ is solvated by H_3PO_4 , as well as H_2O in the 85% H_3PO_4 or just by the H_2O . Plots of y/I vs. y are given in Fig. 3.

The agreement of the data for the binary and ternary systems with the general form of Eq. [7] is satisfactory considering the difficulty of obtaining accurate values for the ratio y/I as y and I both approach zero. Furthermore, the data for the binary and ternary system coincide reasonably well, indicating that the H_3PO_4 , as well as H_2O solvate the proton. If only the H_2O participated in the proton solvation, then the intercept for the ternary system would be twice as great as for the binary system and the intercept of the linear region at low values of y with the limiting y/I value would be at 0.66 rather than 0.5 (see dashed line in Fig. 3).

At lower concentrations in the H_3PO_4 solutions, however, it is not possible with these data to say what fraction of the protons are in the form of H_3O^+ and H_4PO_4^+ . In principle, it should be possible to establish the ionization constants for the TFMSA in the water and H_3PO_4 -water solutions from the curvature in the region between the two linear portions of each curve, but the accuracy does not appear sufficient with the present measurements even if more points were available. Infrared absorption measurements of the OH stretch in the H_3O^+ and H_4PO_4^+ species or proton NMR appear more promising approaches to establishing the predominant species in these solutions.

The half-width of the 1033 cm^{-1} peak has also been examined as a function of TFMSA in both pure water and 85% H_3PO_4 (see Fig. 4). The half-width decreases substantially with dilution in the TFMSA-water solutions approaching the instrumental line width at low concentrations under the particular operating conditions used in these experiments. In contrast, the half-width is essen-

Fig. 3. Ratio y/I as a function of y where y is the mole fraction of H_2O (○) or 85% H_3PO_4 (●). The relative intensity I is taken from Fig. 2. The calculated results for Eq. [7] (—) and [8] (---) are also given.

Fig. 4. Half-width of the 1033 cm^{-1} Raman line vs. concentration of trifluoromethane sulfonic acid in water (open points) and 85% H_3PO_4 (solid points).

tially independent of TFMSA concentration in the 85% H_3PO_4 .

The sources of line width broadening in liquids are severalfold and are the subject of considerable discussion (11). For an anisotropic polarizable rotor such as CF_3SO_3^- , they include rotational diffusion in addition to collision processes, hydrogen bond formation kinetics, and ion pair and ionization kinetics at the very high concentrations involved in concentrated acids, such as involved in the present study. Further, the CF_3 internal rotor, partially restricted by hydrogen bonding to H_2O and H_3PO_4 molecules, can also contribute to line broadening. No one of these factors, however, appears capable of explaining the wide line widths and the concentration dependence in water and lack of such in 85% H_3PO_4 in Fig. 4. Depolarization Raman measurements and NMR measurements would prove helpful in interpreting this behavior.

A few NMR measurements have been performed by the authors on the $\text{CF}_3\text{SO}_3\text{H}-\text{H}_3\text{PO}_4-\text{H}_2\text{O}$ solutions. The proton-spin resonance measurements using a 60 MHz Varian EM 360 permanent magnet NMR spectrometer indicate only a single proton peak at room temperature at concentrations varying from 0 to 100% $\text{CF}_3\text{SO}_3\text{H}$ in 85% H_3PO_4 . If any of the equilibria such as those represented by Eq. [2] and [3] were relatively slow, then more than one type of proton signal would be expected; thus, implying that all the equilibria are fast on the NMR time scale. The line width of the proton peak decreases with increasing $\text{CF}_3\text{SO}_3\text{H}$ concentration. The C-13 spectra of the pure $\text{CF}_3\text{SO}_3\text{H}$ and 10% by volume solutions of this acid in 100% H_3PO_4 showed the expected four peaks with no anomalies or impurity peaks evident.

Conclusion

The Raman spectroscopy studies indicate that the TFMSA is essentially completely ionized in H_3PO_4 and $\text{H}_3\text{PO}_4-\text{H}_2\text{O}$ solutions for a mole fraction X_{TFMSA} below 0.4. NMR measurements on the mixed acid solutions indicate only one proton spin resonance line and the expected C-13 spectrum for the CF_3SO_3^- . Therefore, the acid ionization processes are quite fast. The protons in the mixed acid solutions are most likely in the forms $(\text{H}_4\text{PO}_4)^+$ and $(\text{H}_3\text{O})^+$.

Electron Injection and Avalanche during the Anodic Oxidation of Tantalum

J. M. Albella,* I. Montero, and J. M. Martínez-Duart

Instituto de Física del Estado Sólido (CSIC) and Departamento de Física Aplicada, C-12, Universidad Autónoma, Cantoblanco, Madrid-34, Spain

ABSTRACT

The consequences of the avalanche-breakdown model during the growth of anodic tantalum oxide in H_3PO_4 electrolytes are discussed. Typical values of the injected current density at the electrolyte-oxide interface, the impact ionization coefficient, and the electric field during anodization have been determined from the anodization characteristics at a constant current. The results are interpreted assuming that the injected current has its origin in the electrolyte anions incorporated into the oxide during the anodization process.

The anodic oxidation of valve metals is a process of high technical and scientific interest because of its implications in the manufacturing of electrolytic capacitors, in the preparation of passivating layers in thin film technology, and in the growth of protective and decorative films (1). The practical limit to the maximum thickness of the oxide reached in the anodization process is given by the breakdown voltage across the film. There is a great amount of literature concerning the nature of the breakdown process, and some empirical relations between the breakdown voltage and anodization parameters have been established (2). Kadari and Klein have studied the electrical breakdown during the anodic growth of Ta_2O_5 and Al_2O_3 and explained it by the theory of stochastic succession of avalanches (3). Recently, Ikonopisov has put forward a model of breakdown caused by the avalanche of electrons injected at the electrolyte/oxide interface during anodization (4). This model is able to explain the well-known linear dependence of the breakdown voltage on the logarithm of the electrolyte resistivity. Lately, the model has been extended by Albella *et al.* to explain the curvature of the voltage curve as a function of time in anodization experiments of tantalum at a constant current density (5). In the present paper, we further examine the implications of this model. In particular, by a careful determination of the slope of the voltage curve, dV/dt , the injected current density, j_0 , and the ionization coefficient of the avalanche have been calculated from the anodization curves of tantalum at a constant current. The results are interpreted on the basis of an alternative model for the injected electronic current at the electrolyte/oxide interface.

Theory

Figure 1 shows the mechanism of avalanche breakdown proposed by Ikonopisov. In this model, an electronic current j_0 is supposed to be injected from the electrolyte to the oxide conduction band by a Schottky mechanism. Other injection mechanisms, such as the Fowler-Nordheim tunneling, have been suggested, for example, by Kadary and Klein (3). The injected electrons are accelerated towards the anode by the strong

field of anodization, causing an avalanche breakdown when a certain critical electron current is reached.

In a simple avalanche model of breakdown during anodic oxidation, one can assume that the electronic current density, j_0 , injected to the conduction band of the oxide from the electrolyte/oxide interface, increases exponentially according to an avalanche process (4). Therefore, the electronic current density at the anode, j_e , should be given by: $j_e = j_0 e^{\alpha d}$, where α is the impact ionization coefficient and d is the distance traveled by the primary electrons on their way to the anode. As a first approximation, one can assume d equal to the total oxide thickness.

In anodization experiments at constant current density, j_t , the oxide thickness increases linearly with the voltage ($d = aV$). As a consequence, the differential equation regulating the growth of potential with time is given by

$$\frac{dV}{dt} = Kj_t \quad [1]$$

where j_t is the ionic current density of anodization, and K is the unitary anodization rate, given by

$$K = \frac{ME}{10F\rho} \quad [2]$$

In this formula, M is the molecular weight of the resulting oxide, F the Faraday constant, ρ the oxide density, and E the electric field during anodization (1). Taking into account the presence of the avalanche electronic current j_e during the anodization, the ionic current will be: $j_i = j_t - j_e$, so that

$$\frac{dV}{dt} = K(j_t - j_e) = K(j_t - j_0 e^{\alpha d}) = K(j_t - j_0 e^{\alpha' V}) \quad [3]$$

with α' equal to $\alpha \cdot a$.

The three parameters K , j_0 and α' of Eq. [3] can be obtained through an accurate determination of the variation of the dV/dt values with the voltage in the range of voltages where no scintillation sparks appear. By operating in Eq. [3], one obtains

$$\ln \left(1 - \frac{1}{Kj_t} \frac{dV}{dt} \right) = \ln \frac{j_0}{j_t} + \alpha' V = \ln \left(\frac{j_e}{j_t} \right) \quad [4]$$

Fig. 1. Schematic representation of the band structure and the avalanche breakdown mechanism during anodization.

Therefore, a graphic representation of the values of $\ln \left(1 - \frac{1}{Kj_t} \frac{dV}{dt} \right)$ as a function of the anodization voltage, V , must fit a straight line whose slope is α' , and the intersection with the ordinate axis is given by $\ln(j_0/j_t)$. The first step in this calculation is to find the value of the constant K . An approximate value of K can be obtained from the extrapolated value of dV/dt at $V = 0$, which from Eq. [3], and with the additional condition $j_0 \ll j_t$, is given by

$$K = \frac{(dV/dt)_{V=0}}{j_t} \quad [5]$$

However, in order to find a more accurate value of K , α' , and j_0 , we have followed an iterative method of least squares fitting of the experimental values of dV/dt to the theoretical Eq. [3].

Experimental

In our experiments, tantalum foil from Reframet Hoboken, of 99.96% purity, was anodized at a constant current density. Previously, the samples were cleaned and chemically polished following standard treatments (5). In order to avoid the creeping of the electrolyte and the spurious effects at the edges of the foil during anodization, a sample holder was used (see Fig. 2), which only exposed to the electrolyte a circular area of $1.18 \pm 0.04 \text{ cm}^2$ of the foil. Optical microscope observations of the anodized area showed that the penetration of the electrolyte under the holder was always less than $10 \mu\text{m}$ wide, resulting in a variation of the surface area during the anodization less than 0.4%. During the experiments, the total current supplied by the source was kept constant within $\pm 0.1\%$. All anodization experiments were performed in an electrolyte of phosphoric acid dissolved in water (0.01%) giving a resistivity of $2280 \Omega \cdot \text{cm}$. By using a stirred thermostat bath, the temperature of the electrolyte close to the sample was always maintained at $20^\circ \pm 0.2^\circ\text{C}$.

Figure 2 shows the experimental setup used in our experiments. The data acquisition system, composed of the HP 3497A digital voltmeter (input impedance $> 10^7 \Omega$) and the HP85 microcomputer, allowed us to obtain directly the variation of the anodization voltage with time, its derivative, and the parameters j_0 , K , and α' which best fit the dV/dt curves. In the measurement of the $\Delta V/\Delta t$ values, the voltage increments were always kept below a few volts. Therefore, fixed time intervals of measurement were adjusted according to

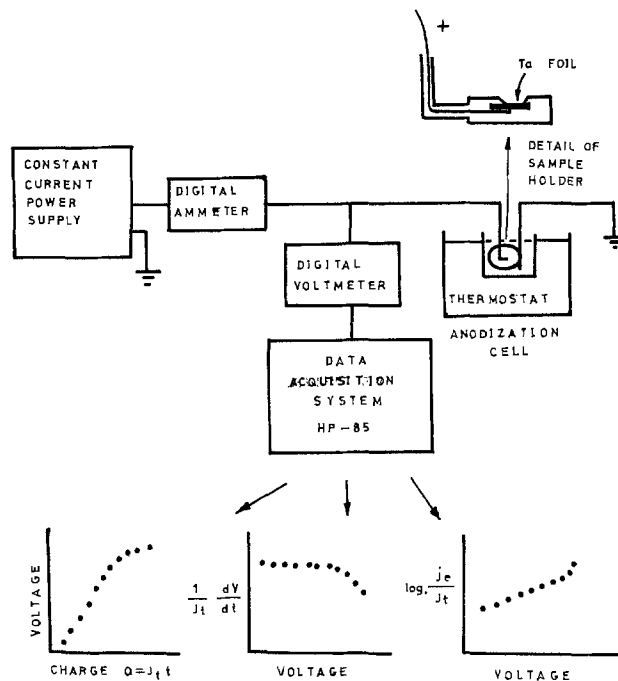

Fig. 2. Experimental setup

the magnitude of the anodization current. Taking into account the resolution in the measurement of voltage (1 mV) and time ($10 \mu\text{s}$) the overall error in the derivative was always below 0.1%. It is important to emphasize that the voltage-time curves are generally reported in the literature as being linear, even at high anodization voltages. However, the nonlinearity effects, which become more apparent in the derivative curve, are very important, since they can be related to the avalanche and breakdown mechanisms.

Results and Discussion

Figure 3 (curves a-e) gives some examples of the variation of the unitary anodization rate ($1/j_t$) (dV/dt) vs. V in typical experiments at different current densities. As can be observed, there is a slight diminution of the $(1/j_t)$ (dV/dt) values with the anodization voltage, until the scintillation voltage, V_s , is reached. For voltages higher than V_s , the experimental values of dV/dt are erratically scattered, due to the onset of the breakdown process. According to the method previously described, we have computed from the data shown in Fig. 3, the values of K , j_0 , and α' in Eq. [4]; this should fit the computed values of $\ln(j_0/j_t)$ to a straight line.

Fig. 3. Unitary anodization rate as a function of the anodization voltage for different current densities (lines indicate the theoretical values calculated according to the model by a least squares fitting).

Fig. 4. Fitting of the experimental values of $\ln(j_e/j_i)$ to a linear variation with the anodization voltage, according to Eq. [4] (symbols as in Fig. 3). There has been a vertical displacement of the curves so that each straight line is bounded between the 10^{-1} and 10^{-2} values of j_e/j_i , as for the top line.

The adjustment is shown in Fig. 4. As it can be appreciated, a good linearity in the calculated values of $\ln(j_e/j_i)$ is obtained within a wide range of the anodization voltage.

The electric field E present during anodization can be directly evaluated from Eq. [2], once the value of K has been determined. Using the value of $\rho = 8.03 \text{ g} \cdot \text{cm}^{-3}$ for the density of the oxide (6), Fig. 5 gives a plot of the calculated values of the electric field as a function of the ionic current density $j_i = j_t - j_e$. As can be observed, there exists an approximate exponential dependence of the ionic current on the electric field, in agreement with the experimental results obtained by Dell'Oca and Young (dashed curve in Fig. 5) based on the direct measurement of the oxide thickness corresponding to a definite anodization voltage (7). According to Dignam's analysis (8) of the high field ionic conduction in solids, the field E , and therefore dV/dt , decreases as the film grows. Specifically, the exponential dependence of E on the thickness d for a fixed current density j should be the same as the dependence of E on j for fixed d . This fact implies that the predicted diminution of E during the film growth should be the same as the increase of the field with the ionic current density (see Fig. 5). It might appear at first that the variation of dV/dt measured in our work could be caused by this effect. However, a straightforward

Fig. 5. Ionic current density as a function of the anodization field [the broken line corresponds to the results of Ref. (7)].

calculation shows that the variations in our values of dV/dt and the decrease in E predicted by Dignam's model differ by a factor of about four. For example, from Fig. 3, the decrease in E [calculated from the variation of $(1/j_i)$ (dV/dt) for a tenfold increase of voltage (20 to 200V)] is on the average 3% for a given current density. However, the increase shown by E for a 1 decade change in current density in Fig. 5 is nearly 12%.

It is interesting to compare the calculated values of the injected electronic current, j_e , and the ionic current of anodization. The log-log plot of Fig. 6 gives a straight line whose slope is nearly 45° , thus indicating that the electronic current varies linearly with the ionic current, independently of the value of the total anodization current. The quotient j_e/j_i is about $4 \cdot 10^{-2}$ which means that for the particular anodization electrolyte used in this work, the electronic current amounts to 4% of the ionic current. This value of the electronic current might seem too high when compared with the reported values of the current efficiency during anodization. As it is known, in the case of tantalum, the current efficiency is close to 100% in experimental conditions similar to ours (9). Furthermore, if the electronic current calculated in this work were injected from the electrolyte into the oxide, it would give rise to a visible evolution of oxygen at the oxide surface. However, no bubbles were observed at anodization voltages below the sparking voltage. Although one may speculate that the reduction of the slope dV/dt may be produced by a decrease of the electric field caused by local heating in the film, this does not seem likely in view of the facts that this effect is exhibited at voltages well below the sparking voltage and that some of the experiments were performed at very low current densities.

Within the analysis of the possible causes of the electronic current present during the anodization, one finds the remarkable fact that the above ratio of the injected electronic current to the ionic current coincides with the reported ratio of the mol concentration of anions incorporated into the outer part of the oxide per mol of Ta^{5+} , which is in the range of 3-5% for the electrolyte used in this work (10, 11). Therefore, one tentatively could associate this "electronic" current with the movement of charged anions across the electrolyte/oxide interface. In fact, according to Amsel *et al.* (9), the way by which the electrolyte species are incorporated into the oxide seems to be in the form of PO_4^{3-} anions. As a consequence, there must be an ionic current through the electrolyte/oxide interface associated with

Fig. 6. Electronic vs. ionic current densities during anodization

the charge transported by these anions. This view is further supported by recent experiments (12) performed with H_3PO_4 electrolytes in different concentrations, which show a strong correlation between the quotient j_0/j_i and the corresponding anion concentration incorporated into the oxide.

Given the absence in the literature of a detailed mechanism of the incorporation of the electrolyte ions into the oxide lattice, it is difficult to put forward a model that can explain the onset of the avalanche process proposed in this work. However, some speculations can be made. One of the possible reactions for the incorporation of the PO_4^{3-} anions suggested by Amsel *et al.* (9) is $\text{PO}_4^{3-} \rightarrow \text{PO}_3^- + \text{O}^-$. Under these circumstances, the PO_3^- ions could act as a source of electrons acting like donor levels. The resulting electrons, probably liberated by a Poole-Frenkel mechanism, can then be accelerated by the strong anodization field, bringing about the avalanche multiplication.

On the basis of the above model, the primary electrons are expected to travel a distance to the anode less than the oxide thickness because the electrons are liberated from sites within the outer layer of the oxide. Some observations about this distance can be made from the calculated values of the ionization coefficient, $\alpha = \alpha'/a$. Table I shows the calculated values of α , using for a the value given by $a = 1/E$. As it can be observed, α increases with the anodization field, in agreement with the avalanche theories (13), although the absolute values of α are somewhat lower than the ones reported in the literature. Kadary and Klein, for example, obtain a value of $\alpha = 1.1\text{--}1.4 \times 10^5 \text{ cm}^{-1}$ from electroluminescence and pulse breakdown measurements in Ta_2O_5 films (3, 14), which is more than twice the value obtained in this work. Since the values of α of Table I are obtained through the product αd , a better agreement of α with the published values results if one considers that the distance traveled by the primary electrons is smaller than d . In relation to this, the ionization coefficient for aluminum oxide calculated by Shimizu (15), on the basis of the results of Ikonopisov *et al.* (16), is $\alpha = 2 \cdot 10^4 \text{ cm}^{-1}$. Shimizu objected that this value is too low for the Ikonopisov's model to be accepted. However, this objection can be partially disregarded in the light of our model for the origin of the primary electron current.

Another important question which often arises is whether the electronic current reaching the anode ($j_0 e^{\alpha d}$, according to this work) is high enough to cause the breaking down of the tantalum oxide. At present, there is not a definite answer to this matter. As it can be appreciated from Fig. 4, the avalanche electronic current departs from the exponential dependence, increasing at a faster rate, when the anodization voltage

approaches the sparking voltage. One can assume that, under these circumstances, a new avalanche process starts, which is triggered by the field originated by the spatial charge left by the ionized atoms. The role of the spatial charge has been studied in detail by Kadary and Klein (3) in their theory of stochastic succession of avalanches, and it might be the direct cause of the abnormal rise of the electronic current at high voltages.

Conclusions

The experimental results on the anodization rate of tantalum in an H_3PO_4 electrolyte with different current densities in a wide range of voltages show a good fit to the theoretical curves obtained under the hypothesis of an exponential increase of electronic current present during anodization. This fact provides strong evidence of the avalanche breakdown model in anodic oxides proposed by Ikonopisov (4), and lately extended by Albella *et al.* (5), in order to explain the scintillation process. On the origin of the primary electrons causing the avalanche breakdown, we propose that these electrons, instead of being injected through the electrolyte/oxide interface, are originated within the oxide itself by the ionization of the electrolyte impurities incorporated into the oxide film during the anodization.

Acknowledgments

We would like to thank Professor S. Ikonopisov and Ms. M. Machkova (Higher Institute of Chemical Technology, Sofia, Bulgaria) for helpful discussions regarding the avalanche mechanisms. We are also indebted to the Comisión Asesora de Investigación Científica y Técnica, Spain, for partial support of this work.

Sputtering Yield of Carbon Atoms in Organic Materials for Oxygen Bombardment

H. Gokan and S. Esho

NEC Corporation, Microelectronics Research Laboratories, Miyamaeku, Kawasaki 213, Japan

ABSTRACT

Etching mechanisms for organic materials in oxygen ion-beam etching has been discussed in terms of sputtering yield of carbon atoms. The sputtering yield, which is defined by the number of sputtered carbon atoms per O_2 ion, exceeds the value of 2 under high oxygen pressure conditions. Mass analysis indicates that the final product during etching is CO. The main reaction for carbon consumption is assumed as being $2C + O_2^+ + nO_2 \rightarrow 2(n+1)CO$, where the nO_2 term expresses the reaction with neutral oxygen molecules. Net sputtering yield is expressed by three factors; physical sputtering, chemical reaction with accelerated oxygen ions, and the ion-assisted reaction with neutral oxygen molecules. The etching model, considering the ion-assisted reaction, qualitatively explains the increase in sputtering yield with decreasing acceleration energy (decreasing current density) and with increasing oxygen pressure.

Reactive ion etching in oxygen plasma has become highly attractive, since it was applied to the etching of thick organic layers in multilevel resist systems (1). The etching provides organic patterns in submicron dimensions with high aspect ratio. However, the etching mechanism for organic materials has not yet been fully understood. In reactive ion etching (RIE), generally, it is difficult to control ion energy and ion current density as well as to separate the radical-species contribution to the etching. However, in oxygen ion-beam etching (IBE), the effect of fundamental parameters, such as acceleration energy and current density on the etch rates, can be investigated qualitatively (2-4), since etching characteristics are investigated in a more controlled environment. In the present paper, etching characteristics and etching mechanism for organic materials are discussed in terms of sputtering yield of carbon atoms for oxygen bombardment.

Etch Rate Measurement

An ion-beam etching system with Kanfan ion source was used in the experiments. Oxygen pressure was monitored at the top of the diffusion pump. Etch-

Key words: oxygen ion-beam etching, resists, sputtering yield.

ing samples were mounted on a water-cooled rotary stage using a heat-sink material, Electron grease (5).

Figure 1 shows etch rates of PMMA and/or Au as a function of oxygen pressure for acceleration energies ranging from 200 to 750 eV. The exposed area of PMMA to the ion beam was about 1 cm^2 . The etch rate for PMMA increases with increasing oxygen pressure and tends to level off at high acceleration energies. Figure 2 shows the loading effect on the etch rate for PMMA. The abscissa shows the exposed area of the PMMA to the ion beams. The data were taken under the condition of 2×10^{-4} torr (2.6×10^{-2} Pa) oxygen pressure, 0.82 mA/cm^2 current density, and 500 eV acceleration energy. It is found that the etch rate slightly decreases when increasing the exposed area of the PMMA. The resist-etch rate was measured for argon bombardment. Figure 3 shows energy dependence for AZ1350J etch rate normalized at 1 mA/cm^2 current density. The reason why AZ1350J is used instead of PMMA is that AZ1350J is more stable than PMMA under high energy argon ion-beam etching conditions (6). The scattering of data observed at energies lower than 200 eV may be due to the effect of the residual background oxygen

Fig. 1. Etch rates for PMMA and Au as a function of oxygen pressure.

Fig. 2. Etch rate and effective carbon sputtering yield vs. sample area exposed to ion beams.

pressure. Sputtering yields of Au for argon and oxygen bombardments are shown for comparison.

Mass Spectrometric Measurement

For oxygen ion-beam etching, final etch products of PMMA were analyzed by means of a quadrupole mass spectrometer. Oxygen pressure during etching was 5×10^{-5} torr (6.7×10^{-3} Pa). Mass spectra before and during etching are shown in Fig. 4a and 4b. A marked difference in the mass spectra is noticed at CO and H₂ peaks. However, only a small change is observed at CO₂ and H₂O peaks. These results contradict the report that the etch products of stripped photoresist in an oxygen plasma are mainly H₂O, CO₂, and CO (8). This is because, in the present etching system, radical species contribution to the etching is negligibly small (5). Figure 5 shows intensity changes in each species as a function of the acceleration energy. The etch rate for PMMA is also shown for comparison. It was found that, with the increase in etch rate, CO intensity increases, while O₂ intensity decreases.

Definition for Sputtering Yield

Sputtering yield Y_c of carbon atoms in metal-free organic polymers is given by

$$Y_c = \rho V N_c / 60 M J$$

$$= \rho V N_c / 60 N M J \quad [1]$$

where ρ denotes the polymer density (g/cm^3), V the etch rate ($\text{\AA}/\text{min}$), N_c the number of carbon atoms in a monomer unit, N the total number of atoms in a monomer unit, \bar{M} the average atomic weight in a monomer unit (g), M the atomic weight in a monomer unit (g), and J the ion current density (mA/cm^2). Since ρ/\bar{M} is empirically almost constant in metal-free organic polymers, Y_c is expressed by $Y_c \propto V/J \cdot N/N_c$. However, in ion-beam etching, etch rates for organic materials are found to linearly depend on $N/(N_c - N_o)$ factor, not on N/N_c , as reported in the previous paper (5), where N_o denotes the number of oxygen atoms in a monomer unit. This result suggests that the sputtering yield of metal-free organic materials for oxygen bombardment should be considered due to the sputtering yield of "effective" carbon atoms. The term "effective" means subtracting the number of oxygen atoms from that of carbon atoms in polymers. The yield is defined by

$$Y = \rho V (N_c - N_o) / 60 M J \quad [2]$$

Using Eq. [2], effective carbon sputtering yields were calculated from the etch rate data for PMMA, as shown in Fig. 6, where the values of 1.36 and 100 were

used for ρ and M , respectively. Since the current density varies depending on oxygen pressure and acceleration energy, the values are shown in parentheses. The yield increases with increasing oxygen pressure and tends to level off. On the contrary, the yield decreases with increasing acceleration energy under high oxygen-pressure conditions.

Etching Model

Mass spectroscopic analysis suggests that the main reaction for carbon consumption in polymers is expressed by

As shown in Fig. 6, the sputtering yield under high oxygen pressure condition was much higher than 2. However, the maximum sputtering yield of carbon atoms derived from Eq. [3] is 2, provided that the physical sputtering yield is negligibly small. Therefore, Eq. [3] should be modified to closely describe the high sputtering yield. By assuming the contribution of neutral oxygen molecules, a sputtering yield larger than 2 is explained by

Fig. 3. Acceleration energy dependence of AZ1350J etch rate for argon bombardment.

Fig. 4. Mass spectra before and during oxygen ion-beam etching of PMMA.

Fig. 5. Mass spectra for CO, H₂, and CO₂ as a function of acceleration energy. Etch rate for PMMA is shown for comparison.

The other possible factor, which explains the increase in sputtering yield under a high oxygen-pressure condition, is the charge transfer: conversion of a fraction of the ion beam into energetic neutrals. This leads to underestimating the current density under high oxygen-pressure conditions. Since the charge transfer increases with increasing oxygen pressure, the sputtering yield apparently increases with increasing oxygen

Fig. 6. Effective carbon sputtering yield vs. oxygen pressure at 200, 300, 500, and 750 eV acceleration energies.

pressure. The experimental results ruled out the contribution of charge transfer to the yields. That is, as shown in Fig. 1, the sputtering yield for Au does not increase with oxygen pressure in the range presently examined. According to Mayer *et al.* (4), the net sputtering yield of effective carbon atoms in polymer is expressed by three components.

$$Y = Y_1 + Y_2 + Y_3 \quad [5]$$

The first term, Y_1 , is due to physical sputtering yield. The second term, Y_2 , represents chemical sputtering yield due to the accelerated O_2^+ beams itself. Provided that all the incident O_2 reacts with carbon atoms to form the final product of CO, Y_2 equals 2. The last term, Y_3 , represents the sputtering yield due to the ion-assisted chemical reaction (3, 4, 9) with neutral oxygen molecules. Observation of H_2 as etch products suggests that the O_2 bombardment generates a high density of radical sites in the polymers. Neutral oxygen molecules can adsorb on these sites and react with the carbon atoms to form the volatile product CO. The ion-assisted etch rate is represented by the product of the number of oxygen molecules incident on the polymers and the probability of hitting the activated sites left in the polymers. For an equilibrium state, etch rate V is given by

$$V \propto JY_3 = (P - \beta JSY_3)(1 - KJY_3/DJ) \quad [6]$$

where Y_3 denotes the sputtering yield due to ion-assisted reaction, J the ion current density, S the sample area exposed to oxygen ion beam, and D the number of activated sites generated by the accelerated ion-beam incidence per unit current density, respectively. Constants are α , β , and K . The term βJSY_3 represents the loading effect; dilution of the number of oxygen molecules due to the product formation. Equation [6] is written by

$$P/J = \beta SJY_3 + D/\alpha K \cdot (Y_3/(D - KY_3)) \quad [7]$$

Net sputtering yield Y is given by

$$Y = Y_1 + Y_2 + Y_3(P/J, S) \quad [8]$$

Equation [8] suggests that net sputtering yield should be expressed as a function of P/J ratio. Figure 7 shows the net sputtering yield Y as a function of P/J ratio for acceleration energies, where P and J are expressed in the unit of 10^{-5} torr and mA/cm², respectively. At $P = 0$, sputtering yield $Y_1 + Y_2$ represents the reaction of the beam itself. This inherent sputtering yield is given by the ordinate intercept shown in Fig. 7. The term $Y_1 + Y_2$ equals 1.4, which is mostly independent of the acceleration energy. Using Eq. [8], constants are determined so as to fit the data shown in Fig. 2 and 7. Constants α and β are determined to be 0.13 and 0.25, respectively. The values of D/K are also determined to be 6.0 for 500 eV and 4.9 for 200 eV acceleration energies. Although the number of activated sites D generated by the accelerated ion beam per unit current density, generally, strongly depends on acceleration energy, the result indicates that the energy dependence of D is small.

The value of D is considered to be proportional to the physical sputtering yield Y_1 at a fixed ion-beam incidence. The physical sputtering yield is estimated from the data shown in Fig. 3. The sputtering yield of Au for oxygen bombardment is about half as large as that for argon bombardment. This represents the difference in physical sputtering yield, since Au does not chemically react with oxygen. Therefore, the physical sputtering yield for carbon atoms during oxygen bombardment is estimated to also be half as large as that for argon. From the result, Y_1 is estimated to be about 0.16 at 500 eV acceleration energy, using Eq. [2]. This physical sputtering yield shows little dependence on acceleration energies, at least at values higher than 200 eV. This coincides with the estimate that D differs by only 20% between 200 and 500 eV acceleration energies. The fact that the physical sputtering yield for carbon atoms in polymers has little acceleration energy dependence may be explained as follows. For a target having atomic arrays, the general overall collision process is similar to a diffusion process of mobile atoms, where some of the atoms reach the surface with sufficient energy to collide with and liber-

Fig. 7. Calculated sputtering yield vs. oxygen pressure. Sputtering yield is made up of three components; physical sputtering yield Y_1 , chemical sputtering yield Y_2 , and ion-assisted chemical sputtering yield Y_3 .

ate surface atoms. However, since the polymer network is basically two dimensional, momentum transfer process between target atoms and accelerated ions may be terminated only in neighboring polymer chains. Ions with high acceleration energies penetrate the polymers, and surface atoms cannot effectively be liberated by incoming ions at high acceleration energy.

The theoretically fitted curves are described for 500 and/or 200 eV acceleration energies in Fig. 2 and 7. Chemical sputtering yield Y_2 is estimated to be about 1.24. This means that about 38% of the incoming O_2 does not react with and is recoiled from the surface. The increase in sputtering yield with decreasing acceleration energy is attributed to the decrease in current density. This analysis would be useful to describe the observed phenomena and predict the etching characteristics in ion etching with reactive beams.

Conclusion

Oxygen ion-beam etching of organic polymers has been discussed from the view point of "effective" carbon sputtering yield. Mass spectrometric analysis indicates that the final products during etching are mainly H_2 and CO. By assuming the ion-assisted chemical reaction of carbon atoms with neutral oxygen molecules, oxygen pressure, and acceleration energy dependences of sputtering yield are analytically explained. Increase in sputtering yield with decreasing acceleration energy is attributed to the relative increase in an oxygen pressure to current density ratio.

Interaction Between Water and Scaled CMOS FET's with Phosphosilicate Glass Passivation Films

M. Noyori and Y. Nakata

Matsushita Electric Industrial Company, Limited, Central Research Laboratory, Moriguchi, Osaka 570, Japan

ABSTRACT

A phosphosilicate glass (PSG) passivation film (4 weight percent phosphorus) was deposited onto complementary MOS (CMOS) FET's by chemical vapor deposition. After exposure to water vapor (85°C/85% RH), the CMOS FET's were tested at a high temperature bias of 150°C. It was found that a threshold voltage shift or transconductance (GM) degradation occurs pronouncedly in p-channel FET's under gate negative-bias stress, compared with in n-channel FET's under gate positive stress. Furthermore, it was found that there is a critical exposure time at 85°C/85% RH to enhance the shift and degradation. Finally, it was confirmed that the shift and degradation characteristics observed in this study are similar to instabilities due to gate negative bias in hydrogen ambient atmosphere.

Chemically deposited phosphosilicate glass (PSG) is widely used as a top passivation film in MOS LSI's. The PSG film reacts easily with water. Interaction mechanisms between water and the PSG film have been studied by a number of researchers (1, 2). However, as far as we know, interactions between water and MOS FET's with the PSG film have not been studied sufficiently, especially in regard to scaled MOS FET's (3), although the effects of water involved in the gate oxide of n-channel MOS FET's on electrical instabilities have been studied by some researchers (4).

However, scaled CMOS LSI's with the PSG passivation film have been developed and are widely used. The question of reliability problems due to moisture on scaled CMOS LSI's has become extremely important. This is because a small amount of water can induce more severe degradation in scaled devices than in conventionally designed devices.

This paper describes electrical instabilities in scaled CMOS FET's with the PSG passivation film, which was exposed to water vapor, under high temperature bias stress.

Experimental

Device preparation.—p- and n-channel polysilicon gate FET's were tested in this study. In this CMOS device, an n-type (100), 2-3 Ω cm substrate was used, and an n-channel FET was formed in a p-well. The gate length was typically 3 μ m, and additional FET's with a gate length of between 2 and 20 μ m, and a gate oxide thickness of 65 nm, were fabricated in order to investigate the gate-length dependence of electrical instabilities. Phosphorus was doped into the polysilicon gate by $POCl_3$ diffusion in both p- and n-channel FET's. The source and drain were formed by implantation of arsenic or boron ion followed by heat-treatment. After the source and drain implantation, CVD SiO_2 film (300 nm thickness) was deposited onto the substrate at 430°C using a mixed gas composed of SiH_4 and O_2 . The CVD SiO_2 film was densified during heat-treatment at 900°C for 40 min in nitrogen gas. Following the aluminum metallization, the PSG passivation film was chemically deposited onto the substrate using a mixed gas composed of SiH_4 , PH_3 , and O_2 with the substrate at 430°C. The deposition rate was about

100 nm/min. The thickness was 0.8 μm . The phosphorus concentration in the PSG film was typically 4 weight percent (w/o).

Test procedure.—First, devices with the PSG film mounted in nonsealed ceramic packages were exposed to water vapor (85°C/85% RH) for 0–336h. After that, the devices were sealed with metal lids in nitrogen gas at a maximum temperature of 350°C for 10 min. Subsequently, the devices were tested at 150°C under the bias conditions ('1' in Fig. 1). The gate negative and positive bias stresses were applied to p- and n-channel FET's, respectively. These gate bias stresses are also applied to the devices under practical operating conditions.

Measured parameters.—The threshold voltage (V_t) and transconductance (GM) in the nonsaturated region were measured, as shown in Fig. 2, with respect to the p-channel FET. V_t and GM were calculated from I-V characteristics. V_t was defined as the gate voltage (V_g), at the drain current (I_d) of zero, extrapolated from two points ($I_d = 3$ and 6 μA); GM was defined as the value of the slope obtained from the two points. Devices were measured at room temperature.

Experimental Results

p-Channel vs. n-channel instabilities.— V_t shift (ΔV_t) and GM degradation (GM/GM_0) in p- and n-channel FET's are shown in Fig. 1. The devices were exposed

Fig. 1. Time dependence of V_t shift and GM degradation under bias condition '1' at 150°C on p- and n-channel FET's exposed to 85°C/85% RH for 336h. GM_0 means the initial value of GM (after the exposure).

Fig. 2. Typical I-V characteristics of the p-channel FET exposed to 85°C/85% RH for 336h under bias stress '1' at 150°C.

to 85°C/85% RH for an exposure time (t_{ex}) of 336h before the test. It was found that V_t shift and GM degradation in p-channel FET's are much more pronounced than those in n-channel FET's. The V_t shift was towards negative and positive directions in the p- and n-channel FET's, respectively. On p-channel FET's, while $|\Delta V_t|$ increases and saturates with test time, GM degrades relatively early, after which it shows some recovery. Typical I-V characteristics under bias stress are shown in Fig. 2.

Gate length dependence of the instabilities.— V_t shift and GM degradation strongly depend on the gate length or channel length of the FET's. The gate-length dependences of V_t shift are shown in Fig. 3. It was found that $|\Delta V_t|$ increases with the decrease of the gate length in both p- and n-channel FET's. The curves of devices with a silicon nitride passivation film (SIN) shown in Fig. 3 will be discussed below. These results indicate that water-induced instabilities will become more severe with the downscaling of devices, especially in p-channel devices.

Exposure time dependence of the instabilities.—p-Channel FET's were exposed to 85°C/85% RH for several different lengths of exposure time (t_{ex}) for 0 to 336h. Neither ΔV_t nor GM degradation was observed under exposure to water vapor without bias stress. V_t shifts under bias stress are shown in Fig. 4. $|\Delta V_t|$ strongly depends on t_{ex} , that is, $|\Delta V_t|$ increases with the increase of t_{ex} . The relation between $|\Delta V_t|$ at a test time of 500h is shown in Fig. 5. It was found that there is a critical exposure time ($t_{\text{ex,cr1}}$) to enhance additional V_t shift. The time was found to be about 11h. The characteristics of 8 w/o PSG will be discussed later.

Analysis and Discussions

Mechanism.—In order to make clear that the V_t shift and GM degradation shown in Fig. 1 or the gate-length dependence shown in Fig. 3 were caused by water diffusion through the PSG film, the p-channel FET's using a plasma-enhanced silicon nitride (SIN) passivation film (0.8 μm thick) instead of the PSG film were tested after exposure to 85°C/85% RH for 336h. The

Fig. 3. The gate-length dependences of ΔV_t at 500h under bias stress '1' on p- and n-channel FET's with the PSG film or silicon nitride (SIN) film exposed to 85°C/85% RH for 336h.

Fig. 4. Time dependences of V_t shift under bias stress 'I' at 150°C on p-channel FET's exposed to $85^\circ\text{C}/85\% \text{RH}$ for t_{ex} between 0 and 336h.

values of $|\Delta V_t|$ of the p-channel FET's with the silicon nitride film were much less than those of the PSG film, and the devices did not show the gate-length dependence. The test result on V_t shift is shown in Fig. 3. These discrepancies probably result from the difference between the silicon nitride and the PSG films in their protective ability against water attack. In our previous study (5), it was found that the impurity involved in plastic encapsulation, which probably contains moisture, can diffuse into the gate oxide or Si/SiO₂ interface not through the polysilicon gate but through the periphery of the polysilicon gate under high temperature bias stress. Furthermore, it was found that the gate length dependence of the V_t shift results from the impurity diffusion. Therefore, the gate-length dependence found in this study can also probably be explained by the diffusion-path model that water absorbed in the PSG film, resulting from exposure to water vapor, should diffuse to the interface through the periphery of the gate.

Judging from I-V characteristics shown in Fig. 2, not only fixed positive charges but also surface states were generated in the p-channel FET's under the bias stress because I-V characteristics were found to shift along the voltage axis not in a parallel mode; that is, the slope of I-V characteristic (GM) was found to

Fig. 5. Exposure time (t_{ex}) dependences of V_t shift at 500h under bias stress 'I' at 150°C , on p-channel FET's with 4 w/o PSG and 8 w/o PSG films.

change. Two kinds of instabilities induced by the gate negative bias stress have been reported. One is the "slow trapping" (6, 7), and the other is the "secondary slow trapping" (3, 8). In these instability mechanisms, positive fixed charges and surface states are generated at the Si/SiO₂ interface, as observed in this study. Therefore, the instability mechanism observed here is suspected to be similar to these mechanisms.

The instability induced by the slow trapping can be observed not only in MOS FET's with the PSG film, but also in FET's with the silicon-nitride film. The V_t shift of FET's with the silicon nitride film shown in Fig. 3 is considered to be caused by this mechanism. This shift does not depend on the gate length because the origin of this instability is considered to be the defect of the interface related to a hydrogen-silicon bond. Jeppson *et al.* (6) proposed the following reactions

where Si_s means a silicon atom at the surface bonded to other silicon atoms, while Si_o means a silicon atom in the oxide. "." means a dangling bond, and $\dot{\text{Si}}_s$ is assumed to form a surface state. H_i is an interstitial hydrogen.

The instability induced by the secondary slow trapping can be observed in the device with the PSG film, and this instability showed a slight gate-length dependence (5). The origin of this instability is considered to be moisture (or hydrogen). We proposed the following reactions [4]-[7], in the previous study (8)

or

Concerning the instability mechanism observed in this study, it is conceivable that reactions similar to the secondary slow trapping occur at the interface. The major difference of the situation between this mechanism and the secondary slow trapping is probably the amount of water reacted with the interface. That is, the amount of the water in this instability, especially on the device exposed to water vapor for long periods, is much more than the amount of water in the secondary slow trapping. As a result of this difference, the V_t shift or GM degradation in this study is much more pronounced than that in the secondary slow trapping.

ΔV_t and GM degradation increase with the increase of t_{ex} . $|\Delta V_t|$ vs. GM/GM₀ characteristics are shown in Fig. 6, setting t_{ex} as a parameter. The characteristics of the device marked with "H₂" in Fig. 6 will be discussed below. It was found that the characteristics are independent of the value of t_{ex} before GM recoveries, and that the recovery characteristics strongly depend on t_{ex} . These results indicate that the ratio of fixed charge/surface-state formation before the GM recovery does not depend on the amount of water initially absorbed in the PSG film.

Critical exposure time.—In order to analyze the origin of the critical exposure time ($t_{\text{ex,cr1}}$), the reaction between the PSG film and water was investigated. It should be noted that a little ΔV_t occurs in the device exposed for the exposure time below $t_{\text{ex,cr1}}$, as shown in Fig. 5. However, the value of $|\Delta V_t|$ is much less than that of the device exposed for a longer time than $t_{\text{ex,cr1}}$.

PSG film (4 w/o phosphorus, 0.8 μm thick) deposited on a silicon substrate was exposed to $85^\circ\text{C}/85\% \text{RH}$ for 240h. After the exposure, an infrared spectrum was measured by a double-beam infrared spectrometer,

Fig. 6. ΔV_t vs. G_m/G_{m0} characteristics of p-channel FET's exposed to 85°C/85% RH for t_{ex} between 24 and 336h, under bias stress '1' at 150°C. In respect to the characteristic curve on t_{ex} of 336h, 20, 45, and 90h, etc., mean test time under bias stress '1' at 150°C. The curve marked with "H₂" shows the characteristic curve on the p-channel FET with the PSG film, which was mounted in a ceramic package filled with 10 v/o hydrogen gas and was not exposed to water vapor, under bias stress '1' at 150°C for 2400h.

and compared with the spectrum of the film as grown. A typical infrared spectrum is shown in Fig. 7. In the spectrum of the exposed PSG film, the intensity of the peak at 1330 cm^{-1} corresponding to P = O bond decreases. Two new absorption peaks emerge at 930 and 3650 cm^{-1} , which correspond to Si—O—H and H—O—H groups, respectively. From these results, which agree well with the spectrum observed by Levin (1), the interaction between water and the PSG film can be described by the following reactions [8] and [9], in addition, to being physically absorbed in the PSG film.

Furthermore, triple layers composed of undoped silicate glass (USG) (20 nm thick), PSG (30 nm), and USG (20 nm) were formed on a silicon substrate with thermally grown SiO₂. The USG films were formed by the chemical vapor deposition method. The PSG film was formed by the same conditions mentioned previously, except for the thickness and deposition rate. The silicate glass layer was exposed to 85°C/85% RH for either 1 or 17h. After storage in a desiccator at room temperature for 10 days, the profiles of

Fig. 7. The infrared spectrum of the PSG film exposed to 85°C/85% RH for 240h, compared with one of the PSG film as grown.

hydroxyl, hydrogen, and phosphorus concentrations were measured by secondary ion mass spectrometry (SIMS). The PSG film in this experiment is much thinner than that of the film in other experiments. This results from the prevention of charging up in the film under the SIMS measurement. The measurement results are shown in Fig. 8. It was found that hydroxyl and hydrogen concentrations in the PSG film are greater than those in the USG films. These profiles indicate that water diffused into the PSG film can move less easily than water diffused into the USG film.

From these two experiments using the infrared spectrometer and SIMS, it is speculated that diffused water bonded to phosphorus is fixed more firmly than diffused water bonded to Si or absorbed physically on an SiO₂ surface. In the case of a relatively small amount of water vapor diffusing into the PSG film, the former type of water is probably dominant. In the case of a large amount of water vapor, however, the latter type of water cannot be neglected. The critical exposure time is considered to result from the types of water diffused into the PSG film. If this assumption

Fig. 8. Phosphorus, hydrogen, and hydroxyl concentrations in the triple layers composed of USG/PSG/USG exposed to 85°C/85% RH for either 1 or 17h, measured by SIMS. Signal intensities of phosphorus, hydrogen, and hydroxyl were normalized by signal intensity of silicon ions.

is right, the critical exposure time should depend on the phosphorus concentration in the PSG film. In order to confirm the assumption, the p-channel FET's with 8 w/o phosphorus PSG film were tested under bias stress, after exposure to 85°C/85% RH for several kinds of t_{ex} . The test results are shown in Fig. 5. It was found that $t_{ex,cr1}$ of the 8 w/o PSG film is much longer than that of the 4 w/o PSG film.

Instabilities under bias stress in hydrogen ambient.— In the instability due to the exposure to water vapor, hydrogen probably plays an important role, as expected from reactions [4]-[17]. In order to confirm the reactions, p- and n-channel FET's with the PSG film were mounted in ceramic packages filled with a mixed gas composed of 10 volume percent (v/o) hydrogen and 90 v/o nitrogen. The FET's were tested at 150°C under the bias stress ('1' and '2' shown in Fig. 9). Test devices and test conditions are shown in Table I. Test results are shown in Fig. 9. It was found that ΔV_t in p-channel FET's (1p and 3p) with the shorter channel filled with 10 v/o H_2 occur more pronouncedly than in the p-channel FET's (2p and 4p) filled with 100% N_2 , under both bias stresses. However, a significant difference of ΔV_t was not observed in n-channel FET's (1n to 4n).

Furthermore, ΔV_t in a p-channel FET is more pronounced under bias '2' (3p) where a channel current flows than under bias '1' (1p), where no channel current flows. This result suggests that holes play important roles in the reaction at the interface in the p-channel FET's, as well as in the n-channel FET's where Fair *et al.* reported that V_t shifts were induced by the reaction between hydrogen and hole under a certain bias stress (9). At bias '1,' effective holes contributing to the reaction will be furnished only by thermal excitation; however, in bias '2,' holes will be prepared by electrical excitation in addition to the thermal one, especially in the short-channel FET's. This bias-stress dependence of ΔV_t was also found in the p-channel FET's (5p and 6p) exposed to water vapor, as shown in Fig. 9.

V_t shift vs. GM/GM₀ characteristics on the p-channel FET filled with 10% H_2 are shown in Fig. 6. It was found that this characteristic is similar to characteristics on the p-channel FET exposed to water vapor. However, significant recovery characteristics of GM was not observed in the device filled with 10 v/o H_2 , in spite of the bias stress for relatively long hours of testing (2000h). The reason for this is still unclear. There are two kinds of possibilities. One is that the test time is not long enough for the GM recovery to occur. The other is that GM recovery is induced by interaction between hydroxyl and the defects related to induced surface states, as described in the previous study (8). As there is no source of hydroxyl ions in the device filled with 10 v/o H_2 , GM recovery should not occur.

Summary and Conclusions

The instabilities under high temperature bias stress for scaled p- and n-channel FET's with the PSG passivation film exposed to water vapor have been in-

Fig. 9. The gate-length dependence of ΔV_t on p- and n-channel FET's filled with 10 v/o hydrogen or with 100 v/o nitrogen at bias conditions '1' and '2' compared with p-channel FET's exposed to 85°C/85% RH at the two bias conditions. Meanings of labels are shown in Table I.

vestigated, and, as a result, it can be concluded that:

1. The V_t shift and GM degradation occur much more pronouncedly in p-channel FET's under gate negative bias than in n-channel FET's under gate positive bias.
2. The V_t shift in the p-channel FET's strongly depends on the gate length.
3. The V_t shift in the p-channel FET's under high temperature bias stress strongly depends on the exposure time to water vapor. Furthermore, there is a critical exposure time to water vapor to enhance additional V_t shift.
4. The critical exposure time, which depends on phosphorus concentration in the PSG film, probably results from interaction between phosphorus and water in the PSG film.
5. Instabilities under high temperature bias stress after the exposure to water vapor are similar to those under high temperature bias stress in hydrogen ambient, for example, on the gate length dependence of V_t shift, characteristics of ΔV_t vs. GM/GM₀, the differences of ΔV_t and GM degradation between p- and n-channel FET's, and applied bias-stress dependence of V_t shift.

Preparation and Characterization of Plasma-Deposited Silicon Nitride

C. Blaauw

Bell-Northern Research, Ottawa, Ontario, Canada K1Y 4H7

ABSTRACT

This paper reports on the preparation and characterization of films of plasma silicon nitride, deposited on Si substrates from SiH_4 , NH_3 , and Ar. It is shown that the deposition rate and uniformity of the films are strongly affected by the cleaning and loading of the reactor. Pinhole densities are reduced by increase of both the film thickness and the deposition temperature. Several parameters were systematically varied, including the deposition temperature (20°-500°C), RF power (10-300W), chamber pressure (0.5-1.4 torr), and gas flow rates. At 500°C specular films are grown with the following characteristics: refractive index 1.9-2.1, pinhole density 5 cm^{-2} at $1.0 \mu\text{m}$ thickness, 100 Å/min etch rate in buffered HF, and good stability to annealing. Relationships between deposition parameters and film characteristics, including deposition rate, etch rate, and index of refraction, are discussed in terms of current understanding of the deposition process. An explanation is offered for differences in the effect of RF power level on deposition rates observed by other investigators.

Silicon nitride is a hard, chemically inert, dielectric material which forms an excellent diffusion barrier with respect to H_2O , Na, and many other ionic species. It is used extensively in semiconductor technology for the fabrication of thin films for interlayer insulation, device passivation, and mechanical protection. The use of plasma-enhanced chemical vapor deposition (as compared to conventional CVD) has the advantage that the substrate can be held at a relatively low temperature (200°-400°C) during film deposition. It can therefore be used in applications where previous device fabrication steps do not allow higher processing temperatures. It has been shown that silicon nitride films deposited by this technique can provide good adhesion, have good crack resistance, and provide good step coverage. In this paper, results are reported on the preparation and characterization of films of plasma silicon nitride deposited on Si substrates from mixtures of SiH_4 , NH_3 , and Ar.

Experimental

A small, research-oriented plasma reactor, the Tegal P1 100, was used for this work. A schematic diagram of the reaction chamber is shown in Fig. 1. Chamber and electrode assembly are made of aluminum. The gas mixture enters the chamber through a matrix of small holes in the (hollow) upper electrode. The lower electrode contains the substrate and is electrically floating. The electrode area and the distance between the electrodes are $15 \times 15 \text{ cm}$ and 2.5 cm, respectively. The chamber and electrode assembly were cleaned in an RF plasma, using a CF_4 -5% O_2 gas mixture.

The substrates used were polished, single-crystal silicon wafers. For most experiments wafers of 10 cm diam were used, located in a depression on a thin Al

sample holder placed on the electrode. For some runs, wafers of 5 cm diam were used, placed off-center against a ridge at the back of the electrode. The wafers were cleaned prior to deposition using the RCA procedure (1).

Pinhole detection was done electrochemically, using a Gasonics pinhole detector. The wafers are placed in a metal disk (cathode) immersed in methanol. A ring anode, also immersed in the methanol, is held above the wafer, at an applied potential of 40V. At pinhole locations, the substrate is exposed to the methanol, hydrogen evolution takes place, and a stream of bubbles is observed. A Rudolph automatic ellipsometer using a He-Ne laser ($\lambda = 6328\text{\AA}$) was used to measure film thickness and index of refraction. Etch rate measurements were done using buffered HF (NH_4F : HF = 13:2) at 25°C.

Results and Discussions

Film integrity.—The topography of the films was investigated by scanning electron microscopy. Specular films were obtained up to $1 \mu\text{m}$ thickness. At larger thicknesses, a light surface roughness was sometimes observed. The effect of gas composition, RF power, film thickness, and substrate temperature on the pinhole density was investigated. Results are shown in Fig. 2 and 3. The pinhole density was not affected by film composition or RF power density. However, a decrease of the pinhole density with increasing film thickness and deposition temperature was observed.

Nonuniformity of the deposition.—The effect of deposition parameters on the uniformity of the deposition was investigated. It was found that for depositions using SiH_4 -rich gas mixtures the deposition rate decreased with increasing radial distance, whereas for SiH_4 -poor gas compositions the opposite occurred. Re-

Fig. 1. Diagram of the electrode and gas inlet and exhaust assembly of the Tegal PI 100 plasma reactor.

Fig. 2. Effect of film thickness and gas composition on the pinhole density of films of plasma-SiN_x on Si. Deposition conditions: ● Ar = 200 sccm, SiH₄ = 5 sccm, NH₃ = 44 sccm; ○ Ar = 200 sccm, SiH₄ = 10 sccm, NH₃ = 40 sccm; ▲ Ar = 200 sccm, SiH₄ = 17 sccm, NH₃ = 33 sccm.

sults for two depositions are shown in Fig. 4. Several factors are thought to affect the deposition uniformity. Two of these are the radial variation in gas composition due to the differing depletion rates of SiH₄ and NH₃ during the deposition, and the uniform gas flow through the upper electrode, which would give a radial velocity proportional to the radial distance. However, it is not clear how these factors would lead to a radial nonuniformity profile depending on the SiH₄/NH₃ ratio.

A third factor affecting deposition rates is the accumulative amount of deposition following a plasma cleaning of the chamber. Figure 5 shows deposition rate profiles, obtained for a series of consecutive 4 min depositions on 5 cm diam wafers located off-center on the electrode following a plasma cleaning. The deposition-rate profile varied considerably during the first several minutes of deposition; this was followed by a gradual decrease of the deposition rate, eventually reaching a plateau after about 20 min of deposition. When a 10 cm diam wafer was substituted near the end of this series, a deposition profile similar to that obtained during the first deposition was obtained, but at a lower average rate. These results indicate a general decrease in deposition rate as the electrodes are covered with a layer of silicon nitride and that local loading effects are also important. It is thought that the plasma may be affected by the changing surface properties of the electrodes and substrates, as

Fig. 3. Effect of substrate temperature on the pinhole density of 1000 Å thick films of plasma-SiN_x on Si. Deposition conditions: RF power 150W, chamber pressure 0.9 torr. Gas flow rates: Ar = 200 sccm, SiH₄ = 6 sccm, NH₃ = 44 sccm.

they are covered by an insulating layer of dielectric film.

The effect of substrate temperature.—In Fig. 6 the effect of substrate temperature on the index of refraction, the deposition rate, and the etch rate is shown. The significant decrease in etch rate with increasing substrate temperature has been observed by other investigators (2, 3), and is thought to be due to a decrease in hydrogen content of films deposited at higher temperatures. Work done by Chow *et al.* (4) for films of plasma silicon nitride deposited in a number of reactors has shown the etch rate in buffered HF to be very sensitive to hydrogen content and that hydrogen content decreases with increasing deposition temperature. This was also observed in other work (5). From the report of Chow *et al.* (4), we deduce that the hydrogen content in our films decreased from ≈40% at 20°–200°C to ≈20% at 500°C. Additional evidence

for a decreased hydrogen content at higher deposition temperatures is the effect of annealing on the films. It was found that films deposited at 300°C formed blisters which lifted from the substrate, after annealing in a nitrogen ambient at 600°C. This effect has been reported previously (6) and attributed to hydrogen diffusion and accumulation at the film-substrate interface. Films deposited at 500°C remained stable following annealing up to 700°C.

The increase in n with temperature was also observed by other investigators (3, 7, 8), and related to the increase in density of the films (9). The deposition rate vs. temperature curves suggest that at least two mechanisms are involved. A decrease in deposition rate with increasing temperature has been observed more often, in the range of 20°-300°C (7, 8), and may be related to the increase in film density with temperature. At higher temperatures, we observed a reversal of this trend to an increasing deposition rate. It is thought that this is the result of an increase in the rate of diffusion of reactive species to the substrate, due to the higher gas temperature.

The effect of RF power.—In Fig. 7 the effect of RF power on the index of refraction, the deposition rate, and the etch rate is shown. Experiments by Reinberg (8) have shown that the dissociation of SiH_4 and NH_3 increases with RF power and that dissociation of all SiH_4 and NH_3 molecules takes place at a power density (per unit of substrate electrode area) of $\approx 70 \text{ mW/cm}^2$. It is therefore to be expected that deposition rates will increase with RF power density to this value, and then remain constant. This is in agreement with results obtained by other workers, where values of power density can be extracted from the reported results. For power densities $< 60 \text{ mW/cm}^2$, a linear increase of the deposition rate with RF power has been observed (8, 10), whereas for power densities $> 100 \text{ mW/cm}^2$, a constant value was found (9, 11). In other work (3), the RF power range spans the transition region, as a

Fig. 6. Effect of substrate temperature on index of refraction, deposition rate, and etch rate in buffered HF for films of SiN_x on Si. Deposition conditions: RF power 150W, gas flow rates: $\text{SiH}_4 = 6 \text{ sccm}$, $\text{NH}_3 = 44 \text{ sccm}$. ● Ar = 200 sccm, chamber pressure = 0.9 torr; ○ Ar = 160 sccm, chamber pressure = 0.7 torr.

change from a linear increase to a more constant value is observed. Our experiments were done at power densities in the range 50-1000 mW/cm^2 . Therefore, little dependence of the deposition rate on RF power is to be expected. However, increase in power level in this region may increase the degree of dissociation of the reacting species and also the temperature of the gas. Both effects would result in a decrease of hydrogen content of the films and therefore a decrease in etch rate, as was observed. Thus it appears that RF power affects the growth rate of silicon nitride primarily through the degree of dissociation of the reactants and increase of power beyond the level at which all re-

Fig. 7. Effect of RF power on index of refraction, deposition rate, and etch rate in buffered HF for films of SiN_x on Si. Deposition conditions: $T = 300^\circ\text{C}$, chamber pressure = 0.7 torr. actants are partially dissociated does not significantly effect the deposition process.

The effect of gas composition.—For several values of chamber pressure and total gas flow rate, the effect of varying the SiH_4/NH_3 ratio in the gas composition was investigated. Increasing the SiH_4/NH_3 ratio in the gas mixture increases the Si/N ratio in the deposited films. This trend has been well established in previous work (7, 12-14). Because an increase in Si/N corresponds to an increase in n (8), we expect n to increase with increasing SiH_4/NH_3 ratio. Figure 8 confirms this trend, which is generally observed (3, 7, 8, 10-13) and is also seen when N_2 instead of NH_3 is used as the nitriding agent (15, 16). For two films, the Si/N ratio was determined by Auger electron spectroscopy, using a sample of CVD- Si_3N_4 as a reference. Values found for the Si/N ratio were 1.17 and 1.43. The indexes of refraction of these films were 1.95 and 2.17, respectively. From the correlation between Si/N ratio and n , an estimate of the density, σ , of the films can be obtained (8). For both samples a value of $\sigma \approx 2.2$ g/cm² is found, which is a typical value for plasma silicon nitride (7, 8, 17). Using this value of σ , we find that the range of $1.8 < n < 2.1$ corresponds to a range in composition of $1.0 < \text{Si}/\text{N} < 1.3$, within the range of $\approx 0.7 < \text{Si}/\text{N} < 1.5$ reported by most workers (7, 13, 16-18).

Fig. 8. Effect of gas composition on the index of refraction for films of SiN_x on Si. The fraction of silane is defined as $\text{SiH}_4/(\text{SiH}_4 + \text{NH}_3)$. Deposition conditions: $T = 300^\circ\text{C}$, RF power = 150W, gas flow rates; Ar/($\text{SiH}_4 + \text{NH}_3$) = 3.2. ● $\text{SiH}_4 + \text{NH}_3 = 35$ sccm, chamber pressure = 0.5 torr; ○ $\text{SiH}_4 + \text{NH}_3 = 50$ sccm, chamber pressure = 0.7 torr; ▲ $\text{SiH}_4 + \text{NH}_3 = 35$ sccm, chamber pressure = 0.7 torr; △ $\text{SiH}_4 + \text{NH}_3 = 50$ sccm, chamber pressure = 1.0 torr.

The etch rate was found to be strongly correlated with the index of refraction, as is shown in Fig. 9, where data for films deposited under various conditions of chamber pressure and gas flow are shown. Similar results were reported by other workers (3, 10). The significant increase in the etch rate for $n < 1.9$ indicates that films in that region are more susceptible to corrosion and that the refractive index may be a sensitive test of etch rate in applications where a direct measurement is impractical.

Chamber pressure and total gas flow rate did not affect n or the etch rate, i.e., the film composition. The deposition rate increased with pressure and with SiH_4/NH_3 ratio and was on the order of $5[\text{SiH}_4]$, where $[\text{SiH}_4]$ is the silane partial pressure in millitorr and the deposition rate is in angstroms per minute.

Fig. 9. Etch rate in buffered HF vs. index of refraction for films of SiN_x on Si, deposited at various gas flow rates and chamber pressures at $T = 300^\circ\text{C}$ and 150W RF power.

Conclusions

The effect of process parameters on film characteristics was determined for plasma-deposition of films of silicon nitride, deposited on Si substrates from mixtures of SiH₄, NH₃, and Ar. The effects of variations in the substrate temperature, RF power, and gas composition on the deposition rate, the etch rate, and the index of refraction are consistent with present understanding of the deposition process. Furthermore, the following results were obtained:

1. Pinhole densities can be reduced by increasing film thickness or the substrate temperature.
2. Uniformity of the deposition is affected by the composition of the reactant gas mixture and by the thickness of the layer of silicon nitride already present on the electrodes following previous depositions. Plasma cleaning of the reactor chamber prior to each deposition is required to obtain repeatability of the deposition rates.
3. An explanation is given for differences between the effects of RF power on deposition rate reported by different workers.
4. The relationship between index of refraction and etch rate in buffered HF suggests that the former may be a good indicator for the quality of the films, although the relationship may be reactor dependent.

Chromium as a Diffusion Barrier Between NiSi, Pd₂Si, or PtSi and Al

M. Bartur* and M-A. Nicolet*

California Institute of Technology, Pasadena, California 91125

ABSTRACT

We show that the thermal instability that is observed in Schottky diodes with an Al film on NiSi, Pd₂Si, or PtSi contact to <Si> can be removed by proper deposition of a Cr layer, 1000-2000Å thick, between the Al and the underlying silicide layer. The structure can be formed by sequential evaporation of Ni, Pd, or Pt, Cr, and Al, and subsequent thermal annealing to form the contact silicide and sinter the Al contact. Isochronal annealing for 30 min over the temperature range of 350°-500°C shows that the barrier holds electrically at 450°C and fails at 500°C. Forward I-V measurements are used to determine the barrier height, and elemental profiles are investigated using backscattering spectrometry. The successful utilization of the Cr barrier depends on the deposition conditions. Bilayers of Cr and Al deposited at high rates in another vacuum evaporator consistently reacted more rapidly than those usually observed by us and also reported in the literature. We believe that under usual deposition conditions the impurities incorporated in the films are essential for the successful operation of Cr as a sacrificial barrier.

Silicide contacts to Si have received much attention recently and are widely used as material to form ohmic contacts, Schottky rectifiers, IR detectors, and interconnects for integrated circuits. The compatibility of thick Al films with silicide layers is a problem of practical interest, since Al remains a preferred metal for the final contact to other devices or to bonding pads. The direct contact between Al and near-noble metal silicides is unstable: metallurgically, Al forms metal compounds (PtAl₂, NiAl₃, or PdAl₃), and elec-

trically, the Schottky barrier height (SBH) changes when all the silicide layer is consumed.

In a previous paper (1), we suggested that the Al-silicide contact system can be stabilized with a sacrificial barrier between the Al layer and the silicide. A sacrificial barrier exploits the fact that thin adjacent films that react and form a compound often do so in a laterally very uniform fashion. A barrier layer that reacts uniformly with Al and silicide on either side of it effectively maintains a separation of the Al from the silicide as long as the barrier layer is not fully consumed by these reactions. This point in time is predictable when the two reaction rates are known as

* Electrochemical Society Active Member.

Key words: diffusion barriers, chromium barrier, contact metallurgy, solid-solid interfaces.

a function of temperature, provided that precautions are taken to avoid impurities in the films that might alter the reaction kinetics. We have suggested the use of Ti, V, or Cr for such barrier material.

In this paper, we evaluate Cr as a diffusion barrier between Al and NiSi, Pd₂Si, or PtSi. We chose Ni, Pd, and Pt silicides because they can be formed uniformly and reproducibly at relatively low temperatures on a Si substrate. Platinum and palladium silicides are widely utilized in Si contact structures. They also span a wide range of usable SBH (0.66, 0.74, and 0.85 eV for NiSi, Pd₂Si, and PtSi, respectively). We characterize the electrical stability of the contact structure using barrier height measurements as an indicator for the integrity of the Si-silicide interface.

The main results of this study are twofold. We first establish that with films deposited in a conventional fashion Cr does indeed act as the sacrificial barrier model predicts. These results also agree with most observations reported in the literature. We additionally show, however, that Cr fails as a diffusion barrier when the films are deposited in a separate evaporation system and at high rates. Evidence suggests that impurities are critically associated with these different behaviors. In what follows, we therefore distinguish between results obtained with the "slow" or the "fast" evaporation systems.

Experimental Procedures

The Schottky diodes for our study were prepared on 0.003 Ωcm $n^+ \langle 111 \rangle$ silicon substrates covered with a 10 μm thick 10 Ωcm n -type epi-layer. The contact areas (1.16×10^{-2} cm^2) were photolithographically defined and opened using a buffered HF in a SiO₂ layer which was deposited on the wafers by low temperature chemical vapor deposition (CVD). Prior to the loading for metal deposition, the wafers were etched for 10s in 1:10 HF. The metals (Ni, Pd, or Pt), Cr, and Al were sequentially evaporated without breaking the vacuum at pressures less than 5×10^{-7} torr. The depositions were conducted in two systems which are constructed similarly: both use ion pumps and E-guns. The only difference was the deposition rate of the metal layers. In the first ("slow") system, the deposition rate was 10-30 $\text{\AA}/\text{s}$ with intermittent holds due to the manual control, while in the other ("fast") system, the depo-

sition was maintained automatically at a fixed rate of 50 $\text{\AA}/\text{s}$. We also prepared samples only with silicide (no Cr or Al) and without the Cr barrier. For comparison, the silicides of some samples were prepared *in situ* (at 400°C) before the Cr and Al were deposited. Large area samples were prepared simultaneously for backscattering spectrometry (BS) analysis. Subsequent heat-treatments were performed in a vacuum furnace at pressures less than 8×10^{-7} torr, or in N₂ flow in an open-tube furnace.

The SBH was determined from fits of the forward I-V data to the ideal thermionic emission model. The reverse saturation current and Norde plots were also employed, where feasible, to confirm the results. Elemental profiles were detected using BS with a 2 MeV ⁴He⁺ beam.

Results and Discussion

Thin film interactions.—To perform as a sacrificial barrier, Cr must react uniformly with the top Al film and with the bottom silicide layer. It is known that Cr reacts uniformly with Al, forming CrAl₇(2). The Cr consumption rate is $4.5 \times 10^{-14} \times \exp(-1.91 \text{ eV}/kT)$ $\text{\AA}^2 \text{ s}^{-1}$ (2) for annealing in dry nitrogen atmosphere at 300°-450°C temperature range. The reaction of Cr with Pd₂Si has been investigated by Olowolafe *et al.* (3), who demonstrated the uniform layer-by-layer growth of CrSi₂ on Pd₂Si. Also, Zingu *et al.* (4) have clearly shown that the growth rate of CrSi₂ with an interposed Pd₂Si layer is equal to or slower than that on Si, depending on the Pd₂Si thickness. Previous studies of CrSi₂ growth on PtSi(5, 6) or NiSi(6) have demonstrated a uniform layer-by-layer growth of CrSi₂.

Utilizing our slow system, we have investigated the reaction of Cr films with PtSi and NiSi films on Si. For these studies, we have used an initial configuration of Si/metal/Cr or Si/metal silicide/Cr; upon annealing, the former will transform into the latter at temperatures much below those at which Cr begins to react. The uniform formation of CrSi₂ on PtSi is shown in Fig. 1. Similar results are observed for $\langle \text{Si} \rangle/\text{NiSi}$ substrates. There is no detectable (using BS) mixing between the growing CrSi₂ layer and the underlying silicide. We have shown (7) that the growth rate of CrSi₂ on $\langle \text{Si} \rangle/\text{PtSi}$ is slower than on $\langle \text{Si} \rangle$ substrate at the same temperatures. Also, there is a delay time

Fig. 1. Silicide formation of Pt/Cr bilayer. First platinum silicide is formed and then at higher temperatures chromium disilicide is formed.

before the CrSi_2 formation starts. This delay time is longer for Si/metal/Cr structures than for Si/silicide/Cr structures that were formed using *in situ* heater.

Chromium was evaluated metallurgically as a diffusion barrier between Pd_2Si and Al (8) and electrically between PtSi and Al (9). It was shown (8) that Cr acts as sacrificial barrier and inhibits the interaction of Al and Pd_2Si for up to 90 min at 500°C . No electrical evaluations of this contact structure were reported. But, it has been reported that for PtSi there is a sharp drop in the SBH after the Cr layer is completely consumed by CrAl_7 formation (9). We conclude that, metallurgically, Cr is adequate for a sacrificial barrier on top of NiSi and PtSi from our studies ("slow" system), and for Pd_2Si from the results of Ref. (3), (4), and (8).

Electrical stability.—Technologically, the process of sequential deposition without silicide formation (metal/Cr/Al) is preferable, since it eliminates the need for *in situ* heating and allows for a single sintering step outside of the evaporator. In our electrical measurements, we found no basic difference between the behavior of the Si/silicide/Cr/Al and the Si/metal/Cr/Al structures. The reason is that the metal silicide forms much before any other reaction takes place in the above structures. Our shortest annealing time will transform all the metal under the Cr barrier to the silicide layer. We thus consider only the Si/metal/Cr/Al structures and compare them with the Si/metal/Al and the Si/silicide structures. The samples discussed in the following sections were produced in the "slow" Cr evaporation system and annealed in vacuum.

NiSi.—Failure of the Si/NiSi/Al contact structure has been reported (10-12) to occur at 400°C after a very short annealing. The compound NiAl_3 forms, and the SBH rises above 760 mV. For such samples, we observed SBH as high as 800 mV following 350°C , 20 min vacuum annealing. However, isochronal annealing of $\langle\text{Si}\rangle/600\text{\AA}$ Ni/ 700\AA Cr/ 6000\AA Al structures for 20 min at 350° , 400° , and 450°C produced no change in the SBH (Fig. 2). Based on Ref. (1), a failure is predicted

Fig. 2. Schottky barrier height (SBH) of isochronal anneal of: ● $\langle\text{Si}\rangle/590\text{\AA}$ Ni, ○ $\langle\text{Si}\rangle/600\text{\AA}$ Ni/ 700\AA Cr/ 6000\AA Al, × $\langle\text{Si}\rangle/700\text{\AA}$ Pt, △ $\langle\text{Si}\rangle/500\text{\AA}$ Pt/ 5700\AA Al, and □ $\langle\text{Si}\rangle/630\text{\AA}$ Pt/ 1350\AA Cr/ 9440\AA Al. (Formed in "slow" deposition system.)

after 20 min at 465°C . At 500°C for 20 min, the barrier indeed fails. The SBH rises from 667 (which is the barrier height of NiSi) to 680 mV with an increase in the ideality factor. We presume that this is due to localized failures, similar to the failure mode that was suggested for tungsten barrier (12).

Pd_2Si .—The instability of the Si/ Pd_2Si /Al structure has been thoroughly investigated (13-15). A complex ternary phase is observed upon annealing at temperatures as low as 200°C (16). The SBH first decreases after 10 min at 300°C and then rises above its initial value (13). We show that the electrical stability of a $\langle\text{Si}\rangle/650\text{\AA}$ Pd/ 1700\AA Cr/ 7000\AA Al structure at 450°C is maintained for about 120 min (Fig. 3). The barrier height of Pd_2Si , 0.74 eV, is maintained and the ideality factor is constant before the contact fails. Calculation based on our model (1) predicts about 100 min before the barrier is fully consumed; this agrees well with the facts.

PtSi.—The high value of the SBH of PtSi (850 mV) makes this contact very sensitive to any change at the Si/PtSi interface. It has been reported (17) that the Si/PtSi/Al structure shows a reduction in the SBH when all the Pt in the silicide is transformed to PtAl_2 . We find, for Si/Pt/Al sample, an immediate decrease of SBH after 350°C , 20 min annealing of samples without a Cr barrier ($\langle\text{Si}\rangle/500\text{\AA}$ Pt/ 5700\AA Al, see Fig. 2). Also, BS spectra indicate that the atomic composition of the reacted layer is quite Al rich (about 1:6 Pt-to-Al atomic ratio) and that about 0.25 atomic percent (a/o) Pt is contained in the remaining Al layer. The effect of thermal annealing on a $\langle\text{Si}\rangle/700\text{\AA}$ Pt sample is described in Fig. 2 also, because for this silicide, the SBH is altered by annealing (18) even without Al. Figure 2 shows that, after 20 min of annealing, the contact structure $\langle\text{Si}\rangle/630\text{\AA}$ Pt/ 1350\AA Cr/ 9500\AA Al starts to fail above 450°C , where there is a slight decrease in the SBH of PtSi from 0.85 to 0.83 eV. The sacrificial barrier model predicts (1) failure after 20 min at 485°C , which we consider to be excellent agreement. After this 450°C annealing, BS analysis reveals that indeed there is a reaction between the Al and

Fig. 3. Schottky barrier height (SBH) of $\langle\text{Si}\rangle/650\text{\AA}$ Pd/ 1700\AA Cr/ 7000\AA Al as function of isothermal vacuum annealing at 450°C . The ideality factor is also depicted. (Formed in "slow" deposition system.)

PtSi, but presumably not all the PtSi is consumed. Following a 500°C, 20 min annealing, Pt (at low concentration) was detected in the CrAl₇ layer and, as seen from the electrical measurements, the contact has failed.

Impurities effect.—To check our results, we also prepared samples in the “fast” vacuum evaporator. In this case, reduced contamination levels (particularly of O₂) are expected. In a previous study (19) done with the “slow” system, about 7 a/o was detected (using SIMS) in the as-deposited Cr layer. For Cr films deposited in the “fast” system, we found by BS that the Cr reaction rate with Al was about ten times faster than predicted in Ref. (1) at 460°C or than observed with the “slow” system. This annealing was conducted in an open-tube furnace with N₂ flow. When the annealing was conducted in vacuum, the CrAl₇ formation rate was at least 100 times faster than the “slow” case. These samples had a very thick (2 μm) Al layer, but, apparently, the impurities from the annealing environment diffuse quite easily through the Al layer at 460°C. It is important to note that even for such high reaction rates the CrAl₇ forms quite uniformly.

To check the effect of impurities in the Al layer, we prepared a sample in the “fast” system, but stopped the Al deposition after about 2000 Å. The system was opened to air briefly (thin Al oxide formation), and then pumped down again and the deposition was finished (in similar vacuum conditions) until about 2 μm Al was deposited. In these samples, no reaction was observed after 3h at 460°C, and, electrically, the barrier height of the underlying NiSi was maintained. These results directly demonstrate that impurities do indeed affect this contact structure.

Sacrificial barrier holding time.—The holding time of the Cr barrier prepared in the “slow” system reported above and in Ref. (9) agrees quite well with our prediction based on individual reaction rates (1).

However, the results obtained with the fast system indicate that these rates are system dependent. The rates of reaction between Cr and Al reported in Ref. (2) and those extracted from holding times of Pd₂Si/Cr/Al (8), PtSi/Cr/Al (9), and our studies are all consistent with each other, although different systems are involved. One is thus forced to conclude that at least the Cr/Al reaction must be relatively insensitive to impurities above some threshold, but very sensitive below that. The identification of the impurities that affect the Cr/Al reaction, and its quantitative characterization therefore emerges as one of the important issues raised by the present study. A corollary of these observations is that the notion of a sacrificial barrier may have to be reconsidered, because it is conceivable that in reality impurities must always be present to realize that concept.

Titanium films have also been investigated for sacrificial barrier application. One would expect, in light of the preceding comments, that inconsistencies should appear in the holding times reported for barrier structure prepared in different systems. Indeed, conflicting results exist as to the usefulness of Ti as a barrier. Solomonson *et al.* (20) show that Ti really works as a sacrificial barrier and reacts uniformly with the silicide and the Al layer. Merchant *et al.* (9) also tested Ti as a barrier between PtSi and Al; they found that the SBH is constant as long as some unreacted Ti is left. However, the same system was reported by Ting and Crowder (21) to fail much faster than predicted by our original model (1). From their data, we deduce a Ti consumption rate of about 140 Å² s⁻¹ at 400°C, while we predict only 20 Å² s⁻¹ based on Bower (22).

Conclusions

The concept of a sacrificial barrier depends on two assumptions: (i) that the reactions at both interfaces of the barrier layer be laterally uniform, and (ii) that

the reaction rates be known and reproducible. The fulfillment of these assumptions will allow the design of a sacrificial barrier as outlined in Ref. (1). In the cases of Cr and Ti, we find vast variations in the reaction rates with Al, depending on the deposition conditions. The second requirement of known and reproducible reaction rates then is not fulfilled. That fairly consistent values for the Cr-Al reaction have nevertheless been reported by independent investigators strongly suggests that impurities may actually help in equalizing reaction rates. By the same token, impurities may also improve the lateral uniformity of a reaction by reducing grain boundary diffusion. The successful implementation of a sacrificial barrier may thus ultimately depend on the presence of impurities, in which case the concept of a sacrificial barrier emerges as a mere special case of a stuffed barrier. The sacrificial barrier may then be implemented for specific cases and in specific systems where impurities are incorporated consistently from run to run.

Practically, the control of impurities in film deposition or during annealing is difficult. A deliberate incorporation of impurities in the barrier (making it a stuffed barrier) in an amount which exceeds that needed to slow the reaction is a preferable procedure. The utilization of Cr (23) or Al (24) doped with oxygen has been suggested by others. It was shown (19) that oxygen in the Si is more effective in slowing down CrSi₂ formation than oxygen in the Cr, probably because of the fact that Si is the moving species. Since in CrAl₇ formation Al is expected to be the moving species (2), it may very well be that impurities in the Al layer have a dominant role in slowing the reaction rate. Indeed, we observed no degradation of the SBH even after 500°C when the Al was “stuffed” with impurities: most probably oxygen.

Chromium can be utilized as a barrier between Al and NiSi, Pd₂Si, and PtSi at 450°C, if the appropriate amount of impurities is incorporated in the film. Our study does not quantify this amount, but from our experience we can say that the evaporation performed at pressure higher than 1 × 10⁻⁶ torr at a rate lower than 10 Å/s will result in films with a sufficient amount of impurities to make the barrier effective.

Nippon Telegraph and Telephone Public Corporation, Ibaraki Electrical Communication Laboratory, Polymer Section, Tokai, Ibaraki 319-11, Japan

ABSTRACT

Crosslinking reactions in halogenated aromatic polymers which provide useful negative electron resists with high dry etching durability and high contrast were studied. Halogenated aromatic polymers show characteristic features, such as the saturation of crosslinking reactivity with an increase of halogen content and little postirradiation polymerization effect. The reactivity saturation is dependent not on the ring size or main chain structure of the aromatic polymer, but on the kind of halogen atom. The larger halogen atoms tend to exhibit more rapid saturation with halogen content, suggesting a steric effect. The strong participation of radical species formed by the dissociation of the carbon-halogen bond in the crosslinking reaction was verified from studies of radical scavenger effect and electron spin resonance spectroscopy. Considerable amounts of radical species remain after the crosslinking reaction has finished in vacuum, but remain in polymer films without crosslinking because of the high glass-transition temperatures of aromatic polymers and decreasing chain reactivity by halogen atoms, resulting in negligible postirradiation polymerization.

Almost all negative electron resists recently developed for microfabrication involving dry etching technology are derived from aromatic polymers (1-7). This is, in principle, due to the fact that aromatic polymers have relatively high stability against various dry-etching processes and high glass-transition temperatures (T_g), which may help to depress the swelling of crosslinked polymer chains. Polystyrene- (PSt) based polymers have been extensively studied as negative electron resists, because of the availability of PSt, even in a mono-disperse form (8, 9). As the crosslinking reactivity of PSt is very low, various reactive groups such as halogens or epoxy groups were introduced into PSt structure to enhance sensitivity. The use of halogenated groups as a crosslinking unit is preferable to get high resolution, as well as high sensitivity, because these groups can be used to crosslink polymer chains via step-wise reaction (10). However, polymers containing bonds such as epoxy or vinyl groups often crosslink via chain reaction, resulting in very high sensitivity but relatively low resolution (11).

We have synthesized a high performance negative electron resist, chloromethylated polystyrene (CMS), by the chloromethylation of nearly mono-disperse polystyrene (1). The chloromethyl group has proved to give PSt the highest crosslinking reactivity among various halogen groups (2). CMS has a contrast (γ) of 1.4-2.2, depending on the molecular weight and dispersity of the resist used, and shows excellent dry etching durability. For further improvement of the resolution of CMS, we have changed the starting polymer from PSt to nearly mono-disperse poly- α -methylstyrene, which has a much higher T_g (165°C) than PSt (95°C) (6). A new negative electron resist, chloromethylated poly- α -methylstyrene (α M-CMS) exhibits a contrast of 2.2-3.0, which is as high as that of nearly

mono-disperse PSt, and has excellent dry-etch durability and thermal stability. The sensitivity of α M-CMS is about half that of CMS, but still is 30 times higher than PSt when the same molecular weight polymers are used.

As reported previously, an interesting feature is observed in the resist performance of CMS and iodinated PSt (IPS) (5). This is the saturation of crosslinking reactivity with increasing reactive group content. Though the introduction of a small amount of halogen groups drastically increases the sensitivity of PSt, halogen groups introduced beyond a certain level do not contribute further to sensitivity of PSt. Another interesting observation in halogenated PSt resists is a freedom from postirradiation polymerization, which is defined as a phenomenon in which the crosslinking reaction lasts in the very high vacuum of the electron exposure machine. Postirradiation polymerization causes a lithographic nonuniformity in the developed resist thickness and variation of pattern sizes on a wafer according to the exposure order of patterns (12). In this paper, the crosslinking reactivity of various halogenated aromatic polymers was investigated by varying the polymer structure and measuring the ESR spectra as a function of temperature for these polymers, in order to elucidate the reaction mechanism of halogenated aromatic polymers as negative electron resists.

Experimental

Polymer preparation.—Figure 1 shows the structures of the halogenated aromatic polymers used in this study. Polymers with various ring structures were selected. CMS was obtained from Toyo Soda Manufacturing, and α M-CMS was synthesized as described in the previous paper (6). Chloromethylated poly (β -naphthyl methacrylate) (CMN) was prepared by the chloromethylation of poly(β -naphthyl methacrylate).

Key words: resists, electron beam lithography, polymer resists.

Fig. 1. Chemical structures of halogenated aromatic polymers

β -naphthyl methacrylate monomer was synthesized from methacrylic acid and β -naphthol using dicyclohexylcarbodiimide as a dehydration agent. The monomer was purified by repeated recrystallizations. Poly(β -naphthyl methacrylate) was prepared by azo-bis-isobutyronitrile (AIBN) initiated radical polymerization in toluene at 60°C in a sealed tube for 12h. The polymers were isolated by pouring the solution into methanol, washing with methanol repeatedly, and purifying by reprecipitation from tetrahydrofuran (THF) into methanol. Chloromethylation was carried out in chloromethyl methyl ether with SnCl_4 as a catalyst. Copolymers of β -naphthyl methacrylate and glycidyl methacrylate (NGC) with various monomer feed ratios were prepared and purified using the same procedure as described for poly(β -naphthyl methacrylate). Brominated polyvinylcarbazole (Br-PVK) was synthesized from polyvinylcarbazole, obtained from Anan Koryo Company, Limited, and N-bromosuccinimide using benzoyl-peroxide initiator. Poly-1,2-butadiene was obtained from Japan Synthetic Rubber Company, Limited.

Characterization.—Molecular weight parameters (\bar{M}_w and \bar{M}_n) were determined using gel permeation chromatography with a Hitachi Model 675 GPC and a Toyo Soda Model HLC-802UR GPC. Molecular weight measurements were calibrated with the standard polystyrene. The eluting solvents were methylethyl ketone (MEK) for CMS and α M-CMS and THF for other polymers. The chloromethylation ratio of CMS, α M-CMS, and CMN were calculated on the basis of chlorine content from the elemental analysis of polymers. Bromine content in Br-PVK was also determined by the elemental analysis. A maximum of two bromine atoms can be introduced into a carbazole ring. The glycidyl methacrylate (GMA) content of NGC was determined by measurement of the absorption at 310 nm due to the naphthalene ring in the polymer.

The glass-transition temperatures (T_g) of the polymers were determined with a Rigaku Differential Thermal Analysis Unit. Electron spin resonance (ESR) spectra of irradiated polymers were measured with a JEOL JES-PE-3X spectrometer equipped with a temperature-control unit. Powder samples for ESR measurement were evacuated at 10^{-6} torr for 24h and then sealed in a quartz tube before high energy beam exposure. Two kinds of irradiation, ^{60}Co γ -ray source and 150W high pressure mercury lamp with a collimated exposure system, were used to generate radical species in the resist. The sealed samples were irradiated for a specified period before ESR measurement.

Resist working.—Polymers were dissolved in xylene for CMS and M-CMS or in monochlorobenzene for other polymers and then spin-coated onto a silicon wafer having a 1 μm SiO_2 film 0.5–0.8 μm thick. Pre-

baking was carried out under a nitrogen atmosphere at 70°C for NGC, 95°C for CMS and CMN, and 135°C for Br-PVK and α M-CMS for 20 min. The sensitivity of resists to electron beam exposure was examined by exposure with a computer-controlled electron beam exposure machine ESM-301 or ELS-5000 (ELIONIX Company). The accelerating voltage used was 20 kV. The exposed films were developed by dipping in a suitable developer. MEK was used for CMS and α M-CMS, and THF or monochlorobenzene was used as the developer for other polymers. After development, the resist film was rinsed by dipping the sample in isopropanol. The resist thicknesses before and after development were measured with a Talystep (Taylor-Hobson). The electron beam sensitivity was expressed as D_0 , defined as the minimum dose required to form an insoluble gel on the substrate. Since the sensitivity of crosslinking negative resists is proportional to the initial molecular weight, we use the product of D_0 and \bar{M}_w as the measure of polymer reactivity to eliminate the effect of molecular weight. The temperature dependence of resist sensitivity was measured with a temperature-controlled sample stage, details of which are described by Harada (13).

Results and Discussion

Relation between reactivity and reactive group content.—Normally, for polymers in which the chemical composition is constant since

$$D_0 = K/\bar{M}_w G_c$$

where K is constant and G_c is G value of crosslinking. This is obeyed by many crosslinking polymers at low dose (moderate to high molecular weight). The relationship between resist sensitivity and halogen content has been reported in detail for CMS (2) and IPS (5). The sensitivity of IPS shows a saturation beyond about 20 mol percent (m/o) of iodination, whereas the reactivity saturation is observed beyond 40 m/o in CMS. We have measured this relation for various polymers shown in Fig. 1, to clarify the origin of this saturation. Table I summarizes molecular weight parameters, reactive group contents, and $D_0 \times \bar{M}_w$ for the polymers examined.

Figure 2 shows the reactivity of α M-CMS and CMS as a function of chloromethylation ratio (CR). α M-CMS gives the almost same CR dependence as that of CMS. It is very interesting that a quite similar relation

is also observed for CMN, as shown in Fig. 3. All of these polymers have the chloromethyl group as a crosslinkable unit, but their main chain structures are different. CMS and α M-CMS contain benzene ring, while CMN is a methacrylic polymer containing naphthalene ring. PSt, the parent polymer of CMS, is a negative resist, while α M-CMS and CMN have a parent polymer which acts as a positive resist. A small degree of chloromethylation changes α M-CMS and CMN from positive to negative tone. These results suggest that the reactivity saturation observed at about 0.4 of CR is a common feature of the chloromethyl group.

However, the reactivity of Br-PVK, which has a carbon-bromine bond as a reactive group and the carbazole group as an aromatic ring, saturates above about 30 m/o with bromination ratio, as shown in Fig. 4. By taking into account that IPS which has a carbon-iodine bond which shows a reactivity saturation at about 0.2, it can be concluded that the saturation in halogenated aromatic polymers is almost independent of aromatic-ring size and main chain polymer

Fig. 3. Reactivity of CMN as a function of molar chloromethylation ratio.

Fig. 4. Reactivity of Br-PVK as a function of molar bromination ratio.

structure, but is closely related to the kind of halogen atom.

To confirm that the reactivity saturation phenomenon is only observed in halogenated aromatic polymers, the sensitivity of NGC copolymerized with amounts of glycidyl methacrylate unit was investigated. Figure 5 shows the sensitivity curves for NGC and Br-PVK. NGC has low contrast in comparison with Br-PVK. This suggests that NGC crosslinks via chain reactions. Figure 6 indicates no saturation, but rather linear increase of reactivity with GMA content. The same results were obtained for epoxydized polybutadiene (PB) (14) and copolymers of styrene and glycidyl methacrylate (4).

Postirradiation polymerization effect.—Many negative electron resists, such as COP and SEL-N, suffered from postirradiation polymerization (15), which causes nonuniformities in pattern width and thickness on a wafer after development according to the order of exposure. CMS is known to show little postirradiation polymerization effect.

To elucidate the relation between this effect and polymer structure, various polymers were tested. For the evaluation of postpolymerization, the thickness of developed patterns after leaving the sample in an exposure machine for a given period was compared with resist thickness developed immediately after exposure. The results are shown in Table II and Fig. 7. Clearly, the postirradiation polymerization effect in halogenated aromatic polymers is negligible. PB which is a rubber material shows enormous postirradiation polymerization. COP and NGC, which both have the

Fig. 5. Sensitivity curves for Br-PVK-1 and NGC-2

Fig. 6. Reactivity of NGC as a function of GMA content

epoxy group, show a moderate degree of postirradiation polymerization, but the effect is more obvious in COP than in NGC. This could be due to the difference in the T_g of these polymers.

Thus, it can be concluded that polymers with the reactive groups such as vinyl and epoxy group and moreover low T_g tend to result in more postirradiation polymerization. Chain reaction by reactive groups such as vinyl and epoxy group could be a major factor for postirradiation polymerization, but the degree strongly depends on the mobility of polymer chains, that is, T_g .

Effect of radical scavenger.—In order to determine whether neutral radical species are involved in the crosslinking reaction of halogenated polymers, the effect of radical scavenger on the resist sensitivity was measured. As a radical scavenger, diphenylpicrylhydrazyl (DPPH) was added to CMS and α M-CMS resist films. When the crosslinking reaction occurs via radical intermediates, the electron beam sensitivity should be decreased with the addition of radical scavenger (12). Figure 8a shows the variations of the sensitivity curve for CMS with the addition of DPPH. In Fig. 8b, S/S_0 , where S and S_0 are defined as electron beam sensitivity with and without the addition of DPPH, is plotted

against the concentration of DPPH for both CMS and α M-CMS. The sensitivity decreases are observed as the increase of DPPH concentration, which strongly suggests the participation of radical species.

Electron spin resonance (ESR) spectroscopy.—To detect radical species, ESR spectroscopy was studied for various polymers. Figure 9 shows typical ESR signals from CMS and PSt irradiated with 1 Mrad ^{60}Co γ -rays at room temperature. The CR of CMS was 0.71. The signal intensity from CMS is much larger than that of PSt at room temperature, indicating that large amounts of radicals are formed in CMS by high energy exposure and that they still remain alive. Deep UV exposure gave the same results. The ESR signal height of various CMS's are plotted against CR at the same dose in Fig. 10. The quantity of radical species increased almost proportionally with the increase in chloromethylation ratio. These results seem inconsistent with the results of reactivity saturation, but can be explained in terms of the high stability of these radicals. The variation of ESR signal height at room temperature with the aging time in a vacuum is shown in Fig. 11, where only a small decrease in signal intensity was observed, indicating a high stability of the radicals in the solid state. Since it is known that benzyl chloride is easily decomposed by γ -ray irradiation forming relatively stable benzyl radicals [G value for this scission is 4.3 (15)], radical species detected by ESR can be assigned to the benzyl-type radicals in CMS. Figure 12 shows ESR signals from CMS, benzyl chloride, and p-chloromethyltoluene irradiated with high pressure mercury lamp at -120°C . Though hyperfine structure was not finely detected because of spectrum broadening, the ESR signals from low molecular weight materials, especially in the case of p-chloromethyltoluene, were in close agreement with that of CMS. A portion of total radicals formed by the C-Cl bond dissociation in the chloromethyl group would disappear by a radical coupling reaction to produce a crosslink bond, but most remain in a stable form. In CMS, since it has more chloromethyl groups, more radical species form, but the number of stable radicals which are not involved in crosslinking may also increase, causing reactivity saturation. The details of the reaction mechanism will be discussed later.

The high stability of radical species could be attributed to the high T_g of the aromatic polymers, which may restrict the molecular motion of radicals to produce crosslinking bond. To test this speculation, film

Fig. 8. Sensitivity curves for CMS (a, left) and sensitivity variations for CMS and α M-CMS (b, right) as a function of radical scavenger concentration. S and S_0 are defined as electron beam sensitivity with and without the addition of diphenylpicrylhydrazyl, DPPH.

temperature dependences of the ESR signal and electron beam sensitivity were measured. Figure 13 shows these results for CMS and α M-CMS. When the film temperature of CMS was raised to 60°C, the ESR signal intensity started to decrease and was small when the temperature was higher than T_g . The sensitivity of CMS increased with an increase in film temperature, and this dependence closely corresponded to that of the ESR intensity. In the case of α M-CMS, which has a T_g of 170°C much higher than that of CMS, raising the temperature at first showed little effect on both ESR signal intensity and the sensitivity. From 80°-90°C, the signal intensity gradually decreased, while the sensitivity increased with increasing temperature. However, even at 140°C, the ESR signal intensity of α M-CMS was still strong and the sensitivity enhancement due to temperature was not so large. These very close correlations between the temperature dependences of ESR spectral intensity and sensitivity strongly suggest that radical species detected by ESR spectroscopy have

the potential to crosslink polymer, but are firmly fixed in the film without crosslinking in a temperature region well below T_g . With increasing temperature, the restriction in the movement of these trapped radical species becomes less, and crosslinking bonds are formed from these radicals, leading the decrease of ESR signal height. The reason for the onset of motion in these radicals below T_g in both polymers may be related to the local relaxations of polymer chains around this temperature region.

Further evidence indicating the close relation between film temperature and the lifetime of radical species was demonstrated by an ESR study of PB film. A relatively strong and stable ESR signal was observed when a PB film was irradiated with a high pressure Hg lamp at -70°C, as shown in Fig. 14. This signal could not be detected at room temperature. Figure 15 shows the decrease in the ESR signal of PB irradiated at -70°C with aging time at various temperatures. Radicals disappeared rapidly upon raising the temperature. It is known that in the radiation-

induced radical polymerization of a solid vinyl monomer such as acrylonitrile, propagating radicals can be detected by ESR at low temperature, and the post-irradiation polymerization carried out by heating (16). This suggests that PB vinyl-type radicals remain unreactive below T_g but easily crosslink via chain reactions above T_g .

Crosslinking mechanism of halogenated aromatic polymers.—Reactivity saturation.—In a previous paper (2), we proposed a crosslinking reaction mechanism for CMS resist, which is summarized in Fig. 16. The results obtained in this study support this mechanism. In halogenated polymers, major crosslinking reactions start from the dissociation of carbon-halogen bonds as shown in reaction [1]. The formation of radical species by this dissociation was confirmed by the ESR spectroscopy in this study. Reaction [2] is the crosslinking between two benzylic radicals. Reaction [3] is hydro-

gen subtraction by halogen atoms. When radicals formed by this reaction have a potential to crosslink polymer chains, reactions [4] and [5] can occur. In PSt-type resists, methine hydrogen atoms are readily abstracted by halogen atoms, forming benzylic-type radicals. This type of radical could crosslink polymer chains, because its structure is quite the same as that of radicals derived from the reaction [1] in CMS resist. In this case, a cleavage of the carbon-halogen bond makes two reactive radicals.

Some portion of the radicals in reaction [1] disappear via a recombination reaction, which was suggested as the reason for the reactivity saturation in IPS from kinetic analysis by Shiraishi *et al.* (5). However, we cannot agree with this idea, because no reasonable explanation for the relation between halogen content and recombination reaction rate was provided. Our results in Fig. 10 indicate that more radical species survive in more halogenated polymers, strongly suggesting that the total number of radicals formed by electron beam exposure is also increased.

Fig. 16. Proposed crosslinking reaction mechanism for CMS resist

Fig. 17. Reactivity of CMS at 100°C as a function of molar chloromethylation ratio.

The fact that the chloromethyl group gives almost identical dependence between the reactivity and CR, despite a large difference in polymer chain structure, and that larger halogen atoms cause a more rapid saturation, allows us to propose a steric effect on the reactivity saturation. By assuming that two radicals must be located within a certain distance for the coupling reaction, we can explain all of the results with respect to the reactivity saturation. That is, more halogenation could make the average distance between two polymer chains longer, and large halogen atoms further increase this distance. The van der Waals radii of halogen atoms, 1.8Å for Cl, 1.95Å for Br, and 2.15Å for I, seem to correlate with the results of reactivity saturation. The high T_g 's of aromatic polymers may prevent the coupling reaction of two radicals which are separated slightly too far from each other. Since these trapped radicals can be released by heating the resist films, the reactivity of CMS samples with various CR was compared at 100°C, nearly equal to T_g , in order to confirm our model. As shown in Fig. 17, the reactivity saturation is not observed, although the dramatic increase at low CR is still present.

An alternative interpretation for the reactivity saturation may be the energy migration. The fact that CMS shows a high sensitivity to deep-UV light and CMN exhibits a response to mid-UV light indicates that the reaction proceeds via photoexcited states, mainly the triplet state of the halogenated aromatic ring (17). In the case of UV exposure, the same dependence between reactivity and CR was observed, indicating that the same reaction mechanism is operative as in electron beam exposure. It is known that halogenated aromatic rings can act as very effective trapping sites for triplet energy migration in aromatic polymer films (18). When UV light is absorbed in unsubstituted aromatic polymers, the excited states formed can be trapped by various sites, such as excimer sites or structural defects during migration among aromatic rings (19). Since in a slightly halogenated aromatic polymer excited energy is mainly "trapped" by the halogenated aromatic ring, very efficient dissociation of the carbon-halogen bonds are realized. This speculation can readily explain the abrupt sensitivity increase with very low halogen content. Thus, when the halogen content is high enough to form efficient traps, the dominant factor determining the sensitivity of halogenated aromatic polymers

will be not the content of reactive group, but the yield of photoexcited states, thus making reactivity independent of the halogen content. In order to verify this assumption, the primary processes of photophysics in resist films must be investigated.

Postirradiation polymerization.—Experiments with respect to the temperature dependence of ESR and electron beam sensitivity in CMS resists have clearly revealed the reason why little postirradiation polymerization occurs with halogenated aromatic polymers. The high T_g of the aromatic polymer prevents the reactive radical species surviving after the exposure at room temperature from crosslinking, and the low degree of chain reaction with the halogen group in the crosslinking reaction limits the reactions preceding postirradiation polymerization.

By contrast, the situation seems to be complex simple in epoxy-type resists. Recently, Tada studied the postirradiation polymerization effect of poly(glycidyl methacrylate) (PGMA) and PSt by using ESR spectroscopy (20). PSt showed a very weak ESR signal, which is consistent with our result. However, in PGMA, which is a highly sensitive negative resist containing epoxy groups, two kinds of radicals were detected. Short-lived radicals, observed only at low temperature, were assigned to those formed by the cleavage of epoxy rings. The relatively stable and stronger signal was assigned to radicals formed by the scission of the methacrylic main chain. He concluded that postirradiation polymerization in PGMA occurs via the coupling reaction between the latter radicals which survive at room temperature and decrease with time. This does not seem plausible, because main chain scission in methacrylic polymers is a positive-resist reaction. Actually, PGMA changes resist mode from negative to positive when exposed to deep-UV light which is absorbed not by the epoxy group but by the methacrylic unit, suggesting that the crosslinking reactivity of radicals formed by the main-chain scission is not significant.

However, Ohnishi *et al.* also demonstrated that stable radical species are associated with the postirradiation polymerization of COP containing the glycidyl methacrylate unit and the vinyl-type negative resist SEL-N (12). That is, the addition of DPPH considerably decreased the postirradiation polymerization and the kinetic, assuming that the radical coupling reaction occurs during postirradiation polymerization can explain the experimental results. The chain reaction in epoxy group is believed to proceed via ionic polymerization (21). The initiating species is generated by radiation and may be an anion radical, a cation, or a cation radical. The exposure-generated initiator attacks an epoxy moiety and cleaves it to generate a reactive oxygen species which can open a second epoxy group and generate a crosslinking. It is interesting that the addition of DPPH also decreased the sensitivity of these resists. These results indicate that radical species play an important role not only in the postirradiation polymerization but also in the chain-type crosslinking by the epoxy group. However, the origin and the structure of radical species in COP resist are not known, and the crosslinking reaction scheme in epoxy-type resists has not been well understood.

Conclusion

Various aromatic polymers were synthesized to elucidate the crosslinking mechanism of negative electron resists composed of halogenated aromatic polymers. The reactivity saturation with halogen content observed in CMS or IPS is a common behavior in halogenated aromatic polymers, but is not observed in aromatic polymers containing double-bond or epoxy groups. The saturation occurs more rapidly in polymers having larger halogen atoms. More halogenation and larger halogen atoms could make the separation

between reactive sites longer, causing the saturation of crosslinking reactivity. However, a sudden increase in the reactivity of lightly halogenated polymer may be attributed to the effective collection of excited-state energy migrating in the film due to trapping at the halogenated aromatic ring.

The significant participation of radical species in the crosslinking reaction has been demonstrated by ESR spectroscopy of irradiated polymers. The strong ESR signal observed in CMS or α M-CMS can be assigned to a benzyl-type radical formed by the dissociation of the chloromethyl group. This radical species gradually disappears with increasing temperature, and a quite similar variation is observed in the increase of resist sensitivity with temperature. This result strongly suggests that the observed radical species are associated with the crosslinking reaction. Taking into account that little postirradiation polymerization is observed in halogenated aromatic polymers, we propose that these radical species are tightly fixed in rigid polymer chains because of the high T_g of aromatic polymers. Both the high T_g and the step-wise reaction by the halogen group are responsible for the negligible postirradiation polymerization effect.

A Photoelectrochromic Memory and Display Device Based on Conducting Polymers

Olle Inganäs and Ingemar Lundström

Laboratory of Applied Physics, Department of Physics and Measurement Technology, University of Linköping, S-581 83 Linköping, Sweden

ABSTRACT

We report a new photoelectrochromic system for information storage and display applications. This system is based on the electrochromic properties of thin films of electrochemically generated conducting polymers. These materials can be switched between two states of optical absorption: a highly absorbing, almost-black film in the oxidized state, and an almost-transparent film in the reduced state. On an n-type semiconductor surface, oxidation of the conducting polymer requires illumination of the semiconductor surface. A thin film of conducting polymer photoelectrochemically generated onto a semiconductor surface can thus be reversibly bleached by a cathodic potential and blackened by anodic potential simultaneous with a light pulse. Such a device works as an optical memory which can be erased electrically and written optically with a scanning modulated light beam. We report on initial studies of the n-Si/poly(N-methylpyrrole) system in acetonitrile electrolyte.

The photoelectrochemical generation of thin films of conducting polymers (1) on semiconductor surfaces can be employed for pattern generation and optical information storage, but has so far only been used for corrosion protection of the surface (1, 2). The growth of a conducting polymer on a surface, metallic or semiconducting, leads to stronger light absorption—the polymer is generally brown/black—and decreased optical reflectance. A development of this read-only mem-

ory (ROM) is based on the electrochromic effects reported for polypyrrole and polypyrrole derivatives (3, 4). After electrochemical polymerization at a metal electrode, reversal of the potential applied to the polymer film leads to the reduction of the conducting polymer to an insulating and almost-transparent state. This process can be reversed by applying anodic bias. The electrochromic properties of conducting polymers are presently investigated for display purposes (5). Repeated switching of films up to 10^6 cycles has been obtained (6).

Key words: optical memories, photoelectrochemistry, electrochromics, poly(N-methylpyrrole).

In an electrochemical polymerization, oxidation of the monomer to be electropolymerized is suppressed at an n-type semiconductor in the absence of minority charge carriers. These can be generated by light. This is equally true for the oxidation of the reduced polymer film on a semiconductor surface. Thus the oxidized state is reached by applying anodic bias and illuminating the surface. This photoelectrochromic effect can be used for optical storage of information or for display purposes. Similar systems have been reported using metal deposition at semiconductor surfaces (7), photoelectroreduction of heptylviologen at p-GaAs (8) and reversible reduction and photoelectrooxidation of Prussian blue on TiO_2 surfaces (9). All of these systems are based on semiconducting photoelectrodes which generate photocurrents, giving reduction of metal ions or organic molecules or oxidation of a thin film deposited on a semiconductor substrate. The generation of patterns is due to a scanning or modulated light source. Similar electrochemical reactions have also been used on metal electrodes for display purposes (10).

We report studies of a system based on a conducting polymer on n-Si surfaces in an organic electrolyte. This system differs with respect to the first two reported systems in that the electrochromic effect occurs within a thin solid film anchored onto the surface, and that the semiconductor surface is protected by this film (11). It also differs with respect to the third system in that only a fraction of the thin film is actually reduced/oxidized with the polymer (3a), whereas the Prussian blue is fully reduced/oxidized (9). The poly(N-methylpyrrole) polymer was chosen because it is more stable than the pyrrole polymer in electrochromic applications (4).

Experiments

Single crystal n-type silicon ($0.02\text{--}0.03\ \Omega\text{cm}$) (111) were mounted on glass slides using epoxy. An In/Ga eutectic was used for the back contact. After cleaning and etching the front surface (10% HF, 10s), it was transferred to an 0.1M/0.1M N-methylpyrrole/tetraethylammonium perchlorate electrolyte in acetonitrile.

The photoelectrochemical formation of the polymer was performed at 1.0V vs. a saturated calomel electrode (SCE), potentiostated in a three-electrode, two-compartment system. Nitrogen was bubbled through the solution before polymerization in order to exclude oxygen. A tungsten/halogen lamp provided homogeneous illumination at $175\ \text{mW}/\text{cm}^2$ on the $2\ \text{cm}^2$ silicon surface. Different thicknesses of polymer films were used, as calculated from the number of coulombs transferred. The samples corresponded to $80\text{--}100\ \text{mC}/\text{cm}^2$, and the films were smooth and blue/violet. The thickness can be estimated to $0.1\text{--}0.2\ \mu\text{m}$.

The photoelectrochromic studies were performed in a 0.1M $\text{Et}_4\text{NClO}_4/\text{CH}_3\text{CN}$ electrolyte, with oxygen present. No iR compensation was used. The reflectance of the silicon electrode was measured with a very simple setup, consisting of a red LED fed with a sinewave (274 Hz) illuminating the surface at approximately 45° angle of incidence. The primary reflected beam entered a light detector, giving a signal proportional to the reflected-light intensity. This was fed to a lock-in amplifier. The light used for photooxidation (write light) was entered via an optic fiber. No correction was made for light reflected from the windows of the optical cuvette enclosing the electrolyte or from other reflecting surfaces.

Results

The reflectance from a surface coated with the polymer decreases for the samples studied to approximately 25% of that of a bare-silicon surface. When switching the polymer by applying cathodic bias, the reflectance increases. A potentiostatic cycle (Fig. 1) applied to a sample from cathodic potentials towards anodic po-

Fig. 1. Upper curve: the optical reflectance from the surface is recorded as a function of potential. The strong decrease of reflectance occurs during the flow of photogenerated-hole currents. With no write-light impinging on the surface, a small change of reflectance still occurs. This is due to the red LED light and light from the surroundings. Lower curve: potentiostatic sweep at $10\ \text{mV}/\text{s}$ from $-0.4\ \text{V}$ vs. SCE to 0.6 and $0.7\ \text{V}$ vs. SCE of an n-Si/poly(N-methylpyrrole) structure ($80\ \text{mC}/\text{cm}^2$) in the presence and absence of light (approximately $25\ \text{mW}/\text{cm}^2$). The electrolyte was $0.1\ \text{M}\ \text{Et}_4\text{NClO}_4$ in CH_3CN . Only a very small leakage current flows during the sweep in dark. With light on, oxidation of the film starts at $0.0\ \text{V}$ vs. SCE, and the oxidation current reaches a maximum at $0.4\ \text{V}$ vs. SCE.

tential, with and without the write-light ($25\ \text{mW}/\text{cm}^2$), shows the gradual decrease of optical reflectance as light-induced currents flow. In the absence of the write-light, only small changes of the reflectance occur, which probably are due to the LED-light induced photocurrent. After the oxidation of the polymer to the absorbing state, reduction in a two-peaked wave occurs in the range of 0.3 to $-0.2\ \text{V}$ vs. SCE. The optical contrast, in this case approximately 50%, has not been optimized, and can probably be increased by judicious choice of film thickness, angle of incidence, and geometry.

From Fig. 1 it is concluded that writing using a light pulse can be done at potentials more positive than $0.0\ \text{V}$ vs. SCE, and that the erasing process requires at least the potential $0.0\ \text{V}$ vs. SCE. However, it must be noted that the rate of change of the reflectance is highly dependent on the choice of writing and erasing potentials. In Fig. 2 a plot is shown of the reflectance as a function of charge transferred on light-induced oxidation of the film at $0.7\ \text{V}$ vs. SCE at three different light intensities, obtained by the use of gray density filters. Even though the starting points are somewhat different, the R vs. Q graph is identical in shape with light intensities varying over one order of magnitude. The reduction process of the film is also identical for these states, as shown by the cathodic side of the graph. The coulometric efficiency of the process (i.e., the fraction of the anodic charge that is removed during the cathodic polarization) is between 75% and 95%. This points to the possibility of side reactions occurring. It can

Fig. 2. Reflectance vs. charge transferred during three cycles. The right-hand side of the diagram shows the anodic process (write phase) at a potential of 0.7V vs. SCE and at three different light intensities, (a) 100%, (b) 49%, and (c) 9.8% of 25 mW/cm², obtained using gray filters. The left-hand side shows the subsequent cathodic erase phases at -0.7V vs. SCE.

also be concluded from the graph that a minor increase of the reflectance occurs without a perceptible amount of charge being transferred. It should be observed that the graphs are nonlinear in Q .

The oxidation of the polymer to the fully oxidized state occurs with only a fraction of the sites in the polymer being affected (3). Continued oxidation beyond this point leads to only small changes of the optical absorption. Furthermore, the coulometric efficiency tends to decrease with increasing anodic charge.

Discussion

Three parameters are of essential importance for optimizing the switching time of the memory: writing potential, light intensity, and erase potential. The writing gets faster with more anodic potential, as this will bring about a more efficient collection of minority charge carriers. The intensity of light determines the number of charge carriers available for collection. A more cathodic erasing potential should be chosen for rapid switching. However, these potentials should also be chosen so as to give lasting operation, that is, within the stability range of the electrolyte and of the polymer material. Side reactions on the semiconductor surface must also be avoided, as the adhesion of the polymer film is of essential importance with respect to the lifetime of a device.

N-methylpyrrole polymers show much wider stability ranges than do pyrrole polymers (12), and very anodic (>1.0V vs. SCE) write potentials can be chosen without deterioration. However, a strong, focused light beam at 0.1-1 W/cm² will give a very rapid write process, and it may be preferable to use this parameter for optimization of the write process. The reduction of the polymer is probably the process determining the duration of the write/erase cycle, and this can only be enhanced by applying strong cathodic bias. The stability results on poly(N-methylpyrrole) indicate that it should be possible to go to at least -1.0V vs. SCE. The minimal time of switching reported on metals is 0.1s (3, 5).

The nonlinear relationship of reflectance vs. charge transferred may be a difficulty if the structure should be used as an exposure meter, but need not be a problem when used for digital storage in memory and display devices. Optimization of the device also requires choice of the thickness of the polymer with respect to the contrast required, as well as the time required for write/erase cycles. These considerations may be conflicting, as a thick film will be intrinsically slower in cathodic switching, and also slower in anodic writing: less light will be transmitted through the film, generating photocurrent required for oxidation of the

film. However, a thin film may not give the contrast required. Further development of the device would have to address this question.

As to the stability of the electrochromic material, it is reported (13) that oxygen does not affect the redox process of poly(N-methylpyrrole), neither after exposure to atmosphere nor with oxygen present in the electrolyte. With polypyrrole, oxygen attacks both the reduced and oxidized form of the polymer. This is related to the redox potential of the polymer, which is more anodic with the methyl-substituted polymer. With polypyrrole, the presence of water in the organic electrolyte strongly affects the cyclic voltammograms of the redox process (14). It has also been shown that stable electrochromic switching is obtained with aqueous electrolytes (6, 15), at least with some of the electrochemically prepared conducting polymers. No systematic study of the electrochromic characteristics of different electrolytes has been reported.

A major drawback of the system studied is the instability of the oxidized polymer in contact with electrolyte: it will spontaneously revert to the reduced state at open-circuit conditions. The transparent reduced state, on the other hand, appears to be stable.

Conclusion

We have demonstrated the possibility of constructing a photoelectrochromic device based on a semiconductor surface modified with a photoelectrochemically generated conducting polymer. This device could be used as an optical storage memory that can be erased and rewritten. It can also be used as a display device where light is used to alter the optical state of the display, lowering the power-supply requirements. It could also be used as both an optically and electrically readable exposure meter.

The electrochemical growth of conducting polymers on p-type semiconductors is also possible. On a p-type surface, reduction of the polymer to the transparent state is not possible without light, as no electrons are available for reduction (7). This opens up the possibility of a complementary optical device.

The propagation of light in thin films, one of the basic components of optronics, can also be controlled through the use of semiconductor/polymer devices. For instance, optical coupling of two light beams through a thin film of conducting polymer could be used for light amplification.

The use of a liquid electrolyte is one of the major drawbacks of photoelectrochromic systems, and substitution with a solid-state electrolyte would be very attractive. Earlier work in our laboratory (16) has shown the feasibility of using thin films of a polymer

electrolyte, polyethylene oxide, as a contact to semiconductors coated with thin films of conducting polymers. Preliminary experiments show that photoinduced oxidation of the polymer also occurs in these systems, and this indicates the possibility of extending the photoelectrochromic effects to a polymer electrolyte.

A Study of Contamination during Reactive Ion Etching of SiO₂

M. Valente¹ and G. Queirolo*

SGS-Ates Componenti Elettronici SpA, Agrate Brianza, Milano, Italy

ABSTRACT

Plasma-wall interaction during the reactive ion etching of silicon dioxide was studied with Auger electron spectroscopy. An Al containing film was observed to deposit on the substrate to be etched, slowing down or even stopping the etching process; a fluorocarbon film due to CHF₃ plasma polymerization was also found to grow on the contaminating film. The coverage of the cathode surface by a thick continuous fluorocarbon film effectively avoids this plasma-wall interaction, and allows the etching process to continue to the SiO₂/Si interface.

Reactive ion etching (RIE) of SiO₂ in a fluorine deficient discharge (e.g., CHF₃ plus O₂, or CF₄ plus H₂, in suitable ratios) is an anisotropic and selective dry etching technique widely employed to delineate contact holes in VLSI devices. The etching mechanism is not yet sufficiently understood, though it is evident that a polymer formation process is in competition with the etching of SiO₂. The predominance of either polymerization or etching depends on the energy of the impinging ions, the nature of the material, and the ratio of the two gases.

The presence of a significant voltage between the RF electrode and the discharge is of importance because the substrates undergo bombardment by energetic ions (100–500 eV being typical energies). Since the energy threshold for sputtering of metals is exceeded, it is not surprising that purely physical sputtering effects take place, when the cathode is partially or totally covered by certain metals (1) or when a nonerodable metal mask is used in place of a standard photoresist one (2). This consideration is not applied to all metals, but only to those whose fluorides are not volatile.

The aim of this paper is to demonstrate the nature of contaminants during RIE of SiO₂ with Auger electron spectroscopy (AES); we also illustrate the role played by such contaminants and suggest a remedy to completely eliminate the source of contamination in our particular system.

Experimental

Etching system.—All the experiments were performed within a commercial etching system,² with both RIE and plasma etching (PE) capabilities. The etching gas was a mixture of CHF₃ and O₂; the operating pressure was kept constant at 10.7 Pa (80 mtorr); flow rates were held at 60.0 sccm for CHF₃ and 4.0 sccm for O₂. The gas pressure was monitored with an ion gauge and a capacitive manometer;³ RF power density (at 13.56 MHz) was kept at 0.3 W cm⁻². Substrate temperature was monitored and maintained constant at 22°C.

The system is pumped by a two-stage Roots pump backed by a two-vane rotary pump, and has a base pressure of 0.013 Pa (1.10⁻⁴ torr). The system described here was originally designed for use with chlorine containing gas; hence, aluminum and aluminum oxide were chosen as electrode materials.

AES system.—All the measurements given here were performed within a Varian scanning Auger microprobe, equipped with a variable aperture CMA and LaB₆ cathode. The base pressure of the system is 3 · 10⁻⁸ Pa (2 · 10⁻¹⁰ torr). The primary energy and current were adjusted to minimize sample charging problems and to prevent electron beam-induced reduction or desorption effects. Ar⁺ or Xe⁺ ion etching was performed in order to obtain some in-depth information.

² PK 2440, made by Plasma-Therm Incorporated, Kresson, New Jersey 08053.

³ Baratron Type 220, AHS, made by MKS Instruments, Burlington, Massachusetts 01803.

Sample preparation.—RIE experiments were performed using as a test vehicle a MOS device with contact hole dimensions of approximately 3 μm . Auger measurements were performed on much larger areas. A preliminary scanning electron analysis showed, in fact, that the residues found in the contact holes, and described below, were also present in these areas. The layer to be etched was composed of densified phosphorus silica glass (PSG), about 0.9 μm thick and with a phosphorus content of about 10 w/o; the PSG was deposited over a 0.1 μm thick film of thermal silicon dioxide. HPR 204⁴ resist 1.3 μm thick was used; it was hard-baked (140°C, 30 min) before the etching, in order to enhance its stability during the process.

Results with the RIE system in its original configuration.—Samples processed in the RIE system in its original configuration, as described above, showed the presence of a contaminating residue. In some cases, due to this residue, the etching process failed to reach the silicon dioxide/silicon interface and stopped somewhere in between. In other cases, roughening of the surface was evident, with different morphology, depending on the amount of contamination (see SEM photographs in Fig. 1). This film is of an insulating nature, and its uppermost layer originates a quite singular charging phenomenon, described by the $E \cdot N(E)$ vs. E spectrum of Fig. 2.

The spectrum is severely distorted at energies lower than about 250 eV; in particular, no emission was found at energies lower than 140 eV. On the other hand, no

⁴ Hunt Chemical Corporation.

Fig. 1. SEM photographs, showing surface texturing: (a, top) in presence of slight amounts of contaminant (b, bottom) in presence of a heavy contamination.

Fig. 2. Auger spectrum recorded during analysis of the insulating film (surface); K is an accidental contamination in this particular sample.

effect at all was noticed on higher energy peaks (like O_{KII}) which were found to be at their correct energy. This fact means that the higher energy Auger electrons see the sample as neutral, and only the low energy secondary and Auger electrons are affected by the phenomenon. At present, the origin of this behavior is not clear, but it is conceivable that a double layer of negative and positive charges is created in the surface layer; in this case, only electrons generated within this double layer will be affected.

The spectrum distortion decreases as soon as the sample is etched with Ar or Xe ions, and nearly disappears after etching for a few seconds, or after the removal of only a few angstroms. At this point, the AES analysis shows the presence of Al, Si, C, O, and F (Fig. 3). Both the energy and shape of Al and Si peaks are typical of some bonded states (for instance Al₂O₃ or SiO₂). Observation of the peak-to-peak height of the peaks during the ion etching shows that F and C are contained in a film grown over the Al contaminating film.

In general, F adsorbed on Si or Al is very easily desorbed by the electron beam used for the AES analysis, even at current density as low as 10⁻² A/cm², at 2 keV beam energy. On the contrary, the F contained in the fluorocarbon layer exhibits a noticeably strong stability and is only partially desorbed after an electron dose which is several orders of magnitude greater than the above figure. This stability suggests a very strong bond between C and F, similar, for instance, to that found in PTFE [poly(tetrafluoroethylene)]. This statement is in agreement with the data contained in the literature (3), reporting that a Teflon-like polymeric film is one of the main products in a CHF₃ discharge.

For the above considerations, the active role played by the materials exposed to the plasma is evident. Al and Al₂O₃ at the cathode surface are converted, in a CHF₃ discharge, to aluminum fluoride; due to its very low vapor pressure at room temperature, this compound cannot be removed. A similar behavior is described in Ref. (2) for Al and Cu in CF₄ discharge. Such a compound is sputtered from the surface of the cathode by the high energy (500 eV) ions impinging on it; after multiple collisions with the gas molecules, it is eventually scattered back onto samples mounted on the cathode, where it can act as a nonuniform mask and texture the surface. Although the proposed mechanism is still rather speculative, it is a good work-

Fig. 3. Auger spectrum of the sample of Fig. 2 after a short ion-etch.

ing hypothesis and explains all our experimental observations.

Reactor chamber passivation.—In order to fully demonstrate the above statement, we envisaged a procedure that would allow us to passivate the cathode surface and avoid contamination. The configuration of the reactor was reverted to the PE mode, and RF power was fed to the upper electrode, the lower electrode being grounded. A pure CHF_3 (60 sccm) discharge was ignited at the same power density and pressure used for previous RIE experiments in order to deposit a polymer film of thickness higher than $0.5 \mu\text{m}$ over the exposed surfaces of the reaction chamber. In order to further study the nature of the fluorocarbon film without interference from the Al contamination, some (100) polished silicon test wafers were introduced into the chamber during a deposition run. Ellipsometric measurements performed on these samples yielded a refractive index value of 1.39, in agreement with the figure reported for PTFE films (1.30-1.40). Auger analysis showed only C and F; the film appeared to be richer in F than PTFE (see Fig. 4 and 5). A mass spectrometric analysis performed during He reactive ion etching of the former sample showed a high concentration of HF being released by the film under He^+ bombardment. Therefore, we supposed that the fluorocarbon film is a PTFE film, encapsulating large amounts of HF. After the passivation treatment, we restored the initial configuration and processed a few runs with the parameters used previously.

Results after chamber passivation.—No roughening effect was found on samples processed on the passivated RIE system. When the etching process was stopped before reaching the SiO_2/Si interface, an optically clean SiO_2 surface was obtained; interferometric measurements of the remaining SiO_2 thickness were now possible, whereas in the previous experiments ambiguous results were usually obtained. In samples

Fig. 4. Auger spectrum of the fluorocarbon film, deposited on the lower electrode, in the PE configuration.

Fig. 5. Auger spectrum of a PTFE film on silicon.

where the etching had been completed, the silicon surface exhibited very high reflectance without any residue. This was in contrast with the samples processed in the unpassivated chamber. In both cases, no contaminant was detected by AES analysis.

Summary and Discussion

To summarize, any metal on the cathode that is not reactive ion etched by the plasma (*i.e.*, whose halide is not sufficiently volatile) will contaminate the SiO₂ samples, leading to anomalously low etch rates, polymer deposition, roughening of the surface, degradation of the electrical device parameters [as found in Ref. (1, 4)]. We have demonstrated that if a deposition cycle in the PE configuration was performed previously under suitable conditions (without any load), a polymer film can be grown on the cathode that will prevent any contamination in the following etching cycle. This solution can be considered preferable to the use of a perforated catcher plate, described in Ref. (1), because it does not simply minimize this effect but completely eliminates it. On the other hand, this procedure has the disadvantage of requiring periodical regrowth of the polymer film which is consumed dur-

ing the etching cycle. 0.5 μm thick film can last for only one etching cycle, but a thicker polymer film can be grown for more etching cycles.

Acknowledgments

We wish to thank Dr. M. Bergoglio of the Istituto Metrologico Colonnetti, Torino, for calibrating the MKS 220 AHS capacitive manometer, against an interferometric manobarometer.

Molybdenum Taper Dry Etching

Tetsuo Hosoya, Shin-ichi Ohfuji, and Toshitaka Shibata

Nippon Telegraph and Telephone Public Corporation, Atsugi Electrical Communication Laboratory, 1839, Ono, Atsugi-shi, Kanagawa Prefecture, 243-01 Japan

ABSTRACT

A taper dry etching technique for molybdenum films is proposed. The dry etching characteristics of oxygen-doped Mo films in a CCl₄-O₂ discharge are studied. It is found that oxygen-doped Mo films are etched at a higher rate than oxygen-undoped Mo film and that, in oxygen-doped Mo films, undercutting occurs differently from oxygen-undoped Mo film. Making use of the Mo etching characteristics, tapered Mo patterns with little linewidth loss to resist patterns are obtained by plasma etching of the Mo double layer, namely an oxygen-doped Mo film over an oxygen-undoped Mo film. The taper angle is varied from 40° to 60° by varying the thickness ratio of the oxygen-doped Mo film to the total Mo double layer. This technique promises to improve an interconnection yield in LSI's through reduction of wiring disconnection or shorts over the tapered-Mo steps.

In order to increase LSI packing density, pattern dimensions must be fine. For highly accurate transfer of a resist pattern to the lower material, dry etching techniques, especially anisotropic etching techniques such as reactive ion etching, are effective. This is because directional etching prevents the occurrence of undercutting and produces etched patterns whose dimensions differ little from those of the resist patterns.

However, patterns etched by this kind of etching method have a vertical edge profile, that is, the etched pattern sidewalls are perpendicular to the substrate. Etched patterns having the vertical profile are undesirable for the following interconnection metallization process, since metallization becomes thin or discontinuous where it passes over the etched pattern edges, and, as a result, the metal interconnection yield deteriorates.

One method for improving the metal-interconnection yield without making great changes in LSI-fabrication processes is to produce an etched pattern with tapered sidewalls. Several papers have been published which have reported on taper dry etching techniques, such as tapered via etching using an erodible masking material (1) and tapered silicon etching in which a positive bias is applied to the cathode of a parallel-plate reactor with the wafers placed on the anode (2).

This paper proposes a taper dry etching technique for molybdenum films. Mo films have been used as self-

aligned gates and interconnections for MOS LSI's (3, 4). It is known that vacuum-deposited Mo films on SiO₂ are polycrystalline and have a fiber structure, and that the Mo film resistivity increases as the oxygen content in the grain boundary increases (5). Therefore, in order to obtain Mo films with low resistivity, it is essential to eliminate oxygen from the Mo-deposition atmosphere. However, it has been found that the Mo-film etching rate depends on the oxygen content in the etching atmosphere (6, 7).

The dry etching characteristics for oxygen-doped Mo films were studied. It became clear that oxygen-doped Mo films were etched at a higher rate than Mo films containing no oxygen, and that oxygen-containing Mo films were undercut during etching, while undoped films were not. A Mo double layer was formed by depositing the oxygen-doped Mo film on the undoped Mo film. Tapered Mo patterns were obtained in the lower Mo film after dry etching with AZ resist pattern masks.

The experimental procedure is first described. Next, dry etching characteristics for oxygen-doped Mo films and oxygen-undoped Mo film are discussed. Finally, Mo taper dry etching is realized and discussed in application to LSI fabrication processes.

Experimental Procedure

Mo films were deposited by the reactive-sputter method on SiO₂ which was formed on a 3 in. Si wafer by thermal oxidation. The apparatus for Mo sputter depo-

sition was of a RF planar-magnetron type. An 8 in. Mo disk was used as the target. The purity of the Mo disk was more than 99.95%. The distance between the target and the wafer holder was 80 mm. The holder was turned at 7 rpm. The vacuum chamber was evacuated by a turbo-molecular pump to 3×10^{-7} torr. Ar gas was introduced and kept at a constant pressure of 7.5×10^{-3} torr during Mo sputter deposition by adjusting the Ar-gas flow rate. For oxygen-doped Mo films deposition, O₂ gas was introduced simultaneously with Ar gas. The Ar-gas pressure was maintained at 7.5×10^{-3} torr. The O₂-gas pressure, which was measured in the absence of Ar gas, was varied to 2.5×10^{-4} torr of the maximum pressure. Each gas pressure was controlled by adjusting each gas flow rate. The oxygen concentration in Mo films was varied by controlling the O₂-gas pressure. The wafer holder was at room temperature. RF power density was 4.8 W/cm², and the Mo deposition rate was 120 Å/min.

The apparatus used for Mo dry etching was a parallel-plate reactor (IPC Model 5200), as shown in Fig. 1. The RF power (13.56 MHz) was capacitively coupled to the top electrode. The bottom electrode and the chamber walls were grounded. The wafers were placed on the bottom electrode. The surfaces of the top and bottom electrodes were covered with quartz plates in order to avoid heavy metal contamination to the wafers. The distance between the top and bottom electrodes was 25 mm in the wafer area. A CCl₄-O₂ mixed gas was used as the etching gas in order to obtain a high Mo etching rate and a large etching rate ratio of Mo to SiO₂ (7). The total etching gas pressure and RF-power density were studied to determine suitable conditions for Mo etching. The etching rate for Mo films increased with the total etching gas pressure and with RF-power density. The etching rate ratio of Mo to SiO₂ and photoresist increased with the total pressure and with decreasing the RF-power density. The results of these studies were used to pick a suitable process condition for further studies. Namely, the total pressure and the RF power density were fixed to be 0.2 torr and 0.1 W/cm².

Results and Discussion

Oxygen-doped Mo film structure.—The relation between oxygen concentration in Mo films and the Mo-film structure was studied. The oxygen concentration in Mo films was estimated by Auger electron spectroscopy (AES) analysis. The film structure was investigated by x-ray diffraction. The average grain size was determined from the diffraction peak linewidth. It became clear from AES analysis that Mo films which were not intentionally doped contained about 3 atom percent (a/o) oxygen. The relation between oxygen concentration in films and the x-ray diffraction peak height for as-deposited Mo films is shown in Fig. 2 (8). The Mo films exhibit a strong <110> orientation in the

Fig. 1. Etching chamber diagram

Fig. 2. X-ray diffractometer traces from as-deposited Mo films. (a) oxygen undoped. (b) 20 a/o oxygen doped (8).

growth direction at low oxygen doping, and lose the <110> preferred orientation with increasing oxygen doping. The Mo grain size decreases while increasing the oxygen doping. Mo films were amorphous in structure at oxygen doping levels greater than 30 a/o. Thus, at the Mo-deposition stage, oxygen in Mo films is considered to weaken the preferred orientation and to decrease the Mo grain size in Mo films. It was observed that molybdenum oxide was not formed in oxygen-doped Mo films during the deposition stage. However, MoO₂ was formed in oxygen-doped Mo films which were annealed in an N₂ atmosphere at a temperature above 800°C.

Etching characteristics of oxygen-doped Mo films.—**Etching rate.**—The Mo films and SiO₂ etching depths were measured by Talystep, and the etching rate was estimated by dividing the etching depths by the etching time. The photoresist etching rate was obtained by measuring the difference in the thickness before and after etching. The etching rates for Mo films, photoresist, and SiO₂ are shown in Fig. 3 as a function of the fractional O₂ content of the feed gas (O₂/CCl₄ + O₂). SiO₂ is hardly etched in these etching conditions. Etch rates of AZ resist are small. Thus, etching rate ratios of Mo films to SiO₂ and AZ resist are sufficiently large. In Mo film etching at over 80% and at 0% for the fractional O₂ content, a film was deposited on the Mo films during etching and etching did not advance smoothly. It is thought that inferior oxygen compounds of Mo were produced for O₂ concentrations above 80% in a CCl₄-O₂ discharge and polymer was deposited for an O₂ concentration at 0%. In Fig. 3, two remarkable characteristics are found in Mo film etching rates; the etching rate increased with the fractional O₂ content of the feed gas (7), and the etching rate increased with the oxygen concentration in Mo films. These two characteristics suggest that oxygen is needed to enhance the Mo etching in a CCl₄-O₂ discharge. Oxygen contained in Mo films, as well as oxygen in etching gas (7), is considered to contribute to the formation of molybdenum oxychloride compounds, which are volatile at low temperature.

In Fig. 4, the etching rates for Mo films are shown as a function of (110) Mo grain size. The oxygen con-

Fig. 3. Etch rates for Mo films, AZ photoresist, and SiO₂ as a function of O₂ percentage in the feed gas.

Fig. 4. Etch rates for Mo films as a function of (110) Mo grain size.

centrations in Mo films were set at 20 and 35 a/o. The Mo grain size was increased by annealing in an N₂ atmosphere at temperatures of 600° and 800°C after Mo film deposition on an SiO₂ substrate. It is found that the etching rate for Mo films increases with the oxygen concentration in Mo films and with decreasing the Mo grain size in Mo films. Figure 5 shows SEM photographs of etched Mo films. It is suggested that Mo films are etched by Mo grain unit similar to Mo films etching using CF₄ + O₂ plasma (9). This tendency is noticeable for oxygen-doped Mo films (Fig. 5b).

Thus, it is believed that the increase in the etching rate for oxygen-doped Mo films is due to the effects of the existence of oxygen in Mo films and of the decrease in Mo grain size in Mo films.

Etched profile.—Figure 6 shows SEM photographs of etched cross sections of oxygen-undoped Mo film (Fig. 6a) and oxygen-doped Mo film (Fig. 6b). Undercutting similar to wet chemical etching is observed for the oxygen-doped Mo films, whereas oxygen-undoped Mo films show no such undercutting. A dependency of single-crystalline Mo etching rate on orientation was investigated. Results are shown in Table I. A Mo (111) plane and a Mo (100) plane were etched at a slightly higher rate than a Mo (110) plane. The Mo film etching characteristics by CF₄ + O₂ plasma have been reported elsewhere (9). In that study, it was indicated that the etching rate at grain boundaries is extremely large and the etching rate for a (111) plane is three times as large as that for a (110) plane. The under-

cutting process has been interpreted as follows; (i) radicals hardly reach a pattern sidewall before just

Table I. Single Mo etching quantity dependency on orientation

etching because Mo grains around the pattern prevent the lateral motion of radicals; (ii) undercutting occurs after radicals arrive at the sidewall in the over-etching stage. The etched profile of the undoped Mo film (Fig. 6a) can be interpreted in general on the analogy of Mo films etching by $\text{CF}_4 + \text{O}_2$ plasma. However, the oxygen containing Mo films (Fig. 6b) consist of small-size Mo grains with random orientation. Then, it is believed that the etching advanced isotropically, and that consequently undercutting occurred in the oxygen containing Mo films.

Mo taper dry etching using a Mo double layer.—The etching characteristics for oxygen-doped Mo films are such that the oxygen-doped Mo films were etched at a higher rate than oxygen-undoped Mo film, and, in the oxygen-doped Mo films, undercutting occurred in a manner differing from that in the oxygen-undoped Mo film. Making use of these dry etching characteristics, a tapered Mo pattern was obtained. The experimental procedures are as follows. A Mo double layer was formed on SiO_2 . This structure consisted of an oxygen-doped Mo film for the upper layer and an undoped Mo film for the lower layer. The Mo double layer total thickness was fixed to be 3300Å. The thicknesses for the oxygen-doped Mo film/the oxygen-undoped Mo film were varied from 700Å/2600Å to 1650Å/1650Å. The oxygen concentrations in the upper layer were set to be 20 and 35 a/o, respectively. AZ resist patterns were formed on the Mo double layer film. These samples were etched under etching conditions such that the O_2 flow rate was 67% of the $\text{CCl}_4 + \text{O}_2$ gas mixture.

SEM photographs of cross sections of the etched Mo double layer are shown in Fig. 7. A 700Å/2600Å thick and 20 a/o oxygen-doped Mo film structure are shown in Fig. 7a. A tapered etching pattern was obtained in the lower, undoped layer. The tapered pattern has the features that the deviation in width for the bottom of the lower Mo layer is small in regard to the resist pattern and that the tapered shape is convex, differing from the case in which undercutting occurred. The taper angle obtained in the lower layer, measured as an angle made to the substrate surface, was 60° in the structure, as shown in Fig. 7. The angle varied from 40° for a 1650Å/1650Å structure to 60° for a 700Å/2600Å structure at an oxygen concentration of 20 a/o in the oxygen-doped Mo film. The taper angle was controlled by varying the thickness ratio of oxygen-doped Mo film to the total Mo double layer.

The reason for the tapered profile in the lower layer is considered to be as follows. The upper layer, oxygen-doped Mo film, was etched with an undercut, which resulted in the formation of a space between the resist and the lower layer of the Mo film. The etchant entered into the space and side etching of the upper layer advanced. At the same time, the lower layer was etched at the surface under the space. Thus, the taper was produced in the lower layer of the Mo film. The reason for the tapered shape being convex is considered to be the presence of a high etch rate region in the top of the lower layer. This region, which is illustrated in Fig. 7a, was produced probably due to stress rather than O_2 diffusion. This is because the high etch rate (1200Å/min) cannot be explained only by the diffused O_2 concentration shown in Fig. 8.

The other feature of the etched pattern of the Mo double layer is the generation of a reversed taper in

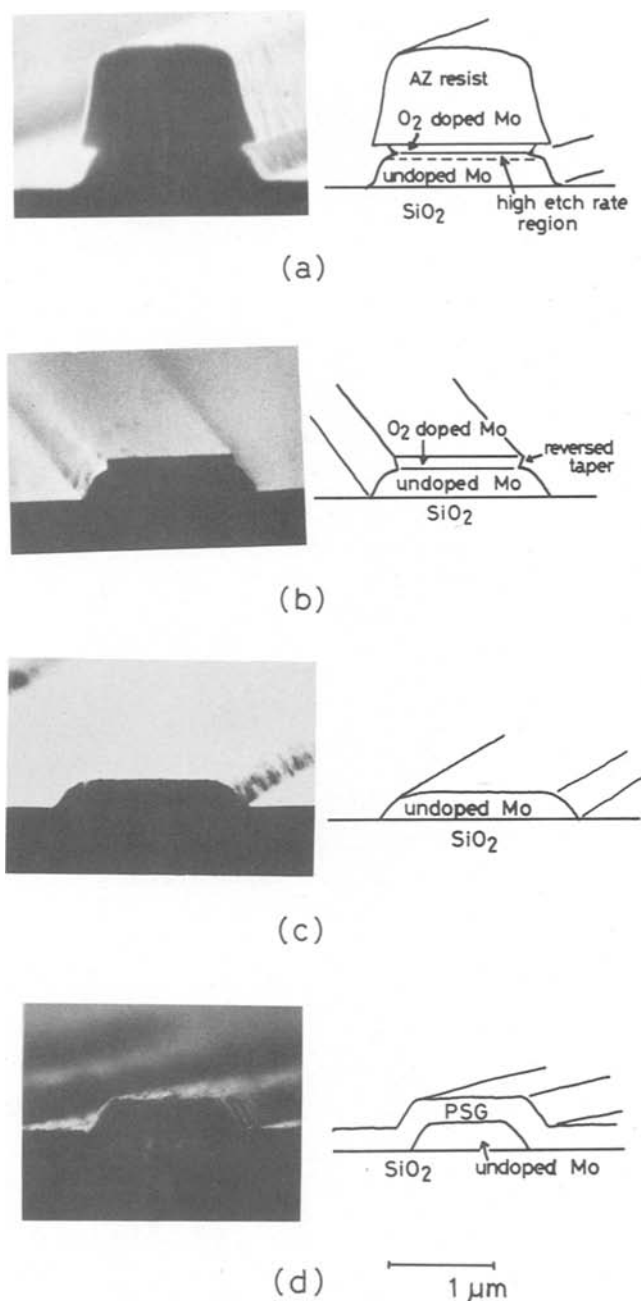

Fig. 7. SEM photographs of etched cross sections of the Mo double layer whose structure is 700Å/2600Å thick and 20 a/o oxygen-doped Mo film for the upper layer. (a) just after etching. (b) after ashing the resist. (c) after etching the upper layer selectively. (d) after PSG deposition over the Mo patterns without glass-reflow treatment.

the upper layer, as shown in Fig. 7a and 7b. The depth profile of oxygen in the Mo double layer investigated by AES analysis is shown in Fig. 8. The piling up of oxygen at the boundary was not found. Therefore, it is thought that the reversed taper in the upper layer was not produced by the piling up of oxygen at the boundary but by stress or disorder in the grain size at the boundary.

Application of Mo taper dry etching.—In order to apply the Mo taper etching technique to LSI fabrication processes, it was necessary to remove the upper O_2 containing layer selectively, after the etching of the Mo double layer pattern. The etching rate ratio for the oxygen-doped Mo films to the oxygen-undoped Mo film is shown in Fig. 9 as a function of flow rate ratio of $\text{O}_2/\text{CCl}_4 + \text{O}_2$. It is observed that the etching

Fig. 8. Depth profile of oxygen in Mo double layer investigated by AES analysis.

rate ratio for the oxygen-doped Mo films to the oxygen-undoped Mo film increases, while decreasing the O₂ flow rate ratio. The 33% O₂ flow rate ratio condition was applied to selective etching of oxygen-doped Mo film. An SEM photograph of the tapered Mo pattern after removing the oxygen-doped Mo film is shown in Fig. 7c. It is obvious that, after selectively etching the upper layer, the reversed taper was cut away and a Mo pattern which had a gentle taper was obtained without serious changes in the pattern dimensions. Figure 7d shows a cross section of the structure in which PSG was deposited over the Mo pattern tapered at 60° without glass-reflow treatment. PSG was deposited with a uniform thickness along the taper, and the good covering of PSG over the tapered Mo pattern was obtained.

Next, the possibility of applying the Mo taper dry etching technique to LSI fabrication processes is discussed with respect to electrical characteristics.

The relation between the PSG coverage angle and the Al electrode resistance was investigated. PSG was deposited on Mo patterns without performing glass-reflow treatment. Al films were deposited on the PSG by the sputter-deposition method using an Al target

Fig. 9. Etch rate ratio for oxygen-doped Mo films to oxygen-undoped Mo film [$R(\text{Mo-O})/R(\text{Mo})$] as a function of O₂ percentage in the feed gas.

containing 2 a/o Si. AZ resist stripe patterns, as shown in Fig. 10, were formed on the Al films. The Al films were etched by a dry etching method. The AZ resist was removed, and the Al electrode resistances were measured after annealing them at 450°C for 30 min in a H₂ atmosphere diluted with N₂. The results are shown in Fig. 11. The mean value for the Al electrode resistance and the standard deviation of the resistance for a 60° taper angle in the Mo pattern decreased by one-half, when compared to values for a 90° taper angle of the Mo pattern. It is noticeable that Al disconnection or shorts, which are caused by thinning of Al lines or Al remaining at the bottom of steps, rarely occurred for the Mo pattern taper angles under 60°.

The Mo-film resistivity and the Mo-film contact resistance to Al were investigated in relation to the oxygen concentration in Mo film. The results are shown in Table II. The resistivity for Mo films containing 35 a/o oxygen was at most twice that for undoped Mo film after annealing at 1000°C for 20 min in an N₂ atmosphere. The contact resistance of Mo films to Al was almost constant, regardless of the oxygen concentration in Mo films. These results reduce the concern for leaving oxygen-doped Mo films on the tapered Mo

Fig. 10. Al stripe patterns over the Mo steps covered with PSG

Fig. 11. Al electrode resistance and disconnection or shorts vs. Mo pattern taper angles.

Table II. Mo film resistivity and contact resistance for Mo films to Al

Oxygen concentration in Mo films (a/o)	Mo film resistivity ($\Omega\text{-cm}$)	Contact resistance for Mo film to Al (Ω/cm^2)
3	9.6×10^{-6}	5.3×10^{-8}

35	2.3×10^{-5}	4.1×10^{-8}

patterns and ease the process for etching oxygen-doped Mo films from the tapered Mo patterns. Thus, the possibility of applying the Mo taper dry etching technique to LSI fabrication processes has been demonstrated.

Conclusion

In plasma etching of Mo films using a $\text{CCl}_4 + \text{O}_2$ mixed gas, it was found that oxygen-doped Mo films were etched at a higher rate than oxygen-undoped Mo film and that, in oxygen-doped Mo films, undercutting occurred in a manner different from that observed for oxygen-undoped Mo film.

Using the characteristics of dry etching for oxygen-doped and undoped Mo films, tapered Mo patterns were obtained by plasma etching of the Mo double layer. The tapered Mo patterns have desirable features; for example, the deviation in pattern width for the etched Mo pattern to the resist pattern is small, and the tapered shape is convex. The taper angle is varied from 40° to 60° by varying the thickness ratio of oxygen-doped Mo film to the total Mo double layer. Good coverage of PSG over the tapered Mo pattern is obtained.

It was found that disconnection or shorts of Al electrodes over the tapered Mo steps covered with PSG layer rarely occurred for taper angles of under 60° .

It was observed that oxygen in Mo films did little to worsen the resistivity characteristics for Mo films and contact resistance for Mo films to Al.

The Mo taper dry etching technique promises to improve an interconnection yield in LSI's through reduction of wiring disconnection or shorts over the tapered Mo steps.

An Etch for Delineation of Defects in Silicon

K. H. Yang*

IBM Corporation, East Fishkill Laboratory, Hopewell Junction, New York 12533

ABSTRACT

An investigation of the $\text{CrO}_3\text{-H}_2\text{O-HF}$ system shows that preferential etching of crystal defects on silicon surfaces is very sensitive to the concentration ratio of CrO_3 to HF. This leads to development of a new etch consisting of one part by volume of 1.5 molal (M) CrO_3 (150 g/l H_2O) and one part of 49% HF. This etch can delineate a wide variety of crystal defects with sharp definition. The shape of dislocation etch pits is uniquely determined by the orientation of wafer surfaces and dislocation lines.

Preferential etch is a simple and fast technique to evaluate the structural perfection of a single crystal. For silicon crystals, such a technique is widely used to crop dislocation-free crystal sections and also to delineate process-induced defects in silicon wafers. A reliable preferential etch is, therefore, extremely valuable in crystal-growth technology and device-failure analysis.

There are several preferential etches currently available for silicon crystals (1-5). Dash etch (1) requires an etch time of several hours and is unsuitable for fast evaluation of crystal perfection. Sirtl etch (2) favors (111) surfaces but fails to reveal dislocation etch pits on (100) surfaces. Due to the increased demand of (100) wafers, three etches have been developed for (100) surfaces (3-5). Secco etch (3) and Schimmel etch (4) yield relatively poorly defined

circular dislocation etch pits. Wright etch (5), in general, gives sharp definition for crystal defects induced by hot processing. However, it is relatively insensitive to dislocations generated during crystal growth. As a result, development of an improved etch for (100) crystals is highly desirable. Furthermore, the influence of chemical composition that leads to the difference in etching characteristics between these etches has not been discussed and is still poorly understood.

This study investigated the capability of the $\text{CrO}_3\text{-H}_2\text{O-HF}$ system for preferential etching. The results lead to the development of an improved etch. This etch is capable of delineating a wide variety of defects on crystal surfaces of different orientations and electrical resistivities. In most cases, manual agitation or ultrasonic vibration is not necessary during the application of this etch.

Experimental

The materials used for this study were mainly 125 mm slugs and 100 mm wafers of p-type, (100) silicon

* Electrochemical Society Active Member.
Key words: silicon, preferential etch, crystal defects, defect delineation.

crystals (1-20 Ω -cm). A group of p-type (110) wafers and n-type (111) wafers (0.5-2 Ω -cm) was also selected for defect delineation. The surface of the slugs was chemically polished, and that of the wafers was chemically-mechanically polished. During etching, one slug or one wafer was placed horizontally and etched in a plastic beaker without the application of manual or ultrasonic agitation. For as-grown slugs and wafers, a volume of 500 ml etch and a relatively long etching time of 10-15 min were used in order to enhance defect delineation for visual inspection. For hot-processed wafers, a volume of 200 ml etch and an etching time of 2-3 min were used. The volume was decreased proportionally for smaller wafers. After etching, the wafers were rinsed, dried, and examined with the optical microscope using Nomarski interference contrast. The validity of etch figures was compared with x-ray topographs. Some of these etch figures were further investigated in a transmission electron microscope (TEM).

Artifacts in the size of several microns were occasionally observed on the wafer surfaces etched longer than 5 min. The artifacts could be easily eliminated by placing the wafer vertically during etching, or by step etching at an interval of 3 min, or by etching in a 30°-tilt cup rotating at 6-8 rpm. All three methods yielded etch figures with sharp definition, smooth background, and freedom from artifacts.

Etching characteristics.—CrO₃-H₂O-HF system.—An investigation of the CrO₃-H₂O-HF system was carried out using different concentrations of CrO₃ and HF. In the first group of these solutions, the volume ratio of CrO₃ solution and HF (49%) remained one to one. The concentration of CrO₃ molal (*M*) in the stock solution and the concentration ratio, *m*, of CrO₃ and HF expressed in *M*/%, in the etch are given in Table I. The value of *m* is an indicator of oxidizing power in the etch. By gradually increasing the concentration of CrO₃, we observed a substantial change in the definition of dislocation etch pits. At a CrO₃ concentration of 0.5*M* (*m* = 0.01, Y1 etch (see Table Ia) gives relatively ill-defined round etch pits (Fig. 1a). The etch rate of the Y1 etch is relatively low. It requires about 30 min to develop a reasonable size of etch pits. As the CrO₃ concentration increases to 1.0*M* (*m* = 0.02), the shape

Fig. 1. Influence of CrO₃ conc. on the definition of etch pits on a (100) slug. A, left: 30 min Y1 etch (0.5*M*). B, center: 15 min Y3 etch (1.5*M*). C, right: 15 min Y5 etch (2.5*M*).

of etch pits delineated by Y2 etch becomes better defined. In the range of 1.5-2.0*M* CrO₃ concentration (*m* = 0.03-0.04), Y3 and Y4 etches yield well-defined etch pits (Fig. 1b). As the CrO₃ concentration increases to 2.5*M* (*m* = 0.05), Y5 etch reveals only a low density of dislocation etch pits (Fig. 1c). This indicates a decreasing capability of preferential etching. At a 3.0*M* CrO₃ concentration (*m* = 0.06), Y6 etch has an absence of preferential etching, and the etched surface is featureless, similar to that revealed by the Sirtl etch (5.0*M* CrO₃).

In the second group investigated, the volume of CrO₃ solution and HF was kept at a two-to-one ratio. By increasing the CrO₃ concentration from 1.0 to 2.0*M*, a substantial change in the capability of preferential etching was again observed. At 1.0*M* CrO₃ concentration (*m* = 0.041), Y7 etch reveals well-defined etch pits similar to those obtained by Y3 etch. However, Y7 etch has a slow etch rate and requires about 60 min to develop a reasonable size of etch pits. Because of the slow etch rate, the investigation of CrO₃ concentrations below 1.0*M* was stopped. As the CrO₃ concentration increases to 1.5*M* (*m* = 0.061), Y8 etch reveals only a very low density of dislocation etch pits, indicating a decreasing capability of preferential etching. At 2.0*M* CrO₃ concentration (*m* = 0.082), Y9 etch lacks the capability of preferential etching.

In the third group investigated, the volume ratio of CrO₃ solution and HF is kept at two to three. At 2.0*M* CrO₃ concentration (*m* = 0.027), Y10 etch gives well-defined etch pits. But it also gives artifacts due to vigorous bubble formation. As the CrO₃ concentration increases to 3.0*M* (*m* = 0.041), preferential etching in Y11 is absent.

The dependency of preferential etching on the concentration ratio *m* was also observed on (111) surfaces. The etch composition and the etching characteristics are given in Table Ib. Figure 2a shows that at *m* = 0.01, Y1 etch again gives round dislocation etch pits. As *m* increases to 0.03, Y3 etch yields well-defined triangular pits, Fig. 2b. The definition of the triangular pits shows no significant changes even as *m* increases to 0.204 (Y16) (Fig. 2c). The capability of preferential etching decreases at *m* = 0.408 (Y17 etch), and finally ceases at *m* = 0.612 (Y18 etch).

The results of this study indicated that preferential etching of dislocations takes place only at a proper concentration ratio *m* of CrO₃ and HF in the etch. The influence of *m* is much more critical on (100) surfaces than on (111) surfaces. The optimum composition of the etch applicable to both (100) and (111) surfaces is that of Y3 and Y4 etches. The etching rate of these two etches is about 1.5 μ m/min. The Y3 etch is chosen for further defect delineation.

K₂Cr₂O₇-H₂O-HF system.—The K₂Cr₂O₇-H₂O-HF system was also investigated for preferential etching. Because of the low solubility of K₂Cr₂O₇ in water, the concentration of K₂Cr₂O₇ cannot be changed significantly. The results of our investigation show that the optimum composition is nearly the same as Secco's (3).

Fig. 2. Influence of CrO_3 conc. on the definition of etch pits on a (111) wafer. A, top left: 15 min Y1 etch (0.5M). B, top right: 5 min Y3 etch (1.5M). C, bottom left: 3 min Y16 etch (10M). D, bottom right: 4 min Y17 etch.

Defect delineation.—Dislocation etch figures.—Dislocation etch figures delineated by the Y3 etch have an excellent correlation with dislocations revealed by the x-ray topography. Figure 3a is the x-ray topograph of a 125 mm (100) slug showing slip dislocations generated during crystal growth. Figure 3b is the etched surface of the same slug. An excellent correlation is clearly established between Fig. 3a and 3b. When the etched surface is examined at high magnification, well-defined etch pits along slip directions are observed (see Fig. 3c). In most cases, the etch pits assume the shapes of A and B, and, in some cases, the square shape C. The pits result from dislocations lying at a steep inclination to the wafer surface.

A comparison of existing etches with Y3 etch is given in Fig. 4. Figure 4a shows that Sirtl etch (2) yields a featureless surface and fails to reveal etch pits as reported previously (3, 5). After 30 min of etching, Wright etch (5) generates a very low density of well-defined etch pits, Fig. 4b. Both Secco etch (3) and Schimmel etch (4) develop ill-defined round etch pits, as shown in Fig. 4c and 4d. A comparison of Fig. 4 with Fig. 1b and 3c clearly indicates that Y3 etch

Fig. 4. Four quarters of a highly dislocated 125 mm (100) slug. A, top left: after 5 min Sirtl etch. B, top right: after 30 min Wright etch. C, bottom left: after 10 min Secco etch. D, bottom right: after 10 min Schimmel etch.

gives a better definition of dislocation etch pits on (100) surfaces.

The Y3 etch is also capable of delineating dislocations lying nearly parallel to the surface. This type of dislocation is frequently observed as dislocation networks in as-grown crystals (Fig. 5a) and as misfit dislocations in phosphorus-diffused layers (Fig. 5b). Application of the Wright etch (5), however, fails to delineate those dislocation networks in Fig. 5a and reveals the misfit dislocations in a lower density and a weaker contrast as shown in Fig. 5c. This clearly indicates that the Y3 etch is more sensitive for delineating this type of dislocations.

The Y3 etch is also capable of revealing dislocations on (111) and (110) silicon surfaces. For (111) surfaces, the triangular etch pits revealed by Y3 etch were already shown in Fig. 2b. Figure 6 shows that both Sirtl and Wright etches produce similar triangular pits, while Secco and Schimmel etches yield round pits. Figure 7 shows two types of dislocation etch figures delineated by Y3 etch on a longitudinal (110) slice cut from a 125 mm (100) crystal. One type is etch pits of slip dislocations, which assume three com-

mon shapes of A, B, and C (Fig. 7a). The shape C is an inversion of the shape B. It is interesting to note the unique shape of etch pits on the (100), (111), and (110) surfaces revealed by this etch. The other type is a group of dislocations lying nearly in the (110) surface (Fig. 7b). Once these dislocations intersect the edge surface, they form etch pits (indicated by arrows).

Swirl patterns.—Swirl patterns are usually observed in a silicon wafer containing substantial oxygen precipitation after hot processings. Figure 8a is an x-ray topograph of such a pattern. Figure 8b is the same wafer after etching. A comparison between Fig. 8a and 8b clearly indicates that the etched surface gives a much more pronounced resolution of the patterns. Examination of Fig. 8b at high magnification shows that some of the etch figures can be clearly identified as oxide precipitates with punch-out dislocation loops (indicated by arrows in Fig. 8c). The formation of dislocation loops due to punch-out from oxide precipitates has been reported previously (6, 7).

However, the majority of the etch figures is beyond the resolution at this magnification. TEM investigation shows that the defects are oxide precipitates with punch-out dislocation loops in a complex form (Fig. 8d).

Oxidation-induced stacking faults.—Stacking faults of both surface and bulk types are often observed in sili-

con wafers after thermal oxidation. Figure 9a shows that the Y3 etch can simultaneously delineate surface faults and unfaulted loops with sharp definition on a (100) surface. These faults are first delineated by 10s of etching. This results in a straight line at the fault location. After subsequent N_2 anneal, most of the faults become unfaulted loops.

Stacking faults of bulk type are shown in Fig. 9b. Most of the faults contain a pit at the fault center. TEM investigation shows that the pit arises from oxide precipitates which act as nucleation centers for fault formation, Fig. 9c.

The resolution of swirl patterns and stacking faults as shown is at least comparable with that revealed by Wright etch (5). However, Y3 etch requires a shorter etching time and no manual agitation. Application of Y3 etch to reveal dislocations on polycrystalline surfaces, resistivity striations in highly doped crystals, and p-n junctions also yields satisfactory results.

Discussion

Mechanism of preferential etching.—The results of this study show that the definition of dislocation etch pits is mainly controlled by the concentration ratio m of CrO_3 and HF. Table I shows that for (100) surfaces, preferential etching takes place only for m below $0.04M CrO_3/\%HF$. The shape of dislocation etch pits is well defined in the range of 0.03 and $0.04M CrO_3/\%HF$. Below $0.03M CrO_3/\%HF$, the shape becomes relatively ill-defined. For (111) surfaces, well-defined etch pits are observed in a wide range of m from 0.03–0.20. Below 0.03, the shape of etch pits becomes ill-defined and above 0.20, the capability of preferential etching decreases.

These results are further supported by our evaluation of existing etches (2–5). For example, Secco, Schimmel, and Y1 etches generate similar round pits on both (100) and (111) surfaces because their oxidizing power is too weak (low m). The value of m is 0.01 for Schimmel and Y1 etches, and 0.003 for Secco etch. The oxidizing power of Sirtl etch ($m = 0.10$) is optimum for (111) surfaces, but is too strong for (100) surfaces. As a result, it favors (111) surfaces but fails to delineate etch pits on (100) surfaces. The m value of Wright etch is difficult to estimate because it contains a combination of conc. HNO_3 and CrO_3 . The etching characteristics of Wright etch, however, are very similar to those of Y6 etch ($m = 0.062$). This suggests that the oxidizing power of Wright etch is slightly too high for (100) surfaces.

The dependence of preferential etching on the concentration ratio m of CrO_3 and HF can be understood

from the following reasoning. The formation of a dislocation pit arises mainly from the strain field associated with a dislocation (8) and/or impurities segregated at a dislocation (9). The strain field and/or the impurity segregation produce a surface potential between the site of a dislocation and the surrounding perfect crystal. The surface potential causes a difference in the etching rate. During the course of etching, HF dissolves silicon when the silicon surface is oxidized by CrO_3 . If the CrO_3 concentration is too high, the strong oxidizing power of CrO_3 tends to minimize the surface potential to a negligible extent. As a result, preferential etching is absent. If the CrO_3 concentration is too low, etching due to HF dissolution is predominant, and the shape of etch pits becomes ill defined. Therefore, the concentration ratio m is very critical to the definition of etch pits.

Influence of surface orientation.—This reasoning can also be extended to explain the influence of surface orientation on preferential etching. As shown before, preferential etching occurs more easily on (111) surfaces than on (100) surfaces. For the low-index surfaces, the surface energy of silicon (10) increases according to the order of $(111) < (110) < (100)$. The surface potential between a dislocation and its surrounding crystal is therefore greater on the (111) surfaces than on the (100) surfaces. The greater surface potential makes preferential etching of (111) surfaces possible with an etch of higher oxidizing power, such as Sirtl etch (2). The (111) etch, however, may not be applicable to the (100) surface. On the contrary, a (100) etch should also be applicable to the (111) surface.

Significance of etch figures.—The etch figures of dislocations are mainly determined by the inclination of dislocations to the surface. For dislocations lying nearly parallel to the surface, dislocation lines are observed. For dislocations lying at a steep inclination to the surface, etch pits result. The basic unit of an etch pit is bounded by the direction of (111) planes intersecting to the surface. The shape of an etch pit can be considered as a superimposition of different sizes of basic units etched at different time intervals along a dislocation. This is shown schematically in Fig. 10.

For the (111) surface, the basic unit is a triangle with three sides in $<110>$ directions. A superimposition of these units along a dislocation in the $[110]$ direction results in an etch pit in the shape of Fig. 10a, in agreement with the shape observed in Fig. 2b and 2c.

For the (100) surface, the basic unit is a square. A superimposition of these squares along two dislocation directions, $[1\bar{1}0]$ and $[2\bar{1}\bar{1}]$, results in two shapes of etch pits as shown in Fig. 10b. These two shapes are frequently observed, as shown in Fig. 3c.

Fig. 9. A, left: oxidation-induced stacking faults (SF) of surface type and unfaulted loops (L) in a (100) wafer delineated by 2 min Y3 etch. B, top right: bulk-type stacking faults delineated by 2 min Y3 etch. Note that the faults contain a pit at the fault center. C, bottom right: TEM micrograph showing that the pit arises from an oxide precipitate.

A. (111) Surface

B. (100) Surface

C. (110) Surface

Fig. 10. Schematic drawing of dislocation etch pits on (A, left) (111) surfaces, (B, center) (100) surfaces, and (C, right) (110) surfaces. D refers to the emergence of a dislocation to the surface. Solid line refers to the shape of an etch pit. Dashed line refers to the basic unit of an etch pit.

For the (110) surface, there are four (111) planes intersecting the surface. Two, the $(\bar{1}\bar{1}\bar{1})$ and the $(\bar{1}\bar{1}\bar{1})$ planes, are perpendicular to the surface, and the other two, the (111) and the $(\bar{1}\bar{1}\bar{1})$ planes, make an angle of 35.3° to the surface. During the course of etching, preferential etch attacks the (111) and the $(\bar{1}\bar{1}\bar{1})$ planes first before reaching the $(\bar{1}\bar{1}\bar{1})$ and the $(\bar{1}\bar{1}\bar{1})$ planes. Therefore, the basic unit is a line in the $[1\bar{1}0]$ direction resulting from the intersection of the (111) and the $(\bar{1}\bar{1}\bar{1})$ planes on the (110) surface. However, etching also takes place at a slower rate in the $[001]$ direction perpendicular to the line. As a result, the basic unit becomes a rectangle. In Fig. 7a, the dislocations lie approximately in three $\langle 110 \rangle$ directions on the $(\bar{1}\bar{1}\bar{1})$ slip plane and slip along the $[\bar{1}\bar{1}2]$ direction on the (110) surface. For those dislocations in the $[110]$ direction perpendicular to the surface, the shape of etch pits can be considered as a superimposition of different sizes of rectangles, and results in shape A in Fig. 10c and 7a. For those dislocations in the $[011]$ direction, preferential etching initiates on both the (111) and $(\bar{1}\bar{1}\bar{1})$ planes, and then proceeds along the $[011]$ dislocation direction. This results in an etch pit consisting of two parts. One part due to preferential etching of the $(\bar{1}\bar{1}\bar{1})$ plane is the upper half of shape A. The other part due to preferential etching of the $[011]$ dislocation emerging to the (111) plane is bounded by the intersections of the (111), $(\bar{1}\bar{1}\bar{1})$, and $(\bar{1}\bar{1}\bar{1})$ planes on the (110) surface. This part is a triangle with three sides in the $[\bar{1}\bar{1}2]$, $[112]$, and $[110]$ directions. These two parts join together at the common line in the $[110]$ direction, and result in an etch pit of shape B, as shown in Fig. 10c and 7a. For the same reason, the dislocations in the $[10\bar{1}]$ direction produce a pit of shape C, an inversion of shape B.

Formation of artifacts.—Artifacts in the size of several microns are occasionally observed in some areas of the etched surface. The formation of the artifacts arises mainly from the fact that Cr^{+6} , once reduced to Cr^{+3} , reacts with F^- to form a green powder of CrF_3 . The CrF_3 powder tends to precipitate on the etched surface and form artifacts in the form of mounds. The rate of CrF_3 formation is much slower in the Y3 etch than in Schimmel and Wright etches. This allows one to use the Y3 etch without manual agitation or ultra-

sonic vibration. Elimination of the artifacts can be easily achieved through the use of three methods described in the Experimental section.

Conclusions

The results of this study lead to the following conclusions:

1. An investigation of the $\text{CrO}_3\text{-H}_2\text{O-HF}$ system shows that preferential etching of dislocations is mainly controlled by the concentration ratio m of CrO_3 and HF.
2. The optimum composition of the newly developed etch consists of one part by volume of 1.5M CrO_3 and one part of 49% HF.
3. This etch is capable of delineating various crystal defects on the (100) surface, as well as on the (111) and the (110) surfaces. The shape of dislocation etch figures is uniquely determined by the orientation of wafer surfaces and the orientation of dislocation lines.

Rapid Annealing Using Halogen Lamps

Juri Kato and Seiichi Iwamatsu

Suwa Seikosha Company, Limited, Fujimi Plant, Fujimi-machi, Suwa-gun, Nagano, Japan

ABSTRACT

A few seconds halogen lamp annealing (HLA) technology is evaluated from the viewpoint of practical application to complementary metal oxide semiconductor (CMOS) very large scale integration (VLSI) processing. $^{49}\text{BF}_2$, ^{11}B , and ^{31}P ion-implanted silicon layers have been investigated on their isothermal short-time annealing behavior of junction leakage current, recrystallization, activation, and junction depth. We have found that a few seconds annealing of 800°C is enough to crystalline regrow the $^{49}\text{BF}_2$ or ^{31}P ion-implanted amorphous layer, to activate $^{49}\text{BF}_2$ or ^{31}P ion-implanted dopants, to form titanium silicide, and to reduce the area leakage current of both n^+p^- and p^-n^- junctions without dopant diffusion. But activation of $^{11}\text{B}^+$ ion-implanted dopants, reduction of perimeter leakage current, molybdenum silicide formation, and phosphosilicate glass (PSG) reflow require a little higher temperature heat-treatment.

Application of short-time annealing (1) technologies to VLSI fabrication processing have become of great interest from the scaling down of electronic device dimensions, which requires shallower junctions. Re-

Key words: ion implantation, annealing behavior, silicon, p-n junction, silicide formation, PSG reflow.

cently, various short-time annealing technologies have been intensively investigated in activation of ion-implanted layers, using pulsed laser (2), electron beam (3), graphite heater (4), flash lamp (5), high intensity arc lamp (6), and halogen lamp (7-9). From the viewpoint of practical application to VLSI fabri-

cation, halogen lamp annealing (HLA) has many advantages. Halogen lamps irradiate a large area at one time in nitrogen gas at atmospheric pressure, cassette-to-cassette, single-wafer processing realizes excellent repeatability, and cold-wall process reduces risk of contamination. The drain gaussian impurity profile fabricated with HLA reduces short-channel effects and hot-carrier effects (10) compared to the drain abrupt impurity fabricated by melting annealing with pulsed laser. A few-second HLA was already applied (8, 9) to 256 kbit CMOS ROM fabrication and realized a good yield over a 4 in. diam wafer.

This paper describes the basic characteristics of ion-implanted silicon with a few second HLA such as, crystalline regrowth, activation of dopant, diffusion, and junction-leakage current. The application of HLA for CMOS VLSI processing is also discussed.

Heating with Halogen Lamps

The halogen lamp system is a radiant furnace with quartz tungsten halogen lamps. The heating chamber is composed of 24 halogen lamps; 12 lamps at top and bottom, respectively, facing each other. The wavelength of the incoherent light ranges from 0.3 to 3.0 μm . The effective volume of the heating chamber is 200(W) \times 264(D) \times 80(H) mm^3 . A silicon wafer is supported on four pointed quartz pins between the top and bottom lamps, keeping a distance of 40 mm from each lamp unit. Radiation from both lamp units is absorbed in the top and bottom surfaces of the wafer. After these lamps are put out, the wafer is cooled only by its radiation to the surroundings. Figure 1 shows one of the temperature-time profiles of the wafer. We have used a 5s rising time throughout this study. We define the annealing conditions by the maximum temperature and its soak time (1). According to this definition, Fig. 1 is the profile of 1100°C and 5s annealing. The temperature is measured by a Chromel-Alumel thermocouple attached to the bottom surface of the wafer.

Regrowth

Czochralski-grown silicon crystal of (100) orientation of 8-12 $\Omega\text{-cm}$ n-type resistivity and 6-9 $\Omega\text{-cm}$ p-type resistivity were used for the experiments. The wafers were chemically and mechanically polished on one side, and the peripheral edges of the wafers were rounded. Wafers were implanted with ^{11}B , $^{49}\text{BF}_2$, ^{31}P , or ^{40}Ar ions, and were annealed with halogen lamps in nitrogen gas at atmospheric pressure for a few seconds.

Fig. 1. Temperature-time profile of 5s rising time, 5s soak time, and 1100°C max temp HLA.

The surface regrowth of ion-implanted layers were measured by low energy electron diffraction (LEED) (11). Figure 2 shows the LEED patterns for ^{31}P , 60 keV, $1 \times 10^{15} \text{ cm}^{-2}$ ion-implanted silicon and for $^{49}\text{BF}_2$, 60 keV, $4 \times 10^{15} \text{ cm}^{-2}$ ion-implanted silicon. Both ion-implanted layers with a 600°C and 10s HLA show no Kikuchi line, and the surfaces are still amorphous. Both LEED patterns with an 800°C and 10s HLA show Kikuchi lines (11), and the surfaces are crystalline. Figure 3 shows the combinations of HLA times and

Fig. 2. LEED patterns of ^{31}P , 60 keV, $1 \times 10^{15} \text{ cm}^{-2}$ ion-implanted silicon and of $^{49}\text{BF}_2$, 60 keV, $4 \times 10^{15} \text{ cm}^{-2}$ ion-implanted silicon with HLA.

Fig. 3. Regrowth as a function of HLA time and temperature. \square , \blacksquare : $^{49}\text{BF}_2$, 60 keV, $4 \times 10^{15} \text{ cm}^{-2}$ ion-implanted silicon. \circ , \bullet : ^{31}P , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ ion-implanted silicon. \bullet , \blacksquare : amorphous layer. \circ , \square : crystalline layer.

temperatures which are sufficient for crystalline regrowth of samples implanted with ^{31}P , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ (open circle) or $^{49}\text{BF}_2$, 60 keV, $4 \times 10^{15} \text{ cm}^{-2}$ (open square).

It is shown that a minimum of about 700°C and 10s HLA or 800°C and 1s HLA is required for the crystalline regrowth of ^{31}P or $^{49}\text{BF}_2$ ion-implanted layer. The wafers that were implanted with ^{11}B ions have Kikuchi lines irrespective of HLA time and temperature. The ^{11}B , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ ion-implanted layers without HLA were still crystalline. The wafers that were implanted with ^{31}P , 60 keV, $1 \times 10^{15} \text{ cm}^{-2}$ and ^{40}Ar , 60 keV, $1 \times 10^{14} \text{ cm}^{-2}$ and were annealed at 1000°C for 10s have Kikuchi lines. But the wafers that were implanted with ^{31}P , 60 keV, $1 \times 10^{15} \text{ cm}^{-2}$ and more than $1 \times 10^{15} \text{ cm}^{-2}$ ^{40}Ar , 60 keV and were annealed at 1000°C for 10s have no Kikuchi line. ^{40}Ar inhibits the regrowth of ^{31}P ion-implanted layer. The samples which were implanted with ^{40}Ar as well as ^{31}P or $^{49}\text{BF}_2$ recrystallized slower than those which were not implanted with argon (12). According to the LEED patterns, ^{11}B ion-implanted layers require no HLA, $^{49}\text{BF}_2$ or ^{31}P ion-implanted layers require a 700°C and 10s HLA, and high dose ^{40}Ar ion-implanted layers require more than a 1000°C and 10s HLA in order to crystallize the surface of silicon.

Diffusion

The scaling down of CMOS VLSI device dimensions requires shallower junctions of both p-type and n-type source-drain regions. High temperature and long time heat-treatment causes diffusion of dopant in both the vertical and lateral directions, which, if excessive, can constrain the density of LSI designs. HLA could control both vertical and lateral redistribution of source-drain region to the minimum, thus easing the short channel effect (9). This section determines the maximum HLA cycle which causes little diffusion of the dopant. The junction depths were measured by spreading resistance method. Figure 4 shows the junction depths as a function of HLA temperature. Soak time is 3s throughout Fig. 4. One (closed circle) was implanted with ^{11}B , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ through 400\AA SiO_2 . The other (closed square) was implanted with $^{49}\text{BF}_2$, 60 keV, $4 \times 10^{15} \text{ cm}^{-2}$ through 400\AA SiO_2 . The junction depth of ^{11}B ion-implanted layer becomes deeper as the HLA temperature goes above 800°C .

Fig. 4. Junction depth of ^{11}B , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ through 400\AA SiO_2 ion-implanted layer (●) and of $^{49}\text{BF}_2$, 60 keV, $4 \times 10^{15} \text{ cm}^{-2}$ through 400\AA SiO_2 ion-implanted layer (■) as a function of HLA temperature. Soak time is 3s.

While HLA temperatures change from 800° to 1100°C , junction depths of both ^{11}B and $^{49}\text{BF}_2$ ion-implanted layers, respectively, do not change. A 1200°C and 3s HLA causes diffusion of the dopant about 1000\AA . It is shown that the maximum of HLA time and temperature which causes little diffusion is 1100°C and 3s for both ^{11}B and $^{49}\text{BF}_2$ ion-implanted layers. Figure 5 shows the junction depths of ^{31}P , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ through 400\AA SiO_2 ion-implanted layer as a function of HLA temperature. The one-soak time (open-triangle) is 3s. The other soak time (closed triangle) is 10s. A 1200°C and 10s HLA causes diffusion of the ^{31}P dopant about 2000\AA . It is shown that the maximum of HLA temperature and time which causes little diffusion is 1100°C and 10s for ^{31}P ion-implanted layer. This result almost coincides with ^{11}B and $^{49}\text{BF}_2$ ion-implanted layers. From the viewpoint of LSI miniaturization, HLA should be carried out within the B region in HLA time-temperature space (see Fig. 15).

Sheet Resistivity

Sheet resistivities were measured by means of the four-probe method. Figure 6 compares the ^{11}B , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ ion-implanted layer with the $^{49}\text{BF}_2$, 60 keV, $4 \times 10^{15} \text{ cm}^{-2}$ ion-implanted layer as a function of HLA temperature. Soak time is 3s throughout Fig. 6. As HLA temperature goes up, the sheet resistivity of ^{11}B ion-implanted layer becomes lower slowly. There is no rapid drop for ^{11}B . It is shown that more than a 1000°C and 3s HLA is required for the activation of ^{11}B ion-implanted layer. In addition to the data shown in Fig. 6, carrier concentrations were measured by spreading resistance method. As the HLA temperature goes up from 600° to 1200°C , the maximum carrier concentration increases for ^{11}B . However, the sheet resistivity of $^{49}\text{BF}_2$ ion-implanted layer drops rapidly at 800°C and 3s HLA. The rapid drop in sheet resistivity at 800°C corresponds to the crystalline regrowth of the amorphous layer at the surface (Fig. 3). While HLA temperature changes from 800° to 1100°C , the maximum carrier concentration does not increase for $^{49}\text{BF}_2$ and the sheet resistivity does not change so much. The further reduction in sheet resistivity above 1100°C is due to the increment of the maximum carrier concentration and of the junction depth (Fig. 4). The difference of sheet resistivity between ^{11}B and $^{49}\text{BF}_2$ ion-implanted layers above 1100°C HLA is mainly due to the difference of junction depth between ^{11}B and $^{49}\text{BF}_2$ (Fig. 4). The

Fig. 5. Junction depth of ^{31}P , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ through 400\AA SiO_2 ion-implanted layer as a function of HLA temperature. Soak times are 3s (△) and 10s (▼).

Fig. 6. Sheet resistivity of ^{11}B , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ ion-implanted (\bullet) and of $^{49}\text{BF}_2$, 60 keV, $4 \times 10^{15} \text{ cm}^{-2}$ ion-implanted layer (\blacksquare) as a function of HLA temperature. Soak time is 3s.

sheet resistivity difference between ^{11}B and $^{49}\text{BF}_2$ from 800° to 900°C HLA is due to the recrystallization effect of $^{49}\text{BF}_2$ amorphous layer at the surface. And the sheet resistivity difference below 700°C is explained because $^{49}\text{BF}_2$ ion-implanted layer is still amorphous and ^{11}B ion-implanted layer is crystalline. Figure 6 indicates that $^{49}\text{BF}_2$ ion-implanted layer is more suitable than ^{11}B ion-implanted layer for CMOS VLSI fabrication with low temperature and few second HLA. Figure 7 shows the sheet resistivity of ^{31}P , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ ion-implanted layer as a function of HLA temperature. One soak time (open triangle) is 3s. The other (closed triangle) is 10s. The abrupt drop in the sheet resistivity at 700°C and 10s HLA or 800°C and 3s HLA is due to the regrowth of the amorphous layer (Fig. 3). After recrystallization, the sheet resistivity be-

Fig. 7. Sheet resistivity of ^{31}P , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ ion-implanted layer as a function of HLA temperature. Soak times are 3s (\triangle) and 10s (\blacktriangledown).

comes lower very slowly as the HLA temperature goes up. Activation of dopant and crystalline regrowth of amorphous layer occur at the same time for both $^{49}\text{BF}_2$ and ^{31}P ion-implanted layers.

A 700°C and 10s or an 800°C and 3s HLA is enough to activate and to crystalline regrow both the $^{49}\text{BF}_2$ and ^{31}P ion-implanted layers. But, ^{40}Ar ion-implanted amorphous layers do not reduce HLA time and temperature of regrowth or of activation. Figure 8 shows the sheet resistivity of ^{31}P ion-implanted layer and of ^{11}B ion-implanted layer as a function of ^{40}Ar dose. More than $1 \times 10^{15} \text{ cm}^{-2}$ ^{40}Ar ion-implanted silicon is amorphous. But ^{40}Ar ion-implanted amorphous layers require more than a 1000°C and 10s HLA in order to regrow and activate dopant. As ^{40}Ar dose goes up, the sheet resistivities of both ^{11}B and ^{31}P ion-implanted layers become higher. The results lead to the conclusion that ^{40}Ar inhibits the activation of ^{11}B and ^{31}P . This ^{40}Ar effect with HLA is the same as that with laser annealing and furnace annealing (13). In Fig. 8, the sheet resistivity of ^{31}P ion-implanted layer is more affected by ^{40}Ar dose compared to that of ^{11}B ion-implanted layer, because the depth of ^{11}B dopant is much deeper than the depth of ^{40}Ar dopant and the depth of ^{31}P dopant is nearly the same as that of ^{40}Ar dopant. The growth rate of $^{49}\text{BF}_2$ or ^{31}P ion-implanted amorphous layer is significantly higher than that of ^{40}Ar as well as $^{49}\text{BF}_2$ or ^{31}P ion-implanted layer. And a 700°C and 10s HLA or an 800°C and 3s HLA activates and regrows $^{49}\text{BF}_2$ and ^{31}P ion-implanted amorphous layers.

Junction Leakage Current

This section describes the electrical characteristics of junction diodes fabricated by the silicon gate CMOS FET process using a few second HLA, and especially puts emphasis on the reverse-bias leakage current as a function of HLA time and temperature. A few second HLA was applied to the silicon gate CMOS FET process. Table I shows the fabrication processing steps that we have used in this experiment. 4 in. diam silicon wafers of n-type 8-12 $\Omega\text{-cm}$ resistivity and (100) orientation were used for the substrate.

This process adopted the halogen lamp system for annealing high dose implanted source-drain layers in place of conventional furnace. At process step 10, the

Fig. 8. Sheet resistivity of ^{31}P , 60 keV, $1 \times 10^{15} \text{ cm}^{-2}$ ion-implanted layer (\triangle) and of ^{11}B , 60 keV, $1 \times 10^{15} \text{ cm}^{-2}$ ion-implanted layer (\bullet) as a function of ^{40}Ar , 60 keV dose. The HLA's are 1000°C and 10s for ^{31}P ion-implanted layers and 900°C and 10s for ^{11}B ion-implanted layers.

wafers were annealed by the halogen lamp system in nitrogen gas at atmospheric pressure for a few seconds. This heating treatment must realize the activation and crystalline regrowth of ion-implanted source-drain region, lessen the junction leakage current, lessen the sheet resistivity of polysilicon (9) or silicide, and densify or flow the phosphosilicate glass (PSG). Three diodes were used in this study. The first has $1000 \times 1000 \mu\text{m}^2$ junction area and $4000 \mu\text{m}$ perimeter. This was used for measuring the leakage current per unit area. The other two diodes have same junction area ($100 \times 100 \mu\text{m}^2$ and $4 \times 2500 \mu\text{m}^2$) but different perimeters (400 and $5008 \mu\text{m}$). They were used for measuring the leakage current per unit length of perimeter. The leakage currents were measured at 5V reverse bias in darkness. Figure 9 shows the 5V reverse-bias area leakage current density as a function of HLA time and temperature. The filled circles stand for ^{11}B , 40 keV, $4 \times 10^{15} \text{cm}^{-2}$ through 400\AA SiO_2 ion-implanted junctions. The open triangles represent ^{31}P , 60 keV, $4 \times 10^{15} \text{cm}^{-2}$ through 400\AA SiO_2 ion-implanted junctions. HLA soak time was 6s throughout this figure. The leakage currents were measured at 24°C . These leakage currents are mainly due to damages in the bulk depletion region.

Fig. 9. 5V reverse-bias area junction leakage current density as a function of HLA temperature for ^{11}B , 40 keV, $4 \times 10^{15} \text{cm}^{-2}$ through 400\AA SiO_2 ion-implanted junctions (●) and for ^{31}P , 60 keV, $4 \times 10^{15} \text{cm}^{-2}$ through 400\AA SiO_2 ion-implanted junctions (Δ). Soak time is 6s. The leakage current was measured at 24°C in darkness.

The shape of ^{31}P ion-implanted junction area leakage current density is similar to the behavior of the sheet resistivity, which is shown in Fig. 7. The rapid drops in both leakage current and sheet resistivity at 800°C HLA correspond to the crystalline regrowth of the amorphous region. The small drop at 1100°C HLA is related to motion of the junction depth, which is shown in Fig. 5. It is shown that crystalline regrowth of the amorphous region reduces the area leakage current density. An 800°C and 6s HLA realizes the area leakage current of $\leq 1.5 \text{ nA/cm}^2$. But, a little motion of junction depth, 1100°C and 6s HLA, is necessary to reduce the area leakage current of ^{31}P ion-implanted junctions to the levels of the junctions with 950°C and 30 min furnace annealing ($\leq 0.8 \text{ nA/cm}^2$). The area junction leakage of the sample implanted with ^{11}B has a small drop at 800°C . This is the same as that of ^{31}P . This is consistent with LEED patterns on ^{11}B ion-implanted silicon having Kikuchi lines, but ^{11}B ion-implanted layers have damage in the bulk depletion region. An 800°C and 6s HLA is necessary to get out the damage and to reduce the area leakage current to the level of $\leq 2 \text{ nA/cm}^2$. The reduction of area leakage current density due to motion of junction depth is not significant in the case of ^{11}B ion-implanted junctions. This may be due to the lightness of ^{11}B ion or to the depth ($\approx 0.4 \mu\text{m}$) of the junctions. In the case of $^{49}\text{BF}_2$ ion-implanted junctions, an 800°C and 6s HLA reduces the area leakage current to the level of $\leq 2 \text{ nA/cm}^2$, too. From the viewpoint of CMOS VLSI fabrication, an 800°C and 6s HLA is good enough for both P channel and N channel source-drain region to reduce the area leakage current uniformly over a 4 in. diam wafer. But the perimeter leakage current becomes dominant (15) in VLSI, because the scaling down of electric devices in VLSI causes the area-to-perimeter ratio of the junction to decrease. When the value of the perimeter length (cm) is about 1000 times as large as the value of the area (cm^2), the perimeter leakage current is not negligible. An 800°C and 6s HLA reduces the perimeter leakage current, too. But the uniformity of the perimeter leakage current with an 800°C and 6s HLA is not good. Figure 10 shows the 5V reverse-bias perimeter leakage current at 80°C as a function of HLA temperature. Soak time was 6s throughout this figure. The leakage current was measured at 80°C in darkness. The filled circles stand for ^{11}B , 40 keV, $4 \times 10^{15} \text{cm}^{-2}$ through 400\AA SiO_2 ion-implanted junctions. Open triangles stand for ^{31}P , 60 keV, $4 \times 10^{15} \text{cm}^{-2}$ through 400\AA SiO_2 ion-implanted junctions. The shapes of both ^{31}P and ^{11}B ion-implanted junction perimeter leakage current are similar to the behavior of the area leakage current density, for temperatures below 1000°C (see Fig. 9). Above 1000°C , higher temperature HLA gets lower and more uniform perimeter leakage current for both ^{31}P and ^{11}B ion-implanted junctions. This means that the deeper junctions have lower and more uniform perimeter leakage current density. Figure 11 shows 5V reverse-bias perimeter leakage current at 80°C as a function of HLA temperature. Soak time is 6s throughout this figure. The leakage current is measured at 80°C in darkness. Closed squares represent $^{49}\text{BF}_2$, 60 keV, $4 \times 10^{15} \text{cm}^{-2}$ through 400\AA SiO_2 ion-implanted junctions. Open triangles are for ^{31}P , 40 keV, $4 \times 10^{15} \text{cm}^{-2}$ through 400\AA SiO_2 ion-implanted junctions. An 800°C and 10 min furnace annealing was carried out before HLA throughout this figure. Figure 11 indicates that higher temperature HLA reduces perimeter leakage current for both $^{49}\text{BF}_2$ and ^{31}P ion-implanted junctions. In addition to the data shown in Fig. 10, the perimeter leakage was measured with the sample at room temperature and found to be less than $10^{-15} \text{ A}/\mu\text{m}$ for 1100°C and 6s HLA samples. Perimeter leakage currents may depend much on the perimeter struc-

Fig. 10. 5V reverse-bias perimeter junction leakage current as a function of HLA temperature for ¹¹B, 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ through 400Å SiO₂ ion-implanted junctions (●) and for ³¹P, 60 keV, $4 \times 10^{15} \text{ cm}^{-2}$ through 400Å SiO₂ ion-implanted junctions (Δ). Soak time is 6s. The leakage current was measured at 80°C in darkness.

tures of junctions. More work is needed to determine the dependence of perimeter leakage current on the perimeter structure.

Two annealings, an 800°C and 10 min furnace annealing and a 6s HLA, for each data point. The leakage current was measured at 80°C in darkness.

Other Applications of HLA

In current CMOS VLSI fabrication processing, refractory-metal silicide gates and interconnects are used to reduce gate resistivity and contact resistivity. From the practical viewpoint of fabrication CMOS VLSI, it is preferable to keep the silicide formation temperature as low as possible in order to avoid the dopant redistribution in source and drain regions. Figure 12 shows sheet resistivities of titanium (Ti) silicide and molybdenum (Mo) silicide (16) as a function of HLA temperature. Soak time is 10s throughout this figure. Sheet resistivities were measured by a four-point probe. Filled circles stand for Mo silicide which was formed on 4 in. diam wafer, 1000Å elemental Mo was sputtered on (100)-oriented silicon substrates and was annealed with halogen lamps to form silicide. Open circles represent Ti silicide which was formed on 4 in. diam wafer, 1000Å elemental Ti was sputtered on (100)-oriented silicon substrates and was annealed with halogen lamps to form silicide. All results in Fig. 12 are for unpatterned deposited layers. Both metal films did not peel or crack during a few second HLA. It is shown that a 900°C and 10s HLA reduces the sheet resistivity of Mo silicide to 5 Ω/□ and a 700°C and 10s HLA reduces the sheet resistivity of Ti silicide to 2 Ω/□. The surface silicide formation was assured by ion microprobe analysis and by LEED. A 1000°C and 10s HLA is enough to form silicide and reduce sheet resistivity for both Mo and Ti without dopant redistribution. At process step 10 in Table I or after the contact window is open, the HLA heating treatment densifies or flows the phosphosilicate glass (PSG). Figure 13 shows SEM cross-sectional view of plasma etched contact opening in 10 m/o, 10,000Å thick PSG for before flow, after a 1100°C and 3s HLA, and after a 1200°C and 3s HLA. A 1200°C and 3s HLA is enough to planarize the surface of contact holes. A 1100°C and 3s HLA slightly smooths the edge of contact holes. It is shown that 10 m/o PSG flow needs more than a 1100°C and 3s HLA. This means that it is difficult to flow 10 m/o PSG without dopant redistribution. When HLA is applied to CMOS VLSI mass production, we must consider the flatness of wafer, slip-line free, and uniformity of electrical characteristics. In annealing rapidly, it occurred as a problem that the wafer was bent and slip lines were produced. The whole wafer annealed with halogen lamps is heated up and cooled down isothermally,

Fig. 12. Sheet resistivity of 1000Å Ti (○) on silicon and of 1000Å Mo (●) on silicon as a function of HLA temperature. Soak time is 10s.

Fig. 13. SEM cross section of contact openings in 10 m/o, 10,000 Å PSG before and after a 1100°C and 3s HLA and after a 1200°C and 3s HLA.

but the thermal losses around the peripheral edge of the wafer generated the drop in temperature (17), which caused the stress. The wafer-edge rounding made the wafer less susceptible to slip. When the temperature of HLA was below 1000°C and the time of HLA was <10s, slip was not induced and the wafers were flat enough to align the photopatterning in CMOS VLSI fabrication. Above 1100°C HLA, leveling the peripheral temperatures of the wafer was required. As a measure of leveling, the peripheral edge of the wafer was heated by peripheral and circular sublamp in addition to the main irradiation, with the result that the whole wafer had the same temperature. By this measure, slip lines disappeared and the peak to valley flatness of the wafer after 1200°C and 10s HLA became as small as (9) that of the conventional furnace-annealed wafer. Figure 14 shows the standard deviation of sheet resistivity within a 4 in. diam wafer as a function of peripheral and circular sublamp power which levels the temperature of the peripheral edge of the wafer. The wafers were implanted with ^{11}B , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ and were annealed at 1100°C for 6s. The average sheet resistivity is 28.44 Ω/\square . The optimum 10% sublamp power realized 1.05% standard deviation over a 4 in. diam wafer. The rounded peripheral edge of the wafer and the optimum peripheral and circular sublamp power realize slip-line free, flatness of wafer, and uniformity of electrical characteristics below 1200°C and within 10s HLA.

Summary

Figure 15 shows HLA time-temperature space for CMOS VLSI fabrication. HLA time-temperature region A is insufficient to regrow the ion-implanted amorphous layer. HLA time-temperature region B is enough to crystalline regrow the $^{49}\text{BF}_2$ and ^{31}P ion-implanted amorphous layers, to activate $^{49}\text{BF}_2$ and ^{31}P dopant, to form Ti silicide, and to reduce the area

Fig. 14. Standard deviation of sheet resistivity within 4 in diam wafer as a function of peripheral and circular sublamp power. The wafers were implanted with ^{11}B , 40 keV, $4 \times 10^{15} \text{ cm}^{-2}$ and were annealed with a 1100°C and 6s HLA. Average sheet resistivity is 28.44 Ω/\square .

junction leakage current without dopant redistribution. HLA time-temperature region C is enough to crystalline regrow the $^{49}\text{BF}_2$ and ^{31}P ion-implanted amorphous layers, to activate ^{11}B , $^{49}\text{BF}_2$, and ^{31}P dopant, to form Ti silicide and Mo silicide, to flow 10 m/o PSG, and to reduce both area and perimeter leakage current with a little (about 1000 Å) dopant redistribution. More than 1000 Å dopant diffusion occurs with HLA time-temperature region D. From the viewpoint of practical application to VLSI fabrication, a few second HLA is substituted for the furnace annealing without changing conventional processing steps, and it is an effective tool, especially for CMOS VLSI mass production.

Some Properties of Semi-Insulating and Si-Implanted GaAs

P. K. Bhattacharya¹ and J. K. Rhee²

Department of Electrical and Computer Engineering, Oregon State University, Corvallis, Oregon 97331

ABSTRACT

Various measurement techniques have been used to characterize semi-insulating and Si-implanted and annealed GaAs. Hall, photoconductivity, and photoinduced current transient measurements yield almost identical energy values for the compensating deep centers in the semi-insulating materials. In undoped GaAs, the dominant donor level, EL2, is at 0.73 ± 0.02 eV below the conduction band, and in Cr-doped GaAs the dominant Cr acceptor level is at 0.82 ± 0.01 eV below the conduction band. In Si-implanted GaAs where implantation has been made directly into the wafer, there are two dominant trapping centers: a 0.52 eV electron trap and a 0.15 eV hole trap. In materials implanted through a silox encapsulant, these centers are absent. Instead, a slow transient, with its time constant almost independent of sample temperature, is observed. It is believed that the transient arises from interface states. Several other electron and hole traps have been observed in semi-insulating and implanted GaAs.

The fabrication of GaAs field effect transistors (FET's) and other microwave devices requires the availability of reliable semi-insulating (SI) substrate materials. The quality of these materials has changed significantly in the last few years. Most of the recent investigations (1-6) on Cr-doped and undoped SI GaAs have been directly related to the electrical and optical properties of the deep compensating levels in these materials. The techniques which have been predominantly used are photoluminescence, dc and ac photoconductivity, and electron paramagnetic resonance (EPR) spectroscopy. Some transport properties in SI GaAs have been determined by Look (7) and Martin *et al.* (8). In addition to the known properties of the compensating deep levels in SI materials, it is important to determine the thermal emission properties of these levels, *viz.*, their activation energies and capture cross sections for electrons and holes. There is also little report on the thermal-emission properties of other defect or impurity levels which might be present. Such information would aid in a better under-

standing of the electrical properties and compensation mechanisms in semi-insulating materials and the active layers subsequently grown on them.

Deep level defects in Cr-doped and undoped SI GaAs, including the compensating levels, were detected and characterized in this study by the photoinduced current transient (PICT) measurement technique, first reported by Hurtes *et al.* (9). This technique must be employed since it is not possible to perform conventional capacitance transient or deep-level transient spectroscopy (DLTS) measurements with Schottky barriers fabricated on materials exhibiting high resistivity. The nature of the traps were inferred by performing the PICT experiments with intrinsic and extrinsic optical excitation. The energy position of some of the more dominant defect levels were also obtained from the variation of the photoconductivity with incident photoexcitation energy and from analyses of these spectra. Transport parameters in the semi-insulating materials were measured at high temperatures using the van der Pauw technique. The variation of resistivity, Hall mobility, and Hall coefficient with temperature, for $T > 350$ K, were determined. The compensation in the materials and other important transport parameters were determined from a solution of appropriate charge neutrality equations.

Key words: ion implantation, deep levels, transport properties, high resistivity gallium arsenide.

Recent progress in ion implantation as a means of controlled doping of elemental and compound semiconductors has led to significant advances in the technology and fabrication of integrated circuits (IC). Implantation of high energy donor ions into SI GaAs and subsequent thermal or laser annealing produce n-type active layers whose thickness and carrier concentration can be controlled by the implant dose and energy. Deep level defects induced by the implant-and-anneal procedure can produce deleterious effects in the performance of FET's and similar devices. Some results on deep levels in Si-implanted and annealed GaAs:Cr (5, 10, 11) have recently been reported, but no detailed studies have yet been made.

Transient capacitance and DLTS measurements were performed on implanted and annealed SI GaAs:Cr and undoped GaAs. Transient current measurements were also made directly on GaAs FET's fabricated by ion-implantation technology. In addition to thermal emission from the deep compensating centers, outdiffusing from the substrate, emission from dominant electron and hole traps and several other traps with thermal activation energies ranging from 0.15 ± 0.01 to 0.90 ± 0.01 eV has been detected and characterized.

Materials Description and Device Fabrication

The semi-insulating (SI) GaAs samples used for this study were grown either by the liquid encapsulation Czochralski (LEC) or by the horizontal Bridgeman (HB) technique and were nominally oriented in the (100) direction. Wafers for the study were generally taken from the midsection of the boules. The undoped LEC material was near stoichiometric. The Cr-doped HB material was usually As rich. The resistivity in the samples is $\sim 10^7 \Omega\text{-cm}$ at room temperature. The same samples were either implanted directly with $^{28}\text{Si}^+$ at an energy of 100 keV, or through a 1000Å silox mask at an energy of 130 keV. Annealing was done at 800° or 850°C for 20 min in an ambient of flowing forming gas ($\text{H}_2:\text{N}_2 = 10:90$) with the implanted layer protected by a 2000Å silox encapsulating layer.

Devices for photoinduced current transient measurements were made from samples of SI GaAs $5 \times 5 \text{ mm}^2$ in area and 200-300 μm thick. A semitransparent circular Au film (diam = 1.5 mm, thickness $\approx 100\text{-}200\text{\AA}$) was deposited on the polished top surface, and a thicker Au layer ($\sim 1000\text{\AA}$) was deposited on the entire opposite face by evaporation under a vacuum of $\sim 10^{-6}$ torr. Similar devices were made by evaporating Cr or eutectic Au-Ge contacts, but they gave rise to low S/N ratio during the measurements.

Circular Au dots with $(1\text{-}2) \times 10^{-3} \text{ cm}^2$ area and 300-500Å thick were evaporated on the implanted and annealed layers to form Schottky diodes for transient capacitance and DLTS measurements. Evaporated and alloyed Au-Ge/Ni ohmic contacts for the diodes were formed on the implanted layers.

Field effect transistors for the transient measurements were fabricated by conventional photolithography and lift-off techniques. The FET's have both gate length and width of 100 μm and source-gate and gate-drain spacings of 5 μm each. Symmetrical samples for Hall measurements were made from the semi-insulating and ion-implanted layers by evaporating small-area ohmic contacts at the four corners and subsequent alloying.

Results and Analysis

Semi-insulating GaAs.—Transport measurements.—Variations of the Hall coefficient, R_H , and dark conductivity, σ , with inverse temperature are shown in Fig. 1 and 2 for SI GaAs:Cr and undoped GaAs. The variations are almost linear in the temperature range of interest. The measured transport parameters at 400 K in SI GaAs:Cr and undoped GaAs are listed in Tables I and II, respectively.

In semi-insulating materials, where two-carrier transport can be assumed to be operative, the appropriate charge-neutrality equations can be solved to obtain expressions for the temperature-dependent conductivity and Hall factor. The position of the Fermi level can also be determined accurately from such an analysis, where full ionization for the shallow levels is assumed. Two distinct cases arise. If the compensat-

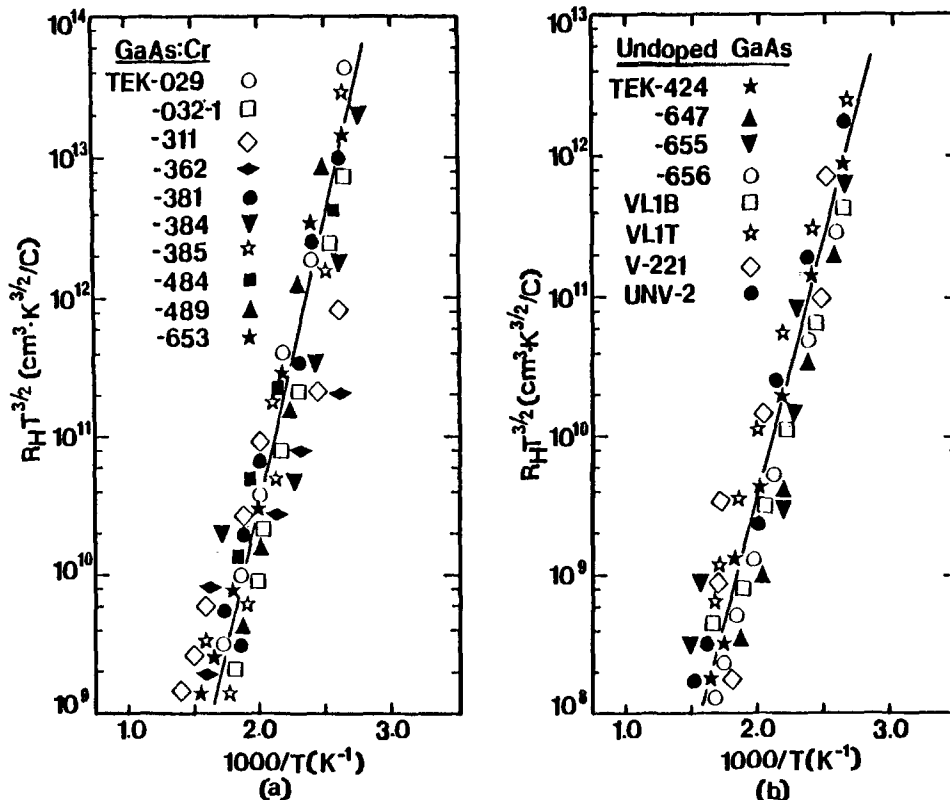

Fig. 1. Measured and calculated variation of $R_H T^{3/2}$ with inverse temperature in (a, left) SI GaAs:Cr and (b, right) SI undoped GaAs.

ing deep level is an acceptor then it can be shown that (12)

$$\sigma(T) = \frac{q\mu_n N_v}{g_{AA} b} [CR - 1] \left\{ \exp\left(-\frac{E_{AA}}{kT}\right) + \frac{g_{AA}^2 b N_c}{N_v (CR - 1)^2} \exp\left(-\frac{E_G - E_{AA}}{kT}\right) \right\} \quad [1]$$

and

$$R_H(T) = r \frac{g_{AA}}{qN_v (CR - 1)} \frac{\exp\left(\frac{E_{AA}}{kT}\right) - g_{AA}^2 b^2 N_c \exp[(3E_{AA} - E_G)/kT]/N_v (CR - 1)^2}{\{1 + g_{AA}^2 b N_c \exp[(2E_{AA} - E_G)/kT]/N_v (CR - 1)^2\}} \quad [2]$$

where $CR = N_{AA}/(N_D - N_A)$. However, if the compensating deep level is a donor, then it can be shown that (12)

$$\sigma(T) = q\mu_n [CRU - 1] g_{DD} N_c \left\{ \exp[-(E_G - E_{DD})/kT] + \frac{N_v \exp\left(-\frac{E_{DD}}{kT}\right)}{g_{DD}^2 [CRU - 1]^2 N_c} \right\} \quad [3]$$

and

$$R_H(T) = r [CRU - 1] \frac{g_{DD}}{qN_v} \frac{\{\exp(E_{DD}/kT) - b^2 [CRU - 1]^2 g_{DD}^2 N_c \exp[(-E_G + 3E_{DD})/kT]/N_v\}}{\{1 + b [CRU - 1]^2 g_{DD}^2 N_c \exp[(-E_G + 2E_{DD})/kT]/N_v\}} \quad [4]$$

where $CRU = N_{DD}/(N_A - N_D)$. In these equations $b = \mu_n/\mu_p$, r is scattering factor which can be taken as unity unless it is strongly temperature dependent, g_{AA} and g_{DD} are the degeneracy factors of the deep compensating acceptor and donor levels, respectively, and N_c and N_v are the density of states in the conduction and valence bands, respectively. The ionization energies E_{AA} and E_{DD} for the acceptors and donors, respectively, are measured from the top of the valence band.

In the samples studied by us, Cr impurities create a deep acceptor in Cr-doped SI GaAs. In the undoped samples, however, compensation is known to occur because of the presence of a deep donor acting as an

electron trap, commonly known as EL2 (13). Therefore, both sets of equations given above are applicable to the materials under study. The solid lines in Fig. 1a and 1b, and 2a and 2b are the theoretically calculated temperature-dependent Hall constant and conductivity in Cr-doped and undoped high resistivity GaAs. The good agreements in each case indicate that the electrical properties of present-day GaAs substrates can be predicted by the models described above. Values for

the deep acceptor and donor concentrations, N_{AA} and N_{DD} , and their energy depth measured from the conduction bandedge, were estimated by fitting the experimental values of $R_H T^{3/2}$ and σ . The estimated values of $(E_G - E_{AA})$ and $(E_G - E_{DD})$ are listed in Tables I and II, and of N_{AA} and N_{DD} are listed in Tables III and IV.

Photoinduced current transient measurements.—Intrinsic photoexcitation generates electron-hole pairs just underneath the circular Au film of the device used. The excess carriers are captured by electron or hole

traps in the sample, if they exist. After removal of the photoexcitation, detrapping due to the thermal reemission gives rise to a transient current between the two contacts. Typical values of the bias applied between the Au contacts varied from 8 to 10V. Arrhenius plots for the emissions detected in SI GaAs:Cr and undoped GaAs are shown in Fig. 3 and 4, respectively. For experiments with intrinsic photoexcitation, the distinction between electron and hole emissions can be made by observing the direction of the transient-current variation. It should be noted that the activation energies, ΔE_T , listed in Fig. 3 and 4 were obtained from

Fig. 2. Measured and calculated variation of dark conductivity, σ , with inverse temperature in (a, left) SI GaAs:Cr and (b, right) SI undoped GaAs.

the slopes of $\ln(T^2\tau)$ vs. $1/T$ plots and include the barrier energy ΔE_B . Similarly, the capture cross sections, σ_c , were obtained from the emission rate prefactor of the detailed balance equation. The true capture cross section of the centers can be obtained from a measurement of the thermal-capture rates (14). In some cases, hole emission was confirmed by repeating the measurements with suitable extrinsic photoexcitation. In this case, the trap population in a large region between the contacts is directly altered.

Photoconductivity spectra in semi-insulating GaAs.—These measurements were performed to confirm some of the results obtained from PICT and high temperature Hall measurements and to detect deep levels which may not have been revealed by the previous measurements. The spectra were recorded in the spectral range 0.4–1.5 eV with a Jarrel-Ash monochromator with an appropriate combination of filters. The device configuration was the same as that for the PICT measurements. The constant electric field across the samples varied in the range $(1.0\text{--}3.5) \times 10^2$ V/cm.

Typical spectra in SI GaAs:Cr at 100 and 203 K are shown in Fig. 5a. Chromium in GaAs is usually located in a Ga site giving rise to a deep lying acceptor impurity. Four charge states of the Cr-related centers

have been reported (15), giving rise to multiple activation energies between 0.56 to 0.9 eV (16). The onset at 0.65 eV has been observed by several investigators and is probably related to oxygen (16, 17). The rise in photosensitivity at 0.81 eV is probably due to Cr (3, 16). The peak at 0.95 eV has been attributed to the intratransition from the 5T_2 ground state to the 5E excited state of Cr^{2+} (18), which is usually observed closer to 0.9 eV. With reference to Fig. 5b, which depicts the typical photoconductivity spectra for SI undoped GaAs, the onset at 0.73 eV has been observed by several investigators and is attributed to the deep donor (19, 20). The transition at 1.2 eV has been observed by Williams (21) and Farbe (22), but its origin is as yet unknown. The peak at 0.9 eV is probably due to an intrastate transition of the donor level. The sharp onsets in both spectra ~ 1.4 eV indicate the bandedge in GaAs.

Si-implanted and annealed SI GaAs.—Electrical properties.—In wafers implanted through silox, the activation of Si was $\sim 40\%$. Variations of activation with implant dose and mobility with sheet electron concentration in undoped GaAs implanted through silox are depicted in Fig. 6a and 6b. The room-temperature Hall mobilities measured in implanted samples in the course of this study are among the highest values attained in device-quality implanted GaAs.

Fig. 3. Arrhenius plots for electron- and hole-trap levels in SI GaAs:Cr detected by PICT measurements. The symbols located arbitrarily represent the different samples and are not data points.

Variation of the Hall mobility with temperature in two Si-implanted GaAs:Cr samples with high electron mobilities is shown in Fig. 7. The solid lines indicate the theoretically calculated mobilities taking into account the relevant scattering mechanisms. Average values of N_A and N_D obtained for the two samples are 0.9×10^{16} and $2.0 \times 10^{16} \text{ cm}^{-3}$, respectively.

Transient capacitance measurements.—Transient capacitance and photocapacitance measurement techniques were used to detect and characterize deep levels in implanted and annealed SI GaAs:Cr and undoped GaAs. Majority and minority carrier trap levels in the depletion region of Schottky barriers made from n-type samples can be filled by a bias or an optical pulse, respectively. The capacitance change of the diode due to thermal emissions from deep levels is monitored by a 1 MHz capacitance bridge and recorded. The activa-

Fig. 4. Arrhenius plots for electron- and hole-trap levels in SI undoped GaAs detected by PICT measurements. The symbols located arbitrarily represent the different samples and are not data points.

tion energy and the thermal capture cross section of the various traps are determined from the measured thermal-carrier emission rates at several fixed temperatures. The trap concentration, N_T , is estimated from the free-carrier concentration and the capacitance change at the termination of the filling pulse. It may be noted that the sensitivity of the measurements, which is primarily determined by the noise added to the transient signal, set the detection limit for traps. It was estimated that traps with concentration 10^{-4} times lower than the free-carrier concentration in the sample would not be detected.

The characteristics of electron and hole-trap levels detected in the implanted and annealed SI GaAs:Cr samples directly implanted with different doses of Si are listed in Table V. The samples implanted were

those listed in Tables I and III and similar wafers. These results are representative of over 30 samples characterized in this study. The electron-trap levels with $\Delta E_T = 0.17 \pm 0.01$ and 0.21 ± 0.01 eV do not appear consistently and are ascribed to unknown impurities and/or defects. Chromium is observed to be present, as evidenced by the 0.85 ± 0.01 eV hole emis-

		—	—	0.15	6.0×10^{-23}

* Thermal annealing of all samples was done at 800°C for 20 min in flowing forming gas.

sion. The electron-trap level with $\Delta E_T = 0.52 \pm 0.01$ eV and the hole-trap level with $\Delta E_T = 0.15 \pm 0.01$ eV were consistently detected in the implanted and annealed Si GaAs:Cr samples. These two trap levels are also the dominant centers in Si-implanted VPE GaAs (26). Arrhenius plots for the two traps are shown in Fig. 8.

Results from the transient-capacitance measurements described above were corroborated by transient measurements on GaAs FET's fabricated on the same GaAs:Cr wafers by ion-implantation technology. A suitable quiescent reverse bias is applied to the Schottky gate of the FET so that near-pinch-off condition exists in the channel. An injection pulse is applied to the gate for the detection of majority-carrier traps. With this pulse, trap levels formerly within the depletion region are filled with electrons. As the trapped electron population returns to equilibrium by thermal emission, the drain-source current, I_{DS} , also returns to its quiescent value. Photoexcitation was used to alter the population of minority-carrier traps. Values of ΔE_T and σ_a for various electron and hole emissions observed in the channel region of GaAs FET's are listed in Table VI. The 0.52 ± 0.01 and 0.15 ± 0.01 eV electron and hole-trap levels, respectively, are again observed consistently.

Fig. 8. Dominant electron and hole traps in Si-implanted and annealed GaAs:Cr with the ions being implanted directly.

Table VI. Characteristics of deep levels in GaAs FET's in Si GaAs:Cr fabricated by ion-implantation technology. The data used were obtained from measurement of transient I_{DS} at several fixed temperatures.

Sample	Implant dose (10^{12} cm $^{-2}$)	Electron trap		Hole trap	
		ΔE_T (eV)	σ_n (cm 2)	ΔE_T (eV)	σ_p (cm 2)
FET 8	2.0	0.52	1.4×10^{-18}	0.94 0.15	1.4×10^{-18} 5.9×10^{-20}
FET 15	3.0	0.51	1.5×10^{-18}	0.86 0.14	1.2×10^{-18} 6.0×10^{-20}
FET 16	3.0	0.52	1.4×10^{-18}	0.85 0.16	1.3×10^{-18} 5.8×10^{-20}
FET 18	4.0	0.53	1.4×10^{-18}	0.85	1.3×10^{-18}
FET 20	4.0	0.53	1.2×10^{-18}	0.86 0.15	1.2×10^{-18} 5.9×10^{-20}

Similar measurements were repeated on Cr-doped and undoped SI GaAs implanted with various doses of Si through a silox protective layer. The results are very different. Minority carrier trapping has not yet been studied by us in detail in these materials, and the following discussion is related only to electron traps in the n-type implanted layers. On application of a majority-carrier pulse at any fixed temperature during transient capacitance measurements, a decreasing capacitance transient was observed. The time constant of this transient is of the order of several seconds and is almost independent of temperature. No other transient was observed in these materials. When deep-level transient spectroscopy (DLTS) measurements were performed on the same samples with a majority-carrier pulse sequence, no peaks due to electron trapping were observed. Any feature due to the slow transients described above would be absent, since the rate windows and delays in this measurement are of the order of milliseconds.

Discussion

The values of N_{DD} , N_{AA} , N_D , and N_A derived from analysis of our data reflect the concentration of background impurities and of the deep levels in present-day semi-insulating GaAs. With the exception of sample TEK 311 (Table III), N_D , N_A , and N_{AA} in Cr-doped samples are $\sim 10^{16}$ cm $^{-3}$. Similarly, in undoped samples, N_D , N_A , and $N_{DD} \sim 10^{16}$ - 10^{17} cm $^{-3}$. An exception is sample TEK 647 (Table IV), which can be considered as an anomaly.

The hole trap with $\Delta E_T = 0.86 \pm 0.01$ eV detected in almost all the SI GaAs:Cr samples, is attributed to Cr (23). The 0.90 ± 0.01 eV electron trap level detected in the same samples is attributed to electron emission from the Cr centers (14). The 0.58 ± 0.01 and 0.53 ± 0.01 eV electron and hole-trap levels, respectively, are ascribed to unknown impurities. The electron trap may be identical to the 0.60 eV electron trap reported by Fairman and Oliver (24) in SI GaAs and center EL3 (0.575 eV) reported by Martin *et al.* (13) in VPE GaAs. The hole trap has thermal activation energy and capture cross section very similar to trap HS1 (0.58 eV) reported by Mitonneau *et al.* (25) in LPE GaAs. The 0.73 ± 0.01 eV hole-trap level, also detected in SI undoped GaAs, has a thermal-activation energy very similar to trap B (0.71 eV) detected by Lang and Logan (14) in LPE GaAs which is related to a native defect. However, the thermal hole-capture cross sections of the latter center are at least 2 or 3 orders higher than for the 0.73 eV centers detected in this study. The 0.16 eV hole-trap level, detected for the first time in this study, can probably be ascribed to native defects since it was detected in both SI GaAs:Cr and undoped GaAs. Fewer deep levels were detected in SI undoped GaAs. The 0.98 ± 0.01 eV electron-trap level, detected for the first time in this study, can be ascribed to unknown impurities. Further studies are necessary to elucidate its origin. The dominant

electron trap EL2 is present in all samples, but is not clearly observed in the transient measurements due to the presence of other electron and hole traps in the same temperature range.

The presence of Cr was confirmed by high temperature Hall and photoconductivity measurements. Similarly, the presence of the deep-donor level at $E_c - 0.73$ eV detected by high temperature Hall measurement on SI undoped GaAs was confirmed by the photoconductivity measurements. Both these deep levels have thermally activated capture cross sections, expressed by $\sigma_n = \sigma_\infty \exp(-\Delta E_B/kT)$, and $\Delta E_B = 80$ and 250 meV have been measured for the EL2 and Cr level, respectively (26). These values indicate the capture process at these centers by multiphonon emission due to lattice relaxation. The relaxation is much larger for the Cr center than for the EL2 center.

It emerges from our studies that there are two dominant centers in directly implanted and annealed SI GaAs, the 0.53 eV electron trap and the 0.15 eV hole trap. The traps are absent when implantation is done through a silox encapsulant. It is therefore thought that the more severe damage in the directly implanted samples is in some way responsible for the creation of these centers, which may be related to native defects. The 0.53 eV electron trap was annealed after a half-hour heat-treatment at 700°C under H $_2$ flow without any encapsulation. The observation of the same centers in Si-implanted VPE GaAs (27) also favors their relation to native defects.

Implantation through an encapsulant will reduce the thickness of the damaged layer, and, therefore, for the same carrier concentration, the depletion layer of a Schottky diode made on such a layer will reach closer to the active-layer substrate interface. However, in material implanted directly, the depletion-layer edge is further removed from the interface. We therefore believe that the slow transients observed in samples implanted through an encapsulant arises from non-discrete levels at the active-layer substrate interface. These emissions may also be partly responsible for backgating effects observed in FET's made from such materials.

Mercury-Pressure-Induced Epitaxy of HgCdTe

H. Ruda, L. Jedral, J. Lagowski,* and H. C. Gatos**

Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

ABSTRACT

A new method for the epitaxial growth of HgCdTe from solution is presented, in which growth is induced under isothermal conditions by an increase in the mercury pressure (pressure-induced epitaxy). A growth kinetics model is developed from mass-transport considerations and is successfully used to explain the experimental dependence of the growth velocity, the layer thickness, and the layer composition on the growth time, the solution height, and the applied pressure differential. Spontaneous nucleation was considered, and it was not found to be limiting.

Increased efforts have been recently devoted to epitaxial growth of HgCdTe layers for IR applications. It has been established that the major difficulty in the growth from solution in open systems is associated with the losses of mercury due to the high mercury pressure (1). In a modified-LPE configuration (1) this difficulty is essentially overcome by the control of the Hg pressure over the whole thermal program, thus preventing Hg loss, which is critical for controlling the solid composition. We have recently shown that in HgCdTe, control of the Hg pressure can be used not only to stabilize the properties of thermally grown layers, but also to induce epitaxial growth with an overpressure of Hg while the temperature of the system is kept constant (2).

Pressure-induced epitaxy (PIE) of HgCdTe is the subject of the present theoretical and experimental study designed to establish quantitatively the characteristics of the new growth process. The theoretical model considers pressure-induced Hg transport in the Te-rich solution as the driving force for the growth. The theoretical relationships are compared with experimental results on HgCdTe layers obtained in an open-system slider boat from tellurium-rich solution.

Process and phenomena.—HgCdTe is a three-component system, which during liquid-phase epitaxial growth exists in three phases. According to the Gibbs' phase rule, there are only two degrees of freedom for such a system, e.g., temperature and pressure. In standard LPE, the pressure is maintained constant, and a temperature decrease is used as a driving force for epitaxial growth. In PIE the situation is reversed, i.e., the temperature is maintained constant, while Hg-pressure increase stimulates growth. In the HgCdTe system, the mercury partial pressure far exceeds either cadmium or tellurium pressures, and thus at a constant temperature the composition of all phases, to good approximation, is controlled by the mercury pressure.

In PIE, a Te-rich solution is maintained at a constant temperature, and the required supersaturation is induced as follows: the temperature of a mercury reser-

voir, in equilibrium with the Te solution, is raised, thereby generating a mercury flux from the reservoir to the growth solution. Mercury is taken up by the solution, resulting in a supersaturation of the solute in solution. The solute gradient across the solution acts as the driving force for solute transport towards the substrate/solution interface, and results in epitaxial growth of HgCdTe on the substrate.

A theoretical model of the PIE growth must consider three processes: (i) transport of Hg, in the vapor phase, to the surface of the solution; (ii) transport of excess Hg (solute) in the solution; and (iii) epitaxial growth on the substrate and associated segregation of the solute (solution) species.

In the following treatment, we will make simplifying approximations in order to reduce the three-phase transport problem to a manageable dimension. The first approximation concerns the surface condition of the solution. We assume that at the initial equilibrium with the vapor, the whole solution is at a constant composition, C_{i0} . Upon raising the Hg reservoir temperature $T_1 \rightarrow T_1 + \Delta T$, the surface of the solution will change its composition to $C_1^i = C_{i0} + \Delta C_1$, where ΔC_1 is a function of ΔT . The capacity of the Hg reservoir and the Hg-vapor transport should be sufficient to maintain a constant value of C_1^i during the growth after an initial transient, which has not been considered here.

The solute transport in the solution and growth on the substrate will be treated in a standard way commonly used in describing the LPE growth. Accordingly, we will assume diffusion-controlled solute transport toward the growth interface, which advances with a (growth) velocity sufficiently small to be ignored in the diffusion equation. The (growth) velocity is, of course, included in the flux-conservation condition. Diffusion in the solid state will be neglected. This assumption, which is commonly made for III-V compounds, is less justified for HgCdTe, and its validity may impose a lower limit on the growth velocity and upper limits on the overall time the layer is kept at elevated temperatures.

The pertinent set of equations used to describe the PIE involves the diffusion equation (contained between

** Electrochemical Society Honorary Member.

Key words: CdHgTe, epitaxial growth, pressure-induced epitaxy.

$x = 0$ and $x = l$)

$$D_1 \frac{\partial^2 C_1}{\partial x^2} = \frac{\partial C_1}{\partial t} \quad [1]$$

the flux-conservation equation at the advancing growth interface

$$D_1 \frac{\partial C_1}{\partial x} \Big|_{x=0} = v \cdot [C_1^s - C_{10}] \quad [2]$$

where C refers to the solute concentration in solution, C^s to its value in the solid, and D is the solute diffusivity. x is a position coordinate. The solution height is l , at coordinate $x = l$ from the solid/liquid interface; v refers to the growth velocity and t to the growth time, while other parameters are defined as before.

The boundary conditions on the solution concentration are

$$\begin{aligned} C_1 &= C_{10} \quad \text{at } t = 0 \quad \text{for all } x \\ C_1 &= C_{10} \quad \text{for } x = 0 \quad \text{at any time} \\ C_1 &= C_1^s \quad \text{at } x = l \quad \text{for } t > 0 \end{aligned} \quad [3]$$

Growth kinetics.—For the HgCdTe system, Eq. [1]-[3] should be solved for two components, i.e., Hg and Cd. However, in the simplified growth-kinetics model presented here we will neglect the effect of Cd on the Hg transport. According to Barnes (3), the solution of Eq. [1] and [3] gives the Hg concentration $C(x, t)$ as

$$\begin{aligned} [C(x, t) - C_{10}] &= (C_1^s - C_{10}) \cdot \left(\frac{x}{l}\right) \\ &+ \frac{2}{\pi} \sum_{n=1}^{\infty} \left\{ \frac{(-1)^n \cdot C_1^s - C_{10}}{n} \right\} \sin\left(\frac{n\pi x}{l}\right) \\ &\exp\left(\frac{-Dn^2\pi^2 t}{l^2}\right) + \frac{4C_{10}}{\pi} \sum_{n=1}^{\infty} \left(\frac{1}{2m+1}\right) \\ &\sin\left(\frac{(2m+1) \cdot \pi x}{l}\right) \exp\left[\frac{-D(2m+1)^2\pi^2 t}{l^2}\right] \end{aligned} \quad [4]$$

From [4] and [2], one gets the expression for the growth velocity

$$\begin{aligned} v &= \frac{D}{l(C^s - C_{10})} \left[\Delta C + \left\{ 2 \sum_{n=1}^{\infty} [(-1)^n \right. \right. \\ &\quad \left. \left. \cdot C_1^s - C_{10}] \exp\left(\frac{-Dn^2\pi^2 t}{l^2}\right) \right\} \right. \\ &\quad \left. + \left\{ 4C_{10} \sum_{n=1}^{\infty} \exp\left(\frac{-D(2m+1)^2\pi^2 t}{l^2}\right) \right\} \right] \end{aligned} \quad [5]$$

where $\Delta C \equiv (C_1^s - C_{10})$ the layer thickness, d , as a function of time, is given by

$$\begin{aligned} d &= \frac{\Delta C}{(C^s - C_{10})} \left(\frac{D}{l}\right) \left[t - \frac{l^2}{6D} \right] \\ &- \frac{2l}{\pi^2 (C^s - C_{10})} \cdot \left[\sum_{n=1}^{\infty} \left[\frac{(-1)^n \cdot C_1^s - C_{10}}{n^2} \right] \right. \\ &\quad \left. \exp\left(\frac{-Dn^2\pi^2 t}{l^2}\right) + 2C_{10} \sum_{n=1}^{\infty} \frac{1}{(2m+1)^2} \right. \\ &\quad \left. \exp\left(\frac{-D(2m+1)^2\pi^2 t}{l^2}\right) \right] \end{aligned} \quad [6]$$

In Fig. 1, the layer thickness, d , is calculated according to Eq. [6] and is plotted vs. time. It is seen that after a certain transient period $t \gtrsim t_c$, t_c can be approximated as $\approx (0.35l^2/D)$, and the layer thickness

Fig. 1. Dimensionless plot of layer thickness vs. growth time. Curve a represents exact solution, and curve b the steady-state approximation.

becomes a linear function of time which corresponds to steady-state growth with a constant velocity. The value of this steady-state growth velocity is

$$v \approx \frac{\Delta C}{C^s - C_{10}} \cdot \frac{D}{l} \quad [7]$$

and the layer thickness becomes

$$d \approx \left(\frac{\Delta C}{C^s - C_{10}}\right) \cdot \frac{D}{l} \left(t - \frac{l^2}{6D}\right) \quad [8]$$

Equations [7] and [8] predict an inverse dependence of the growth velocity and of the layer thickness on solution height, and a linear dependence on ΔC , which itself is dependent on the thermal step across the reservoir ΔT_{Hg} . The quantitative relationship between ΔC and ΔT is not the same for PIE in an open and in a closed system. In a closed system, one can expect direct proportionality between ΔC and small changes of the reservoir temperature ΔT_{Hg} , i.e., $\Delta C = \zeta \Delta T_{\text{Hg}}$ where ζ is a constant.¹ In an open system, however, the mercury pressure over the solution is not uniquely defined by the reservoir temperature. In such a system, a higher reservoir temperature is required to generate a mercury pressure equivalent to that in the closed system. Thus, a specific dependence $\Delta C(\Delta T_{\text{Hg}})$ cannot be readily predicted for an open system, although for small values of ΔT_{Hg} one can still expect a linear dependence of ΔC on ΔT_{Hg} .

The maximum layer thickness.—As in thermal step cooling LPE, the maximum layer thickness for a given change in Hg concentration, ΔC_{Hg} at the surface, will be limited by depletion of cadmium from solution. Hg is not a limiting factor, since it is continuously supplied for vapor transport from the Hg reservoir. A mass balance for cadmium gives

$$\int_0^l C_{\text{Cd}}(x) dx = lC_{\text{Cd}}^0 - d_{\text{max}}C_{\text{Cd}}^s \quad [9]$$

Clearly, in practice, growth will cease before d reaches d_{max} (for a given ΔC_{Hg} at the surface). But for prolonged growth time

$$C_{\text{Cd}}(x) = \begin{cases} C_{\text{Cd}}^0 & : x = 0 \\ C_{\text{Cd}}^s & : x = l \end{cases} \quad [10]$$

Therefore, substitution of Eq. [10] in [9] gives

¹ See Appendix for more detailed treatment.

$$d_{\max} = -\frac{l}{2} \cdot \frac{\Delta C_{\text{Cd}}}{C_{\text{Cd}}^s} : \Delta C_{\text{Cd}} \equiv C'_{\text{Cd}} - C^o_{\text{Cd}} \quad [11]$$

Following Ref. (4), in which mass transfer is determined by a temperature drop at constant pressure, the same approach is applied here to a case of constant temperature but variable pressure. This gives

$$\frac{\Delta C_{\text{Cd}}}{\Delta C_{\text{Hg}}} \equiv \Lambda = \left\{ \frac{z(k-1) + z(2y-1)}{(1-z)(2y-1) - z(k-1)} \right\} \quad [12]$$

and to rewrite Eq. [11] in the form

$$d_{\max} = \frac{l}{2C_{\text{Cd}}^s} \cdot \left\{ \frac{z(k-1) + z(2y-1)}{(1-z)(2y-1) - z(k-1)} \right\} \cdot \Delta C_{\text{Hg}} \quad [13]$$

where z and y refer to composition of the Te-rich solution $(\text{Hg}_{1-z}\text{Cd}_z)_{1-y}\text{Te}_y$ and $k \equiv (x/z)$.

The growth efficiency, E , can be defined as a ratio of the actual layer thickness, d , over the maximum layer thickness, d_{\max} . From [8] and [13], one gets

$$E = \frac{2C_{\text{Cd}}^s D}{(C_{\text{Hg}}^s - C_{\text{io}}) \Lambda} \cdot \frac{1}{l^2} \left[t - \frac{l^2}{6D} \right] \quad [14]$$

Thus, the growth efficiency increases strongly as the solution thickness decreases.

Growth stability.—In PIE, supersaturation is created in the solution region away from the growth interface. This growth configuration can lead to a spontaneous nucleation in the solution rather than on the substrate. We will analyze the possibility of spontaneous nucleation (SN) in terms of the value of the maximum effective supersaturation that may exist in solution, ΔT_{eff} . This supersaturation corresponds to the maximum constitutional gradient that can exist across the solution.

That is

$$\Delta T_{\text{eff}} = m_{\text{Hg}} [C(l, t) - C(0, t)] :$$

$$m_{\text{Hg}} = \frac{\Delta T}{\Delta C} \Big|_l ; \Delta T_{\text{eff}} = m_{\text{Hg}} \Delta C_{\text{Hg}} \quad [15]$$

Using Eq. [15] and $m_{\text{Hg}} = 993.5^\circ\text{C}/\text{fraction}$ (5) we can evaluate $\Delta T_{\text{eff}} \simeq 1.5^\circ\text{C}$ as the maximum effective supercooling to cause spontaneous nucleation. This value is of the same order as typical supercooling in thermal-LPE growth, and hence we do not expect spontaneous nucleation to occur.

Comparison with Experiment

PIE growth procedure.—Experiments were performed using tellurium-rich solutions of $(\text{Hg}_{1-z}\text{Cd}_z)_{1-y}\text{Te}_y$ of initial composition $z = 0.06$ and $y = 0.80$, in an open-tube slider boat system (6). A two-zone gold reflection coated furnace, with the capability to independently control a growth and a mercury zone, was employed. Growth experiments were performed on polished and etched (111)A CdTe surfaces, $10 \times 10 \text{ mm}^2$ in area. The experimentally determined liquidus temperature for this solution was $501^\circ \pm 0.5^\circ\text{C}$, with a mercury reservoir temperature of $294^\circ \pm 0.5^\circ\text{C}$, under a flowing hydrogen ambient. Direct observation of the surface of the solution through the semitransparent gold reflection-coated furnace enabled a visual determination of the liquidus at work.

The experimental procedure was as follows: complete melting of the solution was achieved at a constant solution temperature T , and reservoir temperature, ($T_o < T_1$). The reservoir was then raised to a temperature, T_1 , to establish the equilibrium mercury pressure above the solution at its liquidus. The system

Table I. Typical growth parameters

Run no.	T (°C)	T ₁ (°C)	T ₂ (°C)	t (min)	l (mm)	d (μm)	z Composition
133	501	294	297	45	2.0	31	0.20
148	501	294	297	15	2.0	13	0.23
140	501	294	300	22.5	2.0	29	0.18
141	501	294	295	22.5	2.0	22	0.22
145	501	293	297	22.5	1.6	38	0.17
149	501	293	297	22.5	3.1	15	0.20

was then allowed to equilibrate for 30-60 min, after which period the substrate was brought into contact with the solution and allowed to thermally equilibrate (5-10 min). The temperature of the reservoir was then increased. Growth experiments were performed for durations ranging from 5 to 45 min, using solution thicknesses of 1.5-3.5 mm and ΔT of 0° - 7°C . Experiments were terminated by sliding the solution off the substrate and cooling the system down. Table I summarizes the growth data for typical PIE layers. Generally, the layers appeared smooth and mirrorlike to the naked eye. Cross sections of PIE layers indicated that excellent thickness uniformity was attained, and quite sharp infrared optical transmission spectra (see Fig. 2) indicate good compositional homogeneity.

Layer thickness vs. growth time.—Experimental results on the dependence of the layer thickness on growth time are given in Fig. 3. The experiments were carried out at a constant growth temperature, using the same solution composition and height and the same magnitude of temperature increase of the Hg reservoir.

As can be seen in Fig. 3, the experimental results can be approximated very well by a straight line consistent with Eq. [8] describing steady-state PIE growth. The calculated value of the Hg diffusivity in solution is $D = 4.44 \times 10^{-5} \text{ cm}^2/\text{s}$ and the value of $\Delta C/(C^s - C_o) \simeq 7.45 \times 10^{-3}$. The diffusivity value is close to the values of around $3 \cdot 10^{-5} \text{ cm}^2/\text{s}$ reported by Ambrozimov *et al.* (7).

Layer thickness vs. solution height.—Experimental data on the layer thickness vs. solution height are given in Fig. 4. All other growth parameters were kept constant. The temperature increase of the Hg reservoir was $\Delta T = 4^\circ\text{C}$ and the growth time $t = 22.5 \text{ min}$. The experimental data are consistent with the inverse proportionality $d \sim 1/l$ predicted by the present theo-

Fig. 2. Room temperature optical transmission spectra of typical layers. Curves (1)-(3) correspond to layer runs numbered 129, 116, and 240, respectively. The relationship used to determine alloy composition was $\lambda_{\text{co}}(\mu\text{m}) = [1.28x - 0.2 + 0.264x^3 + 4.22 \times 10^{-4}T(\text{K}) [1 - 2.08x]]^{-1}$ from Ref. (10). The roots of this equation were found numerically with a Newton-Raphson procedure.

Fig. 3. Layer thickness vs. growth time. $\Delta T = 3^\circ\text{C}$, $l = 2$ mm. Points are experimental, line is derived from theory (see text). t_c is calculated at 5.23 min, and $d_{\text{max}} \sim 50$ μm .

retical model. The line in Fig. 4 is calculated from Eq. [8] using $D = 4.4 \times 10^{-5}$ cm^2/s and $\Delta C/(C^s - C_0) = 5.6 \times 10^{-3}$, i.e., exactly the same parameters used to account for the results in Fig. 3.

Layer thickness vs. temperature step, ΔT_{Hg} .—As pointed out in previous sections, the supersaturation ΔC required for the growth is caused by the increase in Hg reservoir temperature. In an open system, $\Delta C(\Delta T_{\text{Hg}})$ is an important empirical relationship essential for control of the growth process. This relationship can be derived from the experimental dependence of the layer thickness on ΔT_{Hg} . Such experimental data are given in Fig. 5 for the layers grown under identical values of other growth parameters ($l = 0.2$ cm and $t = 22.5$ min). Using Eq. [8] and the diffusivity value $D = 4.4 \times 10^{-5}$ cm^2/s , we have determined $\Delta C(\Delta T_{\text{Hg}})$ for our growth system. As shown in Fig. 5, ΔC increases approximately linearly with ΔT_{Hg} . However, it tends to saturate at higher ΔT_{Hg} values. This saturation is most likely an apparent one, and it probably reflects the depletion of solute (Cd) from the solution; this becomes a growth limiting factor at higher growth rate.

It is of interest to compare $\Delta C(\Delta T_{\text{Hg}})$ with a similar relationship for a closed system. Such dependence calculated according to data of Ruda *et al.* (2) is given by the dashed line in Fig. 5. As can be expected, the closed-system relationship is much steeper. For example, $\Delta T_{\text{Hg}} = 3^\circ\text{C}$ in an open system is equivalent to an effective $\Delta T \approx 2^\circ\text{C}$ in the closed system (8).

Electrical and optical characteristics of the layers.—Layer composition was measured using electron microprobe analysis and infrared optical transmission spectra. Typical spectra for three layers are shown in Fig. 2.

Electrical properties of the layers were measured using a standard Hall apparatus in the van der Pauw configuration at 300 and 77 K, on as-grown and annealed layers. All layers were annealed under saturated mercury atmosphere for 6h at $280 \pm 5^\circ\text{C}$. Table II presents the electrical properties of a selection of

Fig. 4. Layer thickness vs. solution height. $\Delta T = 4^\circ\text{C}$, $t = 22.5$ min. Points are experimental. Line a is calculated for $d = d_{\text{max}}$, and line b from the theory (see text for fit parameters).

Fig. 5. Layer thickness vs. Hg-reservoir temperature increase. $l = 2$ mm, $t = 22.5$ min. Points are experimental, and solid lines are calculated (see text).

PIE layers. Electron mobilities in excess of 10^5 cm^2/Vs at 77 K with carrier concentrations in the low 10^{15} cm^{-3} were obtained. These compare favorably with present LPE layers (9).

Summary and Conclusions

We have developed a simplified theoretical model of pressure-induced epitaxial growth which quantitatively accounts for the growth-kinetics data obtained with HgCdTe layers grown from Te-rich solution.

PIE growth proceeds under isothermal conditions and is stimulated by Hg adsorption on the surface of

the solution. The growth kinetics can be controlled by a temperature increase of an Hg reservoir and by the thickness of the solution.

Using PIE, we have grown $\text{Hg}_{0.8}\text{Cd}_{0.2}\text{Te}$ layers with typical growth velocities between 0.5 and 1.5 $\mu\text{m}/\text{min}$. Layers up to about 40 μm thick were grown of quality comparable to thermal-LPE layers.

APPENDIX

Relationship Between ΔC and ΔT_{Hg}

At its initial equilibrium condition (i) at the liquidus, the state of system may be defined in terms of two temperatures (T, T_1), where T refers to the isothermal solution temperature and T_1 to the initial reservoir temperature. Final equilibrium (f) may similarly be specified by the couple (T, T_2), where $T_2 = (T_1 + \Delta T_{\text{Hg}})$ and is the final reservoir temperature.

In the closed-system context, these two equilibrium states may be expressed as

$$a^i(T) = \frac{P^i(T)}{P^o(T)} = \frac{P^o(T_1)}{P^o(T)} = C_{10}\gamma^i(T) \quad [\text{A-1}]$$

$$a^f(T) = \frac{P^f(T)}{P^o(T)} = \frac{P^o(T_2)}{P^o(T)} = C_{10}\gamma^f(T)$$

where $a(T)$, $\gamma(T)$, $P^o(T)$, and $P^i(T)$ refer to mercury activities, mercury activity coefficients, pure mercury pressures, and mercury pressures over the solution, respectively.

In the open-system context, the mercury pressure over the solution is not uniquely defined by the reservoir: generally, a high reservoir temperature is required compared with the closed system to generate the equivalent mercury pressure. In the open system, $P^o(T_1)$ and $P^o(T_2)$ should be replaced by $P^o(T_1)$ and

$P^o(T_2)$ where $T_1 \neq T_1'$ and $T_2 \neq T_2'$, and generally $T' > T_1'$ and $T_2' > T_2$. From Eq. [A-1] and the above considerations

$$C_{10}^i = C_{10} \frac{\gamma^i(T)}{\gamma^f(T)} \cdot R$$

$$R \equiv \begin{cases} P^o(T_2)/P^o(T_1) : & \text{Closed system} \\ P^o(T_2)/P^o(T_1') : & \text{Open system} \end{cases} \quad [\text{A-2}]$$

Therefore

$$\Delta C = C_{10} \left[\frac{\gamma^i(T)}{\gamma^f(T)} \cdot R - 1 \right] \quad [\text{A-3}]$$

In the closed-system context for small ΔT_{Hg} (8)²

$$R \approx \left\{ \left(\frac{7136 \Delta T_{\text{Hg}}}{T_1 \cdot T_2} \right) + 1 \right\} \quad [\text{A-4}]$$

Therefore, from Eq. [A-3] and [A-4] the closed-system case may be generalized to

$$\Delta C = \xi \Delta T_{\text{Hg}}, \quad \text{where } \xi \text{ is constant} \quad [\text{A-5}]$$

²Phase data used to obtain mercury pressure above solution at 501 $^{\circ}\text{C}$: mercury reservoir temperature of 260 $^{\circ}\text{C}$ implied.

Oxidative Removal of Photoresist by Oxygen/Freon® 116 Discharge Products

J. J. Hannon and J. M. Cook

AT&T Bell Laboratories, Allentown, Pennsylvania 18103

ABSTRACT

Microwave discharge products of a few percent of C_2F_6 in O_2 have been used for the study of the removal of Shipley AZ 1350J photoresist as a function of time and temperature. The removal rate was found to increase with increasing C_2F_6 concentration. The activation energy of removal has been determined for C_2F_6 concentrations ranging from 0.048 to 0.81 volume percent. Initially, the activation energy decreases rapidly to 0.34 eV for C_2F_6 concentrations ranging from 0.048% to 0.10% and continues to decrease with increasing C_2F_6 concentrations to approximately 0.16 eV at 0.81% C_2F_6 . The results reported apply to the removal of Shipley AZ 1350J photoresist, but are likely to indicate the oxidative-removal trends of other organic residues.

The gas-phase, oxidative removal of organic materials from semiconductor surfaces during various processing steps has become rather common in the microelectronics industry. These organic materials are generally present either in bulk amounts as photoresists and encapsulants, or as residual, trace contaminants. The former, which must be removed to allow further processing, failure analysis, etc., generally are fairly thick, on the order of several microns. The latter, whose removal can be categorized more as cleaning, are usually only a few thousand angstroms or so thick and are more readily completely removed.

Although we are more concerned with the cleaning category of the removal processes, it is often easier to monitor removal rates as functions of various process parameters by using bulk amounts of organic materials such as photoresist. Since oxidative degradation of organics is primarily a process occurring at the surface of the material being oxidized (1), the results for bulk amounts should be valid for trace amounts as well.

In the work reported here, we have examined the enhancement of the oxidative removal rate of Shipley AZ 1350J photoresist (Shipley Company, Newton, Massachusetts 02162) by the addition of small amounts of Freon® 116 (C_2F_6) to the oxygen before discharging. This removal of photoresist by plasma discharge methods was first suggested by Irving in 1968 (2) and has been the subject of many papers (3-10) since then. Most of the removal studies described utilized apparatus wherein the photoresist-coated samples were contained in the discharge itself, or else immediately adjacent to it. In either case, the photoresist was likely to be subjected to the particles and radiation present in the discharge, both of which can assist in the oxidation of the material since it has an activation energy in the neighborhood of 0.5 eV (3, 11). However, in our case, as in others (9, 10, 12), the circuits to be cleaned are separated from the environment of the discharge. This not only removes the materials from the possibly harmful effects of the discharge, but also allows better control of the process parameters owing to a better understanding of the various phenomena involved in the downstream reactions.

One factor that must be considered when separating the circuits from the discharge is the essentially complete cessation of photoresist removal (when using O_2 , O_2/N_2 , O_2/H_2 or O_2/H_2O) unless supplemental energy (usually heat) is supplied to the material. However, when fluorocarbons are present, either as additives to the O_2 before discharge or in the materials being oxidized, the removal continues readily (9, 12, 13). We have observed an increase in the oxygen atom concentration downstream of the discharge when a few percent of either CF_4 or C_2F_6 was mixed with the O_2 (14), by using an electron paramagnetic resonance (EPR)

spectrometer. Moreover, we have detected fluorine atoms as well, even for very low concentrations of C_2F_6 , which supports the assertion of the F atoms' participation in the reactions (12, 13, 15).

Finally, while only photoresist removal rates are presented here, it is believed that these results are representative of the oxidative removal behavior of other organic residues.

Experimental Apparatus

The experimental apparatus used for this investigation has been described previously (11) and is shown in Fig. 1. Essentially, it consists of an evacuated quartz tube (22.5 mm id) with a Microtron 200 microwave generator operating at 75W that is used to generate the discharge using an Evenson-type (16) microwave cavity. The gas flow through the tube was measured with a Matheson mass flowmeter Model 8160. Adjustment of a throttling valve at the vacuum pump controlled the pressure in the tube, which was measured by an MKS Instruments, Incorporated capacitance manometer. A Research, Incorporated, Variac-controlled, mini-spot IR heater with an Omega proportional controller and a thermocouple at the sample surface was used to control the temperature of the substrate, which was supported in a Teflon carrier.

Test Vehicle

The test vehicles consisted of square ceramic substrates, 14 mm on a side (area ≈ 2 cm²) coated on one surface with approximately 10 μ m of Shipley AZ 1350J photoresist. After fabrication, the substrates were baked at 140°C for 50 min in a nitrogen atmosphere to drive off any volatile components associated with the photoresist processing, leaving a surface coating density of approximately 1 mg/cm².

Experimental Procedure and Results

Each test specimen was individually weighed several times on a microbalance, and the average weight of each sample determined before and after exposing the substrate to the microwave discharge effluent. The maximum variation from measurement to measurement was less than $\pm 0.005\%$. The distance of the substrate from the microwave cavity was 33 cm unless otherwise specified. The flow rate and chamber pressure were $118 \pm$ sccm and 1.0 torr, respectively, in all cases. These values were chosen because of earlier work (11) with pure O_2 that showed that this resulted in reasonable photoresist removal rates.

Figure 2 shows the effects of time and temperature on the photoresist removal rate for two concentrations (0.103 and 0.81%) of C_2F_6 . In one instance, the substrate temperature was maintained at approximately 150°C, while it was uncontrolled in the second. For the case where the temperature was controlled, the substrates were allowed to stabilize for about 1 min prior

to initiation of the discharge. The substrates shown were individually processed to simplify photographing, and are therefore not intended to be quantitative, but rather serve only to indicate the qualitative aspects of the removal process. The thickness of the photoresist was essentially the same for all substrates. It is evident from the photographs that the reaction is greater on the edge of the substrate closest to the discharge, as

would be expected. Also, increasing either the C_2F_6 concentration or the substrate temperature resulted in an increase in the reaction rate. In addition, higher operating temperatures resulted in a more uniform removal over the entire substrate surface, although the more rapid removal upstream is still evident. This increased uniformity is likely due to greater temperature homogeneity across the surface as compared to the case with no external heating.

Figure 3 shows plots of substrate surface temperature as a function of discharge time, for substrates with and without photoresist, in a 0.497% C_2F_6/O_2 atmosphere. The data shown are for substrates located 33, 22, and 11 cm from the microwave cavity. The increase in temperature on the surface of the substrates without photoresist results from heating by gas from the discharge. Initially, the temperature increases rapidly, essentially stabilizing after approximately 50s. The temperature of the surface of substrates with photoresist results from heating by the discharge gas as well as from heat generated in the combustion of the photoresist surface. The peak temperature seems to occur when the surface area of the photoresist is approximately 1/4 of its original surface area.

The increase in surface temperature on a single photoresist substrate as a function of discharge time for C_2F_6 concentrations ranging from 0.048 to 4.61% is shown in Fig. 4. The temperature generated with a particular concentration is reproducible to within $\pm 5^\circ C$ on any given day under similar test conditions: i.e., chamber wall conditions, distance of substrate from microwave cavity, etc. This is within the accuracy of the temperature measuring system used. Larger

Fig. 4. Substrate surface temperature as a function of discharge time and C_2F_6 concentration.

temperature variations were observed in the case of a newly reconditioned quartz chamber.¹ The temperature generated at the surface of the photoresist substrate, during the initial run after reconditioning, was approximately 20°C higher than that measured prior to reconditioning. This effect was temporary and lasted only until the walls of the chamber had reached a steady-state condition with the discharge effluent flowing through the tube. The variation of temperature with resist removal suggests that the temperature might be useful as an endpoint detector. However, since there is a considerable delay between complete removal of resist and the attainment of a steady-state temperature, and this varies depending upon conditions, it would be a difficult method to implement for endpoint detection.

Photoresist weight loss, as a function of discharge time for uncontrolled temperature and C_2F_6 concentration is shown in Fig. 5 and 6. Pressure and flow rate are the same as mentioned previously, i.e., 1.0 torr and 118 ± 2 sccm. After the initial heating period of <1 min, the mass removed is approximately linear with time of exposure. The data have been fitted to a straight line by the least squares method. The removal

¹Reconditioning consisted of etching with 48% HF for 25 min followed by a DI water rinse. The chamber was then pumped overnight before introducing 0.103% C_2F_6 .

Fig. 5. Photoresist weight loss as a function of time and C_2F_6 concentration and no temperature control.

Fig. 6. Comparison of weight loss for two similar mixtures

rates shown in parentheses are in micrograms per second.

In Fig. 5, uncontrolled-temperature weight loss data are plotted for C_2F_6 concentrations ranging from 0.048% to 4.61%. The removal rate increased from 0.36 to 22.3 $\mu\text{g/s}$ with increasing C_2F_6 concentrations.

During the initial investigation with 0.497% C_2F_6 , problems with the balance were detected. Subsequently, two additional experiments were performed. These data are plotted in Fig. 6. Initially, a removal rate of 6.82 $\mu\text{g/s}$ was obtained. The later experiments resulted in values of 5.07 and 5.57 $\mu\text{g/s}$, which agree reasonably well. The small differences observed were attributed to a lack of cooling of the microwave cavity during one experiment, which resulted in a slightly higher substrate temperature and thus the slightly higher removal rate. Also included in Fig. 6 are data for 0.428% C_2F_6 concentration, which resulted in a removal rate of 3.1 $\mu\text{g/s}$. While this value is considerably lower than that of the 0.497% mixture, it does seem the more reasonable of the two when compared to other mixtures. (Unfortunately, this mixture was exhausted, necessitating the use of the 0.497% mixture.)

Two separate experiments were run where the substrate surface temperature was controlled. Weight loss as a function of both time and temperature, for C_2F_6

concentrations of 0.048%, 0.103%, 0.497%, and 0.81% was determined. Temperatures ranged from 120° to 200°C in 20° increments. The substrates were stabilized at temperature for approximately 2 min prior to the discharge's being initiated. The photoresist removal rates given below represent the time period that the ceramic surface area was still completely covered by the resist.

Initially, removal rates were determined for temperatures of 140°, 160°, and 180°C and produced unexpected results in some of the cases having the higher C₂F₆ concentrations. In the second investigation, the range of temperatures was expanded to more accurately determine the activation energy of removal. Before the second investigation, the quartz tube was reconditioned by etching in HF, as discussed earlier. In Table I removal rates as a function of temperature and C₂F₆ concentration are listed for both investigations.

With 0.103% C₂F₆ at 200°C, a residue was observed to deposit on the substrate carrier and the chamber wall approximately 5-6 cm downstream from the test substrate. The carrier and chamber walls were subsequently cleaned by allowing the microwave discharge to operate at uncontrolled temperature for several minutes.

Photoresist weight loss as a function of time for a C₂F₆ concentration of 0.81% at 140° and 180°C with no discharge is shown in Fig. 7. The substrates were allowed to stabilize at temperature approximately 1 min prior to starting the test. Although there is considerable scatter in the data, especially at the higher temperature, there is some indication that reaction of the gas with the photoresist may occur at higher temperatures without the discharge products, although at a much slower rate. However, at the higher temperature the photoresist may well be decomposing. Removal rates determined are 0.07 and 0.73 μg/s at 140° and 180°C, respectively. This effect was not taken into consideration when determining activation energies, since its exclusion does not affect the trends.

Arrhenius plots of the log of $\frac{R}{P} T^{1/2}$ vs. $\frac{1}{T}$ for the various C₂F₆ concentrations are plotted in Fig. 8 for

Fig. 7. Weight loss as a function of time and temperature with no discharge.

data from the second investigation. The data are fitted by the least squares method (in exponential form) with the E_{act} for each concentration given in parenthesis. The activation energy of removal as a function of C₂F₆ concentration is plotted in Fig. 9. In general, the activation energy increases with decreasing C₂F₆ concentration ranging from approximately 0.16 eV at 0.81% to 0.34 eV at 0.048% C₂F₆. Activation energies determined from the initial investigation agree rea-

sonably well and are listed in Table I. These results agree with the suggestions of Mogab (15) with respect to variation of activation energy with changing C₂F₆ concentration.

In Fig. 10 are plotted the relative oxygen and fluorine atom concentrations as functions of the percentage of C₂F₆ in oxygen. (The term "relative" applies only to each species individually; the absolute relationship between the concentrations of the two species is not known, excepting that [F] < [O].) These concentrations were measured at the same distance from the discharge as the substrates had been placed. It can be seen that while the oxygen atom concentration rises rather rapidly and then reaches essentially a plateau, the fluorine atom concentration continues to increase. The observation that the rate increases (and the E_{act} decreases) with increasing C₂F₆ content can be explained by the fluorine atoms' concomitant increase. Very likely the fluorine atoms abstract hydrogen atoms or add to double bonds to form excited complexes that then dissociate. In either case, the fluorine atoms react far more rapidly than do oxygen atoms (17, 18) and by so doing, render numerous sites quite reactive to the excess oxygen atoms and molecules.

Conclusions

The removal rate of Shipley AZ 1350J photoresist, when subjected to microwave discharge products of a C₂F₆/O₂ mixture, increases with increasing C₂F₆ concentrations. Activation energies determined agree reasonably well for both investigations reported here as well as with results determined from EPR spectroscopy studies conducted previously (11). Initially, the activation energy decreases rapidly to about 0.3 eV for C₂F₆ concentrations ranging from 0.048% to 0.10% and continues to decrease with increasing C₂F₆ concentrations to approximately 0.16 eV at 0.81% C₂F₆.

The results reported here may be used to help select appropriate C₂F₆ concentrations and temperatures for application to device processing. The uncontrolled-temperature results would be valid for process application only if very large amounts of photoresist are to be removed from a single sample such that the heat of combustion significantly increases the sample tempera-

Fig. 10. Relative oxygen and fluorine atom concentrations downstream as functions of C₂F₆ concentration.

ture. The data show that the temperature drops substantially once the bulk of the organic material has been removed from the sample.

Care should be taken to maintain the condition of the chamber, since the surface of the chamber can have a great affect on the concentration of the active species. This is especially evident for a newly reconditioned quartz chamber. Once the system is operated for a specified time prior to device processing, the chamber walls reach a point of passivation such that the results are reproducible.

Redeposition of removed material can be a problem, but can be avoided by operating at lower temperatures ($\approx 160^\circ\text{C}$) with no more than 2% C₂F₆ by volume.

Finally, in all our work, as noted, no removal of photoresist was observed in the absence of fluorocarbon doping or supplemental heating. This is in contrast to the observations of Dzioba *et al.* (10), who observed rather rapid removal in a system analogous to ours while using pure oxygen. Our results agree with those reported both by Wang and Galernt (9) and Horiike and Shibagaki (12). This suggests that in the work of Dzioba *et al.* (10) energy was being supplied to the photoresist in some fashion, perhaps via UV radiation from the plasma.

Acknowledgments

We would like to thank Dr. B. W. Benson for enlightening discussions, technical assistance, and his helpful critical review of this paper. In addition, the help of J. S. Solga for test-specimen weight measurements is gratefully acknowledged.

Cleaning of a Rough Rigid Surface: Removal of a Dissolved Contaminant by Convection-Enhanced Diffusion and Chemical Reaction

Radhakrishna Chilukuri¹ and Stanley Middleman

Department of Applied Mechanics and Engineering Sciences, University of California, San Diego, La Jolla, California 92093

ABSTRACT

A model is formulated with which one may calculate the rate of disappearance of a species dissolved in fluid trapped in a microscopic cavity of a surface. The model accounts for diffusion, convection, and chemical reaction. Solutions are carried out, and a numerical example is worked out in order to show the representative time scales of these interacting processes.

When a solid surface is contaminated by a liquid spill, or processed through a series of liquid chemical baths, removal of the liquid is usually effected by a cleaning procedure that involves soaking, flushing, or wiping of the surface. In most situations, the bulk of the contaminating liquid is removed by such action. Several examples may be cited that suggest the need to examine the details of removal of contaminants that may be trapped within the microscopic architecture of the surface:

1. A rough metal may be cleaned to the point that only a miniscule fraction of contaminant remains in the microscopic "valleys" of the surface. If the contaminant is reactive, however, continued exposure of the surface to the contaminant may lead to a deleterious change in the surface properties of the metal.

2. If the contaminant has very high toxicity (possible examples would be radiation or biological hazards) then continued exposure of personnel to the surface would be intolerable, even though "nearly all" of the contaminant had been removed by mechanical means.

3. In the semiconductor industry, one purposefully creates a surface architecture with length scales of the order of 0.1-1 μm on silicon wafers. These wafers must then be washed prior to subsequent chemical steps (such as chemical vapor deposition), and ultimately cleaned of submicron particulates. Traditional gross methods of flushing and wiping may be insufficient to clean such a surface adequately.

If we confine our attention to microscopically rough (or patterned) surfaces, say with length scales of order $\leq 100 \mu\text{m}$, then it is clear that mechanical flushing and wiping may not be an effective means of decontamination. It is necessary, in order to evaluate a proposed or existing mechanical decontamination procedure, to deter-

mine the hydrodynamics induced within a microscopic "pore" or "cavity" in a surface by the external macroscopic flow field. Studies which are in progress have, in general, distinguished between two kinds of hydrodynamic phenomena that occur in cavities in a surface, within which a contaminated liquid resides.

1. In one, the liquid is effectively trapped, but the external cleaning flow can induce circulation within the cavity. If the contaminant is diffusible, then the removal of contaminant is controlled by convective diffusion, and the efficiency of removal depends upon the hydrodynamics within the cavity. The problem of convective diffusion from a circulating flow within a two-dimensional rectangular cavity has been treated recently by Chilukuri and Middleman (1).

2. In the second type of cavity flow, the external flow may penetrate the cavity and remove some of the entrapped liquid. Our studies of this problem are in an early stage, but it appears that on the scale of interest, there would always be a sizable region of trapped liquid which can be set in circulation, but not displaced, from the cavity (2).

Figure 1 illustrates some of these ideas.

Model Formulation

It should be apparent that under conditions such that displacement of a contaminant does not occur (at all, or at a sufficiently high rate), it will be necessary to assist the decontamination process in some way. One possibility is chemical detoxification or decontamination. The study presented herein investigates detoxification of a trapped contaminant. We consider a toxic species T which may react with a neutralizing or detoxifying agent D to produce a harmless neutral product N. The reaction scheme is taken to be according to

¹ Present address: JAYCOR, San Diego, California 92138

Fig. 1. A, top: a microscopic pore contains contaminated liquid, and a flushing flow is imposed in the space above the pore. B, middle: under some conditions, the pore fluid is induced to circulate, but is not displaced from the pore. C, bottom: under other conditions, some of the original fluid displaced from the pore, but, ultimately, a limit to displacement occurs, and there is a streamline which divides the external flow from the internal circulating flow.

where k is the specific reaction rate, defined so that

$$r = k C_T C_D \quad [2]$$

where C_T (C_D) is the molar concentration of the toxic (detoxifying) species, and r is the number of mols of T converted by reaction [1], per unit of volume and time.

The species conservation laws for T and D are, including convection and diffusion

$$\frac{\partial C_T}{\partial t} + u \cdot \nabla C_T = \mathfrak{D}_T \nabla^2 C_T - k C_T C_D \quad [3]$$

$$\frac{\partial C_D}{\partial t} + u \cdot \nabla C_D = \mathfrak{D}_D \nabla^2 C_D - k C_T C_D \quad [4]$$

Here u is the velocity vector within the cavity, and species T and D may have different diffusion coefficients \mathfrak{D}_T and \mathfrak{D}_D .

We will illustrate the analysis by studying a two-dimensional rectangular cavity, as shown in Fig. 2, and assume that the cavity flow is closed, i.e., no streamlines cross the plane $y = H$. In an earlier study (1), we have calculated the velocity field in a closed cavity, assuming either constant velocity or constant shear stress, along $y = H$. In this

Fig. 2. Definition sketch of the cavity geometry. Over the region $(0 \leq x \leq L)$, the plane $y = H$ is a streamline across which there is diffusion, but no flow. A constant shear stress S_0 is assumed along that line in the example problem presented here.

paper, for the sake of illustration, we take the constant shear boundary condition.

Boundary conditions on concentration take the form

$$n \cdot \nabla C_T = n \cdot \nabla C_D = 0 \quad [5]$$

on the walls of the cavity, where n is the normal to the surface. This expresses impermeability of the walls. Along the boundary $y = H$ we assume

$$C_T = 0 \quad [6]$$

$$C_D = C_{D_0}$$

Initial conditions are

$$C_T = C_{T_0}$$

$$C_D = 0 \quad [7]$$

within the cavity. Equations [3] and [4] are nonlinear, because of the assumption of nonlinear reaction rate in Eq. [2]. Note that the equations are coupled through the reaction terms. It is necessary to solve the equations numerically. A finite difference method is used, and details are described by Chilukuri (2). The velocity field u must be obtained separately, also by numerical methods, and a general discussion of the method and results may be found in our earlier works on this topic (1, 2).

Results

The set of equations presented above was solved for the concentrations C_T and C_D within the cavity, as a function of time. Results are illustrated here for $\mathfrak{D}_T = \mathfrak{D}_D = \mathfrak{D}$, and $H = L$.

It is useful to present results in terms of the following dimensionless groups

$$\text{Stoichiometric ratio } R = C_{D_0}/C_{T_0} \quad [8]$$

$$\text{Peclet number } Pe = S_0 L^2 / \mu \mathfrak{D} \quad [9]$$

where S_0 is the shear stress along $y = H$.

$$\text{Kinetic number } K = k L^2 C_{T_0} / \mathfrak{D} \quad [10]$$

We will be interested in the half-time $t_{1/2}$ required for the concentration within the cavity to be reduced to one-half its initial value of C_{T_0} . If there is no chemical reaction, removal of contaminant is by the mechanism of convection-aided diffusion.

The degree to which reaction aids removal of the contaminant may be measured by a factor we call the Enhancement Ratio

$$E1 = t_{1/2}^0 / t_{1/2} \quad [11]$$

where $t_{1/2}^0$ is the half-time in the absence of reaction.

Figure 3 shows some typical results for the Enhancement Ratio, $E1$, as a function of K and R , for $Pe = 100$. As is to be expected, $E1$ approaches unity as K vanishes. For large K (i.e., fast reactions) the enhancement is controlled by the Peclet number and the stoichiometric ratio, R . Figure 4 shows the asymptotic value of $E1$ for large K as a function of R , for two Peclet numbers. Figure 5 shows the effect of Peclet number on $E1$ vs. K , at a value of $R = 10$.

While nondimensionalization is an aid to compact presentation of these results, there is an accompanying obscuring of the meaning and import of the results. It is useful, then, to consider some direct numerical interpretations of the results through the presentation of a case study.

Let us begin with a review of possible mechanisms of decontamination. Figure 6 shows a cavity in a surface, with four possible modes of removal of a contaminant from the cavity. In Fig. 6a we suggest that the external hydrodynamics (agitation, sonication, spray flushing, wiping, or brushing) is capable of physically and instantaneously removing fluid with contaminant from the cavity. This is not a realistic prospect for small cavities, as our studies of the hydrodynamics are suggesting. Nevertheless, the case forms a lower bound on the time re-

Fig. 3. Enhancement ratio in the presence of chemical reaction

quired to clean the cavity. The time is instantaneous, as assumed above. However, we have not detoxified the contaminant.

In some practical cases, it may be sufficient to remove the contaminant from a small cavity, and then dilute it within the large body of cleaning fluid. In other cases, however, it may be necessary to neutralize the contaminant chemically. This is the case of interest here.

If the fluid in the cavity is instantaneously removed and mixed into the external cleaning fluid, and if D is the

C, bottom left: trapped but circulating fluid in the cavity. Circulation aids diffusion. D, bottom right: as in C, but with chemical reaction as well.

Fig. 4. Asymptotic value of $E1$ for large K

dilution ratio (cavity volume/cleaning fluid volume), then chemical neutralization occurs according to Eq. [2], and we write

$$-\frac{dC_T}{dt} = kC_T C_D \quad [12]$$

$$\left. \begin{aligned} C_D &= C_{D\infty} \\ C_T &= DC_{T_0} \end{aligned} \right\} \text{at } t = 0$$

We assume that the external concentration of neutralizing chemical C_D is related to the initial concentration of contaminant in the cavity, so that (as in Eq. [8])

$$C_{D\infty} = RC_{T_0} \quad [13]$$

If we let ξ be the fraction of contaminant neutralized, then

$$C_T = DC_{T_0}(1 - \xi) \quad [14]$$

and

$$\begin{aligned} C_D &= C_{D_0} - DC_{T_0} \xi \\ &= RC_{T_0} - DC_{T_0} \xi \end{aligned} \quad [15]$$

Then Eq. [12] becomes

$$\frac{d\xi}{dt} = kC_{T_0}R(1 - \xi) \left(1 - \frac{D}{R}\xi\right) \quad [16]$$

The solution for $\xi(t)$ is easily found to be

$$\frac{1}{1 - \frac{D}{R}} \ln \left(\frac{1 - \frac{D\xi}{R}}{1 - \xi} \right) = kC_{T_0}Rt \quad [17]$$

The half-time for neutralization then follows upon setting $\xi = 1/2$ in Eq. [17]. Results are shown in Fig. 7. We are now prepared to make numerical comparisons of the modes of removal illustrated in Fig. 6.

We choose the following parameters:

$$\begin{aligned} L &= 10^{-2} \text{ cm (100 } \mu\text{m)} \quad \text{square cavity (} A = 1) \\ \mathcal{D} &= 10^{-6} \text{ cm}^2/\text{s} \\ \mu &= 0.1 \text{ poise} \\ S_0 &= 10 \text{ dyn/cm}^2 \\ C_{T_0} &= 10^{-4} \text{ mol/cm}^3 \\ k &= 10^6 \text{ cm}^3/\text{mol}\cdot\text{s} \\ R &= 10 \\ D &= 10^{-4} \end{aligned}$$

With these parameters we find

$$\begin{aligned} \text{Pe} &= 10^4 \\ K &= 10^4 \end{aligned}$$

Neutralization via instantaneous removal, dilution, and reaction.—We find

$$(kC_{T_0}D)t_{1/2} = 0.693 \times 10^{-5} \quad [18]$$

or the expected half-time is

$$t_{1/2} = 0.693 \cdot 10^{-3} \text{ s} \quad [19]$$

For all practical purposes, the neutralization is instantaneous.

Our hydrodynamic studies suggest that it is not realistic to anticipate that Fig. 6a offers a realistic picture of the physics of this situation. For small cavities, it is much more likely that fluid in a cavity is effectively trapped, and that diffusion plays an important role in removal of the contaminant and its neutralization.

Again with reference to Fig. 6, we examine these other modes of decontamination.

Fig. 7. Half-time for neutralization of contaminant

Diffusion from a trapped and static liquid in a cavity; no reaction.—We have a classical diffusion problem defined by Eq. [3] with $u = 0$ (static liquid) and $k = 0$ (no reaction). Equations [5]–[7] for C_T provide the boundary conditions. The solution of this problem is available in such standard references as Bird *et al.* (3), and from it we find that the half-time for removal is

$$\frac{\mathcal{D}t_{1/2}}{L^2} = 0.194A^2 \quad [20]$$

For the parameters chosen, this gives

$$t_{1/2} = 19.4 \text{ s} \quad [21]$$

Note how much slower the diffusion process is in comparison to the reaction process.

However, diffusion can be accelerated by circulation induced by an external flow. This is the topic of our earlier study (1), and Fig. 6c shows the physics envisioned.

Diffusion from a trapped but circulating liquid in a cavity; no reaction.—We must find an enhancement factor E by which the static diffusion half-time is reduced. For $\text{Pe} = 10^4$ and a square cavity, we find (1; Fig. 3) $E = 5 \times 10^{-2}$. Hence, circulation induced by the external flow speeds up the diffusion process by a factor of 20, and we find

$$t_{1/2} = 0.97 \text{ s} \quad [22]$$

Before proceeding, let us remark on the kind of flushing or wiping flow that would give a shear stress of 10 dyn/cm^2 across the top of the cavity, as assumed here. Suppose we have a surface being cleaned by a rotating cylindrical brush, as suggested in Fig. 8. We imagine the case where, to protect the surface, the brush does not actually contact the surface, but instead comes within a small distance b of the surface. For a linear velocity U the shear stress would be given by

$$S_0 = \mu_t U/b \quad [23]$$

where μ_t is the viscosity of the flushing fluid. For water at 20°C ($\mu_t = 10^{-2}$ poise), using a 2.5 cm radius brush with a clearance b above the surface of $100 \mu\text{m}$ ($b = 10^{-2}$ cm), at a rotational speed of 40 rpm, we find $S_0 = 10 \text{ dyn/cm}^2$. Thus the numbers used here, while arbitrary, are within the range of reasonable operation of equipment.

Reaction and convection-aided diffusion within the cavity.—The half-time for case c, approximately 1s, while quite a bit longer than that of case a, seems short enough to be suitable for a cleaning operation. It is interesting to inquire into the possibility of still faster removal of the contaminant from the cavity through the aid of a chemical neutralizing agent. Instead of assuming, as in case a, that the contaminant is removed bodily from the cavity and then neutralized via reaction, we examine the rate of neutralization due to diffusion of the species D into the cavity, within which it reacts. Of course, this is the mathematical model posed in Eq. [1]–[7]. Figure 5 (for $K = 10^4$, $\text{Pe} = 10^4$, and $R = 10$) gives an enhancement factor $E1 = 0.31$. Thus, for reaction and convection-aided diffusion within the cavity we find (using Eq. [11] and [22])

$$t_{1/2} = 0.3 \text{ s} \quad [24]$$

Fig. 8. Simple model of a rotating-brush cleaner

This is still quite a bit larger than the value to be expected if the cavity fluid could be removed (case a).

From a practical point of view, one would control the rate of cleaning by exercising some control over the characteristics of the brush or jet-spray apparatus that is typically used in surface cleaning. As our model demonstrates, it is the shear stress exerted by the brush- or jet-driven flow across the cavity surface that affects the rate of removal of a contaminant. This shear stress appears in the model only in the Peclet number (Eq. [9]).

Our earlier work (1) predicts that in the range of Peclet numbers of likely occurrence (say $\geq 10^3$ - 10^6), convection aids removal by a factor E which is linearly and inversely proportional to Peclet number, *i.e.*

$$E \sim Pe^{-1} \quad [25]$$

Thus, all other physical and geometrical parameters remaining the same, the removal time is reduced by a factor that is linear in shear stress S_0 . In a brush cleaner, the shear stress may be controlled through the rotational speed of the brush as well as the proximity of the brush to the surface to be cleaned. In a jet-spray apparatus, the dynamics are more complex, and depend upon the jet velocity and the proximity and orientation of the jet with respect to the target surface. The mathematical model illustrated here should be useful to those concerned with the design, improvement, and utilization of cleaning systems, when used in conjunction with appropriate laboratory studies of the cleaning of real surfaces.

Conclusions

A mathematical model has been formulated with which one can assess the time scales associated with removal (by convection-aided diffusion and/or by a neutralization reaction) of a chemical contaminant from a small cavity in a surface. Idealizations of the geometry make solutions possible via relatively simple numerical methods. In principle, more complex geometries and external flows could be considered, but at considerable increase to the cost of computation.

For a fluid hydrodynamically trapped within a cavity, but capable of circulation induced by the external

flushing flow, the time for removal of a diffusible contaminant is strongly dependent on circulation within the cavity. The degree of effectiveness of circulation, and the effectiveness of a neutralization reaction, can be assessed using the models presented here.

Electroluminescence and Photoluminescence of GaAs in Aqueous Redox Electrolytes

Franco Decker,* Milton Abramovich, and Paulo Motisuke

Instituto de Física, UNICAMP, Campinas, Sao Paulo, Brazil

ABSTRACT

Spectral resolved electroluminescence has been observed for n-GaAs in the presence of different hole injecting redox electrolytes from 0.8 to 1.25 μm . Photoluminescence spectra were obtained for n-GaAs in the same electrolytes. Luminescence was observed both in bandgap and subbandgap energy ranges. The presence of a deep acceptor level, attributed to Ga vacancies, is inferred. Efficient charge transfer to this level and/or to the valence band can be observed with a suitable choice of the redox electrolyte.

The occurrence of hole injection from a redox electrolyte into the valence band and/or into an intermediate level (deep level and/or surface state), of a semiconducting electrode can be detected via electroluminescence (EL). This phenomenon has been observed with the one-electron redox injecting electrolyte $\text{Fe}(\text{CN})_6^{3-/4-}$ for GaP (1, 2), and more recently for GaAs by Decker *et al.* with the couples $\text{Fe}^{2+/3+}$, $\text{Ce}^{3+/4+}$, $\text{Fe}(\text{CN})_6^{3-/4-}$ (3). In that work, the mechanism of hole injection was elucidated by the use of the rotating ring-disk technique as well as by elec-

troluminescence. Ring-disk results that are in excellent agreement with the ones in Ref. (3) were also published by Menezes and Miller (4). The electroluminescence measurements reported in Ref. (3) were not spectrally resolved because of instrumental limitations. The present publication is, therefore, mostly devoted to the investigation of the EL spectra up to 1.25 μm , of the relationship between the spectra and the redox electrolyte used, and to the comparison with photoluminescence (PL) spectra of GaAs. Interesting comparisons can be made with previous works on EL from GaAs (5) and from II-VI binary and ternary compounds (6-9). In those papers, the injecting species was a highly active intermediate, like $\text{OH} \cdot$

*Electrochemical Society Active Member.

Key words: semiconductor/electrolyte junctions, luminescence.

or SO_4^{2-} , resulting from the reduction of peroxide or persulfate. The energy-level distribution of such an injecting species is poorly defined, and therefore little information on the energy level at which the hole-injection process takes place can be extracted from the spectra. Using one-electron redox couples like $\text{Fe}^{2+/3+}$, $\text{Ce}^{3+/4+}$, $\text{Fe}(\text{CN})_6^{3-/4-}$, on the contrary, the energetic conditions for hole injection into the valence band or into some intermediate level of GaAs can be analyzed more carefully. Moreover, the use of a redox ion as a hole injecting species allows a steady-state measurement of an EL spectrum, once the mass transport of the electrolyte to the electrode surface is well defined. In practice, this procedure can be employed only if the surface conditions of the electrode do not change too much during the measurement. If drastic changes occur (like from an oxide-coated to a hydride-coated surface) quenching of radiative recombination can take place and a distorted and weaker spectrum results. It is therefore very important to control the electrode potential during EL measurements, since adequate electron concentration at the semiconducting electrode surface has to be maintained. At the same time, side reactions giving H_2 evolution have to be avoided.

Very large cathodic potentials can induce either hole injection due to high concentration of intermediates (10, 11) or ion injection and migration (12, 13) into the semiconducting electrode. Both phenomena can cause luminescence; high cathodic polarization has therefore been avoided in our work in order to confine our study to EL resulting from hole injection by the redox electrolytes.

Experimental Techniques

Electroluminescence.—The use of redox ions in low (10^{-3} – $10^{-2}M$) concentration as the hole injecting species requires an efficient stirring of the electrolyte, in order to guarantee diffusion-controlled hole injection and current high enough to yield detectable EL signals. In Ref. (3) the rotating disk technique was used in order to guarantee efficient mass transport and constant current. Here, this technique is impractical because the image of the rotating electrode onto the spectrometer slit is unstable, causing fluctuations of the detected EL signal. Stirring by means of magnetic stir-bars or other mechanical devices produces enormous oscillations in the hole-injection current and therefore in the EL intensity as well. The best configuration has been found to be an electrolyte jet impinging onto a stationary electrode, the electrolyte flux being sustained by an all-Teflon rotary pump that fills an intermediate reservoir (Fig. 1). The electrolyte level in

Fig. 1 Top view of the experimental setup for photoluminescence and electroluminescence. The inset shows the electrode mounting in detail (side view).

this reservoir is constantly kept ~ 10 cm higher than that in the main cell, to which the electrolyte flows simply by gravity. EL intensity fluctuations of a few percent and even smaller current oscillations have been achieved in this way. The GaAs electrode is set in front of the nozzle (with 1–2 mm separation) and sideways to the cell flat Pyrex window, so that the image of its front edge can be focused onto the spectrometer slit. The EL originating from the flat-crystal surface exposed in front of the nozzle can also contribute to the signal as long as defocusing is not too severe. The optical setup consists of a collecting lens, a long pass filter with cutoff at $0.7 \mu\text{m}$, a Spex spectrometer, and a S-1 EMI photomultiplier. The spectral sensitivity of the photomultiplier decays very steeply for λ greater than $1.1 \mu\text{m}$. Consequently, the photomultiplier relative spectral response was compared to that of a flat photoacoustic photodetector, and correction factors were derived for wavelengths in the range 0.7 – $1.25 \mu\text{m}$. The photomultiplier was cooled with liquid air in order to achieve maximum signal-to-noise ratio. The slit widths of the spectrometer were kept at 1.0 mm in most experiments, which brings a spectral resolution of 16\AA at $\lambda = 1.0 \mu\text{m}$. Measurements of EL for λ greater than $1.3 \mu\text{m}$ were not possible with the present experimental setup both because of photomultiplier insensitivity and because of strong IR absorption in the aqueous electrolyte. A different setup will be assembled for EL measurements in this IR region.

The electronic apparatus consisted of conventional potentiostat and programmer, voltmeter, electrometer, and a double-pen strip-chart recorder. The EL and PL spectra were obtained by driving the spectrometer at the constant speed of $5 \text{\AA} \text{ s}^{-1}$. The electrochemical cell and the reservoir were made of Pyrex and connected to each other and to the pump by Tygon tubes. The three-electrode configuration was always used, and all potentials will be referred to the saturated calomel reference electrode (RE). The electrolytes were prepared with triply distilled H_2O and with high purity reagents. The presence of oxygen did not affect our measurements; therefore, it was unnecessary to deaerate the electrolytes. Graphite was used as the counterelectrode (CE). An n-GaAs sample from Laser Diode Company, doped with a Si concentration at $5 \times 10^{17} \text{ cm}^{-3}$, was used as the working electrode (WE). The ohmic contact was obtained by the evaporation of Sn followed by annealing under N_2 atmosphere during 2 min at 400°C . The sample was mounted on a Teflon rod (as shown in Fig. 1) with the crystallographic (100) face exposed to the solution. The semiconductor surface was etched in $\text{H}_2\text{SO}_4:\text{H}_2\text{O}_2$ (1:1 by volume) prior to use.

Photoluminescence.—The same setup described for EL was used for the PL measurements. The photoexcitation was made by means of a 3 mW He-Ne laser from Spectra Physics focused on GaAs front crystal edge. In this way, the same alignment for PL and EL could be used.

Experimental Results

Photoluminescence of GaAs.—PL of GaAs in air or vacuum has been widely studied for several years, as a function of temperature, doping, and various other parameters (14). It is well known that heat-treatments and surface contamination may affect PL. First, we ran the photoluminescence spectrum at room temperature and in air of GaAs sample as received from the factory, with mirror-like surface finishing. The spectrum (not corrected for photomultiplier sensitivity) is labeled as PL⁰ in Fig. 2: a very strong band-to-band transition is observed in $0.87 \mu\text{m}$, and a weaker and much broader band shows up around $1.1 \mu\text{m}$ (note the 30-fold increase in sensitivity in the IR region).

PL and EL in $\text{Fe}(\text{CN})_6^{3-}$ pH 13.—The GaAs electrode was assembled as previously shown, etched, and introduced into the electrochemical cell filled with a 30 mM $\text{K}_3\text{Fe}(\text{CN})_6 + 0.1M$ KOH electrolyte. This electrolyte composition was chosen because it is well known that

Fig. 2. Uncorrected photoluminescence (solid lines) and electro-luminescence (dashed lines) spectra of n-GaAs in air (PL°) and in aqueous $0.03M K_3Fe(CN)_6 + 0.1M KOH$ electrolyte (PL and EL). During PL, the GaAs electrode was held at open circuit; during EL, at $-1.75V$.

$Fe(CN)_6^{3-}$ injects holes into GaAs in alkaline solutions (3, 4, 15). The PL spectrum (Fig. 2) was obtained with no potential applied to the GaAs electrode. This spectrum is virtually identical to the one obtained in air in the band-to-band region, and shows only minor changes in the IR. It is therefore clear that none of the features observed in the photoluminescence spectra depends on contact with the electrolyte, *i.e.*, the electrolyte ions have no specific effect on PL. When potential is applied to the electrode, and the laser switched off, luminescence from the electrode appears as soon as a cathodic current flows in the cell (Fig. 3). At $-1.75V$, the EL intensity is maximum and very stable in time at all wavelengths (see Fig. 4). Therefore, a steady-state EL spectrum (shown in Fig. 2) was ob-

tained at a constant $-1.75V$ potential. In the EL spectrum both bands at 0.87 and 1.1 μm are observed; however, the intensity of the 0.87 μm band is now much weaker than that observed in PL. A better analysis of the PL and EL spectra can be made after multiplying the measured intensities by the correction factors and after normalization to the same peak height at 0.87 μm . This is shown in Fig. 5. The band-to-band recombination spectrum in the EL is broader than in the PL (see Table I), which is mainly due to the enhancement of the short wavelength side of the peak. In the IR region, the emitted intensities level off in both spectra; however, the ratio of this intensity to that in 0.87 μm is much larger in the EL spectrum than that in PL. It is unfortunate that the photomultiplier is so insensitive for wavelengths greater than 1.25 μm and therefore that the long wavelength tail of the IR peak cannot be seen with this experimental setup. A structure is seen at 0.93 μm in EL, but since it did not appear in all EL measurements, we shall not discuss it.

The complete dependence of EL with electrode potential at constant wavelength is shown in Fig. 3. EL appears

Fig. 3. Current-potential curve for n-GaAs in aqueous $0.03M K_3Fe(CN)_6 + 0.1M KOH$ in the dark (lower part). The corresponding EL intensities recorded as a function of applied potential for two different wavelengths are shown in the upper part. Note the three-fold increase in sensitivity for EL in $\lambda = 1.1$ μm . The potential was swept at a constant rate of -20 $mV s^{-1}$.

Fig. 4. Time dependence of PL (solid lines) and EL (dashed lines) of n-GaAs in $0.03M K_3Fe(CN)_6 + 0.1M KOH$ and in $0.03M Ce(SO_4)_2 + 1.0M H_2SO_4$. At $t = 0$, either the laser was switched on (PL), or the electrode potential was stepped from 0 to $-1.75V$ (EL).

Fig. 5. PL (solid line) and EL (dashed line) spectra of n-GaAs after correction for photomultiplier efficiency and normalization to the same peak height in 0.87 μm . Electrolyte and polarization conditions are the same as in Fig. 2.

only with cathodic currents, starting for $V < -1.0\text{V}$. This is in agreement with previous observations (3), which were confined, however, to $\lambda < 0.9\ \mu\text{m}$. For potentials more cathodic than -1.8V , EL at $\lambda = 0.87\ \mu\text{m}$ is quenched abruptly while EL at $\lambda = 1.1\ \mu\text{m}$ decays slowly and eventually becomes constant.

PL and EL in Fe^{3+} and Ce^{4+} , pH 0.—Electrolytes with 0.03M Fe^{3+} or 0.03M Ce^{4+} in 1.0M H_2SO_4 were used because the equilibrium potentials of these couples are located either in the GaAs bandgap ($\text{Fe}^{2+/3+}$) or overlap with the GaAs valence band ($\text{Ce}^{3+/4+}$).

A number of experimental difficulties arise, however, in acid electrolytes. Although the potential dependence of PL and EL was observed to be similar to that observed at pH 13 (with the exception of a 0.6V shift in the onset of EL), no electrode potential could be found at which EL would be stable during the time required to measure a complete spectrum. PL intensities at fixed wavelength and potential decrease with time, contrary to what occurs in 0.1M KOH. The variation of PL and EL intensities with time are shown in Fig. 4 for Ce^{4+} and $\text{Fe}(\text{CN})_6^{3-}$. An exchange of Ce^{4+} by Fe^{3+} showed a similar decrease in PL and EL intensities with time.

It became clear to us that photocorrosion takes place at the laser spot on the GaAs electrode and the corrosion products are not dissolved quickly enough at pH 0. Corrosion products like gallium oxides are probably left on the surface [see also Ref. (16)], resulting in PL quenching. In fact, moving the laser spot to another region of the electrode restores the initial intensity of PL.

In order to measure EL, we had to apply the same technique previously employed by Ellis *et al.* (6, 7) which consists in short (2s) forward-bias pulses alternated by longer (20s) time intervals in which the GaAs-electrolyte junction is reverse biased. At the same time, the spectrometer was driven at constant speed. The two EL spectra, relative to Fe^{3+} or Ce^{4+} ions in the same 1M H_2SO_4 support

Table I. Characteristics of the luminescence spectra of n-GaAs grown from the melt in the bandgap region (first two columns) and ratios between the luminescence intensities, corrected by photomultiplier efficiency, at 0.87 and 1.1 μm (third column)

	Peak position (Å)	Bandwidth FWHM (Å)	$\frac{I_{0.87}}{I_{1.1}}$
PL ^o in air	8700	343	6.24
PL in $\text{K}_3\text{Fe}(\text{CN})_6 + \text{KOH}$	8700	345	6.71
EL in $\text{K}_3\text{Fe}(\text{CN})_6 + \text{KOH}$	8680	392	0.30
EL in $\text{Ce}(\text{SO}_4)_2 + \text{H}_2\text{SO}_4$	8680	390	0.35
EL in $\text{Fe}_2(\text{SO}_4)_3 + \text{H}_2\text{SO}_4$	8660	408	0.08

electrolyte, are shown in Fig. 6. It is important to notice that the spectra were obtained one after the other without removing either the cell or the electrode. The redox electrolyte was substituted, and otherwise the same experimental conditions were maintained, so that the EL intensities of both spectra can be directly compared. The following remarks are important: (i) the EL with Ce^{4+} is more intense than that with Fe^{3+} , by a factor of 10 in 0.87 μm and by a factor of only 2.2 in 1.1 μm (note the different scales in which EL intensities for Fe^{3+} and for Ce^{4+} are shown in Fig. 6) and (ii) in the Fe^{3+} EL spectrum, the IR peak is more intense than the peak in 0.87 μm .

The more relevant data from PL and EL spectra in the three electrolyte are summarized in Table I.

Discussion and Conclusions

The PL and EL spectra give a valuable insight into processes related to radiative recombination and charge transfer across the semiconductor-electrolyte interface. The band-to-band recombination emission spectrum of the n-GaAs with maximum at $\sim 0.87\ \mu\text{m}$ is observed in PL as well as in EL, but in the latter the spectrum appears slightly broader and its peak is shifted to shorter wavelength, as shown in Fig. 5 and Table I. Since this broadening occurs almost exclusively in the high energy tail we attribute the difference to self-absorption effects, *i.e.*, on average, EL is produced nearer to the GaAs-electrolyte interface than PL. Similar conclusions about EL spectra broadening were drawn by Ellis *et al.* (6); they compared EL and PL spectra of cadmium-sulfo-selenide electrodes. This conclusion is valid for any material where the penetration depth α^{-1} of the exciting photons is of the same order, or greater than the diffusion length L of the injected minority carriers. In particular, for n-GaAs α^{-1} is $\sim 0.3\ \mu\text{m}$ (at $\lambda = 0.63\ \mu\text{m}$) and L_p is of the same order of magnitude, as long as the hole lifetime is in the order of 10^{-9}s . The last hypothesis was not experimentally confirmed here but can be taken as reasonable, since at the semiconductor-electrolyte interface the surface recombination velocity is high (17).

The subbandgap emission bands with its maximum at $\sim 1.1\ \mu\text{m}$, uncorrected to photomultiplier spectral response, are also observed in PL and EL on samples grown from the melt. However, samples grown by us by liquid phase epitaxial (LPE) technique showed no measurable PL signal in this subbandgap spectral region, although a similar laser beam was used to induce bandgap emission of the same intensity as above. Both LPE and melt-grown samples are doped only with Si. However, the LPE samples have a lower density of defects, in particular Ga vacancies, than the crystals grown from the melt. Since there is a good agreement between the energetic position of the subbandgap peak observed by us with that cited in the literature on photoluminescence of GaAs (18), we attribute the 1.1 μm emission band to radiative transition from shallow donor states to deep acceptor states created by gallium vacancies. In the following, only n-GaAs grown from the melt will be considered. As shown in Fig. 2, the spectra of PL with the sample immersed in electrolyte or in air are almost identical, *i.e.*, the electrolyte ions have no specific effect on PL. However, the overall intensities in EL as well as in PL may decrease

Fig. 6. Uncorrected EL spectra of n-GaAs in $0.01M \text{Fe}_2(\text{SO}_4)_3 + 1.0M \text{H}_2\text{SO}_4$ and in $0.03M \text{Ce}(\text{SO}_4)_2 + 1.0M \text{H}_2\text{SO}_4$. The electrode potential was continuously pulsed between 0 (20s) and $-1.75V$ (2s), while the emission spectrum was scanned at 5 \AA s^{-1} . Note the tenfold increase in sensitivity in order to record the spectrum in the $\text{Fe}_2(\text{SO}_4)_3$ electrolyte.

in time, with a time constant depending on the electrolyte composition (see Fig. 4). The photoluminescence quenching in the presence of the electrolyte was attributed to electrode-surface degradation due to photocorrosion effects, which, in fact, can be observed with the naked eye.

The most remarkable difference between PL and EL spectra is the variation of the ratio between the near-bandgap emission peak intensity to the subbandgap emission intensity ($I_{0.87}/I_{1.1}$). As shown in Fig. 5 and Table I, this ratio is smaller by a factor of 22 in EL than PL when the electrolyte is a solution of $\text{K}_3 \text{Fe}(\text{CN})_6 + \text{KOH}$, and by a factor of 78 when the electrolyte is changed to $\text{Fe}_2(\text{SO}_4)_3 + \text{H}_2\text{SO}_4$. This variation can be due to one or more of the following:

1. The density of the acceptor centers is higher in the region near to the GaAs-electrolyte interface. Gallium vacancies, in particular, may have higher density closer to the surface as a consequence of corrosive reactions taking place at the interface.

2. The band-to-band radiative transition is quenched by a more competitive nonradiative recombination at the GaAs electrolyte surface.

3. The electron-transfer rate is larger at the intra-bandgap state energy (gallium vacancy state) than at the valence bandedge energy. We shall discuss this point in the following.

An energy-band diagram is sketched in Fig. 7 for the semiconductor-electrolyte interface, taking as 0.3 eV the distance of the acceptor level (E_{INT}) from the valence bandedge (E_{VB}) of GaAs. This value is in agreement both with the known energy position of gallium vacancies and with our corrected PL and EL spectra, which show a maximum around $1.2 \mu\text{m}$ (Fig. 5). In the electrolyte side, the unoccupied energy levels of Fe^{3+} and Ce^{4+} are depicted as gaussian distributions that have their maximum at an energy E_{R} above the Fermi level of the couple (taken as the redox potential). The rearrangement energy E_{R} is ~ 1.2 and ~ 1.5 eV for the Fe^{3+} and for Ce^{4+} , respectively, (19). The proper matching between electrodes and elec-

trolyte energy levels is obtained knowing the flatband potential of GaAs, which nearly coincides with the conduction bandedge E_{CB} in our n-type samples. The value of -0.5 eV vs. NHE (pH = 0) was chosen for E_{CB} , in agreement with data from the literature (3, 4, 20). The unoccupied energy levels of $\text{Fe}(\text{CN})_6^{3-}$ could also be included in the diagram, provided the shift with pH of the GaAs energy levels is taken into account. For the sake of simplicity, however, we shall consider in Fig. 7 only the energy level distributions corresponding to the Fe^{3+} and Ce^{4+} ions. Due to the redox potentials of the two couples, Ce^{4+} should easily inject holes into the valence band of GaAs, but Fe^{3+} should not. This was indeed confirmed by previous work (3, 4). Here, we did observe bandgap luminescence with Fe^{3+} , although ten times weaker than with Ce^{4+} (Fig. 6). Bandgap luminescence indicates unequivocally hole injection into the valence band. This can be attributed either to an underpotential reduction of Fe^{3+} by valence-band electrons and/or to an upper shift of the GaAs bandedges during the $-1.75V$ potential pulse used in the present EL measurements. This pulse technique differs from the potential sweep technique used previously by Decker *et al.* (3), allowing higher EL intensities. From the EL measurements, and from Fig. 7, we conclude:

1. $\text{Fe}(\text{CN})_6^{3-}$, Ce^{4+} , and Fe^{3+} inject holes both into the valence band and into the intra-bandgap state.

2. The ratio $I_{0.87}/I_{1.1}$ falls from 0.3 [Ce^{4+} , $\text{Fe}(\text{CN})_6^{3-}$] to 0.08 (Fe^{3+}), indicating that the Fe^{3+} injects holes less efficiently into the valence band than the other electroactive species do.

3. The rate of hole injection for Ce^{4+} and $\text{Fe}(\text{CN})_6^{3-}$ is comparable; for Fe^{3+} this rate is lower, both at E_{INT} and at E_{VB} .

Since the energy-level distribution in the electrolyte is very broad, a good overlap of both the deep level and the valence band with empty levels in the electrolyte occurs. Consequently, the electron transfer from the semiconductor to the redox ion can occur isoenergetically, the initial state being either at the valence bandedge or in the

Fig. 7. Energy band diagram for the n-GaAs/redox electrolyte interface. In the semiconductor, the dashed areas represent filled states. E_{CB} and E_{VB} indicate the conduction and the valence band edges; E_{INT} is the energy of the deep level attributed to Ga vacancies. In the electrolyte, the solid and dashed parabolas represent the energy-level distribution of the empty Ce^{4+} and Fe^{3+} states, respectively. E_O^F represents the standard redox potentials, and E_R represents the so-called arrangement energy for the redox couples. The following symbols are used to illustrate the electron transfer across the semiconductor/electrolyte interface. Filled dots: initial states. Open dots: final states. The vertical arrows in the GaAs indicate the radiative transitions taking place in the semiconductor after the electron transfer has occurred.

deep intra-bandgap level. In fact, the energy level model for the semiconductor-electrolyte interface (21) assumes isoenergetic charge transfer, since negligible phonon emission during electron transfer is expected (22). For a single level E , the charge transfer rate is proportional to the density of occupied states in the solid and of unoccupied states in the electrolyte. One can see from Fig. 7 that the density of empty states in the electrolyte is larger at E_{INT} than at E_{VB} . The electron transfer at E_{INT} is then kinetically favored, unless the density of states at the valence band edge overwhelms the density of states at the intra-bandgap level. The small ratios $I_{0.87}/I_{1.1}$ we observed in electroluminescence indicate, indeed, high charge transfer rate at E_{INT} . Our experiments with Fe^{3+} and Ce^{4+} in H_2SO_4 indicate also that the competition between charge transfer to the intra-bandgap state and charge transfer to the valence band is regulated by the redox potential of the couple. As a general conclusion, electroluminescence in aqueous redox electrolytes is a technique sensitive per se to the presence of intra-bandgap states. This conclusion agrees well with previous results of EL measurements on GaP (1).

Finally, the charge transfer from the conduction band of GaAs cannot be excluded. In fact, Fig. 7 shows that the capture of conduction-band electrons can also occur at a high rate without violation of the principle of isoenergetic charge transfer. Indeed, simultaneous charge transfer to distinct energy levels is unavoidable with small bandgap semiconducting electrodes in the presence of aqueous redox electrolytes.

Thermodynamic Stability of Manganese Phosphides from High Temperature Solid-State Galvanic Cells

Clifford E. Myers and Diana J. Simpson

Department of Chemistry, State University of New York at Binghamton, Binghamton, New York 13901

ABSTRACT

The solid-state cells, $\text{Mn, MnF}_2/\text{CaF}_2/\text{MnF}_2, \text{MnP, Mn}_2\text{P}$ and $\text{Mn, MnF}_2/\text{CaF}_2/\text{MnF}_2, \text{Mn}_2\text{P, Mn}_3\text{P}$ have been studied in the temperature range 867-1067 K. The EMF's, together with data from the literature, were used to calculate enthalpies of formation (from red P), $\Delta H_{f, 298.15}^0/R$: MnP , -13.9 ± 1.0 kK; Mn_2P , -20.6 ± 1.0 kK; Mn_3P , -21.8 ± 1.0 kK. The results are in excellent agreement with data reported earlier from this laboratory.

Although the thermodynamic stabilities of the manganese phosphides have been studied in several laboratories (1-4), there are no data in the literature on the stability of Mn_3P other than what may be inferred from the published phase diagram (5). Mn_3P melts incongruently to give liquid and $\text{Mn}_2\text{P}_{(s)}$, which may be taken as evidence that its stability is marginal relative to $\text{Mn} + \text{Mn}_2\text{P}$. Baratashvili *et al.* (2) have reported measurements in the temperature range 851-1067 K on the solid-state cell

for which the cell reactions are

The results of their study were shown to be consistent, within experimental uncertainty, with a combination of results from combustion calorimetry (1) and vaporization studies (3) on $\text{MnP}_{(s)}$. They are also consistent with a combination of results from vaporization studies (3, 4) on $\text{MnP}_{(s)}$ and $\text{Mn}_2\text{P}_{(s)}$. Hence the use of solid-state galvanic cells appears to give reliable results in the Mn-P system, and it was decided to set up cell I as a check on technique and then to study the cell

for which reactions are

The enthalpy of formation of $\text{Mn}_3\text{P}_{(s)}$ is given by

$$\Delta H_{f, 298.15}^0(\text{Mn}_3\text{P})/R = \Delta H_{298.15}^0[2]/R - \Delta H_{f, 298.15}^0(\text{Mn}_2\text{P})/R$$

where $\Delta H_{298.15}^0[2]$ is the enthalpy change for reaction [2].

Experimental

The cell assembly shown in Fig. 1 was constructed following a design (6) generously provided by Dr. Reginald Faircloth. The electrolyte was a 25.3 mm diam \times 2.1 mm thick polished calcium fluoride optical window which was supported by a mullite porcelain tube held in place by a steel compression spring located below the hot zone. The lower electrode pellet (Mn, MnF_2) was supported by a molybdenum or graphite pellet holder set within a molybdenum support block mounted on a smaller mullite porcelain tube placed inside the first and supported rigidly by a brass tube located below the hot zone. The upper electrode pellet (MnF_2, Mn phosphides) was positioned by a second pellet holder which was held in place by a stainless steel plate attached to two stainless steel rods pulled down by tension springs located below the hot zone. Electrical leads of molybdenum wire were connected to the

Key words: Enthalpy of formation, enthalpy of atomization, Mn_3P , Mn_2P , MnP .

respective pellet holders, and a Chromel-Alumel thermocouple was mounted in the support block. The thermocouple was calibrated *in situ* against a U.S. National Bureau of Standards copper freezing-point standard. The entire assembly was enclosed in a mullite porcelain tube which was connected to a vacuum/argon gas system. The argon entered the assembly from the bottom of the apparatus and exited through a slot in the inner ceramic tube and through a stainless steel tube outside the electrolyte-

G: stainless steel tube. H: upper molybdenum lead. J: upper electrode-pellet holder. K: stainless steel plate. L: upper electrolyte pellet. M: CaF_2 electrolyte. N: lower electrode pellet. O: lower electrode-pellet holder. P: molybdenum support. Q: slot.

support tube. The arrangement was such that argon which had come in contact with one electrode pellet did not subsequently come in contact with the other. The argon, stated by the supplier to be 99.998% pure, was passed over activated alumina at room temperature and titanium metal at 600°C before entering the apparatus. In addition, a strip of tantalum foil was placed around each pellet holder to act as a getter for oxygen. In each run, the assembly was first heated under a vacuum of about 10^{-5} torr for several hours to remove adsorbed gases. After being cooled to room temperature, the assembly was brought to atmospheric pressure with argon, and the argon continued to flow slowly through the assembly as it was brought up to temperature, as measurements were made, and as the assembly was cooled again to ambient temperature. The EMF of the cell was measured with a Keithley Model 660A guarded dc differential voltmeter.

The manganese used in the lower electrode pellet and for synthesis of the samples was "flake" obtained from SPEX, Incorporated, and had a stated purity of 99.89%. The red phosphorus used for preparing the samples was obtained from CERAC/Pure, Incorporated, and had a stated purity of 99.9%. The manganese difluoride used in the electrode pellets was obtained from Atomergic Chemical Corporation and had a stated purity of 99.9%. The calcium fluoride disks were purchased from Harshaw Chemical Company, Incorporated. The mullite porcelain tubes were obtained from McDanel Refractory Porcelain Company. The phosphide samples were prepared and characterized in the manner described earlier (7).

The electrode pellets were prepared by pressing an intimate mixture (1:1 by weight) of the powdered components under a load of 10 tons. The pellet materials were examined by x-ray powder diffraction after each run to ensure that the desired component materials were indeed present.

Results

Data collected for the two cells are given in Fig. 2 and Tables I and II.¹ The line in Fig. 2 is calculated from the equation given by Baratashvili *et al.* (2) for the EMF of cell [I]. Despite the efforts described above to exclude oxygen, there was evidence in some runs of formation of green MnO on the surface of the electrode pellets; however, the results did not appear to be affected by the oxide. In a number of runs on cell [I], the EMF, although otherwise in agreement, increased slightly with increasing temperature rather than decreasing as required by the

thermodynamics of the cell reaction. Numerous unsuccessful attempts were made to eliminate this anomaly; these included ensuring that the cell was not subject to temperature gradients, as well as changing electrode contact materials and lead wires. None of these was effective in eliminating the anomalous behavior in an unambiguous manner. In any case, the only data shown in Fig. 2 and Tables I and II are those which did not exhibit this anomalous variation of the EMF with temperature. Thermal functions for MnP and Mn₂P were those used earlier (3); those for Mn were taken from the compilation of Hultgren *et al.* (8). There are no heat capacity nor entropy data for Mn₃P in the literature, and these were estimated. The entropy of Mn₃P was taken to be $S_{298.15}^0/R = 12.44$, which is the value (9) for Mn₃Si, and the heat capacity at high temperatures, $C_p/R = 11.42 + 5.083 \times 10^{-3}T - 1.409 \times 10^{-5}T^2$ was based on the heat capacities (10) of MnP and Mn₂P.

Fig. 3. Atomization enthalpies of transition metal phosphides

Primary thermodynamic data for the two cell reactions are given in Table III. The second law datum is, for each cell, a weighted average (by the number of points) of the second-law enthalpies from the two runs with each cell. For comparison, data are included which were calculated from the equation given by Baratashvili *et al.* (2) for the temperature variation of the EMF of cell [I]. Uncertainty limits are based on differences in second-law enthalpies for replicate runs, uncertainties in published and estimated heat capacities and in estimated entropies, and on scatter in experimental data. Derived stability data for the manganese phosphides from this and previous studies using third-law values are given in Table IV. Data from this laboratory using different techniques show good internal consistency within experimental uncertainty; the enthalpy of formation of MnP obtained by combustion calorimetry (1) appears to be too low. As shown in Fig. 3, the atomization enthalpy of Mn₃P (per gram atom) is such that it is barely stable with respect to Mn₂P and Mn, as had been suggested above.

Acknowledgment

The authors wish to thank Dr. Reginald Faircloth for the description of the cell assembly used as a model for the one described above. Also, thanks are due McDanel Refractory Porcelain Company for a donation of some of

ABSTRACT

The reaction rate of cobalt in SO₂-argon environments has been measured at 650°, 700°, 750°, and 800°C. Product scales consist primarily of an interconnected sulfide phase in an oxide matrix. At all temperatures, the rapid diffusion of cobalt outward through the interconnected sulfide appears to be important. At 650°C, the reaction rate slows dramatically after 5 min due to a change in the distribution of these sulfides. At 700° and 750°C, the reaction is primarily diffusion controlled; values of $D_{Co}(CoS)$ calculated from this work show favorable agreement with values of $D_{Co}(CoS)$ calculated from previous sulfidation work. At 800°C, a surface step becomes rate limiting.

Metals and alloys may be exposed to complex gas environments at elevated temperatures in a variety of industrial applications. Often, combustion of fossil fuels will lead to sulfur oxides which may have deleterious effects on the metal or alloy in question. Nickel and cobalt are important base metals used in turbine components. However, both these metals corrode dramatically faster in SO₂ than in O₂. For nickel at 600°C, the ratio of rates is about 10⁶; for cobalt at 750°C this ratio is about 10⁸. In this laboratory, extensive work has been done on the reaction of nickel with SO₂ and equilibrated SO₂-O₂ mixtures (1, 2). In order to determine if some of the same principles hold for the reaction of cobalt with SO₂, similar experiments were conducted for this metal.

The results for nickel corrosion in SO₂-argon mixtures can be summarized as follows. A porous oxide layer forms during the initial stages of reaction and SO₂ diffuses down the pores to the oxide/metal interface, where the oxygen activity is low enough so that nickel sulfide is thermodynamically stable. Nickel sulfide then forms as a thin layer between the metal and oxide and also grows into the pores of the oxide. A network of interconnected sulfides forms in the oxide matrix and acts as rapid diffusion paths for nickel to the scale/gas interface. These rapid diffusion paths account for the faster reaction rates in SO₂ than in O₂. At the scale/gas interface, the following reaction occurs

Scale growth is initially linear, indicating that a surface step is rate controlling. However, during the later stages of reaction, scale growth obeys an apparent parabolic rate law, since diffusion of nickel outward is primarily rate controlling.

Other investigators have reported that cobalt reacts with SO₂ similarly to nickel (3-10). However, there are still many questions about the details of the reaction mechanism. Among the earliest investigations is that of Konev *et al.* (4), who exposed nickel and cobalt to CO₂ and SO₂ mixtures. For nickel, an outer layer of NiO and an inner layer of Ni₃S₂ were detected. However, for cobalt only CoO was detected. Alcock *et al.* (5) exposed cobalt at 688°C to 2SO₂:1 O₂ streams for 2h. They observed the metal with a thin layer of CoS, followed by a thick layer of CoO, followed by a thin layer of CoSO₄. More recently, Singh and Birks (6) have studied cobalt corrosion in SO₂-argon mixtures from 500° to 900°C. They observed a thin sulfide layer (Co₉S₈) adjacent to the metal followed by a mixed oxide-sulfide layer (CoO-Co₉S₈), and they proposed that the inner sulfide layer forms by penetration of SO₂ into a porous oxide layer, a mechanism similar to that observed for nickel. Holthe and Kofstad (7) have also studied cobalt corrosion in SO₂ from 800° to 1000°C at 10, 100, and 760 torr. They also see duplex scales of oxides

and sulfides. Although tests for sulfate are inconclusive, they suggest that a very thin layer of sulfate may form on the oxide surface. Gesmundo and DeAsmundis (8) have studied cobalt corrosion in 1 atm SO₂ from 450° to 1200°C. At 600° and 700°C, they report approximate parabolic kinetics with increasing deviations at higher temperatures. Finally, Gillot and Garnier (9) have examined cobalt corrosion in SO₂ from 450° to 1200°C at various SO₂ pressures. Generally, at low temperatures they see parabolic kinetics and at higher temperatures linear kinetics. In summary, previous investigators agree that the reaction of cobalt and SO₂ leads primarily to cobalt sulfide and cobalt oxide. However, the kinetics of the reaction are still not clear.

In this work, measurements were taken from 650° to 800°C, below the cobalt-sulfur eutectic. Particular attention was paid to the time dependence of scale growth in order to determine which step is rate limiting and to understand the mechanism of this reaction.
